AB# 1st Author: Title

## Wednesday, August 5, 2020: 11:00am-12:30pm

### Podium Session 1 - Balance and Falls 1

Moderator: Dr. Peter Fino

150	Wei Liu: Biomechanical Mechanisms of Tai-Chi Gait for Preventing Falls	19
275	Kurt Beschorner: A hydrodynamics model to predict under-shoe fluid pressures based on the dimensions of a worn region	20
673	Corbin Rasmussen: Slipping Foot and Recovery Step Yaw After a Turning Slip: A Balance Recovery Mechanism?	21
672	Kyra Twohy: Impact of an Ankle-Foot Orthosis on Reactive Stepping in Young Adults	22
187	Chuyi Cui: Sensitivity of Toe Height to Joint Angles of the Bipedal Linked Chain during Obstacle Crossing	23
536	Noah Rosenblatt: The impact of obesity on trunk control following trip-like treadmill perturbations while standing	24
397	Kari Loverro: Females have greater local dynamic stability than males when walking with military-relevant loads.	25
667	Chang Liu: Does the Reference Axis for Computing Angular Momentum Affect Inferences about Dynamic Balance?	26
278	Gabriella Small: The Influence of Cognitive Load on Dynamic Balance During Steady State Walking	27
50	Daniel Liss: Young Adults Can Perceive Very Small Locomotor Disturbances Even When Distracted	28
365	Brian Selgrade: Susceptibility to Optical Flow Balance Perturbations in Older Adults Prevails Despite Cognitive Distraction	29
441	Chase Rock: Neuromuscular Adaptation after Exposure to Simulated Hypogravity	30

### Podium Session 2 - Sport/Performance 1

Moderator: Dr. Wouter Hoogkamer

588	Sarah Wilson: Application of Inertial Measurement Units and Statistical Parametric Mapping for Assessing Alpine Skiing	31
192	Meredith Wells: A Biomechanical Analysis of the Triple Step in Recreational Swing Dancers	32
805	Joseph Passafiume: Real-Time Visual Feedback on Breathing during Treadmill Running to Exhaustion	33
847	Justin Angelo Ortega: Metabolic Power During Running In Vaporfly Shoes With Intact vs. Cut Carbon-Fiber Plates	34
169	Eric Honert: Foot and ankle kinetics and their interplay during a long duration run	35
266	Torstein Dahlin: Examining the Role of the Toe Flexors in Opposing Foot Arch Deformation	36
586	Matthew Pain: Energy dissipation due to soft tissue movement of the thigh during forefoot and rearfoot impacts at different running velocities	37
414	Micah Garcia: Running Symmetry is not different in Youth Runners with Low, Moderate and High Muscular Symmetry	38
472	Kara Ashcraft: Characterizing Strut Stiffness in Running-Specific Ankle-Foot Orthoses	39
329	Ryan Alcantara: Curve Sprinting With A Split-Toe Running Specific Prosthesis: A Pilot Study, University of Colorado Boulder	40
276	Hiroto Murata: External mechanical work during running after unilateral transfemoral amputation	41
375	Janet Zhang: Effects of a Paralympian With Transfemoral Amputation Using a Prosthesis With & Without a Knee	42

### Podium Session 3 - Locomotion

Moderator: Dr. Jessica Allen

616	Matthew Salzano: Moment Arm Plasticity in Response to Loading History during Growth	43
705	Jeffery Olberding: Reconstructing contractile dynamics from muscle length change	44
859	Emily Abbott: Mechanosensation by muscle spindles during active muscle-tendon work loops	45
627	Samuel Kwak: Muscle Fascicle Dynamics During Collisional Phase of Walking and the Relation to Push-off Phase	46
353	Bryan Schlink: High-Density EMG Reveals Lower Limb Spatial Activity during Walking and Running	47
374	M. Janneke Schwaner: In vivo hind limb muscle function during walking on hard and soft substrates in rats ( <i>Rattus norvegicus</i> )	48
95	Daniel Kuhman: The effects of advanced age and walking speed on mechanical functions of the ankle plantarflexors	49
708	Jonaz Moreno Jaramillo: Are Muscles Tuned to the Preferred Stride Frequency of Walking?	50
484	Alex Denton: Effects of Varying Tendon Stiffness on the Metabolic Cost of Walking	51
66	Noah Pieper: The Metabolic and Mechanical Consequences of Altered Propulsive Force Generation During Walking	52
609	Talayah Johnson: Developmental Plasticity of Locomotor Economy in an Avian Bipedal Model	53
194	Daisey Vega: Reducing the Metabolic Cost of Walking by Using the Arms to Drive the Legs	54

## Thursday, August 6, 2020: 11:00am-12:30pm

### Podium Session 4 - Balance and Falls 2 Neurologic

Moderator: Manuel Hernandez

71	James Tracy: Stroke Survivors Exhibit Little Total Arm Contribution to Standing, Posterior Balance Reactions	55
126	Daniel Kuhman: The effects of advanced age and walking speed on mechanical functions of the ankle plantarflexors	56
220	Leila Alizadehsaravi: Are Improvements of Balance Performance after Short- and Long-term Balance Training in Older Adults associated with changes in H-Reflex Excitability and Muscle Co-Contraction	57

801	Seung Yun Song: Preliminary Study of Spasticity Using the Portable Position, Velocity, and Resistance Meter	58
613	Yang Hu: The Effect of Pain on the Cognitive Control of Balance During the Motor Control Test in Older Women with Osteoarthritis.	59
190	Aiden Payne: People With Worse Balance Have Larger Perturbation-Evoked Cortical Responses	60
495	Gu Eon Kang: Effects of Fear of Falling on Gait and Balance in Chemotherapy-Induced Peripheral Neuropathy	61
341	Brett Meyer: Deep Learning to Classify Fall Risk from Wearable Accelerometer Data During Standing in Persons with Multiple Sclerosis	62
133	Hannah Frame: The Influence of Mediolateral Stabilization on Balance Control during Walking in Individuals Post-stroke	63
700	Carolin Curtze: Dynamics of Turning in People with Parkinson's Disease	64
644	Luis Nolasco: Dynamic Balance During 90-degree Turns in People with a Unilateral Transtibial Amputation	65
750	Peter Fino: Centripetal Acceleration During Turning and its Relationship with Autonomic Function in Mild Traumatic Brain Injury	66

### Podium Session 5 -- Computational Modeling

Moderator: Dr. Brooke Odle

641	Amy Lenz: Talocrural Morphology: A Statistical Shape Modeling Multi-Articulation Joint Approach	67
295	Yu Zhou: Pose-matching MRI-CT co-registration via dynamic X-ray for creating subject-specific neck musculoskeletal models	68
212	Megan Mancuso: Bone Strain Distribution, Not Magnitude, is Affected by Execution of a Forearm Loading Task	69
720	Geng Li: Effect of Pelvis Geometry Personalization on Hip Kinematics and Dynamics	70
42	Reed Gurchiek: Estimating Unmeasured Muscle Excitations: NMF vs Gaussian Process-Based Synergy Models	71
114	Kiisa Nishikawa: Isometric force-length and isotonic force-velocity properties and Hill-type models contain little information needed to predict in vivo muscle forces.	72
727	Benjamin Binder-Markey: Whole Muscle Passive Mechanics Do Not Simply Scale by Architectural Properties	73
434	William Clark: Imaging and Simulation of Inter-Muscular Triceps Surae Contributions to Forward Propulsion During Walking	74
653	William Ferriell: Parametric Analysis and Validation of 3D American Football Faceguard Structural Stiffness Models	75
638	Thanh Tran: Simulation of Speech Muscle Biomechanics to Explains Differences in Corrective Surgery Outcomes	76
690	Julia K. Butterfield: A Split-Belt Rimless Wheel Can Passively Walk Steadily on a Split-Belt Treadmill	77
782	Mingxiao Liu: An Instrumented Glove to Induce Agency-based Performance of Secure Grasp	78

### Podium Session 6 -- Prosthetics/Orthotics/Robotics

Moderator: Dr. Karl Zelik

388	Adam Yoder: Trunk Control during Walking with Below-Knee Amputation: Effects of Prosthetic Ankle-Foot Actuation	79
183	Genki Hisano: Whole-body angular momentum during walking in persons with unilateral transfemoral amputation	80
433	Alexandra Voloshina: Effects of exoskeleton assistance in individuals with unilateral transtibial amputation	81
737	Jay Kim: The Effects of Powered Ankles on Gait Initiation and Termination in Daily Life	82
469	Kara Ashcraft: Characterizing Strut Stiffness in Running-Specific Ankle-Foot Orthoses	83
819	Gwendolyn Bryan: Optimized hip-knee-ankle exoskeleton assistance at different speeds	84
410	Inseung Kang: A biomechanical analysis of adaptive assistance strategy for uphill walking using a powered hip exoskeleton	85
475	Patrick Franks: Hip, Knee, Ankle and Multi-Joint Exoskeleton Assistance Can Reduce Metabolic Cost	86
249	Sarah Bass: Biomechanics of individuals with and without lower limb amputation during dual-task walking	87
287	Katherine Poggensee: How Training, Adaptation, and Customization Contribute to Exoskeleton Assistance	88
772	Dylan Schmitz: Achilles Shear-Wave Tensiometry During Walking With a Passive Exoskeleton: A Proof-of-Concept	89
793	John Chomack: Effects of Prosthetic Socket Design on Residual Limb Motion Using Dynamic Stereo X-Ray	90

### Awards Session

#### Young Scientist Pre-doctoral Award: 11:00am -11:15am

391	Joshua Leonardis: Neuromuscular Compensation Strategies Adopted at the Shoulder Following Bilateral Subpectoral Implant Breast Reconstruction	91
-----	---	----

#### Young Scientist Post-doctoral Award: 11:15am-11:30 am

	Eni Halilaj: An open-source dataset for modeling human pose priors	92
--	--	----

#### CLINICAL BIOMECHANICS AWARD 11:30am-12:00pm

322	Mark Geil: Are Gait Kinematics Different in Young Children Who Receive Working Prosthetic Knees?	93
789	Nicholas Kreter: Preparations for Expected Underfoot Perturbations in Healthy and Concussed Individuals	94

#### JOURNAL OF BIOMECHANICS AWARD 12:30pm-1:00pm

423	Thomas Sandercock: Stress Provides a Lower-Bound Estimate of Shear Wave Velocity in Skeletal Muscle	95
842	Katherine Knaus: 3D Model of the Soleus Reveals Complex Muscle Fascicle and Aponeuroses Deformations during Passive Stretch	96

Thursday, August 6, 2020: 1:00am-2:30pm

### Podium Session 7 - Orthopaedics 1

Moderator: Dr. Jared Kaiser

702	Benjamin Binder-Markey: Whole Muscle Passive Mechanics Do Not Simply Scale by Architectural Properties	97
502	Lomas Persad: In vivo measurement of gracilis muscle-tendon characteristics	98
678	Kristen Jakubowski: Muscle stiffness exceeds tendon stiffness at physiologically relevant levels of muscle activation	99
499	Joshua Pataky: The Effect of Rotator Cuff Tear Severity on Joint Loading During Dynamic Tasks	100
456	Sabreen Megherhi: The Effects of Osteoarthritis and Unicompartmental Knee Arthroplasty on Hip, Knee, and Ankle Joint Kinematics	101
462	Rebekah Koehn: Modular Control and Patient Function in Individuals with Knee Osteoarthritis and Total Knee Arthroplasty	102
470	Ahmad Raeisi Najafi: Effects of age-related changes on fracture resistance of human cortical bone	103
262	Meir M. Barak: Trabecular bone stiffness and yield are not declined after exposure to Staphylococcus aureus	104
487	Sevda Gharehbaghi: Joint Acoustic Emissions as a Biomarker for Knee Health Assessment in Loaded and Unloaded Exercises	105
573	Hope Davis-Wilson: Association Between Daily Steps, Moderate-Vigorous Physical Activity, and Femoral Articular Cartilage Composition in Individuals with Anterior Cruciate Ligament Reconstruction	106
10	Nathan Schilaty: Linear Discriminant Analysis Predicts Knee Injury Outcome from Biomechanical Variables	107
449	Melissa Boswell: Mindsets are related to reductions in pain after a gait modification intervention for people with osteoarthritis, Stanford University	108

### Podium Session 8 - Locomotion

Moderator: Dr. James Finley

553	Emily McCain: Isolating the Energetic Consequences of Mechanically Imposed Reductions in Ankle and Knee Flexion during Gait	109
500	Nicole Rendos: Real-Time Gait Biofeedback Enhances Dynamic Ankle Stiffness and Propulsion in Healthy and Post-Stroke Participants	110
106	Natalia Sanchez: Using visual guidance to acquire work from the treadmill during split-belt walking does not accelerate adaptation	111
69	Jan Stenum: Step time asymmetry optimizes energy cost of split-belt treadmill walking	112
551	Rebecca Krupenevich: The Effects of Age and Locomotor Demand on Foot Mechanics During Walking	113
562	Anahid Ebrahimi: On the Use of Shear Wave Speed to Assess Tendon Loading in Children with Cerebral Palsy	114
483	Skyler Levine: Effects of Ankle Weights During Overground Walking Using a Bodyweight Support System	115
601	Christopher Hurt: Split-belt walking against resistance increases walking propulsion asymmetrically	116
149	Scott Uhlrich: Muscle coordination retraining reduces knee contact force during gait	117
131	E. Dan Syrett: Peak Knee Joint Forces During Asymmetric Split-Belt Treadmill Walking: A Preliminary Study	118
833	Paul DeVita: Surface stiffness affects knee joint kinetics during decline but not level running	119
850	Keaton Scherpereel: Estimating Knee Joint Load with Joint Acoustic Emissions During Walking	120

### Podium session 9- Injury and Injury Prevention

Moderator: Dr. Zachary Domire

173	Zachary Merrill: Predictive Modeling of Serious Injury Risk in Frontal Crashes	121
747	Mohammad Homayounpour: Force and Linear Acceleration Differences after Head Impacts with Clenched and Relaxed Neck Muscles	122
390	Joshua Leonardis: Choosing Mastectomy and Breast Reconstruction or Breast Conserving Therapy: Implications for Pectoralis Major Function	123
398	Whitney Wolff: Quantifying Sternocleidomastoid Material Properties after Definitive Chemoradiation for Head and Neck Cancer	124
238	Emily Matijevich: Estimating Lumbar Loading with Wearable Sensors over a Broad Range of Manual Lifting Tasks	125
530	Jacob Banks: Lower Back Demands During Induced Lower Limb Gait Asymmetries	126
152	Blake Johnson: Material Properties of Human Testicles under Unconfined Compression and Probing with Varying Strain Rate	127
405	Jonathan (FJ) Goodwin: Vertical Stiffness Asymmetry in NCAA Division I Athletes	128
491	Dhruv Gupta: Optimizing whole-body kinematics using OpenSim Moco to reduce peak non-sagittal plane knee loads and ACL injury risk during single leg jump landing	129
529	Brian Diefenbach: Development of an In-Vivo Ligament Loading Device	130
440	Kavya Katugam: Achilles Tendon Material Properties are Resilient to Variations in Load During Growth	131
540	Matthew Ruder: Running Exposure is Associated with Achilles Tendon Shear Wave Speed	132

### Friday, August 7, 2020: 1:00am-2:30pm

#### Podium Session 10 - Orthopaedics

Moderator: Dr. Jessica Goetz

420	Elizabeth Bjornsen: Increased Cervical Spine Musculotendon Strain with Enlarged External Occipital Protuberances	133
356	Julian Acasio: Trunk-Pelvic Coordination during Unstable Sitting at Varying Task Demand	134
431	Tara Diesbourg: The Impact of Sitting on Active Trunk Stiffness and the Mitigating Effect of Age	135

138	Alexa Johnson: Connecting the Pieces: How Low Back Pain Alters Lower Extremity Mechanics in Active Individuals	136
599	Donald Prible: Thoracolumbar and Pelvis Kinematics are Associated with Paretic Force Production	137
686	Emily Levy: Kinetic and Kinematic Comparison of Multiple Hip Pathologies during Sloped and Level Walking	138
195	Ke Song: Periacetabular Osteotomy for Hip Dysplasia Alters Dynamic Flexor and Abductor Muscle Moment Arms and Lines of Action	139
685	Michael Samaan: Hip Joint Muscle and Contact Forces During Sit-to-Stand and Stand-to-Sit Tasks in Patients with Femoroacetabular Impingement Syndrome	140
493	Cara Lewis: Bone-to-bone Distance Changes Are Larger in Patients with Cam Femoroacetabular Impingement Syndrome	141
656	Amber Vocelle: The effect of osteoarthritis on three-dimensional thumb motions and force production	142
107	Bardiya Akhbari: Contact Pattern of Total Wrist Arthroplasty Changes with the Direction of Motion: In-Vivo Study	143
447	Mark Carl Miller: Crista Volume Shows a Relationship to Sesamoid Station	144
72	Junjun Zhu: Development of Injury Risk Functions for Lisfranc Injury	145

### Podium Session 11 -- Prosthetics/Orthotics/Robotics

Moderator: Dr. Elisa Arch

51	Ying Fang: Step Length Biofeedback with Exoskeleton Assistance Can Improve Walking Function and Gait Mechanics in Cerebral Palsy	146
377	Dean Molinaro: Estimating Biological Hip Torque During Overground Ambulation: A Machine Learning Approach	147
577	Dawit Lee: Reducing Human Energetics Using a Bilateral Knee Exoskeleton	148
844	Sabrina Abram: People explore gait dimensions, and reduce this exploration, as they learn to walk with exoskeleton assistance.	
795	Yi-Tesn Pan: The Biomechanical Effect of Bilateral Assistance for Hemiparetic Gait Poststroke Using a Powered Hip Exoskeleton	149
577	Corey Koller: A Case Series Examining the Effects of Wearing a Quantitatively-Prescribed Passive-Dynamic Ankle-Foot Orthosis Compared to Standard-of-Care Ankle-Foot Orthosis	151
151	Tatiana Djafar: Longitudinal Assessment of Gait Quality for Servicemembers with Transtibial Amputation: A Case Series	152
704	Jay Kim: The Effects of Powered Ankles on Gait Initiation and Termination in Daily Life	153
74	Tom Gale: Motion of the Residual Femur Within the Socket During Gait is Associated with Patient-Reported Problems in Transfemoral Amputees	154
488	Christina Lee: The Performance of Implantable Electrodes on the Control of a Myoelectric Prosthesis Over One Year Post-Implantation	155
526	Alexander Klishko: Stimulation of residual sensory nerve modulates walking mechanics in the cat with bone-anchored transtibial prosthesis	156
596	Sarah Hood: Open Dataset of 18 Above-Knee Amputees Walking at 5 Different Speeds with their Prescribed Prostheses	157

### Podium Session 12 - Sport/Performance

Moderator: Dr. Kristin Morgan

19	Glenn Fleisig: Should Baseball Adjust the Mound Height and Pitching Distance?	158
282	Kate Harrison: Influence of Alternative Shoe Fit Configuration on Athlete Biomechanics	159
764	Alex Lurski: Performance Evaluation of Rate Activated Tether (RAT) Football Helmet	160
867	Chenxi Yan: Tibial Bone Strains in Basketball Players during Dynamic Tasks	161
754	Cherice Hughes-Oliver: Racial Differences in Running and Landing Measures Associated with Injury Risk Vary by Gender	162
429	Joshua Weinhandl: Anticipation and an External Target Alter Knee Biomechanics in Volleyball-Specific Task	163
544	Lauren Biscardi: Running to Fractal-Like Stimulus Preserves the Complexity of Stride-To-Stride Fluctuations	164
361	Namwoong Kim: Muscle Contributions to Knee Joint Reaction Forces and Moments during Single-Leg Landing	165
255	Anna Ursiny: Does Sex Influence Interpretations of Control Complexity via Muscle Synergy Analysis?	166
380	Mitchell St. Pierre: Effect of Transcutaneous Vagus Nerve Stimulation on Visuomotor Skill Learning in Humans	167
401	Aakash Bajpai: Human Reaction and Movement Enhancement via Audial, Tactile, and Visual Perceptual Cues	168
432	Anvesh S. Naik: Should I stay or should I go? Stability of digit forces is lowered to enhance maneuverability when expecting to move a pinched object	169

### Posters:

#### Wednesday, August 5

#### Animal, Comparative, and Evolutionary Biomechanics

333	Patrick Hall: Rabbit Hindlimb Ankle Kinematics During Stance Phase of Hopping Gait	170
345	Robert Catena: Gestational Lumbopelvic Postural Changes and Joint Loads in Standing and Walking	171
395	Siwoo Jeong: The effect of active shortening velocity on the ratio of muscle stiffness to muscle force	172
436	Emma Gilmore: Shape Characterization of Bighorn Sheep Horns for Bending and Impact Implications	173
457	Brian Hamilton: Perturbations to the classic force-length relationship of skeletal muscle	174
463	Brooke Christensen: Impact of Surface Grade on Hindlimb Muscle Function in Desert Kangaroo Rats ( <i>Dipodomys deserti</i> )	175
549	Jarrold Petersen: Dynamic changes in force modulate pennate muscle architecture	176
676	Alex Duman: Landing on Compliant Surfaces: Lessons from an animal model of landing control	177

742	Yonghee Lee: EXPLORING HOW FUNCTIONAL IMPROVEMENT IS RELATED TO INTERACTION BETWEEN CHILDREN WITH CEREBRAL PALSY AND HORSES DURING EQUINE-ASSISTED THERAPY: A PILOT STUDY	178
781	Adrien Arias: Limb joint mechanics during quadrupedal walking in alligators	179
808	Nathan Kirkpatrick: DeepLabCut Increases Markerless Tracking Efficiency in Bi-Planar X-Ray Video Analysis of Rat Kinematics	180

### Balance and Falls - General

8	MU QIAO: How do Leg Joint Stiffness Affect Dynamics of Backward Falling: A Simulation Work	181
27	Mituniewicz Austin: Evaluation of an app for vestibular rehabilitation of older adults with motion controlled games and remote monitoring	182
34	Gordon Alderink: Analysis of Coherence between Electromyographic (EMG) signals of Tibialis Anterior, Soleus and Gastrocnemius during Standing Balance Tasks: A Pilot Study	183
59	Mengnan Wu: Human-human hand interactions assist beam-walking balance by haptic communication, not mechanical support	184
73	Caroline Simpkins: Dance Interventions Improving Balance in People with Parkinson's Disease: A Meta-Analysis	185
86	Gordon Alderink: Margin of Stability during Tandem Stance with Dominant Limb Placed Back or Forward: A Pilot Study	186
97	Jocelyn F Hafer: Coordination Responses to a Change in Walking Speed Do Not Differ with Age or Knee Osteoarthritis	187
209	Jiyun Ahn: Effects of Sole Thickness on Recovery from an Unexpected Slip during Standing	188
216	Kitaek Lim: Muscle activation pattern during a fall from standing height	189
239	Farahnaz Fallahtafi: Speed of Walking, as well as Walking Mode (Treadmill vs. Overground), can affect Margin of Stability	190
245	Bummo Koo: Ranking Algorithm for ANN-Based Post-Fall Detection	191
256	Lydia Brough: Biomechanical Response to Altered Foot Placement During Walking	192
294	Heather Vanderhoof: Advancing Stages of Pregnancy on Postural Sway Range in Healthy Females	193
348	Tyler Wood: The Potential Implications of Co-Contraction Index of Neck Muscles on Traumatic Brain Injuries	194
378	Michael Christensen: The Effect of a Reduced Marker Set on the Margin of Stability During Gait	195
379	Jiyeon Kim: Association between Activities-specific Balance Confidence, Dynamic Gait Index, and Physical Activity in People with Parkinson's Disease	196
482	Bianca Tovar: The Effect of Advancing Pregnancy on Postural Sway Velocity in Bilateral and Unilateral Standing	197
519	Erika Pliner: Behavioral risk predicts maximum lateral reach during a roof gutter clearing task	198
524	Bailey Petersen: Characterization of Posturography and Sensory Loss in Lower-limb Amputees.	199
563	Dorien Butter: Influence of Object Characteristics on Patient Safety and Stability During Ambulation	200
570	Claire Zai: Evaluation of the Four Square Step Test as an outcome measure in a novel clinical fall prevention program	201
604	Tom Van Wouwe: Causes of increased step incidence in response to perturbations in older adults	202
629	Claire Martin: Locomotor Response of Older Persons with and without Transtibial Amputation to a Trip Disturbance	203
631	Nicole Stoehr: Balance Control and Muscle Asymmetry in Persons with Lower-limb Amputation During Yoga Poses	204
651	Luis Nolasco: Segment Angular Momenta in People with a Unilateral Transtibial Amputation During 90-degree Turns	205
697	Sydni Wilhoite: Relationship between Postural Control and Lower Body Physical Function in Children with Cerebral Palsy	206
724	Michael Jayson: Foot Structure and Postural Stability in Healthy Young Individuals	207
726	Sam Wilson: The Effects of Golf Specific Footwear on Postural Perturbations	208
730	Sara Elnahas: Preliminary Investigation of Limb Load Symmetry During Quiet Stance & Sit-to-Stand	209
746	Meghan Kazanski: Physical and Perceived Abilities and Motor Planning of Older Adults During A Virtual Beam-Walking Task	210
753	Riley Sheehan: Step Width Variables are not Meaningfully Correlated with Stumble or Fall Incidence in a High Functioning Population with Lower Limb Trauma	211
759	Mitchell Tillman: Early Testing of a Real-Time Balance Sonification System In Single Leg Stance	212
779	Kreg Gruben: A novel measure of standing balance coordination demonstrates greater consistency than traditional measures	213
794	Jennifer Leestma: Spatiotemporal recovery responses used to combat translational platform perturbations during walking	214
814	ABDERRAHMAN OUATTAS: Implimenting A Double-Limb Slip Training Protocol To Reduce Falls And Improve Slip Recovery: A Pilot Study	215
816	Lisa Zukowski: Acute Effects of Virtual Reality Treadmill Training on Gait and Cognition in Older Adults	216
822	Riley Horn: Identification of specific somatosensation and location to predict postural control outcomes	217
851	Meghan Kazanski: Mediolateral Margins of Stability of Older Adults During A Virtual Beam-Walking Task	218
860	Mei Huang: Effect of a multicomponent home-based training on gait performance in older adults with hip fracture: a randomized control trial	219

### Ergonomics and Occupational Biomechanics

57	John Wu: Improvement of Shock Absorption Performance of Construction Helmet using Air-bubble Cushioning- A Preliminary Study	220
58	Emily Miller: Assessment of Surgeon Muscle Fatigue during Microsurgery using a Rat Model	221
68	Joseph Langenderfer: Non-linear analysis of effects of inertial properties on hammer movement variability	222
93	Erika Nelson-Wong: Office Workers Maintain Decreased Sitting Time Long Term When Provided Sit-Stand Workstations	223
98	Stacy Loushin: Surgeon Hand Tremor during Microsurgery using a Rat Model	224

193	Jazmin Cruz: Verifying Joint Space-Based Metabolic Energy Expenditure Models	225
251	John Wu: The Effects of Posterior Shank/Thigh Contact on the Knee Joint Loading during Deep Squatting	226
260	Liying Zheng: Evaluation of a Powered Lumbar-Support Exoskeleton during a Pace-Controlled Lifting Task: A Pilot Study	227
394	Archana Lamsal: Comparison of a Mid-Seated Posture with Seated and Standing Postures	228
415	Matthew Hanks: Glenohumeral Joint Motion Variability during Wheelchair Propulsion in Children and Adults with Spinal Cord Injury	229
416	Caleb Burruss: Neck Kinematic Differences Between Six Computer Monitor Configurations	230
427	Tara Diesbourg: If Sitting Does Not Cause Low Back Pain in Healthy Working Adults, What Does?	231
480	Mustafa Yerebakan: EMG Based Biomechanical Analysis of the Effect Different Writing Surfaces and Postures Have on Forearm Muscles	232
481	Jason Gillette: Exoskeleton Usage, Arm Posture, and Tool Weight Changes Shoulder Fatigue Risk	233
503	Onebin Lim: Effects of a Footrest on the Lumbo-Pelvic-Hip Kinematics and Kinetics, and Low Back Pain during Prolonged Standing Work	234
659	Garrett Weidig: An Engineering and Ergonomic Analysis of Shoulder Posture in a Seated Position Through the Use of an Avatar	235

### **Locomotion - Running**

94	Li Jin: Relationship between Joint Stiffness and Limb Stiffness in Running Across Speeds	236
176	Yo Shih: Lower Extremity Support Moment and Distribution of Joint Moments during Sloped Running	237
285	Kathryn Harrison: Training effects on frontal plane kinematics and coordination in novice runners	238
386	Caelyn Hirschman: How Do Net Mechanical Joint Work and Stiffness Change on Slopes During Running	239
448	Mikaela Smith: Beat the Streets: Music-based Stride Length Intervention to Decrease Injury Risk in Runners	240
461	AmirAli Jafarnehadgero: Long term training on sand changes foot posture and running kinetics in active individuals with over-pronated feet	241
494	Kim Hébert-Losier: Running in the Nike Vaporfly, Saucony Racing Flats, and Own Shoes: Who Wins the Race?	242
511	Heather Hamilton: Coordination Variability in Injured and Uninjured Runners: A Systematic Review	243
513	Victoria Bode: Can Running Shoes be Used for All Activities During Basic Training?	244
518	Jessica Hunter: Novice runners maintain cumulative loads during steady-state running	245
552	Matthew Seeley: EFFECTS OF EXPERIMENTAL ANTERIOR KNEE PAIN ON RUNNING NEUROMECHANICS: A PILOT STUDY	246
592	Allison Hoffee: Relationship Between the Single-Leg Step-Down and Lower Extremity Loading in Adolescent Runners	247
716	Drew Rutherford: Effect of Increasing Running Cadence on Impact Force in an Outdoor Environment	248
717	Laura Healey: Biomechanics during running in Vaporfly shoes with intact vs. cut carbon-fiber plates	249
751	JJ Hannigan: The Effect of Carbon-Fiber Plate Racing Shoes on Running Biomechanics	250
785	Daniel Davis: Application of automatic segment filtering procedure to the kinematics of running	251
826	Bryan Conrad: Visualizing Variation in Vertical Ground Reaction Forces During Running	252
828	Justin Wager: Maximum voluntary ankle plantarflexion moments are unaffected by extension of the metatarsophalangeal joints	253

### **Neurorehabilitation - Stroke, TBI**

142	Lindsey Lewallen: Assessment of Turning Performance and Coordination in Individuals Post-Stroke	254
186	Hogene Kim: 3D Scanned Foot Image: A Potential Biomarker of Spastic Foot Deformity in Chronic Stroke	255
299	Mara Thompson: Narrow walking alters qualitative measures of COM movement in TBI vs. Control subjects	256
366	Shraddha Srivastava: Relationship Between Walking Coordination and Motor Pathways Recovery Following Stroke	257
409	Nicole Rendos: Verbal Instructions and Feedback Enhance Motor Learning During Post-Stroke Gait Retraining	258
531	Ashley Rice: Combination of Ankle Muscle Functional Electrical Stimulation (FES) & Fast Treadmill Walking Therapy Effect on Post-Stroke Motor Control	259
556	Peter Fino: Turning Speed and Performance During a Simulated Urban Patrol Task in People with Mild Traumatic Brain Injury	260
600	Hannah Christianson: Is Faster Always Better? A Subgroup Analysis of the Effects of Walking Speed on Post-Stroke Gait Biomechanics	261

### Introduction

Falls are a threat to the health of older adults and people with neurological dysfunctions. Tremendous efforts have been devoted in developing fall prevention programs. Tai-Chi (TC) practice, as an approach for preventing falls, is growing in popularity worldwide. TC is an ancient Chinese traditional mind-body exercise of self-cultivation and energy preservation. During TC practice, the players focus on slow, gentle, and fluid body movements and breathing. Despite the potential health benefits from TC practice, the underlying biomechanical mechanisms of TC practice reducing the risk of falls are still unclear. Previous TC-based clinical trials adopted certain selected TC forms. However, the scientific rationals of the forms selection is lacking. Without a thorough understanding of such mechanisms, it is difficult to accurately identify and effectively implement optimal TC forms into interventions for preventing falls.

TC gait is a basic and common lower extremity TC movements. Given that the majority of outdoor falls occur during locomotion, like walking, the purpose of this study was to examine the influence of TC gait on dynamic gait stability compared with regular walking gait in adults. As dynamic gait stability is a key risk factor for falls (Yang et al., 2009), examining the impact of TC gait on dynamic gait stability may provide valuable insight into the mechanisms of TC reducing the risk of falls.

### Methods

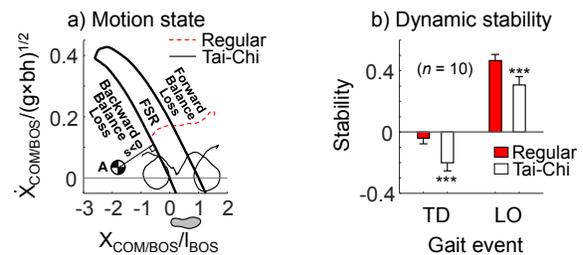

Ten healthy adults (five males,  $58.4 \pm 13.1$  years) with at least two-year experience of TC practice were enrolled into this cross-sectional study approved by the Institutional Review Board. After three-five trials of regular walking over a linear pathway embedded with two force plates (AMTI, MA) at self-selected speed and manner, all participants performed five trials of Yang-style TC gait. Full-body kinematics and ground reaction force were synchronously collected from reflective markers using a motion capture system (Vicon, UK) and the force plates, respectively (Liu et al., 2016).

The last TC gait trial was chosen as the representative one and analyzed. Two events: touchdown (TD) and liftoff (LO), were identified based on the ground reaction force. The filtered marker paths were used to calculate the body COM kinematics (de Leva, 1996). The two components of the COM motion state (i.e., its position and velocity) were calculated relative to the rear of the BOS and normalized by the foot length ( $l_{BOS}$ ) and the square root of the product of the body height ( $bh$ ) and gravitational acceleration ( $g$ ), respectively. Dynamic gait stability at both events was calculated as the shortest distance from the COM motion state to the limit against backward balance loss (Fig. 1a) (Yang and Pai, 2010). The dependent variable (dynamic stability at TD and LO) was compared between TC and regular gait using paired  $t$ -tests with SPSS 24 (IBM) and a significance level of 0.05 was applied.

### Results and Discussion

During stance phase, the COM motion trajectory was lower for TC gait than the regular gait (Fig. 1a). Both types of gait covered a similar range of COM position but COM velocity was lower during TC gait than the regular gait. Notably, COM during the regular gait continuously travelled forward relative to the BOS while it reversed the moving direction four times in TC gait. Overall, participants were less stable when practicing TC gait than in normal gait. Specifically, individuals were less stable during TC gait in comparison with regular gait at both events (Fig. 1b):  $0.038 \pm 0.018$  vs.  $0.190 \pm 0.029$ ,  $p < 0.001$  at TD; and  $-0.201 \pm 0.053$  vs.  $-0.041 \pm 0.037$ ,  $p < 0.001$  at LO.

Our results revealed that individuals are less stable during TC gait than regular gait. A lower stability represents more challenging to the body's postural control system and increase the risk of falling. To respond to the challenge, the body must adaptively develop neuromuscular control strategies to maintain and improve body balance. Improvements in body balance could signify a reduced fall risk. From this perspective, TC practice reflects the overload practice principle (i.e., to increase the difficulty of tasks during practice). This could in part account for the observed TC-induced balance improvements among older adults in previous clinical trials (Lomas-Vega et al., 2017).

**Figure 1:** a) Demonstration of dynamic gait stability defined within the conceptual framework of Feasible Stability Region (FSR). Also shown are the COM motion state trajectories during the stance phase in TC and regular gaits for a representative participant. b) Comparison between TC and regular gaits for dynamic gait stability at TD and LO. \*\*\*:  $p < 0.001$ .

### Significance

Our study represents the first attempt to inspect the biomechanical impact of TC movements on fall risk. A clear understanding of how each TC form affects body biomechanics will lay a solid scientific foundation for future efforts to optimize the effectiveness of TC practice on preventing falls.

## A hydrodynamics model to predict under-shoe fluid pressures based on the dimensions of a worn region

Sarah L. Hemler<sup>1</sup>, Vani H. Sundaram<sup>2</sup>, and Kurt E. Beschorner<sup>1</sup>

<sup>1</sup> Department of Bioengineering, University of Pittsburgh, <sup>2</sup> Department of Mechanical Engineering, University of Colorado, Boulder, Email: \*slh148@pitt.edu

### Introduction

Slips and falls are a major cause of injury in the workplace. As slips occur at the shoe-floor interface in the presence of a lubricant, footwear is an important factor for preventing slips. Previous research has shown that donning completely worn shoes presents a higher slip risk than wearing new shoes [1] and that switching to a new pair of shoes lowers slip risk [2]. While these studies establish wear as a relevant risk factor for slips, the literature fails to present a method of predicting slip risk based on the physical condition of the shoe. Lubrication theory may provide important information on the impact of the size of the worn region relative to the under-shoe performance in the presence of liquid contaminants. As the size of the worn region grows, the drainage ability decreases leading to increased under-shoe fluid pressures and subsequent increased slip risk [3]. The purpose of this study is to assess the ability to predict under-shoe fluid pressures based on shoe wear geometry applied to a theoretical hydrodynamics solution.

### Methods

This study analyzes data from three previous experiments (E1-simulated shoe wear [3], E2-progressive shoe wear [4], and E3-human slipping trials [5]). In each experiment, under-shoe fluid pressures are predicted by a solution of Reynolds equation based on shoe wear geometry measurements.

**E1:** Four right shoes were systematically abraded to simulate wear during gait. At baseline and after each wear cycle, under-shoe peak fluid pressures were measured as shoes were slid across a contaminated surface.

**E2:** 13 participants wore two pairs of shoes in the workplace for one month at a time ( $n_{\text{shoes}}=22$ ). At baseline and after each month of wear, fluid pressures were measured for both sides (L/R).

**E3:** 57 participants experienced a slippery condition, while wearing their own worn shoes. The liquid contaminant was spread across an array of pressure sensors. Under-shoe fluid pressures were measured during the unexpected slipping condition.

For all shoes, the size of the worn region (length,  $l$ , and width  $b$ ) was measured based on the largest region without tread on the heel of the shoe. Measurements were repeated for each wear cycle and month of wear for E1 and E2. The tapered-wedge bearing solution of the Reynold's equation was used to predict the minimum film thickness (PFT) based on the size of the worn region along with the dynamic viscosity of the 90% glycerol used in all experiments ( $\mu = 214 \text{ cP}$ ), the sliding speed ( $u_{E1,E2} = 0.3 \frac{m}{s}, u_{E3} = 0.1 \frac{m}{s}$  [6]), normal force ( $F_{E1,E2} = 250 \text{ N}, F_{E3} = 179 \text{ N}$  [6]), a wedge incline factor ( $K_p = 0.025$ ) [7], and a wedge-fluid, side leakage factor ( $\eta$ ) which was dependent on the worn region size (Eq. 1).

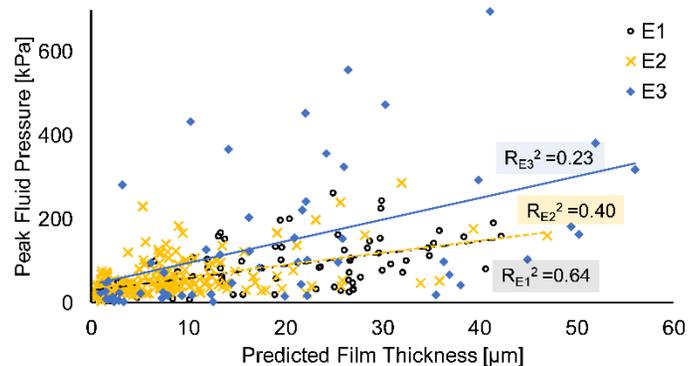

$$PFT = \sqrt{\frac{6\mu ul^2 b \eta K_p}{F}} \quad (1)$$

Three statistical models were used to test the effect of PFT on the peak fluid pressures. Specifically, two repeated-measures

regression models (E1 and E2) and one linear regression model (E3) were used where the independent variables were PFT (E1-3), shoe type (E2), and side (E2), and the dependent variable was the peak fluid pressure (E1-3). Random variables of shoe type (E1) and participant (E2) were included in the models.

### Results and Discussion

PFT predicted peak fluid pressure for all three models: E1 -  $F_{1,75} = 95.7, p < .001$ , E2 -  $F_{1,180} = 47.9, p < .001$ , and E3 -  $F_{1,55} = 16.5, p < .001$ .

**Figure 1:** Peak fluid pressure with respect to the PFT across E1, E2, & E3. Trendlines per experiment and respective  $R^2$  values are shown.

This research validates the use of PFT based on the tapered-wedge solution of Reynolds equation to predict under-shoe fluid pressure in multiple experimental contexts. Consequently, the size of the worn region of the shoe outsole wear is a good indicator of under-shoe hydrodynamics.

### Significance

Shoe traction performance is dependent on effective drainage that minimizes under-shoe fluid pressures. By applying fluid mechanics to a simple metric of shoe wear, this research supplies a clearer understanding of how shoe outsole wear geometry influences under-shoe fluid pressures. This research provides a foundation for developing a measurement tool to assess the worn region of shoe outsoles and supply replacement recommendations. Such a tool would guide appropriate shoe replacement, enhance the performance of workplace footwear [5], and thus reduce slip and fall accidents [5,6].

## Slipping Foot and Recovery Step Yaw After a Turning Slip: A Balance Recovery Mechanism?

Corbin M. Rasmussen<sup>1</sup> and Nathaniel H. Hunt<sup>1</sup>

<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE USA

Email: cmrasmussen@unomaha.edu

### Introduction

A wealth of research has focused on factors and behaviors key to slip recovery and fall prevention, such as trunk angle, recovery steps (RS), and arm swing,<sup>1,2</sup> but little attention has been paid to the role of foot yaw. Side-specific adjustments to foot yaw occur during turning<sup>3</sup> and it is considered a balance strategy in response to small deviations during walking.<sup>4</sup> Whether this extends to larger perturbations like slips has not been explored, possibly due to the mechanical constraints of commonly used slipping methods in the lab. We recently developed a wearable device (WASP) that delivers unconstrained slips, allowing the sliding foot to move and rotate freely.<sup>5</sup> Using this device, we aimed to determine how slipping foot (SF) and RS yaw changes during slips of different contexts, and to investigate the influence of slip severity (i.e. slip distance) on the degree of SF and RS yaw.

### Methods

18 young adults (22.72±2.89 yrs., 9 females) were outfitted with a safety harness, full-body marker set, athletic shoes, and a pair of WASP devices.<sup>4</sup> Subjects were slipped via WASP during early (0-33%), mid (34-67%), or late (68-100%) stance phase of the inside or outside foot as they followed 180° curvilinear turns of 1.0 or 2.0 meter radius. Twelve trials were performed randomly to observe all possible combinations of phase, foot, and radius, however only early stance slips are reported here. All trials were recorded by a 17-camera motion capture system at 200 Hz.

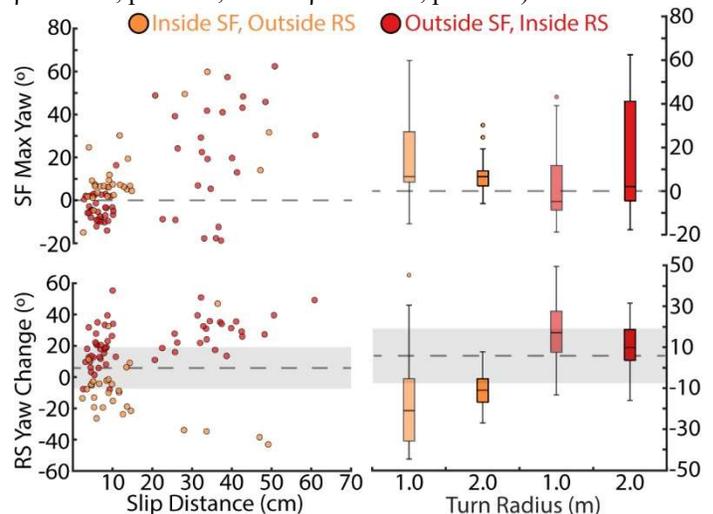

Gait events<sup>6</sup>, slip onset, and slip cessation were determined from kinematics. Foot segments were simplified to a line between the calcaneus and 2<sup>nd</sup> metatarsal head markers. SF yaw change was calculated as the continuous angle between the SF segment throughout the slip and the foot's position at slip onset. Peak external and internal rotation angles were extracted from the resulting time series, and the one with the largest magnitude was entered into the SF analysis. For RS yaw, the angle between the RS foot segment and the center of mass (CoM) velocity vector at step touchdown was derived. The same method was used to obtain unperturbed step (US) yaw at the left and right heel-strike before slip onset.<sup>3</sup> The average US yaw angle for each set of contexts was then calculated and subtracted from RS values under the same contexts to obtain the RS yaw change. Finally, slip distance was the difference between the SF CoM positions at slip onset and cessation. Positive values correspond to external rotation and negative to internal rotation.<sup>3</sup>

Linear mixed effects models were built to examine the effect of curvature and foot on SF and RS yaw. These contexts were treated as fixed effects, and subject as a random effect. Spearman rank correlation coefficients were derived to quantify the relationship between slip distance and SF and RS yaw.

### Results and Discussion

Figure 1 illustrates the following results. Inside SF max yaw was more externally rotated than that of the outside SF ( $t(85)=2.07$ ,  $p=0.042$ ). The effect of turn curvature ( $t(85)=2.13$ ,  $p=0.036$ ) was qualified by foot, with wider turns reducing and increasing

external rotation during inside and outside SF respectively ( $t(85)=-2.18$ ,  $p=0.032$ ). In terms of RS yaw change from US, outside foot RS were more internally rotated, while inside foot RS were externally rotated ( $t(82)=-4.29$ ,  $p<0.001$ ). Sharper turn curvature increased the degree of this trend ( $t(82)=-2.25$ ,  $p=0.027$ ). Regardless of foot, SF max yaw tended to be more externally rotated with increasing slip severity (Outside:  $\rho=0.4683$ ,  $p<0.001$ ; Inside:  $\rho=0.3823$ ,  $p=0.041$ ). RS yaw change tended to increase in magnitude with slip severity, as outside and inside foot slips exhibited externally and internally rotated RS respectively, however the latter was not significant (Outside:  $\rho=0.5797$ ,  $p<0.001$ ; Inside:  $\rho=-0.3187$ ,  $p=0.092$ ).

**Figure 1:** Plots illustrating SF and RS yaws' association with slip severity and context. Shaded areas represent the mean US yaw  $\pm$  1 SD.

### Significance

To our knowledge, this is the first examination of foot yaw during and after a slip perturbation. Our RS results support the notion of foot yaw as a balance strategy,<sup>4</sup> as the magnitude of RS yaw increased with slip severity. RS yaw, particularly if in the direction of a fall, may act to extend the base of support in that direction with a shorter required RS length. The function of SF yaw, specifically whether it is beneficial or detrimental to recovery, is unclear and should be the topic of future research. Overall, these findings should encourage further study of foot yaw's role in slip recovery in fall-prone populations, and to what degree it can be altered by fall-prevention training.

## Impact of an Ankle-Foot Orthosis on Reactive Stepping in Young Adults

Kyra E. Twohy<sup>1</sup>, Kurt Jackson<sup>1</sup>, and Kimberly E. Bigelow<sup>1</sup>

<sup>1</sup>University of Dayton, Dayton, OH

Email: twohyk1@udayton.edu

### Introduction

Ankle-foot orthoses (AFOs) are commonly prescribed to individuals with conditions such as stroke and multiple sclerosis to assist with foot drop and other gait deficits [1]. While AFOs have obvious benefits, there is believed to be some tradeoffs. In particular, the rigidity and support provided by AFOs may restrict ankle movements, which could be helpful for tasks such as sit-to-stand or recovery upon a slip or trip. While there are numerous studies examining reactive stepping after a perturbation to better understand fall mechanisms and fall recovery strategies [2,3], to date, these studies have not included individuals wearing AFOs.

The goal of this pilot study was to examine, first in healthy young adults, differences in step recovery when an AFO was worn compared to a no-AFO condition, using a lean-and-release paradigm. We hypothesized that individuals would prefer to step with the leg not wearing the AFO, and that the presence of an AFO on either the stepping or stance leg would increase the overall time it took to step.

### Methods

Twenty healthy young adults (Age:  $23.7 \pm 2.3$  years, Gender: 14 Male, 6 Female) participated in this study. All individuals gave written informed consent and all study procedures were approved by the University of Dayton Institutional Review Board.

The lean-and-release system followed previous research and set to a  $15^\circ$  forward lean, confirmed with an angulometer [2,3]. To determine release, 2 retro-reflective markers were attached to the harness, which would separate upon release. Each foot was placed on a Bertec in-ground force plate [Models 4060 and 4080].

A total of 30 reactive stepping trials were completed using a lean-and-release set up. No AFO was present for the first 10 trials. Following this, a total of 20 trials with an off-the-shelf traditional plastic AFO were completed (10 per leg, randomized in sets of two). Study participants were instructed to do whatever was necessary to regain their balance. Each participant had retro-reflective markers placed on anatomical locations of the back, hips, thighs, shank, and feet. All trials were recorded with a VICON motion capture system at 150 Hz.

Visual 3D was used to calculate step length, reaction time, step time, and maximum joint angles identified by previous lean-and-release-research [2,3]. Other variables studied included step length and stepping foot preference. Differences between reactive stepping with and without an AFO present was determined by running a one-way ANOVA with a Tukey post-hoc in SPSS to compare the no AFO condition to the AFO on the stepping leg and to the AFO on the stance leg.

### Results and Discussion

Participants, on average, stepped 1.4 times more frequently with the leg not wearing the AFO. This indicates that an AFO does change stepping foot preference to favor keeping the AFO leg in stance. It may be that individuals find the AFO's weight and movement restrictions are less conducive to the speed and adaptability that a reactive step requires; future work will determine how this changes for those in true need of an AFO.

Results of timing and kinematic variables are displayed in Table 1, below. Reaction time was significantly increased in trials without an AFO present as compared to either the AFO worn on the stance or the stepping leg. Differences in step time were not significant, however.

Step length was significantly shorter in the stance and stepping leg AFO conditions, as compared to the no AFO condition. This could be due to a preference for landing flat footed. As the knee extends to complete the step the toes are brought further up with the ankle constrained by the AFO. A shorter step is then needed to minimize ankle extension to be able to land flat footed.

Both the maximum joint angle of the ankle and the knee were significantly different when the AFO was on the swing leg. This difference was expected because the AFO does limit the range of motion at the ankle and as a result the knee angle would be adjusted to account for the change. However, this did not carry up to the hip joint. Future work may also want to examine muscle activation during a reactive step with and without an AFO to understand the underlying adjustments in muscle activation levels and timing needed to alter a stepping response.

### Significance

This is the first known study to examine stepping reactions while an AFO is worn. The findings of this study lay the foundation for future studies focused on assessment of stepping reactions on impaired populations wearing AFOs and, if needed, interventions to improve the likelihood of a successful recovery step.

### Introduction

Tripping while walking is a main contributor to falls [1]. Trip frequency is related not only to the elevation of the swing toe above the ground or an obstacle, but also to the variance in the swing toe clearance [2]. To identify the source of this variance, the sensitivity of the swing toe height to changes in the limb joints has been quantified. However, previous sensitivity calculations have been restricted to only sagittal-plane angles [3], swing limb [3], or unobstructed walking [3,4]. Therefore, the aims of the present study are to (1) quantify the sensitivity of swing toe height to sagittal and frontal plane joint angles during overground walking and while crossing obstacles of varying height, and (2) compare the sensitivity of toe height to angles that are grouped as follows: the frontal plane vs. sagittal plane angles, and the swing vs. stance limb angles.

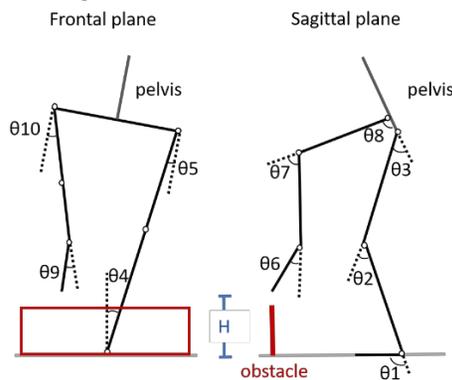

Fig. 1: Lower-limb joint angles that influence toe height.

### Methods

Ten subjects ( $23.8 \pm 3.4$  years, 3 female) crossed obstacles on a 15 m walkway. Ten trials of each condition were recorded (unobstructed, 3, 10, 26 cm obstacle). Whole-body kinematics were measured using a Qualysis motion capture system. Sensitivity of toe height to the lower-limb joint angles was determined at the instant of minimum toe clearance for unobstructed gait and the instant when the first and second foot crossed the obstacle (lead and trail subtasks).

The function relating toe height ( $H$ ) to the lower-limb joint angles ( $\theta_i$ ,  $i=1$  to  $10$ ; Fig. 1) was written:  $H=f(\theta)$ . The Jacobian of  $f$  was derived:  $J=[\partial H/\partial \theta_1 \ \partial H/\partial \theta_2 \ \dots \ \partial H/\partial \theta_{10}]$  and evaluated by substituting the measured values of the joint angles. The values in  $J$  are the changes in  $H$  due to a unit change in an angle, i.e., the sensitivities of  $H$  to individual angles.

Sensitivity of  $H$  to groups of angles within the (1) sagittal vs frontal planes and (2) stance vs swing limbs were compared. Sensitivity to a group of angles was quantified as the singular value of the Jacobian comprising of the partial derivatives with respect to those angles. For example, the singular value of  $J_{\text{frontal}}=[\partial H/\partial \theta_4 \ \partial H/\partial \theta_5 \ \partial H/\partial \theta_9 \ \partial H/\partial \theta_{10}]$  yields the maximum possible change in  $H$  due to the vector  $[\partial \theta_4 \ \partial \theta_5 \ \partial \theta_9 \ \partial \theta_{10}]$  of unit magnitude, and it is defined as the sensitivity of  $H$  to the frontal plane angles. ANOVAs were used to determine if sensitivity was affected by individual joint angles ( $angle \times subtask \times obst\_height$ ), and by angle groups across planes ( $group_{plane} \times$

$subtask \times obst\_height$ ) and across limbs ( $group_{limb} \times subtask \times obst\_height$ ).

### Results and Discussion

For individual angles, toe height was most sensitive to stance hip ab/adduction, consistent with [4]. Toe height was also sensitive to stance ankle flex/extension and ab/adduction, and least sensitive to swing ankle ab/adduction. Sensitivity to individual angles was not consistent across the lead and trail subtasks during obstacle crossing (3-way interaction:  $F_{(27,711)}=6.65$ ;  $p<.01$ ; Fig. 2). For example, sensitivity for the trail subtask was higher than the lead subtask for the swing knee flex/extension, but lower for swing hip flex/extension.

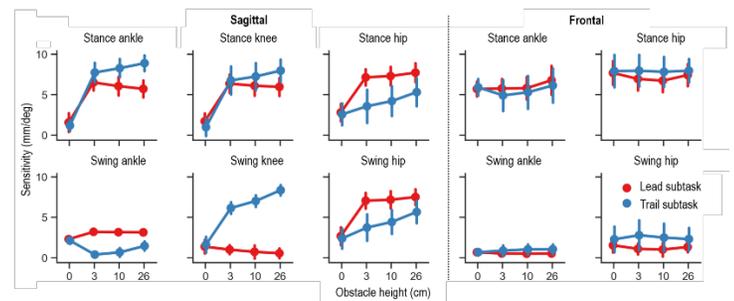

Fig. 2: Mean±SD of toe height sensitivity to individual joint angles.

For groups of angles, toe height was more sensitive to frontal plane angles than sagittal plane angles for unobstructed gait (0 cm obstacle), but this relation is reversed during obstacle crossing ( $group_{plane} \times obst\_height$ :  $F_{(3,135)}=53.06$ ,  $p<.01$ ; Fig. 3A). Toe height was more sensitive to the stance limb joint angles than the swing limb joint angles for all obstacle heights ( $group_{limb}$ :  $F_{(1,135)}=912.9$ ,  $p<.01$ ; Fig. 3B).

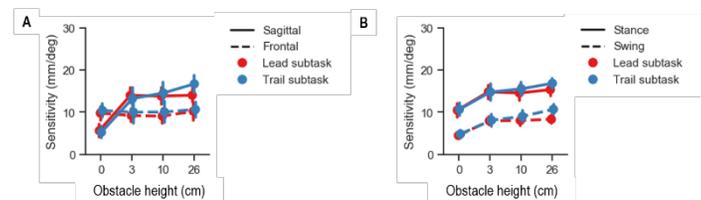

Fig. 3: Mean±SD of toe height sensitivity to groups of joint angles in two planes (A) and in two limbs (B).

### Significance

When individuals/patients report increased frequency of tripping, one should consider weakness or impaired coordination in the ab/adductors as potential sources of the issue. Furthermore, interventions should not be limited to the swing limb, as the stance limb angles, as a group, had greater influence than the swing limb angles, as a group, on swing toe height (Fig. 3B).

## The impact of obesity on trunk control following trip-like treadmill perturbations while standing

Noah J. Rosenblatt.<sup>1\*</sup>, Michael L. Madigan<sup>2</sup>

<sup>1</sup> Rosalind Franklin University of Medicine and Science, North Chicago, IL; <sup>2</sup> Virginia Tech, Blacksburg, VA

Email: \*[noah.rosenblatt@rosalindfranklin.edu](mailto:noah.rosenblatt@rosalindfranklin.edu)

### Introduction

The 30% of older Americans (65+ years of age) who are obese (body mass index (BMI)  $\geq 30$  kg<sup>2</sup>/m) are up to 50% more likely to fall<sup>1</sup> and are at greater odds of sustaining a fall-related injury<sup>2</sup>, than normal weight (BMI: 17.5-25 kg<sup>2</sup>/m) older adults (NW). Obese older adults (OB) may fall at higher rates than NW following a lab-induced trip<sup>3</sup>. A large initial change in angular velocity, such as that imparted by a trip, may present a greater challenge to OB due to a greater increase angular momentum (i.e. more massive trunk)<sup>5</sup>. This may increase the likelihood of a fall, i.e. increase trunk flexion and trunk angular velocity at the instant of recovery step completion<sup>4</sup>. Similarly, increased inertia may be beneficial to balance when there is little initial angular velocity<sup>6</sup>. The purpose of this study was to quantify the effects of obesity on biomechanics of balance recovery in older adults. We hypothesized that following trip-like treadmill perturbations, differences in trunk angle and angular velocity between OB and NW older adults would increase in proportion to the perturbation acceleration. We also explored the extent to which obesity-related impaired trunk control was related to functional mobility.

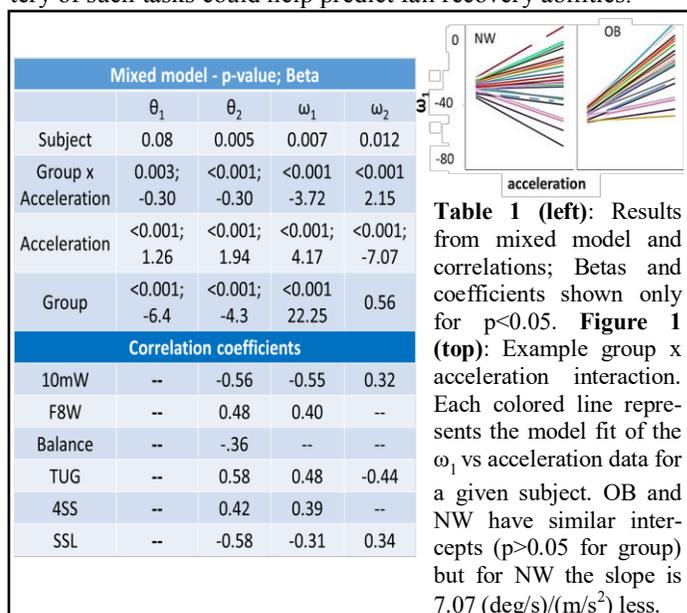

### Methods

We recruited 29 OB and 30 NW with self-reported ability to walk one mile at any pace and normal range of motion in the lower limbs and trunk. Participants were excluded for use of a cane/walker, artificial joint replacement, self-reported history of conditions that interfere with gait or diabetic peripheral neuropathy or osteoporosis. Participants completed the following functional tests: 10m walk at maximum speed (10mW), Timed-up-and-go (TUG), figure of eight walk (F8W), single-limb stance for a maximum of 30 s (SLS), and standing balance using the NIH toolbox. During a separate session they completed 30 perturbation trials, after five practice trials. For each trial, participants stood on a motorized treadmill (C-Mill; Motekforcelink, Netherlands) which suddenly accelerated for 150s in the posterior direction, and then decelerated. There were 10 different accelerations, 1.5-3.75 m/s<sup>2</sup> in increments of 0.25 m/s<sup>2</sup>, each of which was provided three times (all practice trials were performed at 1.75 m/s<sup>2</sup>). The order of accelerations was randomized. A 6 camera motion capture system (Vicon, UK) tracked body movements. For each trial we calculated the angle of the trunk at the instant that the first and second recovery step contacted the treadmill belt ( $\theta_1$  and  $\theta_2$ , respectively) as well as the associated trunk angular velocities ( $\omega_1$  and  $\omega_2$ , respectively). A mixed model analysis (within subject factor: acceleration; between subject factor: group - OB vs NW, referenced to OB; random factor: subject) was used to determine the relationship between trunk kinematics and treadmill acceleration. In the event of a significant effect of subject, we correlated subject-specific slopes with functional measures.

### Results and Discussion

Consistent with our hypothesis, we found significant group x acceleration interactions for all trunk kinematics (Table 1). NW exhibited a smaller  $\theta_1$  and  $\theta_2$  than OB at low accelerations (negative Beta for group), and the rate of increase in  $\theta_1$  with increasing ac-

celeration was nearly 25% greater for OB vs NW (Beta for acceleration for OB is 1.26 vs. 0.96 (1.26-0.30) for NW). With regard to  $\omega_1$  at low treadmill accelerations OB had greater extension velocities (more negative values; positive Beta for group), but  $\omega_1$  increased more quickly with increasing treadmill acceleration (Figure 1). Despite having different  $\omega_1$  at low treadmill accelerations,  $\omega_2$  was similar for both groups at low accelerations ( $p > 0.05$  for group term). Both OB and NW demonstrated increasing trunk extension velocities on the second step with increasing treadmill acceleration, but OB increased extension velocity at a greater rate than NW, perhaps to compensate for differences during the first step. Multiple functional measures were correlated with subject-specific slopes (Table 1). While trunk control strategies for balance recovery, i.e., scaling of kinematics in response to increasing perturbations magnitudes, are thought to be completely distinct from other capabilities, to some extent they may exploit strength and coordination patterns that also facilitate performance of functional tasks. In absence of perturbation paradigms, a battery of such tasks could help predict fall recovery abilities.

**Table 1 (left):** Results from mixed model and correlations; Betas and coefficients shown only for  $p < 0.05$ . **Figure 1 (top):** Example group x acceleration interaction. Each colored line represents the model fit of the  $\omega_1$  vs acceleration data for a given subject. OB and NW have similar intercepts ( $p > 0.05$  for group) but for NW the slope is 7.07 (deg/s)/(m/s<sup>2</sup>) less.

### Significance

We confirm that obesity provides protection against falls at low velocities (e.g., bumped while standing) but not high velocities (e.g., trips or slips). Perturbation based interventions that have been shown to improve trunk control and reduce trip-related falls in NW may be effective at reducing falls by OB. Such intervention could also improve functional mobility in this population.

### Introduction

In the military, load carriage is an unavoidable task. Previous research suggests that kinematic adaptations made in response to added load increases stability during gait. Yet, the stability measures typically used do not quantify a gait pattern's dynamic stability, but rather its kinematic variability. [1] The *local divergence exponent* (LDE) provides a nonlinear measure of gait's *local dynamic stability*. [2] We have reported that LDE (and hence local dynamic stability) is affected by military relevant loads and speeds [3] and that females alter average gait mechanics differently than males in response to these loads. [4] No previous research has investigated if standardized military loads affect local dynamic stability of males and females similarly. As females now have access to all US military occupations, often carrying similar loads to males, it is important to assess if these loads affect the stability of females differently than males. The purpose of this analysis was to determine if local dynamic stability is similarly affected in both males and females when carrying standardized military loads. We hypothesized that local dynamic stability would differ between females and males, with females having lower local dynamic stability compared to males as load increased.

### Methods

Fifteen females (age: 26.0±5.1 yrs, height: 1.65±0.1 m, mass: 67.6±9.4 kg) and fifteen males (age: 26.0±4.8 yrs, height: 1.78±0.08 m, mass: 79.8±9.1 kg) completed 2-minute walking trials on a treadmill under three load conditions (unloaded: 1.2 kg, light: 15 kg, and heavy: 27 kg) at 1.35 m/s. Loads and walking speed were selected based on Army doctrine recommendations. Two minutes of marker data from the trunk (C7) and pelvis (sacrum) segments were collected and low-pass filtered (10Hz). The first-time derivative (velocity) time series was used for analysis. Rosenstein's algorithm was used to calculate LDE for the trunk and pelvis velocity time series in all directions (mediolateral, anteroposterior, vertical), where a larger LDE indicates decreased local dynamic stability. We used a 3x2 repeated measures ANOVA with sex as a between-subject factor, load as a within subject factor, and included the interaction of sex and load. Post-hoc analyses were run if significant interactions of load and sex were detected.

### Results and Discussion

**Table 1:** Mean±SD of Local Divergence Exponent (LDE) for each load by sex condition in each direction.

Direction	Unloaded		Medium Load		Heavy Load		
	Female	Male	Female	Male	Female	Male	
Trunk	Anteroposterior*†	0.36±0.05	0.45±0.05	0.35±0.04	0.45±0.05	0.37±0.04	0.48±0.06
	Mediolateral*†	0.36±0.04	0.38±0.05	0.41±0.05	0.44±0.03	0.43±0.04	0.46±0.03
	Vertical*†	0.59±0.08	0.68±0.11	0.63±0.10	0.73±0.14	0.71±0.09	0.78±0.14
Pelvis	Anteroposterior	0.33±0.06	0.34±0.04	0.33±0.06	0.34±0.05	0.34±0.07	0.35±0.06
	Mediolateral	0.30±0.05	0.33±0.07	0.29±0.08	0.34±0.09	0.32±0.07	0.35±0.10
	Vertical*†	0.46±0.09	0.57±0.09	0.50±0.13	0.62±0.13	0.56±0.12	0.66±0.13

Note: \*Indicates significant ( $p < 0.05$ ) main effect for load, †Indicates significant ( $p < 0.05$ ) main effect of sex

We found no significant interactions of load and sex for LDE of the trunk or pelvis ( $p > 0.05$ ), but did detect main effects of load and sex for all directions of the trunk ( $p \leq 0.03$ ) and in the vertical direction of the pelvis ( $p \leq 0.01$ ). In all directions of the trunk and in the vertical direction of the pelvis, females had significantly lower LDE compared males indicating greater local dynamic stability than males across load. LDE significantly increased with each load in the anteroposterior and vertical directions ( $p < 0.01$ ) of the trunk and the vertical direction of the pelvis ( $p < 0.01$ ). Mediolateral LDE of the trunk was significantly greater at the heaviest load condition compared to the medium and unloaded conditions ( $p \leq 0.002$ ). These results indicate that females have greater local dynamic stability of the trunk than males regardless of load. Local dynamic stability of the trunk is decreased with load in all directions while stability of the pelvis is only affected by load in the vertical direction.

### Significance

Female Soldiers are generally shorter and lighter than their male counterparts. We previously reported that females alter their gait mechanics differently than males when wearing standardized loads, likely due to differences in relative mass carried. We have also reported that increasing load decreases local dynamic stability. We hypothesized that local dynamic stability in females would therefore decrease more with load than males given the higher relative mass carried. However, we found that females had greater local dynamic stability than males regardless of load. The excess load decreases this stability in both males and females, but further analysis is needed to determine if the rates of change in stability differs between females and males.

## Introduction

One common measure of dynamic balance in human walking is whole-body angular momentum (WBAM). To compute angular momentum, one must specify a reference axis about which momentum is calculated. Momentum-based controllers for humanoid robots may use axes that project through either the center of mass (CoM) or the center of pressure [1]. However, biomechanists primarily compute angular momentum about an axis projecting through the CoM to quantify balance during walking [2]–[4]. Here, we asked if the choice of the reference axis influences interpretations of dynamic balance control.

## Methods

Four healthy young individuals walked on a dual-belt treadmill at their self-selected speed. Sudden treadmill accelerations of different magnitude and direction were remotely triggered at foot strike, and belt speed returned to the self-selected speed during swing. Full body kinematics were captured using a 10-camera Qualisys Oqus system. From this data, we estimated whole-body angular momentum (WBAM) as the sum of all segmental angular momenta in the sagittal plane (Eqn.1).

$$\overrightarrow{WBAM}_{ref} = \sum_i [m_i (\vec{r}_{ref-i}^i \times \vec{v}_{ref-i}^i) + I^i \omega^i] \quad (1)$$

Here,  $m_i$  is segmental mass,  $\vec{r}_{ref-i}^i$  is a vector from the segment's center of mass to the reference axis,  $I$  is the segmental moment of inertia about its center of mass,  $\omega$  is the segmental angular velocity, and the index  $i$  corresponds to each limb segment. Two reference axes were used for computing WBAM: a mediolateral axis projecting through 1) the CoM or 2) the leading edge of the base of support (BoS) as estimated by a marker on the first phalanx. Both axes were defined as positive to the person's right.

For both metrics, we used the maximum value of  $WBAM_{COM}$  and  $WBAM_{BoS}$  during single support of the perturbation step to quantify the effect of perturbations. Negative values represented forward rotation, and positive values represented backward rotation. Each measure was normalized by weight, height, and walking speed [2].

We used a linear mixed effect model to determine if the maximum  $WBAM_{COM}$  and  $WBAM_{BoS}$  during the perturbation was associated with perturbation magnitude. The significance level was set at  $p < 0.05$ .

## Results and Discussion

WBAM during the perturbation step deviated from the trajectory during the pre-perturbation step (Fig 1A & B). During treadmill acceleration, WBAM during the perturbation step became more negative than the pre-perturbation step as the body rotated forward. During treadmill deceleration, WBAM became more positive as the body rotated backward.  $WBAM_{BoS}$  magnitude was higher than  $WBAM_{COM}$  as a result of the larger distance between most segments and the reference axis. The maximum  $WBAM_{COM}$  and  $WBAM_{BoS}$  during the perturbation steps were both negatively correlated with perturbation size ( $p < 0.001$ ) (Fig

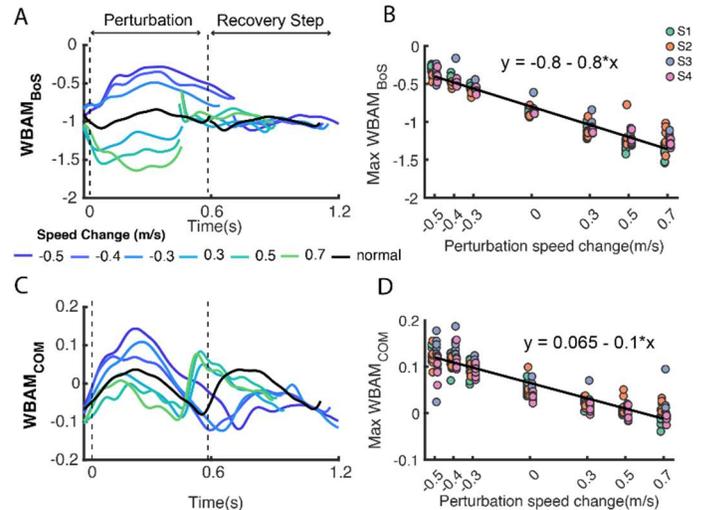

Figure 1:  $WBAM_{BoS}$  (A) and  $WBAM_{COM}$  (C) over time. Maximum  $WBAM_{BoS}$  (B) and  $WBAM_{COM}$  (D) were negatively correlated with perturbation size.

1C & 1D). Thus, peak WBAM is negatively correlated with perturbation size regardless of the reference axis.

One advantage of using a reference axis that projects through the CoM is that it is easier to identify the degree of segmental angular momentum cancellation during perturbation responses as perfect limb cancellation will result in zero angular momentum. Whereas, for  $WBAM_{BoS}$ , one needs to compare the values with the angular momentum generated by the CoM about the contact point with the ground using an inverted pendulum model to quantify the degree of limb cancellation.

## Significance

Our future analysis will determine whether errors in approximating CoM dynamics using simplified kinematic model increase when perturbation magnitude increases. During perturbation responses, coordination of the lower extremities and trunk might change relative to unperturbed walking such that estimating the position of the CoM using pelvis motion may be increasingly inaccurate. We will also whether the choice of reference axis influences our interpretations of how intersegmental coordination patterns contribute to regulation of angular momentum during perturbation recovery.

## The Influence of Cognitive Load on Dynamic Balance During Steady State Walking

Gabriella H. Small, Lydia G. Brough and Richard R. Neptune

Walker Department of Mechanical Engineering, The University of Texas at Austin, Austin, TX

Email: gsmall@utexas.edu

### Introduction

Previous research has used a variety of dual-task (DT) paradigms to exacerbate motor impairments and influence gait performance (e.g., walking while performing a mental task) [1], with most research focusing on the influence of DTs on walking speed and stride length [e.g., 2, 3]. However, these studies may not have used sufficiently challenging cognitive tasks [4]. In addition, only limited research has examined the influence of DTs on controlling dynamic balance, which is critical in preventing falls. The purpose of this study was to assess how healthy individuals prioritize their cognitive resources and control dynamic balance during challenging DT conditions. We hypothesize that as the DT load increases, the control of dynamic balance will decrease.

### Methods

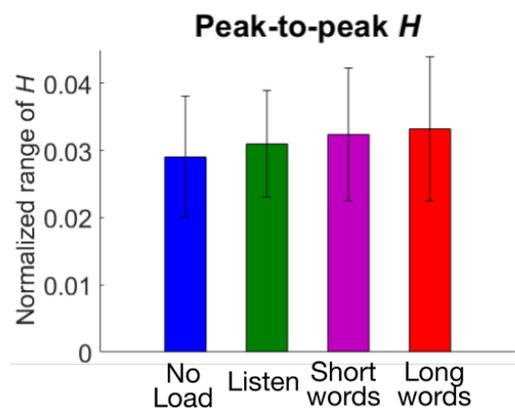

A 10 camera system (VICON, Los Angeles, USA) recorded full body kinematics during steady state treadmill walking for 15 young healthy subjects (age  $25 \pm 4$  years, 9 females) using four increasing levels of cognitive load: no load, passive listening, spelling short 5 letter words backwards and spelling long 10 letter words backwards [4]. Subjects first performed the spelling trials while standing (single task (ST) condition) to create a cognitive baseline. Then they walked on a treadmill at their self selected speed (SS, speed =  $1.35 \pm 0.1$  m/s) and at a fixed speed (1 m/s) while performing the dual task (DT) conditions in a randomized order. Motion data was then analyzed in Visual3D (C-Motion, Germantown, MD) and MATLAB (Mathworks Inc., Natick, MA, USA) to determine changes in dynamic balance across conditions. Dynamic balance was quantified using whole-body angular momentum ( $H$ ), where a higher range of  $H$  correlates with lower clinical balance scores (poorer balance control) [5]. Audio data was examined to detect percent error and correct response rate for the cognitive responses.

### Results and Discussion

As the cognitive load increased in difficulty, peak-to-peak frontal plane  $H$  increased (Fig. 1). No differences were observed in sagittal plane  $H$  between any of the cognitive conditions or walking speeds. Significant increases in  $H$  occurred between the no-load ( $H = 0.0291 \pm 0.009$ ) and long word trials at 1 m/s ( $H = 0.0332 \pm 0.010$ ) ( $p < 0.001$ ) and between the no-load ( $H = 0.0249 \pm 0.008$ ) and long word trials at the SS speed ( $H = 0.0288 \pm 0.010$ ) ( $p < 0.001$ ). Smaller but still significant differences were also found between the no-load and the short word trials for both speeds ( $p < 0.001$ ). These observed increases in  $H$  indicate that as the cognitive load increases, balance control decreases at both fixed and self-selected walking speeds.

Regarding the cognitive task performance, spelling performance did not change between the ST and two DT conditions as measured by the number of errors and response rate ( $p = 0.3$ ). While there was variability in spelling ability between subjects, overall the percent error increased from 3% to 11%, and the response rate dropped by almost half between the short and long word tasks (short word response rate =  $1.79 \pm 0.5$

letter/s, long word response rate =  $0.98 \pm 0.4$  letter/s) ( $p < 0.001$ ), confirming that performance was indeed worse in the longer word (higher cognitive load) task.

**Figure 1:** Normalized peak-to-peak difference in whole body angular momentum ( $H$ , normalized by height, mass and speed of each individual) in the frontal plane for the 4 cognitive loads at the 1 m/s speed.

### Significance

Consistent with previous research, our results suggest that frontal plane balance, as measured by  $H$ , requires more active control than sagittal plane balance [6], and subsequently decreases with higher cognitive loads. Thus, in order to see an influence of cognitive load on balance control in healthy individuals, a sufficiently challenging mental task is needed. A decrease in dynamic balance when walking with increased cognitive loads may increase the risk of falling. Furthermore, the cognitive performance did not change between the ST and DT conditions, which suggests that healthy subjects may prioritize a cognitive task over their balance control during steady state walking. These results provide additional insight into the automaticity of walking and task prioritization in healthy individuals [7], which provides the basis for future studies to determine differences in neurologically impaired populations such as individuals post-stroke.

## Young Adults Can Perceive Very Small Locomotor Disturbances Even When Distracted

Daniel J. Liss<sup>1</sup>, Jessica L. Allen<sup>1</sup>  
<sup>1</sup>West Virginia University, Morgantown, WV  
 Email: [jessica.allen@mail.wvu.edu](mailto:jessica.allen@mail.wvu.edu)

### Introduction

Falls during walking are a leading cause of injuries in both young and older adults (65+ years old).<sup>1,2</sup> Although it is known that concurrent performance of a cognitive task negatively affects both postural control and locomotion,<sup>3,4</sup> the role of cognitive processes in the sensorimotor control of locomotor balance remains unclear. As a first step towards unravelling this role, the purpose of this study was to identify in young adults 1) the threshold of conscious perception of locomotor disturbances (e.g., how small of a locomotor disturbance can be perceived), and 2) the effect of a secondary cognitive distractive task. We hypothesized that performing a cognitive distractive task would impair the ability to perceive small locomotor disturbances.

### Methods

11 young adults (3 M, 22.4±3.1 yrs old) walked on a split-belt instrumented treadmill (Bertec, Inc.) at their self-selected walking speed (SSWS) while randomly experiencing balance disturbances every 8-12 strides. Balance disturbances were imposed through a short duration decrease in velocity of the treadmill belt (dV) triggered at heel-strike. The belt was disturbed to speeds of SSWS-dV, where dV was 0, 0.02, 0.05, 0.1, 0.15, 0.2, 0.3, 0.4 m/s, and returned to SSWS during the subsequent swing phase. Disturbances were randomized and repeated 5 times on the dominant leg with disturbances to the nondominant leg interspersed to reduce learning effects. After each disturbance, subjects were asked if they perceived a balance disturbance and responded “yes” or “no”. Subjects wore noise cancelling headphones to prevent auditory feedback. The conscious perception threshold was determined by fitting a psychometric curve to the proportion correct responses for each dV (Fig. 1A). A subset of subjects (8 subjects, 3M) repeated the same protocol while performing a secondary cognitive distractive task (i.e., counting backwards by 3), and a second conscious perception threshold was calculated. To test our hypothesis that a cognitive distractive task would impair the ability to perceive small locomotor disturbances, we used a one-sample t-test to identify if the change in the conscious perception threshold with addition of the distractive task was significantly different than zero.

### Results and Discussion

Young adults were able to perceive very small locomotor disturbances. Subjects walked at SSWS 1.16 ± 0.08 m/s and perceived disturbances of 0.08 ± 0.04 m/s (7.4 ± 4.0% of the SSWS) during stance. Such low perception thresholds are unsurprising given their intact sensorimotor systems. We expect the ability to perceive locomotor disturbances to get worse with age due to deteriorations in sensory and motor systems.

Young adults maintained the ability to perceive small locomotor disturbances even with the addition of a cognitive distractive task. The average change in conscious perception thresholds between tasks was 0.005 ± 0.027 m/s. In contrast to our hypothesis, the change in perception threshold with the addition of the secondary cognitive distract task was not significantly different than zero (p value = 0.59). This result is

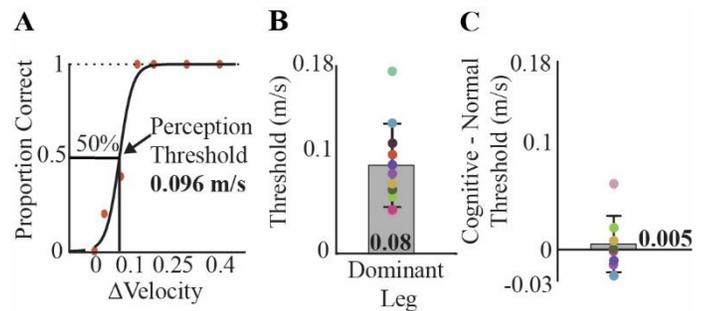

Figure 1: A) Example psychometric curve fitting to identify conscious perception threshold. B) Perception threshold of locomotor disturbances. C) Change in perception threshold with cognitive distractive task. Individual subjects are labeled by a single color.

consistent with prior studies demonstrating high cognitive reserves in young adults. Due to cognitive declines<sup>5</sup>, we expect the cognitive distractive task will have a larger effect on the perception of locomotor disturbances in older adults.

Open questions remain about what sensory feedback is being utilized by young adults to perceive these small locomotor disturbances. For example, are they estimating changes in task-level variables such as body center of mass and/or sensing joint-level changes (i.e., changes in muscle length). Determining where this localization occurs and changes due to aging may provide targets for rehabilitation aimed at improving the ability to maintain balance during locomotion.

In summary, young adults were able to detect very small locomotor disturbances even when performing a secondary cognitive distractive task. We expect that ability to perceive locomotor disturbances will be reduced in older adults due to declines in their sensory, motor, and cognitive systems.

### Significance

Using small level locomotor disturbances, we are investigating the sensorimotor mechanisms responsible for the active control of locomotor balance. Understanding the ability to perceive locomotor disturbances, the sensorimotor contributions to this perception, and changes due to normal aging may provide targets for rehabilitation aimed at improving locomotor balance.

## Susceptibility to Optical Flow Balance Perturbations in Older Adults Prevails Despite Cognitive Distraction

Brian P. Selgrade<sup>1,\*</sup>, Prudence Plummer<sup>2</sup>, and Jason R. Franz<sup>3</sup>

### Introduction

Optical flow perturbations increase gait variability, especially in older adults who rely more on vision to maintain balance [1]. Furthermore, gait variability in older adults is much more susceptible to optical flow perturbations than to a cognitive dual-task [2]. However, cognitive tasks can interfere with motor tasks during walking, reducing gait speed and increasing step width [3]. Those effects are explained by cognitive-motor interference due to the redirection of limited attention to cognitive processing. However, the combined effect of optical flow perturbations and cognitive tasks has yet to be systematically explored; an important gap due to the potential involvement of cognitive resources to either (i) reduce attention and attenuate the impact of, or (ii) disrupt older adult's ability to appropriately respond to, optical flow perturbations during walking. The purpose of this study was to determine the effect of a cognitive task on gait variability in the presence of optical flow balance perturbations. We anticipated that adding a cognitive task would reduce attention to optical flow perturbations; thus, we hypothesized that gait variability in the presence of optical flow perturbations would decrease when performing a cognitive task.

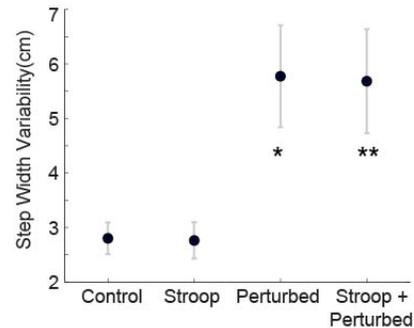

### Methods

Nine older adults (2 male, age: 75.1±3.8 years) gave written informed consent and participated in this study. For each subject, experiments were performed on two different days in randomized order. After participants acclimated to the treadmill over 5 minutes, they completed all walking trials at their preferred speed while viewing optical flow in the form of a virtual hallway projected onto a semi-circular, curved screen in front of the treadmill. Subjects completed four, 2-minute walking conditions: a control trial, a dual-task trial while performing an auditory Stroop task [4], a trial with mediolateral optical flow perturbations, and a trial including both mediolateral optical flow perturbations and the auditory Stroop task. To mitigate any within-subject effect of perturbation training, the perturbation trial performed with the auditory Stroop task was performed in a random order on a different day, separated by one week. Briefly, the auditory Stroop task involved hearing a voice say the words "low" and "high" in a low or high pitch and responding by saying the pitch rather than the word [4]. For all trials, we found step width (SW) by taking the distance between heel markers and calculated step width variability (SWV) and trunk variability quantified as the standard deviation in mediolateral position of the seventh cervical vertebra. A one-way, repeated measures ANOVA with post-hoc t-tests compared condition effects.

### Results and Discussion

There were significant main effects of condition on SWV and mediolateral trunk variability ( $p=0.003$  and  $p=0.002$ , respectively) but not SW ( $p=0.228$ ). Specifically, post-hoc tests revealed significant increases due to the presence of optical flow perturbations whether participants were engaged in the Stroop task ( $p=0.004$  for SWV,  $p=0.006$  for trunk variability) or not ( $p=0.008$  for SWV,  $p=0.018$  for trunk variability). However, we

found no significant effects of the Stroop task on SWV (Fig. 1) or mediolateral trunk variability ( $p \geq 0.43$ ).

**Figure 1.** Effects of a Stroop task on step width variability when walking without (control and Stroop trials) and with perturbed optical flow. Significant difference from control (\*) and Stroop trial (\*\*).

Our hypothesis that the auditory Stroop task would reduce gait variability in the presence of optical flow perturbations was not supported. Indeed, the Stroop task had no effect on SW, SWV, or trunk variability, neither when performed during normal walking nor in the presence of perturbed optical flow. These findings are consistent with some prior studies [4, 5]. However, we chose the auditory Stroop task to deliberately exclude the visuomotor pathways presumably involved when responding to optical flow perturbations. Together, our results allude to a strategy in which attention to balance is prioritized equal to or above cognitive task performance. Adding a Stroop task can cause older adults to reduce gait speed during obstacle negotiation, but this occurred only when subjects walked at faster than preferred speeds [6]. Accordingly, including a more difficult cognitive task or enforcing a faster walking speed could have increased the prevalence of dual-task interference.

### Significance

This study shows that susceptibility to optical flow balance perturbations in older adults prevails even in the presence of distraction from a cognitive dual task. Our findings suggests that walking balance is prioritized over cognitive dual-task performance when walking with balance perturbations.

### Introduction

When falling from a drop or jump, people and other animals preactivate their leg muscles in preparation for landing (1, 2). This preactivation occurs prior to ground contact, indicating it relies on a prediction of the time and force of landing. People are skilled at such predictions, as they readily alter preactivation timing and magnitude to accommodate different jump heights (3). The ability to accurately predict the time and force of landing indicates an implicit understanding of the physics affecting the jump, including the acceleration due to gravity.

We aimed to affect these gravity-based predictions by exposing participants to simulated hypogravity in a targeted jumping task. We hypothesized exposure to hypogravity would result in a delayed preactivation time and lower preactivation magnitude, reflecting an expectation of lower gravity.

### Methods

Ten participants (6 female; Age:  $21.8 \pm 4.0$  yrs; Height:  $1.74 \pm 0.11$  m; Weight:  $615 \pm 98$  N) gave informed consent prior to participating in this Georgia Tech IRB approved study. They each performed targeted countermovement jumps before (Pre), during, and after (Post) exposure to simulated hypogravity. A 0.5G environment was simulated using constant force springs mounted above the participant and attached at their hips. Muscle activity (Vastus Medialis (VM), Lateral (LG) and Medial (MG) Gastrocnemius, and Soleus (SOL): 960 Hz), kinetics, and kinematics data were collected on both legs for each jump.

Preactivation timing was calculated as the time prior to landing when build-up of muscle activity began (3). Preactivation magnitude was calculated as the integrated electromyographic activity between preactivation onset and contact with the ground.

### Results and Discussion

Prior to landing from each jump, participants preactivated the knee and ankle extensor muscles to prepare for landing. Following hypogravity exposure, preactivation onset timing was delayed (compared to Pre) in most muscles by about 15-30 ms (Fig. 1;  $p < 0.05$  for non-dominant VM, LG, MG and dominant VM & SOL). This delay agrees with our hypothesis and suggests the expectation of a longer airtime due to hypogravity.

Preactivation magnitude was significantly reduced ( $p < 0.05$ ) by about half (32 – 52%) in most muscles, except in the dominant leg SOL & LG. A 50% reduction is reasonable as the hypogravity exposure was targeted at reducing participants' body weight by half. This reduction in preactivation magnitude is also in agreement with our hypothesis and likely represents the expectation of a lower muscle load during landing.

Taken together, our results indicate that people adapt both timing and magnitude of muscle activity in jumping to match the requirements of hypogravity exposure. Such adaptation suggests that people are able to successfully adapt to accelerations that do not match the typical acceleration due to Earth's gravity.

### Significance

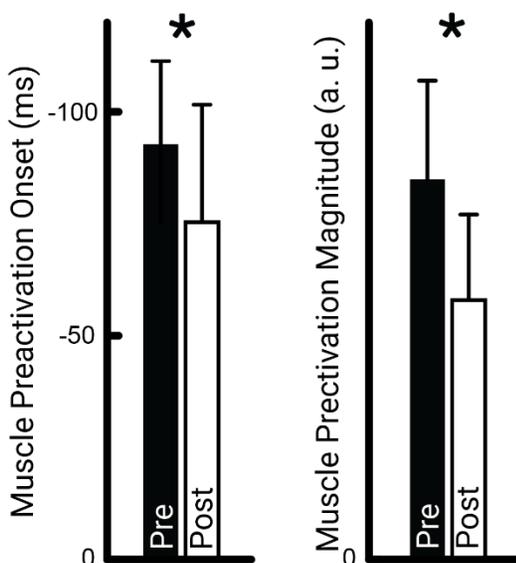

While previous research has shown humans and other animals can predict the timing of landing from a fall under Earth's gravity (1, 2), very few have investigated altered gravities (4). The current study expands on previous hypogravity locomotion paradigms (5, 6) to assess aspects of neural adaptation through the investigation of neuromechanical aftereffects. This new paradigm can be used to explore if this adaptation is isolated to the muscles directly involved in task performance, which may provide important insights on the general nature of how gravity is accounted for during movement control.

## Introduction

Alpine skiing has high rates of orthopaedic injury, but is impractical to study in a laboratory environment. Skiing biomechanics are best assessed with wearable technologies that can be used in the field, such as Inertial Measurement Units (IMUs). While methods exist to determine ski turn transitions using gyroscope signals [1], there is no consensus in the literature of which other timepoints are most relevant to study. Therefore, it is necessary to evaluate the entire turn cycle. Statistical parametric mapping (SPM) allows evaluation of timeseries data, and avoids some biases found in other statistical methods [2].

This study serves as an early proof-of-concept approach to analyzing IMU data with SPM in alpine skiers, while providing analysis framework for future snowsports biomechanics research.

## Methods

Four advanced recreational skiers (aged  $27.5 \pm 4.6$  years, 2 female, no prior lower extremity surgery or injury) consented to participate in this IRB approved protocol. Each skier was instrumented with eight IMUs (APDM, Portland OR, 128hz) secured to the feet, legs, and trunk. Skiers completed four runs through a 10-turn giant slalom style course on moderate terrain.

Gyroscope data was used to determine the start and end times of the middle three turns in each direction from each trial, as previously described [1]. Joint angles were calculated with the IMU manufacturer's software and corrected for offsets in means to account for differences in calibration poses and drift. Kinematics and raw gyroscope data for each turn were filtered at 2hz (per residual analysis [3]) and resampled to 256 points per turn. Foot gyroscope data in the roll (edging) and yaw (turning) axes, and knee flexion, were considered in this analysis example.

SPM analyses were conducted in MATLAB (spm1d.org) to explore three anticipated future use cases: 1) 1-way repeated-measure ANOVAs to determine whether all of a skier's right (or left) turns were performed similarly; 2) 1-way ANOVA to quantify differences between skiers; 3) paired t-test to quantify side-to-side differences within a skier. In all tests, statistically significant results over portions of the turn shorter than 3% were deemed not clinically significant and were disregarded.

## Results and Discussion

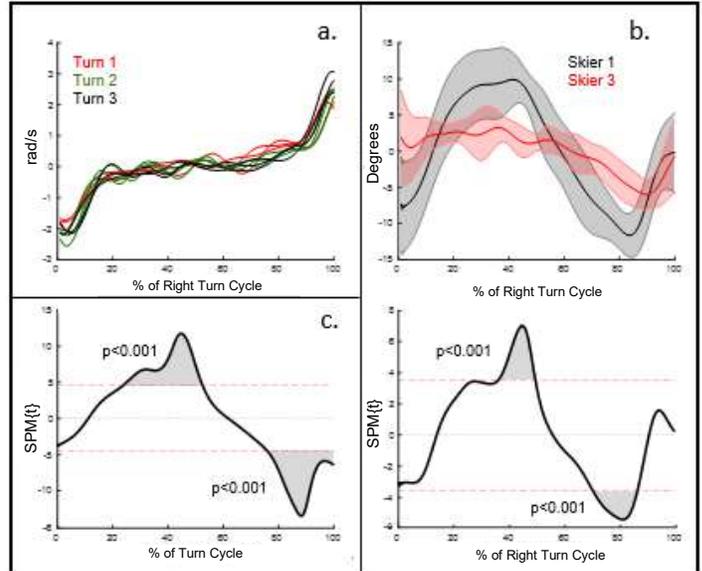

No within-subject differences were found between turns in a repeated-measures ANOVA for roll (Figure 1a), yaw, or knee flexion. These results are course specific; turn-to-turn similarity must be checked for all future skiing biomechanics research study courses before assuming uniformity.

Between skiers, slight differences were observed in roll and yaw over periods shorter than 6% of the turn cycle. However, a 1-way ANOVA revealed differences in kinematics from 0-55% and 67-100% of the turn cycle. In post-hoc t-tests, there were differences in every pair of skiers' knee flexion angles (Figure 1b), and two pairs were significantly different over more than half of the turn cycle.

Side-to-side asymmetries were observed in kinematics of the inside knee between left and right turns for Skier 1 only (Figure

1c). Asymmetries in gyroscope data were observed in three skiers but for less than 9% of the turn in all cases. Side-to-side asymmetry is widely identified as an injury risk factor in other sports, and may be a valuable comparison in future studies.

The discrepancy between the extent of gyroscope and kinematic differences between skiers and limbs suggests that skiers can employ different body position and movement strategies to achieve similar edging and turning mechanics.

**Figure 1:** a) Within-subject repeatability of roll signals between turns on multiple runs. b) Mean and standard deviation of knee flexion angles of two skiers (top) and associated post-hoc t-test (bottom) highlights significant differences as shaded regions that exceed the  $F^*$  threshold. c) Paired t-test found right/left asymmetry in Skier 1 with increased right knee flexion near the turn apex and decreased flexion at turn finish.

These results are preliminary and limited by a small sample size. Additionally, testing for each participant occurred on a different day; while every effort was made to replicate course gate locations, slight differences between turn position and snow conditions for each skier were inevitable.

## Significance

Even with a small sample size in a complex, dynamic sport, significant differences in movement technique can be observed both between and within skiers. This supports the continued use of IMU sensors in the field, and the application of SPM analysis in future skiing biomechanics applications.

# A Biomechanical Analysis of the Triple Step in Recreational Swing Dancers

Meredith D. Wells<sup>1</sup> and Feng Yang<sup>1</sup>

<sup>1</sup>Department of Kinesiology and Health, Georgia State University, Atlanta, GA, USA

Email: mwells19@student.gsu.edu

## Introduction

Traditionally used to refer to the type of jazz music, swing dancing today refers to a cluster of dances developed between the 1920s and 1940s to the swing style of music, including the Lindy hop [1]. Swing dancing is still popular today and continues to draw individuals to it with its lively music and social atmosphere [2]. Yet, dance requires high levels of aerobic power, strength, endurance, and flexibility, making injuries common [3]. There is limited research on the biomechanics of the swing movements which restricts our ability to prevent injuries. Although swing dancing is performed with a partner, it is meaningful to understand whether the biomechanics of swing dancing differ with and without a partner to better develop training protocols.

In swing dancing, the triple step is a common dance element that accounts for the syncopated rhythm of the music and translates it into body movement. This step can be performed by both men and women to the right and left. This step is performed in an upbeat manner with an element of bounce to it. Given the presentative features of the triple step, it is important to analyse the biomechanics underlying this key swing dance element.

The main purpose of this study was to analyse the triple step in recreational swing dancers to determine the biomechanics of the movement and to assess where the greatest risk for injury may lie. It was hypothesized that 1) dancing with and without a partner would not yield biomechanical differences, and 2) that the third step of the triple step would result in the greatest risk for injury.

## Methods

Eight recreational swing dancers who completed 50 sessions of swing dancing within the prior year (age:  $30.9 \pm 4.7$  years; height:  $1.73 \pm 0.07$  m; mass:  $73.6 \pm 13.1$  kg; swing dancing experience:  $4.1 \pm 3.1$  years) participated in the study.

Participants completed a 5-minute dance warm-up of their choosing, and then performed a triple step to both the right and the left with and without a partner in a random order. Three trials were collected for each. Participants performed the dance elements on a vinyl floor wearing a standardized pair of socks.

Three-dimensional lower extremity kinematics and ground reaction force (GRF) were collected via 20 reflective markers using an 8-camera motion capture system (Vicon, UK) and two embedded force plates (AMTI, MA), respectively. Joint power at ankle was calculated using inverse dynamics. The outcome variables (peak vertical GRF and peak ankle power) were identified for all three steps. They were then compared between partnered and non-partnered conditions using paired *t*-tests, and among the three steps using a one-way ANOVA with repeated measures in SPSS v.24 (IBM, NY) with an alpha level of 0.05. Post-hoc tests were run when significant differences were found.

## Results and Discussion

There were no significant differences in the peak vertical GRF between partnered vs non-partnered ( $p > 0.05$ ), which supports

our first hypothesis (Table 1). The ANOVA indicates an overall significant difference in GRF among groups ( $p < 0.05$ ). Follow-up post-hoc analyses further indicated that the first and second steps had significantly greater peak GRF compared to the third step ( $p < 0.05$ ), but were not significantly different from each other ( $p > 0.05$ ). This contradicts our second hypothesis.

Ankle power showed no difference between partnered and non-partnered ( $p > 0.05$  for both), which further supports the first hypothesis. The first and second step showed the greatest amount of propulsion compared to the third step ( $p < 0.05$ ). This is sensible since the dancers paused after the third step and did not move into another step, whereas the first and second step led into consecutive steps making propulsion necessary to keep moving. With ankle power absorption, the second step resulted in the greatest amount of absorption ( $p < 0.05$ ) which contradicts our second hypothesis. However, this is reasonable because when performing a triple step, dancers take a small step to either the right or left, a second step that brings the second foot to meet the first, and then a third step apart again. This element is performed with bounce, so the first and third steps are smoother while the transition from the first to the second step is bouncier as the dancers go up and down when switching from the first to the second foot.

**Table 1.** Mean  $\pm$  SD of the peak vertical GRF (/BW) and ankle power (watts/kg) propulsion and absorption for each of the three steps in the triple step element to the left and right individually (TSL & TSR) and with a partner (TSLP & TSRP).

Element	Step	Outcome		
		GRF	Propulsion	Absorption
TSL	1	$1.41 \pm 0.13$	$4.38 \pm 1.23$	$-1.61 \pm 0.56$
	2	$1.39 \pm 0.12$	$1.76 \pm 1.13$	$-3.50 \pm 0.96$
	3	$1.11 \pm 0.11$	$0.40 \pm 0.22$	$-1.15 \pm 0.64$
TSLP	1	$1.31 \pm 0.12$	$3.78 \pm 1.71$	$-1.26 \pm 0.55$
	2	$1.37 \pm 0.13$	$1.49 \pm 0.48$	$-3.50 \pm 1.34$
	3	$1.07 \pm 0.08$	$0.42 \pm 0.40$	$-0.70 \pm 0.36$
TSR	1	$1.37 \pm 0.14$	$4.04 \pm 1.46$	$-1.28 \pm 0.53$
	2	$1.38 \pm 0.08$	$1.59 \pm 0.82$	$-3.44 \pm 1.03$
	3	$1.10 \pm 0.10$	$0.52 \pm 0.36$	$-1.15 \pm 0.64$
TSRP	1	$1.30 \pm 0.10$	$3.32 \pm 1.08$	$-1.20 \pm 0.60$
	2	$1.36 \pm 0.13$	$1.67 \pm 1.10$	$-2.98 \pm 0.86$
	3	$1.04 \pm 0.06$	$0.41 \pm 0.35$	$-0.96 \pm 0.49$

## Significance

To the best of our knowledge, this is the first study to analyze the biomechanics of swing dancers. Due to the popularity of swing dancing and the potential resulting injuries it is important to understand the internal and external forces acting on the dancers in order to prevent injury and improve performance. This knowledge will be beneficial for the design of future studies to systematically examine the biomechanical aspect of swing dance.

# Real-Time Visual Feedback on Breathing during Treadmill Running to Exhaustion

Joseph A. Passfiume<sup>1</sup>, Nelson A. Glover<sup>1</sup>, Anne R. Crecelius<sup>2</sup>, Ajit M.W. Chaudhari<sup>1</sup>

<sup>1</sup>The Ohio State University, Columbus, OH, USA, <sup>2</sup>University of Dayton, Dayton, OH, USA

## Introduction

Respiratory inductance plethysmography (RIP) is a method of monitoring breathing through the placement of elastic belts around the chest and abdomen, with the most efficient breathing entailing the chest and abdomen expanding and contracting at the same time (in-phase). It is non-invasive and is shown to be reliable and accurate when compared to other measurements of ventilation [1,2]. Because running is such a popular recreational sport, additional knowledge on how breathing efficiency could help runners become more resistant to fatigue may be able to improve overall performance.

In this study, we tested the effect of visual breathing feedback on breathing patterns and time to exhaustion. We hypothesized that receiving visual feedback would encourage more in-phase breathing and longer times to fatigue.

## Methods

13 adult runners (8F,5M; age 25.5±6.5 yrs), who run between 5-20 miles per week, participated in this study. The participants were tested on two days, separated by at least one week, one where they received visual feedback and one without.

On each day, two RIP bands were placed around the chest and abdomen. A neoprene belt holding a BioRadio (Great Lakes NeuroTechnologies, Cleveland OH) was placed around the waist. A chest harness was worn for safety. The participant then ran at a self-selected speed (2.04 ±0.084 m/s) for 5 minutes. After a break, the participants began the fatiguing protocol. The treadmill was inclined to 3°, and speed started at 2.25 m/s. Each minute, the treadmill sped up by 0.083 m/s until the participant signaled they could no longer continue (volitional exhaustion). During this fatiguing protocol, real-time visual feedback was provided on one day (Fig. 1) and not on the other. Breathing data (voltage based on the circumference of the RIP bands) were collected during the 5-minute warm up and during the fatiguing protocol at 250 Hz. Phase angle, a quantity between 0 and 180 degrees (representing the synchrony of the chest and abdomen) [3,4], and time to exhaustion were calculated. The effects of visual feedback and phase angle were analyzed with single-variable regressions for their effects on time to exhaustion.

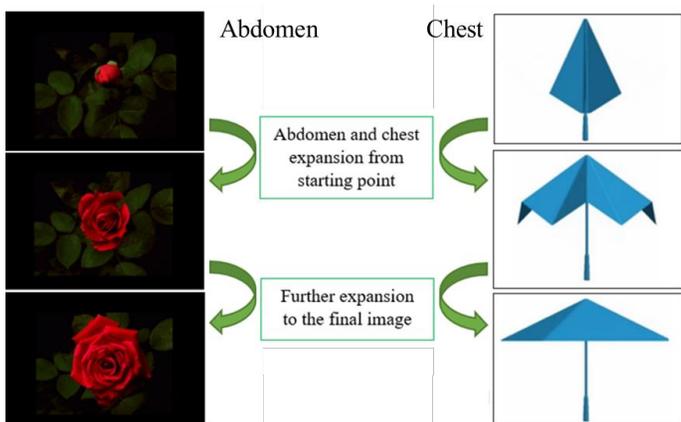

Figure 1: Real-time visualization of the expansion of the chest and abdomen.

## Results and Discussion

Time to exhaustion was not significantly predicted by phase angle ( $p=0.853$ ), nor to having visual feedback ( $p=1$ ). Pearson pairwise correlation coefficients showed that phase angle and having visual feedback provided did have a negative correlation, although not significant ( $r=-0.089$ ). This suggests that having visual feedback decreased the phase angle.

These results suggest that providing visual feedback may be able to reduce the phase angle to create more synchronous breathing. This however, did not improve the time to exhaustion, which was a hypothesized outcome. Figure 2 provides a visualization of each participant's change in phase angle and time to exhaustion with the addition of having visual feedback. One major limitation was the methodology for the run to fatigue. Some participants seemed to ask to end the session due to the speed of the treadmill and participant comfort instead of fatigue.

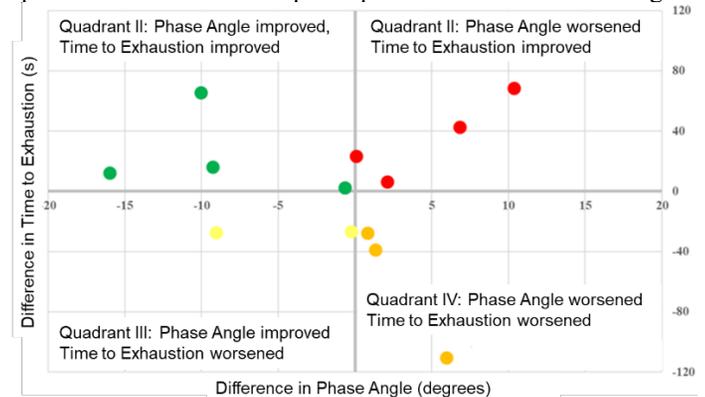

Figure 2: The difference of visual feedback compared to no visual feedback: time to exhaustion versus phase angle for each participant.

## Significance

An improvement in phase angle did not ultimately lead to an improvement in time to exhaustion. Looking only at participants that improved phase angle with visual feedback, there is a possibility that time to exhaustion could be improved with further breathing training. However, because not all participants improved phase angle with visual feedback, the largest obstacle that lies ahead is finding a way to more effectively improve the phase angle. Allowing for time to teach the breathing method and a familiarization with visual feedback prior to running should be implemented in the future in an effort to improve phase angle.

# Metabolic Power During Running In Vaporfly Shoes With Intact vs. Cut Carbon-Fiber Plates

Justin Angelo O. Ortega<sup>1\*</sup>, Laura A. Healey<sup>1</sup>, Dale Haavind-Berman<sup>1</sup>, and Wouter Hoogkamer<sup>1</sup>

<sup>1</sup>University of Massachusetts Amherst, Department of Kinesiology

Email: \* [joortega@umass.edu](mailto:joortega@umass.edu)

## Introduction

Recently, long distance running has been overwhelmed by athletes zooming past finish lines wearing the Nike Vaporfly 4%, which has been shown to lower metabolic power during running by 4% on average (Hoogkamer et al., 2018). The Nike Vaporfly utilizes a full-length curved carbon fiber plate embedded in a lightweight Pebax foam that is both compliant and resilient. These elements together provide a 4% reduction in energetic cost, but it is unknown how much of the metabolic benefits are specifically related to the increased longitudinal bending stiffness (LBS) provided by the carbon fiber plate. We hypothesized that reducing longitudinal bending stiffness by cutting through the carbon fiber plate of the Nike Vaporfly 4% would increase metabolic power during running by about 2%.

## Methods

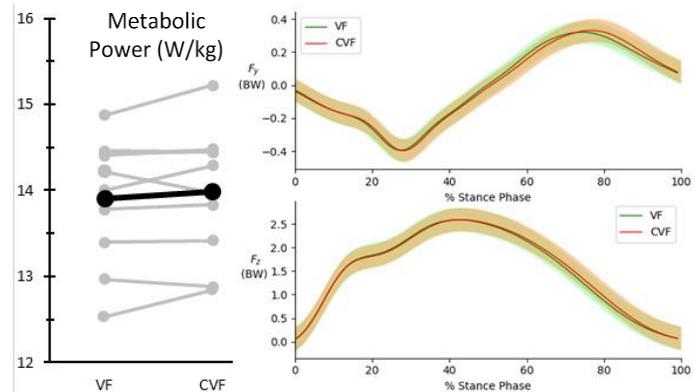

Ten male participants (23.5±4.5 yrs, 70.0±5.0 kg, 174.0±2.5 cm) ran in two versions of the Nike Vaporfly 4% (size US9.5): 1) a standard, unaltered pair (VF), and 2) a pair where the midsole and carbon fiber plate were cut (CVF) (Figure 1). Participants gave written informed consent that followed the guidelines of the University of Massachusetts Amherst Institutional Review Board. Participants completed a 5-minute warm-up trial at a self-selected pace, while breathing through the expired-gas analysis system to allow familiarization. Participants then completed four 5-minute trials at 14 km/h on a force-measuring treadmill (Treadmetrix) while we measured submaximal rates of oxygen uptake and carbon dioxide production (True One 2400, Parvo Medics). Participants ran twice in each shoe condition in a mirrored order that was counterbalanced and randomly assigned. We used shoe covers to blind participants from the condition and we changed the shoes for the participants during 5-minute breaks between trials. Metabolic power was calculated over the last two minutes of each trial using the Peronnet & Massicotte equation (Peronnet & Massicotte, 1991). The average of the two trials in each shoe was used for all metrics. We used two-tailed paired t-tests to compare shoes with a traditional significance level of  $\alpha < 0.05$ .

**Figure 1:** Shoe conditions: VF (baseline), CVF (decreased LBS)

## Results and Discussion

Contrary to our hypothesis, metabolic power was statistically similar between the VF and CVF shoes (13.91±0.74 W/kg vs. 13.98±0.76 W/kg;  $p=0.24$ ;  $\Delta = 0.55 \pm 1.38\%$ ; Figure 2). In the CVF condition, subjects ran with shorter contact

**Figure 2:** Metabolic power was statistically similar ( $p = 0.24$ ) between the VF (13.91±0.74 W/kg) and CVF shoes (13.98±0.76 W/kg) with  $\Delta = 0.55 \pm 1.38\%$ .

	VF	CVF
Contact Time (ms) *	212±2	208±2
Step Frequency (Hz)	3.01±0.12	3.01±0.12
Braking Impulse (N·s)	-0.021±0.002	-0.021±0.002
Propulsive Impulse (N·s)	0.021±0.002	0.021±0.002

**Table 1:** Contact time was significantly shorter in the CVF shoe compared to VF ( $p=0.001$ ). Step frequency, braking impulse, and propulsive impulse were all statistically similar (all  $p>0.17$ ).

times ( $p=0.001$ ) compared to the VF condition (Table 1). Step frequency, braking impulse, and propulsive impulse were all statistically similar between the VF and CVF shoes (all  $p>0.17$ ). Our data suggests that the metabolic savings from the LBS function of the carbon-fiber plate are small. A next step is to quantify the LBS of the two shoe conditions with a materials testing machine, to verify that residual LBS in the CVF was indeed minimal. At this point, our data suggests that the midsole foam and geometry are the main contributors to the metabolic savings, in line with our earlier observations that the midsole returns about 50 times more energy in compression than the plate and midsole combined in bending (Hoogkamer et al., 2019). In addition, the individual sections of carbon-fiber plate between the cuts could enhance the function of the foam by increasing the midsole stability and spreading out the vertical ground reaction forces over a larger foam area.

## Significance

As carbon-fiber plates are introduced into more running footwear, it is important to understand how they affect performance. Although opponents often use words as “spring-plates” and “mechanical doping,” our results indicate that the contributions of the longitudinal bending stiffness of carbon-fiber plates to the overall metabolic savings of Vaporfly shoes are minimal.

## Introduction

With the advent of high performance shoes for long distance running, there is a need to understand the kinetic contributions of the lower limbs and how they change throughout longer duration runs. During a long duration run, there may be a re-distribution of ankle-knee-hip joint work from distal joints to proximal joints [1]. However, the power and work contributions from the foot have been neglected when examining such runs even though studies have shown that there are significant kinetic contributions from the foot during walking [2,3] and running [4]. Additionally, the interactions between the foot and the ankle have been largely neglected during running. The foot and the ankle are traditionally treated as separate work sources due to inverse dynamics assumptions. Yet, there are many multiarticular structures that span the foot and the ankle (e.g., flexor hallucis longus) which can cause kinetic interplay [5]. Evaluating how the ankle and foot interact during running can provide insights into the role of multiarticular connections between the ankle and foot and insights for future prosthetic technology. In total, the purpose of this study is to characterize the kinetic interplay between the ankle joint and the foot during a long duration run.

## Methods

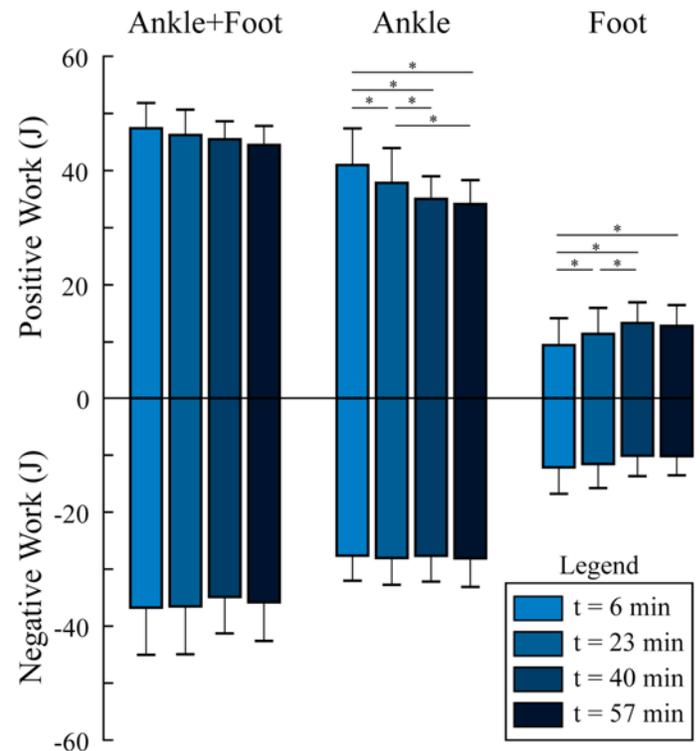

Fourteen recreationally active, heel-strike running, subjects (7 male, 7 female, 25±3 yrs, 1.72±0.08 m tall, 67.7±6.3 kg) provided informed consent and participated in this study. Subjects ran continuously for 58 minutes while we collected kinematic marker data, ground reaction forces and electromyography (EMG). The running speed was randomly varied around the subject's self-reported 10k pace to simulate a typical run. Additionally, subjects ran at 2.8 m/s during four time points in the run: 6, 23, 40 and 57 min. Data were collected for one min. at each speed throughout the run. For simplicity, we present the kinetics from the 2.8 m/s running bouts. We computed six degree-of-freedom ankle joint complex (termed here Ankle), distal-to-rearfoot (termed here Foot) and combined Ankle+Foot power [2]. The Foot power is a net estimate from all structures within the foot as well as the shoe. Positive and negative work for each of the power metrics was computed during stance phase. Friedman and Wilcoxon signed-rank tests with a Holm-Sidak correction were used evaluate differences in work metrics throughout the run ( $\alpha=0.05$ ).

## Results and Discussion

We observed during the positive Ankle work decreased by 17% (6.8 J,  $p<0.001$ ), on average, and positive Foot work increased by 36% (3.4 J,  $p=0.001$ ), on average (Fig. 1) from min. six to min. 57. There was no difference in the combined Ankle+Foot work, negative Foot and negative Ankle work (Fig. 1,  $p>0.05$ ).

Runners did not change how work was absorbed, but rather modulated how work was generated throughout a long run at the Ankle and Foot. The consistent negative work by the Foot throughout the run may indicate that runners do not change how they utilize rearfoot midsole cushioning, as this is one of the structures that can absorb work in the Foot [3]. However, runners

were utilizing more positive Foot work sources during the run which can be attributed to mid-tarsal and metatarsalphalangeal joint positive work [4]. When this Foot work was considered with the positive Ankle work, the Ankle+Foot work was consistent during the run which may indicate kinetic interplay due to multiarticular structures between the Ankle and Foot [5]. Additionally, the Ankle+Foot work provides a realistic expectation, rather than only considering Ankle work, for how running prostheses should perform throughout a run.

**Figure 1:** Positive and negative work for the Ankle+Foot, Ankle and Foot throughout the daily-type run. Asterisks indicate significant differences ( $p<0.006$ ) between different times in the run.

## Significance

This is the first study to characterize the work contributions from the Foot and Ankle+Foot during running over a long period of time. Understanding how work is being performed by the structures of the foot in combination with the shoe can be used to optimize how these structures are interacting to enhance performance. Furthermore, the characterization of the Ankle+Foot can provide design criteria for running prostheses to enhance running performance for persons with amputation.

## Examining the role of the toe flexors in opposing foot arch deformation

Torstein E. Dæhlin<sup>1</sup>, Loren Z.F. Chiu<sup>1</sup>

<sup>1</sup>Faculty of Kinesiology, Sport, and Recreation, University of Alberta, Edmonton, AB, Canada

Email: [eriksend@ualberta.ca](mailto:eriksend@ualberta.ca)

### Introduction

The foot arch may deform when acted upon by external and calcaneal tendon forces [1, 2]. The amount of desirable arch deformation varies between different tasks. To modulate arch deformation, the toe flexor muscles may exert forces to support the arch. Although previous research has found that these muscles may oppose foot arch deformation from external loads, little is known about their capacity to oppose arch deformation caused by combined external load and internal muscle force [1].

Therefore, the purpose of this study was to investigate the role of the toe flexor muscles, by examining the midfoot joint angle and net joint moment (NJM), in opposing arch deformation due to calcaneal tendon forces that exert ankle plantar flexor NJM.

### Methods

A repeated measures design was used to investigate the effect of maximally voluntarily contracting (MVC) the toe flexor muscles on midfoot angle and NJM while the foot was subject to external and calcaneal tendon forces.

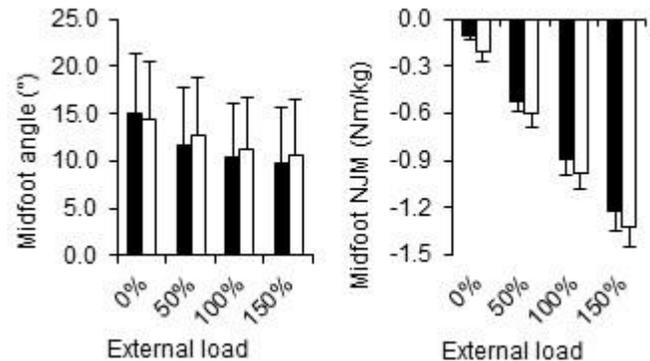

Six male and 6 female healthy adults provided informed consent to participate. Eleven retroreflective markers were placed on their right leg and foot, and recorded using stereophotogrammetry (100 Hz). Ground reaction forces were simultaneously recorded using a force platform (1000 Hz). Participants were seated with the hip and knee flexed approximately 90 degrees and the forefoot resting on the force platform, which was elevated 10 cm from the floor. Loads from 0% to 150% of body mass were applied to the participants' distal thigh in 50% increments in two experimental conditions. In the first condition, participants were instructed to relax their toe flexors. In the second condition, participants performed a toe flexor MVC by pressing their toes as hard as possible against the force platform. To create a condition that would activate triceps surae, participants were instructed to maintain their foot parallel to the ground while the loads were applied.

Repeated-measures ANOVAs with Bonferroni corrected post hoc t-tests were used to analyse the effect of external load and toe flexor MVC on midfoot angle and NJM ( $\alpha$ -level = 0.05).

### Results and Discussion

A condition-by-load interaction and accompanying post hoc tests demonstrated that midfoot angle was lower for each increase in external load ( $p = 0.002$ ; Figure 1). Moreover, midfoot angle was lower in the relaxed compared to MVC condition during the first 50% body mass increment in load.

Further, there was a significant main effect for condition in midfoot NJM, indicating that toe flexor MVC results in larger midfoot elevator NJM than in the relaxed condition ( $p < 0.001$ ; Figure 1). Similarly, there was a significant main effect for load in midfoot NJM ( $p < 0.001$ ; Figure 1). Post hoc comparisons demonstrated that midfoot elevator NJM increased with larger load ( $p < 0.001$ ).

**Figure 1:** Mean and standard deviation midfoot angle (left panel) and NJM (right panel) across the external loads and conditions (black bars = relaxed, white bars = maximal voluntary). Positive values indicate midfoot elevation angle and NJMs, respectively.

Maximal voluntary activation of the toe flexor muscles resulted in smaller decreases in midfoot angle through greater midfoot elevator NJMs. This suggests that the toe flexor muscles have the capacity to oppose foot arch deformation due to combined external and calcaneal tendon forces. However, the magnitude of the differences in midfoot angle and NJM with toe flexor MVC was small. This may be due to the toe flexor muscles also exerting considerable force during the “relaxed” condition. Indeed, Kelly et al. [1] have demonstrated that the intrinsic toe flexor muscles may activate in response to external loading alone. Future research is therefore necessary to determine the practical importance of the toe flexors for opposing arch deformation.

In summary, it appears that the toe flexor muscles may oppose arch deformation resulting from combined external loads and internal muscle forces.

### Significance

The present study provides further insight to the role of the toe flexor muscles in opposing foot arch deformation. Understanding how these muscles operate may help coaches and practitioners develop training protocols for strengthening these muscles in order to maintain normal foot function or enhance performance.

# Energy dissipation due to soft tissue movement of the thigh during forefoot and rearfoot impacts at different running velocities

Matthew T.G. Pain, Dimitrios Voukelatos, and Laura-Anne M. Furlong  
School of Sport, Exercise, and Health Sciences, Loughborough University, UK  
Email: [m.t.g.pain@lboro.ac.uk](mailto:m.t.g.pain@lboro.ac.uk)

## Introduction

Soft tissue deformation has been reported to account for up to 70% of the energy lost in some segments during impacts [1]. Despite the rigid body assumption not holding during dynamic tasks only one single subject study using 2D video analysis has tried to directly calculate energy dissipation in the soft tissues of the thigh during running [2]. The aim of this study was to directly determine energies associated with deforming soft tissue of the thigh during forefoot (FF) and rearfoot (RF) landings whilst running at different velocities using 3D motion analysis.

## Methods

Following university ethical approval and written informed consent, seven healthy, university level runners (age:  $25 \pm 4.5$  years, height:  $1.80 \pm 0.06$  m, mass:  $70.1 \pm 6.6$  kg) participated in this study. Seventy-two retro-reflective 6.4 mm diameter markers were attached around the thigh segment of the right limb, in a  $9 \times 8$  array. This covered 85% of the thigh segment length, defined using markers attached to the pelvis and femoral epicondyles. A triangular area about the size of a hand was left unmarked on the inner thigh as markers were occluded and knocked off when placed here. Marker positions in 3D space were determined using an 18 camera high-speed motion analysis system (750 Hz, Vicon Vantage, Oxford Metrics PLC., Oxford, UK) as subjects ran on a motorised treadmill (HP Cosmos Saturn, Traunstein, Germany) in racing flat shoes at four testing velocities (ascending order of 11, 14, 17 and 20 km/hr). Trials at each velocity were performed with a FF (landing on ball of foot) or RF (landing on heel) strike pattern in a counterbalanced order.

One stance with good marker visibility, correct foot strike and a typical stride length was selected for analysis from each person at each speed. Data were reconstructed, labelled and gap filled using Nexus 2.7 (Oxford Metrics PLC, Oxford, UK). Further post-processing was completed using custom-written Matlab code (MathWorks, Natick, MA., USA), including low pass filter at 100 Hz with a 4th order, zero lag Butterworth filter. The change in distance between the fixed segment centre of mass (COM), based on joint markers, and the soft tissue COM, calculated using a Delaunay triangulation representation of the soft tissue [3], was determined. The relative angles between the principle axes of the rigid segment and the soft tissue segment of the thigh were calculate using quaternions for every frame.

Energy loss due to soft tissue motion was calculated for both rotational and angular motions by first fitting a damped simple harmonic curve to the relative linear and angular motion of the soft tissue to the rigid segment thus obtaining the amplitude, frequency and exponential decay of the oscillation. Subsequently the total energy of oscillation was calculated as the sum of the kinetic and potential energies, using those terms.

## Results and Discussion

The mass of the soft tissue of the thigh calculated from the marker arrays was on average 6.1 kg. As these subjects would typically have a total thigh mass of just over 7 kg [4] it seems that this is a decent estimate of the soft tissue mass. Overall group mean

results showed that energy losses associated with the damped soft tissue motion were greater during RF than FF strike and greater at higher velocities (Table 1). These values reflect the same pattern seen for the shank [5] during these same running trials for the same subjects. However, for these subjects, the energy losses in the thigh are 3-4 times greater than seen in the shank [5] and thus are proportionately greater once segment size is accounted for. Energy losses of up to 17 J per foot strike are not inconsequential in the overall energetics of the system, both from a mechanical perspective of how much work is being done and where, but also from the metabolic perspective.

Assuming typical GRF and kinematics as those previously observed for RF and FF striking, these data support previous suggestions that both magnitude and direction of force applied play an important role in establishing the role of soft tissue motion. This is further highlighted by the fact that the majority of the energy lost was due to rotational oscillations about all three axes not linear oscillations. Standard deviations are high, probably due to a combination of low subject numbers, differences in subject mass and possibly ease or comfort of landing with a RF strike at different velocities for different subjects.

**Table 1.** Energy in the thigh segment during running with a forefoot-strike and rearfoot-strike at 11, 14, 17 and 20 km/hr.

Running speed (km/hr)	Forefoot (J)	Rearfoot (J)
11	$5.7 \pm 1.8$	$7.1 \pm 1.9$
14	$8.9 \pm 3.9$	$8.3 \pm 3.7$
17	$9.1 \pm 4.1$	$13.2 \pm 6.7$
20	$11.2 \pm 5.2$	$17.1 \pm 12.2$

## Significance

Measurement of marker arrays can determine substantial changes in soft tissue motion of the thigh relative to a rigid segment during running. These energy losses are typically unaccounted for in traditional analyses, both with regard to mechanical work and metabolic processes. Given that the energy lost during the damped oscillation of the thigh soft tissue is unlikely to be recoverable to any great extent these losses should be given consideration when dealing with the energetics of running.

# Running Symmetry is not different in Youth Runners with Low, Moderate and High Muscular Symmetry

## Introduction

Unimpaired gait is assumed to be symmetrical [1]. However, some magnitude of asymmetry is normal as side-to-side differences in lower extremity kinematics have been reported in youth runners [2]. Sagittal plane patterns demonstrate very strong side-to-side symmetry in uninjured youth runners, but substantial variability was observed in non-sagittal plane symmetries [2]. A previous study comparing landing mechanics in youth found athletes with a history of ACL reconstruction had greater lower extremity muscular strength asymmetries and greater biomechanical asymmetries during a single-leg landing task than uninjured counterparts [3]. This finding suggests muscular asymmetries may be related to asymmetric movement patterns and injury risk; however, this relationship is unknown in youth runners. The purpose of this study was to investigate if uninjured youth runners with higher muscular symmetry demonstrate higher frontal and transverse plane lower extremity running kinematic symmetry than youth runners with lower muscular symmetries. It was hypothesized runners with high muscular symmetries would have higher running kinematic symmetries than runners with low muscular symmetries.

## Methods

Uninjured youth ages 9-19 who participated in long-distance running activities were recruited for the study (m=60, female=75 age=13.5±2.7 years, height=1.58±1.42 m, mass=48.0±13.5 kg). Bilateral muscular testing included side plank, hip abduction (HABDS), and hip extension (HEXTS). Isometric hip abduction strength was measured side-lying using a handheld dynamometer and isokinetic hip extension strength (60 °/s) was measured prone using an isokinetic dynamometer. To assess symmetry, the absolute Normalized Symmetry Index (NSI) [5] was calculated for the duration of side plank holds and peak hip strength. The NSI reports percent asymmetry between sides where NSI=100% indicates perfect asymmetry. To convert NSI to the magnitude of symmetry, the NSI was subtracted from 100%.

Participants underwent 3D motion analysis while running at a self-selected speed on a non-instrumented treadmill. Participants were instrumented with reflective markers and measured using a 12-camera system (Raptor4; Motion Analysis Corp.; Rohnert Park, CA). Lower extremity kinematic symmetries during stance phase were calculated for frontal plane hip and knee motion as well as transverse plane hip and ankle motion using the Linear Fit Model (LFM) [2, 5]. The LFM provides an R<sup>2</sup> symmetry value where R<sup>2</sup>=1 is perfect symmetry.

For analysis, participants were stratified into low, moderate, and high muscular symmetry terciles for side plank, HABDS and HEXTS NSIs, respectively. Measures were found to be non-normally distributed and Kruskal-Wallis tests ( $P<0.05$ ) compared the mean rank of lower extremity R<sup>2</sup> values for each kinematic measure across muscular symmetry groups.

## Results and Discussion

No significant differences in running symmetries were found among low, moderate, and high muscular symmetry groups. A previous study reported a relationship between hip extension strength and hip rotation during running [7] but our current study found hip rotation running symmetry was not different across HEXT muscular symmetry groups (low=0.52±0.35, moderate=0.58±0.33, high=0.64±0.33;  $p=0.269$ ). Running biomechanics do not appear to be influenced by hip abduction strength [8] and our results indicate the same is true for HABDS symmetry (hip adduction symmetry: low=0.55±0.34, moderate=0.63±0.34, high=0.56±0.33;  $p=0.195$ ).

Our hypothesis that youth runners with high muscular symmetries would have higher running kinematic symmetries than youth runners with low muscular symmetries was not supported. While some level of asymmetry is expected in uninjured populations, previous work demonstrated greater lower extremity strength and single-leg landing asymmetries in youth returning from injury compared to uninjured controls [3]. To our knowledge, the current study is the first to investigate muscular symmetry and waveform symmetry in youth runners. Results from our study indicate running symmetry is not different across varying levels of muscular symmetry in uninjured youth runners. Musculature weakness has been linked to altered running patterns in injured runners [6]. In the current study, muscular symmetry measures did not account for potential musculature weakness as the NSI only quantifies the similarities in strength between sides. When assessing for injury risk, it may be more appropriate to consider the collective influence of muscular strength and side-to-side muscular symmetry on movement symmetry.

## Significance

The importance of running symmetry is unknown, especially in a population of uninjured youth runners. As running injuries are multifactorial, isolated muscular symmetries do not appear to influence running symmetry. Further prospective research is warranted to determine the causes of running asymmetries in youth runners and the factors associated with these asymmetries as they relate to running injuries and performance.

## Effects of Take-off Board Stiffness on Long Jump Performance

Kara Ashcraft<sup>1</sup> & Alena M. Grabowski<sup>1</sup>

<sup>1</sup>University of Colorado, Boulder, CO, USA

Email: Kara.Ashcraft@colorado.edu

### Introduction

Long jump has been a standard component of the Olympic games since their birth in Ancient Greece, and by modern competition rules includes a horizontal jump for distance preceded by a run-up of self-selected length. The factors that determine jump distance are a combination of the horizontal velocity developed in the run-up and the horizontal and vertical velocity at take-off, with maximum run-up velocity being the strongest correlate ( $R^2 = 0.7 - 0.9$ ) with jump distance in non-amputee athletes.<sup>1</sup>

Athletes with leg amputations compete in the long jump using carbon fiber running-specific prostheses (RSPs) that are attached to their residual limb by a rigid socket. Use of RSPs limit force generation during sprinting, which likely limits run-up velocity and may limit the take-off leg's ability to redirect the downward and forward velocity at initial contact into upward and forward velocity at take-off.<sup>2</sup> Willwacher et al. found that use of an RSP by an athlete with a transtibial amputation resulted in a slower run-up velocity but an enhanced take-off technique compared to non-amputees with similar jump distances.<sup>3</sup>

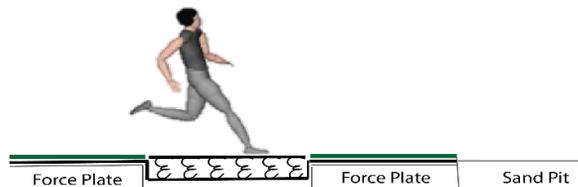

Thus, long jump performance is influenced by maximum horizontal run-up velocity, vertical and horizontal take-off velocity, and likely the in-series RSP stiffness. RSPs are passive-elastic springs that act in-series with the residual limb. To better understand how in-series stiffness affects long jump distance, we measured the effect of take-off platform stiffness ( $k_{surf}$ ) on long jump distance in non-amputees. We hypothesized that regardless of the run-up velocity, decreasing  $k_{surf}$  of the take-off platform would result in longer jump distance by enhancing take-off technique through energy storage and return within the take-off surface.

### Methods

Eight competitive collegiate long jump athletes (5 M, 3 F) gave informed written consent and participated in a 3-day protocol that involved maximum effort jumps on 3 take-off platforms with stiffness values of 84 kN/m, 90 kN/m, and 1628 kN/m. These  $k_{surf}$  were similar to the stiffness values of two typical RSPs, and a regulation track surface, respectively. Each subject completed 4-6 maximum effort long jumps on each of the 3 take-off platforms. We measured ground reaction forces during the take-off step from force platforms (AMTI; 1000 Hz) installed beneath the track and platform surface. We measured maximum run-up and take-off velocities using a radar gun (Stalker; 47 Hz), two high speed video cameras (Casio; 240 Hz), and the force platforms. Jump distances were measured for all completed jumps with a tape measure. We averaged jump distances from 4 jumps per athlete.

We varied take-off  $k_{surf}$  by custom-building a springy platform installed between two force platforms. We used a different number of springs to create two compliant conditions (84 kN/m and 90 kN/m; Fig.1). When a subject landed on the take-off platform, the force applied was distributed between

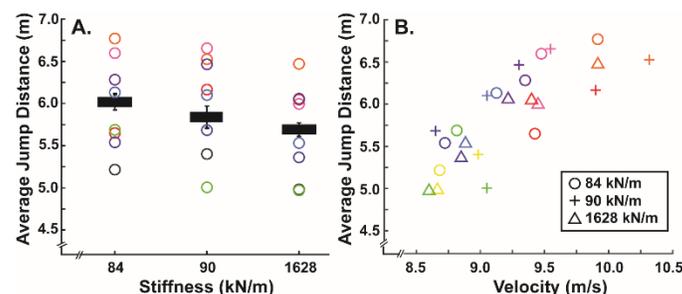

two force plates. We performed a two-way ANOVA to compare jump distance between platforms and used correlations to associate maximum run-up velocity with jump distance.

**Figure 1.** Custom-built take-off platform installed between two force plates. As a subject lands on the platform during the take-off step, the forces produced are recorded by both force plates.

### Results and Discussion

There were no differences in the average maximum run-up velocity attained between platform stiffnesses ( $p = 0.40$ ). There was a moderate correlation between maximum run-up speed and jump distance ( $R^2 = 0.61$ ; Fig.2B). However, average jump distance was longer for the  $k_{surf}$  of 84 kN/m ( $6.02 \pm 0.09$  m) compared to the  $k_{surf}$  of 1628 kN/m ( $5.69 \pm 0.08$  m; Fig 2A), but was not different between these surfaces and a  $k_{surf}$  of 90 kN/m. This suggests that jump distance increases with decreased  $k_{surf}$  independent of maximum run-up speed.

**Figure 2. A.** Average  $\pm$  SE jump distance (black horizontal bars) and each athlete's jump distance (colored circles) for a given take-off  $k_{surf}$ . Jump distance was 5% longer for a  $k_{surf}$  of 84 kN/m compared to 1628 kN/m. **B.** Average jump distance versus run-up velocity for a  $k_{surf}$  of 84 kN/m, 90 kN/m and 1628 kN/m.

### Conclusion

The in-series surface stiffness of the take-off platform affects long jump distance. Though athletes with transtibial amputation using RSPs have a slower maximum run-up velocity compared to non-amputees, the in-series stiffness of an RSP during the take-off step likely affects long jump distance. Future research is planned to better understand the interaction of run-up velocity and the effects of in-series stiffness on take-off technique for the long jump.

# Curve Sprinting With A Split-Toe Running Specific Prosthesis: A Pilot Study

Ryan S. Alcantara<sup>1</sup>

<sup>1</sup>University of Colorado, Boulder, CO, USA

Email: ryan.alcantara@colorado.edu

## Introduction

For athletic track events like the 400 m sprint, over half the race is completed along a curve. Sprinting along a curve imposes different force production requirements [1] and elicits slower maximum sprinting velocity compared to a straightaway [2]. Faster curve sprinting may improve overall performance in these athletic events. Sprinters with transtibial amputations use a passive-elastic running-specific prosthesis (RSP) that is typically made with a solid piece of carbon fiber and torsionally stiff, and thus resists frontal plane rotation during running. Fillauer Composites (Salt Lake City, UT) manufactures an RSP with a “split-toe” design, where a distal portion of the RSP is cut longitudinally, which allows the medial and lateral sides of the RSP to bend independently, reduces torsional stiffness, and potentially increases traction when running on a curve (Fig. 1).

**Figure 1.** Split-toe (top) and solid (bottom) RSPs. Arrow indicates the proximal end of the split.

We hypothesized that maximum sprinting velocity would be faster using the split-toe compared to solid RSP on curves but would be similar between RSP designs on the straightaway. We also hypothesized that participants would elicit greater affected leg stance-average centripetal ground reaction forces (GRFs) on a curve when using the split-toe compared to solid RSP to achieve faster velocities.

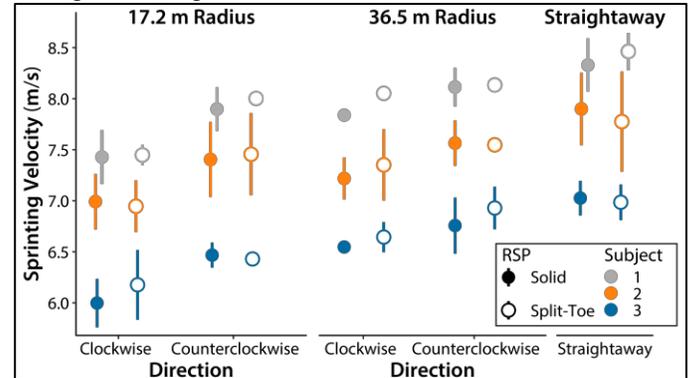

## Methods

Three individuals (2 M, 1 F; mean  $\pm$  SD mass: 72.92  $\pm$  10.72 kg; height: 1.80  $\pm$  0.06 m; age: 25  $\pm$  9 yrs) with a right transtibial amputation participated. Subjects had at least one year of experience competing using an RSP in a sprint event (400 m or shorter) within the past two years. The split-toe and solid RSP had identical shapes, height, and sagittal plane stiffness.

Participants completed a randomized series of 40 m sprints on a flat indoor track. We instructed participants to run as fast as possible for each trial and provided  $\geq$ 8-min rest between trials. Participants performed clockwise and counterclockwise sprints along curves with radii of 36.5 m and 17.2 m and straightaway sprints over 40 m. Athletes ran across two adjacent force plates (1000 Hz) embedded beneath the track surface. We recorded 3D kinematics using high-speed motion capture cameras (100 Hz). The force plates and capture volume were located halfway along the runway. Trials were repeated until athletes successfully landed on the force plates at least once. Participants were not blinded to the RSP designs.

We measured maximum sprinting velocity using average pelvis marker velocity over the length of the force plates (2.4 m). We calculated stance-average centripetal force for the

affected leg. We constructed linear mixed-effects models to determine the effect of RSP design on sprinting velocity and centripetal force production.

**Figure 2.** Mean  $\pm$  SD velocity across conditions. Sprinting velocity using the split-toe running-specific prosthesis (RSP) was 0.13 m/s faster than the solid RSP across curve conditions and directions, but similar during the straightaway. Velocity was 0.34 m/s slower when sprinting in the clockwise compared to counterclockwise direction and 0.33 m/s faster with increased curve radius across directions.

## Results and Discussion

Mean ( $\pm$  SE) sprinting velocity with the split-toe RSP was 0.13  $\pm$  0.04 m/s faster compared to the solid RSP for a given curve radii and direction ( $p < 0.001$ ; Fig. 2). Using the split-toe RSP did not affect maximum sprinting velocity on the straightaway compared to the solid RSP ( $p = 0.705$ ).

Stance-average centripetal force was significantly affected by curve condition ( $p < 0.001$ ) and sprinting velocity ( $p < 0.001$ ), but not RSP design ( $p = 0.180$ ) or running direction ( $p = 0.746$ ). Mean stance-average centripetal force for the affected leg on the 17.2 m radius curve was 0.43  $\pm$  0.15 BW and decreased by 0.19  $\pm$  0.02 BW in the 35.2 m radius curve for both directions.

Centripetal (radial) force ( $F_c$ ) equals  $mv^2/r$ , where  $m$  is mass,  $v$  is tangential velocity, and  $r$  is curve radius. Sprinters running on a curve must apply  $F_c$  to stay within their lane and achieve a fast velocity. We observed statistically significant increases in sprint velocities with the split-toe RSP, but no change in  $F_c$ . Although participants ran along 36.5 m and 17.2 m curve radii, the 1.22 m lane width allows athletes to vary their path traveled for a given curve condition. We suspect that participants decreased the effective radius of the curve they traveled along within the lane when using the split-toe compared to solid RSP, which may potentially explain the faster sprinting velocity without significant increases in  $F_c$ .

## Significance

Sprinters with a unilateral transtibial amputation may be able to achieve faster curve sprinting velocities using an RSP with a split-toe design compared to a traditional, solid RSP.

Email: murata-hiroto@aist.go.jp

### Introduction

Prevalence of running-specific prostheses (RSPs) have allowed unilateral transfemoral amputees (UTFAs) to run by regaining a spring-like leg function in their affected limbs. When non-amputees run at constant speed on level ground, the mechanical energy of the whole body center of mass (COM) is absorbed during the negative work phase and restored during the subsequent positive work phase [1]. Negative external work is equal to positive external work for each step in order to maintain a symmetrical bouncing gait [1]. However, little is known about mechanical work of the body in UTFAs using RSPs. This study aimed to investigate external mechanical work at different running speeds in UTFAs with RSPs.

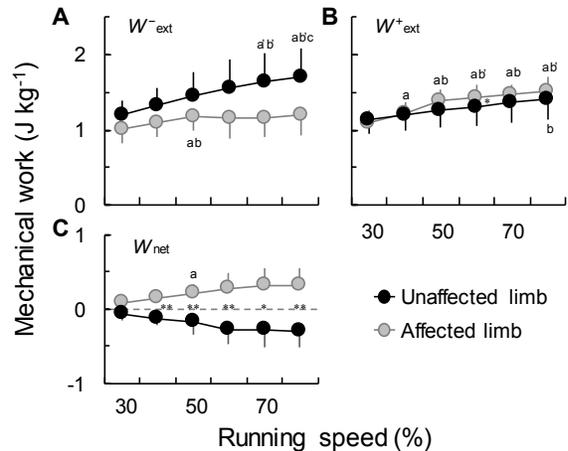

### Methods

Eight UTFAs wearing RSPs (age:  $27 \pm 11$  years, mass:  $64.5 \pm 8.1$  kg, 100-m personal records:  $15.65 \pm 1.03$  s, mean  $\pm$  SD) ran on an instrumented-treadmill (FTMH-1244WA, Tec Gihan, Kyoto, Japan) at incremental speeds (30%, 40%, 50%, 60%, 70% and 80% of the average speed of their 100-m personal records). The mechanical energy of the COM ( $E_{\text{ext}}$ ) was calculated from the vertical and horizontal ground reaction forces (GRF, sampled at 1000 Hz) [2]. External mechanical power ( $P_{\text{ext}}$ ) was calculated as the dot product of the GRF and COM velocity, and  $E_{\text{ext}}$  was the time integral of  $P_{\text{ext}}$ . The negative ( $W_{\text{ext}}^-$ ) and positive external work ( $W_{\text{ext}}^+$ ) per step were computed as the sum of the negative and positive increments of  $E_{\text{ext}}$  curves, respectively [3]. Further, net external work ( $W_{\text{net}}$ ) was calculated as the difference between  $W_{\text{ext}}^-$  and  $W_{\text{ext}}^+$  [3]. We analysed 10 consecutive steps and averaged five steps of each limb to determine the representative values for each speed. Two-way ANOVA (two limbs  $\times$  six speeds) was performed to compare variables between the unaffected (UL) and affected (AL) limbs at six speeds. If significant main effects were observed, Bonferroni post-hoc multiple comparisons were performed. Statistical significance was set to  $P < 0.05$ .

### Results and Discussion

As shown in Figure 1-A, there was a significant main effect of speed ( $P < 0.01$ ) on  $W_{\text{ext}}^-$ . However, no significant effect of interaction was observed. Although it did not reach a statistical significance in limb,  $W_{\text{ext}}^-$  of the AL tended to be smaller than that of the UL across a range of running speeds.  $E_{\text{ext}}$  is mainly absorbed by knee extensor muscles during the negative work phase [4], but UTFAs have lost the function of these muscles in the AL due to amputation. Therefore, the AL with RSPs may exhibit less capability to absorb the  $E_{\text{ext}}$  compared to the UL.

$W_{\text{ext}}^+$  had significant main effects of speed ( $P < 0.01$ ) and interaction ( $P < 0.01$ ); whereas, no significant main effect of limb was observed (Figure 1-B).  $W_{\text{ext}}^+$  in the AL was equal to or greater than the UL across a range of running speeds. These results suggest that the AL could perform  $W_{\text{ext}}^+$  as well as the UL using energy storing and return capabilities of RSPs.

**Figure 1:** The mass-specific external mechanical work per step.  $W_{\text{ext}}^-$  (A),  $W_{\text{ext}}^+$  (B) and  $W_{\text{net}}$  (C) of unaffected (black) and affected (gray) limbs across six running speeds. Error bars represent 1 SD. The asterisks (\*, \*\*) indicate significant differences between the limbs at each speed, at  $P < 0.05$  and  $P < 0.01$ , respectively. Alphabets (a', b', c' and a, b, c) indicate significant differences from 30%, 40% and 50% speed, at  $P < 0.05$  and  $P < 0.01$ , respectively.

Further, statistical analysis revealed significant main effects of limb ( $P < 0.01$ ) and interaction ( $P < 0.01$ ), but no significant main effect of speed on  $W_{\text{net}}$  (Figure 1-C). While the  $W_{\text{net}}$  of the UL was negative, the  $W_{\text{net}}$  of the AL was positive across a range of running speeds. These results indicate that the COM of UTFAs is decelerated in the UL and accelerated in the AL at each step. In this case, the simple spring-mass model (SMM) could not be applied because the  $W_{\text{net}}$  is not zero for the UL or AL.

We observed that external mechanical work during running in UTFAs is not the same for the both limbs. UTFAs with RSPs maintain their bouncing steps with a limb-specific strategy.

### Significance

Generally, the simple SMM has been applied to describe the bouncing mechanism in human running. However, current results suggest that bouncing mechanism in UTFAs should not be described using the simple SMM. Therefore, mechanical energy fluctuations could reveal better biomechanical models to analyse UTFAs with RSPs.

# EFFECTS OF A PARALYMPIAN WITH TRANSFEMORAL AMPUTATION USING A PROSTHESIS WITH & WITHOUT A KNEE

Janet Zhang<sup>1</sup>, and Alena Grabowski<sup>1</sup>  
<sup>1</sup>University of Colorado, Boulder, CO, USA  
Email: Hanwen.Zhang@coloradu.edu

## Introduction

Runners with transfemoral amputation using a prosthesis with an articulating knee combined with a running-specific prosthetic foot (blade) have a lower metabolic cost compared to using a prosthesis with a blade only [1]. However, the biomechanical changes induced by using a prosthesis with a knee are unclear. We compared biomechanics from a Paralympic athlete with a transfemoral amputation who ran using two prostheses, one with a knee and one without.

We hypothesized that the 1) prosthesis with a knee would reduce leg stiffness, increase hysteresis, and reduce peak hip abduction during leg swing in the affected leg (AL) compared to the prosthesis without a knee; 2) biomechanics of the unaffected leg (UL) would not differ between the two conditions; 3) peak vertical ground reaction force (vGRF) would be lower in the knee versus no-knee condition.

## Methods

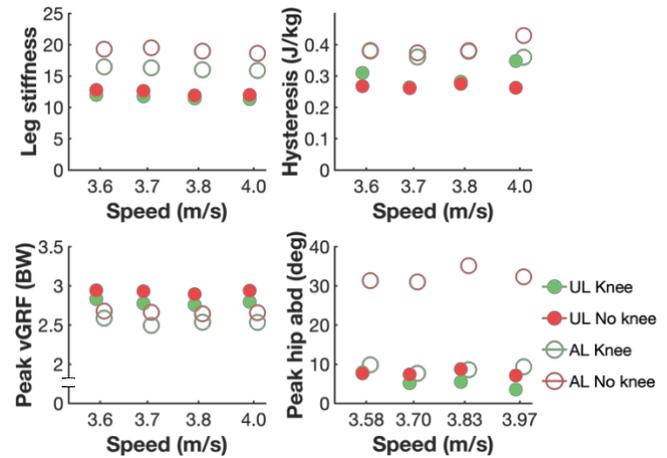

A female with a left transfemoral amputation ran on a force-measuring treadmill (Treadmetrix, Park City, UT) at 3.58 m/s, 3.70 m/s, 3.83 m/s, and 3.97 m/s using two running prostheses. The prosthesis with a knee (Ottobock, Berlin, Germany) was 3.0 kg (knee); the prosthesis without knee (Fillauer Composites, Utah, USA) was 1.2 kg (no-knee).

We measured motion at 100 Hz and vGRF at 1000 Hz (Vicon, Oxford, UK) during each trial and normalized vGRFs to body weight in each corresponding prosthesis. Ten steps from each leg were extracted from each trial. We used the spring-mass model to calculate leg stiffness [2] and calculated hysteresis of the leg spring to compare energy loss during the stance phase [3]. To assess the mechanism underlying leg stiffness, we compared the peak vGRF from each leg. We also calculated peak hip abduction angle during the swing phase. We did not perform statistical analyses for this case study.

## Results and Discussion

In the knee condition, leg stiffness decreased by 14.6-16.3% in the AL, and 3.9-6.8% in the UL compared to the no-knee condition (Fig. 1). At speeds from 3.58-3.83 m/s, the difference in hysteresis between each condition was within 3.6% in the AL. At 3.9 m/s, the prosthesis with a knee increased energy return (lower hysteresis) of the AL by 16.2% but increased hysteresis of the UL by 32.5% compared to the no-knee condition. In the knee condition, peak vGRF decreased by 3.4-6.3% in the AL and by 3.8-5.3% in the UL compared to the no-knee condition. The AL had lower peak hip abduction angles in the knee condition (7.7-9.8°) versus the no-knee condition (30.0-35.1°) and the UL peak hip abduction angles were similar between conditions (Fig 1).

Lower leg stiffness has been associated with reduced metabolic cost in athletes with transtibial amputation [3]. We found that a triathlete with transfemoral amputation had lower

**Figure 1.** Leg stiffness\*, hysteresis, peak vGRF, and peak hip abduction (abd) between prosthetic conditions for the Unaffected Leg (UL) and Affected Leg (AL) during running. (\*Leg stiffness was normalized to body weight (N) and leg length (m) in each prosthetic condition.)

leg stiffness when running with the knee versus no-knee condition. The difference between amputation levels limits the application of our findings. However, the results might explain the lower metabolic cost in participants with transfemoral amputation walking or running (1.12 to 2.01 m/s) using a prosthesis with a knee versus without a knee [1].

In the knee versus no-knee condition, the UL had less of a reduction in leg stiffness compared to the AL. However, the UL and AL had similar reductions in peak vGRF in the knee versus no-knee condition. Thus, changes in AL leg stiffness are likely due to changes in leg compression rather than in peak vGRF. Specifically, the AL was more compliant, and UL was stiffer during stance in the knee versus no-knee condition.

The higher peak hip abduction during swing phase in the AL is likely due to the circumduction required to clear the ground in the no-knee condition. A previous study reported similar findings [4]. Moreover, peak hip abduction was more symmetric in the knee compared to no-knee condition.

## Significance

We compared the biomechanics of a Paralympian with transfemoral amputation using a prosthesis with and without a knee and found that use of a prosthesis with a knee resulted in biomechanics that would presumably lower metabolic cost and improve running performance.

## Moment Arm Plasticity in Response to Loading History during Growth

Matthew Q. Salzano<sup>1,2\*</sup>, Suzanne M. Cox<sup>1</sup>, Stephen J. Piazza<sup>1</sup>, and Jonas Rubenson<sup>1,2</sup>

<sup>1</sup>Biomechanics Laboratory, Dept. of Kinesiology, The Pennsylvania State University, University Park, PA 16802

### Introduction

A muscle's moment arm influences locomotor function since it determines the joint moments produced by a given muscle force and the muscle's shortening velocity for a given rate of joint rotation. While moment arms have been found to vary with locomotor specialization [1], it is not clear how much of this variation is due to nature versus nurture. Here, we investigate whether muscle moment arms are modulated in response to loading history during the growth period in an animal model.

### Methods

Guinea fowl ( $N = 23$ , *Numida meleagris*) were split evenly into three groups at 4 weeks of age: exercise (EXE), sedentary (SED), and botox (BTX). EXE birds were housed in large pen (3.14 m<sup>2</sup>), with ample room for running and perches for jumping. SED and BTX birds were housed in small pens (1 m<sup>2</sup>) with low ceilings to restrict movement and jumping. BTX birds were also given bilateral injections of botulinum toxin-A (4 units (LD50)/kg) in both gastrocnemius muscles every 5 weeks to promote further disuse, while SED and EXE received sham saline injections. The protocol lasted until birds were 6 months-old, for a total of 4 injections for each group, at which point they were sacrificed.

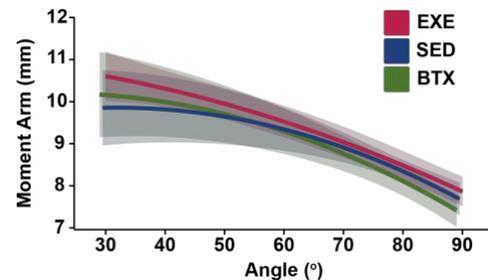

A tendon travel protocol was used to measure plantarflexion moment arms of the Achilles tendon. Retroreflective markers were placed on dissected limbs to track their movement and calculate joint angles. The Achilles tendon was attached to a linear transducer to measure excursion. Third-order polynomials were fit to the excursion-angle data in order to calculate moment arm as the derivative of excursion with respect to angle. Moment arms were found across the range of motion corresponding to that seen during the stance phase of running (30°-90°) [2].

Linear mixed models were run to find the effect of group on moment arm and any interaction between group and angle. The model was run twice: once classifying angle as a continuous variable, to analyze the moment arm curves, and again with angle classified as a categorical variable (at 30°, 60°, and 90°) to permit mean comparisons at each of the three chosen angles.

### Results and Discussion

While there were no large, clear differences in moment arm between groups, there were several indications of moment arm plasticity during the growth period. There were significant group ( $p = 0.040$ ) and interaction ( $p < 0.001$ ) effects when the model was run with angle as a continuous variable, in which the EXE group appears to have a slightly larger moment arm than the other two groups. When angle was treated as a categorical variable, however, no significant interaction or group effect was found ( $p = 0.104$  and  $p = 0.092$ , respectively; Fig. 2). This seemed to indicate no difference between groups but might be explained a lack of statistical power due to a small sample size. Our findings are suggestive of moment arm plasticity and adaptation in response to loading during growth, but the ambiguous results from

statistical tests suggest that caution should be taken when interpreting these results.

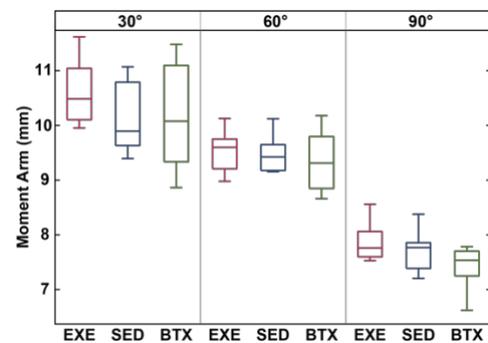

**Figure 1:** Moment arm plotted versus joint angle. Solid lines represent mean moment arm for each group. Shaded regions:  $\pm 1$  SD of the mean.

### Significance

These data are among the first to indicate that muscle moment arms may be affected by loading history across growth. The functional consequences of increases in moment arm remain unresolved. On one hand, muscle moment generating capacity increases with increasing moment arm. This could permit high moments with smaller muscle mass, an advantage for reducing the energy required to grow and maintain muscle tissue. But muscle force capacity may also decrease due to a greater influence of force-velocity effects with a larger moment arm. Further work is required to quantify which of these factors dominates.

We encourage future studies exploring developmental plasticity of muscle moment arms. These studies will benefit from addressing deficiencies in statistical power and examining the mechanisms underlying links to locomotor function.

# Reconstructing contractile dynamics from muscle length change

Jeffrey P. Olberding, Emanuel Azizi, Monica A. Daley  
University of California, Irvine  
Email: olberdij@uci.edu

## Introduction

Understanding *in vivo* muscle dynamics requires knowledge of both force and length changes, but even indirect measures of muscle force prove difficult or imprecise in many systems. One solution has been to model *in vivo* strain profiles and apply them to isolated muscles, commonly seen in sinusoidal work-loop experiments [1]. While sine waves are reasonable approximations of some movements like insect flight and swimming, they fail to adequately capture the complexity of unsteady movement and particularly terrestrial locomotion. An alternative approach is imposing *in vivo* strain and activation on an isolated muscle and measuring the resulting forces, because strain can be measured in most systems for the whole MTU and sometimes for muscle fascicles. However, it has not been directly demonstrated that forces measured during contractions against reproduced strain profiles are similar to those produced during contractions with dynamic external loads.

Here we measure a strain profile for a muscle stimulated to contract against a modeled inertia load moving against gravity through a lever system. We then stimulate the same muscle to contract against the strain profile from the first trial and ask whether the force, power, and work generated are similar to the original contraction.

## Methods

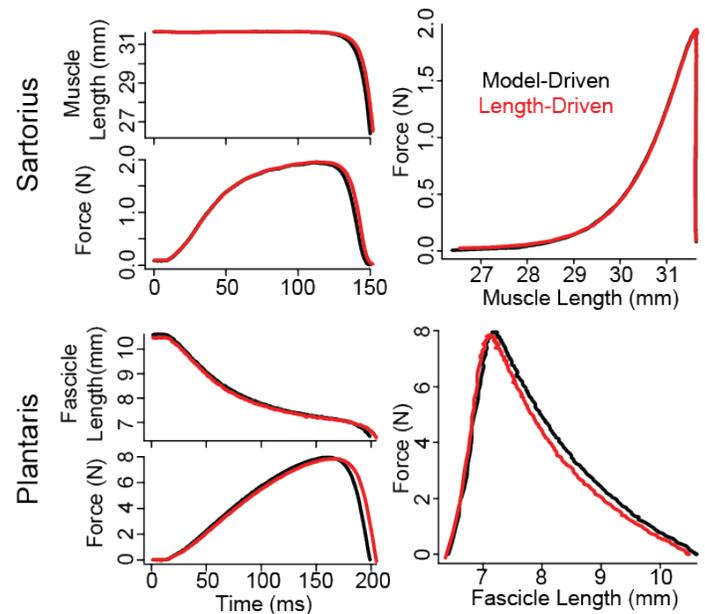

The plantaris longus and sartorius muscles were isolated from bullfrogs (*Lithobates catesbeianus*) and stimulated them to contract against a dual-mode muscle servomotor. Because the plantaris has significant aponeuroses and tendon, sonomicrometry crystals were implanted to measure muscle fascicle length. All muscles were supramaximally stimulated for 500 ms and rested for 5 min between stimulations. First, muscles contracted against the motor while it was controlled via a feedback controller programmed to simulate the motion of a simplified jumper (see [2]). The length changes resulting from that contraction were used for the subsequent trial with identical stimulation and initial length conditions. The force and length of matched pairs of contractions were used to calculate and compare the mechanical output of these two different techniques.

## Results and Discussion

There were virtually no differences between the force and length or resulting power and work calculated for muscles contracting against a simulated inertial load compared with muscle contracting against a prescribed length change. This was true for both the parallel-fibered sartorius muscle, which lacks aponeuroses and tendons, and for the pennate plantaris, which has significant elastic connective tissues.

This experiment creates the best possible conditions for applying a strain profile to recreate contractile dynamics: the same muscle, with identical initial conditions and activation patterns. However, variation introduced to any of those factors could disrupt the tight correlation. Future experiments will explore the sensitivity of the results to variation introduced to

initial conditions by varying the starting length of the muscle between a model-driven contraction and the subsequent length-driven contraction.

**Figure 1:** Model-driven and length-driven force and length profiles are identical, even for the plantaris with significant series elastic elements.

## Significance

This study confirms that applying *in vivo* strain profiles can recreate the dynamics of a muscle contracting against dynamic load. Muscle contractile dynamics result from external forces acting on a muscle interacting with patterns of stimulation and other conditions. From the perspective of the muscle itself, it does not matter how the patterns of external forces are determined, as long as they are the same.

However, the validity of this approach depends on many other conditions being matched between *in vivo* and *in vitro* measurements, including: level of organization, activation patterns, and initial force/length conditions. The degree to which accurately replicating contractile dynamics depends on these factors will be explored in future experiments.

Additionally, when both *in vivo* strain profiles and a dynamic model are available and other conditions are matched, a comparison between these two types of isolated muscle contractions could be used to validate the dynamic model as an accurate representation of *in vivo* loading conditions.

## Mechanosensation by muscle spindles during active muscle-tendon work loops

Emily M. Abbott<sup>1,2</sup>, Paul Nardelli<sup>1</sup>, Timothy Cope<sup>1</sup>, Gregory S. Sawicki<sup>1,2</sup>

### Introduction

While mechanosensation of muscle state is crucial for motor control, our understanding of what mechanosensors encode may be deeply flawed. Classic studies of mechanosensation used passive stretching paradigms and these foundational works concluded that primary muscle spindle receptors (1a afferent nerves) encoded muscle length or velocity while Golgi tendon organs (1b afferent nerves) encoded muscle force<sup>1</sup>. Unfortunately, these results may not accurately represent muscle-tendon functions in a freely moving animal. First, locomotive muscles are not always passive. In a passive stretch a muscle fiber and its associated elastic structure both lengthen, thus force and length are *coupled* in directionality. However, active muscle fibers function with elastic structures such as tendons and aponeuroses. During an active contraction a muscle fiber is activated, it produces force and if the force is great enough, the fiber will shorten and lengthen the elastic structure. Thus, force and length are *decoupled* in directionality<sup>2</sup>. Lastly, during locomotion muscle fiber length change patterns are cyclical and emerge from the interaction of muscle-tendon forces and body dynamics<sup>3</sup>. This perspective motivates us to reevaluate the roles of mechanosensors in encoding sensory information.

### Methods

We combined in situ muscle-tendon (MT) preparations with simultaneous intra-axonal recordings in female Wistar rats (IACUC #A18042; Fig. 1). We compared two dynamic protocols. 1) A passive condition where the MT interacts with a virtual body mass that is dropped and stretches the MT until the mass position is damped. 2) An active work loop protocol where stimulation is applied at a set frequency and the servomotor applies MT length change according to dynamics of a mass in gravity (Fig. 2).

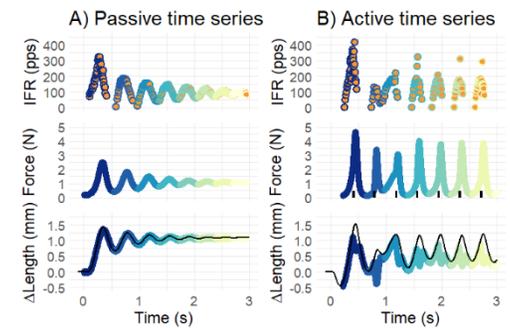

**Figure 1:** Medial gastrocnemius (MG) activated by stimulation of ventral root and instrumented with sonomicrometry crystals to measure muscle fascicle length. Instantaneous firing rate (IFR) of proprioceptors measured with intra-axonal microelectrode in the dorsal root and physiologically characterized as a muscle spindle<sup>4</sup>.

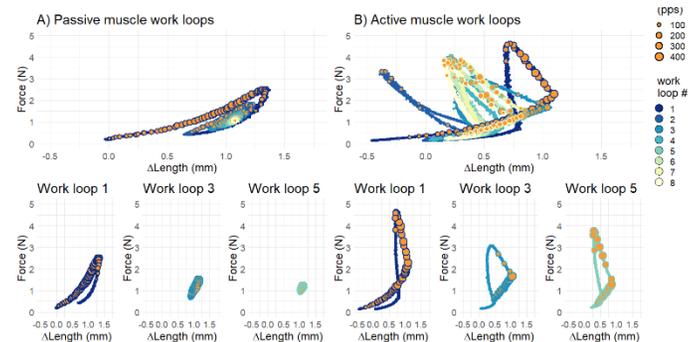

### Results and Discussion

Our long-term goal is to establish a bench top framework for re-evaluating the roles of muscle receptors in encoding sensory information during locomotion.

**Figure 2:** Two real-world conditions with the same muscle spindle recordings. A) passive condition where the MT damps a virtual mass and B) an active condition

where MT is stimulated at 2.6Hz. In the bottom panel, muscle fiber lengths are represented with a color line while MT length is represented with a black line.

**Figure 3:** Work loop dynamics observed under the two conditions with the same muscle spindle recordings. Note that for the same forces or muscle fiber lengths, the muscle spindle responds differently (size = IFR in peaks per second)

Under novel real world conditions where the muscle is active, the fiber length is decoupled from force and it interacts with a virtual body mass, we observe that a muscle spindle operates differently than it does in passive conditions. Specifically, muscle spindles respond to increases in force even when the fiber is shortening. Furthermore, these work loops demonstrate that a muscle spindle response is more complex than a simple stretch receptor.

### Significance

Here, we demonstrate the feasibility of in situ experiments that employ muscle-tendon work loops<sup>2,3</sup> in combination with direct recordings from muscle spindle receptors<sup>4</sup>.

# Muscle fascicle dynamics during collisional phase of walking and the relation to push-off phase

Samuel T. Kwak<sup>1\*</sup>, Ashley Tran<sup>2</sup>, and Young-Hui Chang<sup>1</sup>

<sup>1</sup>School of Biological Sciences, Georgia Institute of Technology, Atlanta, GA, USA

<sup>2</sup>Agnes Scott College, Decatur, GA, USA

Email: \*skwak@gatech.edu

## Introduction

People make rapid gait adjustments, minimizing metabolic cost without direct metabolic sensors, yet the mechanism is not known (1). Negative work done during the collisional phase of walking is a major determinant of metabolic cost, with the tibialis anterior (TA) muscle playing an important role in this energy absorption (2,3). Increased push-off work by the trailing leg can reduce the negative work in the collisional phase, heel strike to foot flat (4).

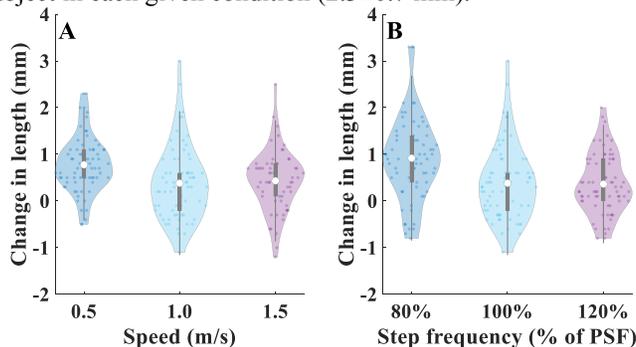

The aim of this study was to understand muscle dynamics during the collisional phase of gait under different gait conditions. We hypothesized that TA muscle fascicles would act isometrically across conditions within a small range of length change ( $\pm 0.5$  mm). We also predicted if significant lengthening occurred, it would correlate with the subsequent ipsilateral push-off impulse as would increases in TA muscle force.

## Methods

Eleven subjects (6 male,  $22.8 \pm 3.6$  years,  $64.4 \pm 9.7$  kg) gave written, informed consent prior to undergoing five walking conditions: fast (1.5 m/s) and slow (0.5 m/s) speeds at preferred step frequency (PSF), and medium speed (1.0 m/s) at 80%, 100%, and 120% of PSF. Kinematics, kinetics, and TA muscle ultrasound (60 Hz) data were collected. Preliminary data on five subjects are presented here. Fascicle length changes for  $69 \pm 4$  steps per condition were manually digitized in ultrasound images containing the initial contact and foot flat gait events (Echo Wave II, Telemed). Push-off impulses were calculated by integrating the positive portion of the anterior-posterior ground reaction force (GRF) for each step and normalized for each subject's body weight and PSF. Peak muscle forces were estimated using the GRF vector and TA muscle-tendon unit vector acting on the ankle joint and normalized for subject body weight.

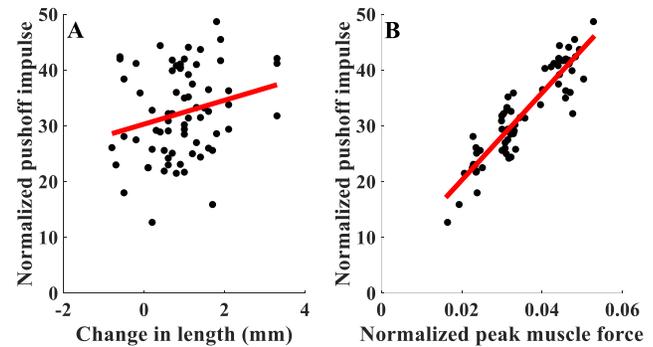

## Results and Discussion

Rather than being isometric across all steps, TA fascicles lengthened on average during the collisional phase of gait across all conditions. The 80% PSF condition had the most lengthening ( $0.9 \pm 0.9$  mm, while also showing isometric and shortening fascicle behavior from step to step (Fig. 1). All conditions with a greater range of fascicle length change than predicted for a subject in each given condition ( $2.3 \pm 0.7$  mm).

**Figure 1.** Fascicle length change due to speed (A) and step frequency (B). Violin plots with distributed values (colored dots) are shown with the mean (white dot), 25-75% quartiles (box), and  $\pm 2$ SD (whiskers).

For the 80% PSF condition, which can be considered the most novel condition experienced (slow, long steps), change in the dorsiflexor muscle fascicle length did not correlate with the ipsilateral push-off impulse ( $R^2=0.06$ , Fig. 2A). However, peak TA muscle force had a strong correlation with the subsequent ipsilateral push-off impulse ( $R^2=0.82$ , Fig. 2B). The contralateral leg push-off impulse showed a smaller correlation with TA muscle force ( $R^2 = 0.64$ ). This correlation was not observed at the less novel 100% or 120% PSF ( $R^2=0.13$  and  $0.11$ , respectively).

**Figure 2.** Fascicle length change (A) and peak TA muscle force (B) compared to the subsequent ipsilateral push-off impulse for the 80% PSF condition with a linear regression (red).

Our data show that TA fascicles on average lengthen slightly during early stance, but are variable enough to also regularly exhibit shortening and isometric behaviour on successive steps. Fascicle length feedback appears to be an unreliable parameter for making step-to-step gait adjustments on the subsequent push-off to control speed or minimize energetic cost. Instead, muscle force feedback may be important for these adjustments.

## Significance

Although TA muscle spindles are sensitive to small length changes (5), this sensitivity may be task-dependent. During the collisional phase of walking, muscle length feedback may not be used for gait adjustments in the same way they are used in standing balance (6). Muscle force feedback may be a more likely candidate for making propulsive adjustments during gait.

# High-Density EMG Reveals Lower Limb Spatial Activity during Walking and Running

Bryan R. Schlink<sup>1</sup>, Andrew D. Nordin<sup>1</sup>, and Daniel P. Ferris<sup>1</sup>

<sup>1</sup>J. Crayton Pruitt Family Department of Biomedical Engineering, University of Florida, Gainesville, FL, USA

Email: \*[bschlink@ufl.edu](mailto:bschlink@ufl.edu)

## Introduction

High-density electromyography (EMG) is a useful technology that records electrical muscle activity using an array of microelectrodes. Although traditionally used in relatively stationary conditions, recent studies have shown the potential of high-density EMG during locomotion. Two of these studies recorded lateral gastrocnemius and biceps femoris muscles during locomotion and found vast differences in peak activation levels across the muscle bellies [1,2]. This suggests that spatial myoelectric activity widely varies within individual muscles.

The goal of this research was to determine if there are similar spatial EMG activity patterns across multiple lower limb muscles at a range of speeds. We hypothesized that: 1) spatial patterns of EMG activity will vary across different muscles, and 2) spatial EMG activation patterns within each muscle will not change as gait speed increases.

## Methods

We recorded high-density surface EMG from five major lower limb muscles from the right leg of 9 healthy subjects (7 M, 2 F) using a 64-channel electrode array. The muscles were the medial and lateral gastrocnemii, vastus medialis, tibialis anterior, and biceps femoris. Subjects walked (1.2 m/s and 1.6 m/s) and ran (2.0, 3.0, 4.0, and 5.0 m/s) on an instrumented treadmill for a duration of twenty strides per leg.

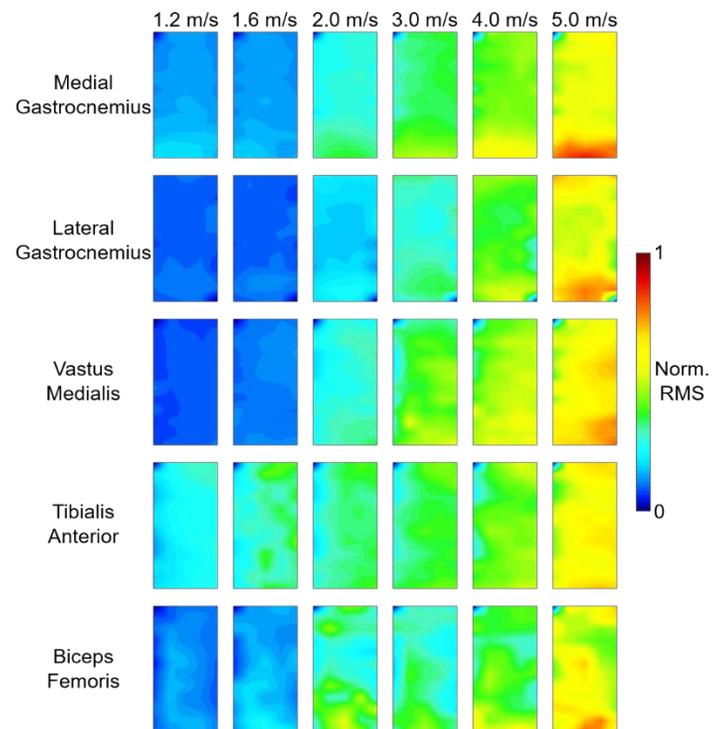

We used canonical correlation analysis to decompose the EMG signals and filter the components from each muscle to remove motion artifacts [3]. We averaged the data from the primary phase of the gait cycle that each muscle is active (stance: medial/lateral gastrocnemii, vastus medialis; swing: tibialis anterior, biceps femoris). We calculated the average root mean square (RMS) value in the target gait phase for each electrode of the array within each speed and normalized the data within each subject to the peak RMS value found across all gait speeds.

## Results and Discussion

The spatial EMG activity patterns differed across muscles, but each muscle's individual pattern was relatively consistent across the different speeds (Figure 1). In all muscles, we observed the highest EMG-RMS activity in the fastest trial (5.0 m/s). The highest EMG amplitude in the medial and lateral gastrocnemii during stance phase was at the distal portion of the muscle, consistent with previous research [2]. There was also increased EMG activity in the distal regions of the vastus medialis and biceps femoris, although the overall pattern of EMG activity was less localized than the gastrocnemii. Tibialis anterior EMG activity was more uniform across the entire muscle, and the change in EMG-RMS amplitude across speeds for this muscle was smaller than the other muscles.

The differences in EMG spatial patterns may be explained by multiple factors. The gastrocnemii typically have a higher percentage of fast-twitch fibers [4], and there may be a larger grouping of these fibers in the distal portion of the muscle that act together during locomotion. Conversely, the tibialis anterior muscle has a higher percentage of slow twitch fibers and a

circumpennate fiber structure. The relative mechanical capabilities of these muscles may also influence the spatial EMG activity. Muscles with greater relative loading during locomotion may have a more distinct focus of EMG activity compared to those with lower relative loading.

**Figure 1:** Average EMG-RMS spatial distribution for all muscles (rows) across all walking and running speeds (columns). RMS values for each subject were normalized to the peak RMS value during running at 5.0 m/s. The EMG profiles for the medial and lateral gastrocnemii and vastus medialis were averaged over the stance phase. The tibialis anterior and biceps femoris EMG patterns were averaged over the swing phase.

## Significance

Our results indicate heterogenous spatial activation for a range of lower limb muscles across locomotion speeds in healthy individuals. It's not clear if this heterogenous activation pattern equates to a heterogenous force loading pattern across the muscle. Understanding the spatial variety in myoelectric patterns may help researchers, clinicians, and therapists develop intervention and rehabilitation programs that target specific muscle regions.

## **Introduction**

Movement is a necessity for animals to find mates, forage, or to prevent becoming food. Most laboratory locomotion studies of animals concern locomotion over solid surfaces [1], which do not reflect complex environments and the variety of unsteady terrains animals experience in the wild.

In this study, we used *in vivo* sonomicrometry (SONO) and electromyography (EMG) techniques to obtain strain and activation patterns of the Vastus Lateralis (VL), a major knee extensor, and the Lateral Gastrocnemius (LG), a major ankle extensor muscle, to elucidate these muscles' role in walking on solid and sandy surfaces in white rats (*Rattus norvegicus*).

## **Methods**

We collected data while rats (N = 4) were walking at 0.7 m/s on a Variable Surface Rotary Treadmill (VSRT) with and without a 2 cm layer of sand. SONO and EMG data were collected at 2000Hz. Walking trials were recorded at 200 frames s<sup>-1</sup> using a high-speed camera (Xcitex Inc, Woburn, MA, USA), positioned perpendicular to the experimental set up. Video data were digitized using ProAnalyst (Xcitex Inc, Woburn, MA, USA), after which the complete dataset was analyzed using a customized analysis script for Matlab (2015a, MathWorks, Natick, MA, USA).

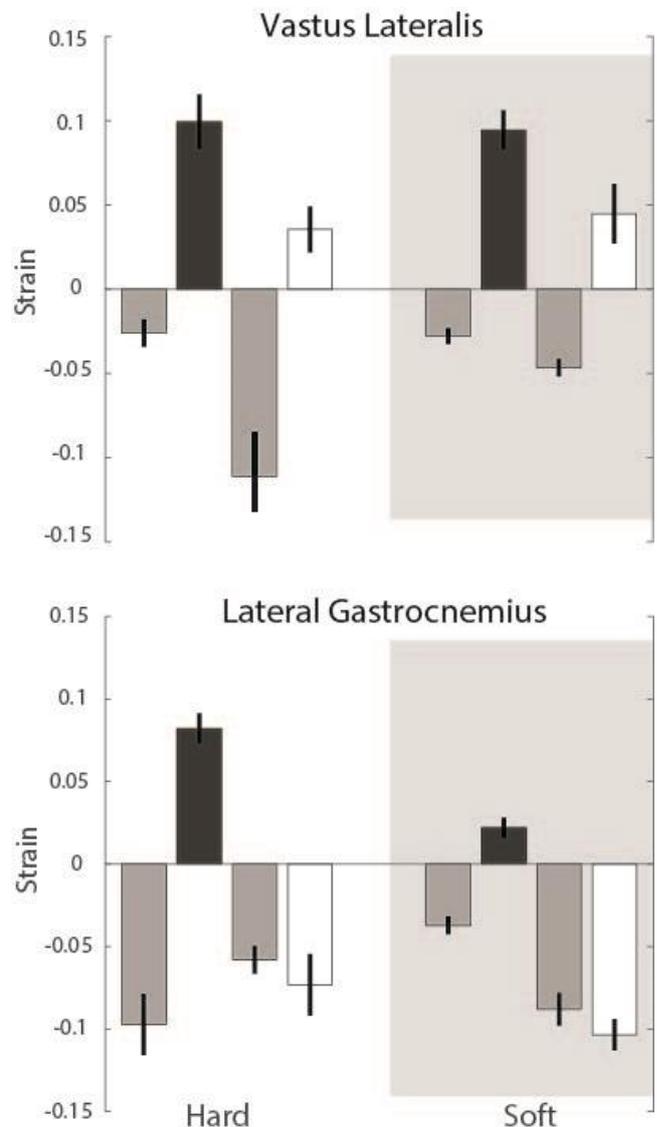

## **Results and Discussion**

Our data shows that during the stance phase, the VL undergoes more net lengthening, due to a decrease in shortening strain during the stance cycle, when an animal walks on sand versus on a hard surface (Figure 1). Alternatively, the LG shows an increase in net shortening, due to a decrease in lengthening and an increase in shortening, during stance while animals walk on a sandy surface.

These preliminary data suggest that rats accommodate for locomotion on soft sand by increasing muscle shortening by the LG, and therefore increase its mechanical output, and less shortening by the VL. Further investigation of swing phase strain patterns, joint kinematics and gait analysis will provide more detailed insight in how rats accommodate changes in surface compliance and increase of mechanical demand.

## **Significance**

Locomotion is widely studied topic, muscle responses to unsteady, dynamic locomotion tasks less so. Elucidating the role muscles play in adapting to variation in surface substrates provides a framework for assessing how animals meet changes in demand and mechanical outputs while moving through their natural environment. It also sets the stage for future bioinspired designs of dynamic robotic devices that are able to navigate through very complex and variable terrain.

**Figure 1.** Muscle strain patterns of the Vastus Lateralis (top) and Lateral Gastrocnemius (bottom) during walking on hard (left) and soft (shaded right) substrates during stance phase. During stance phase shortening (light grey), lengthening (dark grey), and net shortening (white) were characterized.

# The effects of advanced age and walking speed on mechanical functions of the ankle plantarflexors

Daniel J. Kuhman<sup>1</sup>, Jutaluk Kongsuk<sup>1</sup>, and Christopher P. Hurt<sup>1</sup>  
<sup>1</sup>University of Alabama at Birmingham, Birmingham, AL, U.S.A.  
Email: [dkuhman@uab.edu](mailto:dkuhman@uab.edu)

## Introduction

Advanced age is associated with decreased ankle plantarflexor (PF) and increased hip mechanical output during walking [1]. The magnitude of this distal-to-proximal mechanical redistribution increases with task difficulty. For example, old adults disproportionately increase mechanical output at the hip compared to the ankle during maximal versus comfortable speed walking [2] and during uphill versus level-ground walking [1]. In young adults, increasing speed and uphill slope during walking both result in decreased negative and increased positive joint work at the ankle, resulting in more motor-like behavior during these more challenging tasks [3]. Unfortunately, age-related structural (e.g., fiber type) and functional (e.g., decreased strength) changes to muscles and other tissues spanning the ankle may impair their ability to act effectively as mechanical motors [4]. Inability to adapt mechanical behavior of the ankle during more challenging walking tasks may limit the ability of old adults to perform walking tasks which require motor-like behavior (fast, uphill, or accelerated walking). The purpose of this study was to determine the effects of age and walking speed on mechanical behavior of the ankle PFs. We hypothesized that motor-like behavior would increase more in response to increased walking speed in young compared to old adults.

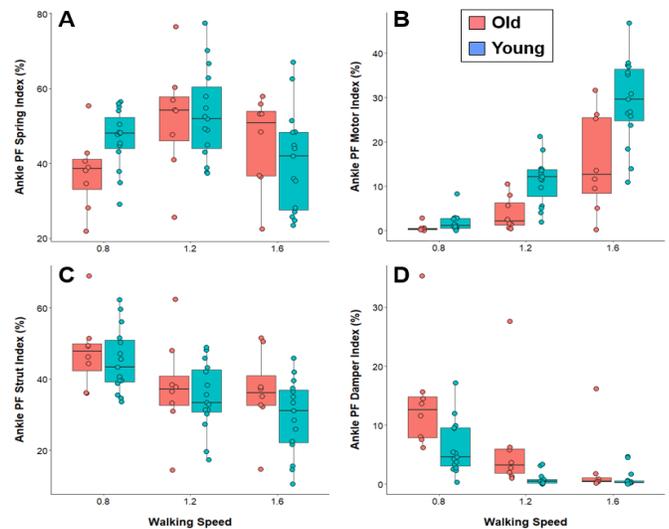

## Methods

Healthy young ( $n = 15$ , age =  $25 \pm 2$  years) and old ( $n = 8$ , age =  $69 \pm 2$  years) adults walked on a dual-belt force-instrumented treadmill at 0.8, 1.2, and  $1.6 \text{ms}^{-1}$ . For each support phase, we quantified strut-, spring-, motor-, and damper-like behavior of the ankle PFs using the functional indexing approach [3]. Each functional index is calculated as a percentage such that the sum of all indices equals 100. To capture the magnitude of the age-related distal-to-proximal shift with a single variable, we used the following ratio: (ipsilateral hip flexor + contralateral hip extensor positive work) / ankle PF positive work. Higher ratios indicate larger reliance on hip relative to ankle joint mechanical output. We used 2-way repeated measures ANOVAs to determine the effects of age, speed, and their interaction on the magnitude of mechanical redistribution and each functional index. Statistical analyses were conducted in R (lme4 package) and the threshold for statistical significance was  $p < 0.05$ .

## Results and Discussion

We found significant main effects of age ( $p < 0.01$ ) and speed ( $p < 0.001$ ) on the magnitude of mechanical redistribution, confirming that the well-established, age-related redistribution of mechanical output existed in our sample. Significant age-by-speed interactions were observed for spring ( $p < 0.05$ ), motor ( $p < 0.01$ ), and damper ( $p < 0.01$ ) indices, indicating between-group differences in response to changes in walking speeds. Supporting our previous work [3], we observed increased

motor-like behavior with increased walking speed in young adults (Fig. 1B). Supporting our hypothesis, old adults displayed the same behavior, but not to the same extent as young adults (age x speed interaction effect). Rather, old adults tended to maintain spring- and strut-like behavior at faster speeds. Age-related structural and functional changes to the ankle PFs may limit their ability to serve as effective motors at faster speeds. Others have reported decreased Achilles tendon stiffness with advanced age, which would theoretically improve its capacity to act as a mechanical spring [5]. This may explain the relative maintenance of spring-like behavior observed here (Fig. 1A). Walking speed and spring index shared an inverted-U shaped relationship in both age groups, which may partially explain lower metabolic costs previously observed at intermediate speeds in both age groups [6].

**Figure 1:** Spring (A), motor (B), strut (C), and damper (D) functional indices across walking speeds in old and young adults.

## Significance

Our results suggest that advanced age is associated with a reduced capacity to utilize the ankle PFs as mechanical motors when task difficulty is increased. Inability to utilize the ankle PFs as motors may limit the ability of old adults to walk at faster speeds or perform other walking tasks which require motor-like behavior (e.g., uphill walking, accelerated walking). Enhancing motor-like behavior of the ankle PFs (e.g., via exercise, exoskeletons) may improve mobility in the aging population.

# Are Muscles Tuned to the Preferred Stride Frequency of Walking?

Jonaz Moreno Jaramillo<sup>1</sup>, Brian R. Umberger<sup>2</sup>

<sup>1</sup>Department of Kinesiology, University of Massachusetts, Amherst MA.

<sup>2</sup>School of Kinesiology, University of Michigan, Ann Arbor MI.

Email: umberger@umich.edu

## Introduction

The energy expended in human locomotion has been an important topic in the field of biomechanics. When humans walk at their preferred walking speed<sup>1</sup> and stride frequency<sup>2</sup>, the metabolic cost of transport (mCoT) is minimized relative to other speeds or stride frequencies. However, mCoT provides no muscle-specific information on why cost is minimized for preferred conditions. Previous studies have considered muscle activation as an indirect way to gain insight into the contributions of individual muscles to the total mCoT during walking<sup>1,2</sup>.

The purpose of this study was to investigate the impact of stride frequency on activation of the major lower limb muscles during level, fixed-speed walking. Based on previous studies<sup>1,2</sup>, we hypothesize that: total muscle activation will demonstrate a U-shaped response to stride frequency with a minimum value at the preferred stride frequency (PSF), while the activation of individual muscles will be minimized at a range of stride frequencies, reflecting the mechanical demands of walking.

## Methods

20 healthy young adults (10 males, 24.5±5.5 yr, 68.6±10.7 kg, 1.71±0.11 m.) walked at a fixed speed (1.3 m·s<sup>-1</sup>) and five different stride frequencies for 2 minutes each with 1 minute rest between conditions. The conditions were PSF, ±12.5% PSF, and ±25% PSF<sup>2,3</sup>. A metronome was used to pace the target stride frequencies. Electromyography (EMG) data were collected during the final 30 s of each condition from eight muscles of the right lower limb: gluteus maximus, gluteus medius, long head of biceps femoris, vastus lateralis, gastrocnemius, soleus, and tibialis anterior. Participants practiced all of the conditions before data collection, and the order of trials was randomized.

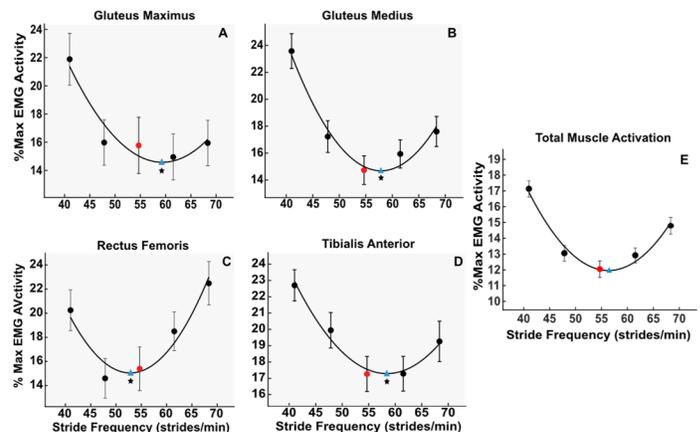

Raw EMG signals were DC-bias corrected, full-waved rectified, and low-pass filtered with a Butterworth digital filter at 5 Hz cut-off frequency to create linear envelopes. The linear envelopes were scaled based on the peak EMG amplitudes observed across all conditions and averaged across 10 strides. Scaled EMG signals within a muscle were integrated with respect to time, and then divided by the total time to create the average EMG amplitude for each muscle, for each participant, for each condition. Total average muscle activation was obtained by summing the average EMG amplitude across muscles for each condition, and dividing by the total number of muscles. We ran orthogonal polynomial contrast on individual muscle activations, and the total activation, to determine the appropriate order polynomial for trend-line fitting. We determined the predicted minimum activation stride frequencies from the trend-lines for comparison with the preferred stride frequency for individual muscles, and the total activation. Paired t-test were used to determine significant difference between the predicted minimum and preferred stride frequencies ( $\alpha = 0.05$ ).

## Results and Discussion

Total muscle activation was minimized at the PSF (Fig. 1E), in support of our first hypothesis and consistent with results for

mCoT<sup>2,3</sup>. Individual muscle activations were not all minimized at PSF. Specifically, activation was minimized in four out of eight muscles at significantly different ( $p < 0.05$ ) frequencies from the PSF, with moderate effect sizes ( $d = 0.62 - 0.87$ ) (Fig. 1A-D). The muscle-specific responses for rectus femoris and tibialis anterior across stride frequencies (Fig. 1C,D) were similar to a previous study that included only four muscles<sup>2</sup>. Our analysis included a more complete representation of lower limb muscles, and generalizes the finding that total muscle activation is minimized at the PSF (Fig. 1E.), mirroring the result for mCoT.

Although individual muscle activations were not all minimized at the PSF, predicted minima stride frequencies were all within 8% of the PSF, and total muscle activation was only modestly increased at ±12.5% of PSF. Thus there is some flexibility to adjust stride frequency without excessive demands being placed on any specific muscle.

**Figure 1:** Average muscle activations as a percent of the maximum observed value across stride frequencies. Red dots indicate preferred stride frequency; blue triangles indicate the predicted optimal stride frequency. Error bars are standard errors. The \* indicates significant differences ( $p < 0.05$ ) between predicted and preferred values.

## Significance

Minimization of total muscle activation may be a primary reason why mCoT is minimized at the PSF in human walking. Moreover, the relatively shallow slope of the U-shaped mCoT curve around the PSF may be due to individual muscle responses. The individual-muscle activation minima at different stride frequencies provides some flexibility to adjust walking to the environment without a large increase in mCoT.

## Effects of Varying Tendon Stiffness on the Metabolic Cost of Walking

Alex N. Denton and Brian R. Umberger

Locomotion Research Laboratory, School of Kinesiology, University of Michigan, Ann Arbor, MI.

Email: [umberger@umich.edu](mailto:umberger@umich.edu)

### Introduction

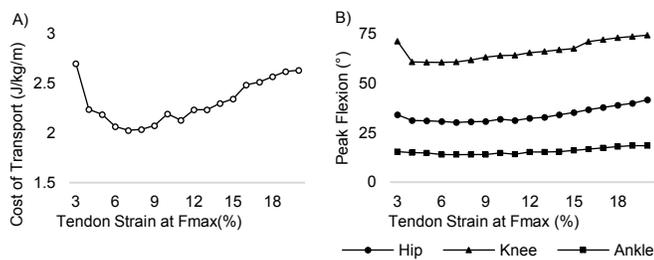

Tendons are compliant structures responsible for transferring muscle force to bone to produce movement. During walking, the triceps surae tendon has been shown to store and return mechanical strain energy as positive work during push-off, reducing the work done by the active muscles.<sup>2</sup> The muscle energetics during walking are sensitive to the stiffness of tendinous tissues.<sup>3</sup> Thus, tendon stiffness should be a factor affecting the metabolic cost of walking.

The triceps surae is often the focus when studying the effects of tendon dynamics on muscle energetics during locomotion due to its superficial and accessible nature. However, the plantar flexors represent only ~25% of the net cost of walking<sup>6</sup>, and the effects of tendon stiffness across all major muscles of the lower limb on the energetics and kinematics of walking are unknown. Tendon stiffness should be expected to affect not only energy cost, but also movement patterns. For example, in simulations of vertical jumping, movement amplitude increased as the triceps surae tendon stiffness decreased.<sup>1</sup> In the present study, we use a similar modeling and simulation approach to estimate the effects of tendon stiffness on walking energetics and kinematics, which would be challenging or impossible to do experimentally.

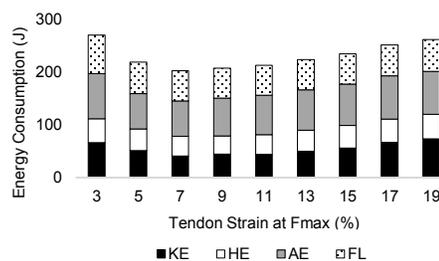

Thus, the purpose of this study was to investigate the effects of tendon stiffness on the COT and kinematics of walking, to enhance the understanding of musculoskeletal function in locomotion. Based on data in the literature<sup>1,4</sup>, we hypothesized: (1) tendons with the stiffness reported experimentally (5% tendon strain at peak isometric force) will yield minimum COT and (2) joint range of motion (ROM) will vary inversely with tendon stiffness.

### Methods

Predictive simulations of walking (1.3 m/s) were generated using direct collocation with a planar model consisting of 9 segments, 11 degrees of freedom, and 18 musculotendon actuators (nine for each leg).<sup>5</sup> The objective function included terms for stability, smoothness, and muscle activation.<sup>5</sup> Tendon stiffness was characterized as percent strain produced at peak isometric force and was varied between 3 and 20% across all muscles in the model. Metabolic COT was predicted using a model of muscle energy consumption.<sup>6</sup>

**Figure 1:** A) Cost of transport and B) peak joint angles of the lower extremities for walking with a wide range of different tendon stiffness.

**Figure 2:** The distribution of energy consumption across muscle groups for walking with different tendon stiffnesses. HE (hip extensors), KE (knee extensors), AE (ankle extensors), and FL (flexors of all joints).

### Results and Discussion

Metabolic COT was minimized at the stiffness corresponding to 7% tendon strain at peak isometric force (Fig 1A). COT gradually increased with tendon stiffness above 7%, whereas the COT rapidly increased with tendon stiffness below 7%. The optimal tendon stiffness was close to, though slightly greater than we predicted, yet fit within the range of reported in vivo measurements.<sup>4</sup> The overall trend in COT (Fig 1A) was driven mostly by the knee extensor muscles, which exhibited a minimum at around 7% (Fig 2).

Over most of the tested range, lower limb tendon stiffness resulted in greater joint ROM at the hip, knee, and ankle (Fig 1B). Peak hip flexion had the strongest correlation with decreased tendon stiffness ( $R^2 = 0.70$ ). Consequently, as tendon stiffness decreased, the optimal step length and distance traveled in the direction of motion per step increased. Thus, there is an interaction among tendon stiffness, metabolic cost, and optimal movement patterns.

### Significance

While the predicted optimal tendon stiffness value was similar to the biological value from the literature<sup>4</sup>, the slight difference between the literature (~5%) and optimal (7%) values may reflect trade-offs associated with task demands beside level walking at preferred speeds. While most attention in the literature has been on the triceps surae<sup>2,3</sup>, minimum cost at optimal stiffness was due primarily to the knee extensor muscles. Additionally, the simulations indicate that optimal gait kinematics depend on tendon stiffness.

<sup>2</sup>University of Florida, Gainesville, FL

Email: jrfranz@email.unc.edu, web: http://abl.web.unc.edu

## Introduction

Compared to young adults walking at the same speed, older adults consume oxygen ~20% faster for reasons that are poorly understood [1]. Simultaneously, older adults exert smaller peak anterior (i.e., propulsive) ground reaction forces ( $F_p$ ) and, despite no change in total positive work, exhibit a characteristic distal-to-proximal redistribution of leg muscle workload [2]. We suspect that more proximal leg muscles, with their longer fascicles and shorter tendons, are less economical for powering the mechanical demands of walking. We recently used a real-time biofeedback paradigm to reveal that young adults targeting smaller than normal  $F_p$  do so by redistributing mechanical workload from the distal to proximal musculature without changing total positive leg joint work [3]. These findings allude to an experimental paradigm that would enable us to study the extent to which a distal-to-proximal contributes to increased metabolic energy cost in the absence of other known age-related changes. Here, we quantified the metabolic and limb- and joint-level mechanical energy costs associated with modulating propulsive forces during the push-off phase of walking. We first hypothesized that when walking with larger than normal  $F_p$ , metabolic energy cost would increase in a manner consistent with (i.e., accompanied by) increases in total positive leg joint work. Conversely, second, we hypothesized that total positive leg joint work would not increase when walking with smaller than normal  $F_p$ , and that metabolic energy cost would instead increase in a manner consistent with (i.e., accompanied by) a redistribution to muscles spanning the hip for power generation.

## Methods

12 young adults (age: 23.3±3.1 years, 8F/4M) completed a series of 5-min walking trials on a dual-belt, instrumented treadmill at their preferred overground walking speed (1.37±0.15 m/s). Immediately following a normal walking trial, a custom Matlab script estimated and stored the stride-averaged  $F_p$  for use in subsequent biofeedback trials. Specifically, subjects then walked while receiving visual biofeedback of their step-by-step  $F_p$  values with instructions to match those values to, in randomized order, target values corresponding to ±20% and ±40% of values from

normal walking (Fig. 1A). We report the following outcomes averaged across the final 2 min of each walking trial: net (i.e., walking-standing) rate of oxygen consumption ( $\dot{V}O_2$ ), net metabolic power [4], and, from the integral of their respective joint power curves divided by stride time, positive stance phase leg joint mechanical work rates.

## Results and Discussion

Biofeedback alone (i.e., targeting normal  $F_p$ ) did not alter metabolic cost ( $p=0.990$ ). Compared to walking normally, subjects increased net metabolic power by an average of up to 47% when targeting larger than normal  $F_p$  ( $p<0.001$ ; Fig. 1B). As hypothesized, this metabolic response was accompanied by and positively correlated with up to an 13% increase in total positive leg joint work rate ( $p=0.003$ ,  $R^2=0.29$ ; Fig. 1C). Conversely, when targeting smaller than normal  $F_p$ , subjects increased net metabolic power by up to 58% ( $p<0.001$ ) but without changing total positive work rate ( $p=0.693$ ) (Fig. 1B). Rather, as hypothesized, this metabolic response was accompanied by up to a 31% increase in positive hip joint work rate ( $p=0.002$ ), offset by modest 10% decreases in positive ankle/knee work rates that did not reach significance.

## Significance

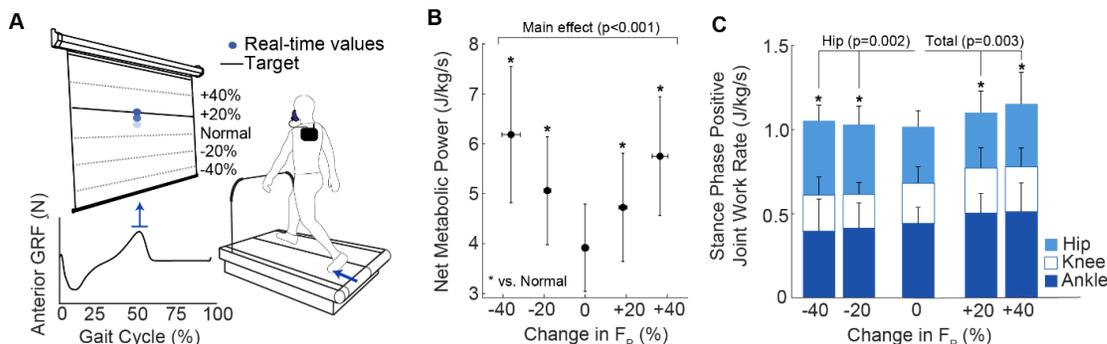

Our findings suggest that the distal-to-proximal redistribution of leg muscle workload due to aging may contribute to the higher metabolic energy cost of walking in older adults.

## Developmental Plasticity of Locomotor Economy in an Avian Bipedal Model

Talayah Johnson, Kavya Katugam, Ian Dechene, Suzanne M. Cox, Stephen J. Piazza, Jonas Rubenson  
Biomechanics Laboratory, Department of Kinesiology, The Pennsylvania State University, University Park, PA, USA  
Email: taj5199@psu.edu

### Introduction

Over an evolutionary time scale, natural selection has resulted in specializations for locomotor economy in cursorial species [1]. Whether adaptations in locomotor economy occur across an individual's life span, however, remains less clear. For example, it remains debated how and if running economy in humans is altered due to training [2]. A recent study that eliminated high-intensity activity during the growth period in an animal model showed no effect on locomotor economy [3]. The results of this study suggest that locomotor economy might not respond plastically to altered amounts of exercise during growth and may be robust to changes in life history.

To understand better the scope of developmental plasticity of locomotor economy, we adopted a bipedal model (guinea fowl) that permitted drastic alteration of musculoskeletal loads across the growth span. We achieved this by increasing distal limb mass experimentally by a factor of  $\sim 2.5x$  over the maturation period. We hypothesized that animals subject to habitual increased limb mass would be more economical at carrying extra limb mass compared to a habitually unloaded control group. We also hypothesized that the limb-loaded animals would have worse economy when walking unloaded when compared to controls.

### Methods

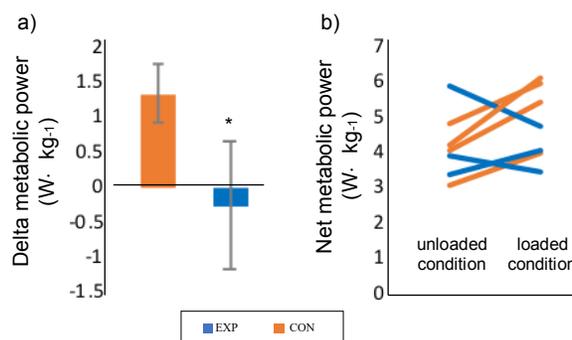

Twelve 1-day old guinea fowl (*Numida meleagris*) were obtained for this experiment (Privett Hatchery, Portales, NM). All birds were raised in large circular floor pens with constant access to food and water. At one week of age, animals were randomly assigned to a control group (CON,  $n=6$ ) and a loaded experimental group (EXP,  $n=6$ ). A lead strip with mass equal to 3.75% of the individual's body mass was chronically added to the right leg of the CON group throughout growth. This leg weight was adjusted weekly to maintain 3.75% of body mass ( $\sim 2.5x$  biological distal limb mass). Starting at three weeks of age, each group was exercised three times per week by herding animals around a circular course in four 5-minute intervals for a total of 20 minutes.

Metabolic power was measured during standing and during treadmill walking ( $0.5 \text{ m}\cdot\text{s}^{-1}$ ) using a flow-through metabolic chamber system [2]. Metabolic power was measured in the habitual condition (CON= unloaded, EXP=loaded) as well as in their novel condition where an equivalent leg mass (3.75% body mass) was added to the CON group and the load was removed from the EXP group. Between 3-5 trials were recorded per condition and the order of conditions was randomized.

### Results and Discussion

At the time of this abstract submission, preliminary analysis of data from three EXP and four CON animals have been made. Average net metabolic power in the limb-loaded condition trended lower in these EXP animals ( $4.1 \pm 0.6 \text{ W}\cdot\text{kg}^{-1}$ ) compared to the CON animals ( $5.3 \pm 0.9 \text{ W}\cdot\text{kg}^{-1}$ ) ( $p = 0.11$ ), but appears more similar in the unloaded condition; EXP ( $4.4 \pm 1.3 \text{ W}\cdot\text{kg}^{-1}$ ) vs. CON ( $4.0 \pm 0.9 \text{ W}\cdot\text{kg}^{-1}$ ) ( $p = 0.65$ ). The average

delta cost of added limb mass was significantly higher in CON vs EXP ( $p = 0.02$ ; Fig 1a). Data for each animal are depicted in Fig 1b.

**Figure 1:** (a) Mean change in net body-mass specific metabolic power between unloaded and limb-loaded (3.75% body mass) walking. Error bars represent standard deviation. (b) Net body-mass specific metabolic power in the unloaded and limb-loaded conditions for each animal. Orange = CON; Blue = EXP.

These preliminary data generally support our first hypothesis; the examined EXP animals exhibit a trend towards lower mean limb-loaded walking economy and exhibit a much lower delta economy of added limb mass. Our preliminary data do not, however, support our second hypothesis that the EXP group would have a higher unloaded walking economy compared to CON. It is interesting to note that for 2/3 EXP animals, walking economy was negatively affected by removing the limb mass. This is surprising given the presumably large reduction in the mechanical work associated with lifting and accelerating the limb. These preliminary data suggest that locomotor economy may be affected by loading history during growth and may be tuned to the habitual loading environment. At present, we have analyzed data from only a small number of animals, so these results must be interpreted with a great deal of caution. Whether sub-optimal locomotor economy in the novel loading environment is the result of musculoskeletal factors or poor motor control and coordination remains to be established.

### Significance

Here we provide new evidence that locomotor economy may be altered based on the loading history during growth. These data have important implications for understanding the long-term effects of childhood activity and inactivity. Further analysis may determine the importance of the growth period on permanent adult locomotor energetics and biomechanics.

# Reducing the Metabolic Cost of Walking by Using the Arms to Drive the Legs

Daisey Vega<sup>1</sup>, and Christopher J. Arellano<sup>2</sup>

<sup>1,2</sup>Department of Health and Human Performance, University of Houston

[dvega4@uh.edu](mailto:dvega4@uh.edu)

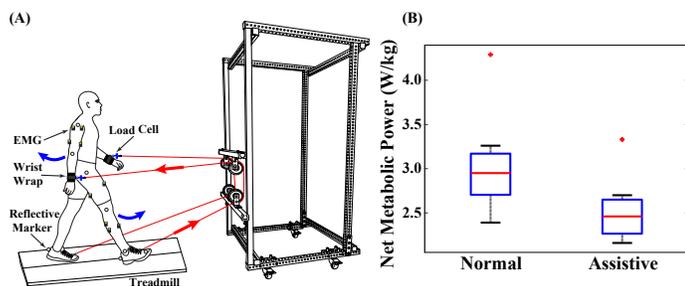

## Introduction

Experiments on recumbent stepping have provided insight into the neural benefits that may arise from coupling the arms and the legs [1], but how we can achieve this coupling effect during walking has remained elusive. Given the out of phase relation between the limbs, we designed a simple, rope-pulley system that facilitates the active use of the arms to drive the legs during walking.

From a biomechanical perspective, we investigated a metabolic trade-off that may arise from coupling the arms and legs during walking. For instance, the cost of leg swing has been estimated to be between 10% and 33% [2-3], which can be explained by an underlying muscular demand. On the contrary, the cost of arm swing has been considered negligible and explained by its passive dynamics [4]. Given these insights, we explored the use of a direct linkage system where individuals directly use the arms to generate an assistive force to drive the legs, whereby arm swing retraction provides an assistive force via a rope to drive the ipsilateral leg forward. While generating arm forces may incur a metabolic cost, we suspected this would be offset by the reduction in muscular demand needed to swing the leg—yielding a net reduction in cost. Therefore, we hypothesized that using the arms to drive the legs would reduce the demand for net metabolic power during walking.

## Methods

Eight subjects participated in this study (3 women and 5 men; mean±s.d.; age: 23.25±3.37 years, mass: 73.86±18.46 kg, height: 173.84±13.95 cm). Subjects performed two randomized trials: (1) Normal Walking and (2) Assistive Walking on a dual belt force measuring treadmill at 1.25 m/s. Each trial was 7 minutes in duration and the following data were collected: rate of metabolic energy consumption, surface electromyography, and ground reaction forces. In addition, arm pulling forces during the assistive walking trial were measured with load cells that attached to the rope-pulley device (Fig. 1A).

**Figure 1.** (A) Subjects walk with an assistive device that allows them to use the arms to drive the legs via a rope-pulley system. Arrows indicate direction of limb motion (blue) and pulling forces directed along the rope (red). (B) Boxplot of net metabolic power for normal and assistive walking trials.

## Results and Discussion

When compared to normal walking (median = 2.95 W/kg), we found that using the arms to drive the legs reduced the demand for net metabolic power by ~17% (median = 2.46 W/kg); Wilcoxon Signed Ranks test,  $p = 0.006$  (Fig. 1B).

In support of our hypothesis, our results show that using the arms to drive the legs during walking reduces net metabolic power, providing proof-of-concept that our method of coupling the arms and legs reduces the overall effort to walk. Further analyses will focus on the potential changes in neuromuscular demand and ground reaction forces. Such insights will enhance our understanding of the biomechanical trade-off that facilitated the reduction in cost during walking. In addition, it may provide future guidance in optimizing the device for a greater reduction in cost, or modifying the system to lower leg demand at different phases of walking.

## Significance

Reducing the effort to walk has implications in a rehabilitation setting for individuals who do not have the endurance and/or neuromuscular strength to do so, and therefore, must rely on manual assistance from physical therapists or more costly robotic devices. In addition, our findings pave the way for future studies to investigate further questions: Can this device be used to promote neural plasticity at crucial stages of locomotor training? Can this device enhance patient autonomy during locomotor training? These questions remain to be answered, but the device shows promise given that an individual can actively use their arms to drive their own legs during walking.

In summary, this device could be used as a simple, but effective means to couple the arms and legs, which may promote neural benefits and help restore an individual's walking ability.

### Introduction

Stroke survivors often have deficient reactive postural control [1] and impaired upper extremity function [2]. These factors are related, as reduced arm function has been associated with falls in stroke survivors [2]. We previously validated a measure of how the arms contribute to posterior balance reactions [3] through counter-rotation about the whole-body COM [4]. The purpose of this study was to test the hypothesis that, compared to those with no neuromuscular impairment, stroke survivors would have a diminished arm contribution in response to standing posterior perturbations.

### Methods

Stroke survivors (n = 10, mean (SD) age = 64.0 (8.8) years, BMI = 30.8 (4.5) kg·m<sup>-2</sup>) and young adults without neuromuscular impairment (n = 11, age = 22.2 (2.3) years, BMI = 22.4 (3.0) kg·m<sup>-2</sup>) participated in this study. All participants completed a single-stepping threshold evaluation on a computer-controlled treadmill to determine the smallest perturbation magnitude that consistently elicited a posterior step [5]. Whole-body, three-dimensional motion was recorded for near-threshold level perturbations to explore the arm contributions and shoulder kinematic responses during recovery.

The rate of change in angular momentum of the body was represented as a compound pendulum ( $M_{TOTAL}$ , Equation 1), where  $r_{COM}$ ,  $r_{COM}$ ,  $m$ ,  $a_{COM}$ ,  $I_{BODY}$ , and  $\alpha_{COM}$  are the COM position, vertical projection of the COM onto the treadmill surface, body mass, linear acceleration of the COM, whole-body moment of inertia about the COM, and angular acceleration of the vector connecting the whole-body COM to the midpoint of ankle-joint centers.

The rate of change of arm-segment angular momentum with respect to the whole-body COM was calculated ( $M_{ARMS}$ , Equation 2), where  $r_i$ ,  $m_i$ ,  $a_i$ ,  $I_i$ , and  $\alpha_i$  are the position, mass, linear acceleration, moment of inertia, and angular acceleration of the “i<sup>th</sup>” segment within the arms (i.e. four total segments),  $R_i$  is the column vector from the whole body COM to the COM of segment i, and  $E_3$  is the 3 by 3 identity matrix.

The total arm contribution ( $\beta_{ARMS}$ , Equation 3) was quantified from the total-least-squares regression of  $M_{ARMS}$  onto  $M_{TOTAL}$  and compared using an independent t-test.

$$[Equation 1] \quad M_{TOTAL} = (r_{COM} - r_{COM}) \times m(a_{COM}) + I_{BODY}\alpha_{COM}$$

$$[Equation 2] \quad M_{ARMS} = \sum\{(r_i - r_{COM}) \times m_i(a_i - a_{COM})\} + \sum I_i(\alpha_i - \alpha_{COM}) - \sum\{m_i((R_i^T R_i) E_3 - (R_i R_i^T)) \alpha_{COM}\}$$

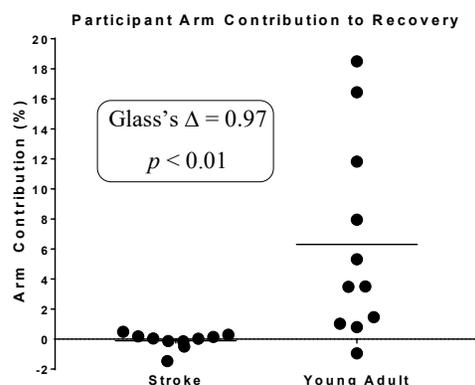

$$[Equation 3] \quad \beta_{ARMS} = M_{ARMS} \cdot M_{TOTAL}$$

### Results and Discussion

In support of our hypothesis, those with chronic stroke had substantially less total arm contribution (mean (SD) = -0.1 (0.6) %) than those with no history of stroke (6.3 (6.6) %,  $p < 0.01$ , Figure 1). In follow-up analyses of shoulder kinematics, we did not detect between-group differences in the peak shoulder flexion velocity of the “faster” ( $p = 0.82$ , Glass’s  $\Delta = 0.10$ ) or “slower” ( $p = 0.20$ , Glass’s  $\Delta = 0.48$ ) arms. Group differences in the arm-

contribution measure may be due to the timing of arm motion, the orientation of the arms, and/or the relative contribution of other recovery mechanisms (i.e. altering the COP location or using the force from deceleration of the treadmill belt).

Those with chronic stroke, and older average age, exhibited little total contribution of the arms when reacting to a posterior perturbation. Shoulder kinematics could not explain this deficit.

**Figure 1: Arm contribution values for all participants.** Stroke survivors showed little total arm contribution (mean (SD) = -0.1 (0.6) %) during slip perturbation recovery while non-stroke participants measured a significantly greater total arm contribution (6.3 (6.6) %,  $p < 0.01$ , Glass’s  $\Delta$  effect size = 0.97).

### Significance

This study provides evidence that impaired reactive balance in those with chronic stroke may be due to an altered “whole-body” response, not just that of the lower extremities. This study also demonstrates the utility of the arms-contribution measure in detecting impairments when shoulder kinematics failed to do so.

Perturbation-based training has improved reactive balance in those with chronic stroke [6, 7]. We do not know if it specifically benefits the use of the arms in such reactions. Our arm-contribution measure represents a modifiable target for such interventions. It is clear from the shoulder flexion velocities that those with stroke moved their arms; therefore, we are optimistic that such motions can be modified in a manner as to improve their contribution.

## Dopamine medication and motor adaptability improve postural control in Parkinson's disease

### Introduction

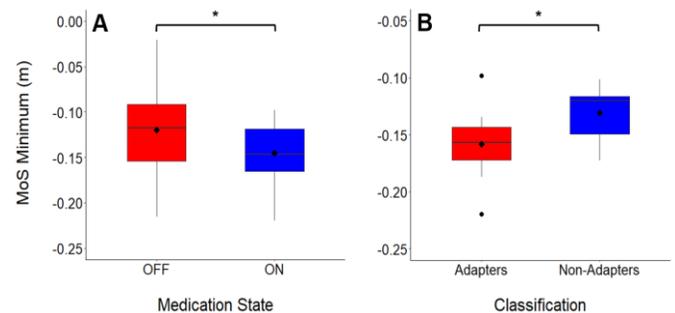

Postural instability is a hallmark motor symptom of Parkinson's disease (PD). In PD, progressive loss of dopamine-producing neurons disrupts cortical-basal ganglia-thalamocortical "loops" [1]. These neural circuits play an important role in sensorimotor integration [2], a process of the nervous system that uses multimodal sensory feedback to guide and modify motor outputs. Inability to accurately sense and integrate contexts of postural perturbations and/or generate appropriate motor outputs to control the body's center of mass (CoM) (i.e., impaired sensorimotor integration) may underpin postural instability in the PD population. If true, two hypotheses can be considered. First, medication which regulates basal ganglia function (e.g., carbidopa-levodopa) should improve CoM control during postural perturbations in PD. Second, individuals with well-functioning sensorimotor integration should display better CoM control than individuals with poorer sensorimotor integration. The purpose of this study was to test these hypotheses.

### Methods

21 individuals with idiopathic PD performed a step threshold assessment on a dual-belt, force-instrumented treadmill off ( $\geq 12$  hours; "OFF") and on dopamine medication ("ON"). Posteriorly directed postural perturbations were delivered via progressively larger treadmill belt accelerations [3]. Perturbations consisted of 200ms acceleration and deceleration phases (400ms total), resulting in triangular waveform velocity profiles with larger peak velocities at higher rates of acceleration. Individuals were explicitly instructed to avoid stepping to recover balance. If the participant did not step to recover balance, the perturbation magnitude was increased; if the participant stepped, the same magnitude perturbation was delivered again. Perturbations began at  $0.5\text{ms}^{-1}$  and increased in steps of  $0.5\text{ms}^{-1}$  until the participant could not recover balance without stepping on four consecutive trials (i.e., the "step threshold"). The largest perturbation magnitude at which each participant could recover balance using a non-stepping response is referred to here as the maximum sub-threshold. To quantify CoM control, we used minimum margin of stability (MoS) [4] during maximum sub-threshold trials. This measure provides an estimate of the maximum amount of instability each participant could withstand without stepping. To address hypothesis 1, a paired-samples t-test was used to compare minimum MoS between OFF and ON conditions. To address hypothesis 2, we compared minimum MoS between individuals who exhibited adaptive motor behavior ("adapters"; switched from a stepping to a non-stepping response at a sub-threshold perturbation magnitude) and those who did not ("non-adapters") using a Student's t-test.

### Results and Discussion

In support of our first hypothesis, minimum MoS during maximal sub-thresholds were significantly more negative in the ON compared to OFF medication state ( $p = 0.006$ , Fig 1A). This finding indicates that individuals were able to withstand larger amounts of instability without stepping (i.e., had greater control over CoM) during the ON state. During ON testing, nearly half (10 of 21) of the participants exhibited adaptive behavior at a sub-threshold perturbation magnitude – that is, they switched from a stepping to a non-stepping response across multiple trials at the same perturbation magnitude. In support of our second hypothesis, minimum MoS were significantly more negative in adapters compared to non-adapters ( $p = 0.031$ , Fig 1B). This finding indicates that individuals with well-functioning sensorimotor integration (measured behaviorally) had greater control over the CoM during postural perturbations.

**Figure 1:** Minimum MoS captured during maximum sub-threshold trials in OFF versus ON medication states (A) and in adapters versus non-adapters (B). More negative minimum MoS values indicate larger "amounts" of instability and greater CoM control.

### Significance

Our results suggest that higher-level, transcortical pathways (e.g., cortical-basal ganglia-thalamocortical neural loops) and processes (e.g., sensorimotor integration) play important roles in CoM control during postural perturbations. If true, interventions seeking to improve postural stability – and CoM control more generally – should incorporate tasks that target such central components. For example, the step threshold assessment used here includes an explicit task goal ("avoid stepping to recover balance") which specifies a "successful" response and may challenge higher-level processes of the nervous system. Results from our comparison of adapters and non-adapters also suggest that challenging motor adaptability (and thus, sensorimotor integration) may be a beneficial intervention strategy.

## Are Improvements of Balance Performance after Short- and Long-term Balance Training in Older Adults associated with changes in H-Reflex Excitability and Muscle Co-Contraction

Leila Alizadehsaravi, Sjoerd M. Bruijn, Jaap H. van Dieën

Department of Human Movement Sciences, Faculty of Behavioural and Movement Sciences, Vrije Universiteit Amsterdam, The Netherlands.

Email: L.alizadehsaravi@vu.nl

### Introduction

Balance training leads to improved balance control in both young and older adults (Muehlbauer et al. 2015). However, the mechanisms underlying balance improvements are unclear, especially in older adults. Therefore, we investigated the influence of balance training (BT) on balance performance, spinal excitability, and muscle co-contraction in older adults. It is well accepted that due to ageing, older adults show poorer balance performance, higher co-contraction and lower H-reflex gains. We hypothesized that after the balance training, balance performance improves and that improvements in balance performance in older adults over time are associated with lower co-contraction and higher spinal reflexes gains.

### Methods

Twenty-two older adults participated in a 3-weeks balance training program. Balance performance was quantified as the mean absolute mediolateral center of mass velocity in perturbed and unperturbed unipedal stance on a robot-controlled platform, before and after the first session (SBT) and after ten sessions (LBT). In addition, durations of co-contraction in soleus and gastrocnemius lateralis (SOL/GL), as well as gluteus medius and adductor longus (GM/AL) muscles were assessed in perturbed and unperturbed unipedal balancing. H-max was acquired from a recruitment curve during bipedal stance. H-reflex gains (H-reflex/background EMG activity 100 ms prior to the stimulus) were acquired at H-max stimulus intensity during bipedal stance.

### Results and Discussion

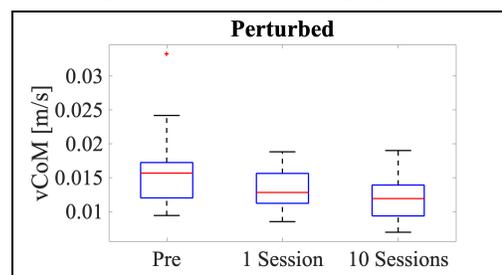

We found decreased vCOM representing an improved balance performance in perturbed stance after SBT ( $t_{19} = 3.015, p = 0.006$ ) and improvement after LBT in both perturbed and unperturbed conditions ( $t_{19} = 3.324, p = 0.003$ ;  $t_{19} = 2.64, p = 0.015$  respectively; Figure. 1). After SBT, duration of co-contraction of SOL/GL was increased in perturbed balancing ( $t_{19} = -2.99, p = 0.007$ ), but duration of SOL/GL and GM/AL was decreased in unperturbed balancing ( $t_{19} = 2.76, p = 0.011$ ;  $t_{19} = 2.57, p = 0.018$  respectively) and, after LBT co-contraction durations had returned to baseline values. H-reflex gains did not change with training.

Correlational analysis indicated that increasing co-contraction coincided with smaller improvements in balance performance ( $r = 0.517, p = 0.02$ , Figure. 2) and increasing H-reflex gains coincided with bigger improvements in balance performance ( $r = -0.518, p = 0.019$ , Figure. 3).

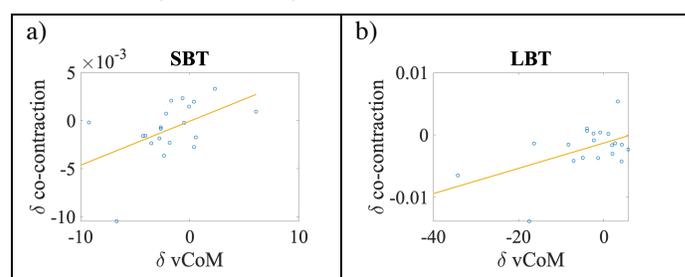

### Significance

Our result indicate that as a result of balance training older adults rapidly improved balance performance, while LBT only slightly increased the improvement acquired. However the mechanisms underlying the improved performance appear to differ between SBT and LBT. After SBT decreased co-contraction and increased spinal excitability, and after LBT decreased co-contraction coincided with larger improvements in balance performance.

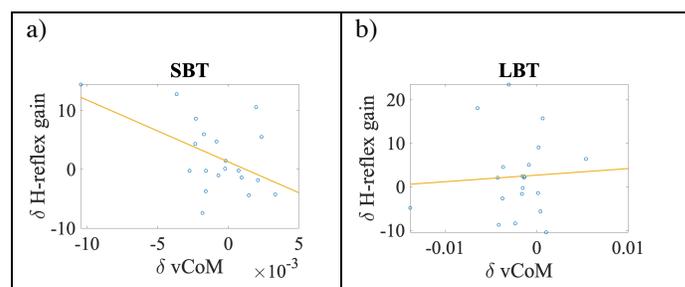

This might suggest a higher spinal excitability as a fast solution and, improved skills reflected in lower co-contraction as a long-term solution adopted in balance training by older adults.

**Figure 1:** The vCOM at the three time points; vCOM decreased after Short- and Long-term training.

**Figure 2:** Decreased vCOM was associated with decreased co-contraction of SOL/GL in unperturbed testing conditions a) after Short-term training and b) after Long-term training.

**Figure 3:** The decreased vCOM after SBT was associated with increased H-reflex gains in unperturbed testing conditions.

## Preliminary Study of Spasticity Using the Portable Position, Velocity, and Resistance Meter (PVRM)

Seung Yun Song,<sup>1</sup> Yinan Pei<sup>1</sup>, Christopher M. Zallek<sup>2</sup>, and Elizabeth T. Hsiao-Wecksler<sup>1</sup>

<sup>1</sup>Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL 61801

<sup>2</sup> Department of Neurology, OSF HealthCare Illinois Neurological Institute, Peoria, IL Email: [ethw@illinois.edu](mailto:ethw@illinois.edu)

### Introduction

Clinical evaluation of spasticity involves direct examiner assessment and grading with qualitative scales, such as the Modified Ashworth Scale (MAS). However, this subjective method heavily relies on the rater's personal experience/interpretation and usually results in poor consistency and low reliability [1]. Quantitative measurement of muscle tone and joint kinematic behaviors could provide objective data for tracking patient progress.

The Position, Velocity, and Resistance Meter (PVRM) can be used to assess joint kinematics and muscle tone during clinical evaluation of patients with neurological conditions, e.g., spasticity or rigidity, or orthopedic conditions, e.g., joint replacement or recovery from injury (Fig 1) [2]–[4]. The PVRM includes a load cell and two inertial measurement unit (IMUs) to measure muscle tone (resistive torque) and joint kinematics (angular position, angular velocity). Two electromyographic (EMG) sensors are monitored to ensure passive movements during joint evaluation.

The goal of this study was to perform a preliminary study using the PVRM to characterize measured muscle tone and joint kinematics for different levels of spasticity, as noted by the MAS.

### Methods

Fifteen patients with spasticity (62.19±12.9 yrs, 9f, 6m, MAS 1: n=3, MAS 2: n=4, MAS 3: n=4, MAS 4: n=3) and 12 age and sex matched healthy control subjects (60.4±12.9 yrs, 7f, 5m) were evaluated during passive elbow extension at four different speeds (slow (5°/s - 20°/s), medium (20°/s - 80°/s), fast (> 80°/s), and clinician's preferred speed) while wearing the PVRM. Each subject's MAS score for biceps were rated by a certified clinician (CMZ) prior to testing. The PVRM collected kinetic and kinematic movement data (i.e., joint angular position ( $\theta$ ), velocity ( $\omega$ ), and muscle resistance ( $\tau$ )), as well as monitoring muscle activity during clinical assessments to ensure a passive stretch. The changes of muscle tone and speed across the range of motion were computed to observe any kinetic and kinematic differences between spastic and healthy test groups.

Figure 1: Main and moving modules of the PVRM.

### Results and Discussion

Spasticity patients clearly displayed different kinetic and kinematic behaviors compared to healthy subjects (Fig 2, Table 1). First, the spasticity patients exhibited stretch speed dependent muscle behavior, as expected. The muscle tone increased as the stretch speed increased after a certain angular velocity was reached. Second, the spasticity patients, especially the more severely spastic patients, demonstrated less range of motion. Finally, the spasticity patients had a distinct catch-release behavior of muscle tone that were more distinct for patients with severe spasticity.

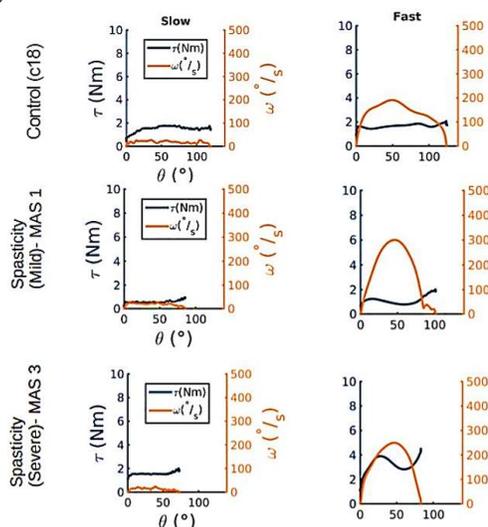

Figure 2: Representative example data of a healthy (top), mildly spastic (middle), and severely spastic (bottom) collected using the PVRM during passive elbow extension at slow and fast speeds.

Table 1: Average  $\tau$  and ROM for different levels of spasticity patients.

	$\tau_{avg}$ (Nm)	ROM (%)
Healthy	2.5	105
MAS 1	4.5	93
MAS 2	5.0	98
MAS 3	6.0	67
MAS 4	7.4	77

### Significance

The PVRM and collected data can allow clinicians to make more reliable assessments, and also help researchers gain additional insights into the quantification of spasticity.

## The Effect of Pain on the Cognitive Control of Balance During the Motor Control Test in Older Women with Osteoarthritis.

Yang Hu<sup>1\*</sup>, Alka Bishnoi<sup>1</sup>, and Manuel Hernandez<sup>1</sup>

<sup>1</sup> University of Illinois at Urbana - Champaign, Department of Kinesiology and Community Health, Urbana, Illinois.

Email: \*yangh3@illinois.edu

### Introduction

Osteoarthritis (OA) is a musculoskeletal disease that affects balance control in older adults [1]. The ability to restore balance following sudden, unexpected perturbations is critical to avoid falls [1], particularly for persons with OA. However, a significant gap exists in our understanding of reflexive postural control changes due to OA, and the mechanisms underlying these changes. Thus, the objective of this study is to 1) investigate the postural control differences between older women with and without OA in the Motor Control Task (MCT); and 2) explore the relationship between postural control, pain, and attention, as measured by prefrontal cortex (PFC) activation, in older women with OA, given the significant contributions of the PFC in the control of balance [2]. We hypothesize that 1) older women with OA will demonstrate different reflexive postural control responses after anterior and posterior translations perturbations in force and COP pattern compared to age-matched healthy controls (HOA); 2) COP sway will be positively correlated with pain and negatively correlated with PFC activations in OA, while there will be no relationship between PFC activation, pain and COP sway among HOA.

### Methods

Ten older women with and without lower extremity OA with a mean age of 66.1 years, Western Ontario and McMaster Universities Arthritis Index (WOMAC) score of 10.5, and BMI of 25kg/m<sup>2</sup> participated in this study. Participants went through the MCT task on Neurocom (Natus Medical Inc), which involved small, medium and large perturbations in both forward (FP) and backward directions (BP). Ground reaction force and COP data were collected by the Neurocom force plate. PFC activation was recorded by a Functional Near Infrared Spectroscopy (fNIRS) system (fNIR Devices LLC, Potomac, MD) during the tasks. Pain was assessed by the first five questions of WOMAC (WS). Custom MATLAB scripts were designed to calculate average oxygenated hemoglobin (HbO<sub>2</sub>) levels from fNIRS raw data, and extract COP sway features (Strength symmetry (SS), absolute anterior-posterior sway amplitude (ABS), COP root mean square (COPrms) in both resultant sway (Y) and anterior-posterior sway (XY), and Max Amplitude XY (MA)). All statistical analyses were performed using RStudio (Version 1.2.1335, RStudio, Inc). A linear mixed model (lmer) appropriate for repeated measures data was specified for each of the main outcomes was fitted to the data with cohort (OA or HOA), direction (forward or backward), condition (small, medium, and large), and their interactions as fixed effects with the subject as a random effect. For HbO<sub>2</sub> data, the location of the optodes was set as an additional fixed effect, and its interaction with the subject has set as an additional random effect.

### Results and Discussion

We found significant cohort effects, cohort x direction (Dir) interactions, or cohort x condition (Cond) interactions in HbO<sub>2</sub>, SS, MA, ABS, COPrmsY and COPrmsXY lmers (Table 1). In addition to the model results, post-hoc test illustrated the specific differences between groups. Significantly higher HbO<sub>2</sub> levels

were observed in BP, relative to FP, in both HOA ( $p < 0.001$ ) and OA ( $p < 0.001$ ) groups. Further, HOA had significantly lower SS scores than OA in overall ( $p = 0.0336$ ), and during BP ( $p = 0.0109$ ). These findings indicate that OA adults prefer right foot strategy with an average total deviation of 11 and BP deviation of 13.6. HOA prefers left foot strategy with an average overall deviation of 10 and BP deviation of 13.5.

Outcome	Effects	F-value	P-value
HbO <sub>2</sub>	Cohort*Dir	18.3421	<0.001
SS	Cohort	7.1216	0.0235
	Cohort*Dir	4.2876	0.0436
MA	Cohort*Dir	5.9212	0.0160
ABS	Cohort*Dir	6.8625	0.0096
COPrmsY	Cohort*Cond	3.9315	0.0214
COPrmsXY	Cohort*Cond	3.3239	0.0384

**Table 1:** Significant effects from linear mixed effect models.

Post-hoc tests also indicate that OA group has higher MA ( $p = 0.0295$ ) and ABS ( $p = 0.0134$ ) in FP compared to BP. Significantly higher COPrms were observed as perturbation levels increased in both groups ( $p < 0.001$ ). No other significant differences were found.

In the anterior direction, we found that there was a significant negative correlation between SS and WS scores among OA adults ( $r = -0.99$ ,  $p < 0.01$ ), which indicates higher WS is associated with greater asymmetry. At the same time, there are significant positive correlations between MA and WS ( $r = 0.96$ ,  $p < 0.05$ ), and between ABS and WS ( $r = 0.96$ ,  $p < 0.05$ ). In terms of condition, OA adults showed a significant correlation between COP sway in Y ( $r = 0.97$ ,  $p < 0.05$ ) and XY ( $r = 0.97$ ,  $p < 0.05$ ), with WS score in medium perturbation conditions, while similar trends were also observed in large perturbation conditions. No other significant correlations were found.

Consistent with our findings of higher postural sway as pain increased in older women with OA, older adults with “symptomatic” OA, relative to healthy controls, without a history of recent falls demonstrated deficits in postural control [3]. Even though higher PFC activations were observed alone with better postural control in BP compared to FP within OA group, no significant cognitive contribution was found.

### Significance

This is the first study investigating reflexive postural control and its mechanisms in lower extremity OA. This work completes the investigation and confirmed OA’s impact on both volitional and passive postural control and illustrates the pain mechanism underneath. Due to the small sample size of this study, future verification on the role of cognitive control needs to be done with a bigger sample size.

### Acknowledgments

We would like to thank all of the subjects and the MFPRL OA research team for their contributions to the study.

## Introduction

A balance disturbance elicits automatic brainstem-mediated corrective motor reactions that can be followed by cortically-mediated control at longer latencies (Jacobs 2007). People with similar biomechanical reactions may differ in the extent to which they rely on automatic vs. cortical control. Dual-task interference studies suggest that older adults with worse balance rely more on cortical control (Shumway-Cook 1997). It is unclear whether cortical involvement differs with balance ability in young adults.

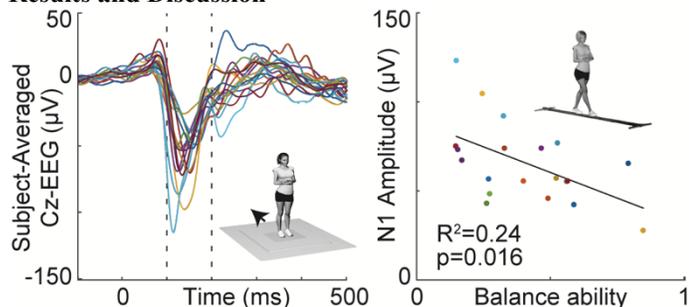

We hypothesized that young adults with worse walking balance ability would have greater cortical activation in response to standing balance perturbations. We measured walking balance ability in a difficult beam-walking task, observing a wide range of performance levels. We measured cortical activation of the N1 response to standing balance perturbations via electroencephalography (EEG). We recently observed greater perturbation-evoked N1 responses in individuals who were unable to recover balance without stepping (Payne 2019). We now test whether the N1 responses are associated with (1) balance ability or (2) stepping behaviors.

## Methods

In 20 healthy young adults (11 female, ages 19-38) we measured individual differences in balance ability based on the ability to walk across a narrow (0.5-inch wide) 12-foot beam (Sawers 2015). We measured the cortical N1 response (Cz-EEG, peak amplitude 100-200ms) evoked by 48 backward translational support-surface perturbations of unpredictable timing and amplitude. Perturbations included a small (8 cm) perturbation that was identical across participants, as well as medium (13-15 cm) and large (18-22 cm) perturbations scaled to participant height to control for height-related differences in perturbation difficulty (Payne 2019). On half of trials we asked participants to take steps, and to keep feet in place otherwise.

We assessed correlations between cortical N1 amplitudes and balance ability across subjects. In large perturbations, we compared N1 amplitudes between stepping and non-stepping reactions, and between planned and accidental stepping reactions, to test for effects of step execution and step planning.

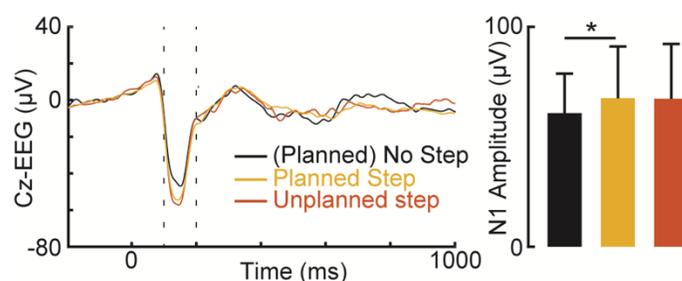

## Results and Discussion

**Figure 1. Individuals with worse balance had larger N1 amplitudes.**

Cortical N1 peak amplitudes (54 µV, SD 18) in response to standing balance perturbations were inversely correlated to the distance traveled in the difficult beam-walking task ( $R^2=0.20$ ,  $p=0.029$ ), suggesting individuals with worse balance have greater cortical activation during reactive balance recovery. The relationship to balance ability was greatest in the difficult large perturbations (Figure 1;  $R^2=0.24$ ,  $p=0.016$ ).

Additionally, cortical N1 responses were 11% (SD 25%) larger when executing planned stepping reactions (Figure 2; black vs. yellow,  $p=0.020$ ), suggesting a possible relationship between the cortical N1 response and subsequent compensatory stepping behavior. The increase in N1 amplitude when stepping could not be attributed to an effect of prior planning because cortical N1 amplitudes did not differ between planned and accidental steps (Figure 2; yellow vs. red,  $p>0.05$ ).

**Figure 2. N1 amplitudes were larger when executing stepping responses (black vs. yellow). When stepping, there was no effect of planning on the N1 amplitudes (yellow vs. red).**

## Significance

Larger cortical N1 amplitudes in individuals with lower balance ability may be related to greater perceived threat (Adkin 2008) or attention to balance (Quant 2004, Little 2015). However, the within-subjects increase in cortical N1 amplitudes when stepping suggests a potential relationship to subsequent balance recovery behavior.

### Introduction

Chemotherapy-induced peripheral neuropathy (CIPN) is a common side effect of neurotoxic chemotherapy that affects up to 70% of people undergoing chemotherapy [1]. People with CIPN often have foot numbness [2] and are at increased risk of fall [3], which is likely to develop fear of falling (FoF) [4]. The development of FoF may further increase risk of fall [5], however its underlying mechanism is not well understood. We aimed to investigate the effect of FoF on habitual gait and postural sway in older adults with CIPN using inertial measurement units (IMUs). We hypothesized that FoF would negatively affect habitual gait and postural sway.

### Methods

We recruited 35 older adults with CIPN ( $\geq 65$  years) that had numbness in their foot. The CIPN group did not have a history of a neurological condition such as Parkinson's disease, stroke and dementia. We also recruited 16 older adults ( $\geq 65$  years) with no history of cancer, diabetes, a neurological condition and fall in the past 12 months as the control group (CON).

We assessed FoF using the Falls Efficacy Scale-International (FES-I; on a scale of 16-64 with 16 indicating no FoF), and used a cut-off score of 28 to classify a group with high FoF [6]. We also assessed foot numbness based on vibration perception threshold using a Biothesiometer (Bio-Medical Instrument, Newbury, OH). We evaluated habitual gait and postural sway using previously validated IMUs (100 Hz, BioSensics, Newton, MA) [7,8]. For habitual gait, two IMUs were attached on the shanks, and participants were asked to walk over 40 feet at their normal pace. For postural sway, two IMUs were attached on the lower back and right shank, and participants were asked to stand quietly for 30 seconds with eyes-open and eyes-closed conditions. Data for habitual gait and postural sway were analysed using commercial software (LEGSys and BalanSens, respectively, Biosensic, Newton, MA). Primary outcomes were gait speed, stride length and cadence for habitual gait, and ankle, hip and center-of-mass (COM) sway area for postural sway.

Among the groups of CIPN with high FoF (CIPN FoF+), CIPN without high FoF (CIPN FoF-) and CON, we compared age, FES-I scores and gait parameters using one-way analysis of variance (ANOVA), and body-mass index and postural sway parameters using Kruskal-Wallis tests. Between CIPN FoF+ and CIPN FoF-, we compared vibration perception threshold and time since a cancer diagnosis using Mann Whitney U tests.

### Results and Discussion

As expected, the FES-I scores were significantly different among the CIPN FoF+ (40.2 $\pm$ 10.7), CIPN FoF- (21.9 $\pm$ 3.0) and CON (19.1 $\pm$ 2.0) ( $p < 0.05$ ). Age and body-mass index did not significantly differ among the CIPN FoF+ (74.1 $\pm$ 5.8 years; 27.25 $\pm$ 4.67 kg/m<sup>2</sup>, respectively), CIPN FoF- (72.1 $\pm$ 4.6 years;

24.57 $\pm$ 3.46 kg/m<sup>2</sup>, respectively) and CON (75.3 $\pm$ 6.8 years; 27.25 $\pm$ 4.67 kg/m<sup>2</sup>, respectively) (all  $p > 0.05$ ). The vibration perception threshold and time since a cancer diagnosis were not significantly different between the CIPN FoF+ (41.5 $\pm$ 10.7 volts; 5.5 $\pm$ 6.1 years, respectively) and CIPN FoF- (36.6 $\pm$ 14.1 volts; 4.6 $\pm$ 5.1 years, respectively) (all  $p > 0.05$ ). Table 1 shows results for habitual gait and postural sway. There were significant differences among the three groups across the tasks.

**Table 1.** Characteristics for habitual gait and postural sway.

	CIPN FoF+ (N=16)	CIPN FoF- (N=19)	CON (N=16)	P-value (ANOVA)
<b>Habitual gait</b>				
Gait speed, m/s	0.78 $\pm$ 0.21	0.93 $\pm$ 0.17	1.17 $\pm$ 0.13	<0.001
Stride length, m	0.99 $\pm$ 0.22	1.13 $\pm$ 0.15	1.26 $\pm$ 0.10	<0.001
Cadence, steps/min	47.09 $\pm$ 7.06	49.47 $\pm$ 4.99	56.00 $\pm$ 4.48	<0.001
<b>Postural sway-eyes open condition</b>				
Ankle sway, deg <sup>2</sup>	2.60 $\pm$ 4.05	1.85 $\pm$ 1.22	0.52 $\pm$ 0.34	0.001
Hip sway, deg <sup>2</sup>	1.84 $\pm$ 2.71	1.77 $\pm$ 1.79	0.59 $\pm$ 0.37	0.036
COM sway, cm <sup>2</sup>	0.49 $\pm$ 0.87	0.31 $\pm$ 0.19	0.10 $\pm$ 0.09	0.003
<b>Postural sway-eyes closed condition</b>				
Ankle sway, deg <sup>2</sup>	4.79 $\pm$ 6.44	2.98 $\pm$ 2.02	1.37 $\pm$ 1.09	0.039
Hip sway, deg <sup>2</sup>	2.45 $\pm$ 2.31	3.45 $\pm$ 3.34	1.32 $\pm$ 0.77	0.076
COM sway, cm <sup>2</sup>	3.83 $\pm$ 9.50	2.23 $\pm$ 2.88	0.25 $\pm$ 0.19	0.001

### Significance

Slower habitual gait speed and corresponding deterioration in stride length and cadence, and poorer postural sway are indicators of increased fall risk. Thus, our findings may reveal how development of FoF further increases risk of fall in CIPN.

### Introduction

Falls are a significant problem for persons with multiple sclerosis (PwMS). Fall risk assessments are reactive, which prevents deployment of preventative interventions and motivates development of new assessments in this population. Previous research has identified measures of postural sway that differ between PwMS who have fallen and those who have not, but many of these biomechanical indices require the use of laboratory-based measurement technologies, preventing deployment outside of research contexts. Wearable sensors may enable characterization of these postural sway metrics outside of the laboratory and subsequently the development of fall risk assessments that can be deployed during daily life. The primary objective of this work was to determine if machine learning methods could be used to develop statistical models for fall risk that are able to differentiate PwMS who have fallen from those who have not.

### Methods

Thirty-six PwMS (18 fallers, 18 non-fallers with mean EDSS scores of  $3.41 \pm 1.39$  and  $2.48 \pm 1.29$  respectively; fall history assessed during the 6-mo immediately preceding the study visit) completed a series of daily life activities and functional assessments. Each subject performed several standing tasks including tandem standing, normal standing, and standing with eyes closed (each for at least 2 minutes). Subjects were instrumented with MC10 BioStamp sensors secured to the chest and anterior aspect of the thigh and set to record three components of accelerometer data (31.25 Hz,  $\pm 16G$ ). Following the approach described in [1], a support vector machine activity classifier was used to identify all 4-second windows when the subject was standing within the test session, including but not limited to data recorded during the prescribed standing tasks.

Several statistical models were trained to identify if windows of standing data had been recorded from a faller or non-faller using a supervised machine learning approach. Specifically, we trained a deep learning (DL) model that uses an LSTM layer to extract features followed by a Bi-LSTM layer to perform the faller/non-faller classification. For comparison, we also trained a random forest (RF) model that took as input postural sway features from previous work investigating postural sway and fall risk [2], [3] and provided the same faller/non-faller classification. Performance, as determined via area under the receiver operating characteristic curve (AUC), of both modelling approaches was established using leave one subject out cross validation. We further explored the impact of different lengths of input data by considering 4, 8, 12, and 16 second windows of consecutive standing data.

### Results and Discussion

The best fall risk classification performance was observed with the DL model using 4-second windows, which achieved an AUC of 0.89 (Table 1). In contrast, the best performing RF model achieved an AUC of 0.61 with 16-second windows.

**Table 1:** Performance (AUC) of deep learning and random forest models as a function of the window size (in seconds) of input data.

Window Size (s)	DL	RF	Dataset Size
4	0.89	0.49	7864
8	0.80	0.54	3725
12	0.77	0.58	2378
16	0.76	0.62	1705

The decrease in DL performance with increasing window size is likely due to the model architecture, which requires more observations to effectively learn the relationship between raw input data and the faller/non-faller labels (longer windows reduce the amount of available training data). The increase in RF performance with increasing window size is likely due to the time and frequency domain features used for making the classification, which require longer window sizes. Previous work on characterizing postural sway with wearable accelerometers has considered a minimum of 30 seconds of data [3]. The shorter window size considered here (max of 16 s) could explain the relatively poor performance of the RF classifier.

### Significance

The results presented herein suggest that deep learning models are able to effectively classify fall risk based on accelerometer measurements during standing. As seen in the presented results, the deep learning methods were able to far outperform the random forest for all window sizes considered here, which are small compared to existing literature, despite these features showing statistically significant differences between persons with Parkinson's Disease and controls [3]. This suggests that the model may be learning novel postural sway measures within the accelerometer signal that are not captured with established metrics. Comparing to other literature in PwMS, Sun et al. found a random forest using force plate data to be 50% accurate when classifying between PwMS with low and moderate fall risk [2]. We found comparable performance (58% accuracy) using RF classification in this study, despite smaller differences in EDSS between groups (1.07 in this study compared to 4.00 in Sun et al). Even still, our results suggest far superior performance using DL classification (81% accuracy). Additionally, the methods presented in Sun et al. require a force plate to collect data, thus limiting potential for deployment. The results presented in this study are broadly useful outside of the laboratory environment as they only require two-wearable sensors and a four-second standing period to provide a very accurate classification of fall risk.

## The Influence of Mediolateral Stabilization on Balance Control during Walking in Individuals Post-stroke

Hannah B. Frame<sup>1</sup>, Christian Finetto<sup>2</sup>, Jesse C. Dean<sup>2</sup>, Richard R. Neptune<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, The University of Texas at Austin, Austin, TX, USA

<sup>2</sup>Department of Health Professions, Medical University of South Carolina, Charleston, SC, USA

Email: hannahbframe@gmail.com

### Introduction

Individuals post-stroke experience higher rates of falls than the healthy elderly [1]. As a result, one goal of post-stroke rehabilitation is to improve functional mobility and reduce fall risk in individuals post-stroke. To reduce fall risk, there is need for evidence-based therapies that target and improve balance control [2]. Mediolateral stabilization (*MLS*) reduces the need to actively control frontal plane balance in healthy adults [3], but it is unknown how individuals post-stroke will respond to *MLS* and whether it will improve walking performance.

The purpose of this study was to quantify the effects of *MLS* on balance control in individuals post-stroke. We hypothesized that *MLS* will improve balance control as evidenced by a reduction in the range of frontal plane whole body angular momentum ( $H$ ), which has been shown to be correlated with clinical balance scores [4].

### Methods

Kinematic data were collected from 20 individuals post-stroke (10 right hemiparesis, 9 male, age:  $50 \pm 16$  yrs) during steady state walking on a dual-belt, instrumented treadmill (Bertec Corp.). Subjects walked for three 30-second trials un-aided (normal) and three 30-second trials with *MLS* (stabilized) at their self-selected walking speed. We focused on those subjects who responded to the *MLS*, i.e., those who reduced their step width between the normal and stabilized conditions as determined by a two-tailed t-test ( $p < 0.05$ ).

$H$  was calculated using a 13-segment inverse dynamics model, which summed the angular momentum of each segment about the whole-body center of mass (*CoM*) and was normalized by subject mass, walking speed and height. The range of frontal plane  $H$  was defined as the peak-to-peak difference in frontal plane  $H$  and pelvis sway was defined as the peak-to-peak difference in the lateral pelvis *CoM* location, both over the paretic stride. Separate paired t-tests assessed for significant differences in metrics between normal and stabilized conditions with  $\alpha = 0.05$ .

### Results and Discussion

Thirteen of the 20 post-stroke subjects responded to the *MLS* through a significant reduction in step width (Responders). The *MLS* successfully stabilized the pelvis by significantly decreasing pelvis *CoM* sway (Table 1), yet range of frontal plane  $H$  significantly increased (Table 1). Applying *MLS* decreased dynamic balance control, thus our hypothesis was not supported. To investigate this significant increase, we examined the contributions of each body segment to overall frontal plane  $H$ .

We found that an increase in the segmental contributions of the trunk and head were the main causes of the increase in peak-to-peak frontal plane  $H$  while stabilized. These increases were driven by a significantly larger range of relative mediolateral velocity between the head and body *CoMs* (Table 1) and the trunk and body *CoMs* (Table 1) during the stabilized trials.

The reduction in step width and pelvis sway in response to *MLS* is consistent with previous work in neurologically intact [4]–[6] and incomplete spinal cord injury [5] populations. Yet, those reductions did not lead to a corresponding decrease in the range of frontal plane  $H$ . This study explored *MLS*'s effects on dynamic balance control by examining the intersegmental dynamics that contribute to an increase in the range of frontal plane  $H$ . While *MLS* may have decreased the absolute motion of the pelvis, it increased the relative motion between the body *CoM* and upper body segments.

### Significance

The increased range of frontal plane  $H$  with *MLS* observed in this study has important clinical implications particularly for gait therapies that constrain the pelvis, such as body weight supported walking. Limiting pelvis sway during gait without also taking care to limit the relative motion between the pelvis and upper body segments may have unintended consequences of destabilizing patients and reducing balance control.

Future work should explore how altered pelvis motion affects segmental contributions to frontal plane  $H$  and dynamic balance control. Subjects were not instructed how to adapt to *MLS* and future studies should determine if training with the *MLS* over an extended period of time and with feedback would improve balance control.

### Introduction

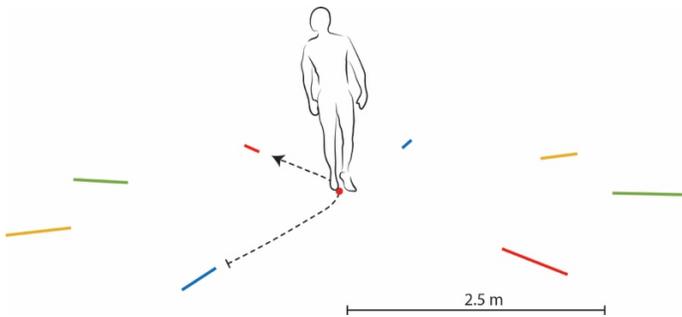

In one of our recent studies, we have shown that when people with Parkinson's disease (PD) take levodopa they walk and turn more quickly, but become unstable during standing and fall more in daily life [1]. Unsafe turning may occur when patients become disinhibited after levodopa intake.

The aim of this study is to determine the effect of antiparkinsonian medication on the dynamics of turning in people with PD.

### Methods

We recruited a total of 23 participants with idiopathic Parkinson's disease. Participants were tested in the morning in their practical OFF state, that is, at least 12 hours after their last intake of antiparkinsonian medications. Subsequently, they were retested in the ON state, that is, 1 hour after a L-dopa challenge dose that was approximately 1.25-fold of their regular L-dopa dose.

Participants performed a series of turns (45°, 90°, 135°, and 180°) to the left and right at normal and fast speed (Figure 1). Synchronized inertial sensors (Opal v1, APDM Inc., Portland, OR) attached to the lumbar and feet were used to calculate the centripetal acceleration and yaw angular velocity on a step to step basis [2].

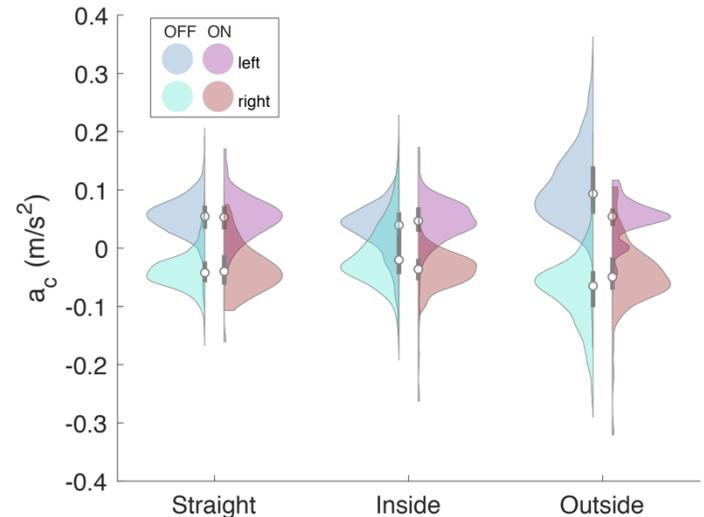

**Figure 1:** Schematic of the experimental protocol.

To determine the effect of antiparkinsonian medication on turning dynamics, linear mixed-effects models were fit for centripetal acceleration for the left, right, inside, outside limb, separately. Each linear mixed-effects model contained fixed effects of angular velocity, the angular velocity x medication interaction and random intercepts for medication state and subject.

### Results and Discussion

In the ON state people with PD exhibited a greater increase in centripetal acceleration as angular rate increased on the inside limb (Figure 2). On the outside limb this interaction effect was absent. Instead, the centripetal acceleration shifted closer to zero for outside limb in the ON medication state. This increase in centripetal acceleration on the inside limb can be interpreted as a

greater translation of the center-of-mass lateral to the stance limb and therefore outside of the base of support.

**Figure 2:** Violin plot depicting the distribution of centripetal acceleration during straight walking and turning stratified by limb for the OFF and ON medication state.

### Significance

Our results suggest that inhibitory control is compromised in the ON medication state, leading to an increase in centripetal accelerations generated on the inside stance limb during turning. This increase in centripetal accelerations generated by the inside limb may put people with PD at a higher risk of falls in the ON medication state.

## Dynamic Balance During 90-degree Turns in People with a Unilateral Transtibial Amputation

### Introduction

Ankle muscles play an important role in regulating dynamic balance during walking. The force modulation of ankle muscles also facilitate changing direction while walking. Specifically during circular turns, plantarflexors contribute to accelerating the center of mass laterally toward the center of curvature [1]. This force modulation likely contributes to the greater whole-body angular momentum during 90° turns compared to straight-line walking [2]. However, inner leg ankle muscles have greater contribution than the outer leg ankle muscles [1]. Thus, for people with a transtibial amputation (TTA), the lack of active ankle control, particularly for the inner leg, may affect their ability to regulate whole-body angular momentum during turning. People with TTA also have reduced prosthetic side ground reaction impulses compared to people without an amputation, regardless of whether the prosthesis is on the inside or outside of the turn [3], indicating that turns are challenging for this population. Thus, the purpose of this study was to determine the influence on turn direction on whole-body angular momentum in 90° turns in people with and without TTA.

### Methods

Eight individuals with TTA (1F/7M; 52 ± 15 years; 99.5 ± 17.9 kg; 1.77 ± 0.08 m) and eight controls (2F/6M; 39±15 years; 80.7±19.5 kg; 1.77±0.09 m) performed straight-line walking and 90° step turns on level ground. Participants made turns with their prosthetic side on the outside and inside of the turn.

Full body kinematics were tracked with 79 reflective markers at 120 Hz using a 20-camera motion capture system. Kinematics were low-pass filtered using a 4<sup>th</sup>-order Butterworth filter ( $f_c = 6$  Hz). A 13-segment model was created in Visual3D. To account for the inertial properties of the prosthesis differing from that of a biological limb, the inertial properties of the prosthesis were adjusted according to [4].

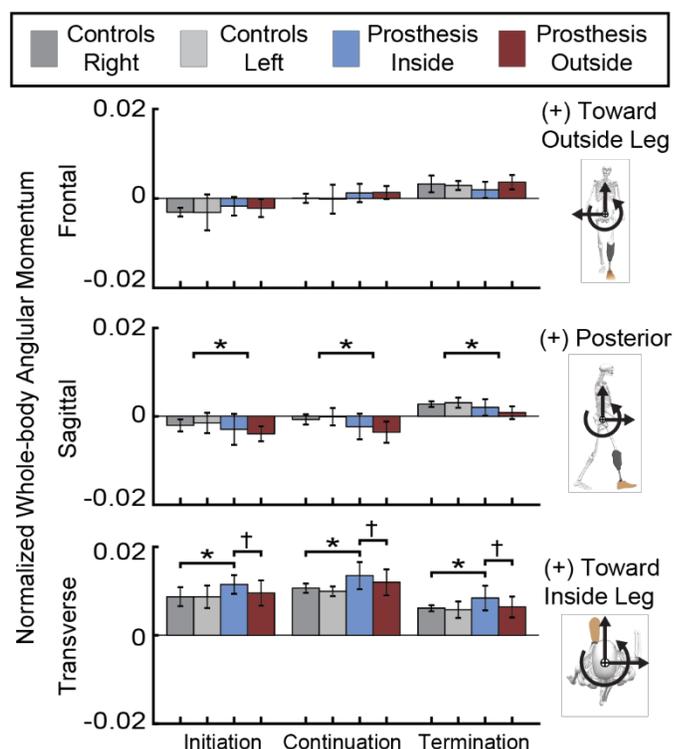

We summed all segment angular momenta about the center of mass to calculate whole-body angular momentum ( $H_{WB}$ ). We then normalized by height, mass, and speed across each stride to obtain a unitless measure. For turning, the angular momentum vector was rotated from the lab reference frame to the center of mass reference frame. Turns were divided into initiation, continuation, and termination strides. We compared the average  $H_{WB}$  between groups (TTA, Controls) and turn type (prosthetic inside/right, prosthetic outside/left) using a series of 2x2 repeated-measures ANOVAs for each plane and stride. A Bonferroni correction was applied to post-hoc tests following significant main effects and interactions.

### Results and Discussion

There were no differences between left and right turns for controls ( $p > 0.41$ ). In the sagittal plane, people with TTA generated greater  $H_{WB}$  during initiation and continuation compared to controls ( $p = 0.02$ ) while controls generated greater  $H_{WB}$  during termination ( $p = 0.02$ ) regardless of turn direction. In the transverse plane, people with TTA generated greater  $H_{WB}$

toward the inside of the turn with the prosthesis on the inside compared to controls ( $p = 0.005$ ) and turning with the prosthesis on the outside ( $p < 0.001$ ) for all turning strides.

People with TTA generated greater  $H_{WB}$  when turning with the prosthesis on the inside compared to when the prosthesis was on the outside of the turn and to controls. As greater force modulation is used with the inside leg during circular turning [1], the inability to modulate forces with the prosthesis likely requires greater generation of  $H_{WB}$  to successfully change direction when the prosthesis is on the inside.

**Figure 1:** Average  $H_{WB}$  over a turning strides across individuals. Significant differences between groups (“\*”) and turns (“+”).

### Significance

Reduced ability to modulate ground reaction forces with a prosthesis suggests the need for rehabilitation to focus on turning toward the prosthetic side. In addition, this information may be useful for powered prosthetic device development as 3D ground reaction force modulation is important for controlling whole-body angular momentum [5]. Future work should investigate muscle activity and compensatory movements people with TTA use to perform 90° turns.

### Introduction

Over 40% of daily steps are turns that require sophisticated integration of time-varying gravito-inertial forces with dynamic changes in heading angle to propel the center-of-mass (CoM) in a new direction of travel.[1] Because turns are ubiquitous in daily life and complex, they can be a useful indicator of mobility.

In people with mild traumatic brain injury (mTBI), abnormal turning is often attributed to sensory integration or vestibular dysfunction.[2] Specifically, we have previously speculated that slower axial rotation during turning may be a strategy to limit symptoms from visual motion and vestibular afferents from the semi-circular canals.[3] However, previous interpretations only considered rates of axial rotation given the reliance on inertial sensors. Rather than turning strictly through upright axial rotation, ambulatory turns are often accomplished through asymmetrical loading and lateral ground reaction forces to generate centripetal force, with corresponding lateral lean to counteract the moment caused by the centripetal force.[4]

Centripetal acceleration,  $a_c$ , during turning also suggests that the integrity of the autonomic nervous system (ANS) may influence turning behaviour. Nausea and headache are elicited when the ANS cannot maintain constant cerebral blood flow in the presence of hydrostatic changes caused by centrifugal acceleration of blood within the circulatory system.[5]

Therefore, the purpose of this study was to examine potential differences in  $a_c$  during turning between individuals with mTBI and healthy control subjects. Additionally, we sought to explore the relationship between the observed  $a_c$  and ANS function.

### Methods

A mixed sample of 17 adults, including eight individuals with mTBI [4F/4M, mean (SD) 35 (11) years] and nine healthy controls [5F/4M, mean (SD) 33 (8) years], provided informed written consent for this IRB approved study. All mTBI subjects were greater than 3 weeks post-mTBI and still symptomatic.

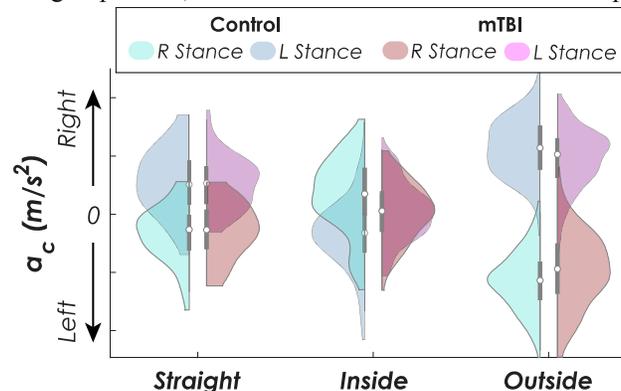

Each participant walked for two-minutes at their self-selected pace around a custom course containing 45, 90, and 135 degree turns. Inertial measurement units (IMUs) (APDM Opals, Portland, OR) on their feet, lumbar, chest, forehead, and left wrist collected tri-axial acceleration, angular velocity, and magnetometer data at 128 Hz. The inertial sensors were used to compute the average  $a_c$  at each step, which is also a valid correlate of lateral margin of stability.[6]

Separately, continuous beat-to-beat heart rate (HR) and blood pressure (BP) were obtained for each participant during a tilt table test (5 minutes supine, 5 minutes head up tilt, 5 minutes return to supine) to assess autonomic function measured through mean blood pressure (MBP) and heart rate (MHR), and variability in blood pressure (BPCV) and heart rate (HRCV).

Linear mixed models with random intercepts compared  $a_c$  values between groups after stratifying for limb and controlling for axial turning velocity. Pearson correlations compared each subject's range of  $a_c$  to MHR, MBP, HRCV, and BPCV.

### Results and Discussion

Individuals with mTBI exhibited significantly lower magnitudes of  $a_c$  for a given axial rotational velocity during turning regardless of stance limb ( $p < 0.001$ ). When the stance limb was on the inside of the turn (i.e., spin turn), the mTBI group exhibited  $a_c$  near zero, while the control group exhibited centripetal accelerations lateral to the stance limb. Similarly, the mTBI group exhibited lower magnitudes of  $a_c$  when the stance limb was on the outside (i.e., step turn). Based on previous validations with respect to margin of stability and lateral inclination,[6] these results suggest the mTBI group adopted a conservative strategy with less lateral inclination into the turn. These results also highlight the reluctance of the mTBI group to exhibit high  $a_c$  during a spin turn, when the CoM is outside the base of support.

**Figure 1:** Violin plots centripetal acceleration,  $a_c$ , during straight and turning gait. Turning gait results are stratified by stance limb and presented separately for inside limb versus outside limb (e.g., the right limb in stance would be the inside limb during a right turn).

The range of  $a_c$  was significantly associated with upright HRCV across all participants ( $\rho = 0.56$ ), and remained associated within each group ( $\rho_{Control} = 0.63$ ;  $\rho_{mTBI} = 0.66$ ). Since HRCV is a measure of the flexibility of the ANS to accommodate different states, these initial results suggest individuals with an inflexible ANS may limit  $a_c$  to prevent an onset of symptoms. However, future work should examine this question more directly while considering the role of oculomotor and vestibular function.

### Significance

Individuals with persistent symptoms from mTBI exhibit conservative turning behavior beyond slower axial rotation. The physiological mechanisms prompting less inclination and  $a_c$  remain unclear, but the role of the ANS should be considered.

### Introduction

Morphometric understanding of the ankle joint has been derived primarily from 2D measurements of conventional radiographs, with little focus given to the fibula and the complete talocrural joint. Volumetric imaging has made it possible to generate 3D reconstructions of the talocrural joint [1]. Weightbearing CT (WBCT) scans provide an added benefit to assess pathology and joint space narrowing that may be overlooked in the absence of load. Statistical shape modeling (SSM) can be used to visualize and analyze morphological differences in 3D and enables the identification of mean bone shapes and shape modes of variation using correspondence particles (mathematically placed points of interest throughout the bone's surface). But, SSM has commonly assessed bone variation independent of joint relationships. The objective of this study was to develop a joint level SSM to evaluate shape differences in combination with joint distance and congruency of the talocrural joint based on WBCT scans.

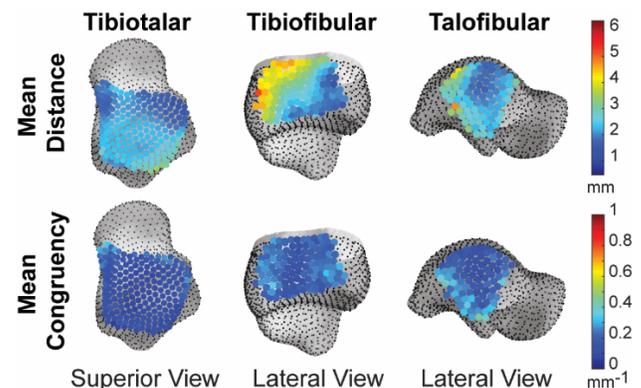

### Methods

Twenty-seven controls (age:  $50.0 \pm 7.3$  years; height:  $169.4 \pm 6.4$  cm; BMI:  $25.3 \pm 3.8$  kg/m<sup>2</sup>; 7 males) underwent weight-bearing CT scans ( $0.4 \times 0.4 \times 0.4$  mm voxels) with IRB approval. The tibia, fibula and talus were segmented to generate 3D surfaces (Amira, v6.0.1). Procrustes analysis removed scaling (i.e. size) as a mode of variation in the shape model. Mean shapes for the tibia, fibula, and talus were generated using ShapeWorks (Univ of Utah). Correspondence particles from the SSM analysis were evaluated using principal component analysis (PCA). Significant PCA modes of variation were identified using parallel analysis. Using the 2nd principle of curvature and a joint coverage calculation in PostView (v2.1.0), the articulating surfaces of the tibiotalar (TT), tibiofibular (TiF) and talofibular (TaF) joints were isolated. The surface mesh within the articular regions were used to calculate joint distance. SSM mean shapes were aligned in joint relationships with articular region correspondence particle locations isolated across all participants. Joint distance and congruency were calculated at each common correspondence particle using MATLAB (R2017b, MathWorks, Natick, MA, USA). The congruency index, which begins at  $0 \text{ mm}^{-1}$  to define perfectly congruent surfaces, was calculated [2]. Joint distance and congruency index values were averaged at common correspondence particle locations.

### Results and Discussion

Seven PCA modes were determined to be significant for the tibia, fibula, and talus, which contained 78.2%, 74.8%, and 65.5% of the overall shape variation for the three bones respectively. SSM models showed bone shape variations including: the width of the

talar trochlea and curvature in the inferior articulating surface, tibial plafond rate of curvature variations and fibular malleolar fossa angulation. In our healthy population during a weight-bearing position, the TT, TiF and TaF mean joint distances and congruency index are shown (Figure 1). Regardless of joint distance variation, mean congruency indices were consistent across the articular regions, with the TT joint being the most congruent (Table 1). Despite morphological differences, congruency remained very consistent in this healthy population. These findings highlight the necessity to consider anatomical variations in the shape of the tibia, fibula and talus as independent bones along with a joint analysis of the interaction of these bones when evaluating a patient's talocrural joint health, alignment and function. Ideally, the combination of high-resolutions volumetric imaging and 3D morphometrics could be used to improve the treatment of patients suffering from OA and other diseases in the talocrural joint. These tools should provide improved metrics for clinicians to link 3D joint morphology findings to individual bone variability seen on weightbearing CT scans.

**Figure 1:** Mean joint distance and congruency for the talocrural joint.

### Significance

Results herein established normative measurements of bone shape variation, joint distance and congruency in the talocrural joint. Computational methods presented a new SSM joint analysis approach to apply in other joints and pathological cases.

## Bone strain distribution, not magnitude, is affected by execution of a forearm loading task

### Introduction

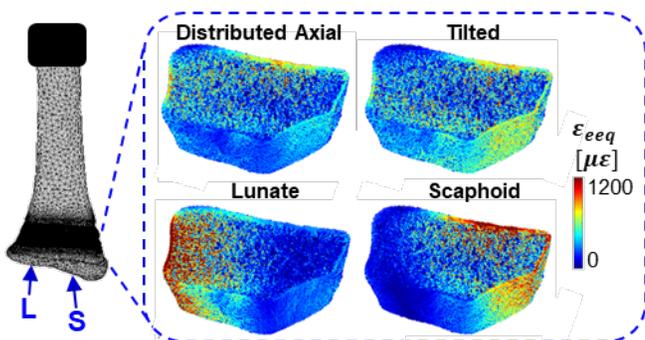

Exercise can increase bone density 1-3%,<sup>1</sup> but the mechanism of load-driven bone adaptation in humans is not completely understood. Previously, we established an upper extremity loading model of human bone adaptation.<sup>2</sup> Women are instructed to lean onto their palm with their arm vertical, applying cyclic, axial loading to the forearm. Distal radius strain is estimated using validated finite element (FE) models based on clinical and high resolution computed tomography (HRpQCT).<sup>3</sup> FE models apply forces at the scaphoid and lunate carpals, representing an axial compressive load distributed through the wrist. However, people likely do not perform this task identically. Here, our purpose was to measure the degree to which actual loading direction and distribution vary using 3D motion capture, and to quantify the influence on bone strain by varying FE model boundary conditions. We hypothesized that changes in loading, within the range of measured variability, will affect bone strain distribution but not the overall magnitude of achieved strain.

### Methods

Six women ages 21-40 completed this institutionally approved study. Markers were placed on the non-dominant hand and wrist, and 100 cycles of forearm loading were performed on a multiaxis force plate within a six-camera motion capture system. The average angle between the force vector and the forearm, as well as the center of pressure relative to the wrist joint center at the instance of peak force, were determined for each participant.

Based on the motion capture data, four boundary conditions were applied to thirteen multiscale FE models generated from CT scans acquired in a prior study: (1) standard distributed axial loading, axial loading through the (2) scaphoid only or (3) lunate only, and (4) a tilted, distributed load. Energy equivalent strain,  $\epsilon_{eeq}$ , was calculated for each element within the cortical and trabecular compartments in the HRpQCT scan region (Figure 1).

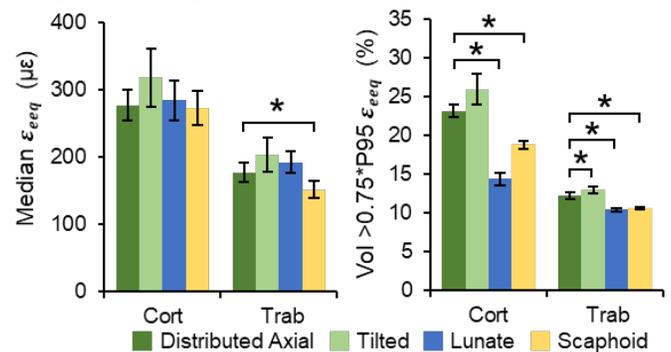

Bone strain magnitude was measured as the median  $\epsilon_{eeq}$ , and load distribution as the percent of bone volume with  $\epsilon_{eeq}$  greater than 75% of the 95<sup>th</sup> percentile value, where a smaller high strain volume indicates more concentrated, less uniform loading. Strain metrics were compared across the conditions using repeated measures ANOVA with Bonferroni posthoc t-tests ( $\alpha=0.05$ ).

**Figure 1:** Representative FE model used to simulate forearm loading through the lunate (L) and/or scaphoid (S) to estimate energy equivalent strain,  $\epsilon_{eeq}$ , in the HRpQCT distal radius scan region.

### Results and Discussion

Across participants, the average force vector was tilted 7.2° in the dorsal-radial direction, relative to the forearm. Within each participant, center of pressure fell either medially or laterally relative to the wrist joint center, at an average distance of 1.4±0.4 cm (mean±sd). Shifting the distributed axial load to the scaphoid only led to a significant, 15.1±3.6% decrease in trabecular strain magnitude (Figure 2). Shifting to the scaphoid or lunate only significantly decreased the volume of bone under high strain in the cortical and trabecular compartments, suggesting less uniform loading compared to the distributed axial condition. Tilting the force vector did not have a significant effect on strain magnitude, but significantly increased the volume of bone at high strains, suggesting more uniform loading compared to the distributed axial condition. Overall, our hypothesis was generally supported, as strain distribution was more sensitive than strain magnitude to changes in loading condition.

**Figure 2:** Strain magnitude, measured as median  $\epsilon_{eeq}$ , and strain distribution, measured as the percent of bone volume with strain >75% of the 95<sup>th</sup> percentile, presented as mean±se (n=13). \*Indicates a significant post-hoc comparison versus distributed axial loading.

### Significance

Our combined experimental-computational approach allows the mechanism of load-driven bone adaptation to be systematically studied in humans. Quantifying the sensitivity of FE-estimated strain to task execution (i.e. loading direction and distribution) helps to identify biomechanical factors that need to be controlled to standardize bone loading across participants, or can be modified to target loading to particular regions within a bone. Ultimately, measuring internal bone loads generated by external forces may enable comparison and optimization of osteogenic exercise programs for specific clinical populations or individuals.

## Effect of Pelvis Bone Geometry Personalization on Hip Kinematics and Dynamics

Geng Li<sup>1</sup>, Mohammad S. Shourijeh<sup>1</sup>, Benjamin J. Fregly<sup>1</sup>

<sup>1</sup> Department of Mechanical Engineering, Rice University, Houston, TX

### Introduction

Personalized models can represent musculoskeletal systems more accurately in simulating gait movement than generic models that are created by averaging data for a population [1]. We seek model personalization of pelvis as a potential way to address the research need of designing more effective treatments for pelvic sarcoma patients. Kinematics, muscle length and moment arms, and reaction loads at hip joints are all important factors to be considered for such treatment design. Therefore, this study investigates the effect of personalizing a pelvis model on estimation of hip joint kinematics, muscle geometry and joint reaction loads during walking, reaction loads.

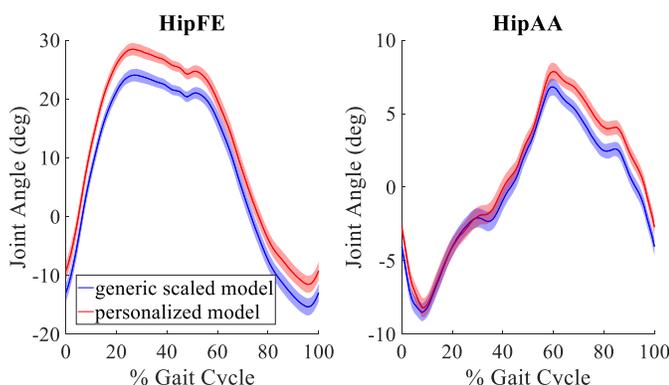

### Methods

We collected motion capture (Vicon Corp., Oxford, UK), and ground reaction (Bertec Corp., Columbus, OH) data of a subject (male, mass 70 kg, age 48 years) walking on an instrumented split-belt treadmill at a self-selected speed of 1.2 m/s for more than 50 gait cycles. reaction loads.

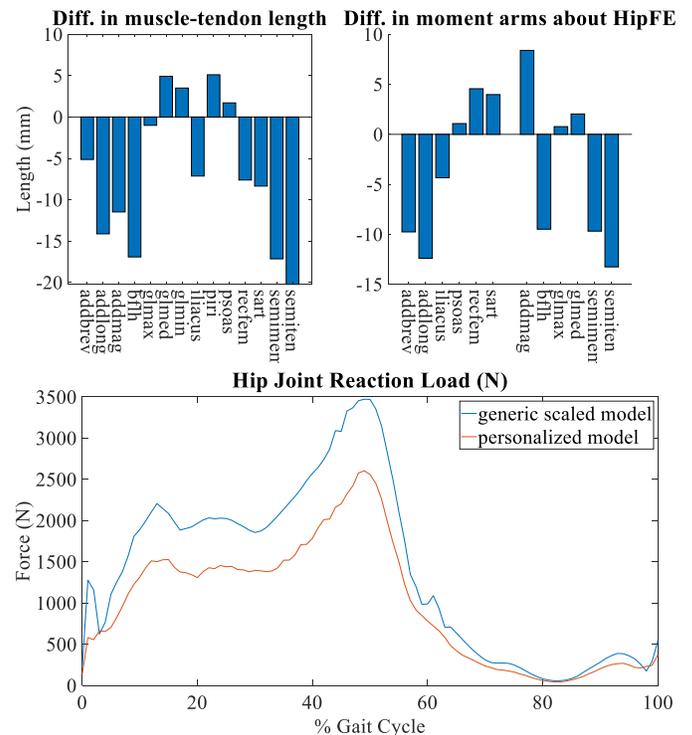

We used a generic OpenSim musculoskeletal model [2, 3] as the base model to create two separate models to represent the subject. The first model was created using the OpenSim scaling tool. We named this model as the scaled generic model. The second model was created from segmentation of CT images of the subject in the pelvic region using software ITK-SNAP [4]. We then replaced the pelvis in the scaled generic model with the segmented pelvis. We updated the muscle attachment locations on the pelvis by registering published data of attachment locations onto the subject-specific pelvic model using affine transformation function of software NMSBuilder [1]. The second model was named as the personalized model. reaction loads.

For both models created, we used OpenSim inverse kinematics tool to estimate the joint kinematics from experimental marker data and subsequently used the OpenSim muscle analysis tool to obtain muscle-tendon length ( $l_{MT}$ ) and moment arms about hip. Muscle forces were estimated using OpenSim static optimization tool. The muscle force estimation was furnished to the OpenSim Joint Reaction analysis to compute the joint reaction loads. reaction loads.

### Results and Discussion

**Figure 1:** (the A) Hip joint angles, (B) Length and moment arms of hip muscles, (C) Joint reaction loads estimated by two models

Generic scaled model on average underestimated hip flexion, and adduction by  $4^\circ$  and  $1^\circ$  respectively in comparison to personalized model (Fig. 1A). The personalized model predicted lower  $l_{MT}$  for adductor and hamstring muscles. Moment arms about HipFE revealed large inconsistency between the two models. Adductor magnus gained 8 mm while other adductor and hamstring muscles lost approximately 10 mm in moment arms (Fig. 1B). As most hip muscles in the personalized model operated in a lower region of force-length curve than those in the generic scaled model, our simulation predicted less muscle forces generated and hence less hip joint load for the personalized model (Fig. 1C). reaction loads.

### Significance

This study highlighted the discrepancy in joint kinematics, muscle lengths and moment arms, and joint reaction loads between a scaled generic model and a personalized one. Imaged-based model should be recommended for the purpose of achieving more accurate simulation of movement. EMG-driven modelling calibration would be used in future work to model muscle activation and predict joint loads more accurately. reaction loads.

### Acknowledgment

## Estimating Unmeasured Muscle Excitations: NMF vs Gaussian Process-Based Synergy Models

Reed D. Gurchiek<sup>1</sup>, Anna T. Ursiny<sup>1</sup>, and Ryan S. McGinnis<sup>1</sup>  
<sup>1</sup>M-Sense Research Group, University of Vermont, Burlington, VT, USA  
 Email: reed.gurchiek@uvm.edu

### Introduction

Advances in wearable sensor technology and estimation algorithms point toward a new approach to healthcare that leverages remote observation of a patient’s symptoms to detect disease and direct treatment decisions. Critical to this vision are technologies that minimize patient burden. This limits the use of many surface electromyography (sEMG)-based techniques for estimating clinically-relevant joint mechanics, as they require information from a large number of muscles which would require unwieldy sensor arrays. However, it has recently been suggested that sEMG data from a subset of muscles may be able to reconstruct the muscle excitations of a complete set [1,2]. To this end, we recently proposed a novel Gaussian process (GP)-based model of the synergistic relationship between muscles which enables estimation of unmeasured muscle excitations from a measured subset (manuscript under review). In this study, we compare the ability of our new technique to estimate unmeasured muscle excitations to the reconstruction accuracy of a non-negative matrix factorization (NNMF)-based approach [2].

### Methods

The sEMG (1000 Hz) of 10 muscles (TA: tibialis anterior, PL: peroneus longus, LG: lateral gastrocnemius, MG: medial gastrocnemius, SOL: soleus, VM: vastus medialis, RF: rectus femoris, VL: vastus lateralis, BF: biceps femoris, ST: semitendinosus) from the right leg were recorded from a single healthy female during a one-minute walking trial (speed:  $1.2 \pm 0.03$  m/s, stride time:  $1.11 \pm 0.02$  s). Data were processed so as to replicate as closely as possible the results presented in [2]. Therefore, all sEMG data were high pass filtered at 30 Hz, rectified, low pass filtered at 6 Hz, and normalized by the maximum value across the walking trial and several muscle specific maximum voluntary contraction (MVC) trials.

Data from 12 seconds (about 10 strides) from the first half of the one-minute walking trial were used to train muscle-specific functions that take as input one-second of sEMG data from each muscle in an ‘included’ subset (the predictor muscles) and output the excitation value of the corresponding muscle (belonging to the ‘excluded’ subset) for the time associated with the middle of the one-second input window. This constitutes the GP-based technique and model ‘training’ amounts to hyperparameter optimization (minimization of the negative log marginal likelihood) and a large matrix inversion [3].

The GP and NNMF methods were compared in their ability to reconstruct the muscle excitations of several ‘excluded’ subsets for a 12 second interval of the latter half of the one-minute walking trial (different data than were used to inform the GP model). The NNMF-based method is described in [2] where synergy vectors and corresponding excitations were determined using an iterative procedure utilizing both the multiplicative update and alternating least squares NNMF algorithms. Synergy weights for the muscles in the ‘excluded’ subset were determined using linear least squares regression [2].

Six different ‘included’ muscle subsets were investigated: (1) TA, LG, RF, BF; (2) TA, MG, ST, VL; (3) TA, MG, ST, VL,

SOL; (4) TA, MG, ST, VL, SOL, LG; (5) TA, MG, ST, VL, SOL, LG, RF; and (6) TA, MG, ST, VL, SOL, LG, RF, PL. Subsets (2)-(6) were chosen based on the most informative muscles according to the analysis presented in [2]. Subset (1) was also included as it was used in our original development of the GP model. The ‘excluded’ subset for each were all muscles not in the ‘included’ subset. Estimation performance was evaluated using mean absolute error (MAE) and variance accounted for (VAF).

### Results and Discussion

The GP-based estimation outperformed the NNMF-based reconstruction across all muscle subsets according to both MAE and VAF (Table 1). The reported error statistics of the NNMF reconstruction essentially represent the training error in that the synergy model was informed partly by the data it sought to reconstruct. For this reason, as noted in [2], the NNMF-based reconstruction does not solve the problem of estimating unmeasured excitations using a measured subset; it only provides insight into the feasibility of doing so. This is in contrast to the proposed approach wherein the GP model was informed by a completely different dataset than it was tested on. To the authors’ knowledge, our GP-based model is the only existing method which maps a subset of sEMG data to unmeasured excitations.

**Table 1:** Comparison of GP estimation and NNMF reconstruction accuracy. Values are mean  $\pm$  standard deviation across all muscles. MAE units are % MVC.

Subset	GP		NNMF	
	MAE	VAF	MAE	VAF
1	$2.0 \pm 1.3\%$	$93 \pm 2\%$	$3.5 \pm 3.2\%$	$79 \pm 11\%$
2	$2.3 \pm 1.1\%$	$88 \pm 4\%$	$3.4 \pm 1.8\%$	$78 \pm 7\%$
3	$2.2 \pm 1.2\%$	$88 \pm 4\%$	$2.7 \pm 1.9\%$	$86 \pm 10\%$
4	$1.8 \pm 1.2\%$	$89 \pm 5\%$	$2.4 \pm 2.2\%$	$87 \pm 12\%$
5	$2.1 \pm 1.1\%$	$88 \pm 5\%$	$2.9 \pm 2.3\%$	$84 \pm 14\%$
6	$1.9 \pm 1.5\%$	$86 \pm 7\%$	$3.2 \pm 3.2\%$	$80 \pm 16\%$

### Significance

Our results support the use of the GP-based technique for estimation of unmeasured muscle excitations across a range of predictor muscles. This approach may enable the use of sEMG informed estimates of clinically relevant biomechanics in remote environments for continuous monitoring and comprehensive patient characterization.

## Isometric force-length and isotonic force-velocity properties and Hill-type models contain little information needed to predict *in vivo* muscle forces.

Kiisa Nishikawa<sup>1</sup>, Nicole Rice<sup>1</sup>, Siwoo Jeong<sup>1</sup>, and Monica Daley<sup>2</sup>

<sup>1</sup>Department of Biological Sciences, Northern Arizona University, Flagstaff, AZ USA; <sup>2</sup>Department of Ecology and Evolutionary Biology, University of California at Irvine, USA

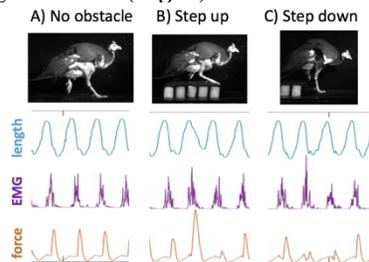

Email: kiisa.nishikawa@nau.edu

### Background

Isometric force-length and isotonic force-velocity relationships [1-2] are useful as standard measures of muscle contractile properties. However, these measures and models based upon them fail to predict muscle force under dynamic conditions [3-5]. This failure is due in part to absence of history-dependence. The goal of this study was to explore *in vivo* muscle force during perturbed running in guinea fowl [6] using a novel *ex vivo* avatar approach, and to test the ability of a 12-parameter Hill-type muscle model from OpenSim [7] to predict forces observed during dynamic length changes. The results provide insights into muscle mechanical behavior and demonstrate the limitations of Hill-type models and the F-L and F-V relationships on which they are based.

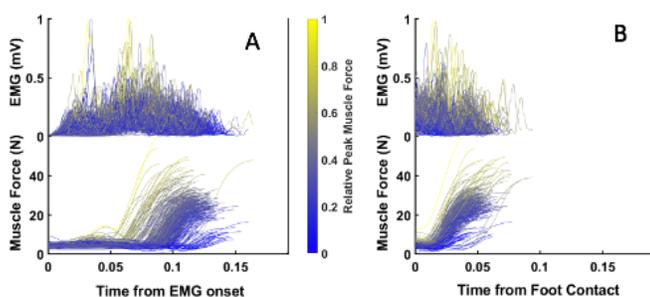

### *In vivo* function of the lateral gastrocnemius (LG) during treadmill obstacle running in guinea fowl

Previous studies [6] demonstrated increased step-to-step variability in muscle force and dissociation of activation and force during *in vivo* treadmill running over obstacles in the LG muscles of guinea fowl (Fig. 1).

**Fig. 1:** Variability in length, EMG and force of guinea fowl LG during treadmill obstacle running. **A)** Normal step with no barrier. **B)** Step up onto obstacle. Force is higher despite average EMG. **C)** Step down onto treadmill. Force is lower despite higher EMG.

In addition, there is a long and variable delay (90-150 ms) between EMG onset and force onset (Fig. 2).

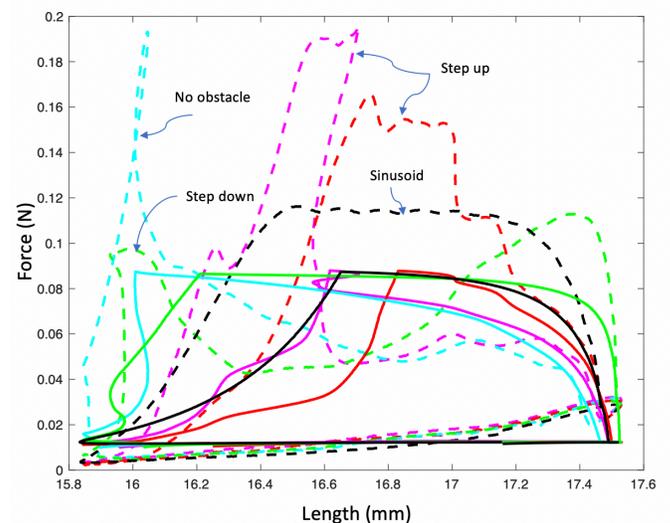

**Fig. 2:** Decoupling between force and activation. Delay between EMG onset and force onset (A) is longer and more variable (90-150 ms) than (B) delay between foot contact and force onset (10-40 ms).

The correlation between peak EMG and peak force ( $R^2 = 0.34$ ) is small compared to the correlation between muscle length at foot contact and peak force ( $R^2 = 0.63$ ) (data not shown).

### Muscle ‘avatar’ approach

To further demonstrate decoupling between force and activation, we used *ex vivo* extensor digitorum longus muscles (EDL) of mice as an ‘avatar’ for the *in vivo* guinea fowl LG. Instead of sinusoidal inputs typically used in work loop experiments, we used strain trajectories matching those from *in vivo* LG recordings as inputs for the *ex vivo* work loop experiments. Work loops recorded from the *ex vivo* EDL using *in vivo* strain trajectories matched the shape of the *in vivo* workloops of the guinea fowl LG. Both *ex vivo* EDL and *in vivo* LG work loops deviate substantially in shape from traditional *ex vivo* work loop experiments. Hill model simulations (Fig. 3) demonstrate that neither the isometric force-length relationship nor the isotonic force-velocity relationship can predict the step-to-step variability in muscle force observed during dynamic *in vivo* movements.

**Fig. 3:** Hill model predictions (solid lines) of force in EDL avatar steps (dashed lines).  $R^2$  for model ranges from 0.41 for level step (no obstacle, cyan, Fig. 1A) to 0.9 for sinusoidal trajectory (black). The model fails to capture effects of strain trajectories on muscle force.

**Conclusions:** The isometric force-length relationship and isotonic force-velocity relationship and Hill models based upon them fail to capture the dynamic step-to-step variability of muscle force during dynamic movements.

## Whole Muscle Passive Mechanics Do Not Simply Scale by Architectural Properties

Benjamin I Binder-Markey<sup>1,2</sup> and Richard L Lieber<sup>1,2</sup>

<sup>1</sup>Shirley Ryan AbilityLab & <sup>2</sup>Department of Physical Medicine and Rehabilitation, Northwestern University, Chicago, IL, USA

Email: bbindermar@sralab.org

### Introduction

Whole muscle active length-tension properties accurately scale from the sarcomere to the whole muscle level [1], but interestingly, in mammalian muscle, passive mechanical properties do not [1,2]. This is largely because the detailed relationship between the passive mechanical properties of fibers, fascicles, and whole muscles are rarely studied. Only in frog muscle, has uniform passive scaling been demonstrated from the fiber to the whole muscle [3]. We believe that this is because intramuscular connective tissue in frog is very poorly developed compared to mammals [2]. Recent work in rabbit muscle demonstrates that fiber, fiber bundle and fascicle mechanics do not simply scale to whole muscle mechanics [4]. Thus, the purpose of this study was to measure whole muscle passive mechanical properties and use modeling to identify sources that could contribute to non-linear scaling from fascicle to whole muscle.

### Methods

Passive mechanical properties from three muscles of varying architecture and function were measured in 12-week C57Bl6 mice: rectus femoris (RF; n=6), semimembranosus (SM; n=6), and tibialis anterior (TA; n=5). Muscles were dissected from origin to insertion, placed in a physiological bath, attached to a 1N force transducer, and lengthened in ~0.5mm increments. Force was recorded after 3-minutes of stress-relaxation. Samples were weighed and physiological cross sectional area (PCSA) was calculated using published architectural properties [5].

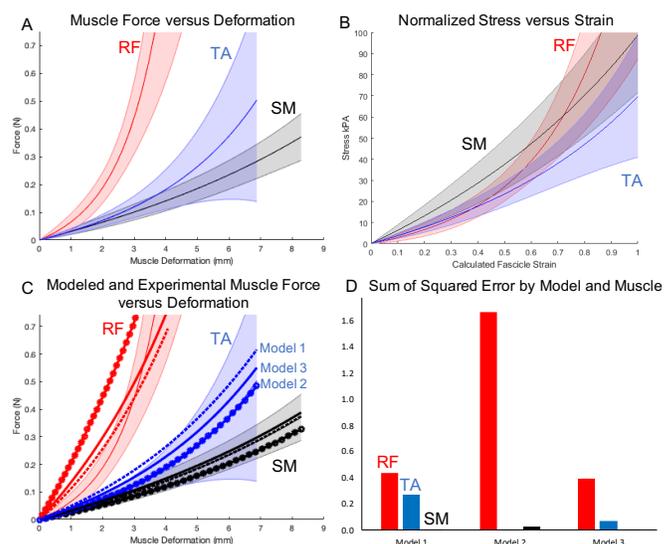

Muscle passive force was normalized to PCSA and muscle deformation was converted to fascicle strain using the fiber length-to-muscle length ratio [5], thus creating a passive stress-strain relationship normalized by architectural parameters for each muscle. Each raw and normalized data set was fit to an exponential [3] and all curves were averaged to create a single exponential describing that muscle's passive force-deformation (Fig. 1A) or stress-strain relationship (Fig. 1B). All curve fits were excellent, exceeding  $r^2$  values of 0.96

To investigate potential sources that might lead to the fascicle differences observed in Fig. 1B, we developed three Hill-type models of progressively increasing complexity. **Model 1:** A simple lumped parameter model normalized fascicle property across muscles that has the form  $\left(\frac{a}{b}(e^{b\varepsilon} - 1)\right)$ ; **Model 2:** Model 1 plus a muscle-specific parallel element elastic element ( $c_m$ ) across the whole muscle representing parallel elastic connective tissue differences among muscles; **Model 3:** Model 2 plus a muscle-dependent inter-fascicular shear factor ( $\tau_m$ ) that resists fascicle rotation. For each model, each parameter ( $a$ ,  $b$ ,  $c_m$ , and  $\tau_m$ ) was optimized in MATLAB by minimizing the sum of the squared error (SSE) between the muscles' modeled force-deformation data and the experimentally collected data (Fig. 1A).

### Results and Discussion

Data from all three muscles were well-fit by the exponential stress-strain curve (RF  $r^2=0.994\pm 0.008$  SD, SM  $r^2=0.991\pm 0.004$

SD, RF  $r^2=0.990\pm 0.012$  SD). The RF was the stiffest muscle, followed by the TA (especially at high deformation) and then the SM (Fig. 1A). Accounting for fiber length differences, stress-strain curves became more similar, but not identical (Fig. 1B).

**Figure 1:** A) Force vs. muscle deformation for RF (red), SM (black), and TA (blue). B) Stress-strain relationship for each muscle normalized by architecture. Data shown as average $\pm$ SD. C) Force vs. muscle deformation of the experimental and modeled RF (red), SM (black), and TA (blue) for Model 1 (dashed), Model 2 (circles), and Model 3 (solid). D) SSE for each model and muscle with lower numbers better fit.

The degree to which more complex models explained experimental data were related to the complexity of each muscle (Figs. 1C and 1D). The SM, which is a very simple parallel-fibered muscle with fascicles running from origin to insertion was best fit by the simplest model, Model 1 ( $SSE=1.35\times 10^{-4}$ ). The TA, in which fascicles run from a broad proximal tibial origin to a single internal insertion tendon was fit best by the slightly more complex Model 2 ( $SSE=3.28\times 10^{-3}$ ). Finally, the RF whose fascicles originate on a central internal tendon and radiate distally to a broad aponeurosis surrounding the muscle was fit best by the most complex model, Model 3. ( $SSE=0.397$ ).

### Significance

These results demonstrate that, to accurately model muscle passive mechanical properties, the model must reflect the complexity of the muscle. To a first approximation, architectural normalization helps (Fig. 1A), but in order to provide high resolution properties, additional terms are needed. The precise structures that represent these mathematical terms are not currently clear and must be the subject of ongoing investigations.

## Imaging and Simulation of Inter-Muscular Triceps Surae Contributions to Forward Propulsion During Walking

William H. Clark, Richard E. Pimentel, Jason R. Franz

Joint Department of Biomedical Engineering, University of North Carolina at Chapel Hill &

North Carolina State University, Chapel Hill NC, USA

Email : [wihclark@unc.edu](mailto:wihclark@unc.edu)

### Introduction

Forward propulsion during the push-off phase of walking is largely governed by differential neuromechanical contributions from the biarticular medial (MG) and lateral gastrocnemius (LG) and the uniaxial soleus (SOL) muscles spanning the ankle [1]. However, the relative contribution of these individual muscles to forward propulsion is equivocal, with important implications for the design and control of wearable assistive devices and for targeted therapeutics. We can indirectly estimate these contributions *in vivo* using empirical measurements (e.g., EMG, ultrasound imaging); yet, neither activation nor fascicle kinematics provide direct measurements of muscle force or work. Fortunately, advances in musculoskeletal (MSK) modelling provide the opportunity to estimate the neuromechanical contributions of individual muscles *in silico*. Although empirically driven, biological complexity of MSK modelling is often exchanged for computational performance, potentially yielding reduced specificity to fully characterize inter-muscular differences. Here, we evaluated the agreement between empirical and model-predicted triceps surae contributions to forward propulsion during walking for the first time in the same group of subjects. We tested the null hypothesis that conclusions based on muscle-specific responses derived from empirical measurements would be consistent with those derived from MSK simulations over a range of tasks that alter the demand for forward propulsion.

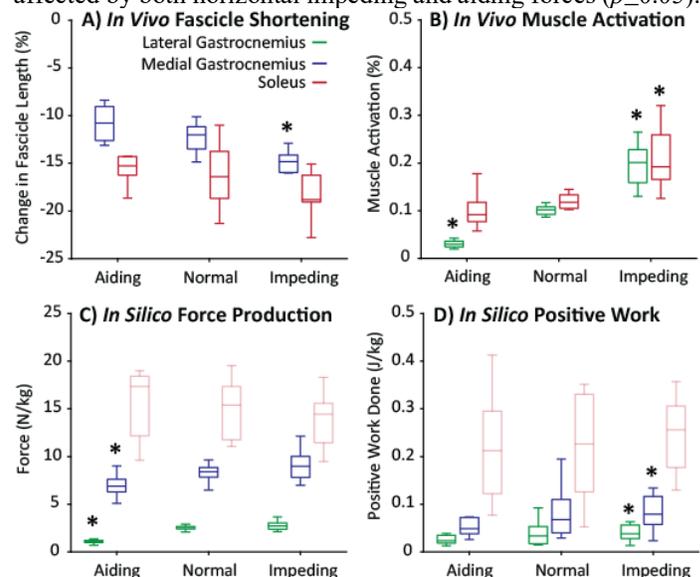

### Methods

We report data for 10 young adults (age:  $23.5 \pm 3.0$  yrs, 5 females). Subjects walked on a treadmill for 1 min each at a range of speeds (0.8, 1.2, 1.6 m/s) and again at 1.2 m/s with: (i) a 5% body weight horizontal aiding force ( $\downarrow$  push-off demand) and (ii) a 5% body weight horizontal impeding force ( $\uparrow$  push-off demand). A 60 mm ultrasound transducer recorded cine B-mode images through the right MG and SOL at 76 fps. Simultaneously, motion capture tracked lower body joint kinematics and wireless electrodes recorded LG and SOL activation. An affine extension to an optic flow algorithm quantified time series of MG and SOL fascicle lengths from 2 strides per condition [2]. Subject-specific, scaled MSK models, driven by measured joint kinematics and ground reaction forces, estimated MG, LG and SOL excitation, force, and positive mechanical work using static optimization [3]. For each muscle, we analysed all data during the “push-off” phase of walking, defined as the second half of stance, ending at the offset of force generation (threshold = 10% peak force) [1]. Two rmANOVAs tested for significant main effects of condition (speed or aiding/impeding) on relative MG and SOL muscle shortening and average MG, LG and SOL kinetics (activation, force, positive mechanical work) during push-off ( $\alpha=0.05$ ).

### Results and Discussion

Our experimental manipulations successfully altered mechanical demand for forward propulsion; peak anterior ground reaction force systematically changed in response to changes in speed and applied horizontal forces ( $p \leq 0.05$ ). *In vivo*, measured MG and

SOL relative fascicle shortening were both significantly affected by increasing speed ( $p \leq 0.05$ ). Conversely, in response to horizontal forces, MG fascicle shortening was more sensitive to altered demands for forward propulsion than that of the SOL (**Fig. 1A**). Compared to walking normally, increased propulsive demand elicited greater relative fascicle shortening in MG ( $p \leq 0.05$ ) but not SOL. *In silico*, model-predicted neuromechanical contributions generally supported our empirically-drawn conclusions. Here, speed similarly affected MG, LG, and SOL average muscle force ( $p \leq 0.05$ ) and similarly unaffected positive mechanical work ( $p \geq 0.05$ ) during push-off. Conversely, in response to horizontal forces, only MG and LG force (**Fig. 1C**) and positive mechanical work (**Fig. 1D**) increased significantly to meet the increased demands for forward propulsion ( $p \leq 0.05$ ). Moreover, only measured (LG, **Fig. 1B**) and model-predicted (MG, LG) gastrocnemius muscle activation was affected by both horizontal impeding and aiding forces ( $p \leq 0.05$ ).

**Fig. 1:** Muscle specific responses to 5% body weight horizontal aiding and impeding forces at 1.2 m/s. Significant main effect represented by opacity, pairwise comparison vs. normal represented by \*,  $p \leq 0.05$ .

### Significance

Based on consistent evidence from empirical measurements and musculoskeletal simulations within the same subjects, we conclude that the biarticular gastrocnemius muscles play a more significant role than the uniaxial soleus in governing forward propulsion during the push-off phase of walking.

## Parametric Analysis and Validation of 3D American Football Faceguard Structural Stiffness Models

William D. Ferriell<sup>1</sup>, Gregory S. Batt<sup>2</sup>, John D. DesJardins<sup>1</sup>

<sup>1</sup>Department of Bioengineering, <sup>2</sup>Department of Food, Nutrition and Packaging Science, Clemson University, Clemson, SC

Email: [jdesjar@clemson.edu](mailto:jdesjar@clemson.edu)

### Introduction

Despite continued efforts to improve American football headgear technology, minimal structural changes have been made to faceguard design in the past 20 years [1]. Although each new helmet system has its own compatible faceguard series, the primary design components have changed little between helmet systems. Additionally, little is known about specific parameters that influence faceguard performance—largely due to variation inherent in laboratory impact testing.

Recently, Bina *et al.* developed a novel testing procedure to analyze the structural stiffness of faceguards independent of the helmet system [2]. The goal of this study was two-fold: to validate a reverse engineering method for developing a library of faceguard models; and to validate the finite element simulation of three common American football faceguards subject to a quasi-static structural stiffness test [2]. This study will result in a validated model to be used in parametric design analysis and computational optimization. Collectively, these studies should inform football athletes, coaches, parents, equipment managers, and headgear manufacturers of design variables relevant to faceguard performance.

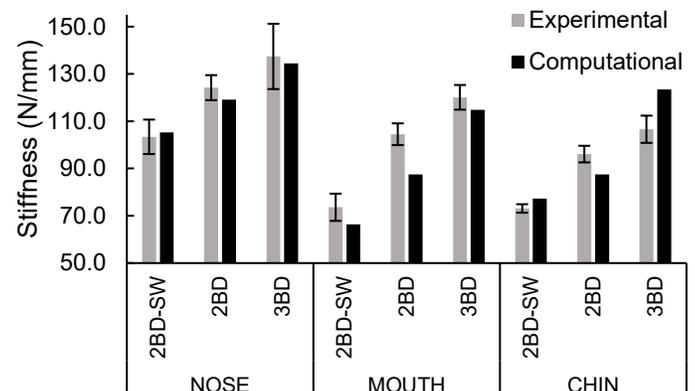

### Methods

Three common Riddell® (Des Plaines, IL) Speedflex™ faceguard styles (SF-2BD, SF-2BD-SW, and SF-3BD) were modelled using a novel reverse engineering approach. The faceguards were modelled as a stainless steel ( $E=193$  GPa,  $\nu=0.31$ ). Each faceguard mesh converged using a 1.5 mm sizing control with quadratic tetrahedral elements.

Each compression location/direction from the literature was simulated on each faceguard [2]. To simulate the experimental setup, the analysis occurred over a singular step lasting 3 seconds. A displacement of 5 mm was prescribed in the posterior (z) direction. The experimental test allows for coronal plane (x, y) translation at clip attachment locations; thus, the corresponding geometry and boundary conditions were applied. To prevent rigid body motion, two boundary conditions were applied: each faceguard was constrained to not deviate from the midsagittal plane; and program controlled weak springs were applied to the entire model. Constraint reaction forces were measured to ensure each did not artificially stiffen the faceguard model. Validation was determined by comparing experimental averages to computational results using a Pearson Correlation test with a 95% confidence interval ( $\alpha=0.05$ ).

### Results and Discussion

The computational results correlated to the experimental results with statistical significance ( $p$ -value=0.001). The Pearson's Correlation coefficient of 0.912 demonstrated a high degree of correlation. Furthermore, a linear regression model  $Comp = 0.98 * Exp - 0.07 N/mm$  further illustrates the near 1:1 comparison between computational and experimental results. Additionally, the weak springs and midline constraint reaction forces were less than 0.01 N and assumed to not have artificially

**Figure 1:** Results comparing experimental data to computational results. Note: The experimental data ( $n=10$ ) have a standard deviation represented by error bars, whereas computational results ( $n=1$ ) do not.

stiffened the faceguard models.

The Nose location was the most reliable with an average percent difference from experimental results of 2.7%, compared to 10.8% and 9.9% at the Mouth and Chin locations, respectively, as shown in Fig. 1.

### Significance

Many studies utilizing computational models of protective headgear lack reported validation of headgear components. This study has validated the structural stiffness of three common faceguards to be used in future computational analyses. Furthermore, advancements in additive manufacturing technologies have opened the door to increasingly complex faceguard design capabilities; however, little is known about specific parameters that influence faceguard performance. With the models validated in this study, parameterized faceguard models should be used to iterate between design variables and assess the contribution of each variable on faceguard structural stiffness. The goal of this study was to influence faceguard design by informing headgear manufacturers of the specific variables that determine faceguard stiffness to improve headgear technologies and athlete safety.

## Simulation of Speech Muscle Biomechanics to Explain Differences in Corrective Surgery Outcomes

Vi-Thanh Tran<sup>1</sup>, Kazlin Mason<sup>2</sup>, Jamie Perry<sup>3</sup>, and Silvia Blemker<sup>1</sup>

<sup>1</sup>Department of Biomedical Engineering, University of Virginia; <sup>2</sup>Curry School of Education, University of Virginia

<sup>3</sup>Department of Communication Sciences & Disorders, Eastern Carolina University

Email: ttt9bu@virginia.edu

### Introduction

Cleft palate is a common birth defect that affects approximately 1 in 700 live births. Cleft palate disturbs velopharyngeal (VP) closure, in which speech muscles, predominantly the levator veli palatini (LVP) muscle, contracts to elevate the soft palate so that it comes in contact with the posterior pharyngeal wall (PPW). All children with cleft palate undergo primary reconstruction of the soft palate before the age of 12 months; however, many of these children need additional surgeries because the LVP muscle still does not function properly, resulting in hypernasal speech. Sphincter pharyngoplasty is one of the most common surgical treatments for hypernasal speech. The goal of the surgery is to facilitate improved VP closure by augmenting the PPW with a muscle graft (3). Despite its wide use, the outcomes of these surgeries are variable and there remains several questions as to why some surgeries fail. It is still unknown whether differences in muscle biomechanical function influence surgical outcomes. The goal of the study is to (i) develop two subject-specific finite element models of the sphincter pharyngoplasty, the LVP muscle, and associated VP mechanism based on medical image data collected from one successful and one failed surgical outcome case, and (ii) use the model simulations to examine the extent to which differences in muscle biomechanics may explain the differences in surgical outcomes between the two cases.

### Methods

Two age-matched male subjects were selected based on the clinically evaluated post-surgical speech outcome to represent a successful and a failed case. A three-dimensional model, including the soft palate, LVP muscle, sphincter graft, and PPW, was developed based on MRI data post sphincter pharyngoplasty surgery. Mechanical properties of muscle and soft tissue were incorporated into the finite element model based on previous studies (2,4). The LVP muscle was activated to simulate VP closure. The reconstructed LVP muscle in the failed case was identified with an asymmetric overlap alignment from original reconstruction. An additional hypothetical simulation with a symmetrical LVP overlap was also modeled to analyze the impact of muscle overlap location on VP closure. The model output of LVP muscle's minimum activation (the amount of muscle effort required for closure) and the amount of muscle fiber shortening (an estimate of how much of the force-length curve the muscle traverses) at initial contact was used to examine the effectiveness of VP closure. Uncertainty quantification for the model was estimated by varying the Young's modulus of the soft

palate with the estimated range of values based on material testing and model input data (1,5).

### Results and Discussion

The minimum required activation and amount of muscle shortening to achieve VP closure was lower in the successful case ( $6.39 \pm 1.7\%$  and  $13.5 \pm 0.6\%$ ) compared to the original failed case with asymmetrical ( $23.6 \pm 12.9\%$  and  $22.9 \pm 1.8\%$ ) and the hypothetical symmetrical LVP overlap ( $13.1 \pm 5.9\%$  and  $18.60 \pm 0.7\%$ ). Furthermore, the required activation for VP closure in the successful case falls within range of previously reported data from a healthy population (5), which agrees with the clinical evaluation that the corrective surgery succeeded in reconstructing healthy VP closure mechanics. In contrast, there is no contact between the soft palate and sphincter graft in simulations of the failed surgery case for both asymmetrical and symmetrical LVP overlap. However, lower activation and amount of fiber shortening for closure in symmetrical LVP overlap indicates that alignment of muscle overlap might have influenced the advantageousness of the LVP muscle to achieve closure. Future research includes using the models to simulate hypothesized sphincter location to examine the impact of sphincter location in VP closure and ultimately in surgical outcome. Additional subject will also be added to confirm the model's applicability.

### Significance

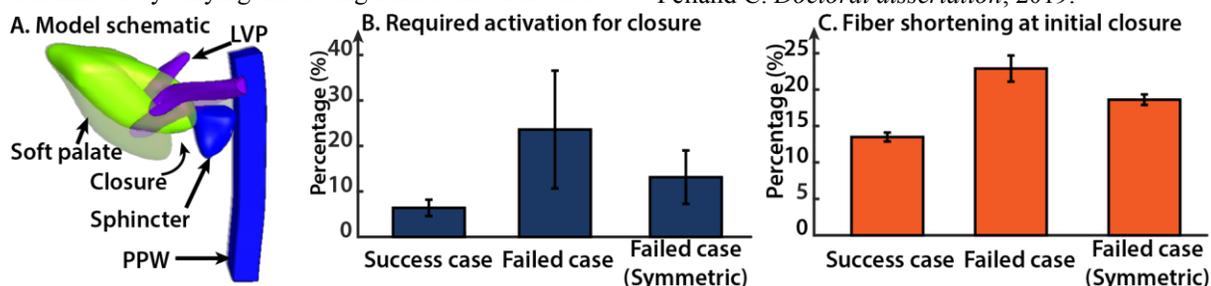

The computational model illustrated how muscle biomechanical function significantly differs between successful and failed post-pharyngoplasty surgeries. Future work will involve developing a streamlined method for creating subject-specific modeling framework to predict the optimal surgical approach on a subject-by-subject basis. Finally, more generally, we hope that this work illustrates how biomechanical analysis of muscles has a wide variety of applications beyond more traditionally studied limb muscles.

## A Split-Belt Rimless Wheel Can Passively Walk Steadily on a Split-Belt Treadmill

### Introduction

Split-belt treadmills are commonly used for motor learning experiments [1] and stroke rehabilitation [2], but we are still learning how people adapt to the two belts moving at different speeds. For example, Sánchez et al. [3] recently showed that after sufficient exposure, participants will self-select a gait with wider leg angles and longer steps onto the fast belt, rather than a gait with equal angles and step lengths as had previously been observed. People can extract positive work from a split-belt treadmill [3], and this may be driving split-belt adaptation. But how do choices like leg angles and treadmill belt velocities affect how energy is harvested from the treadmill?

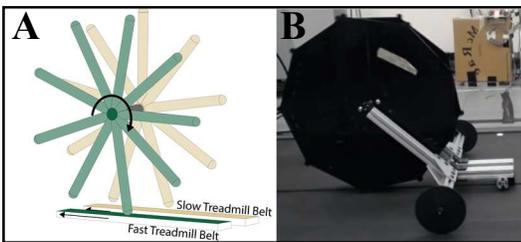

We used a split-belt rimless wheel model to further explore the mechanics and energetics of split-belt walking. A rimless wheel loses energy during its collisions with the ground so must successfully harness energy from the treadmill to walk steadily, an impossible task if the belts are tied. We explored how treadmill conditions and leg angles affect the passive wheel's ability to extract enough energy from the treadmill to walk steadily.

### Methods

We simulated a split-belt rimless wheel (Fig. 1A), two identical sets of spokes that are rigidly attached and offset by a small angle. The spokes are arranged such that only one spoke is ever in contact with the ground, and the wheel alternates contacting the fast and slow treadmill belts. The angular offset results in different inter-leg angles at collision onto the fast and slow belts, just as humans adjust their step lengths during split-belt walking to have different leg angles during the fast and slow steps.

We tested combinations of inter-leg angles and belt speed differences to find initial velocities corresponding to steady walking. If a solution existed, we calculated the wheel's average velocity in the slow belt reference frame, which is the slow belt velocity required for the wheel to station-keep.

We designed and built a physical prototype (Fig. 1B) to demonstrate that the simulation model was physically realistic. For the sets of spokes, we used plates with evenly spaced toes. We added stabilizer wheels to the front to prevent leaning and a rudder to prevent turning.

**Figure 1:** Split-Belt Rimless Wheel Model. A: Simulation Model B. Physical Prototype

### Results and Discussion

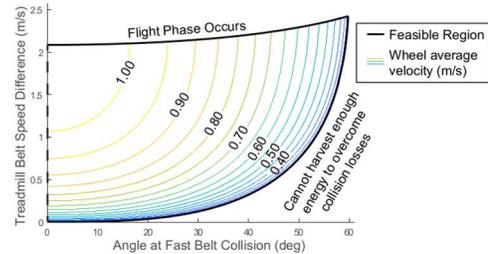

We found a wide range of inter-leg angles and belt speed differences for which the split-belt rimless wheel could harness enough energy from the treadmill to walk. During steady

walking, energy lost in step-to-step transitions is recovered as energy gained during rotation on the fast belt.

Two asymmetries in the system, the difference in belt speeds and the difference in inter-leg angles at collision, enable energy harvesting during the fast belt rotation. Because of the belt speed difference, the foot has non-zero velocity when viewed from the slow belt reference frame. The contact force on the foot then results in work being done on the wheel. Having a wider inter-leg angle at fast collision ensures the net work done is positive by enabling the wheel to primarily rotate upward during this rotation, with the contact force aligned with the foot's velocity.

A counterintuitive result is that increasing the fast belt's backward velocity increases the wheel's forward velocity in the slow belt reference frame (Fig. 2). With complicated underlying mechanics, the wheel travels further backward while on the fast belt but rotates faster through both steps, thereby achieving a greater forward gain per unit time.

The physical model, with radius 0.25 meters and fast and slow belt collision angles of 31 and 9 degrees, walked steadily for belt speed differences from 0.2 to 1.1 m/s and achieved a maximum speed of 0.2 m/s in the slow belt reference frame.

**Figure 2.** With an infinitesimally small angular offset between the plates such that collision onto the slow belt occurs at nearly vertical, the model can walk steadily with a large range of inter-leg angles and treadmill speed differences. Results look similar as the offset increases as long as the fast collision angle remains significantly wider.

### Significance

These results confirm observations from human experiments that extracting positive work from a split-belt treadmill is possible when a wider step is taken onto the fast belt [3]. The belt speed difference, rather than the speeds themselves, is the crucial element contributing to the model's energy-free solutions. Improvements in human split-belt energy economy may be possible, and these results help us understand the limitations of humans' ability to harness energy from a split-belt treadmill.

## An Instrumented Glove to Induce Agency-based Performance of Secure Grasp

Mingxiao Liu<sup>1,2</sup>, Samuel Wilder<sup>1,2</sup>, Sean Sanford<sup>1,2</sup>, and Raviraj Nataraj<sup>1,2</sup>

<sup>1</sup>Department of Biomedical Engineering, Stevens Institute of Technology,

<sup>2</sup>Movement Control Rehabilitation (MOCORE) Laboratory, Email: mliu26@stevens.edu

### Introduction

Improving grasp performance for activities of daily living is a key rehabilitation objective following neuromuscular traumas such as stroke, traumatic brain injury or spinal cord injury. Typical rehabilitation protocols involve intensive or repetitive physical training to reformulate motor connections. Few approaches consider cognitive factors to better motivate and engage patients for more efficient rehabilitation. *Sense of agency* is the perception of true authorship over neuromuscular actions and related consequences. Possessing greater *agency* to improve functional movement appears intuitive, but agency has not been a focus of traditional rehabilitation. We have developed an instrumented glove with onboard force and flex sensors, modules for user feedback, and access to computer processing. The glove reliably predicts secure grasp on an object and alerts the user with various sensory cues to induce greater agency via intentional binding [Moore and Obhi 2012]. In this study, we investigated whether sensory feedback from the glove facilitates improved hand grasp performance.

### Methods

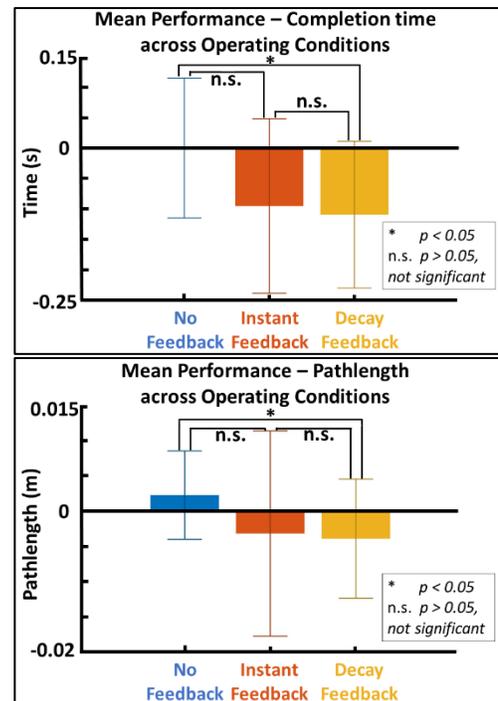

Fifteen participants performed a functional grasp task while receiving visual (LED) and audio (beeper) feedback onboard our *Cognition Glove* during a training session (Figure 1). The functional task involved the participant grasping a small cubic object from one location and placing onto a designated target. A 2-layer feedforward neural network was used to assess secure grasp from flex and force sensor signals based on offline training data. Sensory feedback was provided to the user during training across three distinct conditions: (1) No feedback, (2) ‘Instant’ feedback provided immediately upon achievement of secure grasp, and, (3) ‘Decay’ feedback provided at progressively shorter time-intervals (from 1 to 0 sec) after secure grasp. The third condition was intended to facilitate greater agency through intentional binding, whereby one builds a stronger perception to couple action (secure grasp) with a sensory consequence. The primary performance metrics were minimizing the completion time and pathlength in moving the object. Performance was assessed before and after training with the glove. A motion capture system (*Optitrack, Prime17W* cameras) was used to track motion of the grasped object.

**Figure 1:** A) Experimental setup of the functional grasp task  
B) Participant performing the task while wearing *The Cognition Glove*

### Results and Discussion

The change in mean performance (difference between after training and before training) of the functional task after glove training is shown in Figure 2. ANOVA indicated significant ( $p < 0.05$ ) differences in performance across all three feedback conditions. The greatest reductions in time and pathlength were observed with ‘Decay’ feedback. These results indicate that providing onboard sensory feedback from an instrumented glove to inform secure grasp can improve grasp performance. Furthermore, providing that feedback with intention to induce greater agency may best accelerate the improvement in grasp performance.

**Figure 2:** Results of training effects between different sensory feedback on grasp performance – completion time (TOP) and pathlength (BOTTOM).

### Significance

This study presents a novel approach to predict and inform about secure grasp during a functional task. It will serve as a potential agency-based rehabilitation platform to accelerate gains in functional grasp performance after neuromuscular traumas. This may foster greater user integration and clinical retention of rehabilitation methods. Future work will incorporate *The Cognition Glove* with virtual reality platforms to create mixed-reality rehabilitation intended to further augment sensory feedback capabilities.

Email: \*[xudongzhang@tamu.edu](mailto:xudongzhang@tamu.edu)

### Introduction

Magnetic resonance imaging (MRI) and computed tomography (CT) are commonly used as the “gold standard” to image soft and hard tissues, respectively. The reconstructed 3D muscular models from MRI and skeletal models from CT must be combined in order to create subject-specific musculoskeletal models. However, this MRI-CT co-registration is challenging for complex structures with a substantial number of degrees of freedom such as the cervical spine, because the poses used in two modalities would not have completely coincided. In addition, due to its complex 3D geometry, vertebral bone models segmented from MRI can be subject to volume loss as compared to CT-based bone models, which further compounds the uncertainty and difficulty in the co-registration process [1]. In this study, we present a novel approach that takes advantage of dynamic X-ray data to identify the best matching pose and employs principal component analysis (PCA) to align the bones, thus optimizing the creation of subject-specific neck musculoskeletal models.

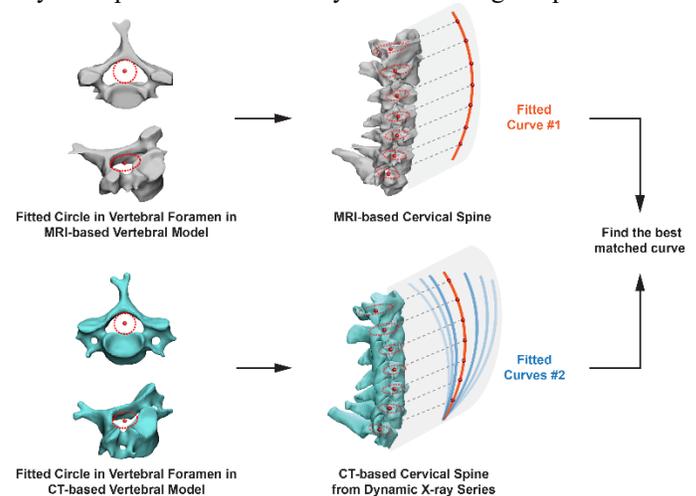

### Methods

We used CT and MRI scans of the neck region, and dynamic X-ray captures of a neck flexion-extension motion collected from five healthy subjects (all male, aged 21–32 years). The CT and MRI scans were first segmented in Mimics 20.0 platform to create 3D vertebrae models. A previously validated CT-model-based tracking algorithm was applied to the dynamic X-ray images to obtain the 3D neck vertebral kinematics [2]. The 3D point clouds of the reconstructed vertebrae models were then exported into MATLAB and the vertebral foramen at the middle height of each vertebra was fitted by a circle with a least-squares method. The centroids of the fitted circles at all levels (C1-C7) were then fitted by a cubic polynomial to characterize the cervical spine curvature. The cervical spine curvature in the MRI was compared with the dynamic X-ray series to identify the best matching pose that minimized the curvature discrepancy measured as Fréchet distance [3]. Next, a PCA algorithm was applied to the point clouds of vertebrae models in both modalities to define the orientation of the superior vertebra with respect to the inferior vertebra. Lastly, the differences in 3D vertebral orientation between vertebra models in MRI and the matching dynamic X-ray frame were quantified as the target registration errors (Figure 1). The CT-based skeletal model with the best matching pose identified in the dynamic X-ray series was thus integrated with the MRI-based muscular model to create anatomically accurate subject-specific neck musculoskeletal models.

### Results and Discussion

The overall mean curvature discrepancy between the two modalities was 0.34 mm of Fréchet distance. The average 3D orientation difference was greater in flexion-extension (1.28°)

than in axial rotation (0.34°) and lateral-bending (0.05°) (Table 1). The greater flexion-extension differences found in the upper (C1-C2 and C2-C3) and the lower (C6-C7) cervical spine may be attributed to a more flattened cervical spine curvature found in the MRI model. The greater axial rotation differences in the upper cervical spine (C1-C2, and C2-C3) could be explained by the fact that the C1-C2 joint is the atlanto-axial joint where C1 and C2 may pivot around one another. In addition, some of the differences in both axial rotation and lateral-bending could be due to that flexion-extension motions captured by dynamic X-ray were performed not strictly in the mid-sagittal plane.

**Figure 1:** Pose-matching MRI-CT registration process via dynamic X-ray.

**Table 1.** 3D orientation differences (mean and standard error) between the MRI and best matching CT models. FE, AR, and LB denote flexion-extension, axial rotation, and lateral-bending, respectively.

(°)	(1.25)	(0.62)	(0.54)	(1.02)	(0.73)	(1.11)

### Significance

The proposed approach to MRI-CT co-registration by utilizing dynamic X-ray data provides a novel solution to the problem of pose variation across the modalities, a major obstacle hindering the development of complex yet accurate subject-specific musculoskeletal models.

## Introduction

Persons with below-knee amputation (BKA) often exhibit abnormal trunk motion during walking, with associations to low back pain and challenged balance [1–3]. We recently identified that altered mechanics of the affected-limb knee and prosthetic ankle have potential to adversely influence trunk rotational dynamics when walking with BKA [4]. As such, modifying prosthetic ankle-foot mechanics (e.g., torque, range of motion) may be an indirect means to influence trunk control. This preliminary analysis explores this concept by comparing ankle contributions to rotational trunk control while wearing three distinct, prosthetic ankle-foot devices.

## Methods

Within scope of clinical trial NCT03505983, one subject with traumatic, unilateral BKA (F, 40yr, 172cm, 63kg, 25 years post-amputation) wore three different ankle-foot prostheses: (1) energy storage and return (ESR, Ossur Proflex XC), (2) ESR with articulation (ART, Ossur Proflex Pivot), and (3) powered with articulation (POW, Ottobock Empower). Each foot was aligned on a replicate socket and granted 1-week daily use acclimation (order: ART/POW/ESR), after which whole-body kinematics and kinetics were measured while walking overground at 1.3m/s. Data processing and simulation mirrored [4]. Briefly, a single patient model was generated by scaling OpenSim Gait2392 to session-averaged anthropometrics. Estimated joint angles and net moments were input to a torque-driven induced acceleration (IA) analysis. Trunk segment rotational accelerations induced by individual joint moments were then compared between prostheses and versus non-BKA normative (NORM) ranges [4].

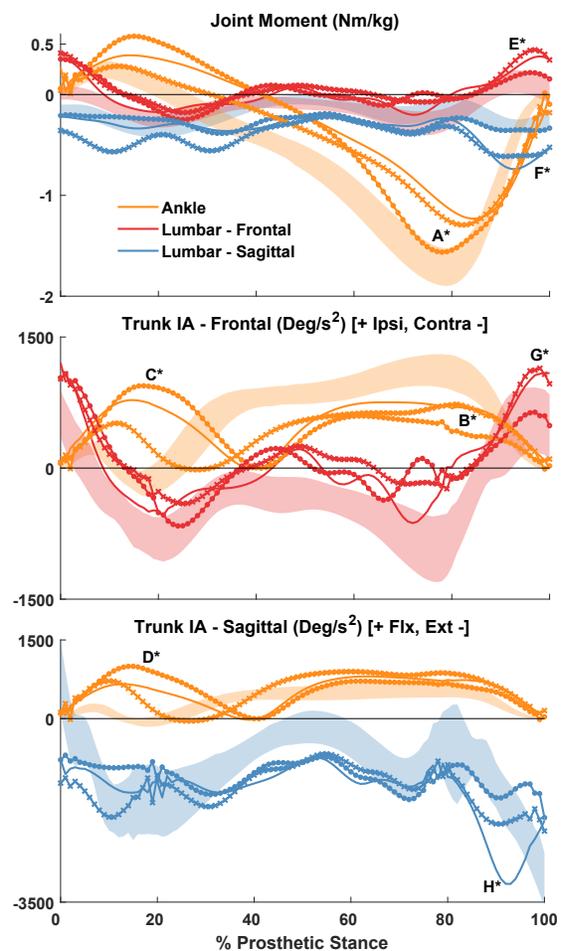

## Results and Discussion

Ankle push-off moment increased 27% with POW versus EST/ART, to within NORM (Fig 1; A\*). This coincided with less ipsilateral, frontal ankle-trunk IA in POW (Fig 1, B\*), and differed versus NORM for all feet (lesser frontal, greater sagittal). Ankle-trunk IA differences were most apparent during loading response, where earlier peaks above NORM acted to flex the trunk forward and ipsilaterally (Fig 1; C\*, D\*). This feature, greatest with POW and least with ART, may indicate high sensitivity of trunk stabilization to prosthetic actuation during weight acceptance. If not balanced by opposing IA contributions from other joints, this has potential to destabilize the trunk [2]. This specific subject exhibited stable, net trunk control; attaining measured trunk kinematics within NORM range for all feet.

During push-off, peak lumbar moments were greater than NORM with ESR/ART (+42% frontal, Fig 1, E\*; +53% sagittal Fig 1, F\*), as were concurrent lumbar-trunk IAs (Fig 1; G\*, H\*). POW appeared to mitigate this, decreasing moments and IAs to within NORM, which may indicate an improved whole-body strategy; i.e. less necessity with POW to actively modulate dynamic postural control via trunk inertia.

## Significance

These observations, albeit patient-specific, highlight that contributions to trunk rotational control can be influenced by varied prosthetic ankle-foot actuation (passive/active power, variable articulation). Further analyses will help determine if similar trends are characteristic of BKA, or individualized. More broadly, this line of inquiry aims to inform new, clinically translatable strategies to modify problematic trunk motion, relevant to mitigating low back pain and dynamic balance [1–3].

**Figure 1:** Joint moments (top) and trunk rotational induced accelerations (IA) in the frontal (middle) & sagittal (bottom) planes, for the ESR (solid line), ART (x), POW (●) ankle-foot prostheses. Shaded areas are mean±1std non-BKA normative ranges (NORM) [4].

# Whole-body angular momentum during walking in persons with unilateral transfemoral amputation

## Introduction

Currently, more than half of lower limb prosthesis users fall at least once each year [1]. Since the greater range of whole-body angular momentum ( $L$ ) about body center of mass during walking would lead to the greater postural control demands, persons with unilateral transfemoral amputation (TFA) must adequately manipulate the whole-body  $L$  to maintain the dynamic stability. Generally, the whole-body  $L$  during walking is kept close to zero through segment-to-segment cancellations by segmental angular momenta. Considering that persons with TFA needs to regulate the whole-body  $L$  using the passive prosthetic components, the range of  $L$  would be different from those of able-bodied (AB) subjects. Therefore, the aim of this study was to investigate the range of whole-body  $L$  during walking with unilateral TFA.

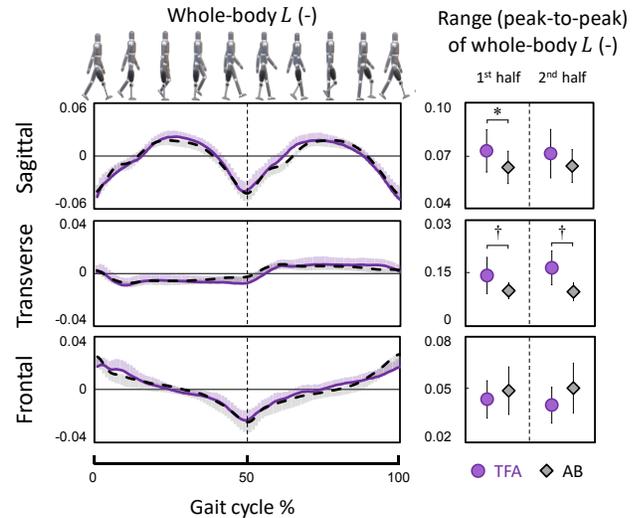

## Methods

Fourteen persons with unilateral TFA and 14 AB subjects performed level walking at a self-selected speed on a straight 10-m walkway. Three-dimensional kinematic data were collected using reflective markers and an optical motion capture system. Ground reaction forces (GRFs) were recorded using nine force plates. Three-dimensional whole-body  $L$  was calculated using a 15-segment model and normalized by body mass, height and walking speed. The range of whole-body  $L$  was calculated as the peak-to-peak value through first and second half of the affected (right for AB) limb's gait cycle. Independent  $t$ -tests ( $\alpha=0.05$ ) were performed to assess the main effects of group (TFA, AB) on the range of whole-body  $L$ .

## Results and Discussion

In the sagittal plane, the range of whole-body  $L$  was greater in TFA compared to AB subjects through the first half of the affected limb gait cycle ( $p = 0.035$ ; Figure 1), but differences were non-significant in the second half ( $p = 0.140$ ). These results indicate that persons with unilateral TFA may require greater demands for maintaining balance during prosthetic limb stance compared to AB subjects. During this phase, persons with TFA must also work to prevent prosthetic knee buckling (i.e., rapid knee flexion), which requires additional postural control demands. If a disturbance due to knee buckling or an external perturbation were to elevate sagittal-plane  $L$  on the affected limb, persons with TFA may be more likely to fall if  $L$  is not successfully managed.

In the transverse plane, the range of whole-body  $L$  in TFA subjects was greater than AB subjects during both the first ( $p = 0.010$ ) and second ( $p < 0.001$ ) half of the gait cycle. In the transverse plane, leg angular momentum is counterbalanced to some extent by that of the arms. As a previous study demonstrated no difference in transverse-plane whole-body  $L$  between persons with unilateral transtibial amputation and AB subjects [2], our results suggest that persons with unilateral TFA are less able to neutralize angular momentum during gait.

**Figure 1:** Whole-body  $L$  during the gait cycle of the affected (right for AB) limb of walking in TFA (bold purple line) and AB (dashed black line) subjects. The shaded area indicates the standard deviation. Range (peak-to-peak) of whole-body  $L$  was compared through first and second half of gait cycle between TFA and AB subjects. An asterisk and a dagger (\*, †) denotes significance at  $p < 0.05$  and  $p < 0.01$ , respectively.

No significant group effects were observed in the range of frontal plane whole-body  $L$  during the first ( $p = 0.305$ ) or second half ( $p = 0.056$ ) of the gait cycle, which is different than findings for persons with unilateral transtibial amputation [2]. Since whole-body  $L$  in this plane is primarily balanced through lower limbs and abdomen/pelvis motion and affected by GRF peaks [2, 3], these results suggest that persons with unilateral TFA are able to regulate frontal-plane  $L$  through these mechanisms similar to AB.

To conclude, persons with unilateral TFA displayed greater ranges of whole-body  $L$  than AB subjects to suggest that they would require greater postural control demands to avoid falling in the presence of a perturbation that elevates sagittal and transverse-plane  $L$ . For a better understanding of the strategy of segmental cancellation, future research should investigate the segmental contributions to whole-body  $L$ .

## Significance

Since the successful management of whole-body  $L$  during walking is essential for recovering from perturbations and preventing falls, understanding how persons with unilateral TFA control whole-body  $L$  can be useful for designing appropriate devices or interventions to enhance gait safety.

## Effects of exoskeleton assistance in individuals with unilateral transtibial amputation

### Introduction

Unilateral transtibial amputation often leads to increased energy expenditure during gait, as well as larger ground reaction forces on the contralateral side [1, 2]. In turn, this causes a higher prevalence of joint pain and early onset osteoarthritis [3], negatively affecting mobility and reducing overall quality of life of individuals with impairment. Powered prostheses may help mitigate some of these issues (e.g. [4]), but the benefits of increased prosthesis work are uncertain [5]. Past research has largely focused on improving active prosthesis control and design, but it is possible that the potential benefits of active devices are limited by changes in motor learning post impairment [6]. The aim of this study was to identify if people with lower-limb amputation adapt to powered ankle exoskeleton assistance applied to their sound leg similarly to people without impairment. Specifically, we assessed changes in energy expenditure in users with impairment when walking with individualized assistance and no assistance at the ankle.

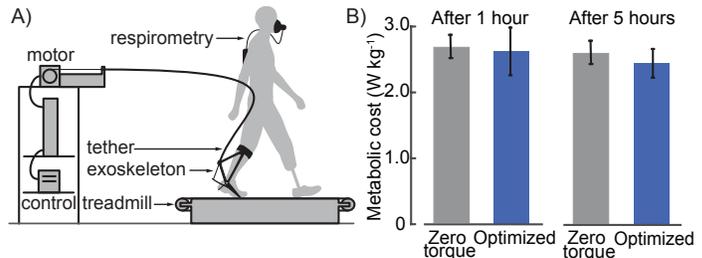

### Methods

We evaluated the benefits of optimized exoskeleton assistance on energy expenditure in individuals with lower-limb amputation by implementing a controller optimization protocol previously shown to lead to an average 24% reduction in metabolic cost in users without impairment [7]. We used an experimental, tethered exoskeleton emulator device to provide plantarflexion assistance during stance (Figure 1A, [8]). To optimize exoskeleton assistance to each user, we used an optimization strategy that continually adapts to changes in user dynamics [7]. This human-in-the-loop approach relies on a standard optimization algorithm to reduce user energy expenditure by systematically updating four parameters that define the exoskeleton torque profile.

Five individuals with unilateral transtibial amputation participated in the study. Each participant walked with their prescribed prosthesis and with the exoskeleton worn on their sound limb. All participants completed 20 optimization bouts, performed over multiple days of testing, with each bout consisting of 8 optimizer-selected control profiles experienced by the user for 2 minutes each. This protocol was longer than in previous studies with unimpaired individuals in order to ensure the optimizer converged and users were fully acclimated to assistance. We performed separate validation trials after 4-6 optimization bouts and at the end of the experiment, measuring user energy expenditure during walking without the device, wearing the unpowered device (zero torque), and with the device providing optimized assistance (optimized).

### Results and Discussion

The first evaluation of user energy expenditure in response to assistance occurred after 4-6 optimization bouts, or 1-1.5hrs of walking, and as dictated by participant fitness level. At this time, participants showed only a 3.6% reduction in net metabolic cost when walking with optimized assistance compared to walking with zero torque (2.63 and 2.73 W/kg, respectively; Figure 1B). In contrast, unimpaired users reduced energy cost on average by

**Figure 1:** A) Exoskeleton emulator system, with the device worn on the sound limb of people with unilateral amputation. B) Average metabolic cost of users after approximately 1 and 5 hours of optimization, during the zero torque and optimized assistance conditions.

24% compared to walking with zero torque, and after only one hour of optimization [7]. Four participants with amputation completed 20 optimization bouts, or more than 5 hours of walking, and showed just a 5.8% reduction between conditions (2.43 and 2.58 W/kg, respectively). Energetic cost during the zero torque and normal walking conditions differed by less than 2%.

Such differences in metabolic cost reduction in response to assistance between impaired and unimpaired individuals imply that lower-limb amputation presents different motor learning challenges in the context of robotic assistance. In addition, these results further suggest that the benefits of powered prostheses could be significantly limited by learning and biomechanical restrictions caused by impairment. New user training and device assistance approaches are likely needed to significantly assist people with amputation.

### Significance

The results of this study show that individuals with amputation adapt to assistive robotics differently from people without impairment. This is likely also true for individuals with other locomotor deficits, such as those following stroke, and advocates for further research into balance, coordination, and learning limitations caused by impairment. In addition, gait rehabilitation protocols post injury likely need to be reevaluated with the introduction of robotic assistive devices.

# Walking to Exhaustion: The Effects of Powered Prosthetic Ankles

Jay Kim and Deanna H. Gates

School of Kinesiology, University of Michigan Ann Arbor, MI

Email: [jaywoo@umich.edu](mailto:jaywoo@umich.edu)

## Introduction

People with lower limb amputation often have difficulty walking for long-durations and infrequently perform activities for more than 15 minutes at a time (< 1 per day) [1]. Despite this, few studies have explored the factors limiting long-duration walking in this population. One study found that people with transtibial amputation (TTA) reduced their intact side ankle power during push-off and increased hip power generation on their prosthetic side after 60 minutes of walking [2]. This suggests that people with TTA alter their strategy, potentially in response to fatigue in the intact limb.

Powered prosthetic ankles have been developed to address lack of ankle plantarflexor power in people with (TTA) [3], which may alter joint kinetics during walking [4]. The purpose of this study was to determine if using a powered prosthesis increased walking endurance and altered ankle and hip kinetics.

## Methods

10 males ( $53 \pm 11$  years old) with unilateral TTA completed two test sessions, one with their prescribed unpowered prosthesis and one with the BiOM T2 (BiONX, Bedford, MA) powered ankle prosthesis in random order. Participants had at least 3 weeks of at-home acclimation time with each device prior to testing. In each session, participants walked overground, on a treadmill until they could no longer continue, and then on level ground again. During overground trials, participants walked at a fixed speed based on their leg length ( $1.18 \pm 0.08$  m/s). The treadmill speed was set as 10% faster than the fixed speed. During overground trials, we recorded kinematics using a motion capture system and kinetics using forceplates. The outcome measures were peak sagittal ankle and hip power during loading response and push-off and peak vertical ground reaction force (vGRF) during the first and second half of stance. We compared the effects of power (unpowered vs powered) and fatigue (pre vs post) using linear mixed models.

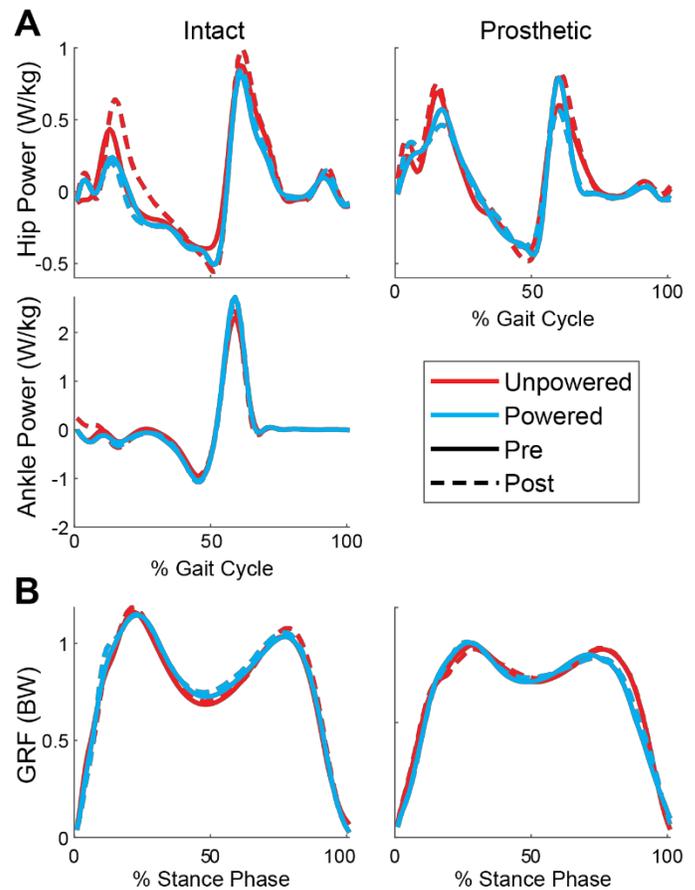

## Results and Discussion

Participants walked for a similar duration with the powered (13.2 min) and unpowered (14.7 min) prostheses ( $p = 0.165$ ). When using the unpowered prosthesis, participants stopped due to pain in their stump ( $n=6$ ), phantom limb ( $n=1$ ), and/or hip ( $n=1$ ). When using the powered prosthesis, three participants stopped walking due to stump or phantom pain rather than fatigue.

With both unpowered and powered prostheses, there were no changes in intact ankle or residual hip power in the loading response or push-off phase. Our results were not consistent with previous findings on the effects of 60-minute walks in individuals with TTA [2]. An important difference in our study was the increased walking speed (10% faster than the fixed speed). Because of this, our participants walked considerably less than 60 minutes, which might not have been enough time for fatigue-induced muscular or kinetic adaptations to be observed.

The treadmill speed was faster than many participants were accustomed to. This may have led to increased socket pistoning. This is supported by the fact that participants reported stopping

due to pain, predominantly in the residual limb. The pain experienced did not result in “off-loading” the prosthetic limb, as the vGRF was not different pre- and post-fatigue.

**Figure 1:** A) Sagittal hip and ankle power. B) vGRF in the intact (left) and prosthetic (right) limbs.

## Significance

More participants were limited by pain than fatigue when walking with an unpowered prosthesis compared to walking with a powered prosthesis. However, the use of a powered ankle did not enable participants to walk for a longer duration. This may suggest that while pain may be a limiting factor for fast-speed walking with an unpowered prosthesis, there may be different limiting factors for powered ankles.

# Characterizing Strut Stiffness in Running-Specific Ankle-Foot Orthoses

Kara Ashcraft<sup>1</sup>, John Collins<sup>2</sup>, Trevor Kingsbury<sup>2</sup>, Alena M. Grabowski<sup>1</sup>

<sup>1</sup>University of Colorado, Boulder, CO, USA

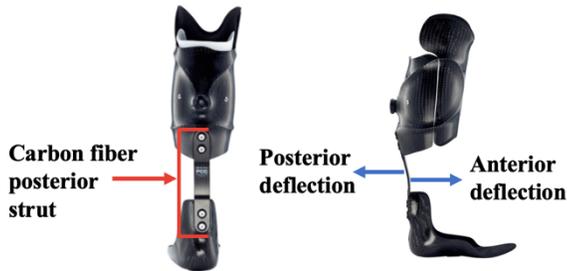

<sup>2</sup>Naval Medical Center San Diego, San Diego, CA USA

Email: Kara.Ashcraft@colorado.edu

## Introduction

Running is well-characterized by a spring-mass model<sup>1</sup> where the legs are represented by massless linear springs and the center of mass (COM) is represented by a point mass. During ground contact, the leg spring compresses and stores elastic energy until mid-stance, and then returns mechanical energy through the end of ground contact.<sup>2</sup> The magnitude of the stored and returned mechanical energy is inversely related to leg stiffness ( $k_{leg}$ ), which equals the quotient of the peak applied force ( $F$ ) and change in leg length<sup>3</sup>: ( $\Delta l$ ):  $k_{leg} = \frac{F}{\Delta l}$ .

Passive-dynamic running-specific ankle-foot orthoses (AFOs) were developed to stabilize the ankle joint of people with salvaged lower-limbs and provide spring-like function. These AFOs include a carbon fiber strut that acts in parallel with the ankle to store and return elastic energy during ground contact (Fig.1).

**Figure 1.** Passive-elastic running-specific ankle-foot orthoses (AFOs) include a carbon fiber strut that flexes anteriorly at initial heel contact, and posteriorly at toe-off.

During running, ankle joint stiffness is similar across speeds.<sup>4</sup> Wach et al.<sup>5</sup> mechanically tested two running-specific AFO's under compression in a materials testing machine and reported that the AFOs (carbon fiber strut and shank components) have curvilinear force-displacement profiles, suggesting that strut stiffness depends on the force applied. The struts of running-specific AFOs are classified into predetermined stiffness categories, which are based on body mass and/or intended activity (slow or fast running).

AFO strut stiffness affects its function, but the stiffness values of these struts have not been systematically determined. Therefore, we quantified the stiffness values of AFO struts, and hypothesized that each strut stiffness would change by the same magnitude for between each stiffness category (Cat). Based on previous findings that an AFO exhibits a curvilinear displacement profile, we hypothesized that the force-displacement profiles of the carbon fiber AFO struts deflected in the posterior and anterior directions would be curvilinear.

## Methods

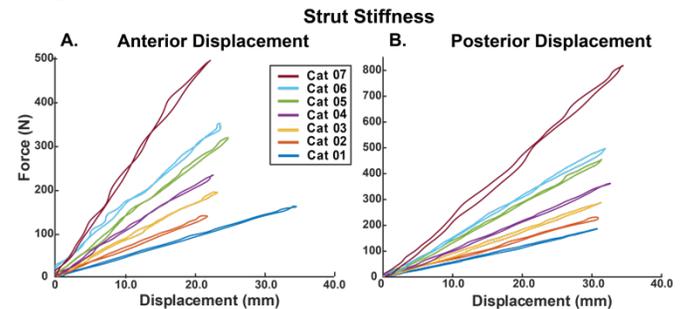

To evaluate AFO strut stiffness, we constructed a custom three-point bending apparatus to recreate the anterior and posterior deflection that typically occurs during ground contact for running. We applied force to 7 struts in three successive loading and unloading cycles, and reached a maximum deflection of 10° in the anterior direction and 7° in the posterior direction based on a previous study.<sup>6</sup> We measured force with

a force transducer (Omegadyne, Stamford, CT), deflection with motion capture (Vicon Nexus, Oxford, UK), and resolved each to be perpendicular with the strut.

We compared average  $R^2$  values from linear and curvilinear force-displacement for all strut categories. We also calculated average stiffness and used a linear regression model to compare stiffness values between strut categories. We used SPSS software (IBM, Chicago, Ill.) and significance of  $p < 0.05$ .

## Results and Discussion

Overall, a linear relationship best characterized the AFO strut force-displacement curves in anterior and posterior directions using a three-point bending apparatus (average  $R^2 = 0.998$ ). In the anterior direction, stiffness increased 2.01 N/mm for each increase in strut stiffness Cat (Fig. 2A). In the posterior direction, stiffness increased 1.90 N/mm for each increase in strut stiffness Cat (Fig. 2B). The exception was Cat 7, which increased 7.34 N/mm from Cat 6 to Cat 7 in both the anterior and posterior directions.

**Figure 2.** Force versus displacement in the anterior (A) and posterior (B) directions for carbon fiber AFO struts, categories (Cat) 1-7.

## Conclusion

Contrary to previous studies, we found that AFO carbon fiber struts exhibit linear force-displacement profiles. This linear relationship suggests that AFO struts have a constant stiffness, much like that of a biological ankle. AFO strut stiffness values changed systematically between categories with one exception. Future research is planned to better understand how a running-specific AFO with different strut stiffness, acting in parallel to the ankle, behaves in dynamic activities such as running.

# Optimized Hip-Knee-Ankle Exoskeleton Assistance at Different Speeds

G. M. Bryan<sup>1\*</sup>, P. W. Franks<sup>1</sup>, R. Reyes<sup>1</sup>, S. H. Collins<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Stanford University, Stanford, USA

Email: \*gbryan@stanford.edu

## Introduction

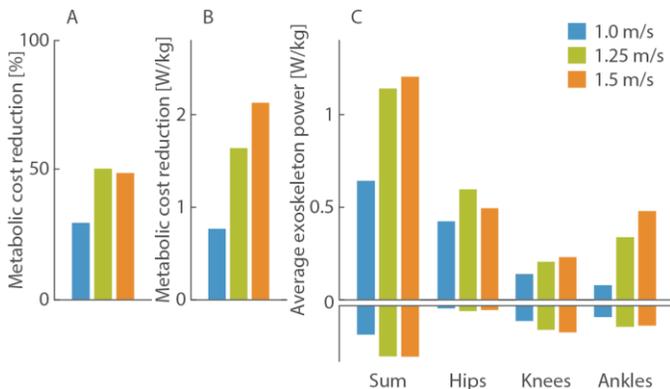

Exoskeletons have led to significant reductions in user energy expenditure during walking [1]. However, these studies are typically limited to one speed, whereas an effective autonomous device will need to assist at a variety of speeds. Optimal exoskeleton assistance at different walking speeds may mimic biological responses such that joint torque, angle excursion and power increase with speed [2]. To investigate the relationship between walking speed and ideal exoskeleton torque, we optimized assistance with a hip-knee-ankle exoskeleton [3] while the participant walked at slow, medium and fast speeds.

## Methods

We optimized multi-joint exoskeleton assistance to reduce user energy expenditure at three speeds with human-in-the-loop optimization [4]. One participant (male, 90 kg, 188 cm) walked with assistance for slow, medium and fast walking (1.0 m/s, 1.25 m/s and 1.5 m/s respectively), while we measured metabolic expenditure, exoskeleton joint angles and ground reaction forces.

## Results and Discussion

The participant experienced a 30% reduction in metabolic energy expenditure for slow walking and a 50% reduction for both medium and fast walking (Fig. 1 A). The participant saw the largest absolute reduction at fast walking (Fig. 1 B).

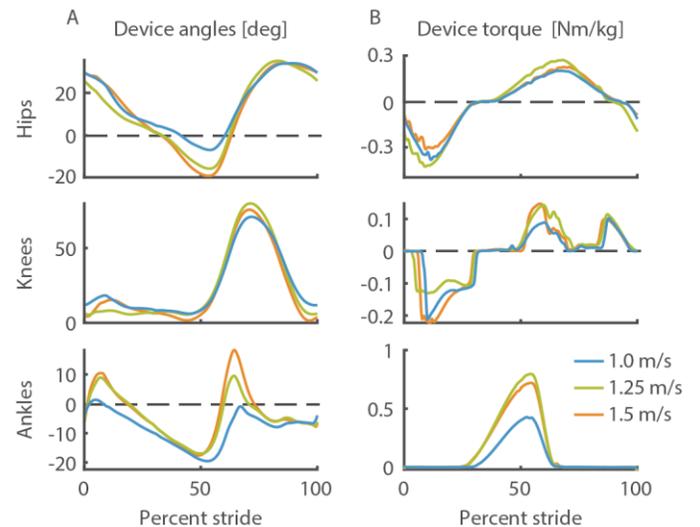

**Figure 1:** Metabolic reduction and exoskeleton power after optimization. (A) Metabolic reduction normalized to metabolic cost of walking with the device turned off. (B) Absolute metabolic reduction relative to walking with the device turned off. (C) Average positive and negative joint power at the hips, knees, ankles, and sum of all three. The y-axis scale for C is half the scale of B.

Ideal exoskeleton power did not linearly increase with speed like biological power. The exoskeleton provided the least amount of power for slow walking and similar amounts of power for medium and fast walking (Fig. 1 C). In contrast, the absolute reductions in metabolic cost increased with speed (Fig. 1 B). This suggests that exoskeleton power cannot fully explain reductions in energy expenditure.

Unlike biological torques, optimized exoskeleton torques did not increase monotonically with speed (Fig. 2 B). Ankle plantarflexion and knee flexion torque at toe off (60% of stride)

were the smallest for slow walking, and all other torque magnitudes were similar independent of speed. Effective torque profiles may work at a range of speeds, but it seems that push-off torque should be lower at slower speeds.

Biological joint angle excursion linearly increases with speed, but the joint angle excursion with assistance did not follow that trend (Fig. 2 A). The hips and ankles saw increased excursion greater than biological around toe-off. With assistance, the knee was relatively straight during stance. However, biological knee excursion during stance increases with speed to reduce the impact from heel strike.

**Figure 2:** Average exoskeleton joint angles and optimized, exoskeleton torques. (A) Average hip, knee and ankle device angles during optimized torque application. (B) Average applied hip, knee and ankle torque. The applied torques at the hip and ankle are torque-time profiles, and the applied torque at the knee is defined by a virtual spring during stance, time based flexion near toe off a virtual damper during late swing.

## Significance

Exoskeletons can reduce the metabolic cost of walking at a range of speeds, with largest improvements seen at faster speeds. Assistance may reduce energy expenditure by replacing positive work done by the muscles, but the positive device power does not fully explain the metabolic reductions.

## Introduction

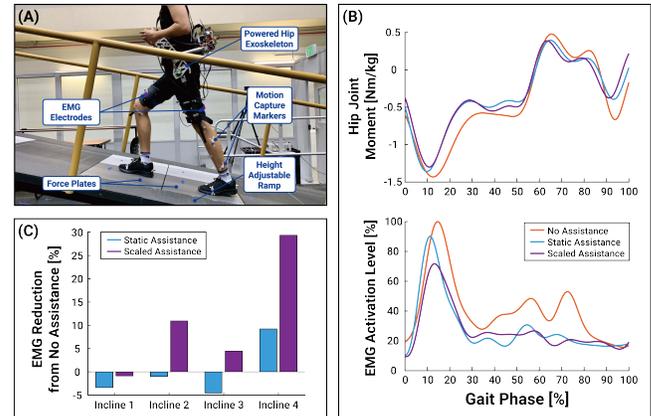

Over the last decade, research groups have explored methods to optimize different assistance strategies to maximize the human-exoskeleton performance in different environmental settings<sup>1</sup>. However, these studies were often conducted at a specific condition and did not capture what a user would experience in a realistic setting. Our previous study indicates that, for a given environmental setting, there is an optimal assistance to maximize the energetic benefit of using an exoskeleton<sup>2</sup>. To maintain an optimal control strategy for dynamic settings, the effect of adapting exoskeleton assistance across different locomotion intensities needs to be investigated. We utilized a powered hip exoskeleton to evaluate the biomechanical effect of applying adaptive assistance during uphill walking. Our hypothesis is that providing hip assistance during uphill walking that scales relative to the degree of incline will have a greater reduction in the corresponding electromyography (EMG) activation compared to the static assistance strategy.

## Methods

One able-bodied subject participated in an IRB approved experiment walking with a preferred walking speed on a height adjustable ramp in four different inclines (7.79°, 9.21°, 10.99°, and 12.42°) while wearing a powered hip exoskeleton (Fig. 1A). Our exoskeleton utilized a state machine-based torque controller providing a hip flexion/extension torque during the region where the corresponding biological hip moment is exhibited. Three exoskeleton conditions were tested: 1) scaling hip extension assistance magnitude relative to inclines, 2) static hip extension assistance across all inclines, and 3) no assistance (exoskeleton controlled to be transparent to the user's movement). Each condition at a given incline consisted of 8 trials of uphill walking. For both scaled and static assistance, flexion assistance magnitude was set constant. We utilized the biological hip moment data during ramp ascent to compute the desired hip extension assistance magnitude (20% of the user's biological hip moment) for different inclines for the scaled assistance condition<sup>3</sup>. For the static assistance condition, we computed the assistance magnitude to be nominal to the scaled assistance across all inclines. During the experiment, we collected motion capture data to analyze the user's kinematic data, instrumented force plate on the ramp for the ground reaction force data, exoskeleton data including the measured joint torque, and EMG data from the user's hip flexor and extensor region.

## Results and Discussion

Overall, our exoskeleton's hip extension assistance (for both controllers) was able to alleviate the corresponding biological demand from the user via reduction in joint moment and EMG activation. While our study is preliminary (N=1), biomechanical benefits of using our assistance strategy were consistent across trials. Across all inclines, scaled and static controllers reduced the average maximum biological hip extension moment (Fig. 1B) by  $8.84 \pm 2.94\%$  and  $4.66 \pm 1.30\%$ , compared to no assistance

**Figure 1:** A) Experimental setup for the study. Powered hip exoskeleton provides hip flexion and extension assistance during the gait cycle. B) Biomechanical effects of providing exoskeleton hip extension assistance during uphill walking (incline 4). Hip joint moment (top) and EMG activation for GM (bottom) are shown for scaled (purple), static (blue), and no assistance (red) conditions. C) Maximum GM EMG activation reduction relative to no assistance mode for scaled and static controllers across different inclines.

mode, respectively. Additionally, the scaled controller reduced the average maximum Gluteus Medius (GM) EMG activation by  $10.98 \pm 13.19\%$  compared to no assistance mode. However, across all inclines, scaled and static controllers increased the average maximum Vastus Medialis (VM) EMG activation by  $21.76 \pm 19.22\%$  and  $24.76 \pm 23.24\%$ , Rectus Femoris (RF) EMG activation by  $15.19 \pm 14.18\%$  and  $24.08 \pm 25.89\%$  compared to no assistance mode, respectively.

## Significance

Our results indicate that providing hip extension assistance during the early stance phase of the gait cycle can aid the user in reducing the relevant hip extensor EMG activation. While the kinetic results showed similar behavior between two controllers, the effect of these assistances showed significant differences in EMG activation. Not only did the scaled controller outperform the static controller by reducing a greater hip extensor EMG, it had lesser effects in antagonist muscles. From an energetics perspective (utilizing our analysis in multi channel EMG), our preliminary results illustrate that scalable assistance magnitude for the assistance may further improve the overall exoskeleton performance in uphill walking.

# Hip, Knee, Ankle and Multi-Joint Exoskeleton Assistance Can Reduce Metabolic Cost

Patrick W. Franks<sup>1</sup>, Gwendolyn M. Bryan<sup>1</sup>, Ricardo Reyes<sup>1</sup>, and Steven H. Collins<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Stanford University, Stanford, CA, USA

## Introduction

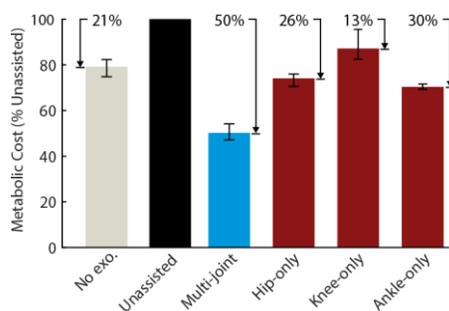

It is well known that exoskeletons can reduce the metabolic cost of walking, but what are the best ways to do so and what are the limits? For example, is it better to assist the hip or the ankle joint? Both joints are associated with a large portion of normal energy use [1] and assistance at each has yielded large improvements [2], but direct comparisons have yet to be made. A related question is: can knee-only assistance reduce metabolic cost? Knee musculature consumes significant energy [1], but assistance at this joint has yet to be effective during level walking. Even more interestingly, if we assist all three joints simultaneously, will the benefits be greater than the sum of their parts? The benefits might be greater, because coupled exoskeleton assistance can offload bi-articular musculature [3]. The benefits might be lesser, because assistance at one joint may already indirectly assist muscles at other joints [4]. And when assisting all joints simultaneously in the sagittal plane, how close can we come to completely eliminating the metabolic cost of walking? We can expect that some energy will be required for frontal and transverse functions, and perhaps for baseline muscle activity related to balance, but how much is unknown.

## Methods

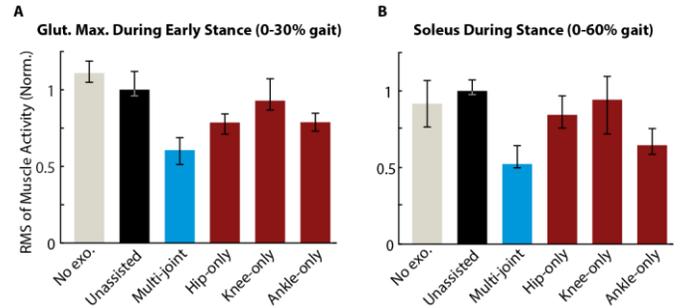

We used a hip-knee-ankle exoskeleton emulator to conduct human-in-the-loop optimization of exoskeleton torque to minimize measured metabolic cost of walking in a manner similar to [5]. Muscle activity was measured using surface electromyography in a manner similar to [6]. Three participants (2M 1F, 61-90 kg) completed the protocol.

## Results and Discussion

Hip-only and ankle-only assistance reduced the metabolic cost of walking by about 26% and 30% respectively (Fig. 1), confirming that both joints are good targets for assistance. Knee-only assistance reduced the cost of walking by 13%, demonstrating that effective knee assistance is indeed possible.

**Figure 1:** Metabolic cost of walking as a percentage of walking in the exoskeleton with no torque (black) for multi-joint assistance (blue) and each single-joint assistance (red), with bars as mean over three participants and range indicated by whiskers. Metabolic cost of walking is calculated by subtracting out the cost of quiet standing. For each assistance, percent reduction relative to no torque is shown.

**Figure 2:** Normalized root-mean-square (RMS) of measured muscle activity for walking without the exoskeleton (gray), in the exoskeleton with no torque (black), with multi-joint assistance (blue) and with each single-joint assistance (red), with bars as mean value and whiskers indicating range. Muscle activity was analyzed for the gluteus maximus (A) during early stance, estimated as 0-30% gait, when it is expected to be active, and for the soleus (B) during stance, estimated as 0-60% gait.

Multi-joint assistance reduced the cost of walking by 50%, the largest improvement to date, showing that at least half of the metabolic energy expended during walking can be saved through exoskeleton assistance. It remains to be seen whether this limit could be exceeded by assisting additional joint functions, such as hip abduction, or aiding balance. The total energy cost reduction was smaller than the sum of its parts (69%), consistent with the idea that optimal single-joint assistance derives a substantial portion of its benefit from indirectly assisting musculature at other joints. This is supported by the muscle activity of the gluteus maximus (Fig. 2A); activity decreased for hip-only and multi-joint assistance as expected, but also decreased during ankle-only assistance, indicating that the gluteus was indirectly assisted by ankle exoskeleton torque. This effect was less pronounced for the soleus (Fig. 2B), where hip-only assistance only slightly reduced muscle activity.

## Significance

Designers of exoskeletons can reduce the metabolic cost of walking by assisting any lower-limb joint in the sagittal plane, but the hip and ankle are the best single joints, and, at least when it comes to energy, all three is better, substantially.

# Biomechanics of individuals with and without lower limb amputation during dual-task walking

Sarah R. Bass<sup>1,3</sup>, Jonathan R. Gladish<sup>1,2</sup>, and Brad D. Hendershot<sup>1,3,4</sup>

<sup>1</sup>Walter Reed National Military Medical Center, Bethesda, MD, <sup>2</sup>Henry M. Jackson Foundation, Bethesda, MD, <sup>3</sup>Uniformed Services University of the Health Sciences, Bethesda, MD, <sup>4</sup>DoD-VA Extremity Trauma & Amputation Center of Excellence  
Email: sarah.r.bass3.civ@mail.mil

## Introduction

Although walking is considered to be primarily a motor task requiring little cognitive effort, individuals with lower limb amputation (AMP) may utilize additional cognitive resources while walking<sup>1</sup>. This may ultimately result in adaptations that lead to poor gait mechanics and increased risk of falls<sup>2</sup>. Previous research in individuals without AMP has shown reduced gait speed and increased gait variability during dual-task walking<sup>3</sup>, as well as variability in spatiotemporal characteristics of gait<sup>4</sup>. Here, we evaluated spatiotemporal features of gait (speed, stride length, and double limb support time) among individuals with and without AMP during dual-task walking, wherein the concurrent task varies in level of difficulty.

## Methods

Ten individuals with unilateral AMP (6 transtibial and 4 transfemoral) and thirteen uninjured controls (CTR) completed three N-back memory tasks (zero back [0B], one back [1B], and two back [2B]) while walking at a self-selected pace (4min each). Each task was completed in a virtual hunting environment, where participants were asked to hit a button on a handheld controller for ducks of matching colors. For the 0B task, participants were asked to only hit a duck matching a given color (e.g., red). For the 1B task, participants were asked to hit the ducks that matched the color of the duck displayed one prior (e.g., red, red). Lastly, for the 2B task, participants were asked to hit a duck that matched the color of the duck displayed two prior (e.g., red, blue, red).

All trials utilized a self-paced treadmill speed algorithm within the Computer Assisted Rehabilitation Environment (CAREN; Motekforce Link, Amsterdam, The Netherlands), which modulates belt speed by responding to changes in fore-aft position of the pelvis. Treadmill belt speed (300 Hz) and kinematic data (120 Hz) were collected continuously throughout the trial. Mean, standard deviation, and the coefficient of variation (COV) in gait speed (GS), as well as stride length (SL) and double limb support time (DLS), were computed within 20-second bins and then averaged across the trial. An independent samples t-test was used to compare group differences across tasks ( $p < 0.05$ ).

## Results and Discussion

SL were larger in the AMP vs. CTR group during the 1B ( $p=0.014$ ) and 2B ( $p=0.039$ ) tasks (Fig 1; left), but similar for the 0B task ( $p=0.064$ ). Across all three tasks, DLS time and GS were

not statistically different (0B-GS:  $p=0.407$ ; DLS:  $p=0.281$ ; 1B-GS:  $p=0.294$ ; DLS:  $p=0.155$ ; 2B-GS:  $p=0.425$ ; DLS:  $p=0.385$ ) between the AMP and CTR groups. Although not statistically different (0B- $p=0.097$ ; 1B- $p=0.397$ ; 2B- $p=0.0145$ ), GS COV tended to be larger among the AMP group (Fig 1; right).

Overall, the CTR group walked with a more conservative and less variable gait, evidenced by slower GS, shorter SL, and longer DLS; all of which are gait adaptations that have been associated with enhanced balance, improved gait stability, and decreased falls<sup>5</sup>. Faster GS, as well as longer SL, therefore suggest the AMP group may be more susceptible to falls during dual-task walking or in response to a trip-inducing perturbation<sup>5</sup>. Furthermore, greater variability in GS and SL may also be associated with an increased risk of falls.

Alterations in spatiotemporal gait characteristics were observed in both groups, suggesting walking became more unstable as task difficulty increased<sup>3</sup>. This may indicate, as shown previously with electroencephalography, that greater cognitive resources are utilized as (concurrent) task difficulty increases<sup>4</sup>.

## Significance

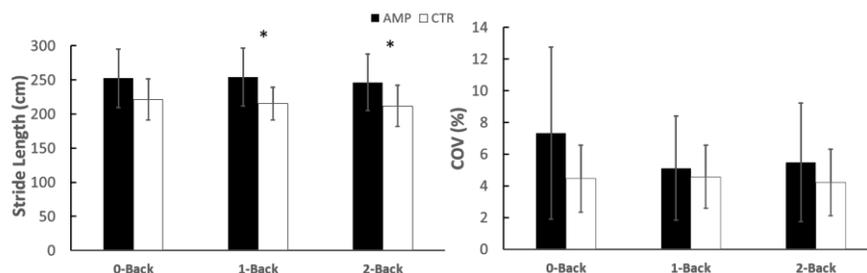

The current study extends previous studies suggesting dual-task walking can lead to poor gait mechanics, and may have implications on the rehabilitation of individuals with AMP; specifically, perhaps incorporating dual-task walking into the rehabilitation plan, which may ultimately assist in mitigating falls during community ambulation.

Email: \*[ktpognc@stanford.edu](mailto:ktpognc@stanford.edu)

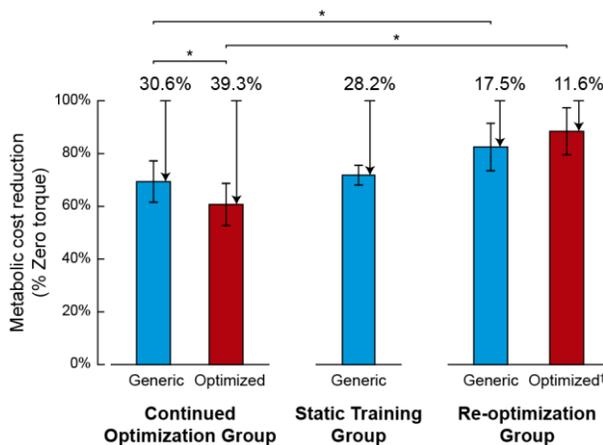

## Introduction

Human-in-the-loop optimization (HILO) methods can be used to identify customized device parameters to best assist human walking [1]. One of the unique features of these methods is that while the algorithm is identifying the ideal parameters, the human is experiencing a range of possible candidate controllers. The long periods of exposure time as well as the variation in the experienced controllers have been suggested as possible reasons HILO can also be used as a training protocol.

We conducted an experiment to determine how training and customization affect exoskeleton performance. We hypothesize that the extended training will contribute the most to reductions in metabolic cost, while customization will provide additional benefit. We also expect a moderate amount of variation to result in better outcomes than static exposure to a fixed controller.

## Methods

Naïve participants (N=15) were randomly sorted into three groups for a six-day protocol. The first day of testing served as a pre-test to determine performance with a generic assistance profile relative to baseline walking trials. On each subsequent day, participants experienced a group-specific adaptation trial for 74 minutes followed by short validation tests. One group (continued optimization) experienced HILO as in [1], where each day was a continuation from the previous day. Another group (static training) experienced the generic assistance for the duration of the adaptation block to decouple the effects of time on training. The final group (re-optimization) experienced HILO with a reset on each day to understand the effects of variation on learning. All groups experienced the generic assistance trial and baseline walking trials during the validation tests. The two optimization groups also experienced their optimized profiles from the end of the adaptation period.

**Figure 1:** Metabolic costs of exoskeleton walking under different types of training, with respect to a zero torque condition. The optimized assistance for individuals in the continued optimization group resulted in the largest reduction in metabolic cost by any exoskeleton to date. The response to the generic condition was significantly worse for the re-optimization group compared to the continued optimization group, suggesting that too much variation can interfere with training.

## Results and Discussion

Initially participants receive very little benefit from exoskeleton assistance, with  $10.0 \pm 11.0\%$  reduction in energy cost compared to walking in a zero torque condition. By the end of the experiment, the continued optimization group exhibits a  $30.6 \pm 8.1\%$  energy cost reduction in response to the generic profile and a reduction of  $39.3 \pm 8.2\%$  for the optimized profile, compared to the zero torque conditions. The latter result is the largest reduction in metabolic cost with an exoskeleton to date. In response to the generic profile, all participants learned to reduce their metabolic cost (Fig. 1).

Participants in the static training group reduced their energy cost by a statistically similar amount by the end of the experiment, though at a slower rate. This result indicates that some amount of variation may speed training. Participants in the re-optimization group were significantly worse at walking with the generic assistance by the end of the experiment than participants in the continued optimization group, indicating that there is a limit to the amount of beneficial variation training. Because this group was not properly trained, their customized profiles were less beneficial.

In addition to reducing the energy cost of walking, participants simultaneously reduced the mechanical power received from the ankle exoskeleton. This result is in contrast with the idea that increasing mechanical power should decrease the metabolic cost of walking with an assistive device.

These results illustrate the importance of training in exoskeleton studies. Customization can also increase the benefits of walking with an assistive device, provided that the user is properly trained. Previous exoskeleton failures may have actually been failures of training.

## Significance

Exoskeletons can enhance human mobility, but we still know little about why they are effective. In this study, people learned how to use ankle exoskeletons through different training methods. Their performance was measured to understand the relative importance of training, human adaptation, and device customization. We found large benefits, reducing the energy cost of walking by 39%, of which about half was due to training and a quarter to customizing assistance. Training type had a strong effect on training time and expertise. Our results show that work to improve training could be more important than robot design for developing better gait aids.

# Achilles Shear-Wave Tensiometry During Walking With a Passive Exoskeleton: A Proof-of-Concept

Dylan G. Schmitz<sup>1</sup>, Darryl G. Thelen<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, USA

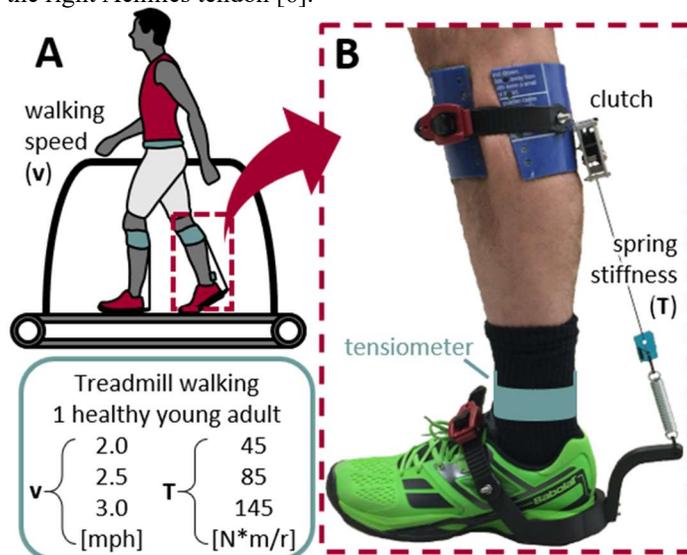

Email: [dgschmitz@wisc.edu](mailto:dgschmitz@wisc.edu)

## Introduction

Passive exoskeletons that can reduce the metabolic cost of locomotion have garnered considerable interest [1,2]. Subsequent studies have probed the biomechanical factors that underlie metabolic improvement by: 1) modeling muscle-tendon actions in the presence of passive assistance [3] and 2) measuring how exoskeletons alter natural gait and muscle-tendon mechanics [4,5]. Such studies have shown that passive elastic torque about the ankle during push-off alters the operating lengths and velocity of the triceps surae and that such effects are speed-dependent [4]. Hence, it is important to understand how such modulations of muscle kinematics affect force production of the muscle-tendon unit when passive assistance is provided. We have begun investigating this question by using shear wave tensiometry to gauge changes in in Achilles tendon force patterns with and without passive assistance.

## Methods

We built passive ankle exoskeletons based on the design of Collins et al. 2015 [1]. The clutch was 3D printed from fiberglass-reinforced nylon. The exoskeleton attached to the shank with a calf wrap and to the foot with a fiberglass-reinforced heel cup. A spring was attached in parallel with the clutch (Fig. 1). A healthy young adult walked on a treadmill while wearing the passive exoskeleton bilaterally. After adequate adaptation to walking with the exoskeleton, a grid of three speeds [2.0, 2.5, 3.0 mph] and four stiffnesses [0, 45, 85, 145 N\*m/rad] (12 total conditions) were enforced. Shear wave speed was measured at 50 Hz for 10 sec at each condition using a shear wave tensiometer secured over the right Achilles tendon [6].

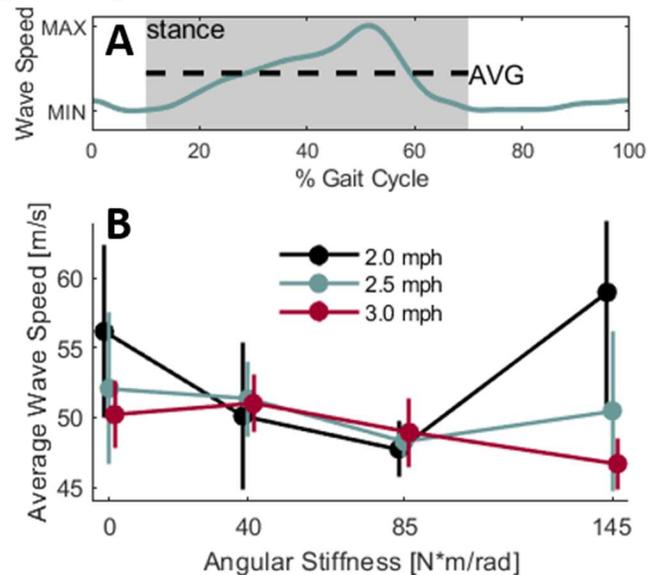

**Figure 1:** A) Treadmill walking at three speeds and four spring stiffnesses. B) The passive exoskeleton, based on [1].

## Results and Discussion

Both walking speed and spring stiffness markedly influenced the tendon wave speed patterns (Fig. 2). For all speeds, tendon wave speed magnitudes decreased with some level of elastic assistance,

suggesting that the exoskeleton was successful in offloading the triceps surae. The greatest reduction in tendon loading occurred at an effective ankle spring stiffness of 85 Nm/rad (2, 2.5 mph) or 145 Nm/rad (3 mph), depending on the walking speed. These stiffnesses are lower than that observed by Collins et al. [1], but could result from our calf wrap introducing additional compliance into our system. Achilles tendon wave speeds were most sensitive to spring stiffness at slower walking speeds, which is consistent with subjective assessments and may arise from the slower walking speed being considerably below the subject's preferred speed.

**Figure 2:** A) Stride-average wave speed profile (2.5 mph, 145 N\*m/rad shown). B) Average stance wave speed for each condition (10-70% gait cycle). Standard deviations were computed on per-stride averages within each condition.

## Significance

This pilot study demonstrates that shear wave tensiometry can detect changes in tendon loading arising from the use of exoskeletons. The simple noninvasive nature of shear wave sensors could be leveraged to track biomechanical adaptations arising from exoskeletons during unconstrained locomotion outside a laboratory. Such usage could aid translation by uncovering the benefits and detriments of real-world use of exoskeleton usage, and thereby improve devices designed for gait compensation, rehabilitation, and augmentation.

Email: [john.chomack@va.gov](mailto:john.chomack@va.gov)

## Introduction

A well-fitting prosthesis is essential for individuals with lower extremity amputation (LEA) to achieve functional independence and reduce secondary comorbidities [1]. However, common clinical practices often hold subjective and observable input above objective, quantifiable outcomes during prosthetic fitting and fabrication, which can limit independence. Currently there is little existing data on dynamic, in vivo residual limb-socket kinematics, but an advanced imaging technology, known as Dynamic Stereo X-Ray (DSX), can detect submillimeter in-vivo bone movement in 6 degrees of freedom. The goal of this study was to quantify in-vivo bone movement for individuals with transfemoral amputation (TFA) using two socket types: compression/release and stabilization (CRS) and traditional encapsulation and containment (TRAD). We hypothesized that the CRS socket would provide greater rotational and translational control the the residual femur compared to the TRAD socket.

## Methods

Five individuals with unilateral TFA were recruited from Veterans Affairs New York Harbor Healthcare System (VANYHHS) and the Providence Veterans Affairs Medical Center (PVAMC). Participants were randomized to start with either the TRAD or CRS and acclimated to the sockets for 4 weeks each. Participants then received CT scans of their residual limb and sockets and completed DSX and optical motion capture (OMC) testing at Brown University. DSX was utilized to record dynamic X-ray sequences in a 60° antero-posterior orientation simultaneously with OMC for 16 trials of treadmill walking at self-selected (SS) speed (0.36 - 0.80 m/s) recorded at 120fps. CT scans of the residual femur were segmented, creating 3D polygonal mesh objects and a digitally rendered radiographs (DRR) in a DSX suite of software (C-Motion, Germantown, MD). Image data was then calibrated and time synchronized to the OMC data. Residual femur DRRs were matched to two non-coplanar views of the X-ray video sequences. DRRs were manually positioned in each view to match the X-rayed femur which generated an exact bone pose (position and orientation) during the gait cycle. A biomechanical assessment of the DSX bone pose and OMC data was performed in Visual3D (C-Motion, Germantown, MD) producing kinematic motion of the residual bone within the socket. Residual femur movement was expressed as the excursion of the translations and rotations between TRAD and CRS sockets. To assess soft-tissue artifact, a linear fit method (LFM) was used to quantify the agreement between knee kinematics derived from both the DSX and OMC data.

## Results and Discussion

The TRAD socket had significantly less axial translation ( $1.55 \pm 0.66\text{cm}$ ) compared to the CRS socket ( $2.03 \pm 0.59\text{cm}$ ;  $P < 0.05$ ) (Figure 1) during SS treadmill walking. No other differences were found in the anteroposterior and medial-lateral translations or rotations in any plane. While the CRS socket was designed to

stabilize the residual femur through strategically placed struts in the socket wall, it offered less axial control of the residual limb. It may be necessary to increase the localized

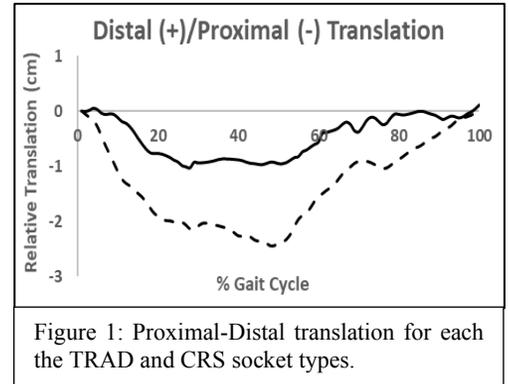

Figure 1: Proximal-Distal translation for each the TRAD and CRS socket types.

pressure of the struts to improve axial control of the femur, but due to the thickness of the thigh, this may not be tolerable to the patient or may severely reduce blood perfusion to the tissue [2]. The LFM analysis was used to determine the agreement of knee kinematics derived from DSX and OMC data. No significant differences in  $R^2$  values for the sagittal, transverse, and frontal planes were found between socket conditions ( $P > 0.5$ ). Average  $R^2$  values showed strong agreement between DSX and OMC in the sagittal plane for both the CRS ( $0.934 \pm 0.07$ ) and TRAD ( $0.922 \pm 0.04$ ) sockets, which was in contrast to the  $R^2$  values for the medial-lateral (CRS:  $0.502 \pm 0.30$ ; TRAD:  $0.359 \pm 0.25$ ) and axial (CRS:  $0.177 \pm 0.10$ ; TRAD:  $0.259 \pm 0.12$ ) planes. These results reinforce OMCs limited capabilities of tracking residual limb movement during gait in non-sagittal planes, while also demonstrating the capability of DSX to accurately evaluate in-vivo, dynamic bone movement of the residual limb within a prosthetic socket.

## Significance

Ensuring a proper socket fit is partially predicated on the analytical and experimental tools that aid in modeling bone pose within a prosthetic socket. DSX demonstrated the ability to detect small changes in bone movement between different socket designs during dynamic movements. Furthermore, LFM analysis showed the systematic differences between DSX and OMC and the ability of DSX to accurately track underlying residual bone movement. The ability to accurately assess the dynamic interaction between the residual limb and socket is necessary to develop effective, evidence based prosthetic solutions to reduce secondary physical comorbidities and degenerative changes that result from complications of poor prosthetic load transmission.

## Introduction

Following mastectomy for breast cancer, most women will have a breast reconstruction to return the look and feel of healthy breast tissue. The most popular reconstructive approach is a subpectoral tissue expander and implant, which requires the disinsertion of the pectoralis major muscle from its inferior attachments. The pectoralis major is a primary contributor to shoulder adduction and internal rotation. Clinical practice assumes that the remaining, intact shoulder musculature increase their contributions to shoulder function in the absence of the pectoralis major<sup>1</sup>. However, there is no empirical evidence to suggest this occurs. Therefore, the purpose of this study was to assess how patients adapt their neuromuscular compensation strategies at the shoulder following bilateral subpectoral implant breast reconstruction.

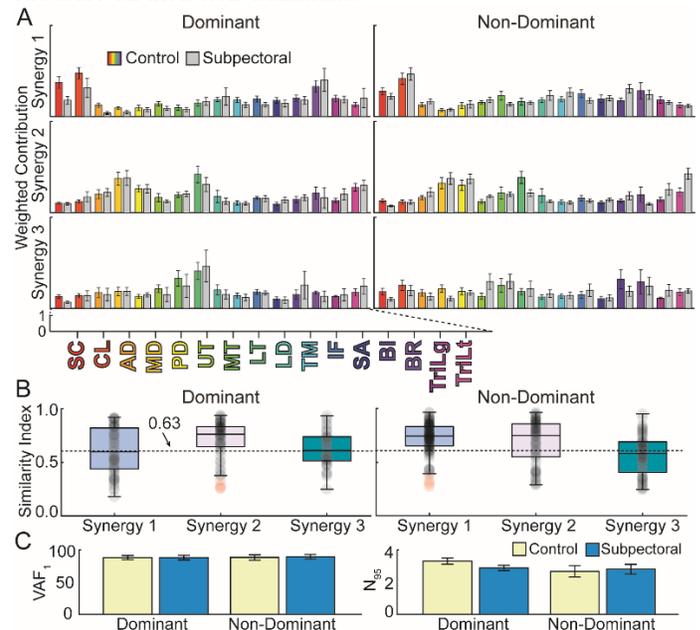

## Methods

Fourteen bilateral subpectoral implant breast reconstruction patients (>2.5 years post-operative, mean±SE age: 49±3 yr, height: 1.66±0.1 m, weight: 73±4 kg) and 10 healthy controls (age: 55±2 yr, height: 1.62±0.2 m, weight: 62±2 kg) generated maximum voluntary shoulder torques with their dominant and non-dominant arms. Participants then performed 8 submaximal, three-dimensional shoulder torques in 5 arm postures bilaterally. Each arm was assessed in a random order. Surface electromyography recorded activity from 16 shoulder muscles per arm<sup>2</sup>. Non-negative matrix factorization revealed the muscle synergies underlying shoulder torque generation, while the normalized similarity index (SI) assessed between group synergy similarity. An SI ≥0.63 indicated two synergies were more similar than is expected by chance. Neuromuscular complexity was evaluated using the total variance accounted for by the principal (first) synergy (VAF<sub>1</sub>) and the number of synergies required to account for more than 95% of variance in experimental data (N<sub>95</sub>). Group and arm differences in shoulder strength were assessed with linear mixed-effects models. A linear mixed-effects model assessed group and arm differences in VAF<sub>1</sub> while Kruskal-Wallis tests assessed differences in N<sub>95</sub>.

## Results and Discussion

Our experimental groups did not differ with regard to shoulder strength on either arm (all p>0.11). Three-dimensional torque generation was described by three muscle synergies, regardless of group or arm (Figure 1A). These synergies were visually similar to shoulder muscle synergies previously derived from healthy participants<sup>2</sup>. Synergy structure was influenced by subpectoral implant breast reconstruction only on the dominant arm (Figure 1B). Specifically, Synergies 1 and 2 were more similar than expected by chance between the groups on the non-dominant arm, whereas only Synergy 2 was more similar than expected by chance on the dominant arm. Synergy 1 is characterized by primary contributions from the pectoralis major. A reduction in contributions from the sternocostal fiber region of the pectoralis major is likely driving differences in the structure of Synergy 1 between the groups on the dominant arm. This is not surprising given this region of the muscle is most impacted by subpectoral implant breast reconstruction. Interestingly,

bilateral subpectoral implant patients do not experience those same adaptations on the non-dominant arm. An assessment of neuromuscular complexity, as measured by VAF<sub>1</sub> and N<sub>95</sub>, revealed no differences between our experimental groups, regardless of arm (all p>0.07). Combined with our findings regarding muscle synergy structure, these results suggest that subpectoral implant breast reconstruction patients maintain neuromuscular complexity after surgery by altering synergy structure on their dominant arm, and maintaining synergy structure on their non-dominant.

**Figure 1:** (A) Non-negative matrix factorization revealed the synergies underlying shoulder torque generation on the dominant and non-dominant arms of our experimental groups, while the SI (B) assessed group differences in synergy structure. (C) Neuromuscular complexity was assessed using the total variance accounted for by the principal synergy (VAF<sub>1</sub>) and the number of synergies required to account for more than 95% of variance in experimental data (N<sub>95</sub>). Bars represent mean ± SE, while boxplots represent median ± interquartile range.

## Significance

Clinical practice assumes that intact synergist muscles increase their contributions to shoulder function following the disinsertion of key shoulder musculature such as the pectoralis major. The current study provides the first ever evidence of this phenomena, by quantifying changes in shoulder muscle synergy structure and neuromuscular complexity following bilateral subpectoral implant breast reconstruction. The results of this work provide insight into other clinical situations where an otherwise intact nervous system must adapt to the disinsertion of shoulder musculature, such as in the reconstruction of large resections of tissue using latissimus dorsi or serratus anterior muscle flaps<sup>3,4</sup>.

## Introduction

Traditionally, young children with limb loss who require a prosthetic knee joint do not receive a working knee in their initial prosthesis, based on the assumption that a child cannot learn to stand and walk with a knee that can passively flex. An alternative to this "Traditional Knee" (TK) prescription protocol is an "Early Knee" (EK) protocol that provides a working, articulating knee in the first prosthesis, during development of crawling.

The timing of knee provision is controversial. Even within the same medical text, different chapters provide conflicting advice to clinicians.<sup>1</sup> A few previous studies have noted advantages of the EK protocol,<sup>2,3</sup> but no study has characterized gait of separate samples of children in each protocol. The purpose of this study was to describe knee flexion and clearance adaptations in young children at a site where TK is the standard of care and a site where EK is the standard of care, along with age-matched typically developing children.

## Methods

This was a multi-site comparison with a convenience sample of 18 children aged 12 months to five years in three groups: six with unilateral lower limb loss at or proximal to the knee at an EK site, six with unilateral lower limb loss at or proximal to the knee at a TK site, and six age-matched typically developing controls (C). Children with limb loss used their prosthesis daily without assistive devices and had the same knee protocol from the time of their first prosthesis. Fitting and alignment of each prosthesis was performed by an ABC board-certified prosthetist with pediatric experience at each hospital. The protocol was approved by human subjects review boards at each institution, and informed parental consent was obtained.

To ensure inter-lab reliability, a single typically developing four-year-old test subject was assessed at both sites within two weeks in a separate, approved protocol. Both laboratories utilized similar Vicon motion capture systems with identical models and software, and examiners followed standardized video training for marker placement.

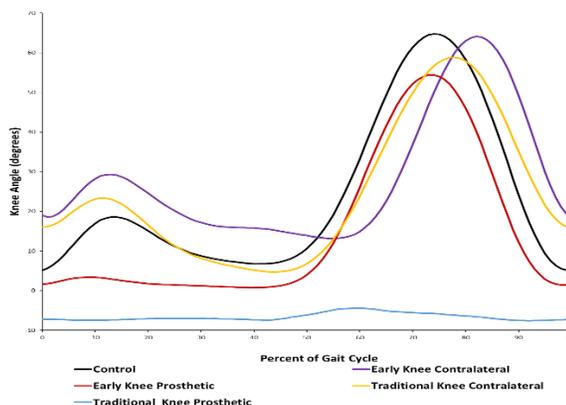

Children at each site walked at self-selected speed on a level overground walkway with no external assistive devices. Temporospatial and kinematic data were analysed. Three of the authors reviewed reconstructed 3D motion from each trial for each subject to provide subjective documentation of clearance adaptations. Observers were blinded to condition. The two clinicians (CC and BG) were primary observers, and the third (MG) broke any ties. These results were compared to literature-based numerical calculations for hip hiking, valuting, and circumduction.

## Results and Discussion

Two children (one EK and one TK) were excluded from the final analysis. One was the only subject to use crawling as the primary mode of ambulation, and one had recently transitioned from a locked to an articulating knee at the time of the study. Therefore, the data from sixteen children were analyzed. All EK and TK

subjects had congenital limb deficiencies. The TK group had a mean age of  $25.20 \pm 9.04$  months, and the reasons for amputation were varied. The EK group had a mean age of  $44.60 \pm 22.15$  months, and all had Proximal Femoral Focal Deficiency (PFFD). Differences between groups affected analysis. An age-matched C was recruited for all TK and EK children, but direct age-matched comparisons between EK and TK were limited. Therefore, analysis focused on description of gait in each group, with consideration of relative levels of development.

All children in the EK group flexed their prosthetic knees during swing (Fig 1). Mean prosthetic peak knee flexion over all steps and all EK subjects was  $59.8^\circ \pm 8.4^\circ$ . The mean for the C group was  $68.4^\circ \pm 3.8^\circ$ . Contralateral side knee flexion was  $69.3^\circ \pm 5.8^\circ$  and  $75.0^\circ \pm 5.5^\circ$  for EK and TK, respectively.

**Figure 1:** Knee flexion angle (degrees), averaged for right and left for C, and displayed separately for prosthesis side and contralateral side for EK and TK.

Clearance adaptations were present in both prosthesis groups, and some children utilized multiple adaptations. Based on clinical observation, no adaptations were present in the C group, six were observed in the EK group, and twelve in the TK group.

## Significance

Young children with limb loss utilize a flexing prosthetic knee joint if it is provided to them. Given that there is often no monetary cost associated with provision of a knee joint in the first prosthesis, and the possibility of improved gait, the Early Knee protocol should be considered as a standard of care, replacing the traditional protocol.

### Introduction

A wide range of abnormal gait parameters have been well documented in concussed populations. While most of the previous research examined gait over flat surfaces<sup>1</sup>, uneven terrain is regular in everyday life. Walking over uneven terrain requires constant pre-planning and cortical control of gait. Prior to stepping on uneven terrain, anticipatory adjustments to trunk position are often used to mitigate the effects of the upcoming disturbance.<sup>2</sup> Concussion-related motor deficits may alter the ability to select appropriate motor plans prior to a known gait disturbance. For instance, concussed athletes demonstrate altered trunk motion when crossing a known obstacle.<sup>3</sup> However, such obstacle crossing studies still maintained a flat support surface around the obstacle. Few, if any studies have examined the effects of concussion to underfoot perturbations common in everyday life, such as stepping on a small rock or pebble.

The purpose of our study was to compare anticipatory adjustments to expected overground perturbations delivered by a mechanized shoe in healthy and recently concussed adults. We hypothesized that the concussed and control groups would differ in their preparations for expected perturbations.

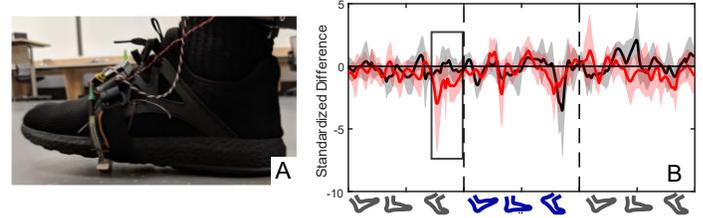

### Methods

Five healthy [4F, mean (SD) age = 23.8 (4.7) yrs] and five recently concussed [2F, mean (SD) age = 24.6 (5.2) yrs] adults provided informed written consent and participated in this IRB-approved study. Each participant wore a pair of custom mechanized shoes containing a small aluminum block just proximal to the 5<sup>th</sup> metatarsophalangeal joint.<sup>4</sup> The small block was recessed into the sole of the shoe and could rotate outward, eliciting approximately 12° of eversion when it was deployed.

While wearing the shoes, participants completed several walking trials including walking with and without a perturbation. During 12 of the 36 trials, a single perturbation was delivered to the left foot at a random step in the trial. Half of the perturbation trials contained a loud beep one stride prior to the perturbation to warn the participants of the upcoming disturbance. Four of these expected perturbations occurred within a randomized block consisting of trials with and without the perturbation.

Inertial sensors were placed at the feet, lumbar region, trunk and wrists to collect accelerations, angular velocities and magnetic field potentials during walking. Raw data were collected at a sampling frequency of 128 Hz and filtered with a 4<sup>th</sup> order recursive low-pass Butterworth filter with a cutoff frequency of 10 Hz. Data was processed with a continuous wavelet transform to identify specific gait events, and for trials with a perturbation, the time of the perturbation. Data for the stride prior to, during and following the perturbation was isolated and each stride segment was time normalized to 200 samples. The standardized mean difference of accelerations between perturbation and non-perturbation trials was calculated for each subject using 1-dimensional statistical parametric mapping (1D SPM). The mean of the standardized difference for the region one quarter of a stride before the perturbation was calculated for the left foot and trunk and a mixed-effects model compared the effect

of group and sensor on this mean standardized difference with post-hoc pairwise t-tests.

**Figure 1A.** Example of perturbation delivered from the mechanized shoe. **Figure 1B.** Standardized mean difference of accelerations between expected perturbation and non-perturbation trials for control (black) and concussed (red) subjects. The box indicates the 1/4 stride before the perturbation extracted for analysis.

### Results and Discussion

The mixed-effects model revealed no difference between groups at the foot sensor. However, there was a difference at the trunk sensor and a group-by-sensor interaction. A post-hoc t-test confirmed the between groups difference at the trunk sensor ( $p=0.03$ ,  $d=-1.64$ ). The results indicate that the concussed group prepared by limiting their lateral trunk movement prior to the upcoming perturbation while the control group did not alter their trunk motion relative to a normal stride. A reduction of trunk acceleration increases stability at the trunk during walking and limits the likelihood of a loss of balance. The conservative strategy used by the concussed group is similar to the strategy seen in other neurodegenerative populations, such as older adults, walking over uneven terrain.<sup>5</sup> The reduction of trunk movement prior to the perturbation suggests that the individuals with concussion may overestimate the scale of the perturbation.

The small sample size and reliance on acceleration limit our conclusions. Future work will explore these effects in a larger sample using positional marker data in addition to accelerations.

### Significance

Individuals with recent concussion demonstrated anticipatory trunk motion prior to a small expected perturbation. This trunk motion, not observed in controls, may reflect a compensatory strategy to maintain balance when confronted with uneven terrain common to everyday living.

# Stress Provides a Lower-Bound Estimate of Shear Wave Velocity in Skeletal Muscle

Tom Sandercock<sup>1</sup>, Michel Bernabei<sup>2</sup>, Sabrina Lee<sup>3</sup>, and Eric Perreault<sup>2,4</sup>

## Introduction

Shear wave elastography can be used to characterize the mechanical properties of unstressed materials. This technique, which involves measuring shear wave propagation, has been used to study muscle during loaded and unloaded conditions. In many studies of contracting muscle, measurements of shear wave velocity (SWV) have been assumed to be directly related to the material properties of muscle, most commonly stiffness. Some have also used measures of SWV to estimate force, since muscle stiffness and force covary during active contractions. However, few have considered the direct influence of muscle force on SWV, independent of the force-dependent changes in muscle stiffness, even though it is well known that force in a material influences shear wave propagation [2]. We previously used an experimental manipulation to demonstrate that SWV is sensitive to changes in muscle stiffness that occur independent from changes in muscle force [1]. Here we perform a complementary experiment to evaluate the influence of force on SWV. Our purpose was to determine how well changes in muscle force alone can explain measurements of SWV in passive and active muscles.

## Methods

Experiments were designed to test the null hypothesis that force alone could be used to predict SWV, comparing experimentally measured changes in SWV to predictions from a theoretical model of shear wave propagation [2]. Data were collected from six isoflurane-anesthetized cats; three soleus muscles and three medial gastrocnemius muscles were tested. Muscle force was measured directly along with SWV, the latter using ultrasound elastography. Measurements were made across a range passively and actively generated forces, obtained by varying muscle length and activation. Some muscle lengths were well beyond physiological lengths. Activation was controlled by stimulating the sciatic nerve. Muscles not being tested were denervated. Measured forces were normalized by physiological cross-sectional area resulting in estimates of stress that could be compared across muscles.

## Results and Discussion

We found that the theoretical model of how stress influences SWV predicted our experimental results well for passively stretched muscles (Fig. 1). The errors for this model were not significantly different from zero ( $0.20 \pm 0.22$  m/s; mean  $\pm$  95% CI;  $p=0.08$ ). In contrast, this same model significantly underpredicted the SWV in active muscles ( $2.72 \pm 0.44$  m/s;  $p<0$ ). Results were consistent in the soleus and medial gastrocnemius muscles, suggesting our results generalize across muscles with different architectures and fiber types. These findings demonstrate that SWV is sensitive to changes in muscle stress and that a model of how stress influences SWV can be used to predict the SWV in passively stretched muscles. This same model provides a lower bound on the SWV in active muscle,

presumably due to activation-dependent changes in muscle stiffness. Together, our results provide further clarity on the factors influencing shear wave propagation in muscle.

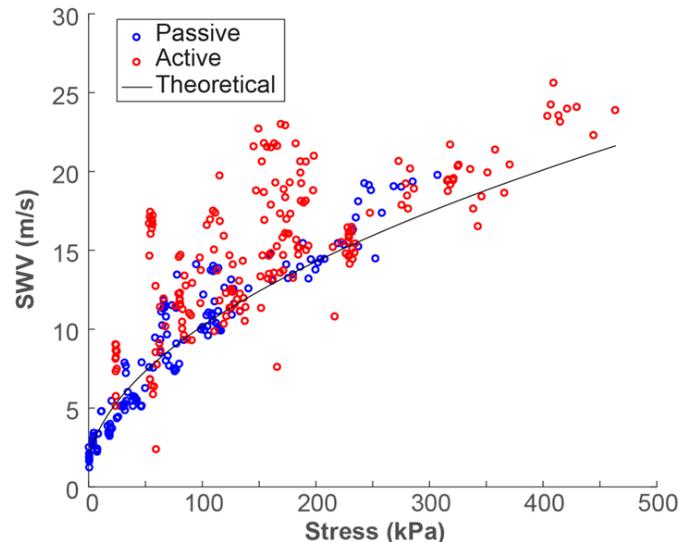

Figure 1. Comparison of experimental data and theoretical model describing stress-dependent changes in shear wave velocity (SWV). Data are from passively stretched and actively contracting soleus and medial gastrocnemius muscles.

## Significance

Our results show SWV provides a good measure of passive tension. Active tension is more complex and our results suggest changes in muscle stiffness also contribute to SWV. SWV may provide a good tool to measure muscle properties, but before it can be used in active muscle the source of the increase in SWV must be understood.

# 3D Model of the Soleus Reveals Complex Muscle Fascicle and Aponeuroses Deformations during Passive Stretch

Katherine R. Knaus<sup>1</sup> and Silvia S. Blemker<sup>1</sup>

<sup>1</sup>Department of Biomedical Engineering, University of Virginia, Charlottesville, VA; Email: \*ker4e@virginia.edu

## Introduction

The soleus muscle is an important generator of the plantarflexion torque required for locomotion. In musculoskeletal simulations, which are widely used to understand typical and pathologic gait, muscle function is predicted using lumped-parameter models. These models assume a simplified representation of 3D muscle fascicle architecture while combining the mechanical behavior of the external tendon and aponeuroses into a single series elastic element. The soleus muscle has complex 3D fascicle architecture comprising multiple compartments with different pennation<sup>1,2</sup> as well as complex aponeurosis morphology with broad and thin interdigitating structures that differ significantly from the thick external Achilles tendon<sup>3</sup>. In the case of the soleus, a lumped parameter model cannot fully represent the interaction of the muscle fascicles and aponeuroses and may not accurately predict this muscles' *in vivo* force generating capacity.

Our goal was to develop a finite element (FE) model of the soleus that represents its complex 3D structure in order to simulate excursion of this muscle during ankle motion. We hypothesize that the model will predict deformations in the aponeuroses and fascicle length changes that differ between the anterior and posterior portions of the soleus and would then be inconsistent with the assumptions of a lumped-parameter model.

## Methods

Based on segmentations of high-resolution magnetic resonance images of the lower limb, a 3D geometric model of the soleus muscle was constructed with distinct structures for the anterior and posterior muscle compartments and the anterior and posterior aponeuroses. Fiber directions were assigned for each muscle geometry, using aponeuroses surfaces to define fiber origins and insertions, by performing Laplacian flow simulations<sup>4</sup>.

To perform FE simulations, the 3D model was meshed into tetrahedral elements. Muscle was modelled as a transversely isotropic material using the assigned fiber directions, while aponeurosis was modelled as an isotropic Neo-Hookean material. To simulate passive soleus stretch in ankle dorsiflexion, the distal end of the posterior aponeurosis, at the Achilles tendon attachment, was displaced 20 mm distally, while the attachments of the anterior aponeurosis to the tibia and fibula were fixed.

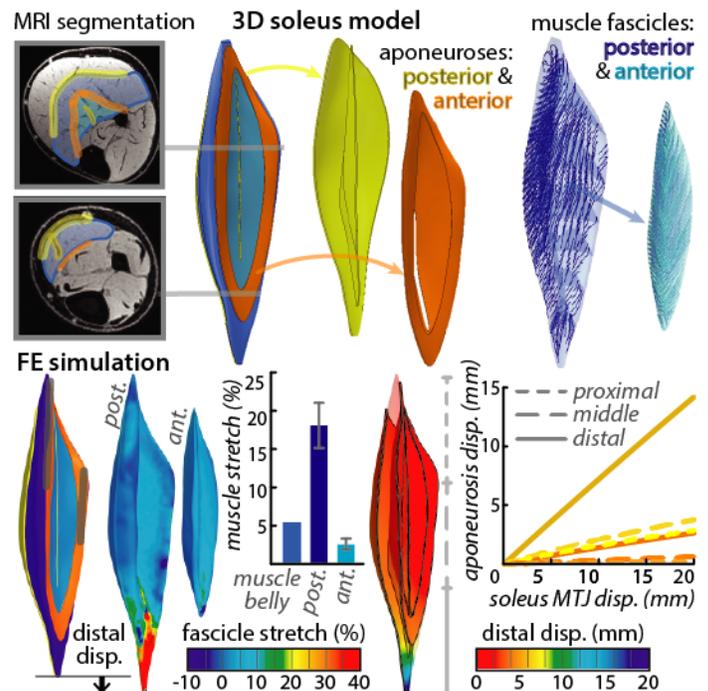

To validate predicted architecture, fascicle tracts were created with streamlines and compared to soleus measurements made with diffusion tensor imaging (DTI)<sup>2</sup>. Fascicle stretch in the posterior and anterior compartments were compared to muscle belly stretch and displacement of the anterior and posterior aponeuroses were determined in proximal-distal directions.

## Results and Discussion

Model fascicle tracts were similar in length (posterior: 31.6±12.3 mm; anterior: 25.0±14.0mm) and pennation angle (post: 37.9±16.7°; ant: 23.2±12.9°) to DTI measurements of the soleus (post: 35.8±7.4mm, 36.6±6.2°; ant: 37.6±9.4mm, 24.6±5.0°) [3], giving us confidence that our fluid simulations provided a reasonable representation of soleus muscle architecture for FE simulations.

With a prescribed distal displacement of the soleus MTJ, the muscle belly lengthened by 5.4%. Average stretch in the soleus

compartments were very different: posterior fascicles lengthened by 18.1±2.9%, while the anterior fascicles lengthened by 2.5±0.7%. However, fascicle stretch was highly variable throughout the muscle with greatest stretch in the distal portion, suggesting that fascicle measurements in a single location would not capture full soleus kinematics. We measured aponeuroses displacement by averaging the proximal, middle, and distal portions of each and found the greatest displacement in the distal portions (Fig. 1). The posterior aponeurosis experienced greater displacement and stretch than the anterior, again demonstrating nonuniformity in the soleus muscle-tendon unit, now in the series elastic element.

**Figure 1:** 3D muscle and aponeurosis geometry were constructed based on MRI. Muscle fascicle tracts were computed from Laplacian flow simulation results. FE simulations of passive stretch were performed. Predicted fascicle stretch and aponeurosis displacement are shown.

## Significance

Development of this model helps us better understand the role of complex fascicle architecture and aponeurosis morphology in the muscle function. This model improves our ability to predict the *in vivo* force generating capacity of the soleus in order to probe its contributions to human locomotion. Such predictions may be especially important for investigating age-related gait changes, characterized by reduced plantarflexor output, enabling further study of muscle and tendon structure-function relationships.

## DENSE INTRAMUSCULAR CONNECTIVE TISSUE DRIVES COLLAGEN CONTENT VARIATION WITHIN MUSCLE

Benjamin I Binder-Markey<sup>1,2</sup>, Nicole Broda<sup>1</sup>, Richard L Lieber<sup>1,2</sup><sup>1</sup>Shirley Ryan AbilityLab & <sup>2</sup>Department of Physical Medicine and Rehabilitation, Northwestern University, Chicago, IL, USA

Email: bbindermar@sralab.org

**Introduction**

Collagen content is often used as a surrogate for connective tissue quantity to infer muscle stiffness and load bearing capacity. However, a single collagen content may not be adequate because collagen content (Fig. 1A) and connective tissue distribution (Fig. 1B) vary throughout a muscle [1]. Determining the relationship between muscle's connective tissue quantity and collagen content would greatly enhance our ability to create biomechanical models that relate collagen content to muscle load bearing. The purpose of this study was to determine how a muscle's intramuscular connective tissue structure impacts collagen content.

**Figure 1:** A) Muscle collagen content $\pm$ SEM variation by region (n=6 muscles/bar) of RF, SM, and TA. B) Average area fraction $\pm$ SEM (shaded region) along the normalized length of RF (top), SM (middle), and TA (bottom) (n=4/muscle).

**Methods**

The relationship between collagen content determined via hydroxyproline assay, and dense connective tissue structures (internal tendons and aponeurosis), quantified histologically, was determined from samples of the rectus femoris (RF), semimembranosus (SM), and tibialis anterior (TA) muscles of 12-week old C57Bl6 mice using three independent approaches.

(1) Linear regression analysis used to quantify the relationship between biochemically measured collagen content and histologically measured connective tissue area fraction of coresponding muscles and regions (Fig. 2).

(2) Predictive modeling to compare experimentally data obtained above to a modeled relationship of total collagen content and connective tissue quantity using a law of mixtures model:

$$Col_{tot,p} = \frac{Col_{ct}V_{ct}\rho_{ct} + Col_mV_m\rho_m}{V_{ct}\rho_{ct} + V_m\rho_m} \quad (1)$$

where  $Col_{tot,p}$ , total collagen content, was predicted throughout a range of connective tissue and muscle volume fractions,  $V_{ct}$  &  $V_m$ , using experimentally measured collagen content values of dense connective tissue (n=21),  $Col_{ct}$ , and baseline muscle tissue (n=24),  $Col_m$ , and literature densities for  $\rho_{ct}$  [2] and  $\rho_m$  [3].

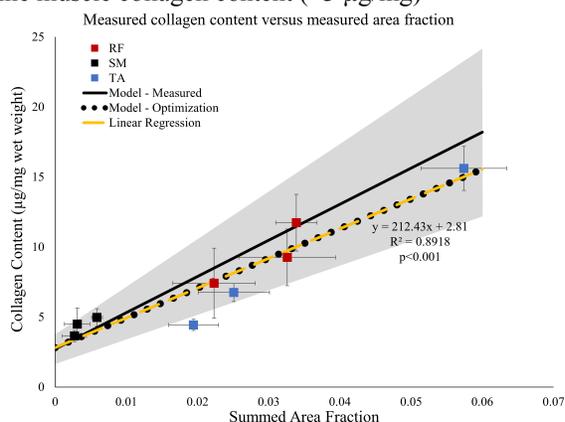

(3) Non-linear optimization to predict  $Col_{ct}$  and  $Col_m$ :

$$\min_{Col_{ct,p}, Col_{m,p}} \left[ Col_{tot}^{M,r} - \frac{Col_{ct,p}V_{ct,m}\rho_{ct} + Col_{m,p}V_{m,m}\rho_m}{V_{ct,m}\rho_{ct} + V_{m,m}\rho_m} \right] \quad (2)$$

where  $Col_{tot}^{M,r}$  is the average collagen content measured in a specific muscle (M) and region (r) and  $V_{ct,m}$  is the average summed area fraction of that respective muscle and region.

**Results and Discussion:**

Using these three approaches, we obtained results strongly suggesting a relationship ( $r^2=0.89$  for both linear regression and non-linear optimization) between a muscle's connective tissue distribution and collagen content that falls within 1 standard deviation of our predicted relationship (Fig. 2). Specifically, we found that muscle collagen content is driven primarily by its dense connective tissue structures due to the extremely high collagen content of connective tissue (204.45 to 276.85  $\mu\text{g}/\text{mg}$ ) compared to muscle tissue (2.72 to 2.81  $\mu\text{g}/\text{mg}$ ). As demonstrated in our analyses, for every 1% increase in collagen volume fraction, collagen content is predicted to increase by 2.04-2.77  $\mu\text{g}/\text{mg}$ . These are substantial changes in light of the very low baseline muscle collagen content ( $\sim 3 \mu\text{g}/\text{mg}$ )

**Figure 2:** Average measured collagen content $\pm$ SEM vs. summed area fraction $\pm$ SEM from Figure 1. Linear regression (dashed yellow line), predicted relationship based on the law of mixtures (eq. 1) (solid black line  $\pm$ 1SD shaded region), and relationship using non-linear optimized values of connective tissue and muscle (black dotted line).

These results demonstrate that a single collagen content measurement typically will not accurately represent a muscle's connective tissue structures. However, measured collagen content throughout a muscle will directly reflect the internal connective tissue structures throughout the muscle. Future studies must account for collagen content variation and connective tissue structure location in order to determine more accurate relationships between collagen content measurements and whole muscle passive mechanics.

**Significance**

This study demonstrates that collagen content variations within and among muscles were driven by the complex connective tissue's distribution within muscle. A consequence of these findings further suggests a single collagen content measurement does not accurately represent the distribution of connective tissue in a muscle and potential load bearing capacity of that muscle.

**In vivo measurement of gracilis muscle-tendon characteristics**Lomas S. Persad<sup>1</sup>, Filiz Ates<sup>1</sup>, Alexander Y. Shin<sup>1</sup>, Richard L. Liber<sup>2</sup>, and Kenton R. Kaufman<sup>1</sup><sup>1</sup>Department of Orthopedic Surgery, Mayo Clinic, Rochester, MN<sup>2</sup>Shirley Ryan AbilityLab, Chicago, ILEmail: [Kaufman.Kenton@mayo.edu](mailto:Kaufman.Kenton@mayo.edu)**Introduction**

Musculotendon experimental data are needed to develop and validate muscle-driven biomechanical models. Most of these data are obtained from cadavers. The aim of this study was to obtain *in vivo* gracilis muscle-tendon parameters experimentally. These parameters included isometric force-length properties, muscle-tendon unit (MTU) length at various joint configurations, and muscle architectural data. Cadaveric data were also obtained for the gracilis MTU. These included passive force during knee flexion and hip abduction trials, and the gracilis tendon stress-strain relationship. These novel data can help limit assumptions and ensure biological accuracy when modelling the action of the gracilis muscle.

**Methods**

*In vivo* data were collected during a free functioning muscle transfer surgery of the gracilis to the upper limb in patients with brachial plexus injuries (n=9). Force-length and MTU length data were obtained from the muscle *in situ*, prior to its removal from the leg. After the muscle was freed, it was weighed and photographed. Muscle-tendon unit dimensions were measured from images of the freed MTU. *In vivo* muscle force was measured by stimulating the muscle via the obturator nerve at 50% of the maximum compound muscle action potential (CMAP) current at 20 Hz. This was repeated for four joint configurations throughout the muscle excursion range. Both *in vivo* and cadaveric force-length data were recorded using a buckle force transducer attached to the gracilis tendon. The gracilis distal tendon was harvested from three cadavers and mounted on a materials testing system where forces from 0N to 200N were applied at a constant strain rate of 25%/s.

**Results and Discussion**

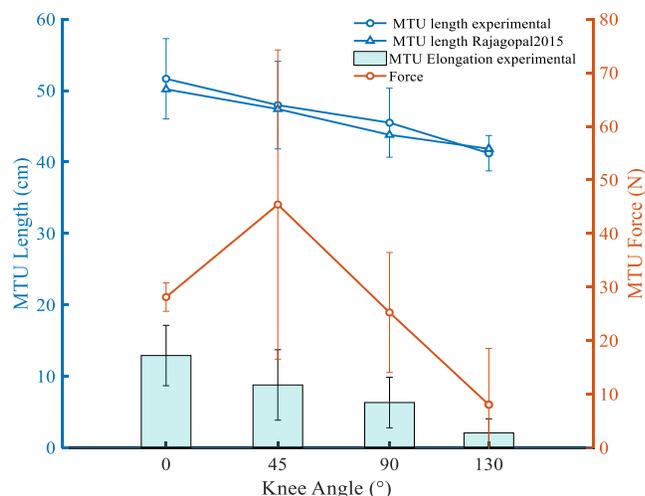

This study successfully obtained novel *in vivo* gracilis muscle-tendon data (Table 1). *In vivo* gracilis muscle length was similar to values reported by Ward *et al.* and Dzedzic *et al.* Muscle mass was 4 times greater and tendon cross-sectional area was 1.6 times smaller when compared to cadaveric data. Tendon slack length was 11.2 cm which was similar to the 13.9±1.85 cm reported by Dzedzic *et al.* Previous studies have shown tendon slack length strongly affects muscle force generation. Models created by Arnold *et al.* and Rajagopal *et al.* were both based on the same cadaveric dataset where they modeled tendon slack length to be 16.9 cm and 17.2 cm respectively. Our results demonstrate the errors associated with using cadaver data versus *in vivo* data.

Muscle mass (g)	229± 63
Muscle-tendon length (cm)	39.2 ± 2.7
Muscle length (cm)	29.2 ± 3.0
Tendon length (cm)	11.2 ± 2.5
Tendon cross-sectional area (cm <sup>2</sup> )	0.2 ± 0.1

**Table 1:** *In vivo* gracilis muscle-tendon parameters. Values expressed as average ± standard deviation (n=9; height 178±7.8cm, weight 94±19.5kg)

Gracilis fiber length was calculated to be 23.06 cm using a fiber length:muscle length ratio of 0.79 (Ward *et al.*). The measured average tendon length was less than muscle fiber length indicating that the gracilis is a stiff musculotendon unit, meaning the tendon would not stretch greatly.

Force length data demonstrated that when the knee was flexed to 45° while the hip was at 60° and 45° of flexion and abduction respectively, the muscle was at its optimal length (Figure 1). The tendon and muscle lengths at this position were calculated to be 11.34 cm and 36.63 cm respectively. This resulted in an optimal muscle fiber length of 28.94 cm. The data presented here quantify gracilis muscle-tendon compliance, muscle fiber lengths, tendon slack length and optimal fiber length, all of which are important parameters in modeling this muscle.

**Figure 1:** Gracilis force-length data for three subjects. MTU lengths are presented for all nine subjects.

**Significance**

*In vivo* muscle length and force data presented here demonstrate that differences exist between experimentally measured parameters and those predicted using current musculoskeletal models. We present these novel *in vivo* data augmented with cadaveric data that can be used to validate musculotendon parameters currently being employed in biomechanical models of the gracilis muscle.

## Muscle stiffness exceeds tendon stiffness at physiologically relevant levels of muscle activation

Kristen L. Jakubowski, Daniel Ludvig, Sabrina S.M. Lee, and Eric J. Perreault

Northwestern University, Evanston, IL

Email: [kristen.jakubowski@northwestern.edu](mailto:kristen.jakubowski@northwestern.edu)**Introduction**

Successfully navigating our environment, such as adapting to uneven terrain and resisting postural disturbances, requires appropriate regulation of joint impedance [1]. The impedance of a joint is strongly dependent upon the mechanical properties of the muscle-tendon units spanning it. While joint impedance has been well characterized [2], it is currently not possible to quantify the contributions from individual muscles and tendons. This presents a critical gap as these structures can be selectively altered by aging, pathology, or injury, resulting in functional impairments. Understanding how these structures contribute to the impedance of the joint over a range of activation levels will provide a clearer understanding of their respective roles in unimpaired and impaired control of posture and movement.

Muscle and tendon stiffness, the static component of impedance, have been estimated *in vivo*. However, most previous estimates have been limited to a range of muscle activations greater than 40% of maximum voluntary contraction (MVC) [3], whereas lower levels of activation are typical in common tasks such as standing (10% MVC) and walking (30% MVC) [4]. These estimates are also mostly restricted to assessing a single structure, limiting our understanding of the interaction between the muscle and tendon. Only one study has simultaneously assessed both muscle and tendon stiffness during standing [5]. However, a combination of experimental and model-based estimates are used and it is unclear if this finding is applicable to other tasks and levels of muscle activation. The lack of experimentally based data across a range of physiologically relevant activation levels hinders our ability to determine the respective roles of the muscle and tendon in the control of posture and movement. We recently developed a novel technique using ultrasound to address this gap. We can simultaneously quantify the impedance of the muscle, tendon, and joint. The aim of this study was to quantify the contribution of the muscle and tendon to the impedance of the ankle over a physiologically relevant range of plantarflexion torques.

**Methods**

Four healthy adults (2 male) were seated with their right foot rigidly secured to a rotary motor with the ankle positioned at 90°. Small, quick, stochastic perturbations of ankle angle were applied while ankle angle and torque were measured. The muscle-tendon junction (MTJ) of the medial gastrocnemius muscle was imaged using B-mode ultrasound. During each trial, subjects generated voluntary isometric plantarflexion torques of either 0, 10, 20, or 30% maximum voluntary contraction (MVC).

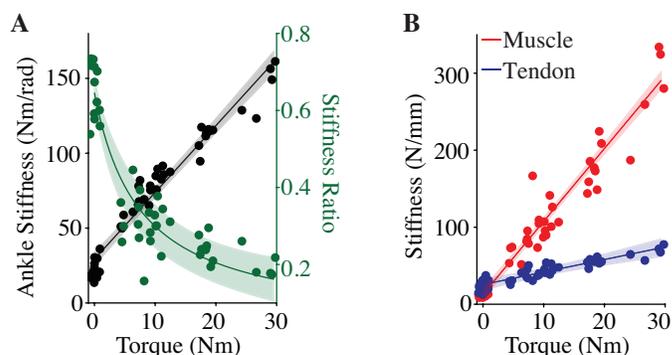

We estimated ankle impedance as the dynamic relationship between the imposed ankle rotations and the torque generated in response. We also estimated the frequency response function relating ankle rotations to the resultant MTJ displacements. This relationship represents, when scaled by Achilles tendon moment arm, the ratio of the net musculotendon impedance to muscle impedance, a relationship we refer to as the *impedance ratio*. Achilles tendon moment arm was estimated as the mean across subjects from Clarke et al. [6] with an ankle angle of 90°.

The muscle and tendon were modeled as two impedances in series. Under this assumption, muscle and tendon impedance can be derived from the experimental estimates of ankle impedance and the impedance ratio. We report the stiffness component of the measured and computed impedances due to its relevance in the

control of posture and movement. Stiffness values were estimated by averaging the magnitude of each frequency response function from 1.0 to 3.0 Hz, over which they had a constant magnitude.

**Results and Discussion**

Ankle stiffness increased with voluntary torque, as previously reported [2]. As torque increased, the stiffness ratio decreased, indicating that muscle stiffness increased proportionally faster than muscle-tendon unit stiffness (Fig 1A). Muscle and tendon stiffness increased with volitional torque, but the muscle was stiffer than the tendon for torques greater than ~3 Nm (Fig. 1B). Since ankle stiffness is dominated by the most compliant component within the muscle-tendon unit, our results indicate that ankle stiffness is determined largely by the mechanical properties of the Achilles tendon at almost all tested levels of activation. It is commonly concluded that the increase in ankle stiffness is driven by the increase in muscle stiffness. However, these results indicate that the increase in ankle stiffness is due to the strain-dependent increase in tendon stiffness. This finding is fundamental to our understanding of how muscle and tendon contribute to the control of posture and movement.

**Figure 1** **A)** Ankle stiffness (black) and the stiffness ratio (green) and **B)** muscle (red) and tendon (blue) stiffness for all subjects across the range of plantarflexion torques. Solid lines represent a fitted model and shaded area represents the 95% confidence interval for the respective model.

**Significance**

We demonstrated that muscle stiffness exceeds tendon stiffness at almost all physiologically relevant levels of muscle activation, and that the mechanics of the ankle are dominated by the nonlinear mechanics of the Achilles tendon during the isometric conditions of our protocol. Our novel approach that allows for simultaneous assessment of muscle, tendon, and ankle impedance is not only useful for understanding the unimpaired control of movement but may be useful for tracking the mechanisms contributing to altered ankle mechanics with age and injury.

## The Effect of Rotator Cuff Tear Severity on Joint Loading During Dynamic Tasks

Joshua Pataky<sup>1</sup>, Sujata Khandare<sup>1</sup>, Ali A. Butt<sup>1</sup>, Meghan E. Vidt<sup>1,2</sup>

<sup>1</sup>Biomedical Engineering, Pennsylvania State University, University Park, PA, USA

<sup>2</sup>Physical Medicine & Rehabilitation, Penn State College of Medicine, Hershey, PA

### Introduction

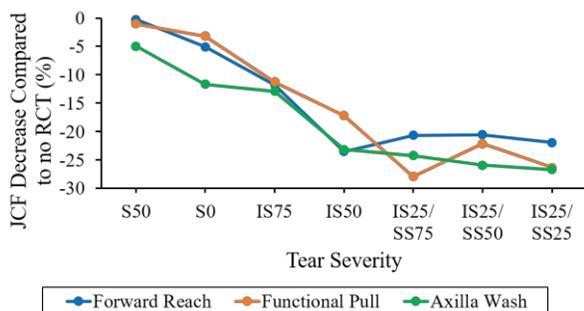

Rotator cuff tears (RCT) are common in older adults, which can negatively affect function.<sup>1</sup> RCT severity ranges from a partial thickness supraspinatus tear to a massive tear including tendons of the supraspinatus, infraspinatus, and subscapularis muscles. Previous simulation-based studies observed that with increased RCT severity, glenohumeral joint contact force (JCF) is relatively consistent for a given static posture, but changes across different postures.<sup>2</sup> These outcomes suggest dynamic task performance may alter glenohumeral JCF magnitude and orientation and exacerbate the RCT or lead to development of secondary injury (e.g. subacromial impingement). Our objective was to determine how glenohumeral JCF changes with increased RCT severity during performance of several dynamic tasks.

### Methods

A computational musculoskeletal model of the upper limb<sup>3</sup> was developed in OpenSim (v.3.3)<sup>4</sup> to represent mean muscle force-generating characteristics of healthy older adult males<sup>5</sup> (age=75.6yrs; body weight (BW)=81.0kg). The model was modified to represent 8 different RCT severities by systematically reducing peak isometric force of supraspinatus (S), infraspinatus (IS), and subscapularis (SS) muscle paths. Kinematics for forward reach, functional pull, and axilla wash motions measured from a representative healthy older adult male from a prior study were used.<sup>6</sup> With each model and the dynamic tasks kinematics, a series of computational simulations were performed using OpenSim's Computed Muscle Control (CMC)<sup>7</sup> and Joint Force Analyses tools to predict muscle activations and associated glenohumeral JCF, respectively. All combinations of model and kinematics were run, for a total of 21 permutations. The peak resultant JCF was identified for each tear severity and compared to the no RCT model.

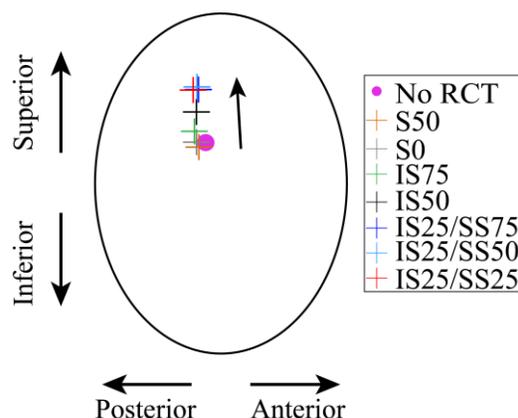

### Results and Discussion

Results revealed that JCF magnitude and orientation changed with RCT severity during each dynamic task. All tasks had comparable decreases in percent change of JCF at each tear severity when compared to no RCT (Fig. 1). For forward reach, when compared to the no RCT model, JCF magnitude decreased by 21.9% in the most severe (IS25/SS25) RCT model. When

**Figure 1.** Percent change of peak JCF magnitude for increasing RCT severity for forward reach, functional pull, and axilla wash kinematics.

using kinematics for functional pull, JCF magnitude decreased by 26.3% in the most severe tear model compared to the no RCT model. For axilla wash kinematics, JCF magnitude decreased by 26.7% in the most severe tear model compared to the no RCT model. When projected onto the glenoid fossa, the resultant JCF vector for forward reach (Fig. 2), functional pull, and axilla wash kinematics were oriented more superiorly for models with greater RCT severity, although all vectors remained within the glenoid

**Figure 2.** Forward reach kinematics resultant JCF vector projected onto the glenoid fossa across increasing RCT severity. Arrow indicates trend in JCF location observed across tear severities.

rim. Decreased JCF magnitude and superior trend of the orientation are consistent with expectations, as fewer intact muscles contribute to overall force distribution across the joint.

### Significance

Observed changes in JCF with increased RCT severity support clinical reports of increased risk of secondary injury.<sup>8</sup> Ongoing work continues to explore how JCF magnitude and orientation change with increased RCT severity during dynamic tasks that require a variety of postures to complete. Additional work seeks to examine the compensatory role of uninvolved muscles in the shoulder and how their contribution changes with increased RCT severity.

## The Effects of Osteoarthritis and Unicompartamental Knee Arthroplasty on Hip, Knee, and Ankle Joint Kinematics

Sabreen Megherhi<sup>1</sup>, Clarissa LeVasseur<sup>1</sup>, Tom Gale<sup>1</sup>, Ken Urish<sup>1</sup> and Wiliam Anderst<sup>1</sup>  
 Department of Orthopedic Surgery, University of Pittsburgh, Pittsburgh, PA, USA

### Introduction

Total knee arthroplasty (TKA) is one of the most common surgical procedures in the USA, with approximately 600,000 TKA procedures performed in 2014 [1]. TKA is predominately performed due to end-stage osteoarthritis (OA). For eligible patients that have OA in only the medial or lateral portion of the tibiofemoral joint, a unicompartamental knee arthroplasty (UKA) can be a viable alternative. UKA is associated with less post-operative pain, faster rehabilitation, and younger patients who desire high post-operative activity levels [2,3].

Previous studies that compared lower body joint kinematics and kinetics in patients before and after TKA reported changes in joint moments, but not in joint kinematics at the hip, knee and ankle during gait [4]. In contrast, there is a lack of research focusing on bilateral lower body joint kinematics pre and post UKA. The aim of this study is to compare side-to-side differences (SSD) in hip, knee, and ankle joint kinematics during walking, both pre and post-surgery, in patients receiving a UKA. It was hypothesised that pre-operative SSD in the hip, knee, and ankle kinematics would be resolved after UKA.

### Methods

Ten patients scheduled to receive a medial UKA consented to participate in this IRB-approved study. Nine patients (age: 62±5 years, 4F, 5M) completed pre-surgical (3 weeks before) and post-surgical (7±2 months) testing. All patients walked across a 7m lab walkway at their self-selected pace for at least 6 separate trials while a 12-camera Vicon motion capture system collected data at 100 Hz. We used a custom set of 31 markers, based on anatomical positions from Visual 3D recommendations and custom tracking markers. An average of 9 steps were included per person per leg each day. Bilateral hip, knee, and ankle joint angles were calculated using Visual 3D. Average bilateral hip, knee, and ankle flexion/extension and ab/adduction were normalized to percent gait cycle and averaged across all trials. Average joint kinematics were calculated for each leg pre and

post-surgery. Statistical parametric mapping was used to compare kinematics curves of the UKA and contralateral limbs using a two-tailed paired t-test with significance set at  $p < 0.05$ .

### Results and Discussion

We were unable to identify any significant side-to-side differences in sagittal or frontal plane joint kinematics pre or post-surgery (Figure 1). These results agree with a previous study that found no changes in ankle, knee, and hip kinematics from pre to post-TKA [4]. Interestingly, we did observe trends toward restoration of knee frontal plane kinematics that were accompanied by greater side-to-side differences in ankle kinematics post-surgery (Figure 1). These observed trends suggest the need for larger studies focused on the effect of UKA on adjacent joint kinematics.

### Significance

The results of this study suggest that kinematic differences at the hip, knee, and ankle in the sagittal and frontal plane are small prior to and after UKA. Studies using conventional motion capture and large patient cohorts might be able to identify side-to-side differences in frontal plane joint kinematics prior to and after UKA. While UKA may restore native knee kinematics, the effects of UKA on ankle and hip kinematics and kinetics is worthy of further investigation.

## Modular Control and Patient Function in Individuals with Knee Osteoarthritis and Total Knee Arthroplasty

 Email: [koehn.19@osu.edu](mailto:koehn.19@osu.edu)

### Introduction

Individuals who undergo total knee arthroplasty (TKA), the end-stage treatment for knee osteoarthritis (KOA), often experience suboptimal outcomes.<sup>1</sup> Multiple studies have been conducted to determine the source of these functional deficits, yet few have explored neuromuscular control. A recent study<sup>2</sup> suggested that neuromuscular control strategy, demonstrated by motor modules (or synergies),<sup>3</sup> may be associated with the range of post-operative functional outcomes. However, it is unknown how modular control may change during recovery or relate to functional outcomes. The purpose of this study was to determine the relationship between function and modular control during gait before and after TKA. We hypothesized that participants who demonstrated better function would demonstrate modular control that was (i) more complex (i.e. more modules) and (ii) resembled healthy age-matched controls.

### Methods

36 individuals (38 knees, 19R/19L) with medial compartment KOA provided written informed consent prior to undergoing TKA and were tested before and 6- and 24-months after surgery. During over-ground walking trials, we collected surface electromyography (EMG) data from rectus femoris (RF), vastus medialis and lateralis (VM,VL), medial hamstrings (MH), biceps femoris (BF), medial and lateral gastrocnemii (MG, LG), and soleus (SO) on the TKA-involved limb. Using previously described methods,<sup>4,5</sup> we extracted muscle modules and selected one representative trial for analysis. We defined modular complexity as the number of modules extracted. We defined modular organization as the distribution of significantly active muscles within each module ( $W_{\text{muscle}}$ ).<sup>6</sup> Modular organization was only evaluated in participants with 3 modules. We used the 6-minute walk test<sup>7</sup> (6MW) to categorize patients as high- or low-functioning based on published age-, height-, mass-, and gender-specific thresholds.<sup>8</sup>

We performed individual one-way ANOVAs to determine the relationship between modular complexity and function. We compared muscle weights to healthy age-matched controls (HC)<sup>9</sup> using Pearson correlations to define module quality,<sup>10</sup> and performed 2-sample t-tests to determine the relationship between module quality and 6MW performance (all  $\alpha=0.05$ , *a priori*).

### Results and Discussion

Modular complexity was not related to function before or after surgery (all  $p \geq 0.406$ ). This contrasts Ardestani et al.,<sup>2</sup> who found that low-functioning patients exhibited fewer modules during gait than high-functioning patients 1-year post-TKA.

Although we did not find a difference in module quality between the high- and low-performing 6MW groups (all  $p \geq 0.284$ ), both groups showed changes in modular organization. The healthy controls demonstrated quadriceps (QUAD), plantarflexors (PF), and hamstrings (HAM) dominated modules (Table 1). In comparison, the 6MW-high group had more significantly active muscles in all modules before surgery and decreased in  $W_{\text{muscle}}$  and  $W_{\text{muscle}2}$  throughout the timecourse of recovery, moving toward healthy organization. However, the

6MW-low group had fewer active muscles before surgery and either increased or remained constant in  $W_{\text{muscle}}$  and  $W_{\text{muscle}2}$ . All 6MW-low modules did not consistently move toward healthy throughout recovery, most notably in the HAM module.

**Table 1.** Significantly active muscles in high- and low-functioning participants (n) demonstrating 3 modules before, 6-months after, and 24-months after TKA (Pre, 6m, and 24m, respectively) compared to healthy controls (HC). ■: 95% confidence interval (CI) of weights does not include 0; ▨: CI does not include 0, upper bound is <0.25; ▩: CI includes 0 and 1;  $W_{\text{muscle}}$ : number of ■ & ▨;  $W_{\text{muscle}2}$ : number of ■ & ▩.

### Significance

Our findings indicate that there may be an underlying relationship between module characteristics and function in this population. The plasticity of modular control, despite not receiving specific neuromuscular control training after 6-months post-TKA, is a novel finding in the TKA population, which may influence functional outcomes in populations with orthopaedic disorders. Such a relationship between modular control characteristics and patient function may open opportunities for further investigations of neuromuscular control as a factor which influences function in populations with orthopaedic disorders and may inform novel rehabilitation protocols to improve patient function.

## Effects of age-related changes on fracture resistance of human cortical bone

### Introduction

During an individual's lifetime, microcracks are formed in the bone tissue due to fatigue and cyclic loading [1]. The formation and growth of the microcracks are affected by the morphology and heterogeneity of the microstructure [1]. However, the bone microstructure and composition undergo significant changes by aging [1]. Aging has a negative impact on the effectiveness of toughening mechanisms acting at different length scales of the bone structure and therefore decreases the fracture resistance of bone [1]. However, the reasons for these age-related changes in bone are complicated and require more extensive investigations.

In the present study, the objective is to investigate the effects of microstructure and bone mechanical characteristics by aging upon fracture phenomenon and the microcrack propagation. In order to capture different toughening mechanisms, we use a brittle model of the phase-field method to analyze the crack growth.

### Methods

At the microscale level, the human Haversian (osteonal) cortical bone has been considered as a composite material and modeled as a fiber-ceramic matrix. We consider osteons as fibers and the interstitial tissue as the matrix [1]. We also define the interface between the osteons and interstitial tissue as the cement line. We use human microscopic images obtained from the tibias of female donors (60 and 81-year-old) to create 2D plain-strain models (Figure 1). We investigate the region-dependent fracture behavior of the cortical bone. We also evaluate the influence of mechanical properties of the cement line on crack growth. We adopt a brittle model of the phase-field method developed by Molnár *et al.* [2]. We implement the brittle model into a subroutine using Abaqus software. The boundary conditions of the models are shown in Figure 1.

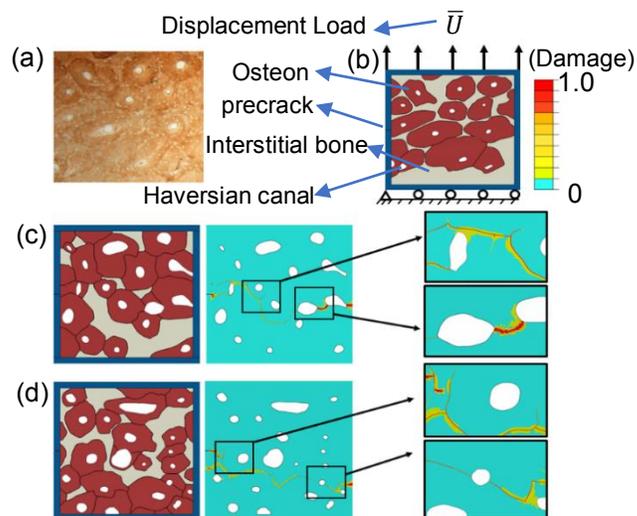

### Results and Discussion

Our results show that aging changes the crack growth trajectory in the cortical bone microstructure. Aging also affects the rate of damage. Our simulations show that the rate of damage increases by aging. This rate is highly dependent on the critical energy release rate of the osteons. The difference between the elastic moduli of the osteons and the interstitial bone also affects damage growth.

We also observe crack branching in our models. Crack branching is determined as one of the toughening mechanisms in the simulations. It happens when there are multiple osteons ahead of the main crack. Our simulations show that sometimes microcracks could reach Haversian channels by passing through cement lines. In this case, reaching microcracks to Haversian channels could lead to catastrophic failure due to the high-stress concentration associated with the channels.

We also evaluate the important role of the cement line in crack deflection. Our results indicate that crack deflection is affected by a decrease in the critical energy release rate of the cement line (i.e., decreasing the resistance of the cement line to fracture). Therefore, the microcrack is arrested along the cement

line. The simulations reveal that the crack stops once it enters in a high osteon density bone tissue. We also observe that debonding mostly happens in the cement line where the interstitial bone and osteon are tougher and stiffer than the cement line. Our results also reveal that the toughness of the cortical bone microstructure is dependent on the area density of osteons. An increase in the area density of the osteons leads to an increase in the toughness of the cortical bone microstructure.

**Figure 1:** (a) A cross-section of the cortical bone in 60-year-old human tibia, and (b) the 2D model of the cortical bone microstructure. Fracture patterns and 2D models of the anterior region at the same cross-section of the cortical bone for two different ages (c) 60-year-old, and (d) 80-year-old. Damage with 1.0 shows the crack path and the zero value presents that there is no damage.

### Significance

The findings of the present study show the region-dependent fracture behavior of the cortical bone in human tibia and this leads to improving the materials used in orthopedic implants. We can also predict the probability of failure in human tibia by monitoring the rate of damage in various regions.

### Acknowledgments

The authors acknowledge the high-performance computing resources (PROTEUS: the Drexel Cluster) and support at the Drexel University. We would like to express our special thanks to Dr. Lamyia Karim and Taraneh Rezaee for providing us with the cortical bone samples from human tibias. We also thank Dr. Theresa Freeman for using her facilities and providing invaluable support with the staining and imaging process.

### Introduction

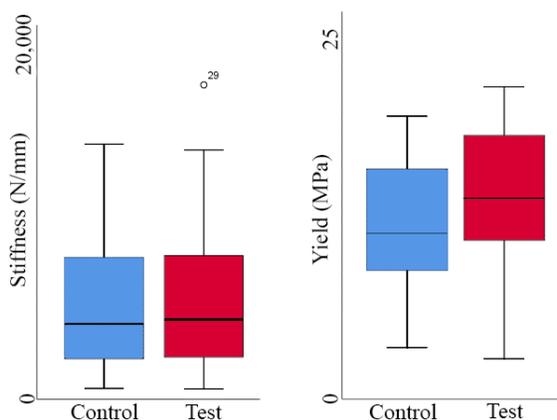

Bone infection (osteomyelitis) due to *Staphylococcus aureus* (*S. aureus*) is challenging to treat due to the difficulty of early diagnosis and growing antibiotic resistance. While the cellular mechanisms of *S. aureus* and osteomyelitis have been studied, little information exists on the biomechanical effects of such infections on bone tissue. With the growing number of osteomyelitis cases diagnosed, and with the increased usage of bone banks as a source of bone graft supply, it is necessary to understand the possible long term effects of *S. aureus* induced osteomyelitis on the mechanical properties of bone. In a recent study conducted in our lab (Kunde et al. 2018), we found that *S. aureus* was able to penetrate cortical bone tissue, yet no significant difference in bone stiffness was found between the test group, exposed to *S. aureus*, and control group, immersed in distilled water (dH<sub>2</sub>O). Due to the porous nature and increased surface area of trabecular bone tissue, the potential of *S. aureus* to penetrate and negatively affect trabecular bone material properties is markedly increased. Thus, we hypothesized that bone exposure to *S. aureus* for 72 hours would significantly decrease both the stiffness and yield of trabecular bone tissue.

### Methods

One hundred and three trabecular cubes (5 mm<sup>3</sup>) from the proximal tibiae of nine white-tailed deer were cut, sterilized and then swabbed to confirm sterilization before inoculation with *S. aureus*-ATCC-12600 (test group, n = 51) or sterile nutrient broth (control group, n = 52) for 72 hours. All cubes were tested in compression along the axial direction until yield using an Instron 5942 machine. Structural stiffness (N/mm) and yield (MPa) were calculated and compared between the two groups.

### Results and Discussion

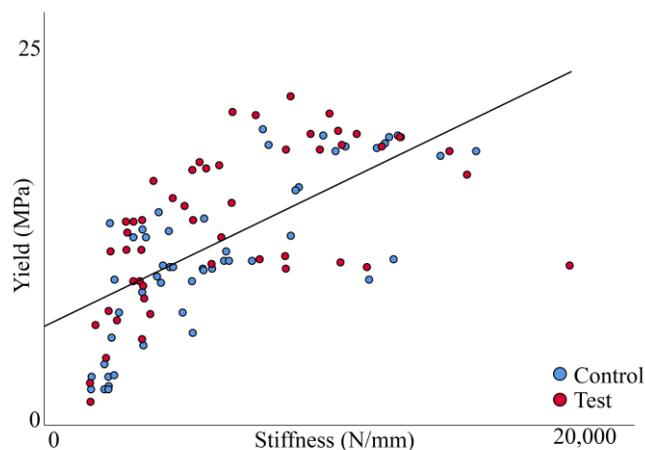

Mean axial stiffness of control and test groups were 5561 ± 4027 and 5798 ± 4182 N/mm, respectively (Fig. 1, left). Mean axial yield of control and test groups were 11.0 ± 5.1 and 12.9 ± 4.9 MPa, respectively (Fig. 1, right).

**Figure 1:** Boxplots comparing stiffness (left) and yield (right) between the control and test groups and the test group.

An ANCOVA (with bone density as the covariate) revealed no significant difference between groups for both stiffness and yield ( $P > 0.05$ ), thus refuting our working hypothesis.

A Spearman's correlation statistical test revealed a significant positive correlation between stiffness and yield ( $r = 0.72$ ,  $P < 0.001$ ; Fig. 2).

**Figure 2:** Scatterplot showing significant positive correlation between stiffness and yield ( $P < 0.001$ ).

The axial direction corresponds to the primary physiological direction of loading of the proximal tibia that would occur during normal activities (walking, running, jumping, etc.). Thus, these results indicate that acute exposure to *S. aureus* probably does not adversely affect trabecular bone stiffness or yield during daily compressive loading activities.

### Significance

The end-result of untreated osteomyelitis is bone necrosis and destruction of bone structure, which leads to a decrease in the ability of bone to support physiological loads. With the increase usage of bone banks as a source for bone graft supply, it is important to screen for any possible pathology that may affect the bone graft success to function normally in the receiving patient. Currently, according to the FDA's guidelines, eligible bone donors must not have had a diagnosis of sepsis "immediately preceding death," but there is no mention of previous osteomyelitis diagnosis as a donor restriction. Our findings support the current tissue collection screening methods employed by bone-graft banks.

### Introduction

Juvenile idiopathic arthritis (JIA) is the most common childhood arthritis. Diagnosing and treating JIA is challenging due to its highly variable presentation and lack of reliable biomarkers. The knee is commonly affected in JIA which appears with chronic synovitis and inflammation causing damage to the underlying cartilage and bone. The internal friction of articulating joints generates acoustic emissions (AE) which can potentially be used as a digital biomarker of the disease [1]. In this study, knee AEs are compared in loaded and unloaded exercises in patients with JIA as well as healthy controls.

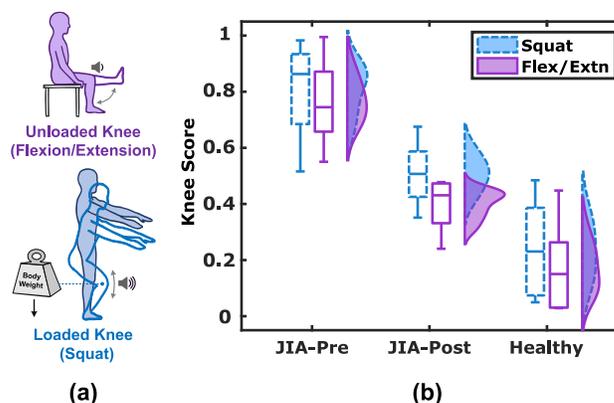

### Methods

In this study, knee AEs were acquired from 38 participants under a protocol approved by the Georgia Institute of Technology and Emory University Institutional Review Boards. The participants were divided between two age-matched groups consisting of 18 healthy controls (15 female/3 male,  $12.5 \pm 3.2$  years) and 20 subjects with JIA (17 female/3 male,  $12.9 \pm 2.5$  years). To measure longitudinal changes in the knee AEs during the course of treatment, 10 subjects with JIA had a follow-up recording, 3-6 months after initial measurements.

In this protocol, subjects were asked to perform two sets of exercises as shown in Fig. 1(a): 1) unloaded knee flexion/extension (flex/extn) while seated, and 2) loaded knee squats while bearing body weight. The joint AEs were divided into individual movement cycles ( $\sim 4$  seconds each) and bandpass filtered with a 250Hz–10kHz bandwidth to suppress the noise and interference. Each cycle is divided into 200 ms frames with 50% overlap. An automated algorithm was used to detect the rubbing noise associated with loose microphone contact [2], and the detected frames were excluded from the analysis to increase the reliability and accuracy of the analysis. Next, audio features [1] were extracted for each signal frame, which includes temporal features, band powers, spectral features, and mel-frequency cepstrum coefficients. The mean, median, and standard deviation of these features for cycle frames were calculated and imported to a soft classifier with corresponding subject labels (0 for control and 1 for arthritis). A logistic regression classifier is trained using the top 44 features, selected through a forward-feature-selection process to reduce the possibility of overfitting. The classifier assigns a knee health score for each movement cycle, which is the estimated probability that a given knee signal belongs to an involved knee with JIA (0 for control and 1 for arthritis).

### Results and Discussion

The classifier performance is analyzed with leave-one-subject-out cross validation (LOSO-CV) and achieved a subject-wise accuracy of 89%. The outputs of the classifier – knee health scores – are illustrated in the box plot in Fig. 1(b), and the key results are summarized as follows: 1) The post-treatment scores in subjects with JIA were always lower than the pre-treatment scores, which correlates with these subjects' clinically reported

**Figure 1:** (a) Loaded vs. unloaded knee exercises and (b) knee health score box plots for healthy controls and subjects with JIA (pre/post-treatment).

successful treatment; 2) the median of pre-treatment knee scores in subjects with JIA for squats (loaded) is higher compared to flex/extn (unloaded), suggesting that the squat is more difficult exercise to perform than the flex/extn and AEs associated with JIA are more pronounced in squats; 3) Similarly, the median of post-treatment scores for squats are also higher compared to flex/extn, and the difference is statistically significant ( $p < 0.05$  using two sample Kolmogorov-Smirnov test).

In summary, subjects with JIA exhibit significantly different knee AEs compared to healthy controls, and a successful treatment can move AE characteristics of subjects with JIA closer to those of controls. AEs produced during the loaded activity showed less of a trend toward healthy control values than the unloaded activity. We hypothesize that the loaded exercise increases interjoint friction which may make the AEs more sensitive to micro changes in the knee architecture. Future work should investigate longitudinal data taken more frequently and over longer periods of time to determine the kinetics of AEs such that these digital biomarkers can be used to titrate care in JIA.

### Significance

The results of this study support the use of knee AEs as affordable and quantitative digital biomarker of knee health assessment in wearable systems. Additionally, analysis and classification of AEs from unloaded and loaded activities reveals that these two exercises contain different, possibly clinically-relevant, information that could be used to further improve this novel assessment modality in JIA.

## Associations Between Daily Steps, Moderate-Vigorous Physical Activity, and Femoral Articular Cartilage Composition in Individuals with Anterior Cruciate Ligament Reconstruction

Hope C. Davis-Wilson<sup>1</sup>, A.C. Hackney<sup>1</sup>, J. Troy Blackburn<sup>1</sup>, Louise M. Thoma<sup>1</sup>, Jason R. Franz<sup>1,2</sup>, Lara Longobardi<sup>1</sup>, Brian Pietrosimone<sup>1</sup>

### Introduction

Alterations in biomechanical loading may lead to deleterious changes in cartilage composition consistent with the development of early post-traumatic osteoarthritis (PTOA) in individuals with anterior cruciate ligament reconstruction (ACLR).<sup>1</sup> It is unknown how habitual loading, objectively measured via daily steps and time in moderate to vigorous physical activity (MVPA) with an accelerometer, influences changes in cartilage composition post-ACLR. T1rho relaxation times (T1rho) measured with magnetic resonance imaging (MRI) provide an *in vivo* estimate of proteoglycan density in the articular cartilage.<sup>2</sup> Decreased proteoglycan density, or increased T1rho, are indicative of early compositional changes consistent with PTOA development. The primary purpose of this study was to determine the association between T1rho in the femoral articular cartilage and daily steps and MVPA in individuals post-ACLR. Second, we evaluated the modifying influence of sex on these associations.

### Methods

Twenty-six individuals (61% female, age: 21±4 years, body mass index: 24.9±2.9 kg/m<sup>2</sup>) within 18 months of a unilateral patellar-tendon autograft ACLR were asked to wear an ActiGraph GT9X Link triaxial accelerometer placed over their right-hip for seven consecutive days. A valid wear-period for the ActiGraph was considered a minimum of 4 days (3 weekdays and 1 weekend day) and no less than 10 hours/day. T1rho MRI were acquired on the ACLR and uninjured contralateral limb. The articular cartilage of the medial femoral condyle (MFC) and lateral femoral condyle (LFC) were manually segmented and sectioned into regions of interest (anterior, central, and posterior) based on the location of the meniscus in the sagittal plane. T1rho in the ACLR limb were normalized to values in the same regions of the

uninjured limb and presented as interlimb ratios (T1rho of ACLR limb/T1rho of uninjured limb). Separate univariate linear regressions were conducted to analyze the association between separate independent variables (daily steps and MVPA) and separate dependent variables (T1rho in each region of interest). Second, we stratified the analyses by sex.

### Results

Greater time in MVPA associated with greater T1rho in the central LFC in the entire cohort (Table 1). Greater daily steps demonstrated greater T1rho in the anterior, central, and posterior MFC, and greater time in MVPA associated with greater T1rho in the anterior, central, and posterior MFC as well as the anterior LFC, in males (Table 1). Greater daily steps, but not MVPA, associated with lesser T1rho in the central and posterior MFC, in females (Table 1). Overall, greater time in MVPA associated with worse MRI outcomes in the entire cohort. Greater daily steps and MVPA associated with worse femoral articular cartilage composition in males, while greater daily steps associated with better cartilage composition in females.

### Significance

Personalized targets for habitual loading are needed early following ACLR. Females post-ACLR may benefit from therapeutic interventions aimed at increasing habitual loading.

### Introduction

Continued evidence supports that knee abduction moment is a factor that contributes to non-contact anterior cruciate (ACL) injury,<sup>1,2</sup> with the non-contact mechanism accounting for 70-80% of ACL injury.<sup>3</sup> However, there are also concomitant injuries that occur with non-contact ACL injury, including the medial collateral ligament (MCL) and the medial meniscus. The most commonly damaged structures of the knee are the ACL, MCL, and menisci.

Given that these injuries present as either isolated or concomitant, it follows that these events are driven by specific mechanics versus mere coincidence. This study was designed to investigate the multiplanar mechanisms and determine the important biomechanical and demographic factors that contribute to classification of specific injury outcomes.

### Methods

*In vivo* kinetics/kinematics of 42 healthy, athletic subjects were measured to determine stratification of injury risk (i.e. low, medium, and high) in three degrees of knee forces/moments (knee abduction moment, anterior tibial shear, and internal tibial rotation). These stratified kinetic values were input into a cadaveric impact simulator to assess ligamentous strain and knee kinetics during a simulated landing task.<sup>1</sup> Uni-/multi-axial load cells and implanted strain sensors were utilized to collect mechanical data for analysis. Data analyses were performed on 41 specimens [age 44 (37.5, 47.5) years; 79.3 (64.0, 100.9) kg; 21M:20F]. Of the 41 specimens included in this study, there were 5 different classifications of injury (**Table 1**). Linear Discriminant Analysis (LDA) was utilized to determine classification of injury outcomes from biomechanical variables.

### Results and Discussion

Three LDA models were generated: 5-, 10-, and the optimized 11-factor model. The 5-factor model was 14% less accurate than the 10-factor model, but could properly classify 63.4% of injuries [area under the curve (AUC)  $\geq 0.68$ ] with 'excellent' prediction of 4 of 5 injury classifications. The 10-factor model improved accuracy (77.5%; AUC  $\geq 0.94$ ), especially with the ACL+MCL injury group (AUC improved from 0.68 to 0.94). Finally, the optimized 11-factor model improved accuracy (87.5%; AUC  $\geq 0.96$ , **Fig. 1**). It should be noted that since there are 5 outcomes possible, the random chance for selection of the appropriate outcome would be 1 in 5 (20%). These data demonstrate that these particular knee injuries are not random occurrence, but are determined by specific biomechanical forces/torques at the time of injury.

Utilization of LDA accurately predicted the outcome of knee injury from kinetic data from cadaveric simulations with the utilization of a mechanical impact simulator. Thus, it is possible to use knee joint kinetics to determine clinical risk of injury as well as differentiate the likely type of presentation during knee injury. LDA demonstrates that injury outcomes are largely characterized by specific mechanics that can distinguish

ACL, MCL, and medial meniscal injury. Furthermore, as the mechanics of injury are better understood, improved interventional prehabilitation can be designed to reduce these injuries.

**Table 1. Confusion Matrix of 11-Factor LDA.**

		Predicted Count				
		ACL	ACL+MCL	ACL+MCL+Meniscus	ACL+Meniscus	MCL
Actual Count	ACL	21	2	0	0	0
	ACL+MCL	2	8	0	1	0
	ACL+MCL+Meniscus	0	0	1	0	0
	ACL+Meniscus	0	0	0	3	0
	MCL	0	0	0	0	2

Note: Highlighted boxes demonstrate agreement between predicted and actual values. Values in the diagonals denote correct predictions.

### Significance

This study demonstrates that knee injury outcomes are not mere coincidence, but are driven by specific injury mechanics. These specific injury mechanics can *predict* the type of knee injury outcome with high confidence. This classification paradigm is an important step in future production of machine learning algorithms that can rapidly assess complex, covariate data and determine specific risk of musculoskeletal injury.

**Figure 1:** ROC Curves of the 11-Factor Linear Discriminant model of Knee Injury. The plots demonstrate the AUC and prediction sensitivity/specificity for each injury classification.

## Mindsets are related to reductions in pain after a gait modification intervention for people with osteoarthritis

Melissa A. Boswell<sup>1</sup>, Sean R. Zion, Scott D. Uhlrich, Jennifer L. Hicks, Alia J. Crum, and Scott L. Delp

<sup>1</sup>Department of Bioengineering, Stanford University

Email: boswellm@stanford.edu

### Introduction

Psychological factors and the context of an intervention (e.g., personal interactions, beliefs about the outcomes, intervention presentation) can affect outcomes above the direct effects of the intervention alone [1]. For example, telling individuals they have a high-endurance genotype increases their cardiorespiratory capacity during running, regardless of their actual genotype [2]. Mindsets, which are core assumptions about the nature of things and processes in the world, are psychological factors that orient people to a particular set of expectations, explanations, and goals. Patients with more adaptive mindsets about chronic illness (e.g., “my illness may be challenging, but it can be managed”) report improved physical and mental health compared to patients with less adaptive illness mindsets (e.g., “my illness negatively impacts all parts of my life”) [3].

The relationship between mindsets and biomechanical interventions is unknown, yet likely influences intervention efficacy and patient outcomes. As a first step towards understanding this relationship, we evaluated the association between mindsets about chronic illness and changes in pain after introducing a gait modification for people with knee osteoarthritis, a chronic disease. We hypothesized that a more adaptive mindset about chronic illness would be associated with larger reductions in pain. By studying mindsets and interventions together, we can understand how they influence each other, and how they both influence health.

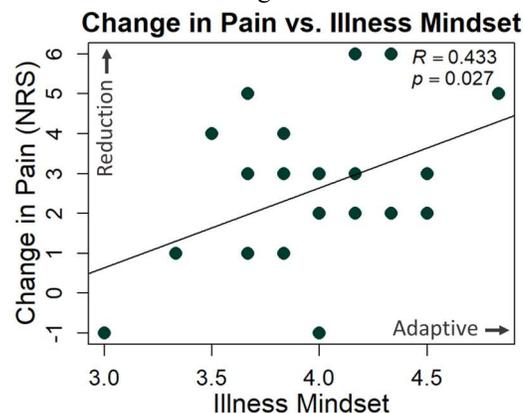

### Methods

Twenty-six individuals with radiographic knee osteoarthritis completed one year of gait retraining aimed at reducing the loading in the medial compartment of their knee (via reducing the knee adduction moment). During 13 visits to the gait lab, participants were trained to adopt their modified gait pattern. Medial knee pain was assessed with the 11-point numerical rating scale (NRS) from no pain (0) to the worst imaginable pain (10). Reduction in pain was defined as the difference in NRS pain score between the beginning and end of the study (where a positive value indicates less pain at the end of the study). At the end of the study, participants’ mindsets about illness were assessed with the Illness Mindset Inventory (IMI) [3]. The participants’ illness mindsets were calculated as a composite variable (from 1-6) using the catastrophe and manageable subscales of the IMI, with higher scores reflecting the mindset that chronic illness is manageable. We calculated Pearson’s correlation coefficient ( $R$ ) to evaluate the association between illness mindsets and reduction in pain.

### Results and Discussion

Illness mindset was positively correlated with pain reduction ( $R=0.433$ ,  $p=0.027$ ), meaning a more adaptive mindset was related to a larger reduction in pain (Figure 1). On average, participants experienced significant reductions in their pain ( $p<0.001$ ) and knee adduction moment ( $p<0.001$ ) with their personalized gait modification. These results suggest that the

illness mindset may influence pain outcomes in addition to the reduction in medial knee loading.

**Figure 1:** Change in pain vs. illness mindset. A reduction in pain is associated with a more adaptive illness mindset.

Due to the cross-sectional nature of this study, we cannot determine causality. Mindsets at the end of the intervention are likely shaped by the participant’s experiences and expectations both before and during the intervention. If biomechanical interventions affect mindsets, we can leverage the influence on mindsets for optimal intervention compliance, design, and outcomes. For example, even if a biomechanical intervention, such as a gait modification, reduces knee loading, patients that do not have the mindset that they can manage their disease may not receive the maximum benefit from the intervention. In addition to psychological improvements, these benefits can include physical improvements as mindsets can influence physiological processes, such as inflammation. On the other hand, mindsets may influence the efficacy of interventions by mediating outcomes, such as changes in pain. This research motivates future work to understand the mechanisms by which biomechanical interventions affect mindsets and vice versa.

### Significance

We found that an individual’s mindset about chronic illness is related to changes in pain after a biomechanical intervention. By bridging the gap between psychology and biomechanics, we can design traditional biomechanical interventions more effectively. Integrating subtle nudges towards more adaptive mindsets, such as presenting an intervention as an opportunity to manage pain or chronic illness, may improve intervention compliance and health outcomes.

## Introduction

Post-stroke gait is influenced by paretic limb weakness and marked by increases in metabolic cost. Weakness at the ankle is associated with reduced peak ankle power and propulsion, and knee extension is the cornerstone of “stiff-knee gait,” which results in compensatory mechanics including hip hiking and circumduction [1]. Post-stroke gait interventions often seek to improve paretic ankle and knee function thereby reducing the need for the compensations assumed to contribute to increased metabolic cost [2, 3]. However, the design of these interventions is limited since ankle and knee flexion are interrelated, making the independent roles of ankle and knee dysfunction on metabolic efficiency difficult to discern. Using a knee brace and custom 3D printed ankle stay, this study isolated the contributions of unilaterally reduced ankle flexion, knee flexion, and ankle+knee flexion on walking outcomes and energetics. Our hypotheses are: (h1) reduced ankle and knee flexion will result in decreased propulsion and increased circumduction, respectively, (h2a) Reduced ankle + knee flexion will yield the highest metabolic cost, and (h2b) limiting ankle flexion will be more metabolically expensive than limiting the knee.

## Methods

Data were recorded for 15 (7M/8F) unimpaired controls walking ( $0.8\text{ms}^{-1}$ ) for 7 mins in the following conditions: braced control (*unlocked*), unilaterally fixed ankle (*uni-ank*), unilaterally fixed knee (*uni-knee*), and unilaterally fixed ankle and knee (*uni-a+k*). We converted recorded rates of oxygen consumption and carbon dioxide production to metabolic powers [4]. A motion analysis system recorded 3D positions of markers placed on the pelvis and lower limbs. Simulations performed in OpenSim (v3.3) used a lower limb model adapted from a full-body model and scaled to participants [5]. Inverse kinematics, inverse dynamics, and analysis tools were used to compute joint angles, moments, and powers, respectively. Limb circumduction was calculated as maximum lateral foot displacement during swing [1]. Ground reaction forces measured on an instrumented dual-belt treadmill were used to identify peak propulsion. Outcome measures were averaged over 10 consecutive gait cycles, and statistical significance between conditions was determined by paired t-tests ( $p < 0.05$ ) with Bonferroni correction for multiple comparisons.

## Results and Discussion

Peak propulsion on the locked limb (**Fig 1a.**) was significantly decreased in *uni-ank* and *uni-a+k* conditions compared to *unlocked*, demonstrating that restricting the ankle limited subjects’ capacity to propel forward. Additionally, hip circumduction (**Fig 1b.**) was significantly higher in *uni-knee* and *uni-a+k* conditions as compared to *uni-ank* condition, reinforcing the interaction between reduced knee flexion and circumduction. These results support h1 and demonstrate the effectiveness of mechanical bracing to elicit compensatory strategies characteristic of post-stroke gait.

While metabolic cost (**Fig 1c.**) in the *uni-a+k* condition was significantly higher than *unlocked* and *uni-knee*, it was not significantly higher than the *uni-ank* condition, so we reject h2a. Additionally, the *uni-ank* condition was not significantly ( $p=0.17$ ) more metabolically expensive than *uni-knee* condition; therefore, we reject h2b. However, we note that both the *uni-ank* and *uni-a+k* conditions are significantly higher than the *unlocked* condition, indicating that regardless of restrictions in knee flexion, any direct restriction on the ankle is metabolically detrimental. Further, the significant increase in metabolic rate between *uni-knee* and *uni-a+k* suggests that combined restriction of the ankle and knee is more metabolically detrimental than restriction of the knee in isolation.

## Significance

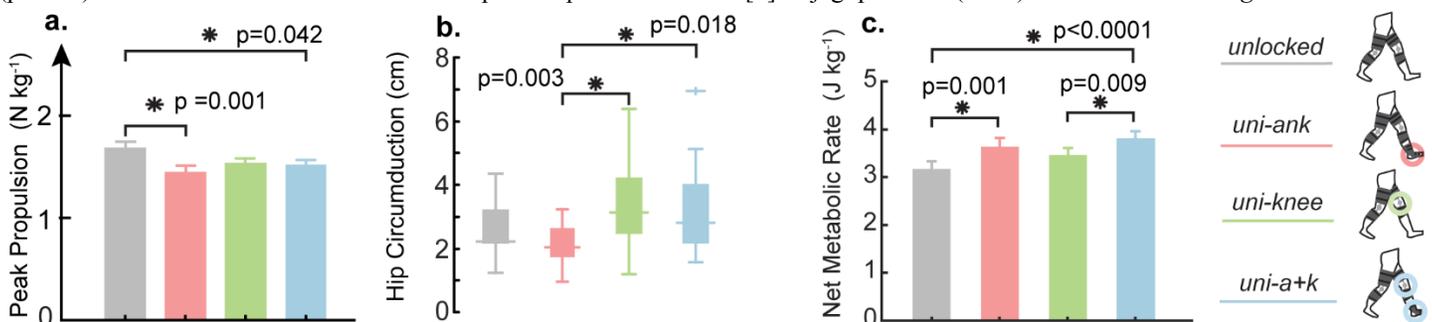

These results confirm that the combined impacts of reduced ankle and knee flexion are more detrimental metabolically than reduced knee flexion alone, providing support for the potential of ankle-based rehabilitative technologies in persons post-stroke to provide a metabolic benefit.

## Introduction

Individuals with post-stroke hemiparesis demonstrate decreased propulsive force generation from the paretic leg during late stance, measured as anteriorly-directed ground reaction force (AGRF).<sup>1</sup> Reduced paretic AGRF adversely impacts gait speed, inter-limb symmetry, and walking function.<sup>1,2</sup> Gait interventions such as treadmill training, functional electrical stimulation, and gait biofeedback have shown improvements in paretic AGRF.<sup>3-6</sup>

Gait biofeedback (BF) provides the user with instantaneous, quantitative information regarding a targeted gait variable with the intent to improve gait impairments. Previously, we showed that a single session of real-time AGRF BF improves peak AGRF in post-stroke and young able-bodied individuals, with concomitant short-term improvements in gait variables such as plantarflexor (PF) moment and trailing limb angle.<sup>5,6</sup>

PF moment and ankle power generation during the mid- to late stance phase of gait contribute to propulsive force generation, which is crucial for normal stance-to-swing transition, and are reduced in individuals post stroke.<sup>2</sup> Dynamic ankle-joint stiffness (DAS) during gait is the resistance to an applied moment, with contributions from both active and passive mechanisms.<sup>7,8</sup> DAS can be modulated in response to mechanical demands of walking and contributes to propulsion.<sup>9</sup> The relative contributions of active (e.g. PF moment and power) versus more passive (e.g. stiffness) factors to gait propulsion are poorly understood, especially post-stroke. The purpose of this study was to examine the contributions of peak PF moment and DAS on BF-induced increases in AGRF in able-bodied and post-stroke individuals.

## Methods

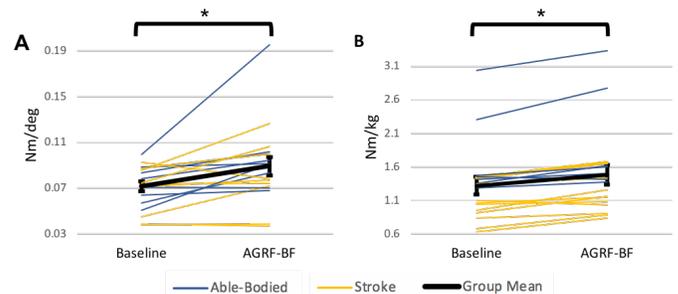

Baseline gait data were collected on 9 individuals with post-stroke hemiparesis (6 M, 3 F,  $63 \pm 9.8$  y,  $44.9 \pm 36.0$  months post-stroke) and 9 able-bodied individuals (2 M, 7 F,  $24.6 \pm 3.0$  y) as they walked at a self-selected pace on an instrumented treadmill (Baseline). Next, during a BF trial at matched speed (AGRF-BF), participants were provided audiovisual feedback to increase peak AGRF in the paretic (stroke) or right (healthy) leg by 25% compared to baseline.<sup>5,6</sup>

Gait biomechanics data were collected with (AGRF-BF) and without (Baseline) AGRF biofeedback. Dependent variables included peak AGRF, peak PF moment, and DAS of the targeted limb. DAS was calculated as the average of ankle moment-ankle angle slopes during dorsiflexion during the stance phase of gait.<sup>7,8</sup> Repeated measures ANOVAs and % change scores (AGRF-BF versus Baseline) were calculated to examine the effects of AGRF-BF. Correlation analyses evaluated relationships among % change scores for each combination of dependent variables.

## Results and Discussion

As intended, BF targeting peak AGRF successfully increased peak AGRF during stance of the target leg in both post-stroke and control subjects by 150.7% and 61.6%, respectively. ( $F_{(1,17)} = 44.78, p < .001$ ). AGRF-BF increased PF moment in both paretic (stroke) and right legs (able-bodied) with increases of 15.9% and 11.0% respectively ( $F_{(1,17)} = 26.06, p < .001$ ). Similarly, AGRF-

BF increased DAS in both the paretic (post-stroke) and right leg (control), with increase of 17.1% and 31.8%, respectively ( $F_{(1,17)} = 9.22, p = .007$ ). Although AGRF-BF induced significant increases in peak AGRF, PF moment, and DAS, correlations among these % change scores were weak ( $R^2 = 0.03-0.2$ ).

**Figure 1.** (A) DAS and (B) Peak PF moment data. \*indicates significant increase between Baseline to AGRF-BF.

While both stroke and able-bodied groups showed significant improvements in both DAS and PF moment during AGRF-BF versus baseline, smaller increases in DAS were observed in the paretic limb post-stroke (17.1%) than in able-bodied individuals (31.8%). We speculate that post-stroke, there may be greater contributions of passive versus active mechanisms to DAS<sup>8</sup>, explaining smaller BF-induced increases in DAS on the paretic leg post-stroke compared to controls, in contrast to similar improvements in PF moment (15.9% vs. 11.0%). Additionally, lack of correlation among % change scores may reflect variable movement strategies as participants develop individualized biomechanical solutions to achieve greater propulsion during BF.

## Significance

Our results take a step toward elucidating potential contributions of passive and active mechanisms to propulsion during late stance in individuals post-stroke, using gait biofeedback as a probe. Future studies will investigate intrinsic factors contributing to DAS during gait in able-bodied versus post-stroke individuals, by concurrent measurement of joint excursion and angular velocities, EMG, and clinical measures. This work has potential clinical implications for gait rehabilitation targeted at enhancing propulsion and gait speed in individuals post-stroke.

## Introduction

Human gait patterns are influenced by our surroundings, and when introduced to potential sources of assistance, our neuromotor system adapts our gait to take advantage of this assistance. We recently found that split-belt treadmills can act as assistive devices by performing positive work on the body during walking [1]. During initial split-belt adaptation, step lengths are longer with the leg on the slow belt, but as time progresses, people lengthen the steps on the fast belt [2] and gradually reduce the mechanical work performed by the legs [3] and metabolic cost [4]. As people bring their fast leg further forward to walk with longer steps on the fast belt, they generate net negative work with the legs such that people can exploit the work done by the treadmill to reduce the positive work by the legs [1]. However, the emergence of this gait requires at least three times longer than is typically allotted in adaptation experiments [5]. Whether instructing individuals to walk with a gait that minimizes the amount of positive work by the legs would change the timescale of the adaptation process has yet to be determined. We hypothesized that providing people with guided experience of a gait that exploits positive work from the treadmill will accelerate adaptation toward a less energetically costly gait [6].

## Methods

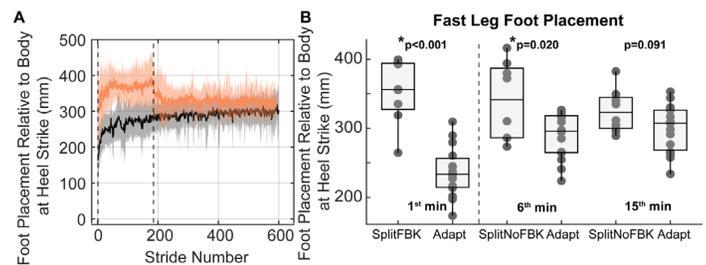

Eight people walked on an instrumented split-belt treadmill with left and right belts moving at 0.5 m/s and 1.5 m/s, respectively. We measured ground reaction forces and the location of ankle markers. We defined step lengths as the distance between ankle markers at heel strike and step length asymmetry (SLA) as fast minus slow step length, normalized by the sum. Participants used visual feedback to maintain an SLA of +15% for five minutes (SplitFBK), and after five minutes, we turned the feedback off (SplitNoFBK) without stopping the treadmill and participants walked for an additional 10 minutes. We calculated the mechanical work rate using the individual limbs method [3,7]. We compared fast limb placement at heel-strike and fast leg work rate for the first minute (1<sup>st</sup> min) of SplitFBK and the first and last minute after feedback was turned off (SplitNoFBK) to data at the same time-points (6<sup>th</sup> and 15<sup>th</sup> min) from a previous unguided adaptation study [5] using independent samples t-tests.

## Results and Discussion

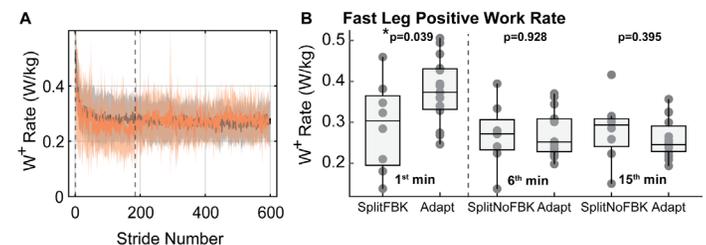

During SplitFBK, participants rapidly increased forward placement of the fast leg compared to unguided adaptation (Fig. 1A & B,  $p=6.69 \times 10^{-6}$ ). This increase in forward foot placement led to a positive SLA ( $0.08 \pm 0.05$ ). Initially, during SplitNoFBK, limb placement remained further forward compared to unguided adaptation (6<sup>th</sup> min,  $p=0.020$ ). By the end of adaptation, limb placement was not different between participants who experienced guided vs. unguided adaptation [8] (15<sup>th</sup> min,  $p=0.090$ ). The initial increase in forward foot placement was accompanied by a lower positive work rate by the fast leg during SplitFBK compared to unguided adaptation (Fig. 2A,  $p=0.039$  1<sup>st</sup>

min). Thus, participants acquired and accepted positive work by the treadmill to reduce the work by the legs at initial exposure to the split-belt treadmill. However, after removing feedback, participants generated similar amounts of work as seen in unguided adaptation (Fig 2B, 6<sup>th</sup> and 15<sup>th</sup> min).

Results suggest that short-term, guided experience with a less energetically costly gait can aid in increasing external assistance, but is not sufficient for people to retain this gait when guidance is removed. Therefore, performance using guided experience is not an indication that individuals have learned how to adjust their gait to accelerate energetic optimization.

**Figure 1.** Foot placement on the fast belt relative to the body. A) Timeseries. Off-red: Guided adaptation. Black: Data from previous adaptation study. Vertical lines: start of SplitNoFBK trial. B) Foot placement at specific timepoints during our study and a previous unguided adaptation study (Adapt).

**Figure 2.** Positive work rate by the fast leg. A) Timeseries. B) Positive work rate at specific timepoints.

## Significance

The success of assistive devices for reducing energy cost depends not only on their design but also on the neuromotor system's ability to adapt coordination to take advantage of external assistance. Accelerating adaptation to assistive devices will lead to more effective implementation of these systems both in healthy and pathological populations. Here, we show that despite the effective use of external assistance with guided feedback, individuals do not retain coordination patterns that allow them to effectively take advantage of assistance in the absence of feedback. Therefore, short exposure with less energetically costly gaits is not enough to accelerate adaptation of locomotion to use external assistance.

### Introduction

Hemiparetic and amputee gaits are often asymmetric and uneconomical [1]. Consequently, asymmetry has been thought to explain the added cost of pathological gait. But it is also possible that gait asymmetry may be adopted if it is energetically optimal.

Adaptability of gait asymmetry is often shown using a split-belt treadmill. Following an adaptation period, step lengths return to symmetry while step times become asymmetric [2]. Recent studies have estimated the energetically optimal value of step length asymmetry [3], but it is unknown how step time asymmetry affects energy cost of split-belt treadmill walking.

Here, we tested the hypothesis that the preferred asymmetry in step times and step lengths adopted during split-belt treadmill walking are selected to optimize energy cost. We tested this hypothesis in 3 speed-difference conditions in which the average speed was kept constant at  $1.25 \text{ m s}^{-1}$  while speed-differences were set at  $0.5 \text{ m s}^{-1}$ ,  $1.0 \text{ m s}^{-1}$  and  $1.5 \text{ m s}^{-1}$ .

### Methods

We recruited 10 healthy, young participants that walked on a split-belt treadmill in 3 speed-difference conditions ( $\Delta 0.5 \text{ m s}^{-1}$ ,  $\Delta 1.0 \text{ m s}^{-1}$  and  $\Delta 1.5 \text{ m s}^{-1}$ ) on separate days. Speed-differences between the belts were set at  $0.5 \text{ m s}^{-1}$ ,  $1.0 \text{ m s}^{-1}$  and  $1.5 \text{ m s}^{-1}$  while the average belt speed was constant at  $1.25 \text{ m s}^{-1}$ . During each visit, participants walked: 1) with tied-belts at  $1.25 \text{ m s}^{-1}$ ; 2) in an adaptation trial with belts split to assess preferred asymmetry; and 3) in cost mapping trials with belts split. Cost mapping consisted of one set of trials with step time asymmetry enforced to  $-0.10$ ,  $-0.05$ ,  $0$ ,  $+0.05$  and  $+0.10$  of the preferred value (obtained during adaptation) and another set of trials with step length asymmetry enforced to  $-0.10$ ,  $-0.05$ ,  $0$ ,  $+0.05$  and  $+0.10$ . Asymmetry is calculated as the difference between the 2 steps divided by their sum. We express metabolic cost as the percentage of net metabolic power of split-belt walking relative to its value during tied-belt walking. Energetically optimal values of asymmetry were estimated for individual participants from the cost mapping trial with minimal metabolic cost. We used paired *t*-tests to test if the preferred asymmetry in step times and step lengths were different from the energetically optimal value of asymmetry.

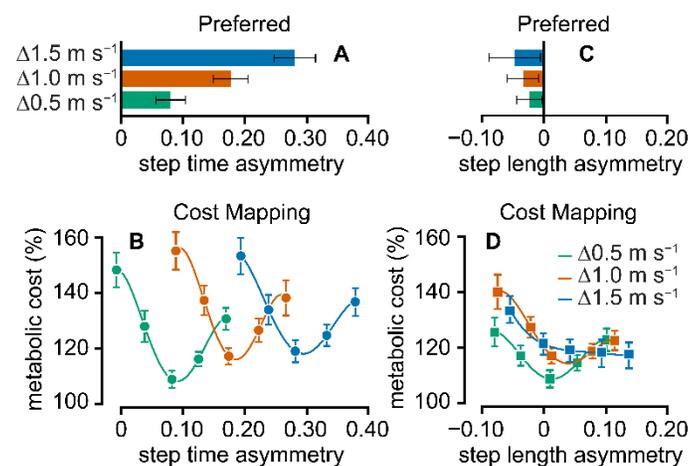

### Results and Discussion

Participants increased their preferred value of step time asymmetry with greater speed-differences between belts (Fig. 1A;  $0.080$ ,  $0.178$  and  $0.282$ ,  $F_{2,18}=288.1$ ,  $P<0.001$ ; post-hoc tests  $P<0.001$ ). Participants' preferred value of step time asymmetry tracked the energetically optimal values (Fig. 1B;  $0.082$  for  $\Delta 0.5 \text{ m s}^{-1}$ ,  $P=0.407$ ;  $0.183$  for  $\Delta 1.0 \text{ m s}^{-1}$ ,  $P=0.545$ ;  $0.302$  for  $\Delta 1.5 \text{ m s}^{-1}$ ,  $P=0.096$ ). This suggests that participants adopted asymmetric step times in order to optimize energy cost.

Participants' preferred values of step length asymmetry remained constant, and nearly symmetric, with greater speed-differences (Fig. 1C;  $-0.024$ ,  $-0.034$  and  $-0.047$ ,  $F_{2,18}=4.0$ ,

$P=0.037$ ; post-hoc tests  $P\geq 0.168$ ). In contrast to step time asymmetry, preferred values of step length asymmetry were not energetically optimal (Fig. 1D;  $0.036$  for  $\Delta 0.5 \text{ m s}^{-1}$ ,  $P=0.001$ ;  $0.061$  for  $\Delta 1.0 \text{ m s}^{-1}$ ,  $P<0.001$ ;  $0.086$  for  $\Delta 1.5 \text{ m s}^{-1}$ ,  $P<0.001$ ). While modifying step length asymmetry may lead to energy savings during the adaptation period [2,3], our results suggest that the preferred value of step length asymmetry is not selected in order to optimize energy cost.

Our findings show that humans will adopt an asymmetric gait to optimize energy cost and suggest that energy optimization of gait asymmetry is associated with the control of temporal gait asymmetry.

**Figure 1:** Preferred asymmetry and cost mapping during split-belt treadmill walking. Preferred step time asymmetry (A) and step length asymmetry (C) obtained from adaptation trials (error bars are S.D.). Metabolic cost of step time asymmetry (B) and step length asymmetry (D) from cost mapping trials (error bars are S.E.M.). Metabolic cost is net metabolic power relative to its value in tied-belt walking at  $1.25 \text{ m s}^{-1}$ .

### Significance

We have shown that healthy humans adopt asymmetric step times during split-belt treadmill walking that are energetically optimal. Our results support the idea that gait asymmetry may be adopted if asymmetry is energetically optimal. This suggests that the gait asymmetry commonly seen in clinical populations may be adopted because it is an economical gait pattern for these individuals and that enforcing a symmetric gait pattern will result in increased energy cost. Of special notice is whether gait asymmetry is manifested in the spatial or temporal domain since our results suggest that it is only the control of temporal gait asymmetry that is associated with energy optimization.

## Introduction

Older adults exhibit a substantial reduction in push-off intensity during walking that is often attributed to deficits in mechanical output from the plantarflexor muscles. Yet, muscle strengthening has been generally unsuccessful in improving habitual gait performance [1], indicating the plantarflexors are not the sole source of age-related reductions in push-off intensity. Recent studies have revealed an important role for foot structures in governing push-off power during walking [2]. The structures of the foot (e.g. plantar aponeurosis and intrinsic muscles) are uniquely suited to function as both a stiff lever for push-off and an elastic energy storage and return system [3] for economical locomotion. However, the effect of age on foot mechanics during walking is unclear. The purpose of this study was to quantify age-related differences in foot mechanical work during walking. Consistent with evidence of age-related decreases in the stiffness of elastic tissues spanning the foot and ankle [4], we hypothesized that (i) older adults would exhibit less positive foot work and more net negative foot work compared to young adults – effects that would (ii) increase with locomotor demand.

## Methods

9 young (24±3 yrs, 76.5±10 kg, 1.7±0.1 m, 5M/4F) and 9 older adults (73±4 yrs, 69.3±6.8 kg, 1.7±0.1 m, 5M/4F) walked barefoot on an instrumented treadmill at three speeds (0.8, 1.2, and 1.6 m/s). Subjects also walked at 1.2 m/s while wearing a waistbelt connected to a motor that prescribed constant horizontal pulling forces (impeding or aiding) equal to 5% body weight. Lower limb kinetics and kinematics were recorded during all walking trials. We calculated foot work in Visual3D using a unified deformable foot model, accounting for contributions of structures distal to the hindfoot's center-of-mass [5]. Two mixed-factor ANOVAs were performed to test for the effect of age and speed (0.8, 1.2, 1.6 m/s) or horizontal pulling force (1.2 m/s, aiding, impeding) on positive and net foot work.

## Results and Discussion

Consistent with our first hypothesis, we found that older adults generated, on average, 38% less positive and 76% more net negative foot work across speeds ( $W^+$ :  $p=0.007$ ;  $W^{net}$ :  $p=0.014$ ) and pulling forces ( $W^+$ :  $p=0.001$ ;  $W^{net}$ :  $p=0.007$ ) compared to young adults (Fig. 1). Contrary to our second hypothesis, the effect of age on positive and net foot work did not change with increasing speed (age×condition,  $W^+$ :  $p=0.527$ ;  $W^{net}$ :  $p=0.108$ ) or pulling force (age×condition,  $W^+$ :  $p=0.251$ ;  $W^{net}$ :  $p=0.543$ ). Although both age groups responded similarly to changes in locomotor demand, greater energy losses via foot structures would appear to place older adults at more of a mechanical disadvantage to young adults during walking tasks with greater demand for power generation; specifically, impeding forces are functionally analogous to accelerating or walking uphill.

## Significance

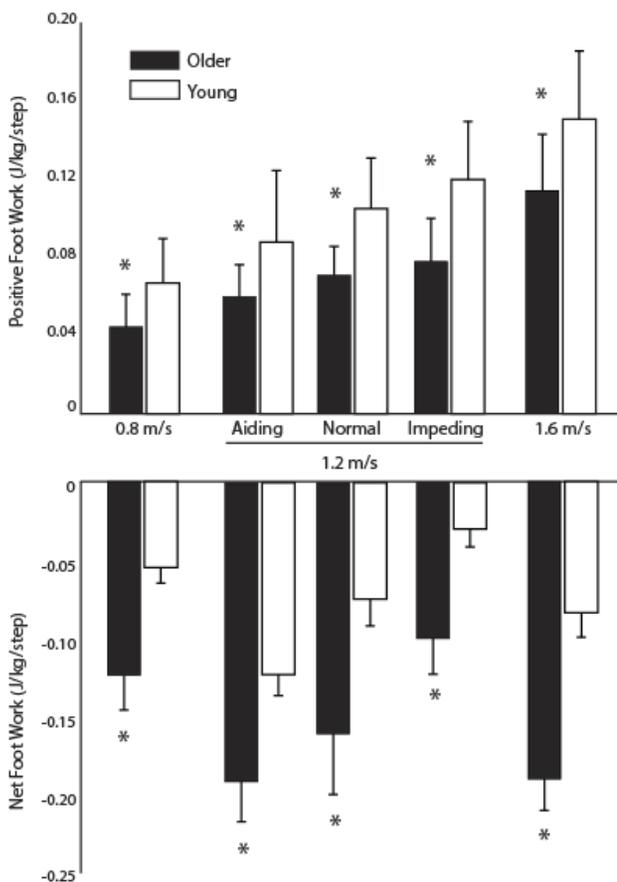

Age-related differences in foot mechanics may contribute to reduced push-off intensity - directly via foot mechanical energy loss, and indirectly via the misappropriation of ankle power output. Moreover, mechanical energy losses via the foot may have metabolic consequences with additional functional relevance. Ultimately, these findings emphasize the need for broader perspective in our biomechanical understanding and thus clinical management of walking ability limitations in our rapidly aging population.

## Introduction

Children with Cerebral Palsy (CP) often exhibit contractures, spasticity and impairments in selective motor control [1], which collectively contribute to inappropriately timed and modulated muscle forces during walking. This can result in severe gait disorders that make daily activities challenging and exhausting [2]. Treatments for gait disorders in children with CP, e.g. spasticity treatments, muscle lengthening procedures, and tendon transfers, are intended to alter muscle-tendon mechanics. However, conventional gait analysis cannot be used to infer the underlying muscle-tendon mechanics, particularly in pathological gait. We are exploring the use of shear wave tensiometry [3] to directly gauge muscle actions during gait in children with CP. In this study, we tested the hypothesis that tendon shear wave patterns would be distinct from joint torques.

## Methods

Nine children with CP (cases) and fifteen typically developing children (controls) participated in this study. The cases were all GMFCS levels 1 or 2 and had previously received one or more orthopaedic treatments. Shear wave tensiometers were secured over the Achilles and patellar tendons of the more affected limb of the cases, and on the right limb of the controls. Tendon wave speeds were measured at 50 Hz during preferred speed walking. We normalized wave speed to the peak value and subtracted the minimum wave speed (which approximated a zero-load state). Lower extremity kinematics and EMG activities were measured bilaterally throughout [4]. Sagittal knee and ankle torques were calculated using inverse dynamics and normalized to body mass.

We calculated both the Pearson correlation and mutual information (MI) index [5] between patellar or Achilles tendon wave speeds and knee or ankle torques, respectively. MI values were normalized such that 0.0 would indicate no synchrony between the two variables and 1.0 would indicate that the two variables covary exactly together. Monte Carlo resampling (100) was used to determine significant MI values [6].

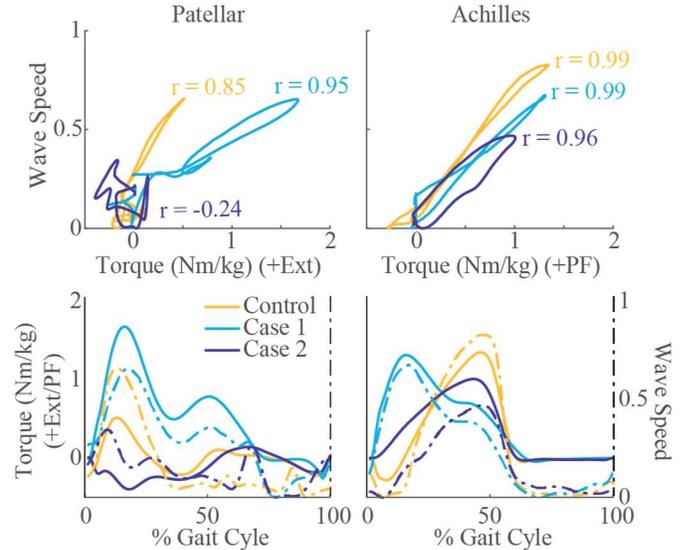

## Results and Discussion

We found a high correlation between Achilles tendon wave speed and ankle torque in both the cases and controls (Table 1). The mutual information between Achilles tendon wave speed and ankle torque was significant in 8/9 cases (MI range: 0.1-0.5) and 13/15 controls (MI range: 0.1-0.3). It is notable that the correspondence was evident across the varied gait patterns seen in the patients with CP. For example, equinus gait gives rise to early triceps surae loading that is visible in both the Achilles tendon wave speed and ankle torque signals (Fig 1).

**Table 1:** Mean (SD) linear correlation coefficient between tendon wave speed and joint torque.

	Cases	Controls
Patellar/Knee	0.70 (0.37)	0.76 (0.13)
Achilles/Ankle	0.97 (0.02)	0.96 (0.03)

Relative to the ankle, there was significantly less ( $p < 0.01$ ) and more variable correlation between patellar tendon wave speed and knee torque (Table 1). The mutual information index was significant in 8/9 cases (MI range: 0.1-0.4) and 8/15 controls (MI range: 0.1-0.4). We noted in individual trials periods of high patellar tendon wave speed and low knee torque (Fig 1), which can arise from co-contraction of the knee extensors and flexors.

**Figure 1:** Representative data shows strong correspondence between Achilles tendon wave speed and ankle torque, even in cases where temporal patterns differ. Correspondence between patellar tendon wave speed and torque is more variable.

## Significance

We are assessing whether shear wave tensiometry can be used to guide treatments of gait disorders in CP. Our data shows that Achilles tendon wave speeds can capture the net ankle loading seen in pathological gait. Patellar tendon wave speeds were shown to both track periods of knee extensor loading and may also capture periods of co-contraction. We note that our current analysis has been limited to patients with CP who are GMFCS levels 1 and 2 and who exhibited relatively mild gait disorders. Ongoing testing is evaluating whether these results extend to more severe gait disorders and to evaluate how tensiometry can be used to evaluate specific treatments.

# Effects of Ankle Weights During Overground Walking Using a Bodyweight Support System

Skyler M. Levine, Patrick M. Costello, Mhairi K. MacLean, and Daniel P. Ferris

<sup>1</sup>University of Florida, Gainesville, Florida, USA

Email: [skylerlevine@ufl.edu](mailto:skylerlevine@ufl.edu)

## Introduction

Bodyweight support can be used in biomechanics research to study the relationship between weight support and joint dynamics. Bodyweight support is also widely used as a rehabilitation therapy after neurological injury. Increasing the amount of harness bodyweight support decreases peak extensor moments of the ankle, knee, and hip [1]. One possible way to alter lower limb joint flexor muscle loading is to add ankle weights, a strategy used in strength training and rehabilitation. Given past debates about the role of plantar flexion power at the end of stance [3], we decided to investigate how ankle weights would affect joint dynamics during walking with and without bodyweight support. If plantar flexor power contributes substantially to accelerating the trailing limb for swing, then adding ankle weights would lead to increased plantar flexion peak power regardless of bodyweight support level.

## Methods

Twelve participants (5 male, 7 female, 26±4 years old, 70±8 kg in mass) walked across an overground walkway at a speed of 1.2 m/s. Participants were supported at 100%, 76%, 55% and 31% gravity (G) via a harness connected to constant force springs which were attached to a trolley mounted on a ceiling I-beam. At all support levels, participants walked with and without 1.81 kg (4-pound) weights attached at the bottom of each shank. 3 force plates along the walkway and a motion capture system were used to record both kinetics and kinematics.

We used Visual3D to model and calculate joint angles, moments and powers. To account for the mass added to the shank, we made a second Visual3D model for each participant with modified mass, center of mass, and moment inertia properties for the shank. We normalized data to body mass, stride, and averaged across participants.

## Results and Discussion

The angle, moment, and power of the lower limb joints were all affected by level of bodyweight support (Fig. 1). Increased bodyweight support decreased the magnitude of flexor and

extensor moment and power for all joints. The impact of the ankle weights on joint kinetics was generally small, but varied by joint and gravity level. In particular, ankle weights led to a larger decrease in the plantar flexion peak power at lower gravity levels (higher bodyweight support) than at 1.0G (Fig. 1).

The large burst in ankle plantar flexion power at the end of stance contributes both to redirecting the center of mass to vault over the stance limb and to accelerate the trailing limb into swing [2]. Our findings show a large decrease in ankle push-off power with increased bodyweight support at the torso, which is in agreement with the theory that ankle push-off contributes to moving the center of mass. We also found that push-off power increased with the addition of ankle weights, supporting the theory that ankle push-off contributes to acceleration of the trailing swing leg. These results support both interpretations of ankle plantar flexor mechanical power at the end of the stance phase.

## Significance

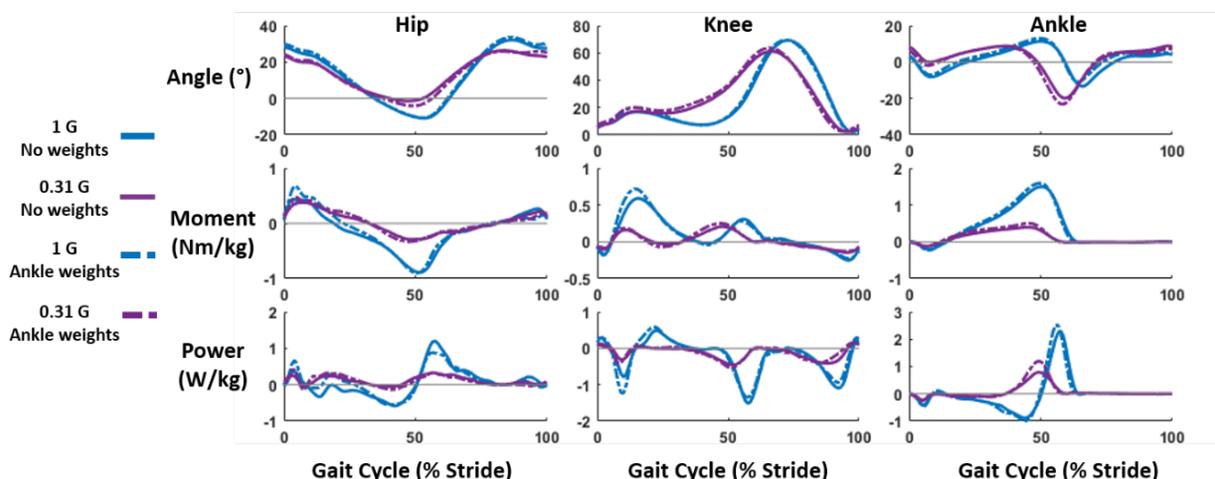

The results from this experimental intervention supports the theoretical effects of ankle joint function during human walking [2]. It also provides some useful data for considering how to use bodyweight support and ankle weights to target specific muscle groups and gait deficiencies during rehabilitation after neurological injury. Lastly, with the development of powered lower limb prostheses and robotic lower limb exoskeletons, having a good understanding of how mass added to the lower limb affects walking biomechanics can be useful for future assistive technology design.

## Acknowledgments

# Split-belt walking against resistance increases walking propulsion asymmetrically

Hurt CP, Kuhman D, Baumann A, Jiang W, Marsh K,

<sup>1</sup>University of Alabama at Birmingham, Birmingham, AL, U.S.A.

Email: \*[cphurt@uab.edu](mailto:cphurt@uab.edu)

## Introduction

Progression of walking requires the generation of positive work on the center of mass in the direction of travel, which is primarily generated by locomotor propulsive forces applied by the stance limb. Symmetric lower extremity propulsive force production is a hallmark of normal gait and related to similar positive work production between limbs as well as relatively low energetic cost of walking<sup>1</sup>. In certain patient populations with kinematic limb asymmetry (e.g., persons post-stroke), this compensatory gait adaptation is related with slower gait speed, higher energy utilization and asymmetric lower extremity force production<sup>2</sup>. Interventions to mitigate asymmetries have primarily focused on modifying kinematic strategies to reduce step length asymmetry using a split-belt walking paradigm whereby one belt goes faster than the other. It is unclear if increased propulsive forces account for the reported improved symmetry. Other novel interventions encourage greater propulsive force output using impeding forces<sup>3</sup>. We performed a study whereby we combined split-belt treadmill walking with increasing impeding forces (hill walking) in young healthy individuals to assess the ability to specifically target increased force output in given limb.

## Methods

We recruited 10 healthy, young adults to participate in this study (mean age: 25.3; mean height: 1.72 m; mean mass: 72.27 kg). Individuals were excluded if they had any lower extremity injury within 6 months prior to participation. We collected kinematics and ground reaction forces (GRF) simultaneously using an 8-camera motion capture system (Vicon) and a dual-belt, force instrumented treadmill (Motek), respectively. Data was processed in Visual 3D and Matlab. Participants walked under the following belt speed configurations: both belts tied at 0.5 m/s and at 1.0 m/s, belts split, with the left belt at 1.0 m/s and the right belt at 0.5 m/s for all participants. After each split-belt trial the participant walked with the belts tied at 1.0 m/s to serve as a “wash out” trial. These conditions were performed in the order listed above at 0 degrees, +5 degrees, and +10 degrees of treadmill incline. Thus, each participant performed a total of 11 walking trials. The “wash out” trials were collected until the participants felt that their gait had normalized and visually appeared to have returned to a normal gait pattern. Brief periods of rest were provided between each trial. For this abstract, only split-belt data on the 0 degrees, +5 degrees, and +10 degrees of incline are presented. Prior investigations have used multiple measures to assess asymmetric force production such as peak propulsive force, peak power production, propulsive impulse and positive ankle work generation<sup>4</sup>. A repeated measures ANOVA was used to assess the effect of limb and incline on these measures with a Bonferoni post hoc analysis.

## Results and Discussion

For propulsive GRF impulse, we observed an interaction effect of belt speed and slope ( $p < 0.001$ , Figure 1A) where the GRF impulse of the limb on the slow belt increased at a greater rate than the fast belt. Stance time did not change with slope ( $p=0.546$ ) but was different between limb ( $p<0.001$ ) however

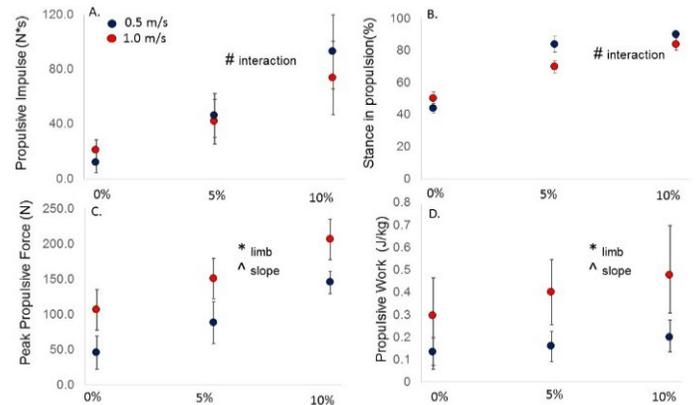

Figure 1. Result of the split belt incline conditions. 1A Propulsive impulse with incline 1B % stance with respect to split-belt and incline, 1C Peak propulsive force with respect to split-belt and incline 1D propulsive work with respect to split belt and incline #significant interaction, \*significant effect of limb, ^significant effect of slope

the interaction was not significant (0.818), suggesting that this variable did not explain the interaction effect on propulsive impulse. Time spent in propulsion (i.e. positive GRF) however, increased with slope to a greater amount for the slow limb compared to the fast limb ( $p<0.05$  interaction) explaining the propulsive impulse finding. Peak propulsive GRF forces for both limbs increased at the same rate ( $p<0.001$  main effect of slope) and the limb on the fast belt generated a larger peak GRF ( $p<0.001$  main effect of limb Figure 1C), with no significant interaction ( $p=0.939$ ). Ankle joint work increased with slope ( $p<0.01$ ) while the limb on the fast belt performed 70% more positive work than the limb on the slow belt ( $p<0.01$  Figure 1D). This data may suggest that under these conditions increased propulsive impulse may relate to increased time spent in the stance phase on the slow belt supporting body weight, whereas the increased positive ankle work by the limb on the faster belt is in response to an increased propulsive stimulus to that limb (faster belt+increased resistive forces via treadmill belt incline). It would be of interest to extend this analysis to the hip extensors as well.

## Significance

Split-belt treadmill walking paradigms may create opportunities to improve asymmetric gait adaptations that negatively impact walking in patient populations. Addition of resistive force (e.g., incline walking) to forward progression showed that, depending on the variable used, different decisions can be made about which limb to put on the fast belt and which limb to put on the slow belt to improve kinetic asymmetric gait adaptations. This requires an assessment of goals for the training be carefully laid out.

# Muscle coordination retraining reduces knee contact force during gait

Scott D. Uhlrich<sup>1</sup>, Rachel W. Jackson<sup>1</sup>, Ajay Seth<sup>1</sup>, Julie A. Kolesar<sup>1</sup>, Scott L. Delp<sup>1</sup>

<sup>1</sup>Stanford University, Stanford, CA, USA

email: suhlrich@stanford.edu

## Introduction

Reducing knee contact force (KCF) during gait is the target of many non-surgical interventions for knee osteoarthritis<sup>1</sup>. Muscle forces are responsible for 50-75% of KCF during walking<sup>2</sup>, but most joint-offloading interventions do not target the muscle contribution to KCF. Musculoskeletal simulations suggest that minimizing the activation of the gastrocnemius muscle, without changing joint-level kinetics, could reduce the second peak of KCF<sup>3</sup>. However, it is unknown what muscle compensations are necessary to walk without activating the gastrocnemius and whether humans can change the relative activation of redundant muscles during a complex task like walking. The aims of our study were to identify the coordination changes necessary to walk with minimal gastrocnemius activity, to test whether healthy individuals could learn this new coordination pattern with biofeedback, and to evaluate if the intervention reduced the second peak of KCF.

## Methods

To investigate the differences between natural and “gastrocnemius avoidance” coordination patterns, we simulated walking in OpenSim<sup>4</sup> with two static optimization objective functions: one that minimized the sum of activations squared and another that additionally penalized gastrocnemius activation. Walking without the gastrocnemius required increased soleus and hamstrings activation to generate the necessary ankle plantarflexion and knee flexion moments.

Based on the simulation results, we chose to retrain the relative activation of the ankle plantarflexors, with the goal of reducing gastrocnemius activity without altering the ankle plantarflexion moment. Ten healthy adults (26±4 years old, 4 female) performed five 6-minute walking trials on an instrumented treadmill: a baseline trial, three feedback trials, and a retention trial. During all feedback trials, a real-time bar plot instructed participants to reduce their gastrocnemius to soleus activation ratio, which we defined as the ratio of the average electromyogram (EMG) linear envelopes. During the final two feedback trials, participants were given additional feedback (bar color) to reduce average gastrocnemius EMG. No feedback was given during the retention trial. To evaluate the effect of gastrocnemius avoidance gait on KCF, we simulated five gait cycles from the baseline and retention trials using a custom static optimization algorithm that minimized activations squared while constraining the simulated gastrocnemius to soleus activation ratio to match the ratio from EMG.

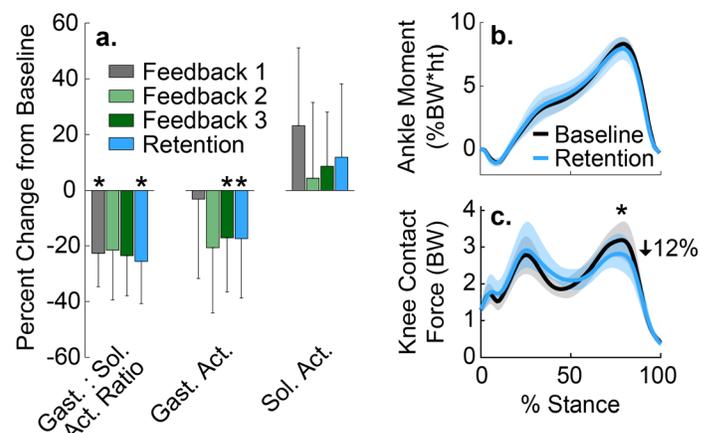

Muscle activity and KCF were compared between trials using t-tests ( $\alpha=0.05$ ) with a Benjamini Hochberg correction. We compared average ankle moments using a TOST equivalence test with equivalence bounds of 1 baseline standard deviation. Average values are reported as mean ± standard deviation.

## Results and Discussion

During the retention trial, participants reduced their gastrocnemius to soleus activation ratio by 25±15% ( $p=0.003$ ) and their average gastrocnemius activation by 17±19% ( $p=0.036$ ),

Fig. 1a). The average ankle plantarflexion moment during the retention trial trended towards being equivalent to baseline ( $p=0.063$ , Fig. 1b). These results demonstrate that when provided with interpretable EMG biofeedback, healthy individuals can quickly learn to change the activation of redundant muscles while maintaining normal joint kinetics.

The 8 participants who retained a reduction in gastrocnemius activation reduced their second peak of KCF by 0.41±0.34 bodyweights (12%,  $p=0.011$ ) compared to baseline (Fig. 1c). This KCF reduction is similar to the effect of losing 20% of bodyweight<sup>5</sup>, suggesting that gastrocnemius avoidance gait may be a promising new intervention for knee osteoarthritis.

**Fig. 1:** (a) During the retention trial, participants reduced their gastrocnemius to soleus activation ratio ( $p=0.003$ ) and average gastrocnemius activation ( $p=0.036$ ) compared to baseline (b) without substantially changing their average ankle moment ( $p=0.063$  equivalent to baseline). (c) The 8 participants who retained a reduction in gastrocnemius activation reduced the simulation-estimated second peak of knee contact force by 12% ( $p=0.011$ ). (\*  $p<0.05$ )

## Significance

Simulation-guided coordination retraining is a promising tool for reducing joint contact force in the knee as well as in other redundantly-actuated joints that often experience osteoarthritis, such as the hip. More generally, we show how simulations and biofeedback can be coupled to design coordination retraining interventions that achieve non-intuitive but clinically-meaningful objectives. This approach may allow individuals to optimize muscle coordination for a variety of rehabilitation, injury prevention, and sports performance applications.

# Peak Knee Joint Forces During Asymmetric Split-Belt Treadmill Walking: A Preliminary Study

E. Dan Syrett<sup>1</sup>, Carrie L. Peterson<sup>1</sup>, and Benjamin J. Darter<sup>1</sup>

<sup>1</sup>Virginia Commonwealth University

Email: syretted@vcu.edu

## Introduction

Certain pathologies, such as lower limb amputation or stroke, can cause individuals to walk asymmetrically. An increase in knee joint contact forces (KJCF) may be a consequence of gait asymmetry and is hypothesized to contribute to osteoarthritis (OA) development.<sup>1</sup> Musculoskeletal modeling and simulation provides a means to non-invasively estimate KJCF.

A previous simulation study showed that changes in symmetry affect KJCF in a 2D model based on normative data.<sup>2</sup> However, no study has used data from *in vivo* collections where gait symmetry is manipulated to inform simulations and estimate KJCF. A split-belt treadmill (SBTM) is a unique tool that utilizes two belts moving at different speeds to provoke gait asymmetries (most robustly in step length) in a systematic manner. The purpose of this preliminary study was to determine the effect of provoked step length (SL) asymmetry during a SBTM walking program on peak KJCF in healthy individuals.

## Methods

The analyses were conducted on previously collected data from 15 healthy adults who completed a standardized SBTM test.<sup>3</sup> The test consisted of Baseline slow walking (both belts 0.5 m/s), a Split adaptation period with a random belt-limb assignment ("Fast" belt speed 1.5 m/s, and "Slow" belt speed 0.5 m/s), and a Post "wash out" period after the Split condition (both belts 0.5 m/s). Of significance, the limb assigned to the Fast belt for the Split condition has a longer SL relative to the limb assigned to the Slow belt during the Post condition. As such, SL is symmetric during Baseline walking but more asymmetric early in the Post condition.

Full-body motion capture data (100 Hz) and SBTM-integrated force plate data (1000 Hz) were collected with analyses completed on 5-second epochs from late in the Baseline condition and early in the Post condition. Using OpenSim's suggested workflow and the gait2392 model, muscle activation patterns were determined using computed muscle control and KJCF was calculated. Axial KJCF curves for each limb were created and normalized to the subject's body weight (BW) and to the gait cycle. SL (in meters) and peak KJCF (peak force) were calculated then averaged for each condition. A symmetry value for SL (SLSym) and peak force (PFSym) were calculated using a previously established method<sup>3</sup> for each walking condition in which 0 reflects perfect symmetry.

Paired t-tests were used to compare SL, peak force, SLSym and PFSym values between belts and walking conditions. A Pearson correlation between PFSym and SLSym was also calculated to examine their association.

## Results and Discussion

SLSym and PFSym values revealed symmetric SL and peak force values during the Baseline condition and asymmetric SL and peak force values during the Post condition (Table 1, both comparisons  $p < 0.01$ ). SL/SLSym values behaved as expected for this testing paradigm.

There was a significant negative correlation between SLSym and PFSym values (Figure 1,  $r = -0.64$ ,  $p < 0.01$ ). This indicates that

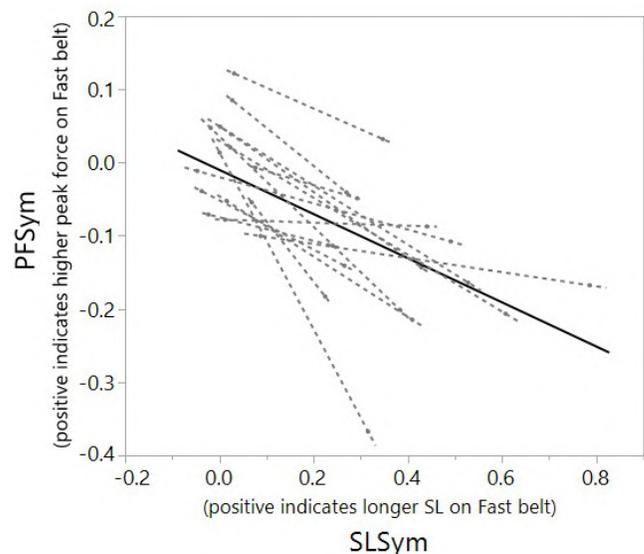

as the relative SL of the Slow belt limb compared to the Fast belt limb decreases, the peak force experienced on the Slow belt limb compared to the Fast belt limb increases.

**Table 1.** Average values for SL, peak force, SLSym, PFSym for each walking condition and paired t-test significance results.

Variable	Belt	Baseline	Post	p
SL (m)	Fast	0.41±0.04	0.44±0.06	0.02*
	Slow	0.39±0.03	0.20±0.08	<0.01*
SLSym		0.02±0.04	0.40±0.15	<0.01*
Peak Force (BW)	Fast	3.28±0.40	2.62±0.33	<0.01*
	Slow	3.29±0.38	3.51±0.45	0.10
PFSym		-0.00±0.06	-0.14±0.09	<0.01*

(mean±SD), \*= $p < 0.05$

These preliminary results suggest that an increase in SL asymmetry may be associated with an increased asymmetry in peak knee joint forces between limbs during gait in healthy individuals. When SL asymmetry occurs, the limb with a shorter SL appears to demonstrate higher peak knee force.

**Figure 1.** Negative correlation between PFSym and SLSym. Solid line indicates overall best fit. Dashed lines indicate fit between Baseline and Post for each subject.

## Significance

This study suggests that step length asymmetry may correlate with peak knee joint forces during gait, a modifiable factor thought to contribute to the increased prevalence of knee OA seen in certain clinical populations.<sup>4,5</sup> If these preliminary results hold, rehabilitation techniques may consider addressing gait symmetry to mitigate the development of knee OA.

# Surface stiffness affects knee joint kinetics during decline but not level running

Paul DeVita<sup>1</sup>, Joey Casadonte<sup>1</sup>, Nick Murray<sup>1</sup> and John Willson<sup>2</sup>

<sup>1</sup>Department of Kinesiology and <sup>2</sup>Department of Physical Therapy, East Carolina University  
Email: \*devitap@ecu.edu

## Introduction

Running provides numerous health benefits and detriments including increased cardiovascular health and knee joint injuries, respectively. Here we focus on knee joint loading as a potential mechanism for tissue conditioning and knee injury. External loads in running, i.e. GRFs, are affected by surface inclination (1) and surface stiffness (2) with downhill running and stiffer surfaces associated with relatively large GRFs. Since runners increase their lower extremity stiffness with less stiff surfaces (3) the effect of surface stiffness on actual knee loads is difficult to predict (and is not in the literature) as is the interaction of inclination and stiffness. Indeed, we envision the potential of softer surfaces to reduce knee loads in decline but not level running because the displacement of the surface material during runner-surface interactions may be greater in decline running; i.e. the runner's momentum would be directed more along the surface in decline vs level running. We therefore hypothesized an interaction effect between surface inclination and stiffness on knee joint loads: a less stiff surface will reduce knee loads more in decline and less in level running. The purpose of this study was to test the effect of surface stiffness on knee joint loads in decline and level running.

## Methods

14 healthy runners (22 yrs, 71 kg, 8 males) provided written informed consent to university approved procedures. Knee joint patello-femoral compression and tibio-femoral compression and shear forces were modelled (4) from GRFs and kinematics during 10° decline and level running at a controlled speed (mean 3.2 ms<sup>-1</sup>), both with and without a 3 cm thick polyvinyl chloride (PVC) sponge shock absorbing mat (closed cell, Shore 00 65) placed along the entire runway. All trials used a heel-strike pattern. Maximum forces were analysed with 2-way (inclination x surface stiffness) ANOVA followed by Scheffe post hoc tests, all p<0.05.

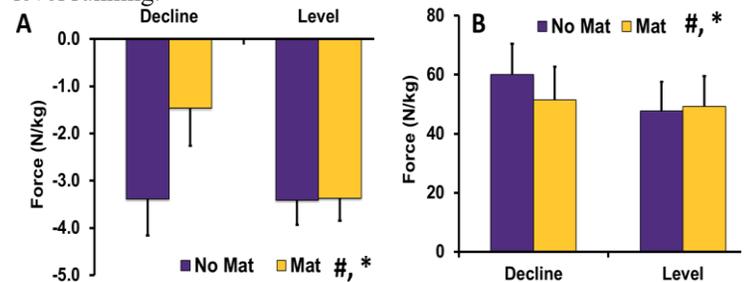

## Results and Discussion

Significant interactions were observed for the four forces in figures 1 and 2. Decline running on reduced surface stiffness lowered the posterior GRF 56% and the patello-femoral compression, tibio-femoral compression and shear forces 15%, 6%, 15%, respectively, compared to the stiffer surface, all p<0.05. Whereas, surface stiffness had no effect on these forces in level running (all p>0.18).

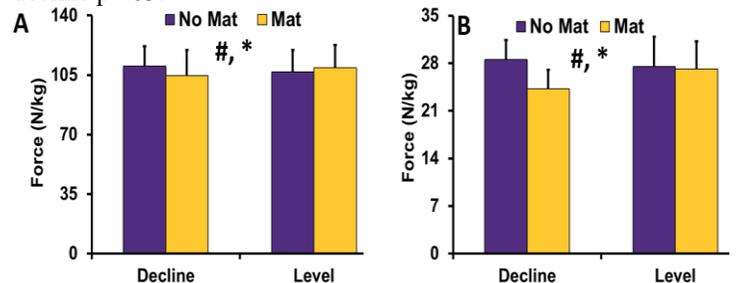

Maximum vertical GRF was not affected by inclination angle or surface stiffness (data not shown). We suggest that the mat reduced knee forces in decline but not level running because the impact between runner and surface was more in line with the surface in decline producing a larger displacement of the mat material (thus the reduced Ant/post but not vertical GRF). We note the general similarity between the magnitude of the decline and level forces may have been due to the 10% shorter stride length in decline (means, 2.21 m vs 2.44 m, p<0.001)

These data may be specific to the declination angle, running speed, and amount and quality of the cushioning mat surface. At lower and higher angles of decline running smaller and larger

differences may have been observed between decline and level running, respectively. At faster speeds, the differences between surface inclinations may be reduced if the given mat could not dissipate the loads sufficiently in decline running. Different mat thicknesses and shore specifications could also yield different results. Given these limitations, we observed support for the hypothesis that reductions in surface stiffness during decline running would reduce knee joint forces more so than during level running.

**Figure 1:** A) maximum posterior ground reaction force, B) maximum patello-femoral compression, #interaction p<.005, \* decline p<.05.

**Figure 2:** A) maximum tibio-femoral compression, B) maximum tibio-femoral shear, #interaction p<.005, \* decline p<.05.

## Significance

We demonstrated that within our limitations, reducing surface stiffness does not reduce knee joint loads in healthy, young adults during moderate speed level running. Further, the same reduction in surface stiffness can reduce knee loads during moderate angled decline running. These data provide a basis to hypothesize about tissue conditioning and running injury and the interactions highlight the need for more comprehensive analyses when investigating running biomechanics.

# Estimating Knee Joint Load with Joint Acoustic Emissions During Walking

Keaton L. Scherpereel<sup>1</sup>, Nicholas B. Bolus<sup>2</sup>, Hyeon Ki Jeong<sup>2</sup>, Omer T. Inan<sup>2</sup>, and Aaron J. Young<sup>1</sup>  
<sup>1</sup>Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, USA  
<sup>2</sup> School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, GA, USA  
Email: keaton@gatech.edu

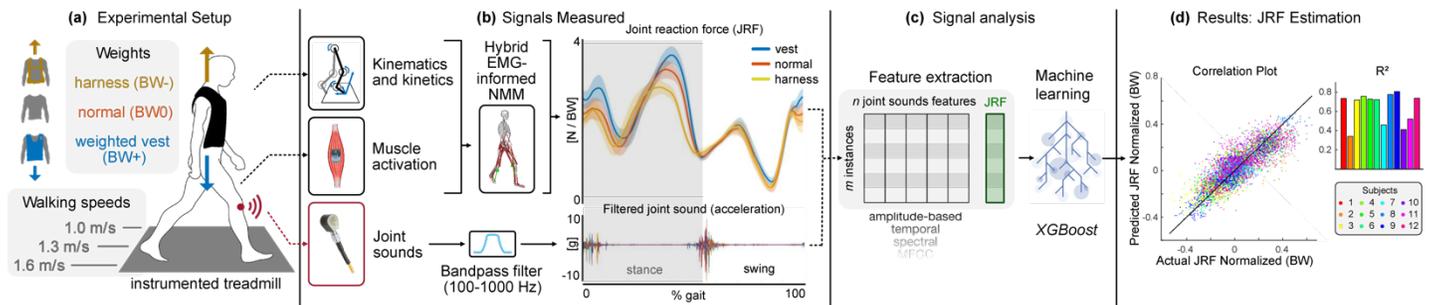

Figure 1: Summary of the experimental setup, data acquisition, analysis, and results.

## Introduction

Joint load during dynamic activities is an important metric for understanding the mechanics of knee joint injuries [1], assessing the progression of disease [2], and evaluating rehabilitation and prevention procedures [3]. However, knee joint load cannot be measured directly but instead must be estimated in facilities that have access to advanced data acquisition tools (including motion capture systems, force plates, and often surface electromyography (EMG) sensors) [4]. A wearable solution that could offer continuous monitoring of joint load and be readily integrated into a brace or wearable exoskeleton would offer new possibilities for clinicians to assess rehabilitation procedures and for device designers to incorporate joint load into adaptive control schemes.

Joint acoustic emissions can enable differentiation of healthy and injured knees [5], evaluation of the progress of knee injury rehabilitation [6], and detection of changes in mechanical load during controlled flexion-extension tasks [7][8]. This study investigates whether joint acoustic emissions can be used to estimate joint load, specifically during walking.

## Methods

Twelve able-bodied subjects with no history of surgery or symptomatic injury within the past year were recruited to participate in a single day, IRB approved, gait analysis study. The experimental protocol consisted of level ground walking for two minutes on a split-belt force-instrumented treadmill for nine conditions (three loading conditions, three speed conditions). During this study, joint acoustics from two locations on the left knee (Dytran contact accelerometers), EMG for 7 muscles on the left leg (Delsys), kinematics (Vicon motion capture), and ground reaction forces (Bertec) were collected (Figure 1a).

The latter three measures were processed using conventional gait analysis tools (OpenSim) and used to estimate joint reaction forces (JRF) using a hybrid EMG-informed neuromuscular model [9]. The joint acoustic emissions were bandpass filtered between 100-1000Hz, split by gait cycle, and features (time-based, spectral, MFCCs, etc.) were extracted from 50ms windows of stance phase for the instrumented leg (excluding heel strike). Finally, a regression model, based on the machine learning algorithm XGBoost, was developed to estimate joint load from the acoustic features. The data for each condition were split using the first minute of each trial for training and the

second minute for testing. A model was developed for each subject (Figure 1b,c).

## Results and Discussion

The results show that the joint load for a three-cycle average can be predicted with a root-mean-squared error of  $73.2 \pm 10.5\text{N}$  and a mean absolute percent error of  $3.3 \pm 0.4\%$  of the total load. For the correlation plot (Figure 1d), the JRF for each subject was normalized to the normal body weight condition at 1.3 m/s. Ongoing work includes examining the relationship between joint acoustics and varying walking speeds, as well as developing a subject-independent model for estimating joint load. The key result of this study is that joint acoustic emissions contain information about loading that can be extracted during walking in order to estimate joint load.

## Significance

Joint acoustic emissions have the potential to estimate joint load accessibly and non-invasively, which may provide clinicians with a wearable means of monitoring joint load outside of a research facility through a cumulative, ambulatory load estimate. Such a device could open possibilities for developing new adaptive device control strategies that respond to the physiological state of patients and for utilizing joint load as a metric to better evaluate the effects of rehabilitation strategies and devices.

## Predictive Modeling of Serious Injury Risk in Frontal Crashes

Zachary Merrill<sup>1\*</sup>, Omid Komari<sup>1</sup>, Kevin Toosi<sup>1</sup>

<sup>1</sup>BioEx Consulting, Pittsburgh, Pennsylvania

Email: \*zfmerrill@bioexconsulting.com

### Introduction

Previous research has shown differences in the prevalence of serious injuries and fatalities based on obesity, mass, and sex [1-5], particularly for the risk of lower extremity, spine, and head injuries [2,3]. Explanations for these differences include alterations in seatbelt kinematics [4,5], as well as interactions with the steering wheel in frontal collisions [6].

The objective of this study was to use a Bayesian logistic regression approach to further investigate the effects of anthropometric parameters including sex, age, and BMI on the probabilities of serious injury, based on the Abbreviated Injury Scale, or death in frontal car crashes with airbag deployment. This analysis will improve upon existing research [1,2] by observing cases specifically involving airbag deployment, describing the full probability distributions of the outcomes, and validating the predictive abilities of the models. The results will serve as a jumping-off point for future work describing the ranges of probabilities for specific injuries based on accident parameters.

### Methods

Car crash and occupant injury data were collected from the National Automotive Sampling System for 2010 through 2015. Variables of interest included occupant age, BMI, sex, restraint use, and injury severity/fatality, as defined by the maximum abbreviated injury score (MAIS), along with the principal direction of force due to impact and airbag deployment status.

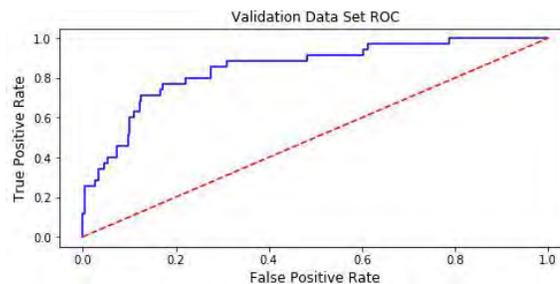

Data were filtered to only include cases containing all variables of interest for front seat occupants ( $N = 3,171$ ), and the 2010 through 2014 data were used as the training data set, while the 2015 data were used for model validation. The analysis was performed using a custom Python script, with a Markov Chain Monte Carlo algorithm to determine the relationships between age, sex, BMI, and restraint use and the probability of serious injury (MAIS 3+) or death over a range of peak longitudinal change in velocity during a crash (delta-V) in the training set.

Outcomes of interest included the odds ratios and credibility intervals of each parameter of interest, as well as the risk of serious injury or death across a range of delta-V for sets of parameter inputs. The logistic models were validated based on the ROC plot and area under the curve (AUC) for the 2015 injury outcomes and predicted injury probabilities.

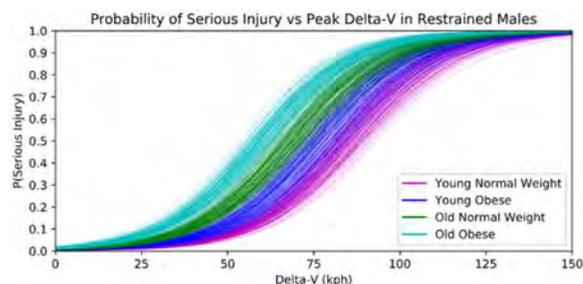

### Results and Discussion

Age, restraint use, and BMI all had significant predictive abilities on the risk of serious injury or fatality in crashes with frontal airbag deployment. The ROC plot (Figure 1) AUC value of 0.851 indicated that the resulting models had excellent accuracy in predicting serious injury risk. The overall results indicate that increased age and BMI, and lack of restraint use are associated with increased risk of serious injury in frontal collisions involving airbag deployment (Figure 2).

While obesity is a known risk for certain types of automobile crash-related injuries [4], this work highlights the specific probabilities of overall serious injury or death depending on anthropometric inputs and crash parameters and quantifies the statistical effects of aging, obesity, sex, and restraint use.

**Figure 1:** ROC plot for the validation data set. AUC = 0.851.

**Figure 2:** Probability of serious injury or death for restrained front seat male occupants for delta-V ranging from 0 to 150 kph, stratified by age (20 and 60 years) and BMI groups (20 and 40 kg m<sup>-2</sup>).

### Significance

This analysis defines the overall serious injury and fatality risk as it applies to a wide range of occupant age and BMI in frontal crashes involving airbag deployment. Future work will apply this methodology to observe the risk of differing levels of injury severity to various body regions (for example, how spine or lower extremity injury risks related to age and obesity), as well as fatalities and their specific causes from different types of automobile accidents. This work will be particularly useful to the forensics field, where delta-V (and other relevant crash parameters) can be derived from vehicle crush calculations and data from event data recorders, and can be used along with individual occupant information to determine the real-world risk of specific injuries occurring during a given crash. The inclusion of airbag deployment status is especially important for injury prediction due to the lack of clear airbag deployment thresholds based only on the delta-V experienced during an accident [7].

Utilizing a Bayesian approach for predicting injury and death risk will also allow for the future predictive models to incorporate prior knowledge, such as the prevalence of pre-existing conditions within the general population, as well as age, sex, and obesity-related trends in these conditions, and how they may affect the probability of specific injury occurs due to a motor vehicle accident while avoiding the potential statistical disadvantages of previous work [1], which employed a stepwise elimination process [8].

### Introduction

Concussions in sports occur at an alarming rate, with nearly 4 million concussions in the United States each year [1]. Experimental data are needed first to understand how a person responds to an impact and then to propose strategies to reduce the risk of concussion.

Although muscle activation at the time of impact can be a useful protective mechanism, muscles are not fast enough to fully activate at the time of impact. [1]. Several studies have indicated that stronger necks reduce concussion risk [2], but other literature reports opposing viewpoints [4], [5]. Experimental studies that involve safe impacts on participants in laboratory settings suggested active neck muscles may reduce the risk of injury [2]-[3]. Also, we hypothesized that the peak force of the impact increased when the participants clenched their necks. In this article, we investigate the effect of neck muscle activation on the force profile and linear acceleration of the head during impact.

### Methods

Ten male participants (Age:  $24.9 \pm 3.5$  y.o and  $72.3 \pm 16$  kg) were studied using a custom head impact testbed described in prior work [6]. Each participant experienced 50 impacts in four different directions. In 7 of those 50 impacts, 1 second before the impacts, participants were warned with an audio signal and clenched their neck prior to the impact. In 10 control trials, participants did not know about the incoming impact (Unwarned). The direction of the impact was unknown for both conditions. Impact force was measured using an S-type load cell at 2kHz, and the linear acceleration of the head was measured using an instrumented mouthguard at 2 kHz. A linear mixed model was used for statistical analysis and paired t-test used for the post-hoc analysis. P-value < 0.05 is considered statistically significant.

**Figure 1:** Resultant linear acceleration and applied force to the head at impact.

### Results and Discussion

As it is depicted in Figure 1, the resultant linear acceleration of the head shows a significant reduction in the warned condition,  $45.6 \pm 1.5$  m/s<sup>2</sup>, compared to  $54.3 \pm 2.5$  (mean±StdErr) m/s<sup>2</sup> in the control condition. The neck muscle contraction reduces the peak resultant linear acceleration by 16%. The participants' strength was not significant in the linear mixed as a fixed factor ( $p = .7$ ), but it improves the accuracy of the model significantly as a random slope. Peak linear acceleration of the head was not significant in front impact,  $45.2 \pm 7.5$  (mean±Std) m/s<sup>2</sup>, versus back impact,  $45.7 \pm 5.9$  m/s<sup>2</sup>, but both of them were significant compared to the lateral impacts,  $58.1 \pm 30.25$  m/s<sup>2</sup>. These results suggest that there is greater force dampening of an impact in the sagittal plane from the anterior or posterior versus a lateral impact.

The peak force in a warned condition of  $42.38 \pm 4.1$  N is not significantly different from the control condition,  $41.37 \pm 4.0$  N, however, the area under the curve for the warned condition,  $1.057 \pm 0.071$  N.s, is significantly higher than the control condition,  $1.003 \pm 0.081$  N.s. Also, the peak force is not significantly different in lateral impact compared to the front and back impact, but the peak linear acceleration of the head is significantly different in all of these cases. Although we hypothesized that stiffer neck muscles would increase the peak force, we failed to reject the null hypothesis. The flexibility of the headband strap may have contributed to this unexpected finding.

### Significance

A reduction in head linear acceleration for the impacts with warning compared to control trials suggests that active neck muscles can help to dampen the force of impact. These results do not suggest there is a benefit of muscle strength in the reduction of linear acceleration. We cannot suggest the elimination of the neck strength program from the training as the forces are concussive level. Also, we would not suggest using the force of an impact as the only predictor for linear acceleration because the direction of the impact and the neck muscle activation significantly affect the resultant acceleration.

## Choosing Mastectomy and Breast Reconstruction or Breast Conserving Therapy: Implications for Pectoralis Major Function

Joshua M. Leonardis<sup>1</sup>, Adeyiza O. Momoh<sup>2</sup>, and David B. Lipps<sup>1</sup>

<sup>1</sup>School of Kinesiology, University of Michigan, USA, <sup>2</sup>Section of Plastic Surgery, University of Michigan, USA

Email: jleo@umich.edu

### Introduction

Traditionally, breast cancer that is localized to the breast is managed with breast conserving therapy (BCT) which refers to the combination of lumpectomy and radiotherapy. A lumpectomy removes the tumor and a small volume of soft tissue, while radiotherapy minimizes recurrence. However, an increasing number of women eligible for BCT are opting for a mastectomy, which is a surgical procedure that removes all of the breast tissue. The majority of women undergoing mastectomy will also have a reconstructive surgery performed to restore volume to the chest with an implant or autologous tissue<sup>1</sup>. The most common breast reconstruction is a two-stage subpectoral implant, which requires the disinsertion of the pectoralis major from its inferior attachments. Pectoralis major function is likely impacted by both BCT and mastectomy with a subpectoral implant breast reconstruction, but there has been no direct comparison of these treatments for managing breast cancer<sup>2,3</sup>. Therefore, the purpose of this study was to assess the effect of subpectoral implant breast reconstruction and BCT on the material properties of the pectoralis major at rest and during the generation of planar shoulder torques.

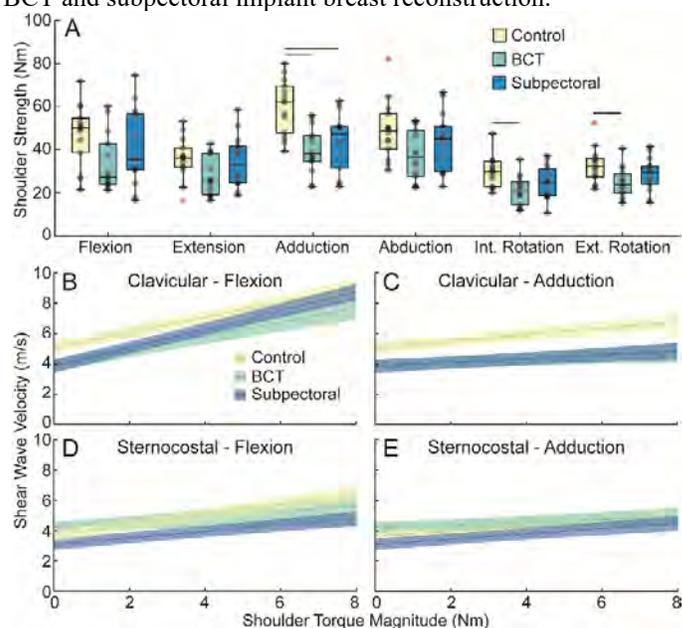

### Methods

Fourteen BCT patients (mean: 602 days post-treatment, age: 54 yr, height: 1.61 m, weight: 69 kg), 14 subpectoral implant breast reconstruction patients (570 days post-operative, age: 50 yr, height: 1.63 m, weight: 71 kg), and 14 healthy, age-matched controls (age: 52 yr, height: 1.64 m, weight: 65 kg) generated maximum voluntary shoulder torques with their treated (BCT and subpectoral implant) or dominant arms (controls). Next, an Aixplorer ultrasound elastography machine measured the shear wave velocity (SWV) of the clavicular and sternocostal fiber regions of the pectoralis major while participants either remained at rest or generated shoulder torques scaled to 10% of their maximal strength in flexion or adduction<sup>4</sup>. When obtained at rest and during active contraction SWV provides insight into a muscles contributions to joint function. Linear mixed effects models assessed group differences in shoulder strength. Separate linear mixed effects models assessed the influence of the experimental group and shoulder torque magnitude on SWV obtained from each fiber region of the pectoralis major.

### Results and Discussion

Healthy control participants were significantly stronger during the generation of shoulder adduction, internal rotation, and external rotation torques when compared to BCT patients (all  $p \leq 0.02$ ), and significantly stronger during the generation of adduction torques when compared to subpectoral implant patients ( $p = 0.004$ ) (Figure 1A). We observed that in all three groups, SWV within the clavicular fiber region increased with increasing flexion torque magnitude and sternocostal fiber region SWV increased with increasing adduction torque magnitude (all  $p \leq 0.037$ ). This is to be expected based on the anatomy of the pectoralis major, as the clavicular fiber region's largest moment arm is in flexion, while the sternocostal fiber region's largest moment arm is in adduction. However, we found that healthy participants utilize the clavicular fiber region more during the generation of shoulder adduction torques (all  $p \leq 0.049$ ) (Figure

1C) and the sternocostal fiber region more during the generation of flexion torque (Figure 1D) when compared to BCT or subpectoral implant participants (all  $p \leq 0.002$ ). These results suggest that in healthy participants, the entire pectoralis major contributes to shoulder function, whereas the individual fiber regions contribute only to their primary function in BCT and subpectoral implant participants. Finally, we found that the clavicular fiber region increased its contributions to shoulder flexion torques in subpectoral implant patients when compared to healthy controls ( $p = 0.016$ ) (Figure 1B). The clavicular fiber region is the only intact fiber region in subpectoral implant participants, so it is not surprising that it increases its contributions to shoulder flexion. Together these results indicate that pectoralis major function is fundamentally altered following BCT and subpectoral implant breast reconstruction.

**Figure 1:** (A) Box plots representing group median  $\pm$  interquartile range differences in shoulder strength. Individual subject data are presented as transparent black dots, while outliers are presented in red. Horizontal bars signify significant group differences at  $p < 0.05$ . (B-E) The influence of shoulder torque magnitude on mean SWV obtained from the fiber regions of the pectoralis major during the generation of shoulder torques. Lines represent the resultant linear mixed model fits for each experimental group. Shaded regions represent 95% confidence intervals.

### Significance

Women who undergo BCT or mastectomy and breast reconstruction may experience significant, long-term shoulder strength deficits. Our results suggest that these deficits are driven in part by fundamental changes to the underlying function of the pectoralis major. Findings from this study will better inform patient choice for BCT eligible women interested in mastectomy and breast reconstruction.

## Quantifying Sternocleidomastoid Material Properties after Definitive Chemoradiation for Head and Neck Cancer

Whitney L. Wolff<sup>1</sup>, David B. Lipps<sup>1,2</sup>

<sup>1</sup>School of Kinesiology, <sup>2</sup>Department of Biomedical Engineering, University of Michigan, MI, USA

Email: wolffw@umich.edu

### Introduction

Definitive chemoradiation for head and neck cancer is associated with multiple morbidities, including pain, progressive tissue sclerosis, and decreased strength<sup>1</sup>. However, these deficits have not been objectively quantified and there is no post-treatment standard of care for alleviating or preventing these morbidities. Other neck pathologies like chronic neck pain cause the sternocleidomastoid muscle (SCM) to reduce the focus of its neural activity (i.e. increase coactivation)<sup>2</sup> and alters SCM passive material properties<sup>3</sup>. However, it is unclear how chemoradiation for head and neck cancer influences the material properties of the SCM. Therefore, the purpose of this study was to quantify the early changes to SCM material properties following chemoradiation treatment for head and neck cancer. We hypothesized that patients would display increased antagonist SCM contribution and altered material properties of the SCM (increased shear wave velocity) after chemoradiation treatment.

### Methods

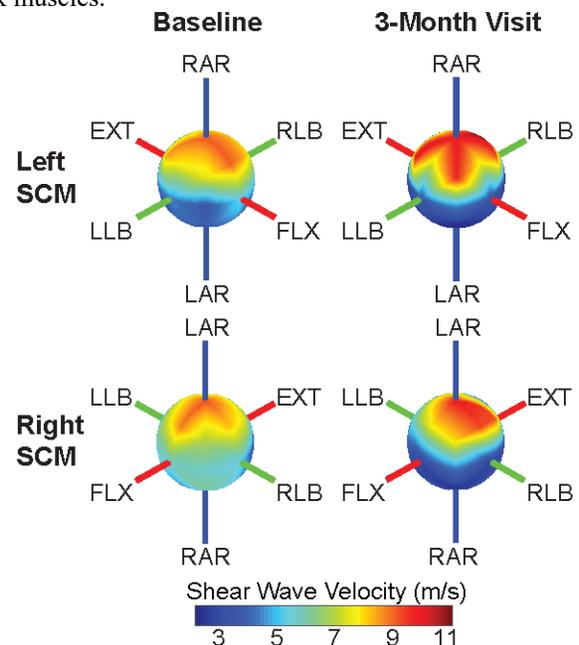

Four patients prescribed definitive chemoradiation for non-metastatic head and neck cancer participated in this study. Patients completed a baseline visit within 2 weeks prior to starting treatment and a second visit 3 months after starting treatment. Patients were seated with their head secured in a halo attached to a 6 degree-of-freedom load cell. They then generated 3-D neck torques to match 26 targets representing combinations of neck flexion, extension, right/left lateral bending, and right/left axial rotation. During the first visit, four blocks of 26 targets were completed. Two blocks were scaled to 40% maximum voluntary contraction (MVC) in axial rotation, and 2 blocks were scaled to 60% MVC. During the second visit, 2 blocks were scaled to 60% of the participant's current MVC in axial rotation, and 2 blocks were scaled to 60% MVC from the first visit. In total, 108 trials were performed per visit.

Ultrasound shear wave elastography images (Supersonic Imagine Aixplorer, France) were collected bilaterally from the SCM at rest and while they matched the previously described targets. Mean shear wave velocity (SWV) provides insight into the shear modulus of the tissue, with greater SWVs indicating higher shear modulus. SWV for each target was used to calculate the SCM's preferred direction (PD) (representing the azimuth and elevation angles where shear modulus was greatest) and focus (the angular spread of SWV relative to the PD). Paired t-tests were used to compare each variable (PD, focus, mean SWV nearest the PD) from baseline to the 3-month visit.

### Results and Discussion

The PD of the SCM was a combination of flexion, ipsilateral bending, and contralateral axial rotation. Neither the azimuth nor elevation angles of the PD were significantly different at the 3-month visit when compared to baseline (all  $t_6 < 0.18$ ,  $p > 0.31$ ). The mean SWV nearest the PD was significantly greater at the 3-month visit (mean $\pm$ SD: 7.9 $\pm$ 2.2 m/s) when compared to baseline (6.3 $\pm$ 2.0 m/s) ( $t_{13} = -3.4$ ,  $p = 0.005$ ) (Figure 1). This increase in active SWV of the SCM after chemoradiation treatment for head and neck cancer may be a response to pain or deep cervical muscle dysfunction<sup>2</sup>.

In contrast, passive SWV of the SCM significantly reduced from baseline (3.2 $\pm$ 0.4 m/s) to the 3-month visit (2.8 $\pm$ 0.4 m/s) ( $t_{13} = 4.7$ ,  $p < 0.001$ ). These results are contrary to increased tissue sclerosis following radiation treatment to the neck. However, the late effects of chemoradiation have likely not developed at our 3-month follow-up. Lastly, the focus of the SCM's PD significantly increased from baseline (0.13 $\pm$ 0.07) to the 3-month visit (0.19 $\pm$ 0.08) ( $t_{13} = -4.6$ ,  $p < 0.001$ ), meaning there was narrower range where the SCM contributed to stability following treatment. Future work is needed to determine if this reduced focus after treatment is indicative of altered behavior of other neck muscles.

**Figure 1:** Representative intensity plots of shear wave velocity (SWV) data from both the right and the left SCM from baseline to the 3-month visit. Warmer colors indicate greater SWV magnitude. All targets were scaled to 60% of the axial rotation MVC collected during the baseline visit. FLX=flexion, EXT=extension, RLB, and LLB=right and left lateral bending, RAR and LAR=right and left axial rotation.

### Significance

This study provides novel insights into how the material properties of the SCM adapt to definitive chemoradiation treatment for head and neck cancer. The SCM exhibits greater SWV during volitional torque production at the neck. However, we did not observe increased antagonistic contribution or passive SWV. The results of this study highlight the need to quantify the late effects of chemoradiation on neck function to accurately identify patients in need of early physical rehabilitation.

## Estimating Lumbar Loading with Wearable Sensors over a Broad Range of Manual Lifting Tasks

Emily S Matijevich<sup>1</sup>, Peter Volgyesi<sup>1</sup>, Karl E. Zelik<sup>1</sup>

<sup>1</sup>Vanderbilt University, Nashville, TN, USA

Email: \*[emily.matijevich@vanderbilt.edu](mailto:emily.matijevich@vanderbilt.edu)

### Introduction

Low back pain is a disabling condition experienced by 60-85% of adults within their lifetime [1]. High and/or repetitive forces on lumbar muscles and discs are known to be major risk factors. There are numerous opportunities for reducing pain and overuse injury risk if the repetitive forces on the back could be easily monitored in daily life (e.g. via biofeedback).

Wearable sensors are an exciting tool for monitoring human movement non-invasively in daily life. However, there are many complex and intertwined questions involved in using wearable sensors to estimate musculoskeletal loading. The objective of this study was to estimate lumbar moment (torque about the L5/S1 joint) over time using wearable sensors for a diverse range of manual lifting tasks. Specifically, we 1) adapted a machine learning algorithm to estimate sagittal lumbar moment using wearable sensor signals and 2) identified a minimal set of sensor signals necessary for estimation.

### Methods

This study involves participants each performing >300 manual lifting tasks in a motion analysis lab; one of the largest data sets of its kind. Here we summarize results from the first participant. Testing is ongoing and multi-subject results will be presented at the conference. Tasks covered a broad range of leaning, twisting, and lateral bending postures while moving boxes of 5-23 kg (**Fig. 1**). Full-body kinematics and ground reaction forces were collected. *Lab-based* lumbar moment was estimated using bottom-up inverse dynamics ( $M_{lumbar}$ ), and was chosen as the target metric for this study due to its relation to lumbar muscle forces and resulting compressive spine force [2].

Inertial measurement unit (IMU) based kinematics (XSENS) and plantar pressures (Novel Pedar) were collected synchronously with lab-based data. These *wearable* data were normalized and used as feature inputs to a machine learning model to provide time-series *wearable* lumbar moment estimates ( $M'_{lumbar}$ ). Wearable features were: lower limb and lumbar joint kinematics, and normal force and center of pressure under each foot. The regression model was built with Gradient Boosted Decision Trees [4] using 200 estimators. The dataset was divided so 85% of samples were used for model training and 15% were reserved for testing. The root mean squared (RMS) error was computed for this test set. Our target accuracy was 10% of the expected peak  $M_{lumbar}$ , or <35 Nm, a desired error used by other wearables [3]. The trained model also returns normalized feature importances, indicating how valuable each feature was in estimating lumbar moment.

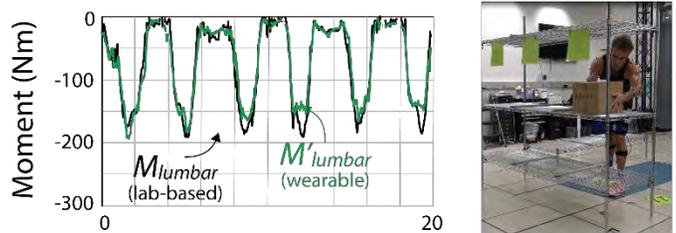

### Results and Discussion

Our *wearable* algorithm estimated sagittal lumbar moment with average RMS error of 20 Nm.  $M_{lumbar}$  and  $M'_{lumbar}$  were strongly correlated ( $r^2=0.9$ ). Thus this wearable algorithm distinguishes tasks of lower vs. higher lumbar moment (**Fig. 1**).

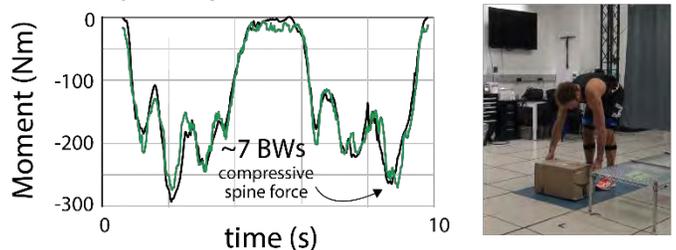

Model training identified four features as having a relative importance >5%. Retraining the model using only these key features yielded an RMS error of 21 Nm, a similar error to the

model using all the feature inputs. For reference, an error of 20 Nm in lumbar moment equates to ~0.5 bodyweights of error in compressive spine force using a single equivalent muscle approximation. It is promising that a wearable device embedded with just a small set of sensors could estimate sagittal lumbar moment with this accuracy across a broad range of manual lifting tasks.

#### A) Placing a 5kg box at 3 locations on a waist height shelf

#### B) Moving a 15kg box between the floor and a low shelf

**Figure 1:** Lab-based ( $M_{lumbar}$ ) and wearable algorithm ( $M'_{lumbar}$ ) estimates of sagittal lumbar moment across two subsets (A, B) of the ~300 manual lifting tasks. Of note, subset (A) was part of the test set, and subset (B) was part of the model training set. BWs = bodyweights.

### Significance

To the authors' knowledge, this is the first study to synchronously collect both lab-based and wearable kinematic and kinetic data over such a broad range of manual lifting tasks. Errors <21 Nm suggest wearable sensors can be used to estimate lumbar moments outside the lab environment, providing exciting opportunities for understanding lumbar spine loading and preventing low back pain and overuse injury risk.

## Lower Back Demands During Induced Lower Limb Gait Asymmetries

Jacob J. Banks and Graham E. Caldwell

Department of Kinesiology, University of Massachusetts, Amherst, MA, USA

Email: jbanks@umass.edu

### Introduction

Walking is an intrinsic form of exercise and therapeutic relief<sup>1</sup>. For those with asymmetric gait it is also associated with increased prevalence of lower back pain (LBP)<sup>2</sup>. Asymmetric gait can arise from various clinical conditions, but its impact on lower back demands such as joint and muscle kinetics has largely been reported in amputees<sup>2,3</sup>. Lower back demands are reportedly larger for amputees than in able-bodied controls, but these studies were limited by within-group heterogeneity and an absence of an appropriate baseline comparison<sup>2,3</sup>. In addition, lower back demands have generally been estimated with a static optimization approach that may not reflect actual muscle recruitment strategies<sup>4</sup>, particularly in those with asymmetries.

An alternative to heterogeneous amputee populations and static optimization is to perturb able-bodied participants to artificially induce asymmetry and to include electromyography (EMG) within the optimization algorithm<sup>5</sup>. Such a controlled and participant-specific experiment may provide unique insights into why gait asymmetry is associated with LBP. Therefore, the objective of this study is to investigate how different asymmetric perturbations impact lower back demands as estimated from EMG optimization<sup>5</sup>. We hypothesized that lower back demands would be larger in perturbations inducing greater gait asymmetry.

### Methods

A convenience sample of twelve healthy participants consented to the study. Conventional biomechanical techniques were used to record each participant's full-body kinematics (Qualisys AB, Sweden), external kinetics (Treadmetrix, USA), and muscle activity from 12 trunk muscles (Delsys Inc. USA). After a treadmill acclimation period, five different gait conditions were recorded: 1) baseline of normal walking (Control), and walking with 2) a ~1.2 kg ankle weight (AW), 3) a ~2.54 cm "leg lengthener" on the shoe sole (LegL), 4) both the ankle weight and leg lengthener (AW&LegL), and 5) a walking boot that restricted ankle and toe movement (Boot). All perturbations were assigned to the right leg while participants walked at 90% of their self-selected preferred speed. The degree of gait asymmetry between right and left step lengths was quantified by an asymmetry index (AI)<sup>8</sup>.

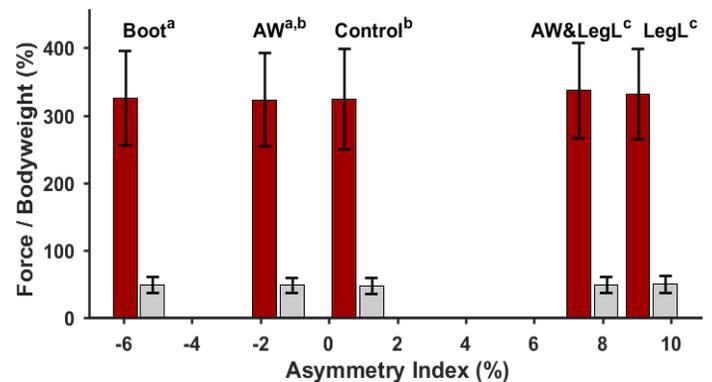

The *in silico* model<sup>7</sup> developed for this study was modified from an existing OpenSim model<sup>8,9</sup>. A MATLAB (Mathworks, USA) custom API<sup>10</sup> was developed to integrate EMG, kinematic and kinetics to estimate lower back demands at L5/S1 via an EMG optimization approach<sup>5</sup>. Bodyweight-normalized peak L5/S1 compressive, peak resultant shear, and AIs from an average of three consecutive strides were used as dependent variables in one-way repeated measure ANOVAs, with Tukey post hoc tests for differences ( $\alpha=0.05$ ) across the five gait conditions.

### Results and Discussion

The five gait conditions yielded three unique levels of asymmetry (Fig. 1), with longer left than right steps in the Boot (AI ~-6%), but the reverse in the LegL conditions (AI ~+9%). The AW alone

and the control conditions were both approximately symmetrical (AI~0). Despite these AI differences, the L5/S1 compressive and shear forces were similar across all conditions. These results did not support our hypothesis.

This study is the first to investigate how lower limb perturbations in healthy able-bodied participants can impact lower back compressive and shear forces. Previous work has reported significant changes in EMG and joint kinematics during similar perturbations or the lower back demands of amputees<sup>11,12</sup>. A preliminary analysis of our EMG and kinematic data shows significant between-condition differences, supporting that our AI values reflect gait asymmetry. The similarity in compressive and shear forces across conditions we observed may be due to the choice of the L5/S1 joint or other musculoskeletal limitations.

**Figure 1:** Normalized peak L5/S1 compression (maroon) and shear (grey) forces across different gait conditions and degrees of asymmetry (labeled). A positive asymmetry index represents longer perturbed (right) vs. unperturbed (left) steps. Superscripts following each condition denote post-hoc pairings of asymmetry indexes. There were no significant differences between peak L5/S1 forces across conditions. See Methods for details on each gait condition.

### Significance

Our results suggest that the high LBP incidence associated with asymmetric gait<sup>2</sup> may not be the consequence of increased lower back demands during normal level walking. Although non-significant but repeated subtle increases in joint demands could eventually result in tissue injury and lead to LBP, perhaps other gait tasks (e.g. turning, stairs, carrying) or secondary conditions are responsible for the high incidence of LBP in individuals with asymmetric gait.

## Material Properties of Human Testicles under Unconfined Compression and Probing with Varying Strain Rate

Blake Johnson, PhD<sup>1</sup> and Naira Campbell-Kyureghyan, PhD<sup>1,2</sup>

<sup>1</sup>U Department of Industrial and Manufacturing Engineering, University of Wisconsin-Milwaukee, Milwaukee, WI, USA

<sup>2</sup>Department of Mechanical Engineering, Merrimack College, North Andover, MA, USA

Email: john2742@uwm.edu

### Introduction

Knowing the material properties of human tissue can lead to advancements in many fields such as forensics, prosthetics, diagnosis, surgical training, etc. The human testicle is an organ that needs advanced understanding of its mechanical behavior as injuries resulting from genitourinary trauma is increasing [1]. Virtually no mechanical testing has been conducted on this organ and characterizing the properties would be valuable for the scientific community.

It has been found that in other human organs the testing methodology and strain rate have been factors that influence material properties [2,3]. To date the strain rate dependence for the testicles is not known. It is hypothesized that as strain rate increases the elastic modulus of testicle tissue will increase. It is also hypothesized that the modulus of testicle tissue measured in a probing protocol will be different than in an unconfined compression protocol.

### Methods

Six testicles were surgically removed from the scrotum of cadavers, and remained intact for testing. Each testicle was subjected to both nondestructive probing and unconfined compression protocols at rates of 1%/s to 25%/s. After each non-destructive testing trial the specimen was allowed to relax until initial height was restored. Destructive compression testing was performed at rates from 25%/s to 500%/s. Failure was defined as a 5% reduction in stress or a 3% increase in strain with no increase in stress.

Stress and strain were continuously collected throughout all trials. The secant slope at the most linear portion of the stress-strain curve was used to determine the elastic modulus ( $E$ ). Failure stress and failure strain were found in each of the destructive testing trials. An ANOVA was performed to test the statistical significance of strain rate on stiffness. A two sample t-test was used to determine if the two non-destructive protocols were statistically different. Alpha was set at 0.05 for all tests. Statistical tests were not performed on failure stress or strain because of the limited sample size.

**Table 1:** Average (std) elastic modulus from the tested rates of 1%/s to 25%/s for both non-destructive probing and unconfined compression protocols.

Protocol	Elastic Modulus (MPa)			
	1%/s	5%/s	10%/s	25%/s
Unconfined Compression	0.0025 (0.0006)	0.0034 (0.0008)	0.0039 (0.0006)	0.0046 (0.0011)
Probing	0.0053 (0.0012)	0.0063 (0.0016)	0.0079 (0.0015)	0.0104 (0.0039)

**Table 2:** Failure stress and strain from destructive compression testing.

Strain Rate	Fstress (MPa)	Fstrain
25%/s	0.27	48%
50%/s	0.60	57%
100%/s	0.59	51%
250%/s	0.66	53%
500%/s	0.87 (0.04)	57% (0.03%)

### Results and Discussion

Both non-destructive compression and probing modulus (Table 1) increased with increases in strain rate ( $p < 0.05$ ). The stiffness from non-destructive testing increased by 36% from 1%/s to 5%/s and from 5%/s to 25%/s. The effect of strain rate was observed to be linear between the rates of 1%/s to 25%/s. An increase in stiffness of 20% was observed between 1%/s and 5%/s, and a 65% increase from 5%/s to 25%/s.

The stiffness measured from the probing protocol was higher at all rates compared to the unconfined compression protocol ( $p < 0.05$ ). The largest difference between protocols was a 126% increase from the unconfined compression protocol to the probing protocol with an average of 108% across all rates. An increase in measured modulus in the probing protocol could be due to the smaller compression area. Using a probe will result in increased stiffness as there are parts of the tissue surrounding the probe that is not included in the calculation.

Failure stress was observed to increase as strain rate increases (Table 2). Failure stress was 0.27 MPa at 25%/s and increased by 191% to 0.87 MPa at 500%/s. Failure strain was not affected by strain rate. The failure strain at 500%/s (57%) was only 9% higher than at 25%/s (48%), with the other tested failure strains falling within this range.

### Significance

This study characterized the material properties of the human testicle in both unconfined compression and probing protocols. These properties will enable researchers to model the testicle and run various simulations. The models developed can improve surgical simulation, injury diagnosis, forensics, and other areas. The failure threshold has also been established at multiple rates. This study additionally determined how much stress is required to rupture the human testicle which can lead to improvements in protection.

The factors of methodology and strain rate were determined to influence the material properties of the human testicle. Understanding these factors further expands the knowledge of testicle material properties and can lead to improved modelling for this tissue which expands the significance of the results explained above.

## VERTICAL STIFFNESS ASYMMETRY IN NCAA DIVISION I ATHLETES

Jonathan (FJ) S. Goodwin<sup>1</sup>, Mason L. Moore<sup>1</sup>, Benjamin T. Ivey<sup>1</sup><sup>1</sup>Department of Physical Therapy Education, Elon University, Elon, NCEmail: [fgoodwin@elon.edu](mailto:fgoodwin@elon.edu)**Introduction**

Athletic injuries are often unavoidable in sport participation and injury rates among NCAA Division I athletes have risen over the past ten years with injury rates reported to be as high as 13.79/1000 athlete-exposures in collegiate athletes [1,2]. Recent efforts have been made to identify a testing battery that can successfully identify athletes who are at an increase for injury [3].

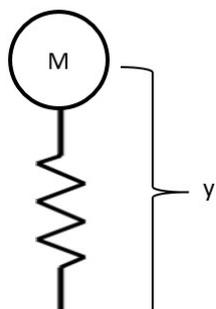

Vertical stiffness ( $K_{\text{Vert}}$ ) is a modifiable biomechanical measurement that is associated with potential lower extremity injury risk [4].  $K_{\text{Vert}}$  is the resistance to deformation of the lower limb during the ground contact phase of dynamic movement accounting for relative kinetic load of the lower extremity [5].  $K_{\text{Vert}}$  is typically modelled as an inverted pendulum.  $K_{\text{Vert}}$  asymmetry between limbs is correlated to an increased risk of soft tissue lower extremity injury development within an athletic population during an athletic season [6].

The purpose of this study is to identify if there is a significant difference in  $K_{\text{Vert}}$  between dominant vs non-dominant limbs among athletes entering intercollegiate Division I athletics.

**Methods**

Twenty-seven (15f/12m; 18.9±0.87 y.o.; 18-21 y.o. range 71.0±12.2 kg; 1.75±0.09 m) incoming Division I NCAA athletes volunteered for this study. Subjects consisted of 9 women's soccer, 8 men's soccer, 6 women's tennis, and 4 men's football athletes. Subjects were required to be cleared by physician for physical activity and be currently injury-free.

Subjects were fit with retroreflective markers on the torso, pelvis and bilateral lower extremities to collect three-dimensional kinematics. Subjects completed a shod single-leg hopping protocol for 20 seconds at a self-selected frequency on an embedded force plate [7]. This was completed for both limbs in a counter balanced order. During the hopping protocol ground reaction forces and whole-body kinematic data were sampled.  $K_{\text{Vert}}$  was calculated as the maximum vertical ground reaction force ( $F_{\text{max}}$ ) divided by the vertical displacement of center of mass during ground contact ( $\Delta y$ ) and averaged over 10 successive hops ( $F_{\text{max}}/\Delta y$ ) (Figure 1) [5].  $K_{\text{Vert}}$  values were compared utilizing a dependent t-test between the dominant and non-dominant limb ( $\alpha=0.05$ ).

**Figure 1:** Idealized model for  $K_{\text{Vert}}$  during hopping.

**Results and Discussion**

There was an average non-dominant limb stiffness of 16.7±3.1 KN/m and an average dominant limb stiffness of 16.4±3.1 KN/m. There was no significant difference in  $K_{\text{Vert}}$  between dominant and non-dominant limbs. ( $p=0.56$ ).

However, the differences between limbs were highly variable with an average difference of 1.5±1.0 KN/m and a range 0.06-3.6 KN/m. This equated to an average difference of 9% in  $K_{\text{Vert}}$ . Previous literature states that a 4.5% average difference in  $K_{\text{Vert}}$  has been linked to increased risk for lower extremity soft tissue injury [6]. Given these data, there is a need to screen athletes for lower extremity stiffness before beginning a season and monitor those individuals who displayed higher asymmetries in  $K_{\text{Vert}}$ .

**Significance**

Our study built upon previous studies by including both male and females athletes as well as a variety of sports. We believe by screening athletes from a variety of sports this will provide a more robust understanding of  $K_{\text{Vert}}$  and its utility in injury prevention screenings.

$K_{\text{Vert}}$  is a potentially clinically feasible assessment without a significant amount of needed training and resources compared to a typical motion capture laboratory. With greater understanding of its associated injury risk,  $K_{\text{Vert}}$  assessments could provide a wide variety of health care practitioners the ability to screen for injury risk. This could allow for implementation of preventative rehabilitation techniques to reduce lower extremity soft-tissue injury burden.

### Introduction

Every year over 200,000 anterior cruciate ligament (ACL) injuries occur in the US [1]. Out of these, approximately 60% are non-contact in nature, with >90% occurring during single leg landing or sidestepping [2]. Anterior tibial force in conjunction with non-sagittal plane (valgus, varus and internal rotation) knee moments during the weight acceptance phase has been shown to place the maximum strain on the ACL [3, 4]. We used OpenSim's forward dynamics residual reduction algorithm (RRA) to identify optimal whole-body kinematics that would reduce non-sagittal plane knee moments during side-stepping and single leg jump landing (SLJL) [5, 6]. This process involved two steps: 1) optimise model parameters (all actuators and tracking weights) to generate simulations with near zero residuals and 2) reduce non-sagittal plane knee moments and tracking weights to identify associated optimal kinematic patterns. Each of these steps used RRA and an outer level optimization routine [7, 8]. Although this technique is powerful, it is computationally expensive. Therein, it can take as long as 13 hours to run a single 70 ms simulation, with approximately 90% of the time spent on reducing residuals.

The use of direct collocation [9] is a known method capable of improving the speed of musculoskeletal simulations. OpenSim Moco [10] is a novel software package built to reduce the computational complexity of direct collocation technique. Both RRA and OpenSim Moco find control trajectories of a model's actuators over time, but they use different methodologies to solve for them. RRA finds controls at each time frame and numerically integrates model state derivatives to step forward in time, while direct collocation finds controls simultaneously with model states over an entire movement trajectory, which drastically reduces computational time. This approach also removes the need for model residuals to generate a stable simulation. The purpose of this study was to a) use OpenSim Moco to predict the optimal kinematics linked to reduced non-sagittal plane knee moments during SLJL and b) compare the optimal kinematics generated by OpenSim Moco to those generated using the RRA approach.

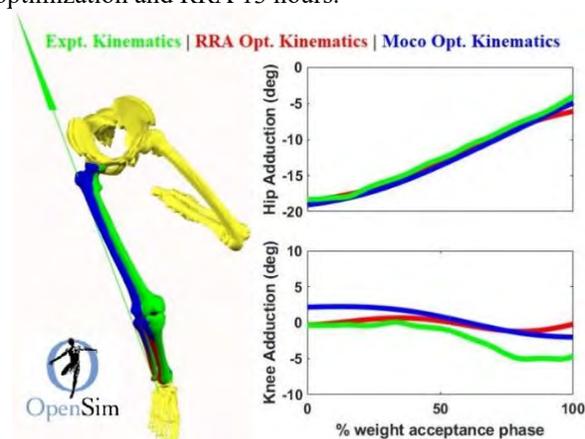

### Methods

We used data from two participants performing SLJL. We started with the same generic actuators, tracking weights and scaled model. We applied similar constraints and costs to the OpenSim Moco approach as the second step of the RRA approach which were reducing the maximal torque capacity of the knee varus/valgus and int/ext rotation actuators, the sum of squared activation of the actuators and tracking weights of the joint coordinates. We then compared the optimal kinematic solutions and reductions in non-sagittal plane knee moments generated by the two approaches.

### Results and Discussion

The mean difference in optimal kinematics generated by the two approaches was  $0.8^{\circ} \pm 0.35^{\circ}$  and  $0.7^{\circ} \pm 0.32^{\circ}$  for the two

participants (P1 & P2). The reduction in peak resultant non-sagittal plane knee moments for each participant pre-to-post optimization were 75% (P1) & 45% (P2) for RRA, and 63% (P1) & 74% (P2) for the OpenSim Moco respectively. Both optimization methods resulted in similar kinematic strategies to reduce the peak non-sagittal plane knee moments, which was to re-positioning the knee towards the GRF vector, effectively reducing its moment arm (Figure 1). OpenSim Moco took 6 hours per optimization and RRA 13 hours.

**Figure 1:** Comparison of Experimental, optimal RRA and optimal Moco kinematics (P2).

**Table 1:** Comparison of optimization approaches

Similarities	Over 40% reduction in peak non-sagittal plane knee moments
	Similar post-optimization kinematics
Differences	OpenSim Moco did not require residuals
	OpenSim Moco takes 50% less time

### Significance

The use of OpenSim Moco reproduced the findings of an established forward dynamics approach (RRA) in one half the time. This improvement was accomplished as OpenSim Moco uses direct collocation, which is more computationally efficient than the previous approach. Our results for a high velocity movement like landing suggest that OpenSim Moco may perform even better for low velocity 'real world' applications within time constraints of clinical settings to treat movement disorders.

### Acknowledgments

Experimental data was collected under NHMRC grant 400937.

## Development of an In-Vivo Ligament Loading Device

Brian J. Diefenbach<sup>1</sup> & Zachary J. Domire<sup>1</sup>

<sup>1</sup>Department of Kinesiology, East Carolina University, Greenville, NC,

Email: diefenbach8@gmail.com

### Introduction

Prevention of ACL injuries is important, as ACL injuries are associated long term with the development of knee osteoarthritis, increased pain, functional limitations, and decreased quality of living [1]. Despite the focus on numerous ACL injury prevention mechanisms, ACL injury rates are still on the rise. Investigating a way to strengthen the ACL may be an alternative method to prevent ACL tears.

Traditionally, tissue strengthening would occur through a high magnitude load, applied a limited number of times. However, as ligaments are designed to restrict unhealthy joint movement, high magnitude loading of ligaments is likely non-desirable, making high frequency, low magnitude loading an intriguing possibility. Previous studies have shown that high frequency, low magnitude loading has been very successful in bone. Bone clearly demonstrates the ability to adapt and even strengthen in response to this type of mechanical loading [2], and it would make sense that ligaments, the connective tissue connecting two bones together, would also exhibit similar adaptive properties. However, there is limited research on a typical in-vivo ligament response to mechanical loading. Therefore, the purpose of this study was to develop a device capable of applying an in-vivo, high frequency, low magnitude load to the ACL.

### Methods

A custom built device, the RACL Loader (Rabbit Anterior Cruciate Ligament Loader), was used to load the ACL. The motor on the device turns a pulley system, which moves one of two sliders. A spring connects the two sliders, and the second slider is attached to a cord which pulls on a tibia cast, applying tension to the ACL (Figure 1). The frequency and magnitude of loading can be adjusted through varying spring stiffness and length.

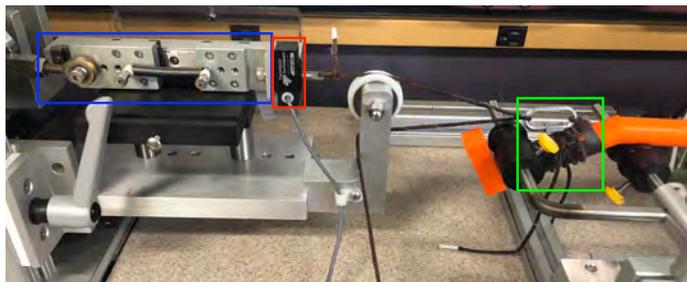

Figure 1: RACL Loader – The spring and sliders (blue box) are attached to a tension/compressive load cell (red box) to measure the tensile force applied to the shank cast/ACL (green box).

The loading parameters from previous successful high frequency, low magnitude bone loading protocols were modified due to differences in material properties between bone and ligament. Therefore, the optimal parameters of ligament loading were determined to be at an oscillating low-magnitude load (~2.0-13 N), and a high-frequency (~15-30 Hz) for 20 minutes [2]. This loading magnitude was determined based on the strain of ligament during normal activity and the percentage of load

applied to the knee that would actually translate to the ACL. To ensure the loading occurred along the longitudinal axis of the ACL, the hip was extended, knee positioned at 30° knee flexion, with the device pulling on the tibia at 35-40° to apply tibial anterior translation [3]. As the device is sized to eventually load a rabbit ACL, a 3D printed model rabbit leg was used to test the device. Five springs of varying stiffness and length were tested in the device to determine the which spring would result in the desired high frequency, low magnitude loading.

### Results and Discussion

Based on the resulting magnitudes and frequencies from loading the model rabbit leg using each of the five springs, spring C was successful in applying an oscillating loading magnitude from 2-13 N, at a frequency of 15 Hz (Table 1). Additionally, spring C tested during in-vivo loading on the left leg of a New Zealand White Rabbit was successfully able to apply the desired frequency and magnitude of loading on the rabbit's ACL.

Spring	A	B	C	D	E
Magnitude (N)	2 – 10	2 – 18	2 – 13	2 – 6	2 – 8
Frequency (Hz)	10	15	15	5	6

Table 1: Magnitudes and frequencies produced by the different springs tested in the RACL Loader.

Due to the pulley/gear ratio, the maximum frequency produced by the RACL loader was around 15 Hz. While this loading frequency is on the low end of the desired range, we are confident that this is still a great enough frequency to stimulate a ligament response. This is the first device to our knowledge that is able to load a ligament in-vivo at a high frequency, low magnitude load.

### Significance

This device was successful to load a ligament, in-vivo, at the desired high-frequency and low-magnitude parameters. Future studies should perform mRNA-sequencing tests on the extracted ligament following in-vivo loading, to better understand the genetic response to loading. Based on the ligaments genetic response, we can then consider characterization of optimal loading parameters (i.e., loading frequency, magnitude, and duration of load). This technique may be a novel way to tackle a well-established, ACL injury problem, and may long-term, be the basis for clinical high-frequency, low-magnitude loading as a prevention mechanism to protect against ligament injuries.

### Acknowledgments

## Achilles Tendon Material Properties are Resilient to Variations in Load During Growth

Kavya Katugam<sup>1\*</sup>, Suzanne M. Cox<sup>1</sup>, Matthew Q. Salzano<sup>2</sup>, Adam De Boef<sup>1</sup>, Tim M. Ryan<sup>3</sup>, Stephen J. Piazza<sup>1</sup>, Jonas Rubenson<sup>1,2</sup>

### Introduction

Variations in tendon properties can affect the tendon's strength and safety factor. They can also alter the force capacity and power of muscles, directly influencing performance. However, we do not yet have a clear understanding of how tendons change over time. Material properties of adult tendon responds directly to mechanical load [1,2], but evidence of the plasticity of tendon in growing individuals is less consistent. Since developmental plasticity can alter adult phenotype, uncovering the influence of activity levels during childhood on musculoskeletal development is necessary to inform variation in adult locomotor capacities.

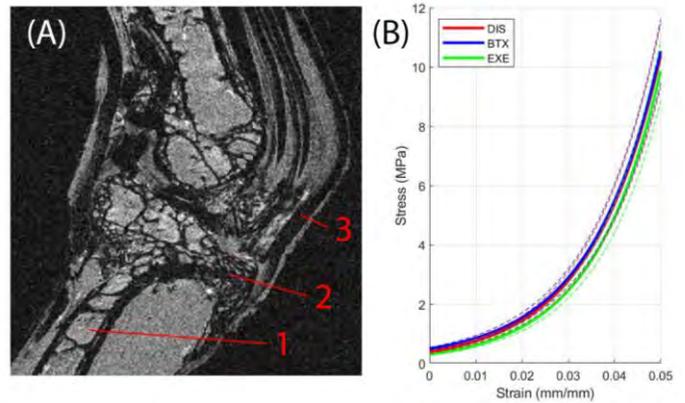

Given the growing concern of the health consequences of decreases in physical activity in children [3], we investigated the developmental plasticity of tendon to decreases in load. First, we investigated the spring quality of the tendon by assessing the stiffness and modulus of the entire free tendon. Secondly, we assessed the bone-tendon junction, a region which has been shown to be susceptible to tendon rupture [4].

### Methods

To address our questions, we systematically altered the mechanical load environment across the growth span in an avian model (guinea fowl; *Numida meleagris*). Animals were divided at two weeks of age into three groups: 1) a control group permitted to undertake regular exercise (EXE,  $n = 8$ ); 2) a disuse group restricted from exercise (DIS,  $n = 8$ ); and 3) a third group that were restricted from exercise and in which the gastrocnemius muscles were partially paralyzed using repeated bouts of bilateral Botulinum toxin-A (botox) injections (4 units/kg per leg; BTX,  $n = 8$ ). At skeletal maturity (27-28 wks) animals were sacrificed for tendon analysis. The left limb was kept fresh and scanned with high-field MRI (Bruker, 7T) from which the cross sectional area of the tendon was quantified in 1 mm increments. The left limb was kept fresh-frozen and used for material testing (MTS Bionix 858 Mini Bionix II), combining stress-strain loading and digital video capture to assess regional properties.

### Results and Discussion

Achilles tendon length, average cross sectional area (CSA), stiffness ( $K$ ), modulus of elasticity ( $E$ ), and hysteresis ( $H$ ) were not statistically different between groups (at  $\alpha$  set to 0.05). Tendon stiffness across all animals correlated with modulus ( $R^2 = 0.743$ ,  $p < 0.01$ ), but not with average tendon CSA ( $R^2 = 0.007$ ,  $p = 0.698$ ). Morphological and mechanical properties of the bone-tendon junction found a moderately higher tendon stress in the DIS group, but this, nor tendon strain, were statistically different between groups.

**Figure 1:** (A) Sagittal plane MRI of the guinea fowl ankle joint. 1: TMT. 2: Hypotarsus of the TMT, where Achilles tendon attaches. 3: Achilles Tendon. (B) Average loading stress-strain curve by condition. Dashed lines indicate one SD above and below the mean. Red (DIS) and blue (BTX) curves and corresponding SDs are superimposed.

### Significance

We found that variations in loading during growth did not significantly alter tendon properties at adulthood, contrary to both of our hypotheses. Our results suggest that either 1) developmental factors override the load-induced remodeling that has been demonstrated in adults of the same species [1] or that 2) plastic changes due to offloading may not be predictable from responses to increased loading. Consistent with these findings, a previous study using botox to alter Achilles loading in growing mice has shown similar minimal changes to tendon properties [5]. This resilience to load history during growth suggests that differences in activity level during growth may not greatly affect juvenile tendon development. These results are important for our understanding of musculoskeletal function and tendon health in growing individuals.

## Running Exposure is Associated with Achilles Tendon Shear Wave Speed

Matthew C. Ruder<sup>1</sup>, Rebekah L. Lawrence<sup>1</sup>, Michael J. Bey<sup>1</sup>  
<sup>1</sup>Bone and Joint Center, Henry Ford Health System, Detroit, MI  
 Email: mruder1@hfhs.org

### Introduction

Achilles tendinopathy is one of the most common injuries among runners [1]. The etiology of Achilles tendinopathy in runners is not well understood, but is likely influenced by a number of factors. For example, previous research has reported that Achilles tendon injuries are prevalent in high-volume runners [1], which supports the idea of running exposure (i.e., overuse) leading to injury. Previous research has also suggested that increased tendon stiffness may contribute to Achilles tendinopathy [2], supporting the notion that changes in tendon material properties may be a risk factor in the development of Achilles tendinopathy [3]. Lastly, it has also been shown that Achilles tendinopathy is more likely to affect experienced/older runners [1], suggesting that aging may influence the likelihood of a runner developing Achilles tendinopathy. Taken together, these previous studies suggest there are likely complex relationships between age, running experience, running mileage, Achilles tendon stiffness, and Achilles tendinopathy that are not particularly well understood. As an initial step toward understanding these complex relationships, the objective of this study was to use ultrasound shear wave elastography (SWE) – an imaging modality that provides a non-invasive estimate of soft-tissue material properties – to assess the extent to which measures of running exposure are associated with shear wave speed (SWS). We hypothesized that runners with higher running exposure would have higher Achilles tendon SWS.

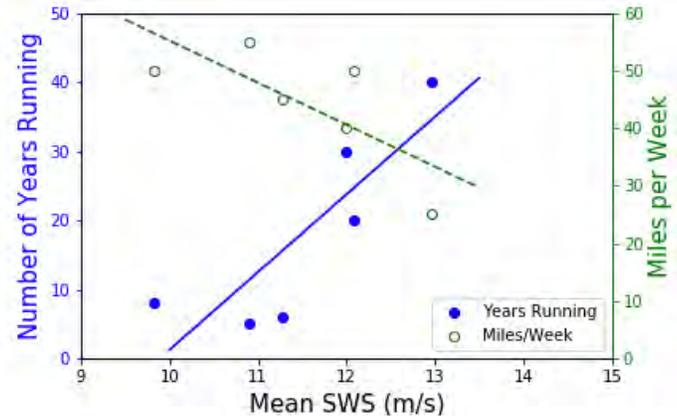

### Methods

Following IRB approval, six male runners (age:  $46 \pm 8$ ) with no history of Achilles tendinopathy were recruited. Subjects reported their running history as number of years running, average runs per week over the past 3 months, and average weekly mileage over the past 3 months. To assess tendon material properties, each subject first walked on a treadmill for 5 minutes at a self-selected pace to precondition the Achilles tendon. Next, each participant was positioned prone with their lower legs fully extended off the back of an examination table. Five SWE images (Siemens ACUSON S3000) were collected for the free Achilles tendon on both left and right sides.

Data were analyzed using a custom MATLAB program to isolate the Achilles tendon region of interest (ROI) from the remaining tissues on the ultrasound B-mode image. SWS data within this ROI were extracted from the SWE image and then averaged to result in a mean SWS for each trial. Next a mean SWS was calculated across all trials and sides (left, right) to reflect the cumulative effect on both tendons for each subject. Correlation coefficients were calculated between SWS and measures of running exposure (years running, miles per week). The correlation between age and SWS was also examined to assess for the potential confounding relationship between age and running exposure. Significance was set as  $p < 0.05$ .

### Results and Discussion

A strong positive correlation was observed between SWS and number of years running (Figure 1,  $r = 0.85$ ,

**Figure 1:** The relationship between Achilles tendon shear wave speed and running exposure (miles per week and years running).

$p = 0.03$ ). A strong negative association was observed between SWS and weekly mileage, but this did not reach statistical significance (Figure 1,  $r = -0.74$ ,  $p = 0.09$ ). SWS was not associated with age ( $r = 0.07$ ,  $p = 0.88$ ). Finally, there was a strong negative association between years running and weekly mileage ( $r = -0.87$ ,  $p = 0.03$ ).

The findings from this preliminary study may lend insight into the development of Achilles tendinopathy in runners. Specifically, low(er) SWS was associated with fewer years running (i.e., less running experience) and higher weekly mileage. Low Achilles SWS is important, because individuals with Achilles tendinopathy have been shown to have lower SWS than healthy subjects [4]. To further understand the significance of low(er) SWS, it's important to recognize that the most experienced runners in this study had the lowest weekly running mileage. Taken together, these findings may suggest that the less experienced, high mileage runners may be at greater risk for Achilles tendinopathy than the more experienced, low mileage runners. Furthermore, these findings may suggest that long-term mechanical loading (i.e., running over several decades) may not necessarily have a negative effect on the Achilles tendon, even though previous research has identified years running as a risk factor for Achilles tendinopathy [1]. However, given the low sample size in this study and without the assessment of tendon pathology, these implications are largely speculative and further research is needed to fully understand the complex relationships between running exposure, Achilles tendon SWS, and the development of Achilles tendinopathy.

### Significance

Ultrasound SWE may aid in understanding the role of mechanical loading in the development of Achilles tendinopathy in runners.

## Increased Cervical Spine Musculotendon Strain with Enlarged External Occipital Protuberances in Young Adults

Elizabeth S. Bjornsen<sup>1</sup>, Anita N. Vasavada<sup>2</sup>, and Kaitlin M. Gallagher<sup>1</sup><sup>1</sup>University of Arkansas, Fayetteville, Arkansas<sup>2</sup>Washington State University, Pullman, WAEmail: [kmg014@uark.edu](mailto:kmg014@uark.edu)**Introduction**

In 2019, 81% of all Americans owned a smartphone, with ownership increasing to 96% for young adults 18-29<sup>1</sup>. Tablet and smartphone use have increased, accompanied by a flexed neck posture during device use<sup>2</sup>. Cervical extensor muscles, including the splenius, semispinalis, suboccipital muscles and superior trapezius, all aid in supporting the head's weight<sup>3</sup>. Any increase in flexion, which is common with device usage, may limit muscle function. Further, increased cervical flexion has been associated with reclined and semi-reclined positions when compared to an upright posture<sup>4</sup>.

New research has identified that prominent exostoses at the base of the neck are more prevalent in the young adult population<sup>5</sup>. The presence of an enlarged external occipital protuberance (EEOP) could influence cervical flexion and increase cervical spine musculotendon (MT) strains. Therefore, the purpose of the study was to compare cervical flexion and cervical extensor MT strains between those with and without an EEOP. We hypothesized that:

- (1) Individuals presenting with and without an EEOP will have different cervical flexion range of motion.
- (2) Cervical extensor MT strains when in full flexion will differ among individuals who present with and without EEOP.

**Methods**

Twenty-two participants (21.32±1.25yrs) with no history of neck injury had cervical x-rays in neutral and full cervical flexion. The presence of an EEOP was defined by a ≥10mm measurement from the occipital squama to the most distal portion of the protuberance<sup>5</sup>. Cervical flexion in the fully flexed x-ray posture was computed with respect to neutral using individualized landmarks in Image-J (Rasband, WS). Individualized output from a cervical spine biomechanical model (SIMM) calculated 27 MT segment strains in full flexion using the neutral posture as the reference. Between group (presence vs. absence of EEOP) comparisons were conducted using t-tests for MT strain and range of motion (SAS, Cary, NC) with a Bonferroni correction of  $p < .0019$  to account for multiple comparisons. Hedge's  $g$  effect sizes were computed, recognizing .80 as a large effect<sup>6</sup>.

**Results**

41% (n=9) of participants met the criteria for having an EEOP. Hypothesis 1 was not supported, as cervical flexion range of motion was not statistically different between groups. Cervical flexion was  $15.0^\circ \pm 2.5^\circ$  and  $16.3^\circ \pm 6.7^\circ$  for EEOP presence and EEOP absence respectively. Hypothesis 2 was partially supported. Five of the twenty-seven MT segments were significantly different between ( $p < .0019$ ) (Table 1). Two of the three deep multifidus MT segments ( $p < .002$ ), two of the three superior multifidus MT segments ( $p < .001$ ) and the semispinalis cervicis observed significant strain differences between groups ( $p < .001$ ). In all cases, higher MT strains were observed for EEOP present individuals.

TABLE 1. Musculotendon Strains (mean ± standard deviation) and Hedge's  $g$  effect size for EEOP presence/absence. \* $p < .0019$

MT Segment (name-origin-insert)	Presence	Absence	Effect Size
deepmult-C4/5-C2 *	.3221 ± .0655	.214 ± .0546	1.84
deepmult-C5/6-C3 *	.3192 ± .0540	.195 ± .0661	2.01
deepmult-C6/7-C4	.3304 ± .1272	.2262 ± .0849	1.02
semi_cerv_C2C7 *	.2587 ± .0353	.1793 ± .0457	1.88
supmult-C4/5-C2	.3195 ± .0916	.2355 ± .0682	1.08
supmult-C5/6-C2 *	.3507 ± .0606	.2424 ± .0568	1.86
supmult-C6/7-C2 *	.4054 ± .0561	.2684 ± .0719	2.06

**Discussion**

The study supports previous findings of EEOP presence in young adults<sup>5</sup>. While not all MT segments had between-group strain differences, all affected MT segments had insertion points on the C2 vertebrae. The multifidus<sup>7</sup>, which observed significance in four of six MT segments, and semispinalis cervicis, are responsible for cervical stabilization<sup>8</sup>. None of these MT have insertions on the skull. Muscle attachments near the EEOP are the trapezius (not modelled in this study) and the semispinalis capitis (not significantly different). While it is unclear why other MT segments were unaffected, repetitive mechanical loading, a mechanism for exostoses development<sup>9</sup>, at the C2 attachment site could increase MT strain of other tissues in the cervical spine and contribute to exostoses development.

**Significance**

Technology has transformed society and highlights a new area of clinical concern, especially in young adults. Long-term, cervical flexion associated with smartphone and tablet use may have clinical implications. Therefore, future studies should continue to explore the relationship between hand-held technology use and the presence of an EEOP. Additional research should examine the risk of neck pain development for individuals with an EEOP, potentially reducing the need for clinical interventions.

**Introduction**

Unstable sitting is commonly used for evaluating trunk postural control (TPC) [1,2]. TPC measures during unstable sitting are typically derived from center-of-pressure data [3], but these measures do not necessarily quantify the underlying control or movement strategies. Methods that more directly characterize trunk-pelvic coordination, such as vector coding (VC) – which has been used in walking [4], turning [5], and lifting [6] – may provide additional insights into movement control strategies during unstable sitting. The purpose of this study was thus to quantify trunk-pelvis coordination during unstable sitting using VC, and to compare these outcomes across varying levels of task demand. We hypothesized that as task demand increased the frequency of anti-phase movements would increase, with a corresponding decrease in the frequency of in-phase movements.

**Methods**

Thirteen uninjured individuals (2 female) participated, with mean (SD) age = 28.7 (7.2) yr, stature = 177.1 (6.3) cm, body mass = 74.6 (11.4) kg. Each sat on an unstable chair [1] at four levels of instability, in a random order, relative to each individual's gravitational gradient ( $\nabla G$ ) [2]: 100, 75, 60, and 45 % $\nabla G$ . Three 60-second practice trials were administered to attenuate learning effects, after which one 60-second test trial was completed and analyzed. Trunk and pelvic kinematics were tracked (120 Hz) via an 18-camera motion capture system.

Tri-planar trunk-pelvic coordination was assessed using VC analyses [4], and coupling angles classified movements into: 1) anti-phase (trunk and pelvis move in opposite directions); 2) in-phase (trunk and pelvis move in same direction); 3) trunk-phase (only trunk motion); and 4) pelvic-phase (only pelvis motion). Main effects of instability level (% $\nabla G$ ) were assessed using single-factor ANOVAs ( $p < 0.05$ ). Post-hoc Bonferroni-corrected  $t$ -tests assessed between-condition differences ( $p < 0.0125$ ).

**Results and Discussion**

With decreasing % $\nabla G$  (i.e., increasing instability), we found [Fig. 1]: increased anti-phase movement in the sagittal ( $p = 0.011$ ) and

frontal ( $p = 0.005$ ) planes; decreased in-phase movement in the sagittal ( $p = 0.003$ ) and frontal ( $p = 0.055$ ) planes; increased in-phase movement in the transverse plane ( $p < 0.001$ ); and increased pelvic-phase movement in the transverse plane ( $p = 0.003$ ).

Supporting our hypothesis, increased in-phase motion in the sagittal and frontal planes at lower levels of instability suggests the use of a stiffening strategy, in which the trunk and pelvis move in unison. As the task goal was to minimize chair motions, this strategy likely assisted in limiting extraneous movement and maintaining balance. With increased instability (lower % $\nabla G$ ), participants face larger perturbations and stiffening becomes more difficult. Instead, participants appeared to adopt a strategy involving more anti-phase movements of the trunk and pelvis, which may offset the gravitational effects of each segment and prevent excessive leaning in any one direction.

**Significance**

VC techniques were able to discriminate between levels of instability during unstable sitting, and thus may serve as useful TPC measures that are more indicative of the underlying movement strategies. Moreover, these results can serve as baseline data for future work investigating populations with impaired TPC (e.g., individuals with low back pain or limb loss).

### Introduction

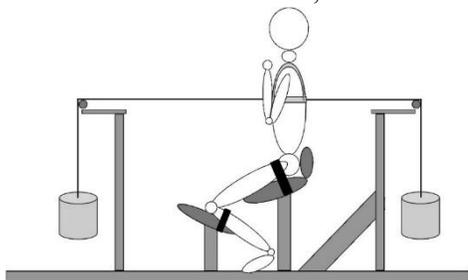

The spine has evolved over time to provide an optimal level of stability to the human body [1]. Researchers have suggested that this stability may be affected by prolonged sitting, which could leave workers at an increased risk for injury, particularly in occupations where dynamic movements immediately follow prolonged periods of seated work [2,3]. To date, this hypothesis has yet to be tested. Numerous methods have been used to assess the dynamic stiffness of the trunk [4,5,6], a variable that represents the trunk's ability to withstand a perturbation, a quality that would be indicative of spinal stability. The purpose of the current study was to determine whether prolonged sitting affects the trunk's ability to react to a perturbation.

### Methods

Forty-six individuals (18 males, 28 females) who work sedentary jobs were recruited from three age groups (18 – 28 years:  $n = 17$ , 38-48 years:  $n = 14$ , and 58-68 years:  $n = 15$ ). Volunteers were excluded if they were experiencing low back pain, or if they had experienced low back pain significant enough to cause them to seek medical attention or to miss school or work in the past 12 months. Active stiffness of the low back was measured immediately before and after the participants sat in a backless office chair for 60 minutes.

Low back active stiffness was measured through a forward-perturbation protocol as described in literature [4] whereby participants adopted a semi-seated position in a custom apparatus. 15% of their body weight was suspended from the front and back of their torso by way of a chest harness (Figure 1). At a random time and in a random order, one of the two suspended

weights was dropped by releasing an electromagnet. The remaining weight caused a perturbation either forward or backward depending on which weight

**Figure 1:** Schematic of custom active stiffness apparatus with participant in neutral position.

was dropped. The participants were instructed to sit as relaxed as possible prior to the weight dropping, and to return to their upright position as quickly as possible afterwards. For the purpose of this analysis, a faster response and shorter displacement were used to denote an increase in active stiffness.

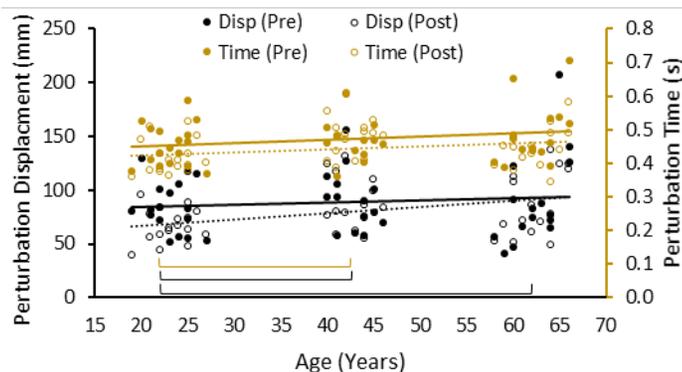

Statistical analysis consisted of paired-samples t-tests to identify differences in active stiffness before and after sitting, as well as correlations and one-way ANOVAs with Bonferroni adjustments to identify relationships and associations between age and active stiffness.

### Results and Discussion

Paired-samples t-tests revealed a significant difference between variables measured before and after sitting with perturbation displacement ( $t(45) = 2.25$ ,  $p = 0.03$ ) and response time ( $t(45) = 3.22$ ,  $p = 0.002$ ) decreased after a bout of prolonged sitting.

The correlation analysis revealed no relationship between either active stiffness variable before sitting, but a moderate positive relationship between age and perturbation displacement after sitting ( $r = 0.245$ ,  $p = 0.02$ ).

Lastly, the one-way ANOVA showed an interaction between age and both active stiffness variables after prolonged sitting but not before (Figure 3). A post-hoc analysis with Bonferroni adjustments revealed that after sitting, the younger group displaces significantly less than the middle-aged ( $p = 0.041$ ) and older groups ( $p = 0.046$ ) and responds faster than the middle-aged group ( $p = 0.039$ ).

**Figure 2:** Perturbation displacement (black) and response time (gold) with age before sitting (closed circles, solid trendlines) and after sitting (open circles, dotted trendlines). Between-group differences ( $p < 0.05$ ) after sitting are shown by square brackets at the bottom of the figure.

### Significance

The results of the current analysis suggest that contrary to previous beliefs, spine stability appears to increase following a bout of prolonged sitting. This could be a protective mechanism of the spine to prevent injury when dynamic motions are required immediately following a bout of sitting. It also appears, however, that this protective mechanism may be reduced with age, where older individuals do not show an increase in spine stability but rather, maintain their pre-sitting level. This could leave older workers at an increased risk for injury should they be required to lift and/or bend after sitting for an hour or more and further investigation is needed to determine the mechanisms involved. With the average age of the global workforce steadily increasing [7], this research could impact the health of workers everywhere.

### Introduction

More than 80% of individuals experience an episode of low back pain (LBP) at some point during their lifetime.[1] In active populations, up to 37% suffer from LBP,[2] and military populations report 70% higher prevalence than the general population.[3] Further, compensatory movement strategies are often used to alleviate pain and often impact lower extremity loading patterns. Those who suffer from chronic low back pain tend to walk and run slower and with less trunk and pelvis coordination and variability.[4] Individuals with LBP also exhibit greater knee joint stiffness during walking.[5] Moving with less joint coordination and more stiffness may be potential compensatory movement strategies aimed at avoiding pain. Therefore, the purpose of this project was to determine how individuals who suffer from chronic LBP present with altered patient reported outcomes and lower extremity strength, and biomechanics during landing.

### Methods

Individuals who suffer from chronic LBP and healthy controls (CTRL) were recruited for this study. Individuals completed the Knee Injury and Osteoarthritis Outcomes Score (KOOS), a patient reported outcome geared toward understanding an individual's self-perceived knee function, measured in five subscales, Symptoms (SYM), Pain, Activities of Daily Living (ADL), Sports and Recreation (S&R), and Quality of Life (QOL).

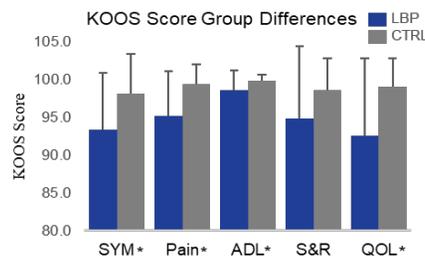

Lower extremity mechanics were collected during a drop vertical jump, single leg hop, and crossover hop using motion analysis system with two in-ground force plates. Joint angles at initial contact, and peak joint angles during the landing phase of all tasks were calculated. Peak vertical ground reaction forces (PVGRF) were identified as the maximum vertical ground reaction force during the landing phase of each task. Average loading rate was assessed as the mean of the derivative of the vertical ground reaction force curve from ground contact to PVGRF.

Independent t-tests were used to assess differences in KOOS sub scores, bilateral kinematic and kinetics between LBP and CTRL participants for all tasks. An alpha value of  $\alpha=0.05$  was set for all analyses.

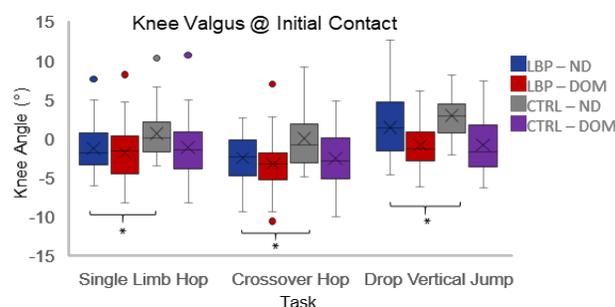

### Results and Discussion

Twenty-eight individuals with LBP (mass:  $72.06 \pm 12.1$  kg; 21F, 7M) and 28 matched individuals in the CTRL group (mass:  $72.66 \pm 13.2$  kg; 21F, 7M) completed testing. Those with LBP presented with lower self-perceived knee function compared to the CTRL group in four KOOS subscales (Figure 1), including SYM ( $p=0.007$ ), Pain ( $p=0.002$ ), QOL ( $p=0.021$ ), and ADL ( $p=0.003$ ). There were no significant differences between the two groups in the KOOS Sports and Recreation Score.

Individuals in the LBP group presented with greater non-dominant limb knee valgus angles during initial contact during the single limb hop ( $p=0.033$ ), crossover hop ( $p=0.020$ ), and drop vertical jump ( $p=0.043$ ; Figure 2) compared to the CTRL group.

**Figure 1:** Mean and standard deviation of KOOS scores between groups, \* indicating significantly different subscale scores between the LBP and the CTRL group.

**Figure 2:** Knee valgus angle at initial contact of all tasks, \* indicating significantly different subscale scores between the LBP and the CTRL group.

Additionally, during the drop vertical jump individuals with LBP exhibited significantly higher PVGRF ( $22.15 \pm 5.9$  N/kg) during landing compared to the CTRL group ( $19.13 \pm 3.3$  N/kg;  $p=0.023$ ). It is possible that individuals with LBP present with worse KOOS scores due to pain avoidance strategies. Overall, pain avoidance may drive mechanical compensations, such as increased knee valgus angles during landing, which over time, could potentially influence how individuals with LBP perceive their knee function.

### Significance

Assessing knee function in individuals with LBP may provide the clinician with a more holistic view of overall levels of physical function and performance. While KOOS scores of individuals with LBP are not as severe as those who have recently sustained a knee injury, they are lower than a healthy population. Thus, it may be beneficial for clinicians to assess self-perceived knee function to potentially delay the onset of any further complications.

**Thoracolumbar and Pelvis Kinematics are Associated with Paretic Force Production**

Donald Prible, PT, DPT<sup>1</sup>, Hao-Yuan Hsiao, PhD<sup>1</sup>

<sup>1</sup>The University of Texas at Austin, Department of Kinesiology and Health Education  
Email: prible@utexas.edu

**Introduction**

In individuals with hemiparesis, decreased propulsive force generation and weight bearing ability in the paretic limb are associated with slower walking speeds and increased disability [1]. It has been suggested that the head-arm-trunk system modulates lower extremity force production and foot trajectory during gait [2]. Given that impairments in thoracolumbar strength and coordination exist after a stroke [3] and are predictive of functional outcomes [4], it is conceivable that impairments in thoracolumbar function following stroke interfere with the mechanism of force production during hemiparetic gait. The purpose of this study was to identify relationships between thoracolumbar movement and paretic lower limb force production during stance phase of gait in individuals post-stroke.

**Methods**

Participants (n = 19) with chronic hemiparesis following stroke walked at their self-selected walking speed on a treadmill (mean speed = 0.76 ± 0.37 m/s). Kinematics were measured via an 8-camera motion tracking system using a cluster of markers around the sacrum and markers at each acromion. Ground reaction forces (GRFs) were captured via an instrumented split-belt treadmill. Peak vertical and anterior (propulsion) GRFs were calculated and normalized to body weight.

Frontal and transverse plane pelvis position and thoracolumbar angle (thorax relative to pelvis) were calculated in Visual3D. Positions at the start of stance as well as the peak changes during stance were calculated. This generated eight independent variables: (pelvis and thoracolumbar) x (frontal plane and transverse plane) x (initial position and peak change in position).

Pearson’s correlation was used to determine relationships between thoracolumbar and pelvis kinematics and GRF variables. Stepwise linear regression was used to identify predictors of peak paretic vertical GRF and propulsion.

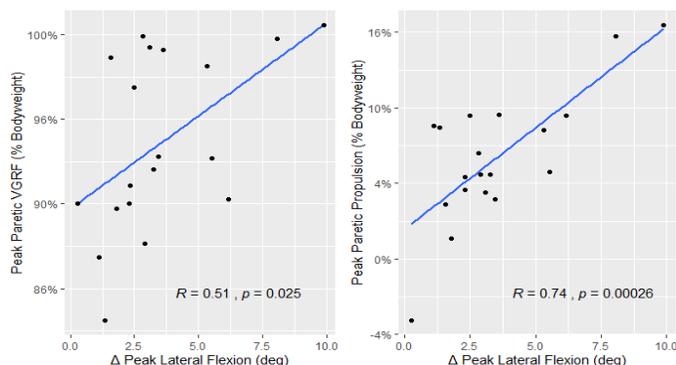

**Results and Discussion**

Peak change in thoracolumbar lateral flexion (LF) during stance phase was correlated with peak paretic vertical GRF and propulsion (Figure 1). It was also the only significant predictor of peak paretic force production (Table 1), indicating that the movement of the pelvis *relative to* the thorax affects weight bearing and forward progression more than movement of the pelvis alone. Additionally, frontal plane kinematics demonstrated significance while transverse plane kinematics did not.

The model predicts that for each additional degree of LF during stance, the propulsive force *increases by 1.34% of body weight*. Given that the maximum propulsive force among participants is approximately 16% of bodyweight, this may suggest that relatively small changes in LF are associated with meaningful changes in force production.

Initial pelvis position independently contributed to the model predicting peak vertical GRF, indicating that altered pelvis

position may affect paretic limb weight bearing capacity during stance.

**Figure 1:** Correlation between peak trunk lateral flexion (degrees) and peak VGRF/propulsion (normalized to body weight) during paretic stance phase at self-selected walking speed.

	Normalized Peak Force During Paretic Stance	
	VGRF	Propulsion
Initial Pelvis Tilt in Frontal Plane	-0.00642 +	
Peak Δ Thoracolumbar Lateral Flexion	0.0105 *	0.0134 ***
R <sup>2</sup>	0.403*	0.553***

**Table 2:** Coefficients of linear regression model of peak forces against thoracolumbar and pelvis variables at self-selected walking speed. Significance Level: \*\*\* 0.001, \*0.05, +0.1

**Significance**

Our findings suggest that thoracolumbar lateral flexion movement during stance is an important factor for functional weight bearing and propulsive force production. This supports a thoracolumbar-mediated mechanism of force production that may inform future rehabilitation strategies.

## Periacetabular Osteotomy for Hip Dysplasia Alters Dynamic Flexor and Abductor Muscle Moment Arms and Lines of Action

### Introduction

Developmental dysplasia of the hip (DDH) is characterized by abnormal bony anatomy, which causes abnormal joint loading and leads to early onset of hip osteoarthritis.<sup>1,2,3</sup> To reduce the risks for joint damage, periacetabular osteotomy (PAO) is commonly prescribed to correct hip anatomy for young adults with DDH. PAO restores femoral coverage and usually relieves symptoms;<sup>2</sup> however, chondral damage has been found in many hips post-PAO,<sup>3</sup> indicating hip loading may still be abnormal after surgery. The bony anatomy of DDH also alters hip muscle moment arm lengths (MALs) and lines of action (LoAs), which affect the muscles' ability to generate forces and may contribute to abnormal hip loading.<sup>4,5,6</sup> However, despite muscles being a key factor in pre- and post-PAO hip mechanics, it is unclear how their force-generating abilities are changed by PAO. Thus, our objective was to compare hip muscle MALs, LoAs and forces during gait before and after PAO using subject-specific musculoskeletal models. We hypothesized that due to the medialization of the lateralized hip joint centers (HJCs) during PAO,<sup>7</sup> hip abductor MALs will be increased, medial LoAs will be reduced, and medial hip loading will be lower than pre-op.

### Methods

5 female patients with DDH (25.0 ± 6.8 y/o, BMI: 23.2 ± 1.6 kg/m<sup>2</sup>) participated after IRB approval and consent. Gait data were captured for each subject pre-PAO and again post-PAO (4-7 months) using near-infrared cameras, skin markers and an instrumented treadmill. Pre- and post-op MR scans of the pelvis and femurs were both reconstructed in 3D. First, the pre-PAO 3D geometries were added in OpenSim to create models with subject-specific bony anatomy, HJC locations and muscle paths.<sup>8</sup> Then, post-PAO models were created by updating the MR-based post-PAO 3D hemi-pelvis, HJC location, and origin of the rectus femoris muscle (altered by PAO) on the surgical side. Using each pre- and post-PAO model and corresponding gait data, muscle forces over a gait cycle were estimated via static optimization. Dynamic muscle MALs were computed using a generalized-force method;<sup>5</sup> muscle LoAs were extracted as a unit vector with antero-posterior, supero-inferior, and medio-lateral components, which represent the percentage of each net muscle force in these 3 directions.<sup>6</sup> Lastly, hip joint reaction forces (JRFs) were computed from muscle forces. Hip JRFs, muscle MALs, LoAs and forces were compared between pre- and post-PAO models at the times of JRF peaks in early and late stance (paired *t* or Wilcoxon tests,  $\alpha = 0.05$ ).

### Results and Discussion

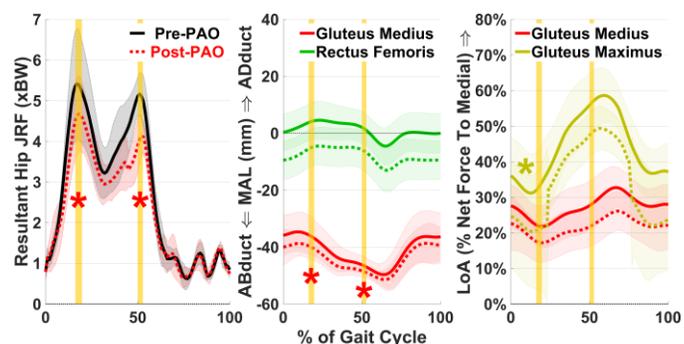

After PAO, both resultant ( $p \leq 0.04$ ; **Fig. 1**, left) and medial hip JRFs (1.34 vs 0.86 ×BW in late stance,  $p = 0.03$ ) significantly decreased compared to pre-PAO. As past studies found elevated medial JRFs in DDH,<sup>9</sup> current results suggest PAO may be effective for lowering the excessive hip JRFs.

As we hypothesized, hip abduction MALs (**Fig. 1**, center) for gluteus medius increased after PAO ( $p \leq 0.05$ ). Such change

may be attributed to medialization of the HJC after PAO (pre: 9.4 mm, post: 8.7 mm from median plane), which reduces the relative distance between HJC and the abductor muscle paths. Consequently, abductor muscle forces decreased (e.g. gluteus medius, 1.59 vs 1.11 ×BW late stance,  $p = 0.03$ ), which supports findings that hip loading is sensitive to HJC medialization.<sup>7</sup>

Due to the repositioned muscle origin of rectus femoris on the reoriented acetabulum, its hip flexion MALs increased markedly (37.6 vs 44.1 mm in early stance,  $p = 0.01$ ). Frontal-plane MAL also changed from near-neutral to abduction (**Fig. 1**, center), which may have affected its net force (0.68 vs 0.33 ×BW in late stance,  $p = 0.05$ ) and contribution to the hip JRFs.

Muscle LoAs were also altered by PAO (**Fig. 1**, right). Medial LoAs became lower in the gluteus maximus ( $p \leq 0.05$ ) and gluteus medius, which supports our hypothesis and means that forces produced by these muscles were oriented less medially, which may have helped reduce the medial hip JRFs.

**Figure 1:** Hip JRFs (left), muscle abduction-adduction MALs (center), and medio-lateral LoAs (right) pre- and post-PAO over a gait cycle.

### Significance

PAO considerably influenced the hip muscle MALs and LoAs during gait. Increased hip abduction MALs and reduced medial LoAs lowered resultant and medial hip muscle forces and JRFs. These results elucidate how PAO can help reduce hip loading via modification of the HJC locations and muscle paths, thereby restoring hip muscles' dynamic force-generating abilities.

Because muscles are major contributors to joint loading, identifying the changes in dynamic hip muscle paths and force-generating abilities improves our knowledge of the mechanistic efficacy of PAO for correcting abnormal joint mechanics. This knowledge can inform future surgery and post-op rehabilitation to minimize the likelihood for hip joint damage in DDH.

### Introduction

Osteoarthritis (OA) is one of the leading causes of ambulatory disability, with symptomatic hip OA affecting at least 4% of Americans over 50 years of age [1]. Developmental dysplasia of the hip (DDH) and femoroacetabular impingement (FAI) are two of the primary causes of premature hip degeneration [2]. These structural deformities hinder the ability of the articular surfaces to properly transfer loads during movement. While anatomical diagnosis of joint morphology can be accomplished using imaging, these lack quantitative assessment during everyday tasks.

Several studies have investigated peak measures of gait alterations in level walking biomechanics for FAI and DDH, separately. Yet, this practice excludes other regions in the gait cycle and many researchers suggest more challenging tasks are needed to provide a detailed understanding of both DDH and FAI and inform targeted treatment strategies for each group [3].

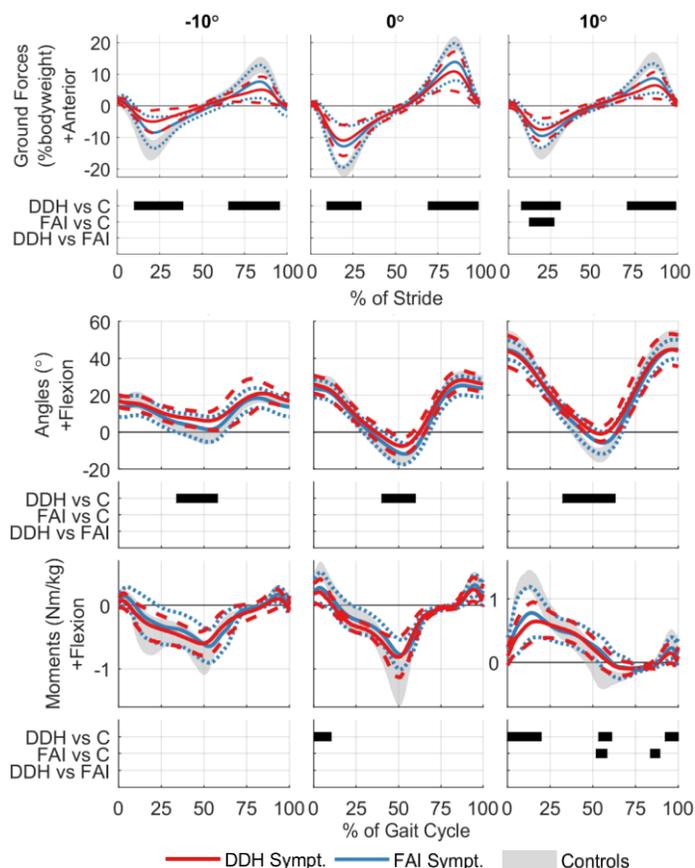

The purpose of this study was to quantitatively assess hip kinematics and kinetics during level, incline, and decline walking of individuals with diagnosed DDH and FAI compared with asymptomatic controls. We hypothesized that the DDH patients would show larger differences than controls in decline, while FAI would show larger differences than controls in incline walking, with overall similar behaviour of both groups relative to controls during level walking.

### Methods

Thirteen patients with DDH, thirteen patients with FAI, and eight asymptomatic controls (C) provided informed consent, and the 26 patients were scheduled for hip preservation surgery. On the day of scheduled surgery, subjects performed one-minute walking trials at self-selected speeds on level, incline (10°), and decline (-10°). An instrumented splitbelt treadmill (Bertec, Inc.) collected 3D ground reaction forces (GRF, 1000 Hz), and a 10-camera motion capture system (Vicon, Inc.) tracked 46 reflective markers (100 Hz). Kinematic and kinetic data were applied low-pass Butterworth filter (6 Hz cut-off) using Visual3D (C-Motion, Inc.). Statistical Parametric Mapping (SPM) *t*-tests ( $\alpha=0.05$ ) were computed to compare between group GRF and hip joint angles and moments of the affected leg in sagittal plane, as a function of the gait cycle [4].

### Results and Discussion

Some hypotheses were supported and some were not. DDH showed significant ranges of reduced braking and propulsive forces during early and late stance at all slopes, reduced hip extension during middle and late stance at all slopes, and reduced extension moment during early stance for level and incline, possibly due to reduced speed but still suggestive of reduced impact on the joint. Both FAI and DDH showed more flexion-biased moments in pre-swing on the incline, suggesting this may be a protective mechanism that the hip patients used to reduce the range of hip extension. FAI showed lower braking forces, also suggesting a guarding mechanism. FAI and DDH patients both

**Figure 1:** Hip sagittal plane biomechanics. For each subfigure, the top row shows the patient means (solid lines)  $\pm$ SD (dashed or dotted for DDH or FAI, respectively) and the controls mean  $\pm$ SD (shaded gray). The bottom row illustrates solid black bars as regions of statistical significance for SPM *t*-tests ( $\alpha=0.05$ ).

exhibited gait modifications relative to controls, with the most widespread changes occurring throughout the stride in DDH, especially on the incline.

### Significance

Quantifying gait modifications across multiple tasks shed light on the issues these patients face during daily ambulation that occurs on non-level terrains. Different behaviors relative to control subjects were observed in each group suggesting these data could help diagnose these groups or even inform different options available for therapeutic and surgical treatments [5].

### Introduction

Patients with femoroacetabular impingement syndrome (FAIS) exhibit abnormal hip joint morphology and gait mechanics as well as severe hip joint pain and cartilage degeneration[1]. Abnormal hip joint loading patterns within the FAIS population may be due to hip extensor weakness[2]. More specifically, hip extensor weakness is associated with higher anterior hip joint contact forces[3]. Hip extensor weakness may help to explain the utilization of higher hip joint demand during the sit-to-stand task in patients with FAIS[4] yet the effects of hip extensor-related biomechanical abnormalities that occur during the stand-to-sit task within the FAIS population are unknown.

The purpose of this study was to assess hip joint muscle and contact forces (JCF) that occur during the sit-to-stand and stand-to-sit tasks in patients with FAIS and asymptomatic controls. We hypothesized that patients with FAIS will exhibit weaker hip extensors, lower hip extensor muscle force production and higher anterior hip JCF during both tasks compared to controls. We also hypothesized that FAIS patients would perform the sit-to-stand task with lower hip extensor muscle force and higher anterior hip joint contact force compared to the stand-to-sit task.

### Methods

Six pre-surgical female patients with FAIS (age: 31.8±12.0years; BMI: 28.0±6.11kg·m<sup>-2</sup>) and 5 female age- and BMI-matched asymptomatic controls (CONT; age: 36.0±12.9 years; BMI: 26.9±3.20kg·m<sup>-2</sup>) without clinical indications of hip impingement (negative FADIR test) underwent 3D gait analysis of the surgical (FAIS) or dominant limb (CONT) during the sit-to-stand and stand-to-sit tasks[4]. All participants also underwent unilateral isokinetic strength testing (60°·s<sup>-1</sup>) to assess concentric hip flexor, extensor, abductor and adductor strength (Nm·kg<sup>-1</sup>).

Musculoskeletal simulations of both tasks were performed using Opensim[5] utilizing a musculoskeletal model developed for deep hip flexion tasks[6]. Hip flexor, extensor, abductor and adductor muscle forces were estimated using Static Optimization. Hip JCF were computed using Joint Reaction Analysis within OpenSim. The average peak muscle force, anterior, superior and medial hip JCF during both tasks were extracted. Also, the average angle of application and angular distribution of the hip JCF in the sagittal, axial and coronal planes were computed. Both hip joint muscle and JCF were normalized by bodyweight (BW).

Between group differences in muscle strength and hip joint mechanics during both tasks were assessed using independent t-tests (p<0.05). Within group differences both tasks were assessed using paired t-tests (p<0.05).

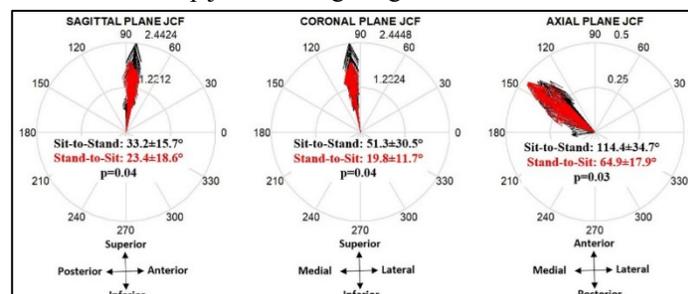

### Results and Discussion

Patients with FAIS exhibited weaker hip abductors to asymptomatic controls (CONT: 1.33±0.23Nm·kg<sup>-1</sup>; FAIS: 0.64±0.46Nm·kg<sup>-1</sup>; p=0.01). No between-group differences were

observed in hip muscle forces or JCF parameters during the sit-to-stand and stand-to-sit tasks.

The CONT exhibited significantly lower angular distribution of the hip JCF in the sagittal ( $\Delta = -7.91^\circ$ ; p=0.02) and axial ( $\Delta = -44.3^\circ$ ; p=0.01) planes during the stand-to-sit task compared to the sit-to-stand task. Patients with FAIS exhibited trends of lower hip adductor muscle forces (stand-to-sit: 0.64±0.51BW; sit-to-stand: 0.76±0.53BW; p=0.07) and peak superior hip JCF (stand-to-sit: 2.73±1.64BW; sit-to-stand: 3.44±1.64BW; p=0.09) during the stand-to-sit task compared to the sit-to-stand task. Patients with FAIS exhibited significantly lower angular distribution of the hip JCF in sagittal ( $\Delta = -9.76^\circ$ ; p=0.04), coronal ( $\Delta = -31.4^\circ$ ; p=0.04) and axial ( $\Delta = -49.4^\circ$ ; p=0.03) planes during the stand-to-sit task compared to the sit-to-stand task (Figure 1).

Weaker hip abductors in patients with FAIS may lead to a more adducted hip joint during the stand-to-sit task, which may cause hip joint impingement. Patients with FAIS in this study may reduce the risk of hip impingement and avoid pain during the stand-to-sit task by lowering the hip adductor muscle force and superior JCF yet this neuromuscular compensation causes a more focalized loading pattern on the hip joint articular cartilage, which leads to hip joint cartilage degeneration.

**Figure 1:** Angular distribution of the hip JCF in all 3 planes within the FAIS group during the sit-to-stand (black) and stand-to-sit (red) tasks.

### Significance

Despite our hypothesis being incorrect, the results of this study indicate that the stand-to-sit task may be sensitive in detecting abnormalities in the hip JCF within the FAIS population. Future studies should investigate the effects of hip abductor strengthening interventions in reducing hip JCF abnormalities during the stand-to-sit task in the FAIS population.

## Bone-to-bone Distance Changes Are Larger in Patients with Cam Femoroacetabular Impingement Syndrome

### Introduction

Cam-type femoroacetabular impingement syndrome (FAIS) is a painful, motion-related structural hip disorder. Patients present with a loss of sphericity of the femoral head which may cause the hip to lever- or cam-out as it articulates, leading to instability [1]. However, a quantitative description of hip instability in this patient population is lacking. Traditional motion capture techniques rely on tracking of markers adhered to the skin, and are prone to large errors due to misidentification of the hip joint center [2, 3]. We have developed a dual fluoroscopy (DF) system that quantifies in-vivo hip motion through direct imaging of the pelvis and femur during dynamic loading. The primary aim of this study was to apply DF to provide a quantitative description of hip instability. We hypothesized individuals with cam FAIS morphology would have larger changes in bone-to-bone distance as compared to controls, thereby indicating a less stable hip.

### Methods

Seven participants diagnosed with cam FAIS (5 males, 2 females; age, 29±7 yrs; height, 179.1±10.1 cm; mass, 78.9±15.2 kg) and eleven asymptomatic individuals with typically-developed anatomy (6 males, 5 females; age, 23±2 yrs; height, 173.3±10.4 cm; mass, 63.8±10.9 kg) provided informed consent for study participation as approved by the University of Utah Institutional Review Board. The femur and pelvis were reconstructed in 3D from CT images (Figure 1, left) (Amira, ThermoScientific). In-vivo hip motion during walking on a level and inclined (5°) treadmill was recorded using DF (see [3] for details). For processing purposes, gait was normalized to 100 time points.

Biomechanists quantify joint translations to measure instability. However, in the case of cam FAIS, the femoral head does not conform to canonical geometry (i.e., sphere, ellipsoid), and thus, measurements of hip translation would be biased. We circumvented this issue by calculating bone-to-bone distances, which are independent of the definition of the hip joint center. Minimum bone-to-bone distance was calculated for six regions of the acetabulum that were divided by 60° increments (Figure 1, left) (PostView 2.0). The change in the minimum distance was quantified as the range of distance values for each time point.

Linear regression with two within-subject factors (*activity*, *region*) and one between-subjects factor (*group*) was performed in SPSS. We modeled the main effects and interaction terms, and applied a generalized estimating equation correction to account for repeated measures. Significance for all tests was set at  $p < .05$ .

### Results and Discussion

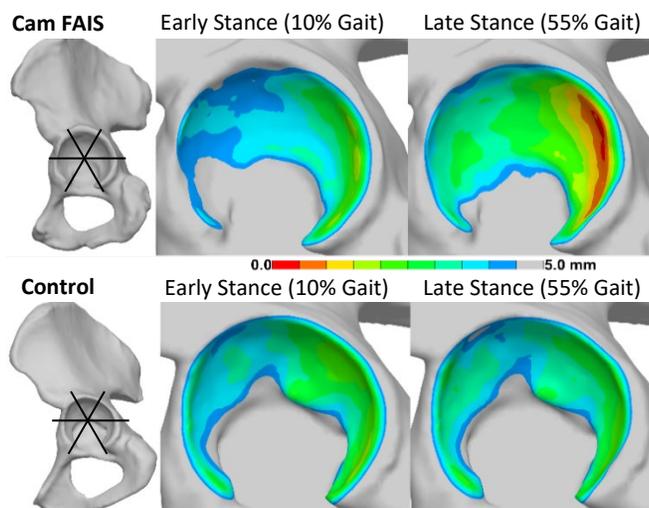

The change in the minimum bone-to-bone distance was larger in the cam FAIS group than controls for all regions except the

**Table 1.** Mean (standard deviation) change in minimum bone-to-bone distance (mm).

Activity	Group	Region					
		Superior*	Anterior-Superior	Anterior-Inferior*	Inferior†§‡	Posterior-Inferior*	Posterior-Superior*§
Walk	Cam	1.56 (.52)	1.86 (.41)	2.07 (.46)	1.38 (.58)	2.17 (.60)	2.54 (.57)
	Control	1.16 (.50)	1.67 (.65)	1.56 (.72)	1.35 (.62)	1.74 (.52)	1.84 (.44)

	Control	1.22 (.49)	1.72 (.63)	1.41 (.59)	1.34 (.53)	1.56 (.47)	1.57 (.65)

Significance: †Interaction of Activity and Group; §Effect of Activity; \*Effect of Group; ‡Effect of Group for Incline Activity only.

anterior-superior region (Table 1). In the inferior and posterior-superior regions, the change in minimum bone-to-bone distance was also affected by activity, highlighting the importance of examining multiple activities. The observed differences in bone-to-bone distance are highly suggestive of a less stable hip amongst those with cam FAIS. While it is possible that heterogeneity in the thickness of the cartilage and labrum may have affected the observed results [4], all patients and controls had normal joint spacing as observed on plain film X-rays and CT. We plan to develop finite element models that include cartilage and labrum morphology to better understand interactions between hip instability and chondrolabral damage.

**Figure 1.** Bone-to-bone distance in representative participants (FAIS and control) at early and late stance.

### Significance

The finding that patients with cam FAIS had abnormal hip joint articulation during walking is significant because it suggests that even low-demand activities may cause deleterious biomechanics.

### Introduction

Thumb osteoarthritis (OA) affects one in two aging adults; it causes joint pain, reduced grip strength, and loss of function and independence [1]. Little research has evaluated the effects of OA on thumb strength itself and whether the the loss of thumb force production is uniform or affects forces in some directions more than others. Similarly, although planar motion abilities are reduced in persons with thumb carpometacarpal osteoarthritis, there is limited research investigating the effect of osteoarthritis on three-dimensional (3D) complex thumb motions. As osteoarthritis of the thumb carpometacarpal joint progress, the first webspace contracts and the distal thumb joints become mal-aligned [3]. This aberrant alignment may suggest that the joint's motion and force ability may be asymmetrically compromised. We hypothesize that thumb osteoarthritis causes 1) assymetrical thumb force changes and 2) altered motions during complex 3D movement tasks.

### Methods

**Participants:** All testing occurred under IRB approval. 58 participants were tested: 23 young healthy (22.5 years SD 3.1, 12 males; YH), 11 older healthy (66.3 years SD 8.4, five males; OH), and 21 older with doctor-diagnosed OA (69.4 years SD 5.8, six males; OA). All participants were right handed and their dominant hand was tested.

**Testing:** Thumb force and motion testing was completed by each participant. Thumb forces during radial abduction (RAB), radial adduction (RAD), palmar abduction (PAB), and palmar adduction (PAD) were measured using a custom built apparatus attached to an AMTI multi-axis load cell (Figure 1a).

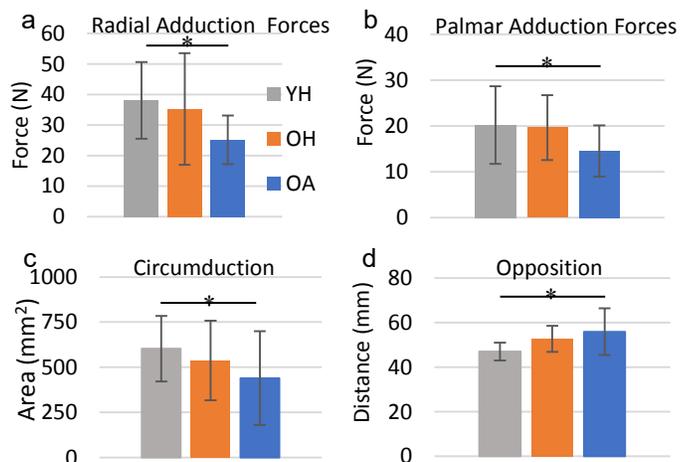

**Figure 1:** Participant testing. a) Multi-axis load cell with custom built apparatus, b) marker placement for motion testing, c) thumb opposition motion testing, and d) thumb circumduction motion testing.

Thumb motion data were collected using reflective markers (Figure 1b) and a motion capture system (Qualisys): movements included radial and palmar ad/abduction; and complex thumb motions: opposition (Figure 1c) and circumduction (Figure 1d). Force and motion data were analysed using one-way ANOVAs.

### Results and Discussion

**Forces:** All groups had the greatest thumb forces during RAD. OA females produced significantly less RAD and PAD forces than YH females (Figure 2a and b). These data suggest that OA may produce an asymmetrical loss of force production in abduction motions.

**Figure 2:** Motion and force data. Female thumb forces during a) RAD and b) PAD. Combined sex data of c) circumduction area enclosed and d) opposition distance from base of fifth finger. \* denotes  $p < 0.05$ .

**Motions:** Both OH and OA groups had a mildly reduced PAD-PAB (OH 42.3°, OA 43.9°, and YH 46.7°;  $p > 0.05$ ), but not RAD-RAB (OH 48.2°, OA 47.5°, and YH 47.5°;  $p > 0.05$ ) compared to YH. Yet, OA significantly reduced thumb circumduction area ( $p = 0.0292$ ) and significantly reduced the ability to reach during opposition ( $p = 0.0007$ ) compared to YH (Figure 2c and d). These data suggest OA significantly reduces 3D motion, prior to significant changes in planar motion tasks typically tested.

Our findings are in line with our hypotheses; OA 1) asymmetrically reduced thumb forces during adduction motions and 2) reduced thumb motion during 3D complex tasks *prior* to a loss of motion during simple planar tasks. This work suggests that analysis of thumb specific forces and 3D complex motions may provide insight into thumb pathology and should be considered in clinical and research testing settings.

### Significance

This research indicates valuable information can be gathered through the use of multi-directional thumb forces and motions, beyond what can be obtained using hand grip or planar thumb motions alone. Early 3D complex motion changes have the potential to be early identifiers of OA development and may aid in earlier OA diagnosis [2]. Both thumb forces and multi-directional thumb motions have the potential to act as new therapeutic targets for therapy and surgical intervention.

## Introduction

Total wrist arthroplasty (TWA) has a history as long as hip and knee arthroplasty; however, success rates in the wrist are inferior.<sup>[1]</sup> Current TWA designs have developed empirically, in the absence of rigorous biomechanical studies. Abnormal forces and stresses due to incongruent articulation of TWA components may lead to the carpal component loosening;<sup>[2]</sup> however, the TWA *in-vivo* pattern of articulation has not been examined to date. Direct methods of measuring contact are mostly invasive, and indirect methods such as biplane video-radiography (BVR) could be used for estimating the contact. Thus, our goal is to use BVR to establish contact pattern of the TWA components and its association with motion.

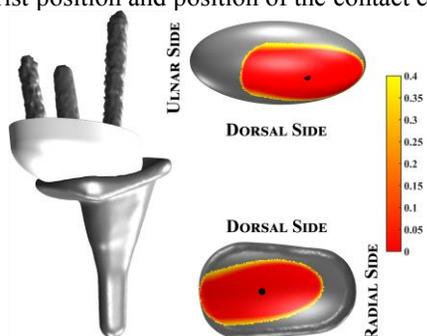

## Methods

Six osteoarthritic patients (74.7 ± 5.6 yrs, 2F, 2R) with size 2 Freedom<sup>®</sup> TWA implants (Integra LifeSciences) participated in this study. A CT scan was acquired of each wrist (0.39mm × 0.39mm × 0.625mm), and surface models of the TWA carpal component (CC), 3<sup>rd</sup> metacarpal (MC3), and resected radius (RAD) were generated using Mimics.<sup>[3]</sup> Models of the radial component and polyethylene cap were constructed using a 3D scanner and were superimposed on RAD and CC, respectively.

BVR (75 kV/80 mA, 200Hz) was used to capture dynamic implant motion while each study participant performed five active tasks of wrist motion. Positions of CC and MC3 were calculated relative to a mathematically fixed RAD in the neutral pose using a 2D to 3D registration software (Autoscooper). Wrist kinematics described relative motion of MC3 with respect to RAD using helical axes of motion. Pure flexion-extension and radial-ulnar deviation positions (positions with secondary wrist motion less than 5% of the maximum range) were selected for further contact processing.

Contact of the polyethylene cap and radial component was calculated using distance fields (D).<sup>[4]</sup> The distance exclusion threshold (T) was selected using a Monte Carlo simulation that incorporated the accuracy<sup>[3]</sup> of the BVR. Contact centroid was calculated by weighting the distances by  $(T - D)^2$ , and it is mathematically alike to the center of pressure. The sensitivity of our approach was evaluated by varying T in 0.05 mm steps.

Linear regression was used to evaluate the association between wrist position and position of the contact centroid.

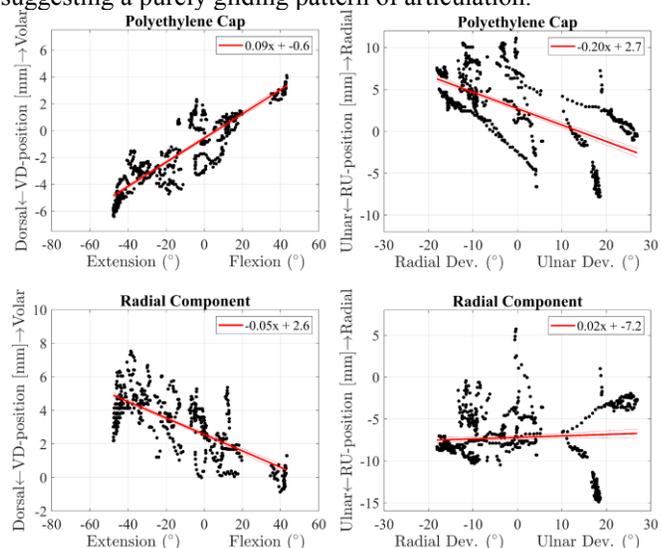

**Figure 1:** An example of the articulation of TWA components, and the contact patch on both polyethylene cap (top) and radial component (bottom). Black dots demonstrate the weighted contact centroid.

## Results and Discussion

Our sensitivity analysis established 0.4 mm as the resolution of our system and thus the lower limit of our contact localization.

The contact centroid moved from dorsal to volar on the polyethylene cap and from volar to dorsal on the radial component during flexion-extension (Fig. 2, Left.  $R^2 = 0.80$  and  $0.56$ , respectively), indicating the joint rolls and glides in opposite directions (i.e., forward roll and backward glide). This behavior might result in the impingement and restriction of range-of-motion at certain extreme poses, and it could be due to the structure of surrounding soft tissue or the design of the implant. The contact centroid of polyethylene cap was also located more radially, which shows the components surfaces were not uniformly in contact throughout this *in-vivo* motion.

The contact centroid moved from radial position to ulnar position on the polyethylene cap during radial deviation to ulnar deviation, but its location was essentially constant on the radial component (Fig. 2, Right.  $R^2 = 0.39$  and  $0.00$ , respectively) suggesting a purely gliding pattern of articulation.<sup>[5]</sup>

**Figure 2:** Contact centroid movement for pure flexion-extension (left panel) and pure radial-ulnar deviation (right panel).

## Significance

We computed the contact pattern and showed the possibility of localized force concentrations during TWA radioulnar deviation. Our findings could help inform the design and protocols for wear/stress testing of the total wrist arthroplasty implants.

### Crista Volume Shows a Relationship to Sesamoid Station

AJ Clarke, SF Conti, L Williams, MS Conti, S Ellis, Amr A Fadle, \*MC Miller

\*Allegheny General Hospital

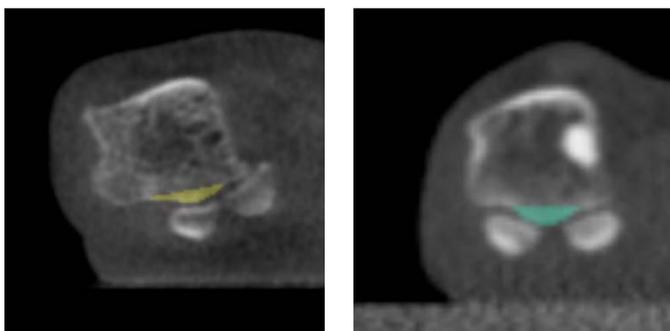

Email: \*[mark.c.miller@ahn.org](mailto:mark.c.miller@ahn.org)

#### Introduction

The progression of hallux valgus (HV) deformities results in dislocation of the sesamoids from their position (station) under the plantar surface of the distal first metatarsal. With this dislocation, the crista separating the two sesamoids erodes as the contact of the medial sesamoid with the crista applies pressure with weightbearing. Recently, three dimensional (3D) reconstructions of the metatarsals and first phalanx have demonstrated a means to quantify first metatarsal pronation, showing that three-dimensional models have application to HV problems. The purpose of the current investigation is to examine the relationship of the volume of the crista to pronation, sesamoid station, and intermetatarsal angle (IMA) using three dimensional models. It is hypothesized that crista erosion is directly related to sesamoid subluxation, intermetatarsal angle, hallux valgus angle and first metatarsal pronation in HV deformities

#### Methods

Twenty five HV patients, sixteen from HSS (NY, NY) and nine from UPMC Passavant (Pgh, PA), and ten normal subjects from UPMC Passavant underwent CT imaging with weightbearing or weightbearing equivalent (WBCT) methods after approval by the relevant Institutional Review Board. Weightbearing images were obtained in a PedCat (CurveBeam, Inc) and WBCT images were obtained with a pedal device in a LightSpeed VCT (GE, Inc.).[1][2] Using the program Mimics, segmentation was performed to create 3D solid models. Pronation, IM angle and HV angle were quantified from the 3D reconstructions.[1] Crista cross-sections in each CT slice were demarcated by slices thickness, the volume was computed. Sesamoid station was quantified using the four stage AOFAS scale. (Figure 1)

**Figure 1:** Calculation of the crista volume on weightbearing CT scans. Left: the crista has eroded with the medial sesamoid subluxation. Right: the crista cross-section in a normal subject.

The mean sesamoid station was calculated and the HV and normal stations were compared using a Mann-Whitney test. The sesamoid station was simplified into two categories – mild medial sesamoid subluxation (less than 50% of the medial sesamoid was lateral to the nadir of the crista) and severe medial sesamoid subluxation – and crista volume, IM angle, HV angle and pronation angle between these two groups was compared using a t-test for the HV subjects. Linear regressions were performed to

determine if the volume of the crista was associated with the IM angle, HV angle, and the pronation angle.

#### Results and Discussion

The median sesamoid station in HV subjects was 4 and in normal was 2 and the Mann-Whitney test indicated that the two groups were different. The mean crista volume of HV patients was  $86 \pm 25 \text{ mm}^3$  and was  $148 \pm 30 \text{ mm}^3$  in normal patients, with the t-test showing  $p < 0.001$ .

T-tests using simplified sesamoid station to compare crista volumes, IM angle, and HV angle of HV subjects only were all found to be statically significant ( $p_{\text{vol}} = 0.012$ ,  $p_{\text{IM}} = 0.011$ ,  $p_{\text{HV}} < 0.001$ ). However, the t-test using simplified sesamoid station to compare pronation was found to not be statistically significant ( $p_{\text{pro}} = 0.87$ ). The regression of crista volume against the IM angle and pronation angle in HV subjects did not show statistical significance ( $p_{\text{IM}} = 0.09$ ;  $p_{\text{pro}} = 0.40$ ). The regression of crista volumes against the HV angle in HV subjects did show statistical significance ( $p = 0.03$ , but  $r^2 = 0.19$ ).

In Hallux Valgus, it has been hypothesized that the medial sesamoid erodes the crista resulting in arthritis. This is often overlooked as a source of pain in these patients. Our study found that crista volume, HV angle, and IM angle were all related to a simplified taxonomy of sesamoid position. Pronation of the first metatarsal, however, was not correlated with the sesamoid position.

That sesamoid station appears to be related to IM angle but IM angle does not appear to be related to crista volume needs further investigation. The HV deformity is characterized by the medial angulation of the first metatarsal and the change in sesamoid station reflects that fact. That the IM angle would then not correlate to the crista volume may be a result of a large variance and a sample size of only 25. The relationship between the HV angle and crista volume does, however, agree with expectations because a large HV angle would malposition the sesamoids to cause crista erosion.

The overall results emphasize the need to further analyze 3D data to relate the HV deformity and crista wear. Operative outcomes and early detection of HV offer possible implications for the importance of crista erosion and sesamoid malposition.

#### Significance

This study is the first to demonstrate that medial sesamoid subluxation as determined by sesamoid station results in erosion of the crista. This supports the hypothesis that sesamoid subluxation, arthritis, and crista erosion are important components of the HV deformity.

### Introduction

The Lisfranc joint complex, and the tarsometatarsal (TMT) joints specifically, constitute important structural support of the transverse arch of the midfoot [1, 2]. Injuries to these joints are relatively rare (~0.002%); however, they are significantly higher in football players (~4%) yet are missed or misdiagnosed in 1 of every 5 patients. It can severely reduce mobility and diminish performance and can be associated with long-term disability and residual deformity if missed [3]. To date, no study has quantified the precise mechanism or tolerances of Lisfranc ligament injury. Such an injury risk function (IRF) is a necessary predicate for any objective optimization of injury prevention technologies, such as might be implemented in cleats or turf design. Therefore, the objective of this study was to reproduce Lisfranc injury in cadavers using real-world boundary conditions and to subsequently develop an IRF based upon experimental metrics.

### Methods

With Institutional Review Board approval, sixteen male cadaveric lower extremities were disarticulated at the knee and tested (mean age=49.1±14.8). During the test, each specimen was secured onto a material testing frame with a custom loading fixture (Figure 1A). Each limb was positioned and supported by a U-bolt through the tibiofibular interosseous hiatus distally, and a heel block below the calcaneus. Bones were affixed with 10 sets of 4-ball retroreflective marker arrays for 3-D kinematics capture (Figure 1B). The Achilles tendon was clamped to resist dorsiflexion imparted by the lowering crosshead. Group 1 (n=7) was loaded in a neutral internal/external rotation posture through a block at the plantar distal first metatarsal. Group 2 (n=9) was similarly tested with the foot maximally externally rotated at the talocrural joint and with the addition of a 100N abducting force at the distal first metatarsal (Figure 1C).

**Figure 1:** [A] Custom loading fixture. [B] 3-D kinematic targets. [C] Cadaveric specimen instrumented and mounted.

### Results and Discussion

Post-test necropsies confirming Lisfranc complex disruption were conducted by a board-certified orthopaedic surgeon with expertise in Lisfranc fixation. Group 1 tests resulted in the midfoot buckling laterally for most specimens and injuries occurring primarily at the tarsometatarsal joints. Group 2 resulted in the midfoot buckling medially for most specimens and injuries occurring primarily along the medial ray of the foot. Injury timing was determined based on the time-synchronized force, strain, and kinematic data. These values were fit using survival analysis (Weibull distribution). Injury risk functions of the Lisfranc ligament injury were developed based on the correlation between injury and four measurable kinematic metrics: 1) resultant force along the long axis of the first metatarsal, 2) change of the foot length, 3) the resultant angle of transverse and sagittal bending and 4) weighted resultant angle.

**Table 1:** Injury Risk Functions for each injury indicator.

Injury Indicator	Injury Risk Function (IRF)
Resultant force	$P_{Injury}(RF) = \begin{cases} 1 - e^{-\left(\frac{\text{resultant force}}{3326.96309}\right)^{3.77639}} & x \geq 0 \\ 0 & x < 0 \end{cases}$
Compression Percentage	$P_{Injury}(\%C) = \begin{cases} 1 - e^{-\left(\frac{\text{compress \%}}{11.00855}\right)^{3.68318}} & x \geq 0 \\ 0 & x < 0 \end{cases}$
Resultant Angle (M)	$P_{Injury}(M) = \begin{cases} 1 - e^{-\left(\frac{M}{24.77794}\right)^{9.82709}} & x \geq 0 \\ 0 & x < 0 \end{cases}$ <p>Where <math>M = \text{acos}(\cos(\text{Transverse Angle}) * \cos(\text{Sagittal Angle}))</math></p>
Weighted Resultant Angle (W.M)	$P_{Injury}(W.M) = \begin{cases} 1 - e^{-\left(\frac{W.M}{0.9565}\right)^{7.24589}} & x \geq 0 \\ 0 & x < 0 \end{cases}$ <p>Where <math>W.M = \frac{M}{4.5(\arctan(\frac{\text{Transverse angle}}{-\text{Sagittal Angle}}) + \frac{\pi}{2}) + 19}</math></p>

### Significance

This study is the first to report quantitative, mechanism-based injury risk functions of Lisfranc ligament injury. The results serve as baseline data for evaluation of the Lisfranc injury risk in sports-related scenarios and provide fundamental information needed for the development of countermeasure protection and treatment options for Lisfranc injury. The injury risk functions might also provide enlightenment to rehabilitation program development to minimize re-injuries of Lisfranc joints.

## Introduction

Many people with cerebral palsy (CP) have impaired walking ability resulting from reduced ankle function [1]. We previously demonstrated that ankle exoskeleton assistance can improve gait mechanics in individuals with CP. However, we also observed decreased muscle activity, which could lead to atrophy [2,3]. Gait training with biofeedback can incentivize people to change their walking behavior [4,5]. Seeking to maximize the benefit of wearable assistance, the **purpose** of this study was to investigate the combined effects of real-time step length biofeedback and exoskeleton assistance on muscle function and gait mechanics in CP.

## Methods

Seven participants with CP (Table 1) completed walking trials while wearing shoes (Shod) and while using the ankle exoskeleton [2] with visual biofeedback of step length (Biofeedback-plus-Assistance) (Figure 1B).

We collected motion, force, and muscle activity of the soleus and vastus lateralis for both conditions (Figure 1A). Step length and symmetry index were calculated from the coordinates of the heel markers. Joint angles and moments were derived in OpenSim 3.3 [6]. Average joint power and integrated electromyography (iEMG) were calculated for the stance phase. All parameters were averaged between limbs. Paired one-tailed t-tests ( $\alpha \leq 0.05$ ) were used to assess if outcomes improved with the intervention.

**Figure 1:** Depiction of the (A) experimental set up and (B) visual interface and algorithm for biofeedback.

## Results and Discussion

Walking with Biofeedback-plus-Assistance improved lower-extremity gait mechanics but did not alter muscle activity compared to Shod walking. Participants increased their step length by 20.3%, but decreased step length symmetry when they walked with Biofeedback-plus-Assistance (Figure 2A, B). Combining biofeedback with assistance elicited immediate improvements in gait mechanics by increasing hip (9.7°) and knee extension (7.8°) and ankle (23.3%) and knee power (44.2%) (Figure 2C, D). Soleus peak EMG and iEMG, and VL iEMG were similar during walking with Biofeedback-plus-Assistance compared to Shod, suggesting that the feedback was effective in

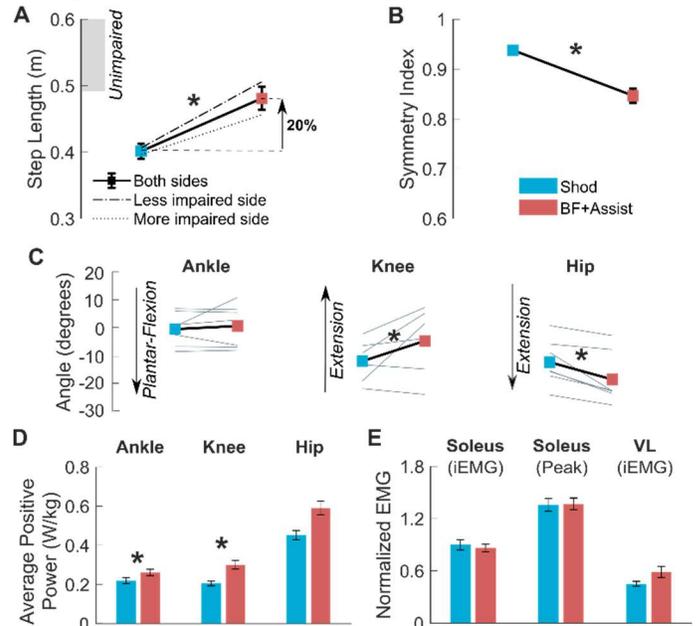

increasing neuromuscular engagement during assisted walking (Figure 2E).

**Table 1.** Participant characteristics.

	Age (Years)	Sex	Height (m)	Mass (kg)	GMFCS
P1	13	M	1.51	43.8	I
P2	31	M	1.70	53.3	II
P3	9	M	1.37	31.1	I
P4	10	M	1.39	38.5	I
P5	23	F	1.47	43.8	III
P6	6	M	1.10	17.2	II
P7	6	M	1.18	17.6	I

GMFCS: Gross Motor Function Classification System.

These results demonstrate that step length biofeedback can augment gait outcomes and increase neuromuscular engagement during exoskeleton-assisted walking.

**Figure 2:** Comparison of all variables between walking with Biofeedback-plus-Assistance (BF+Assist) and shoes (Shod). Error bars indicate standard error of the mean.

## Significance

Providing real-time step length biofeedback can increase neuromuscular engagement and improve outcomes during walking with wearable ankle assistance, paving the way for longitudinal investigations with this combined intervention.

# Estimating Biological Hip Torque During Overground Ambulation: A Machine Learning Approach

Dean D. Molinaro<sup>1,2</sup>, Inseung Kang<sup>1</sup>, Jonathan Camargo<sup>1,2</sup>, and Aaron J. Young<sup>1,2</sup>

<sup>1</sup>Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, USA

## Introduction

As gait biomechanics research continues to progress, it is important to quantify biological hip torque in unstructured environments, such as those outside of the lab. Wearable sensors provide an opportunity to compute joint dynamics without the need for external sensing. Linked-segment model-based approaches require sensors distal to the joint of interest, such as pressure insoles, which are subject to low resolution GRF measurements and often result in cumbersome, multi-joint sensor suites<sup>1,2</sup>. Machine learning (ML) methods can compute biological joint torque without direct measurement of GRFs by leveraging the limited domain of joint torques during ambulation<sup>3,4</sup>; however, generalizability of these methods to changing ambulation modes remains unknown. Thus, we conducted our study, hypothesizing that hip torque RMSE and peak magnitude and timing error estimated by a neural network (NN) are less than those resulting from an average curve of each ambulation mode.

## Methods

Five able-bodied male subjects completed the IRB approved experimental protocol by ambulating over 0°, ±7.8°, ±9.2°, and ±12.4° slopes while wearing a bilateral robotic hip exoskeleton. The hip exoskeleton was used to collect hip encoder and 6-axis thigh-mounted inertial measurement unit (IMU) data during ambulation. Data was transformed into the ML model feature space by computing the mean, standard deviation, and most recent value over a 350 ms sliding time window for each exoskeleton sensor channel. Biological hip torque was computed using the Inverse Dynamics Tool in OpenSim with motion capture and force plate data collected during each trial<sup>5</sup>. A 4 layer NN with 30 nodes per hidden layer was trained using the exoskeleton feature data, labelled by the corresponding hip torque values (Fig. 1A). Additionally, the baseline method was fit as the average hip torque curves for the level ground (LG), ramp ascent (RA), and ramp descent (RD) conditions. The two methods were evaluated using three criteria compared to the ground truth hip torque values: 1) estimation RMSE; 2) peak magnitude error, computed as the absolute difference between the peak estimated and ground truth values; and 3) peak timing error, computed as the absolute difference in gait phase during peak

estimated and ground truth values. A paired t-test ( $\alpha = 0.05$ ) was used to compare the NN and baseline methods for each criteria.

## Results and Discussion

The estimated hip torque of the NN and baseline methods are shown for an example step during RA in Fig. 1C. On average, the NN model reduced hip torque RMSE, peak magnitude error, and peak timing error by 29.7±12.2%, 32.6±17.4%, and 12.8±13.9% compared to the baseline method, respectively ( $p=0.015$ ,  $p=0.057$ ,  $p=0.117$ ) (Fig. 1B). Thus, the NN model more accurately estimated the shape and magnitude of varying ambulation modes compared to the baseline method as expected; however, both the NN and baseline methods accurately estimated peak torque timing to within 2% of the gait cycle due to the low variability in this metric among ambulation modes. Thus, the NN model is a useful approach for estimating biological joint torques when the estimate must be sensitive to shape and magnitude of the curve, such as in gait analysis and exoskeleton control.

## Significance

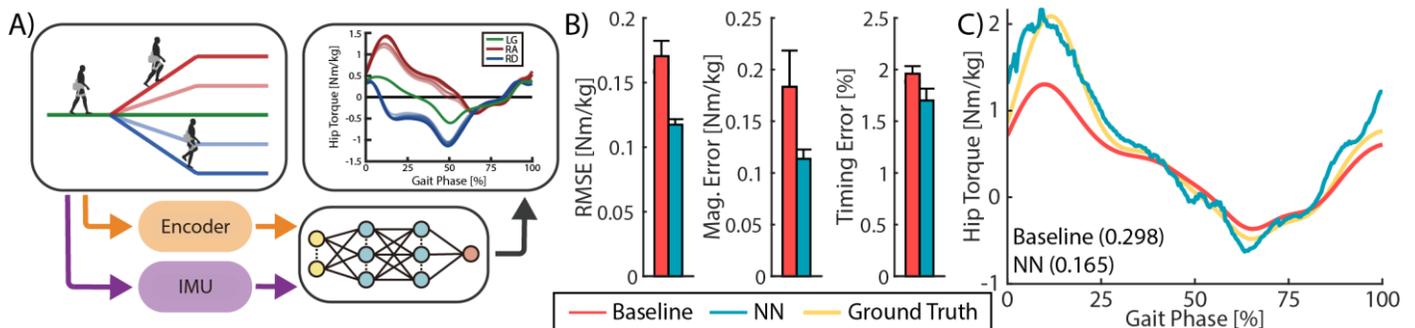

This study validated an ML algorithm for estimating biological hip torque using only mechanical sensors during various ambulation modes. We demonstrated the benefit of using this model compared to the baseline method of average values due to its improved accuracy and reduced requirement of user state information, such as ambulation mode. Thus, our study provides a promising method for estimating biological joint torque for applications including out-of-lab experiments and exoskeleton control while varying ambulation modes.

## Introduction

Incline walking increases the demand of the knee joint positive power generation during the early stance phase of the gait cycle, exhibiting a high extension moment. Assisting the joint during the phase of incline walking using a robotic exoskeleton could yield a metabolic benefit. We previously tested the biomechanical effects of powered assistance using a unilateral knee exoskeleton on able-bodied adults during incline walking, and only half of the participants achieved metabolic reduction with the assistance [1]. The participants who increased metabolic cost with the assistance in the study exhibited biomechanical compensation on the unassisted leg that contributed to the increase. Therefore, assisting the user's knee joints bilaterally would potentially eliminate the issue. In this study, we tested whether bilateral assistance during the early stance phase would lead to metabolic reduction compared to the unassisted condition with three types of controllers: a biological torque controller (BT), an impedance controller (IM), and an adaptive proportional myoelectric controller (PMC). The hypothesis was that the metabolic cost of the user would be reduced with assistance.

## Methods

We used a bilateral robotic knee exoskeleton, one degree of freedom (flexion/extension). The tested walking conditions consisted of three assistance conditions and an unassisted condition (UN) on the 15% gradient incline surface (1.1m/s). The biological torque controller is a timing-based controller in which a parabolic shaped assistance profile is generated for the first 30% of the gait cycle. The impedance controller simply behaves like a virtual spring in which the magnitude of the assistance is the stiffness multiplied by the angular deviation of the knee joint angle from the equilibrium angle, 0 degrees. The assistance was active for the first 40% of the gait cycle under IM condition. The PMC used for this study is largely similar to the PMC developed by Koller et. al [2]. We computed activation levels of the Vastus Lateralis and Vastus Medialis, multiplied each activation level by its own adaptive gain to scale it to the assistance magnitude, and averaged the assistance magnitude values between the two

muscles. The motor was powered-off under the UN, which yields the RMS interaction torque of 0.4 Nm between the user and the device during walking. Nine able-bodied adults participated in this study. The experiment consisted of two visits. Each subject was asked to practice walking under each assistance condition for 15 minutes during the first visit. Data collection occurred during the second visit where the subjects walked each condition for 5 minutes prior to 6 minutes of data collection. The order of conditions was randomized. After the completion of all walking conditions, the subjects were asked to rank the controllers based on which helped walk with the least amount of effort (rank 1-4 where rank 1 is the best and 4 is the worst). We used repeated measures one-way ANOVA with post-hoc pairwise testing using a Bonferonni correction.

## Results and Discussion

All assistance conditions had significantly lower metabolic cost than the UN ( $p < 0.05$ ). The metabolic cost was  $8.20 \pm 0.15$  (mean  $\pm$  standard error of mean) W/kg for UN,  $7.95 \pm 0.14$  W/kg for BT,  $7.96 \pm 0.18$  W/kg for IM,  $7.95 \pm 0.16$  W/kg for PMC. This seems to be resulted largely by removing the role of the unassisted leg that caused an increase in metabolic cost with unilateral assistance [1]. The level of metabolic reduction was very similar across the assistance conditions: 3.1% with BT, 2.9% with IM, and 3.1% with PMC. The user preference rank data also showed that the subjects preferred walking with the conditions with the assistance over the UN condition (UN:  $3.9 \pm 0.1$ , BT:  $2.0 \pm 0.1$ , IM:  $1.7 \pm 0.3$ , PMC:  $2.4 \pm 0.2$ ). Besides one subject, all subjects ranked the UN as the condition that required the most physical effort among the four walking conditions. The IM condition was preferred the most by the users, and no subject preferred PMC the most.

## Significance

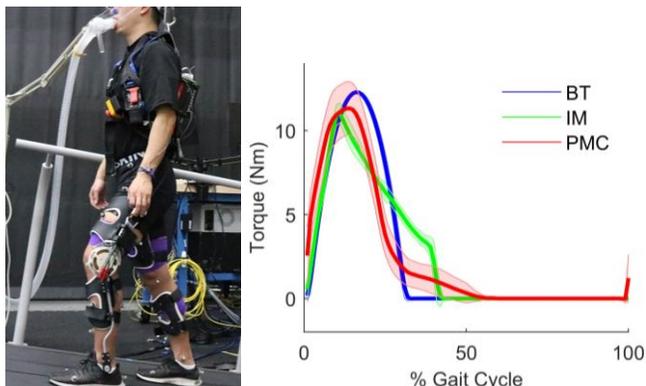

This study is one of the few studies exploring energetics with a powered knee exoskeleton. This study shows that bilateral assistance was able to achieve metabolic reduction more consistently than unilateral assistance [1]. The study indicated that early stance phase assistance, regardless of control strategy, had similar metabolic reductions during uphill locomotion. Subjects preferred BT and IM over PMC mostly because walking under the two controllers was more predictable and stable than under PMC during continuous walking at a fixed speed.

## Introduction

The success of assistive devices relies on users learning to take advantage of the assistance [1]. In everyday walking, the nervous system is faced with the dilemma between exploiting, perhaps erroneously, previously learned strategies and exploring new, unknown strategies that may improve its objective [2]. Here we aim to understand how people balance this trade-off when learning to walk with ankle exoskeleton assistance. First, we hypothesized that people explore many candidate gait dimensions as they determine which dimensions are relevant to their objective. Next, we hypothesized that people reduce this exploration with experience as they learn to exploit new strategies.

## Methods

We performed a post-hoc analysis of data from Poggensee et al. [3]. In this study, ten participants completed a training session per day for a total of 5-6 days, where they walked on a treadmill while wearing a bilateral, tethered, torque-controlled ankle exoskeleton emulator. Participants completed a validation trial each day where they experienced a generic assistance controller for two, 6-minute trials. They also completed an adaptation trial from Day 2 onwards, where they periodically experienced 2 minutes of generic assistance during a protocol that otherwise differed according to how Poggensee et al. randomly grouped participants. In our current study, we analysed how users learned to walk with this repeated exposure to the generic assistance controller.

In this experimental setup where the pattern of assistive torque was controlled on a step by step basis, users could 1) influence the torque timing by varying their step frequency, and 2) influence the power and work applied to the ankle by varying their ankle kinematics. We determined exploration at the level of the whole movement, the joint, and the muscle by quantifying step-to-step variability along gait dimensions of step frequency, ankle kinematics, and total ankle extensor muscle activity. In all gait dimensions that we measured, we tested how variability changed over multiple days by comparing average variability in the final 3 minutes of the 6-minute validation trial between the first and last day. We also normalized this variability to participant's average variability in normal walking (or zero-torque for ankle angle that was approximated using the exoskeleton) across all days. Finally, we tested for systematic changes along gait dimensions by comparing average adaptation in the final 3 minutes of the 6-minute validation trial between the first and last day.

## Results and Discussion

When the nervous system has minimal experience walking with exoskeleton assistance, it explores along many gait dimensions in search of new strategies. We observed higher variability than normal walking at the beginning of the multi-day protocol ( $p=6.6 \times 10^{-5}$ , Figure 1A;  $p=8.0 \times 10^{-8}$ , Figure 1B;  $p=3.6 \times 10^{-4}$ , Figure 1C;  $p=1.2 \times 10^{-4}$ , Figure 1D).

The nervous system reduces exploration with experience. Participants had lower step frequency variability ( $p=2.0 \times 10^{-5}$ ) and ankle angle variability ( $p=2.1 \times 10^{-5}$ ) on the last day compared

to the first day, and reduced this variability with time constants ( $\tau$ ) of  $107.8 \pm 107.1$  minutes and  $162.0 \pm 204.7$  minutes, respectively (mean  $\pm$  SD). They also reduced their total soleus ( $p=8.0 \times 10^{-4}$ ,  $\tau=20.2 \pm 46.1$  minutes) and medial gastrocnemius ( $p=2.3 \times 10^{-3}$ ,  $\tau=25.9 \pm 45.9$  minutes) variability.

With experience, variability along some gait dimensions converges on the baseline variability observed in the absence of exoskeleton assistance, suggesting that exploration was in part purposeful. Participants' variability converged on their average variability in normal walking for step frequency ( $p=0.38$ ) and total soleus activity ( $p=0.68$ ). However, variability in ankle angle ( $p=8.0 \times 10^{-6}$ ) and total medial gastrocnemius activity ( $p=2.2 \times 10^{-4}$ ) remained elevated, suggesting that some learning may still be in progress or that there is some added experimental variability.

Exploration only results in systematic changes along some gait dimensions, suggesting that the nervous system did not know a priori which dimensions to adapt. Participants did not have large adaptations in their step frequency ( $p=0.073$ , Figure 2A) or ankle angle range during stance ( $p=0.053$ , Figure 2B) on the last day compared to the first day; however, they did learn to adapt their total soleus ( $p=4.6 \times 10^{-4}$ , Figure 2C) and medial gastrocnemius activity ( $p=9.5 \times 10^{-4}$ , Figure 2D).

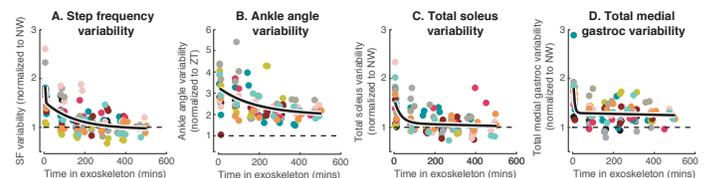

Figure 1: Variability in (A) step frequency, (B) ankle angle, (C) soleus and (D) medial gastroc activity. Each colour represents each subject. Solid black lines are fitted double exponentials.

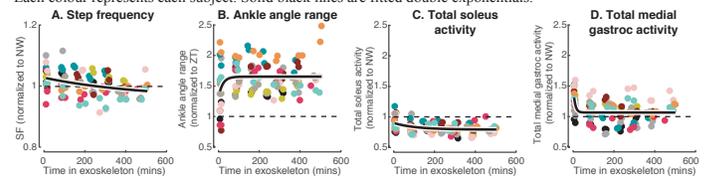

Figure 2: Adaptation in (A) step frequency, (B) ankle angle range, (C) soleus and (D) medial gastroc activity.

## Significance

Our findings suggest that people balance an explore-exploit trade-off along many gait dimensions as they learn to reduce their metabolic cost of walking with exoskeleton assistance [3]. These insights into the nervous system's algorithms may be beneficial for training older adults and clinical populations to walk with assistive devices. That is, we may customize, and perhaps lower, training time by using baseline variability as a benchmark to indicate when people begin to exploit new strategies.

# The Biomechanical Effect of Bilateral Assistance for Hemiparetic Gait Poststroke Using a Powered Hip Exoskeleton

Yi-Tsen Pan, Inseung Kang, Kinsey Herrin and Aaron Young\*  
School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, USA  
Email: \*aaron.young@me.gatech.edu

## Introduction

The asymmetric nature of hemiplegic walking generally leads to inefficient walking pattern in persons poststroke<sup>1</sup>. A common characteristic of hemiparetic gait is the reduced push-off power on the paretic side, which can significantly limit walking capability. Many assistive devices targeting the ankle joint have been developed, however improvements to gait are not clearly shown<sup>2</sup>. Recent studies have shown that augmenting hip work may provide more energetic benefits with the same amount of power at ankle.<sup>3-4</sup> This study presents a control framework to bilaterally assist hip movement during walking. The aim is to examine the biomechanical effects of hip assistance on hemiparetic walking to identify the optimal assistance strategy between paretic and nonparetic sides. We hypothesize that stroke survivors with unilateral impairment will benefit from the bilateral nature of the hip exoskeleton and thus improve gait performance when optimal assistance is applied on each side.

## Methods

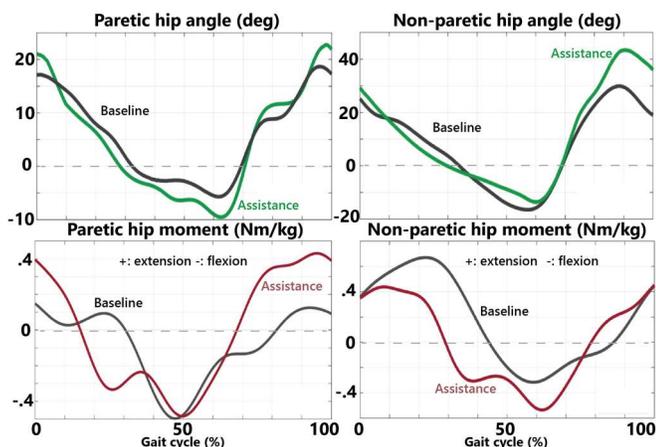

A recently developed powered hip exoskeleton (abbreviated as “exo”)<sup>4</sup> was used to deliver assistive torque to both the paretic and nonparetic hip during gait. A state machine-based impedance controller was developed to determine the magnitude and onset timing of the assistive profile. The amount of torque was calculated by adjusting the stiffness of virtual torsional springs acting about the hip joint during the hip flexion and extension states. The desired equilibrium in each state was set to a predefined ratio of range of motion (ROM) from the maximum flexion/extension which is the same position that triggers the state transition.

Following informed consent of our IRB approved protocol, three stroke subjects (mean±SD age: 51.6±10.6 years, 3 males) with chronic hemiparesis were evaluated for biomechanical effects of different levels of hip assistance in improving the stroke survivor’s gait. All subjects can walk without support at a walking speed greater than 0.4 m/s. Two subjects are right-sided paretic and have aphasia (Subject 1 and 3). Subjects were asked

to walk on a force-plate treadmill and a 6-meter instrumented walkway at their preferred speed. Four walking conditions were (1) no exo (baseline); and exo in three different assistance levels: (2) low (3) medium and (4) high, with peak torque corresponding to about 8%, 10%, and 12% of the subject’s weight. Hip kinematics/kinetics and gait parameters were recorded and evaluated using VICON motion capture system and an instrumented walkway, respectively. The primary outcome measures are gait asymmetry (ASI) and walking speed. ASI is defined by the difference between the paretic and nonparetic mean step length over one half of the total mean step length on both sides.

## Results and Discussion

In the medium level of hip assistance condition, ASI reduced (Subject 1: -18.6 cm; Subject 2: -2.1 cm) and walking speeds increased in two of three subjects compared to baseline condition; ASI reduced in the low assistance condition in Subject 1 (-10.6 cm) and 2 (-2 cm) compared to the baseline condition while the same trends were not seen in walking speed. Subjects 2 and 3 increased the ASI (S2: +2.6 cm; S3: +3.4 cm) and Subject 3 decreased speed when the high assistance condition was applied. Overall, with the low and medium levels of hip assistance, subjects demonstrated a trend with improving gait symmetry and step length, while the same trend was not observed in walking speed. Improving gait performance may be associated with the increasing net torque resulted from the exo. In Fig 1, representative trials show increasing hip flexor moments on both sides and hip extensor moments (red lines) on the paretic side with the hip assistance. Range of motion also increased when walking with assistance on both sides. We also found that such hip assistance could vary considerably among subjects, which may be due to different compensatory strategies used by each subject, or the amounts of assistive torque was not efficient on each leg. In conclusion, the current study shows the feasibility of a hip exoskeleton in increasing hip ROM and net torque, resulting in enhanced gait symmetry and walking capability.

**Figure 1:** Hip kinematics and kinetics results in 1) baseline (black) and 2) assistance (colored) conditions from representative trials of subject 1.

## Significance

Understanding the hip assistance strategy and how different assistive profiles affect hemiparetic gait will aid the implementation of robotic exoskeletons capable of supporting stroke survivors in community ambulatory activities. Future work will explore optimal assistance ratios between the paretic and nonparetic sides to encourage aid more efficient gait patterns in stroke survivors.

## Introduction

Individuals post-stroke often have insufficient control of the shank's forward rotation during mid-to-late stance due to plantar flexor weakness [1]. Passive-dynamic ankle-foot orthoses (PD-AFOs) are commonly prescribed to these individuals [2]. PD-AFO bending stiffness is a key orthotic characteristic that can potentially assist the plantar flexors [3] by providing resistance to control the shank's forward rotation [2]. Previous studies have only focused on clinically-prescribed AFOs or AFOs with the same stiffness values for all participants [4,5]. We have developed a prescription model that can quantitatively-prescribe PD-AFO bending stiffness based on an individual level of plantar flexor weakness [6]. For the first time, we provided individuals quantitatively-prescribed PD-AFOs to wear during their daily lives for four weeks. This two-person case series aimed to evaluate the effects on post-stroke gait after four weeks of wearing these PD-AFO compared to wearing the standard-of-care (SOC) AFO. We hypothesized that the participants who improved their mean net peak plantar flexion moment with PD-AFO use would show improvements (toward typical) in biomechanical parameters.

## Methods

Two individuals with chronic stroke (> six months post-stroke) underwent an instrumented gait analysis to gather baseline data. From these data, PD-AFO bending stiffness was prescribed by subtracting the participant's mean peak plantar flexion moment from the mean, speed-matched, typical peak plantar flexion moment from our normative database (typical-participant) and then dividing this quantity by the typical average change in ankle angle during stance-phase dorsiflexion (12°) [6]. The individuals then wore the newly prescribed PD-AFO for four weeks. After four-weeks, the individuals underwent another instrumented gait analysis while wearing his/her SOC-AFO and PD-AFO at his/her self-selected walking speed.

## Results and Discussion

Two individuals participated in the study (male: 1, age: 64.5 (0.7) yrs, mass: 92.8 (4.2) kg, height: 1.7 (0.1) m). P1 and P2's self-selected walking speed were 0.58 and 1.17 m/s, respectively.

Both participants improved their net peak plantar flexion moment while wearing the PD-AFO compared to wearing the SOC-AFO (Table 1). However, improving net peak plantar flexion moment did not necessarily improve overall gait biomechanics (Table 1). Through examining ankle and hip mechanics, the orthosis in which participants exhibited more of an "ankle strategy" (improved ankle plantar flexor mechanics toward typical to push the limb forward as opposed to pulling the limb forward with the hip flexor muscles) showed improvement in other gait biomechanics. Specifically, P1, who exhibited more of an ankle strategy with the SOC-AFO had increased (toward typical) paretic step length, peak paretic propulsion force, and peak paretic trailing limb angle with the SOC-AFO compared to

the PD-AFO. In contrast, P2 exhibited more of an ankle strategy with the PD-AFO and had increased (towards typical) paretic step length, peak paretic propulsion force, and peak paretic trailing limb angle while wearing the PD-AFO compared to wearing the SOC-AFO.

**Table 1:** Participant's mean ankle plantar flexion kinetics, hip flexion kinetics, and trailing limb angle during the stance phase of gait and step length are shown.

AFO Conditions:	P1		P2	
	SOC	PD	SOC	PD
<b>Kinematics:</b>				
Trailing Limb Angle (°)	11.62	9.73	18.08	20.14
<b>Paretic Ankle Plantar Flexion Kinetics:</b>				
Net Peak Moment (Nm/kg)	-0.88	-0.94	-1.02	-1.25
Peak A/P Force (% BW)	8.90	5.62	12.7	13.3
Angular Impulse (Nms/kg)	-0.53	-0.47	-0.39	-0.43
Peak Power (W/kg)	0.60	0.40	1.40	1.62
<b>Paretic Hip Flexion Kinetics:</b>				
Net Peak Moment (Nm/kg)	0.27	0.30	0.47	0.52
Angular Impulse (Nms/kg)	0.07	0.08	0.09	0.09
Peak Power (W/kg)	0.21	0.24	0.75	0.59
<b>Temporal:</b>				
Step Length (m)	0.53	0.50	0.75	0.79

## Significance

These data suggest that the quantitatively-prescribed PD-AFO has the potential to substantially improve gait biomechanics, for some. Further, parameters beyond just the peak plantar flexion moment – specifically use of the hip vs. ankle strategy – may be a better indicator of which AFO is best for a given individual.

# Longitudinal Assessment of Gait Quality for Servicemembers with Transtibial Amputation: A Case Series

Tatiana E. Djafar<sup>1</sup>, Julianne M. Stewart<sup>1</sup>, John D. Collins<sup>1,2</sup>, and Trevor D. Kingsbury<sup>1</sup>  
<sup>1</sup>Clinical Biomechanics Laboratory, Naval Medical Center San Diego, San Diego, CA, USA  
<sup>2</sup>BIOMS, University of Delaware, Newark, DE, USA  
 Email: [tatiana.e.djafar\\_ctr@mail.mil](mailto:tatiana.e.djafar_ctr@mail.mil)

## Introduction

Persons with amputation often develop secondary musculoskeletal conditions over time, such as knee osteoarthritis in the intact limb and low back pain [1]. Young servicemembers who undergo amputation fortunately have access to specialized programs and advanced prosthetic devices at Advanced Rehabilitation Centers, which results in excellent function early in rehab. However, little is known about their physical function long after they disengage from active rehabilitation.

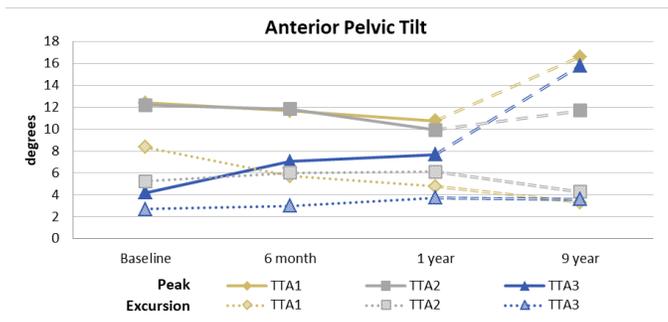

The purpose of this case series is to longitudinally assess gait quality for patients with transtibial amputation (TTA).

## Methods

Three male servicemembers with unilateral TTA (age: 31.7±2.1yrs, height: 1.8±0.1m, mass: 91.2±9.8kg) underwent instrumented 3D gait analyses throughout their rehabilitation (Baseline, 6 months, 1 year) as well as 9 years following their initial baseline study. Variables of interest included self-selected walking speed, anterior pelvic tilt (APT), and knee adduction moment peaks (KAM).

## Results and Discussion

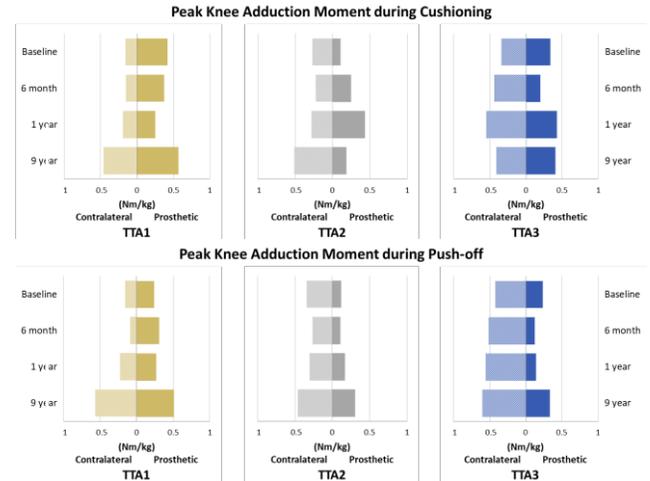

Walking speed increased throughout rehabilitation and was maintained at the 9 year study for all patients (Table 1). The sustained speed implies good physical function, which is confirmed by the patients' self-reported occupations and/or hobbies (e.g. police officer, weightlifting, etc.).

**Figure 1:** Peak and excursion of APT for each patient over time

APT excursion was maintained or decreased over time for all patients, suggesting good pelvic stability (Figure 1). Peak APT was greater for two patients in their 9 year follow-up, but TTA2 was able to maintain a similar peak as compared to his time during rehab (Figure 1). Anecdotally, per subjective report, TTA2 maintains a focus on core and pelvic stability to be mindful of his low back health, which is reflected in his

pelvic motion data. This suggests personal investment can play a large role in minimizing risk of injury.

**Figure 2a&2b:** Peak KAM of both limbs during cushioning (a) and push-off (b) for each patient over time

Peak KAM varied for all patients (Figure 2). TTA1 subverted expectations entirely, loading his prosthetic side more throughout rehab and improving symmetry at his 9 year study. This is likely due to his contralateral limb injuries sustained during initial trauma. TTA2 had a much larger peak KAM in his contralateral limb during cushioning at his 9 year study but was more symmetrical at push-off, while TTA3 was symmetrical during cushioning at his 9 year study with a larger peak KAM in his contralateral limb during push-off. As both patients are highly functional and active individuals, difference in loading symmetry could be due to different compensation strategies and/or different prosthetic devices.

## Significance

Few, if any, studies have been published that show longitudinal data for young servicemembers with TTA. Despite exceptional physical function, there is still risk of secondary complications, but being mindful of one's own body may help alleviate risk factors.

# The Effects of Powered Ankles on Gait Initiation and Termination in Daily Life

Jay Kim and Deanna H. Gates

School of Kinesiology, University of Michigan Ann Arbor, MI

Email: [jaywoo@umich.edu](mailto:jaywoo@umich.edu)

## Introduction

Individuals with transtibial amputation (TTA) typically do not walk for long durations at a time [1], which suggests that a significant portion of their steps are to initiate or terminate bouts of walking [2]. Transition steps may be more difficult for individuals with TTA as they lack ankle musculature, which contributes significantly to generating and dissipating energy. Powered ankle prostheses have been developed to replace this lost function by generating push-off power during walking [3]. While they have been shown to increase steady-state walking speed [3], their effect on transition steps is unknown. The purpose of this study was to compare the effect of unpowered and powered prostheses during initiation and termination of gait. We examined transition strides by calculating the velocity profile of the foot during late stance and early swing. We hypothesized that the powered ankle would yield greater peak velocity compared to the unpowered prosthesis.

## Methods

10 males ( $53 \pm 11$  years old) with unilateral TTA and 14 individuals without amputation (13 male;  $44 \pm 15$  years old) participated in this study. All participants wore a foot-mounted inertial measurement unit (IMU) on their prosthetic foot (non-dominant foot for controls) for two weeks. Individuals with TTA completed two weeks of monitoring both with their prescribed unpowered prosthesis and with the BiOM T2 (BiONX, Bedford, MA) powered ankle, in random order.

Walking data were segmented into strides using heel strikes, detected by finding local peaks in the gravity-corrected acceleration signal. This signal was integrated to calculate foot velocity. We included strides with lengths between 0.1 and 2.0 m and examined bouts of walking that consisted of at least 5 consecutive strides. Forward and vertical velocity peaks of the initiation and termination strides were compared between groups (control, unpowered, powered) using a linear mixed model.

## Results and Discussion

We analyzed velocity profiles in  $730 \pm 630$  bouts per participant for the unpowered prosthesis, in  $930 \pm 1070$  bouts for the powered ankle, and in  $1850 \pm 910$  bouts for controls.

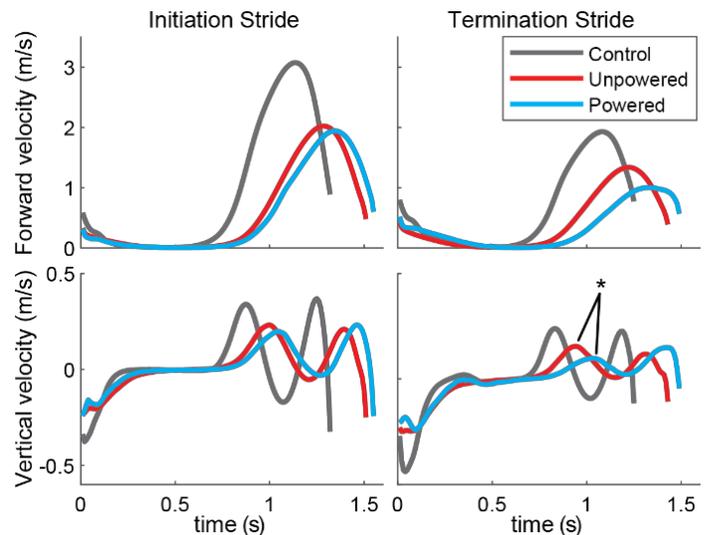

Compared to controls, participants with TTA had shorter initiation and termination stride times ( $p < 0.003$ ). They also had lower forward and vertical velocity peaks in both initiation and termination strides ( $p < 0.003$ ; Fig 1).

For participants with TTA, there were no differences in stride times between prostheses. Compared to the unpowered prosthesis, the powered prosthesis had a lower first vertical velocity peak during the termination stride ( $p = 0.023$ ) and tended to be lower during the initiation stride ( $p = 0.084$ ).

The first peak of the vertical velocity profile (Fig 1) represents the upward motion of the foot during push-off and early swing, which is facilitated in part by the push-off power at the ankle joint. Unsurprisingly, controls had greater peaks of upward velocity compared to individuals with TTA. This was consistent with a previous study that used ground reaction forces

and found greater initiation and termination step velocities in people without amputation compared to people with TTA [4,5].

The powered prosthesis should produce mechanical work at the ankle joint comparable to that of the biological ankle [3]. However, there were no differences in the velocity profiles of the initiation and termination strides. The lower vertical velocity with the powered prosthesis compared to unpowered prostheses suggests that participants may have decreased their push-off to facilitate a more gradual stop. In contrast, control participants produced greater vertical velocities on a quicker termination stride, indicating they tend to stop more abruptly.

**Figure 1:** Forward (top) and vertical (bottom) velocity profiles plotted for the initiation (left) and termination (right) strides.

Because our approach uses a single IMU on the prosthetic foot, we do not know whether participants used their prosthetic or intact foot for the first and last steps, though previous studies have found that individuals with TTA usually preferred to initiate with a prosthetic step and terminate gait with an intact step [4,5].

## Significance

The powered prosthesis did not normalize the velocity profile of initiation and termination strides to resemble that of controls. Our results suggest that the powered ankle may not be well suited for power absorption during slowing-down transitions.

# Motion of the Residual Femur Within the Socket During Gait is Associated with Patient-Reported Problems in Transfemoral Amputees

Tom Gale<sup>1</sup>, Shumeng Yang<sup>1</sup>, Richard McGough<sup>1</sup>, William Anderst<sup>1</sup>

<sup>1</sup>University of Pittsburgh, Department of Orthopaedic Surgery

Email: [thg17@pitt.edu](mailto:thg17@pitt.edu)

## Introduction

Lower limb amputees are generally found to have reduced mobility and lower quality of life compared to the general population [1], and is believed that poorly fitted prosthetic sockets exacerbate these problems [2-4]. Although a properly fit socket is believed to limit motion between the residual limb and the socket, there is no evidence to confirm that reducing motion between the underlying residual femur bone and the socket will improve patient-reported outcomes.

The purpose of this study was to evaluate the relationship between residual femur motion during gait and patient reported outcomes. A secondary goal was to assess within- and between subject variability in residual femur motion during gait.

## Methods

Following Institutional Review Board (IRB) approval, 7 participants (1 female, 6 male; average age: 52.9±7.1 years) gave informed consent to participate in this study. All participants were unilateral transfemoral amputees that were ambulatory using a socket suspension prosthetic.

Up to five trials of synchronized biplane radiographs of the socket/distal femur were collected (100 images/s for 1.0 s) for each participant during treadmill walking at a self-selected speed (avg 0.7 ± 0.2 m/s). Additionally, one neutral standing trial was captured for baseline measurements. Concurrently, skin mounted marker motion capture of the full body was collected (Vicon, UK, 100 Hz), with the thigh markers placed on the prosthetic socket. Ground reaction forces during walking were recorded at 1000 Hz using a dual-belt instrumented treadmill (Bertec Corp, Columbus, OH). After motion testing, a CT scan was collected (0.57x0.57x1.25 mm/voxel resolution) and used to create a subject-specific 3D model of the entire residual femur for each participant. A previously validated volumetric model-based tracking technique was used to match digitally reconstructed radiographs created from the subject-specific CT scans to the biplane radiographs [5].

The coordinate system for the residual femur was established using anatomical landmarks placed on the shaft and femoral head. Surface mounted markers were used to create the socket coordinate system (Fig 1). Euler angle decomposition was used to calculate 6 degree-of-freedom kinematics of the residual femur relative to the socket for all walking trials. All trials were averaged within subject for analysis.

Questionnaire for persons with a transfemoral amputation (Q-TFA) was also administered at the time of testing. Correlation of Q-TFA scores with residual femur kinematics relative to the socket were tested using Spearman's rho ( $\alpha=0.05$ ).

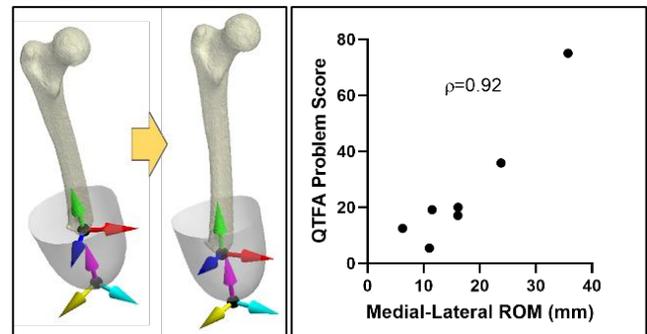

## Results and Discussion

Average rotation ROMs of the femur relative to the socket over full gait cycle were 9.7°±4.2°, 18.3°±3.9°, and 9.0°±5.3° for anterior tilt, internal-external rotation, and varus-valgus, respectively. Average translation ROMs were 17.2mm±9.8mm, 31.1mm±16.2mm, and 30.0mm±13.2mm for medial-lateral,

superior-inferior (pistoning), and anterior-posterior directions, respectively. The average within-subject trial-to-trial variability was 1.1°±0.4°, 2.7°±1.2°, and 0.9°±0.3° for anterior tilt, internal-external rotation, and varus-valgus, respectively, and 1.0mm±0.4mm, 1.2mm±0.5mm, and 1.9mm±0.7mm medial-lateral, pistoning, and anterior-posterior directions, respectively.

Although residual femur ROM varied across subjects, consistent patterns of motion were observed across subjects for pistoning, medial-lateral shift, and varus-valgus rotation. All subjects displayed pistoning greater than 20mm, with maximum compression achieved by 20% of gait cycle. Most subjects achieved approximately ±5mm of pistoning relative to the static trial, with one outlier subject achieving >20mm of compression past the neutral position with a ROM of 62mm. All subjects exhibited a lateral shift of the end of the femur as the limb was loaded after foot strike. The residual femur of most subjects started more medial at foot strike relative to the static trial, with one outlier starting more laterally. There was also a consistent pattern of the femur-socket complex going into varus alignment as the limb was loaded after foot strike for all subjects.

Increased medial-lateral motion was strongly correlated to a higher Q-TFA problem score (Fig 2,  $\rho=0.929$ ,  $p=0.003$ ), which suggests that residual bone motion is a factor in prosthetic performance and comfort.

**Figure 1:** (Left) The femur and socket and their coordinate systems shown at terminal swing and mid-stance for one subject.

**Figure 2:** (Right) Scatter plot of medial-lateral residual femur range of motion relative to the socket vs Q-TFA Problem Score.

## Significance

Residual femur range of motion within the socket during gait is repeatable within subjects, but inconsistent across subjects. Individualized socket modifications that reduce medial-lateral motion between the residual femur and socket may lead to increased performance and comfort for transfemoral amputees.

# The Performance of Implantable Electrodes on the Control of a Myoelectric Prosthesis Over One Year Post-Implantation

**Christina Lee**<sup>1</sup>, Alex Vaskov<sup>1</sup>, Philip Vu<sup>1</sup>, Alicia Davis<sup>1</sup>, R. Brent Gillespie<sup>1</sup>, Stephen Kemp<sup>1</sup>, Theodore Kung<sup>1</sup>, Cindy Chestek<sup>1</sup>, Paul Cederna<sup>1</sup>, Deanna H. Gates<sup>1</sup>

<sup>1</sup>University of Michigan  
Email: chslee@umich.edu

## Introduction

Currently available myoelectric upper limb prostheses (MYO) rely on surface electromyography (EMG) recordings to control the terminal device. However, using surface EMG can result in inconsistent prosthetic control due to skin and sweat-based impedances, cross-talk between muscles, and day-to-day differences in electrode placement.<sup>1</sup> Intramuscular recordings have been proposed to address the limitations of surface EMG. We have previously demonstrated the ability to use machine learning algorithms with intramuscular signals to control a prosthesis in a virtual environment with high accuracy.<sup>2</sup> As a next step, it is important to investigate how these algorithms can be used to control a prosthesis in a physical environment, where users may have different muscle activation depending on physical interactions with objects, movement of the limb and differences in arm postures. In this case study, we assessed a person's ability to complete functional assessments using a MYO prosthesis controlled via signals from indwelling electrodes over one year following electrode implantation. Additionally, we explored the movement strategy by quantifying trunk motion as a measure of whole body movement.

## Methods

The participant was a 54 year old female with right transradial amputation who used a body-powered prosthesis (BP) at home. One year after amputation, a surgeon implanted five indwelling bipolar EMG electrodes (Synapse Biomedical, Oberlin, OH) into residual muscles of the forearm. One month after surgery, she began real-time control experiments in a virtual reality environment (MuJoCo).<sup>3</sup> A single DOF linear decoder was developed using EMG signals from the index flexor digitorum profundus (FDPI) and the extensor digitorum communis (EDC). This decoder was used to control the tripod grasp of a MYO prosthesis (iLimb Quantum, Ossur, Iceland).

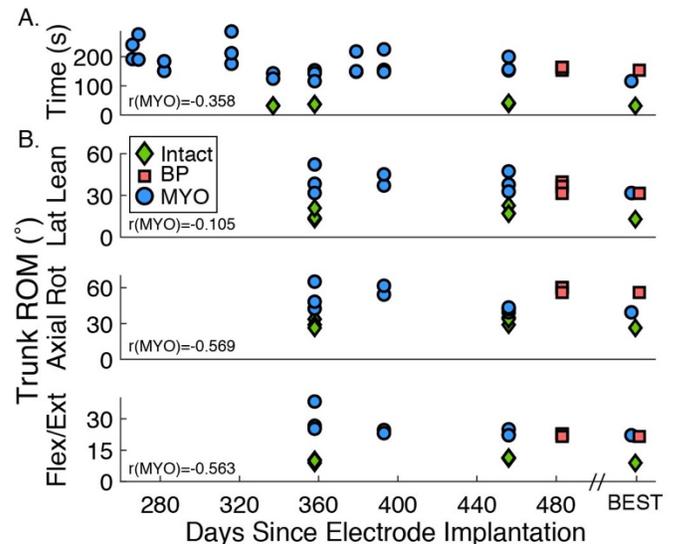

We assessed performance using a modified version of the Box and Blocks Test<sup>4</sup> (MBBT). We placed 16 blocks in an elevated grid and measured how long it took to move all 16 blocks from the ipsilateral to the contralateral side. The assessments were performed standing and repeated 2-3 times per session, depending on participant fatigue. On days 358, 393, and 456 after implantation, we also collected upper limb and trunk motion using a 17-camera motion capture system. From this, we calculated the range of motion (ROM) of segmental trunk angle in all three planes of motion. All tasks were completed with the MYO, intact limb (days 337, 358, 456) and BP (day 483). We assessed changes in these measures over time using linear regression.

## Results and Discussion

After one year of implantation, the iFDP and EDC signals still demonstrated a high signal-to-noise ratio (SNR) of 94.1 and 11.3, respectively. The participant was able to complete MBBT with the same decoding algorithm consistently for over 200 days of evaluation ( $r = -0.358$ ,  $p=0.09$ ). She completed the task in 36.6s

with her intact hand, 160.3s with her BP, and most recently, 169.6s with the MYO (Fig 1A).

Compensatory trunk motion during the MBBT did not change over time ( $0 > r \geq -0.569$ ,  $p > 0.14$ , Fig 1B). ROMs were similar when using the MYO compared to the BP, but both were larger than those when using the intact limb.

**Figure 1:** (A) MBBT completion time and (B) segmental trunk range of motion (ROM) during MBBT for the intact limb, BP, and MYO.

Overall, she had similar performance with the MYO that she only used in the lab to her at-home BP. This is notable due to the documented improvements that occur with training,<sup>5</sup> the difference in weight between the prosthesis (BP: 1.1 lb, MYO: 2.25 lb), and differences in prosthesis length. The participant had a small stature (1.41 m) and a medium-length residual limb. As such, the prosthetic side was slightly longer than her intact limb and could not accommodate a wrist flexion unit. Future work will explore the impact of implanted electrodes on the control of multiple degrees of freedom, including wrist motion.

## Significance

A participant with upper limb loss was able to perform functional tasks using a control algorithm developed with intramuscular signals from two residual muscles for over one year following implantation. She completed the task with trunk movements similar to those used with her at-home body-powered prosthesis.

# Stimulation of residual sensory nerve modulates walking mechanics in the cat with bone-anchored transtibial prosthesis

Alexander N. Klishko<sup>1</sup>, Hangu Park, Gina Grenga<sup>1</sup>, Celina Zhang<sup>1</sup>, Kyunggeune Oh, Kinsey R. Herrin<sup>2</sup>, John F. Dalton IV, Mark Pitkin, Boris I. Prilutsky<sup>1</sup>

<sup>1</sup>School of Biological Sciences, <sup>2</sup>School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, USA  
Email: boris.prilutsky@biosci.gatech.edu

## Introduction

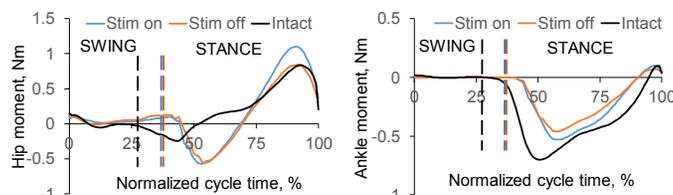

Previous research has suggested that bone-anchored prostheses provide lower limb amputees with more comfort, range of motion, and osseoperception (Branemark et al. 2014). However, locomotion with a unilateral bone-anchored prosthesis is still asymmetric (Jarrell et al. 2018) even if prostheses are powered (Montgomery and Grabowski 2018). In addition, the current solid titanium percutaneous pylons for prosthesis attachment cause a high rate of skin infection (Branemark et al. 2014). A new porous titanium skin & bone integrated pylon (SBIP, Poly-Orth International, USA) has demonstrated a substantial reduction of the skin infection rate in a rat study (Farrell et al. 2014). It could also be used as an interface between the prosthesis and peripheral nerves and muscles for bidirectional prosthetic control (Pitkin et al. 2012) – to drive a prosthesis actuator using EMG from residual muscles and to provide touch perception of prosthesis contact with the external environment by stimulating residual sensory nerves. This bidirectional control is more intuitive and potentially could improve quality of prosthetic locomotion. The goal of this study was to examine effects of stimulation of the residual distal tibial nerve, innervating skin on planar surface of the foot, on joint moments of the prosthetic limb during walking in the cat.

## Methods

All experimental procedures were consistent with the Principles of Laboratory Animal Care of the NIH and approved by the Georgia Tech Institutional Animal Care and Use Committee. We recorded kinematics and ground reaction forces during walking of one adult purpose-bred cat that had a bone-anchored, transtibial, powered prosthesis for 29 months; for details see (Jarrell et al. 2018; Park et al. 2016; Park et al. 2018). The proximal stump of the distal tibial nerve was sutured to residuum skin during amputation surgery. An onboard prosthesis stimulator delivered stimulations of the residual nerve during stance phase to modulate muscle activity (Duysens and Pearson 1976). Contact with the ground also triggered prosthetic ankle extension. We investigated intact locomotion before surgery, as well as prosthetic locomotion with and without nerve stimulation.

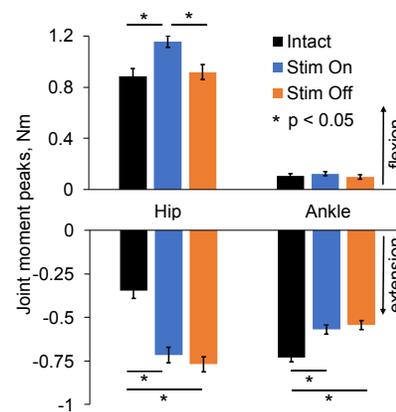

## Results and Discussion

We found that joint moment patterns of the prosthetic limb were

**Figure 1:** Mean hip and ankle moments during intact and prosthetic stimulated and non-stimulated walking. Negative values - extension.

similar to the intact patterns (Figure 1), but the moment magnitudes differed significantly. For example, prosthetic peak extension moments at the hip/ankle were higher/lower than in the

**Figure 2:** Mean ( $\pm$ SE) peak joint moments of intact and prosthetic limbs.

intact limb ( $p < 0.05$ , Figure 2). Nerve stimulation increased the hip flexion moment peak compared to intact and non-stimulated prosthetic hindlimb (Figures 1, 2). Nerve stimulation also increased peaks of knee flexion and extension moments, positive ankle power and negative hip power, and decreased negative knee power compared with no stimulation. Intact ankle extension moment was greater than the prosthetic ankle extension moment with or without stimulation and was compensated by greater prosthetic hip extension and knee flexion moments. These results indicate that nerve stimulation may change certain aspects of prosthetic locomotion; however, nerve stimulation parameters used in this study (Park et al. 2016) did not eliminate locomotor asymmetry.

## Significance

The main findings of the study are that (1) the residual distal tibial nerve responds to electrical stimulation 29 months after surgery and (2) stimulation of residual distal tibial nerve, containing mostly cutaneous afferents, modulates kinetic variables of prosthetic walking. Although nerve stimulation parameters taken from (Park et al. 2016) did not eliminate asymmetry of prosthetic walking, it might be possible to optimize stimulation parameters to further modulate locomotor performance (Duysens and Pearson 1976). Additional improvements in symmetry of prosthetic walking could be achieved by using a different operation mode of the prosthesis, in which ankle extension is controlled by both ground contact and EMG activity of a residual extensor muscle (Park et al. 2018).

## Acknowledgments

# Open Dataset of 18 Above-Knee Amputees Walking at 5 Different Speeds with their Prescribed Prostheses

Sarah Hood<sup>1\*</sup>, K. B. Foreman<sup>1,2</sup>, and Tommaso Lenzi<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering and Utah Robotics Center, University of Utah, Salt Lake City, UT, USA

<sup>2</sup>Department of Physical Therapy and Athletic Training, University of Utah, Salt Lake City, UT, USA

\* Corresponding Author Email: [sarah.hood@utah.edu](mailto:sarah.hood@utah.edu)

## Introduction

Motion capture is fundamental to improve the understanding of gait abnormalities [1], to assist treatment decision making [2], and to drive the design of new prostheses for individuals with lower-limb amputations [3]. Unfortunately, the use of motion capture is limited by the need for dedicated space, expensive equipment, and specialized technicians, as well as the difficulties in recruiting the patient population. To address these issues, we present the first openly available dataset of 18 above-knee amputee subjects walking at 5 different speeds [4].

## Methods

Eighteen individuals with an above-knee amputation (Table 1) were enrolled in this study approved by the University of Utah Institutional Review Board and provided written informed consent. Each participant's walking speed was evaluated to determine their classification as either a limited community ambulator (K2) or full community ambulator (K3) using the threshold of 0.8 m/s [5]. A different set of walking speeds were defined for each group. The K2 speeds were (0.4, 0.5, 0.6, 0.7, 0.8) m/s and the K3 speeds were (0.6, 0.8, 1.0, 1.2, 1.4) m/s.

The biomechanics data was collected in a single visit using a 10-camera Vicon system and a split-belt Bertec Fully

Instrumented Treadmill. A modified Plug-in-Gait model consisting of 67 reflective markers was applied to each participant (Figure 1). A static, functional, and joint center calibration was collected for participant specific calibrations. Each participant walked at a single speed to collect 5 dynamic trials capturing 10 full strides and was offered rest between speeds. Participants were encouraged to walk without using the handrails and any handrail use was noted by the experimenter [4].

## Results and Discussion

Pre-processing was performed on the marker trajectories and gait events using Vicon Software. A low-pass Butterworth filter with a cut-off frequency of 15 Hz and 6 Hz was applied to the force plate data and marker trajectory data, respectively. The kinetics and kinematics were calculated using Visual 3D following the default assumptions for the intact limbs. The knee prosthesis was modelled as 1/3 weight with a center of mass 25% below the knee joint [6]. All raw and processed Vicon data and kinetics and kinematics will be made publicly available [4,7]. Subject specific information, including prosthesis components and patient demographic information, is deidentified. All data can be found in a Figshare database [4,7].

## Significance

Many unknowns can be address with motion capture leading to an increased understanding of gait abnormalities in the above knee amputee population. Yet, no dataset is available for the biomechanics community to analyse. By making this dataset openly available to the community [4,7], we expect that researchers, clinicians, and therapists will be able to improve rehabilitation techniques [1], treatment decision making [2], and the design of new technology [3].

Table 1: Averages of Patient Demographics

## Should Baseball Adjust the Mound Height and Pitching Distance?

Glenn S. Fleisig\*<sup>1</sup>, Alek Z. Diffendaffer<sup>1</sup>, Jonathan S. Slowik<sup>1</sup>

<sup>1</sup>American Sports Medicine Institute, Birmingham, AL, USA

Email: \*glennf@asmi.org

### Introduction

From 2000 to 2015, there was a steady decline in runs scored in Major League Baseball (MLB), causing many fans and experts to call for measures to increase offense. One suggestion was to lower the pitching mound again. (MLB previously lowered the mound in 1969, and offense rose significantly in the following years). Another suggestion was to move the mound farther back, as today's pitchers have higher ball velocity than ever and moving the mound back could give batters more time. Any change enacted by MLB would also be adapted by minor league baseball and most likely by collegiate and high school baseball. A pair of studies were conducted, one varying mound height and one varying pitching distance. The hypotheses tested were that pitching kinematics, pitching kinetics, and ball flight would vary significantly with mound height and pitching distance.

### Methods

In the first study, 20 collegiate pitchers were tested pitching five fastballs and five curveballs from four mound heights (15, 20, 25, and 30 cm).<sup>1</sup> Reflective markers on the pitcher were tracked with an 11-camera motion capture system (Motion Analysis Corp, Santa Rosa, CA) while the ball was tracked with a separate system (Rapsodo Inc, Fishers, IN).

For the second study, 26 collegiate pitchers were tested pitching sets of five fastballs from three distances (18.44, 19.05, and 19.41 m).<sup>2</sup> Reflective markers on the pitcher were tracked with an 12-camera motion capture system (Motion Analysis Corp, Santa Rosa, CA) while the ball was tracked with a separate system (SMT, Freemont, CA).

Repeated measures ANOVA were used to test for differences ( $p < 0.05$ ) in each study. Pairwise differences were identified with Tukey post-hoc tests ( $p < 0.05$ ).

### Results and Discussion

Comparison among mound heights showed no significant differences in ball motion, but several differences in pitching kinematics for both fastballs and curveballs. There were no kinetic differences within curveballs, but five differences for fastballs (Table 1). Decreased kinetics with lower mounds was consistent with a previous study finding lower kinetics from flat ground,<sup>3</sup> but were not found in a previous study of adolescent pitchers.<sup>4</sup>

There were no significant differences in fastball pitching kinematics or kinetics associated with pitching distance. However, the ball's duration of flight, horizontal motion, and vertical motion increased with pitching distance (Table 2). A previous study of adolescent pitchers found kinetic changes with pitching distance, but the range of pitching distances were more extreme in that study.<sup>4</sup>

Table 1. Significant differences ( $p < 0.05$ ) in fastball kinetics. Mean values shown.

	Mound height				p
	15cm	20cm	25cm	30cm	
Shoulder anterior force (N)	360 <sup>a</sup>	360 <sup>b</sup>	367 <sup>a,b</sup>	365	0.002
Shoulder internal rotation torque (N·m)	90.4	90.4	91.7	91.7	0.013
Elbow proximal force (N)	1011	1009	1023	1020	0.027
Elbow varus torque (N·m)	89.9	89.8	91.0	91.0	0.048
Elbow flexion torque (N·m)	56.9	56.9	58.1	57.8	0.041

Matching superscripts indicate pairwise post-hoc difference

Table 2. Significant differences ( $p < 0.05$ ) in fastball motion with pitch distance. Mean values shown.

	Pitch distance			p
	18.44m	19.05m	19.41m	
Ball flight (s)	0.43 <sup>a,b</sup>	0.45 <sup>a,c</sup>	0.46 <sup>b,c</sup>	<0.001
Horizontal break (cm)	2.7 <sup>d</sup>	3.3 <sup>d</sup>	3.9	<0.001
Vertical break (cm)	15.0 <sup>e,f</sup>	16.6 <sup>e</sup>	16.8 <sup>f</sup>	<0.001

Matching superscripts indicate pairwise post-hoc difference

### Significance

Lowering the mound would not increase kinetics and likely would be safe for pitchers, however the current study does not show any benefit for the batters. Increasing pitching distance a moderate amount (1 m or less) would have no significant effect on pitcher kinematics or kinetics. It is unknown if increased distance would help batters (due to longer pitch flight time) or hinder their ability (due to increased ball break).

### Acknowledgments

Both studies were supported by grants from MLB.

## Influence of alternative shoe fit configurations on athlete biomechanics

Kate Harrison<sup>1</sup>, Bradley Davidson<sup>2</sup>, Moira Pryhoda<sup>2</sup>, Nick Nelson<sup>2</sup>, Brett Vladika<sup>1</sup>, and Daniel Feeney<sup>1</sup>

<sup>1</sup>BOA Technology

<sup>2</sup>Human Dynamics Lab, Department of Mechanical Engineering University of Denver

Email: kate.harrison@boatechnology.com

### Introduction

The ability to change direction quickly during jumping and cutting is important for sports performance, however, such tasks entail a high risk of injury. Thus, athletic shoe design needs to optimize both performance and injury risk. While the impact of the midsole and outsole of athletic shoes is the focus of much research, little is known about how the upper impacts athlete biomechanics. Shoe uppers specially designed to fit and contain the foot better than a traditional lace system improved key performance measures during rapid direction changes (speed, ground contact time, force generation).<sup>1</sup> However, how the biomechanical mechanisms underlying these performance improvements,<sup>2</sup> as well as the effects on potential injury risk factors,<sup>3,4</sup> are unknown. The purpose of this study was to evaluate how specially-designed shoe fit configurations affect athlete biomechanics during agility and speed drills requiring rapid changes in direction. We hypothesized athletes would produce a greater peak propulsive joint powers and moments, and range of motion in the plane of movement, and decrease motion in other planes of motion in the alternative configurations.

### Methods

The dataset from a previous study was reanalysed.<sup>1</sup> Thirty-one NCAA Division 1 and club athletes performed countermovement and skater jumps in four shoe conditions. We prototyped three different fit configurations (Lace replacement, Tri panel, and Y wrap) and tested them against a laced baseline shoe (Figure 1). We instructed each athlete to move as quickly and as forcefully as possible. 3D force and motion data were captured during the agility drills. Ankle and knee range of motion, moments and propulsive powers were compared between footwear conditions using a linear mixed effects model.

Figure 1. Shoe fit configurations.

### Results and Discussion

During vertical countermovement jumps and lateral skater jumps, peak ankle and knee concentric power and knee extension moment were greater in alternative shoe fit configurations compared to laces (Table 1). These results help explain improved agility performance during repeated vertical and lateral jumps in these shoes.<sup>1</sup> In countermovement jumps, sagittal plane knee range of motion was greater in alternative shoe fit configurations, while ankle frontal plane range of motion and kinetics were lower. These characteristics are associated with decreased injury risk.<sup>3,4</sup> In contrast, during skater jumps, sagittal plane knee range of motion and peak ankle plantarflexion motion were lower in

Table 1. Biomechanics in alternative shoe closure systems, compared to a baseline laced shoe.

\*\*\*p<.001, \*\*p<0.01, \*p<.05

alternative fit configurations, while frontal plane ankle moments were higher.

These results indicate that alternative shoe fit configurations allow athletes to direct force along the intended line of movement without unneeded and uncontrolled joint motion. This helps to explain improved agility performance and biomechanical efficiency previously measured in these athletes.<sup>1</sup>

### Significance

Intentional upper design that enhances foot wrapping can help optimize force and motion in such a way to enhance performance in rapid movements by 1-5%,<sup>1</sup> while also mitigating potential injury risk factors. This could be due to mechanical influence of the shoe upper on foot motion, and/or improved proprioception due to better conformity to the foot.

## Performance Evaluation of Rate Activated Tether (RAT) Football Helmet Suspension

Alex J. Lurski<sup>1,2</sup>, Ryan J. Neice<sup>1,2</sup>, Thomas A. Plaisted<sup>1</sup>, and Eric D. Wetzel<sup>1</sup>

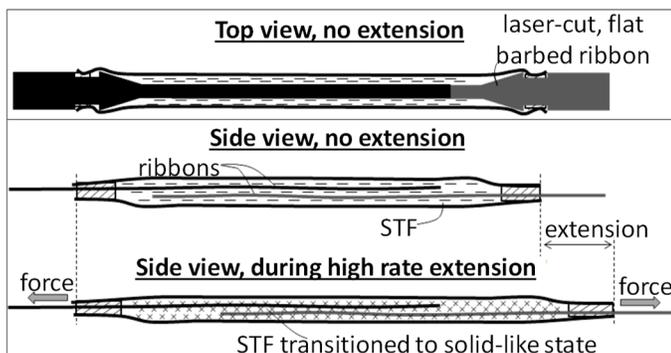

<sup>1</sup> CCDC Army Research Laboratory, Weapons and Materials Research Directorate, Aberdeen Proving Ground, MD, USA

<sup>2</sup> Oak Ridge Associated Universities, Oak Ridge, 37831 TN, USA

Email: alexander.j.lurski.ctr@mail.mil

### Introduction

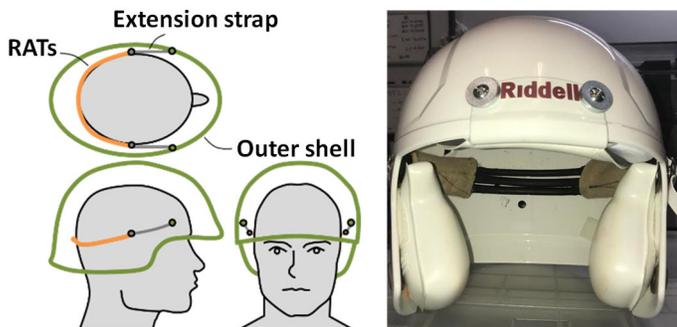

Heightened awareness in the football community on sports-related traumatic brain injury has fueled research efforts to improve the performance of helmets. ARL has developed a rate-dependent strapping material, referred to as rate activated tethers (RATs), that has demonstrated improvements in blunt impact protection for crown impacts [1]. As shown in **Figure 1**, RATs consist of an elastic tube containing two thin ribbons immersed in shear thickening fluid (STF). When pulled in tension the ribbons cause a shearing action in the STF, generating increased resistance with higher extension rates. It is hypothesized that a RAT based helmet suspension will decrease head injury metrics when compared to a conventional padded football helmet.

**Figure 1:** Diagram of rate activated tether (RAT) technology.

### Methods

As a proof of concept, the suspension system was focused on reducing the head injury metrics in impacts to the rear of the head. The rear pads in a 2014 Riddell Revolution Speed helmet were removed from the helmet and replaced by a RAT-based helmet suspension system as shown in **Figure 2**. The ends of three RATs were attached to the front of the helmet shell, with the RATs then closely wrapped around the rear of the head. Impacts to the rear helmet shell induce stretching of the RATs. Both conventional padded helmets and RAT-modified helmets were subject to the twin-wire based NOCSAE football helmet test standard for rear impacts [2].

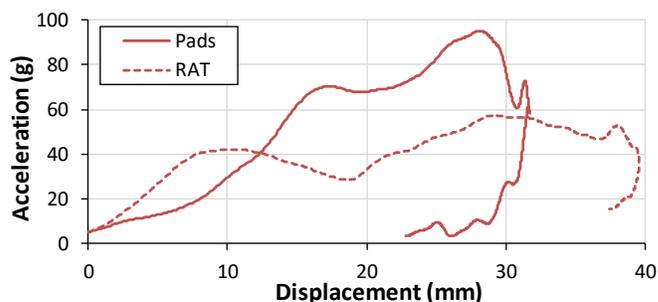

**Figure 2:** Rate activated tether (RAT) helmet suspension system.

### Results and Discussion

Parameter	Units	Ambient Temperature		High Temperature			
		Pads	RAT	Pads	RAT		
Impact velocity	(m/s)	3.50	3.49	5.67	5.56	6.04	5.57
Peak acceleration	(g)	45.0	39.8	93.5	57.7	80.7	55.7
Severity Index (SI)		99	67	393	190	339	176

**Figure 3:** NOCSAE twin-wire rear-impact results for both helmets.

As shown in **Figure 3**, the RAT based suspension system decreased both peak acceleration and Severity Index (SI) for each rear impact case in the NOCSAE twin-wire test. At high velocity, the RAT based suspension shows a dramatic improvement in performance.

**Figure 4:** Headform acceleration vs. displacement for both helmets at high velocity and ambient temperature.

### Significance

The increased performance of the RAT-based helmet suspension is attributed to three primary characteristics, showcased in **Figure 4**, that differentiate it from traditional padded helmet suspension systems. First, the RAT suspension absorbs energy in a tension over the entire distance (stroke) between the head and helmet shell, while pads do so in compression until the point of densification. Second, the energy attenuating profile of the RAT follows a near square wave energy attenuating response, decelerating the head at a near constant level over the entire stroke, which is inherently more efficient than typical padding. Third, the RAT system decelerates the head earlier in the event compared to the pad system, which is more delayed in its ability to engage the head and decelerate it at a tolerable level. These results show that RATs could fundamentally and disruptively change design concepts and performance expectations for helmets.

## Tibial Bone Strains in Basketball Players During Dynamic Tasks

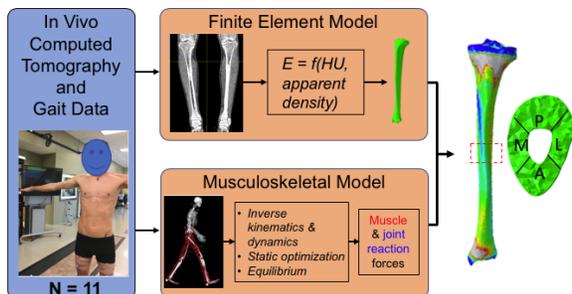

Chenxi Yan<sup>1</sup>, Stuart Warden<sup>2</sup>, Mariana E. Kersh<sup>1</sup>  
<sup>1</sup>University of Illinois at Urbana Champaign  
<sup>2</sup>Indiana University Purdue University Indianapolis  
 Email: [\\*cyan5@illinois.edu](mailto:*cyan5@illinois.edu)

### Introduction

Bone serves a mechanical role; however, repeated loading increases stress fracture risk. Basketball players experience tibial stress fractures. It is crucial to understand tibial loading during basketball activities to develop preventive and management strategies. We hypothesized activities involving rapid direction changes and impact loading would have greater tibial strains relative to walking, and would load different parts of the bone.

### Methods

Collegiate-level basketball players (n=11) had biomechanical data recorded during walking, sprinting, a drop-jump task, and lateral sprinting using reflective markers attached to anatomical landmarks (Fig. 1). A force plate recorded ground reaction forces (GRFs). Computed tomography (CT) scans of the tibia, along with density phantoms, were obtained.

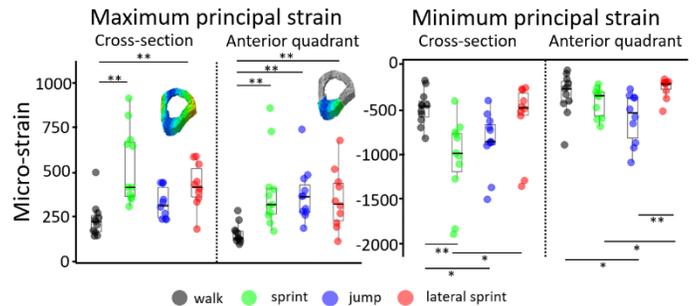

**Fig. 1:** Pipeline: gait data were applied to musculoskeletal models for finite element analysis of strain at the tibial midshaft.

Marker and GRF data were filtered in Matlab, then run through inverse kinematics, inverse dynamics, and static optimization analyses in OpenSim to obtain muscle and joint force predictions. The tibia was segmented from the CT data and used to create a finite element (FE) model of each subject that included density-based heterogeneous material properties. Muscle and joint forces were applied to the tibia using quasi-static FE analyses for the stance phase of each task. The proximal tibia was unconstrained in the proximal-distal direction. Spring elements were used to simulate soft tissue constraints at the distal tibia. Maximum and minimum principal strains of the cross-section and the anterior aspect of the middle diaphysis of the tibia - where fractures have been reported to occur - at the time of peak strains were analyzed.

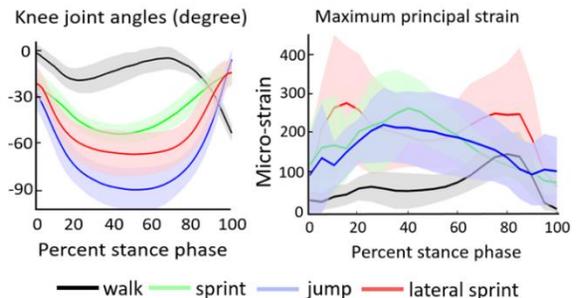

### Results and Discussion

The tibia experienced bending. Minimum principal strains (compressive) were nearly double maximum principal strains (tensile). At the cross-sectional level, sprint and lateral sprint resulted in higher tensile (max principle) strains ( $133 \pm 46\%$ ,  $90 \pm 66\%$ ) than walking. However, within the anterior quadrant, landing from a jump resulted in greater tensile strain than walking ( $146 \pm 70\%$ ). Meanwhile, sprinting and jumping resulted in significantly greater compressive strain than walking at the cross-sectional level ( $134 \pm 110\%$ ,  $94 \pm 90\%$ ). In the anterior quadrant, jumping induced greater compressive strain than walking ( $155 \pm 115\%$ ) and lateral sprinting ( $175 \pm 170\%$ ) (Fig. 2).

**Fig. 2:** Principal strains at the entire cross section and anterior aspect (\* $p < 0.05$ , \*\* $p < 0.01$  between activities).

Peak strains during sprinting occurred at 40% of the stance phase which coincided with the time of peak knee flexion (Fig. 3). However, knee flexion is likely not the sole predictor of strain.

**Figure 3:** Knee angles, maximum principal strains at anterior quadrant.

Bone is weaker in tension compared to compression. Within the anterior quadrant, all three tasks resulted in increased tensile strains relative to walking. However, fractures seldom occur during sprinting but rather occur during jumping. Our results indicate a modest, but not significant, increase in strains during jumping compared to either sprinting or lateral sprinting tasks possibly explaining the fracture risk associated with jumping.

### Significance

Strain gauges were used in the late 90's to measure tibial strains in vivo [1]. However, strain gauging is invasive and limited to small regions. Here, we use for the first time a computational technique to analyse tibial strains during basketball activities. Our results provide insights on tibial loading and the relationship between kinematics and strain. These data may provide direction for the prevention and treatment of stress fractures using biomechanically informed training programs.

# Racial Differences in Running and Landing Measures Associated with Injury Risk Vary by Gender

<sup>5</sup>Department of Exercise Science, University of South Carolina, Columbia, SC, USA

Email: cnh4ph@vt.edu

## Introduction

Running and landing are commonly associated with risk for overuse injuries like stress fractures and impact injuries like tendon ruptures and anterior crucial ligament (ACL) tears. Racial health disparities in the incidence rates of these injuries have been documented between African Americans (AA) and white Americans (WA)<sup>1,2,3,4</sup>. It is unknown whether running and landing mechanics differ between racial groups and whether such differences, if they exist, could result in differential injury risk between racial groups and contribute to racial health disparities.

The purposes of this study were to test the hypothesis that racial differences exist in running and landing mechanics between AA and WA, and that such differences could be explained by a combination of anthropometric, strength, and health status factors in women only as these factors were previously unable to account for racial gait differences in men.

## Methods

92 participants equally divided between gender and self-identified race were recruited. 3D motion capture and force plate data were recorded during 7 running (3.2 m/s) and 7 drop vertical jump (31cm box height) trials. Stance time and non-normalized time series data were exported from Visual 3D. Heart rate, blood pressure, stress questionnaires, activity level, anthropometry, lower extremity strength, and blood levels of glucose, interleukin-6, C-reactive protein, and cortisol were also collected. Outcome measures included impact peak, peak vertical ground reaction force (pvGRF), average and maximum loading rate (LR), peak knee flexion (pKFA) and hip adduction angles (pHAdA) during running and pvGRF, average and maximum LR, impulse, pKFA, peak knee abduction angle (pKAbA), and frontal plane knee range of motion (fKROM) during landing.

Univariate ANOVA models determined main and interaction effects of gender and race (JMP Pro 15,  $\alpha=0.1$ ). Partial eta squared effect sizes were computed for each effect. If interactions or gender effects were observed, separate analyses were run for men and women. For each outcome measure with an observed racial difference, race was locked as a predictor in a stepwise linear regression model. Independent variables that differed between racial groups ( $p<0.1$ ) and were correlated with the outcome measure ( $p<0.2$ ) were included as predictors. If race was no longer significant in the regression model after the inclusion of the independent variable(s), those variables were considered to have explained the effect of race. Landing pvGRF, LR, impulse, and fKROM were log-transformed due to non-normality.

## Results and Discussion

Interactions between gender and race existed in stance time [ $p=0.073, \eta_p^2=0.040$ ], pvGRF [ $p=0.059, \eta_p^2=0.044$ ], and pHAdA [ $p=0.091, \eta_p^2=0.035$ ] during running. Landing interactions were found in pvGRF [ $p=0.018, \eta_p^2=0.065$ ], average [ $p=0.080$ ,

$\eta_p^2=0.036$ ] and maximum LR [ $p=0.023, \eta_p^2=0.060$ ], and fKROM [ $p=0.079, \eta_p^2=0.036$ ]. Smaller pvGRF and pHAdA were found in AA men compared to WA men but were unable to be explained by any assessed factors. AA women had longer running stance times compared to WA women, which was partially explained by higher heart rate and larger crural index. No racial differences were found during landing in men. In women, higher pvGRF, average and maximum LR, and fKROM were found in AA during landing. All racial differences in women were explained by some combination of shorter height, higher levels of chronic perceived stress, higher BMI, and weaker knee flexion strength.

Modifiable factors such as BMI and knee flexion strength may provide targets for interventions aimed at injury prevention and targeted rehabilitation. The direction of the racial differences observed in the current study align with the higher incidence of tendon rupture in AA compared to WA but opposes the lower incidence of ACL injury in AA, which may be explained by lower physical activity levels and potentially limited sport specific landing training in the AA women based on the inclusion criteria. Future investigations should evaluate whether modifiable factors could be targeted to reduce or eliminate racial health disparities in experienced athletes.

These results partly support our hypotheses concerning racial differences, although the possibility for additional factors to explain the observed racial differences in running and landing should be investigated further, especially for men. These findings suggest the need for racially diverse normative running and landing datasets and emphasize the importance of stress control for injury prevention, particularly for racial minorities.

## Significance

The impact of race and gender on running and landing measures associated with injuries were explained by innate, modifiable, and environmental factors in women. These racial differences and identified explanatory factors suggest the need for racially diverse normative datasets and targeted interventions focusing on modifiable factors including BMI, strength, and stress management. This data allows development of protocols that could assist in reducing racial health disparities in running and landing related injuries.

## Introduction

Noncontact anterior cruciate ligament (ACL) injuries are the most common severe injury in NCAA volleyball, accounting for 26% of severe injuries [1]. Certain sagittal- and frontal-plane knee ACL injury risk factors have been identified during landing [2], especially during landings that involve a rotational movement after landing [3]. Additionally, a primary concern in biomechanics research is the lack of a realistic, game-like environment during data collection. It has been shown that including both external objects [4] and unanticipated tasks [5] in the testing environment can better represent game-like scenarios in the lab. Currently, it is unknown how including both an external object and an unanticipated task affects knee biomechanics during a volleyball-specific block landing.

Therefore, the purpose of this study was to determine the effects of a physical overhead goal and a subsequent unanticipated lateral cut on knee kinematics and kinetics of the dominant-leg during the landing of a volleyball block. It was hypothesized that ACL injury risk factors would increase in both the with-target conditions and unanticipated conditions.

## Methods

Fourteen healthy and recreationally active females (age: 21.2±2.7yrs; height: 1.74±0.06m, mass: 68.35±8.86kg), with a minimum of two years high school volleyball experience, completed four volleyball-specific block-and-cut testing conditions – with a target and an anticipated cut after landing (WTA), with a target and an unanticipated cut after landing (WTUA), no target and an anticipated cut after landing (NTA), and no target and an unanticipated cut after landing (NTUA).

3D marker coordinate data were collected using a 12-camera Vicon system (200Hz), and ground reaction forces were collected with two AMTI force plates (2000Hz). A suspended volleyball and volleyball net, set to regulation-standard height, were used in the WT conditions. 3D knee sagittal and frontal plane kinematics and internal moments, normalized to body mass, were calculated. 2×2 (target × anticipation) repeated-measures ANOVAs were performed to detect both main effects and interactions between target and anticipation conditions for initial contact (IC) and peak knee angles, and peak knee moments ( $\alpha=.05$ ).

## Results and Discussion

Significant interactions were present for peak knee abduction angle ( $p=0.021$ ) and peak knee adduction moment ( $p=0.025$ , Table 1). Participants demonstrated greater peak knee abduction angles in WTA compared to WTUA ( $p=0.004$ ). Post hoc comparisons showed no differences for peak knee adduction moment. Significant target main effects were present for IC knee flexion angle ( $p=0.021$ ), which were decreased in the with-target condition, and peak knee extension moment ( $p<0.001$ ), which were greater in the with-target condition. Significant anticipation main effects were present for IC knee abduction angle ( $p = 0.001$ ), which were greater in the anticipated condition, and peak knee flexion angle ( $p=0.021$ ), which were greater in the unanticipated condition.

Creating a more realistic testing environment by including external targets and unanticipated movements altered knee landing mechanics and may allow for better evaluation of ACL injury risk factors in female volleyball players. Females landed in a more erect posture, as well as experienced greater sagittal plane knee loading when a target was present, giving a potentially better representation of the loads that are sustained during gameplay during a block-and-cut task.

## Significance

Changing the testing environment so it better represents gameplay can improve the methods researchers use to find more conclusive evidence in the mechanisms of ACL injury in female volleyball players. While including a target during the block-and-cut movement did result in altered knee biomechanics, using an unanticipated secondary movement resulted in a larger number of biomechanical changes, suggesting that it may be more important to include decision-making tasks in the testing environment to better simulate gameplay.

### Introduction

Pacing strategy during long distance running reflects complex, nonrandom behavior and long-range memory effects in both speed and stride length.[1] It has been reported that self-preferred racing (SPR) displays optimal variability compared to faster and slower running speeds, and imposes the least biological stress on the system.[2,3] Fluctuations in inter-stride-intervals (ISI) during SPR exhibit fractal-like properties and long-range correlations.[2] This suggests an intrinsic physiologic control scheme that purposefully integrates different regulatory systems. The use of periodic metronomes as a pacing strategy during running is common. The long-range correlations of human gait were altered when pacing to a periodic metronome, indicating breakdown of these internal regulatory control processes.[4] Thus, we aimed to investigate the effect of a fractal-like stimulus in running to preserve the natural healthy complexity of the system observed in SPR.

### Methods

Thirteen male participants (22.80±3.65yrs, 1.74±0.07m, 67.85±8.96kg, VO<sub>2max</sub> 49.90±5.45ml/kg/min) completed four 8-minute treadmill running trials (10.38±0.75km/h).

Testing was completed in 3 sessions conducted on separate days. In session 1, participants completed an incremental test to exhaustion to determine peak VO<sub>2</sub>, maximal aerobic speed (MAS) and the first ventilatory threshold (VT1). These values were used to determine running intensity for the treadmill trials. In the experimental trials, participants ran in a heavy intensity domain (20 % Δ (VT1 + 0.20 x (MAS - VT1))).

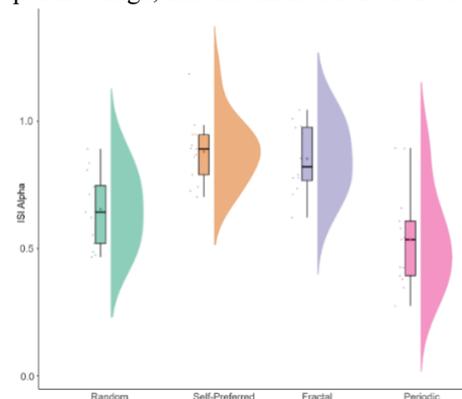

Session 2 began with a SPR condition without a stimulus. The stride time from SPR was used to design individualized stimuli for 3 randomized cued conditions: periodic (PER), random (RND), and fractal (FRC). The stimulus was provided via a moving horizontal bar projected on a screen. Participants were instructed to synchronize their heel strike to the moving bar. The first of 3 randomized trials was completed 45 minutes after the SPR trial. In session 3, participants completed the remaining two randomized trials, separated by 45 minutes rest. Detrended fluctuation analysis (DFA) was used to validate the temporal structure of the FRC and RND stimuli.

An accelerometer (1000 Hz), placed at the ankle, was used to determine gait events. The first 15-seconds of each trial were discarded prior to analysis. A 4<sup>th</sup> order, zero lag low-pass Butterworth filter with a cutoff frequency of 20Hz was applied. ISI were calculated as the time difference between heel strikes. DFA was used to determine the fractal-scaling exponent from inter-stride intervals (ISI $\alpha$ ). ISI $\alpha$  values >0.5 indicate a positively persistent long range correlation, while values <0.5 indicate anti-persistent correlations. A repeated measure ANOVA was used to determine the effects of condition on ISI $\alpha$ , p<0.05.

### Results and Discussion

A significant main effect for condition was observed for ISI $\alpha$  (F<sub>1.60,17.55</sub>=16.04, p < 0.05). Pairwise comparisons showed that ISI $\alpha$  was significantly higher in SPR (0.88±0.13) and FRC (0.85±0.14) conditions than both RND (0.65±0.15) and PER (0.54±0.19). No other significant differences were found (p>0.05).

**Figure 1:** Violin plots generated for data distribution of ISI $\alpha$  for each condition: RND, SPR, FRC, PER. It represents the boxplots with interquartile range, and the distribution of the data.

### Significance

Pacing to a FRC metronome does not alter the natural system complexity observed in self-paced running, and preserves long-term correlations of the locomotor system during running. Conversely, we found a breakdown in gait complexity with PER and RND metronomes. A viable approach to preserve gait complexity is to alter the metronome temporal structure. The use of PER and RND conditions significantly decreased ISI $\alpha$ , compared to both SPR and FRC conditions. This suggests that the structure of the variability introduced into the temporal structure of the metronome is vital to preservation of long-range correlations in human running gait.

Our findings advocate that structured variability in a metronome pacing stimulus preserves the complexity and long-term correlations observed in SPR running for healthy adults. Thus, a FRC metronome stimulus may be more appropriate than PER metronomes to preserve the natural long-term correlations found in SPR strategy. However, it remains to be determined its impact on running performance (i.e., VO<sub>2</sub>).

# Muscle Contributions to Knee Joint Reaction Forces and Moments during Single-leg Landing

Namwoong Kim<sup>1</sup>, Todd Leutzinger<sup>1</sup>, Brian A. Knarr<sup>1</sup>

<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE, USA  
Email: namwoongkim@unomaha.edu

## Introduction

Approximately 80,000 to 250,000 ACL injuries occur per year in the United States [1]. Seventy to eighty percent of ACL injuries are caused by a non-contact mechanism such as cutting or landing. Knee joint loading such as tibiofemoral anterior shear force, valgus moments, and internal rotation moments has been associated with an increased risk of ACL injury. Muscles are one of the primary factors in determining knee joint loading during dynamic movements. Therefore, understanding the role of individual muscle contributions to knee joint loading is required. Ultimately, knowledge of individual muscle contributions to the knee joint loading may help to develop interventions that target specific muscles in order to prevent ACL injuries.

Musculoskeletal modeling provides a means to quantify individual muscle contributions to the knee joint loading that have been associated with ACL injuries during dynamic movements. Therefore, the purpose of this study was to identify the role of individual muscle contributions to shear joint reaction forces, valgus moments, and internal rotation moments during single-leg landing. We hypothesized that quadriceps musculature will contribute the most to anterior shear force during single-leg landing. We also hypothesized that hamstring musculature will contribute the most to varus moments and external rotation moments during single-leg landing.

## Methods

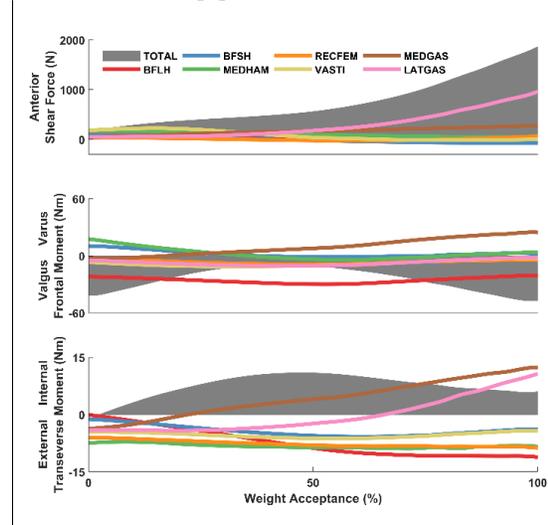

Ten healthy adults participated in this study (5 females, age:  $26.6 \pm 1.35$  years; height:  $1.75 \pm 0.7$  m, mass:  $71.1 \pm 14.1$  kg). Three-dimensional marker position data were collected at 200Hz using a 3D motion capture system while the participants performed single-leg landings from a height of 45 cm onto a force platform. Each participant performed single-leg landings with their dominant leg until they had 3 successful trials.

Ten subject-specific models were developed in OpenSim for data analysis [1,2]. Each model had a total of 31 degrees-of-freedom (DOF) and 92 musculotendon actuators. Muscle induced ground reaction force was calculated using Induced Acceleration Analysis in OpenSim. A total of 240 Joint Reaction Analysis was performed to calculate individual muscle contributions to knee joint loads by applying muscle force in isolation and corresponding muscle induced ground reaction forces [3]. Our analysis was focused on the weight acceptance phase of landing (from initial contact to peak vertical ground reaction force). Muscles that span the knee joint were analyzed in this study.

## Results and Discussion

The lateral gastrocnemius contributed the most to tibiofemoral anterior shear force (961.95 N) during single-leg landing. The medial gastrocnemius provided the greatest contribution to knee varus moment (24.81 Nm). The medial hamstrings (semitendinosus and semimembranosus) also contributed

significantly to knee varus moment (17.66 Nm). Although the biceps femoris long head contributed the most to external rotation moment (11.19 Nm), it also made the greatest contribution to knee valgus moment (29.87 Nm). Therefore, further investigation of the biceps femoris is necessary to determine if this muscle has potential to reduce the risk of ACL injury. The medial gastrocnemius and medial hamstrings have great potential to reduce the risk of ACL injury by providing varus moments during single-leg landing. Interventions targeting these muscles may be necessary to prevent ACL injuries because of their ability to resist valgus loading during single-leg landing. Future analysis is required to determine the muscle contributions of non-knee-spanning muscles during landing tasks as these muscle groups have been shown to play an important role in determining knee joint loading during dynamic movements [3].

**Figure 1:** Individual muscle contributions of knee spanning muscles to knee joint loading during single-leg landing. The shaded gray area represents each total reaction load. BFLG: biceps femoris long head; BFLH: biceps femoris short head; MEDHAM: semitendinosus and semimembranosus; RECFEM: rectus femoris; VASTI: vastus medialis, laterals, and intermedius; MEDGAS: medial gastrocnemius; LATGAS: lateral gastrocnemius.

## Significance

Knowledge of individual muscle contribution to knee joint loading may help to develop preventative exercises or rehabilitation strategies for ACL injury.

# Does Sex Influence Interpretations of Control Complexity via Muscle Synergy Analysis?

Anna T. Ursiny<sup>1</sup>, Reed D. Gurchiek<sup>1</sup>, and Ryan S. McGinnis<sup>1</sup>  
<sup>1</sup>M-Sense Research Group, University of Vermont, Burlington, VT, USA

## Introduction

Muscle synergy analysis during gait has been proposed for exploring the effects of neurological impairment on motor control [1,2]. For example, previous research has shown that a lesser number of muscle synergies is required to explain some threshold percentage of the variance accounted for (VAF) in measured muscle excitations for populations with neurological impairment (e.g., Parkinson's disease [1], cerebral palsy [2]) as compared to unimpaired populations. This observation is thought to indicate a less complex motor control strategy attributed to the neurological impairment. These conclusions assume that the observed differences are not confounded by other variables such as sex and age [3]. However, it has been shown that sex can influence observed gait mechanics in impaired populations [4,5] and that sex may impact motor control in activities other than gait [6]. These results provide a basis for questioning the assumption that sex does not influence conclusions concerning motor control complexity via muscle synergy analysis. An understanding of the potential influence of sex on muscle synergy analysis during gait is necessary for clinical interpretation, however, this has not been tested directly. Thus, in this study, we explore the effect of sex on muscle synergy analysis during gait and present preliminary results suggesting the effect of sex is not significant.

## Methods

Surface electromyograms (sEMG, 1000 Hz) of 10 muscles (biceps femoris, lateral gastrocnemius, medial gastrocnemius, peroneus longus, rectus femoris, soleus, semitendinosus, tibialis anterior, vastus lateralis, vastus medialis) of the right leg were recorded for 16 unimpaired subjects (10 males: age =  $22 \pm 2$  yo and 6 females: age =  $21 \pm 3$  yo) during a one-minute level walking trial on a treadmill at a self selected speed. All sEMG data were high pass filtered at 30 Hz, rectified, low pass filtered at 6 Hz, and normalized by the maximum value across the walking trial and several muscle specific maximum voluntary contraction (MVC) trials. One to nine synergies were extracted from all subjects using non-negative matrix factorization to

consider all possible synergy configurations. We compared synergy-based characteristics of motor control complexity between males and females according to statistical techniques that have been used to compare impaired and unimpaired populations [1,2]. To this end, the total VAF across all muscles for each number of synergies extracted was compared between males and females. The normality of the VAF distributions for each group and each number of synergies was confirmed using the Kolmogorov-Smirnov test. Average VAF between males and females was compared for each number of synergies extracted using independent t-tests as seen in [5,6]. Further, following the analysis presented in [1], we also compared muscle specific VAF for the four- and five-synergy configurations using 10 independent t-tests (one for each muscle). Finally, the number of synergies needed to exceed a 95% VAF threshold was compared between males and females using Fisher's Exact Test [1]. The level of significance was set to 0.05 for all statistical tests.

## Results and Discussion

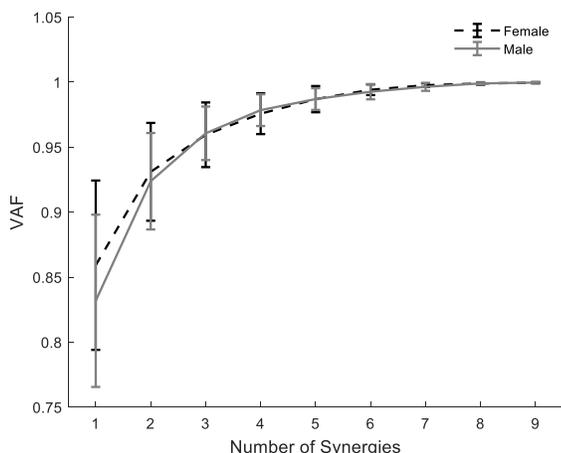

A similar trend for both males and females was observed in the total VAF with respect to the number of synergies extracted and the differences between sexes were not significant for each synergy configuration (Figure 1). The Fisher's Exact Test revealed no differences between males and females in the number of synergies required to exceed the 95% VAF threshold. In similar analyses, others have shown that impaired populations will exceed a given VAF threshold with significantly fewer synergies. This preliminary analysis suggests sex is not a confounding factor using this approach. Further, Rodriguez et al. (2013) found differences between impaired and unimpaired populations on the basis of muscle specific VAF (increased VAF for impaired relative to unimpaired for specific muscles) [1]. However, in this study, the same approach applied to compare males and females revealed no differences in VAF for any muscles for the four- or five-synergy configurations. Thus, this analysis suggests sex does not influence the interpretation of synergy analysis as it relates to motor control complexity.

## Significance

Our preliminary analysis suggests that sex does not significantly influence interpretation of motor control complexity via muscle synergy analysis. From a clinical perspective, this is worthy of attention as it eliminates the need to consider sex when assessing a patient's motor impairment. Further work will consist of analyzing a larger sample size and exploring the effect of age on motor control complexity via synergy analysis.

# Effect of Transcutaneous Vagus Nerve Stimulation on Visuomotor Skill Learning in Humans

Mitchell St. Pierre<sup>1</sup> and Minoru Shinohara<sup>1</sup>

<sup>1</sup>School of Biological Sciences, Georgia Institute of Technology, Atlanta, Georgia, United States

Email: [mstpierre@gatech.edu](mailto:mstpierre@gatech.edu)

## Introduction

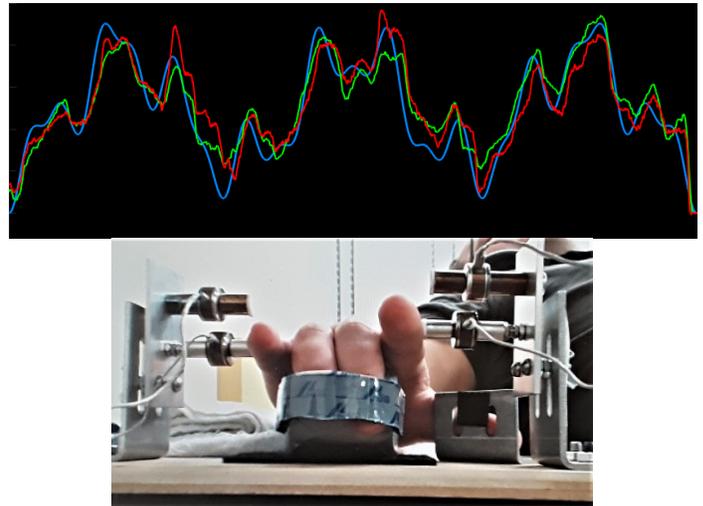

Loss of functional movement can occur with advanced age and with neuromotor disorders such as stroke and spinal cord injury. Rehabilitative training is commonly employed to help restore motor strength and ability in individuals with such deficits, and pairing neuromodulatory interventions with training may enhance the effects of rehabilitation. In rat stroke models, afferent vagus nerve stimulation (VNS) with implanted electrodes promoted motor recovery when VNS was applied during rehabilitation exercise [1]. While the underlying mechanisms for this efficacy are unknown, it is possible that stimulation of afferent vagus nerve connecting to the locus coeruleus affects neuromodulators in the cortex, and consequently neuromotor performance and adaptation. The applicability of the efficacy of VNS on motor recovery in rats to humans is unknown. Furthermore, implantation of VNS electrodes can be risky and costly, so the viability of transcutaneous VNS (tVNS) in humans must be explored. The purpose of this study was to examine the potential effects of pairing tVNS with motor training on motor skill improvement in healthy young humans. We hypothesized that motor skill improvement due to motor training is altered with tVNS that is paired with the execution of the training task.

## Methods

Sixteen healthy young adults completed five days of experimentation. Subjects were assigned to either the tVNS group or Sham group pseudo-randomly to match for initial performance of the motor skill test. Weak electrical stimulation was administered at the tragus for tVNS or at the earlobe for Sham. Over the course of five days, subjects trained for 170 trials of the visuomotor skill task of tracking complex trajectories. The task consisted of accurately tracking complex target trajectories for 20 s with finger forces normalized to their maximum forces (Figure 1). Subjects were instructed to follow the target pattern as close as possible with the abduction forces of their index and little fingers simultaneously while electrical stimulation to the tragus or earlobe was applied concurrently with the task execution during training. Subjects were provided with knowledge of results after each trial, shown as a score based on the inverse of root-mean-square error (RMSE) from the target trace, averaged across fingers. The same visuomotor skill was tested each day without electrical stimulation before and after the training. To assess the progress of skill learning, preliminary analysis was performed on RMSE that was tested before each training. To examine the transfer of learned motor skill, subjects were additionally tested on tracking non-practiced square-wave trajectories on the first and last test days without electrical stimulation.

## Results and Discussion

The initial test performance before the training period had comparable RMSE between groups for both complex and square-wave trajectories ( $p > 0.05$  for both). RMSE in test trials were normalized to this initial performance to minimize variability between subjects for further analysis.

**Figure 1:** *Upper*, visual feedback during the task. Index finger force (green), little finger force (red), and the target trace (blue) were shown. *Lower*, subjects used abduction forces of index and little fingers to track the target trajectories

When this normalized test RMSE for the practiced complex trajectories was compared during the subsequent four test days, subjects in the tVNS group showed higher RMSE compared with the Sham group by ~20% across days, on average ( $F = 11.78$ ,  $p < 0.01$ ; main effect of group). This difference was prominent in the initial days but not the final test day. Both groups had significant reductions in RMSE of the practiced trajectories across days ( $F = 22.56$ ,  $p < 0.01$ ; main effect of day). After the training period, the average reduction in RMSE of the practiced trajectories was comparable across groups, i.e. ~56% compared with before training. Average reduction in RMSE of the non-practiced square-wave trajectories was also comparable across groups (~13%,  $p > 0.05$ ). All these trends were observed in both finger forces.

## Significance

The results indicate that application of tVNS during visuomotor skill training may delay the initial improvement of practiced skill while the final improvement is comparable to non-tVNS training in healthy young adults. The findings contrary to those of implanted VNS in stroke rats suggest the need to consider the specificity of VNS procedure, species, health/clinical status of subjects, and motor task in understanding and expecting the effect of VNS on motor rehabilitation outcome.

# Human Reaction and Movement Enhancement via Audial, Tactile, and Visual Perceptual Cues

A. Bajpai<sup>1</sup>, A. Mazumdar<sup>1</sup>, and A. J. Young<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Georgia Institute of Technology

Email: abajpai31@gatech.edu

## Introduction

The U.S. department of labor cites “equipment contact” as accounting for roughly half of nonfatal occupational injuries that involve days away from work [1]. Improving worker’s situation awareness can help them avoid rapidly evolving threats such as moving machines or falling debris. Previous work has quantified how different individual (tactile, audio, and visual) and combined cue modalities affect failure rates and reaction times [2]. However, providing information about the object direction may not be the best approach to inform people of imminent threats. Providing guidance to a safe area, thereby skipping the cognitive evaluation needed for a safe response, would likely yield improved safety in complex environments. However, first we must determine what perceptual cue/cue combination should be used. In this research, experiments were conducted in a virtual reality environment that simulates objects rapidly moving toward the participant. We are interested in how different cues can incite different dodge rates and reaction times.

## Methods

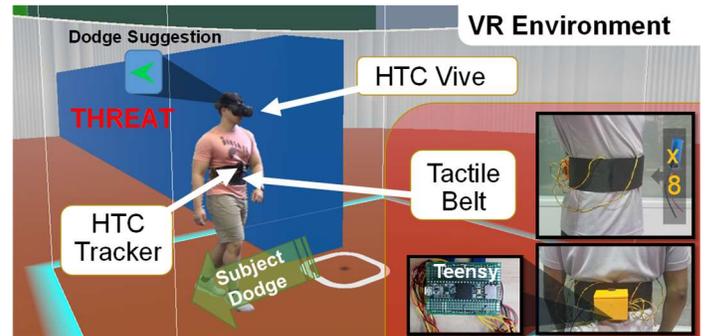

Eighteen able-bodied subjects ( $\alpha = 0.05$ , Power = 0.8) participated in an experimental protocol, approved by the Georgia Tech Institutional Review Board (IRB H18363) [2]. After the participants give written, informed consent, participants were placed in the virtual environment and oriented with the space (3m x 3m area). Participants wore a custom tethered tactile belt (located on torso), HTC Vive headset and tracker (for COM estimation). After getting oriented to the VR space and an initial training period, the participant was instructed to dodge 27 threats over several conditions (three from each direction) (Fig. 1). The different conditions of this experiment included: 3D audio (A) originating from the object, tactile indicating a safe path (T), and a visual (V) arrow pointing in a safe direction, and combinations of these cues (AT, ATV, AV, TV). The order of the threat speed/direction/width are randomized across conditions, and held constant within subjects (order changes but not the set).

Three metrics used in this study include the hazard avoidance failure rate, reaction time, and movement time. The failure rate is determined per trial block as the percent of the time the participant was hit by a threat. The reaction time is measured by comparing the time the cue(s) were sent to the participant and the time the participant’s speed (low-pass filtered at 15 Hz) exceeded twice their nominal speed. Escape time is the time it takes, after the reaction time, for the subject to leave the path of the threat.

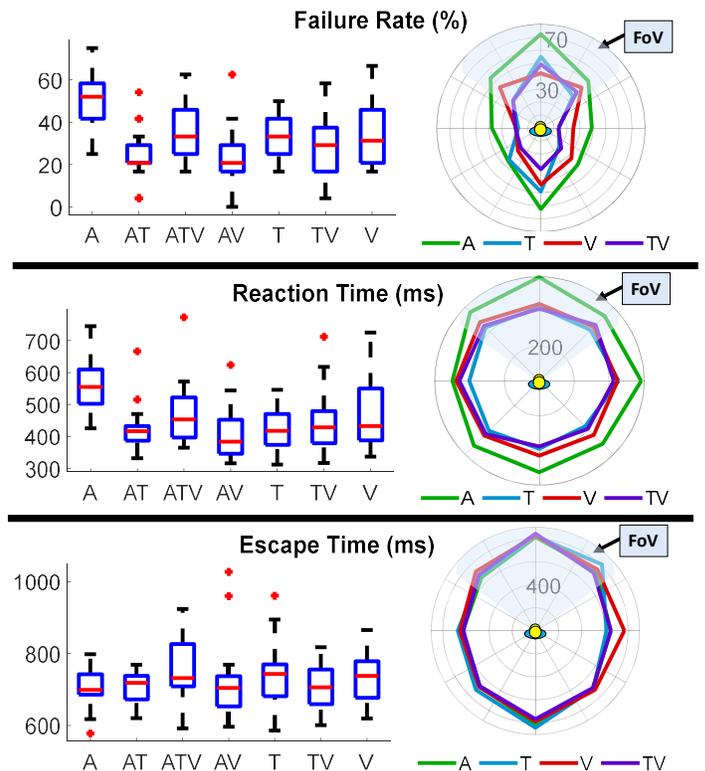

## Results and Discussion

Three one-way repeated measures ANOVAs with posthoc t tests and bon-ferroni corrections were conducted for the three metrics. Results indicate that there is no statistical difference among cues in terms of escape time but 3D audio yields statistically longer reaction time and higher failure rate ( $p < 0.01$ ). Finally, results indicate it is more difficult to escaping sagittal plane threats vs. frontal plane threats.

Conducting a t test of aggregated object information direction vs. escape direction, reveals no statistical difference. This indicates that people can dodge well in the presence of one

**Figure 1:** VR Environment. Subject is alerted to an incoming threat (represented by blue walls) from behind and dodges to maintain safety. Objects move at varying rates (8.5, 9.25, and 11 m/s) and come in varying sizes (0.1, 0.35, 0.5 m) from the four cardinal and four intercardinal directions.

**Figure 2:** Box and whisker plots of all conditions with accompanying polar plots with selected conditions for (A) dodge failure rate, (B) reaction time, and (C) escape time. Plots omit cue combinations with tactile/visual object information.

threat and find safety without guidance. Future work will include incorporating path planning guidance for multiple objects as nonguided performance may decline in more complex situations.

# Should I stay or should I go? Stability of digit forces is lowered to enhance maneuverability when expecting to move a pinched object

Anvesh S. Naik<sup>1</sup> and Satyajit Ambike<sup>1</sup>

Department of Health and Kinesiology, Purdue University, West Lafayette, Indiana

Email: [naik20@purdue.edu](mailto:naik20@purdue.edu)

## Introduction

Stability of the motor system is the ability to maintain a desired motor state, and maneuverability is the ability to transition between motor states. Stability and maneuverability are antagonistic and animals often trade off stability of the current task to enhance maneuverability [1]. In prehension, maneuverability refers to transitions between different patterns of object manipulation, and it is essential for performing activities of daily living. Yet, the stability-maneuverability tradeoff is not studied in human prehension.

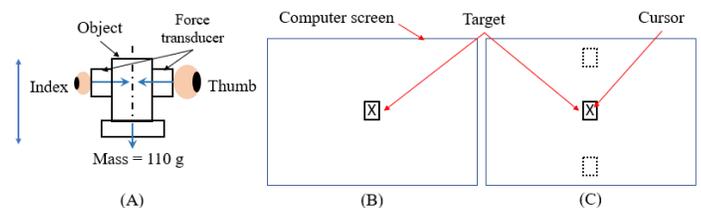

We studied whether the trade-off is evident in the vertical movement of an object held in a pinch grasp (using the thumb and the index finger; Fig. 1A). When an object is moved vertically, the digit forces normal to the digit-object interface increase to compensate for the inertial load due to the object's acceleration. However, these changes depend on movement direction: for upward movement, the digit forces increase before the object accelerates, whereas for downward movement, the digit forces increase after the object accelerates [2]. We leveraged this difference to explore the tradeoff. We computed the stability of the forces during the *foreperiod* of a choice reaction-time task (CRT), when the object is held steady, but the participant expects to move it either upward or downward in response to a visual cue. During the foreperiod, the participant expects to change the digit forces in a somewhat different way depending on the movement direction. We compared the stability during the foreperiod with that computed in tasks when the object is held steady without any expectation of movement (i.e., 'steady' task). We hypothesize that (1) compared to the steady task, the stability would be lower during the foreperiod of the CRT to facilitate the upcoming changes in the digit forces, and (2) greater decline in the stability will be associated with lower response times (RT) in the CRT – which serves as our measure of maneuverability in this study. This association will demonstrate the stability-maneuverability tradeoff in human prehension.

## Methods

Healthy young adults (N=11, 4 female, 24.4±5 years) participated in the study. Participants held a vertically-oriented object with a pinch grasp in their dominant (right) hand and tracked a target provided on a computer screen by moving the object vertically. Digit forces were measured using force transducers (Nano-17, ATI), and movement kinematics were measured using a motion capture system (Vicon Vero). Visual feedback of the object's position was provided as a cursor on the screen (Fig. 1B, 1C).

In the steady task, participants were aware that the target will not move, and therefore, they did not expect any object movement in the future. They held the object stationary so that the cursor remained inside the target. The CRT began similar to the steady task, but participants expected the target to jump up or down at any moment. They were required to track the target as quickly as possible by moving the object. Both tasks were performed 15 times. We used the uncontrolled manifold (UCM) method to analyse the digit forces with the object was stationary

in the steady trials, and when it was stationary during the foreperiod of the CRT trials. The analysis provides a stability index ( $\Delta V_z$ ), which quantifies the covariation in the digit forces that stabilize the value of an important output variable – the difference between thumb and index finger normal forces in this case. A low value of  $\Delta V_z$  implies lower stability of the force difference, and vice-versa. RT in the CRT trials was calculated as the interval between the instant when the target jumped to the instant when the object velocity first crossed 5% of the peak velocity during the subsequent movement. A two-sample t-test was used to compare  $\Delta V_z$  values between the steady task and CRT. A linear regression between  $\Delta\Delta V_z$  (the difference between  $\Delta V_z$  values of the steady task and CRT) and RT across participants was used to assess the stability-maneuverability tradeoff.

**Figure 1:** Instrumented object held in a pinch grasp (A), steady task: target does not move (B), choice reaction-time task target jumps at arbitrary time (C).

## Results and Discussion

No significant difference was observed between  $\Delta V_z$  values for the two tasks ( $t_{(29)}=0.1$ ,  $p>.05$ ). Six out of 11 participants reduced stability while others increased stability in the CRT. However, the regression between  $\Delta\Delta V_z$  and RT was significant ( $p<.05$ ,  $R^2=0.72$ ; slope=61.4 ms). Participants who reduced stability for the CRT were more maneuverable (lower RT).

## Significance

This is a first study demonstrating the stability-maneuverability trade-off in human prehension, and our results are consistent with this trade-off seen in postural control tasks [3]. Our results have implications for understanding the loss of manual dexterity with age, which has a serious negative impact on the quality of life of older adults. Aging leads to slower switching between manual tasks, which arises from system-wide neuromuscular and cognitive changes. This study is the basis for identifying a novel motor mechanism that may also underlie dexterity loss, and may lead to novel interventions for arresting the loss. Finally, individual differences in young participants suggest that our methods could be used for early identification of individuals at a higher risk of dexterity loss with aging.

## Rabbit Hindlimb Ankle Kinematics During Stance Phase of Hopping Gait

Patrick T. Hall<sup>1</sup>, Caleb Stubbs<sup>1</sup>, Cheryl Greenacre<sup>2</sup>, David E. Anderson<sup>2</sup>, and Dustin L. Crouch<sup>1</sup>  
University of Tennessee, Knoxville (UTK) – Tickle College of Engineering<sup>1</sup> and College of Veterinary Medicine<sup>2</sup>

### Introduction

Animal models are essential tools for conducting musculoskeletal research and translating medical devices. Rabbits are commonly used for testing a wide variety of orthopaedic devices, procedures (e.g. immobilization), and injuries (e.g. tenotomy). For many such cases, the effect of the intervention on sensorimotor function is vital. As with other animals, locomotion is one of the most important tasks for motor function. Before investigating the effect of interventions on locomotor function, there is a need to quantify locomotion variables in healthy rabbits.

Rabbit hindlimb biomechanics during hopping gait was previously reported [1] but required surgical implantation of bone pin markers to track motion. Such invasive methods are able to track the bone motion more accurately but are relatively difficult to implement, may mechanically interfere with movement, or disrupt movement by causing discomfort. Additionally, the previous study did not report hindlimb kinematics, only ground reaction forces and joint moments. The goal of our study was to quantify hindlimb ankle kinematics and vertical ground reaction forces during the stance phase of hopping gait using a noninvasive motion tracking technique. We hypothesized that there would be no bilateral difference in kinematics and forces.

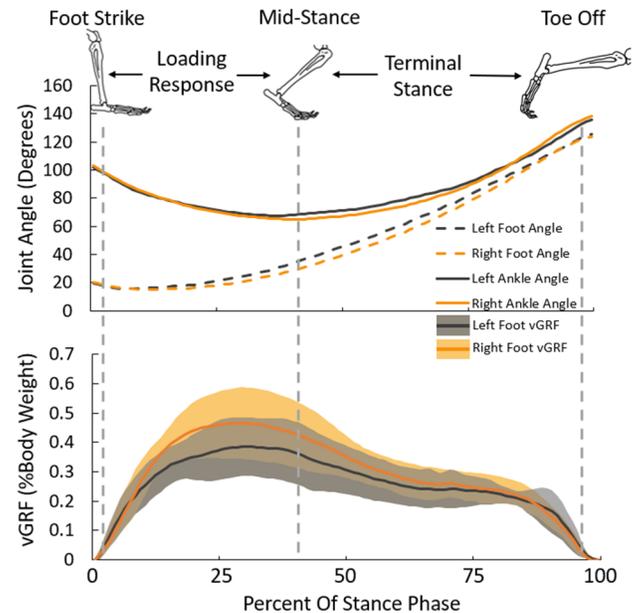

### Methods

All research presented was approved by the UTK IACUC. Six musculoskeletally mature New Zealand White (NZW) rabbits (weight =  $2.70 \pm 0.33$  kgs) hopped through a clear acrylic tunnel when given negative reinforcement (prodding). While rabbits were in the tunnel, we synchronously recorded ground-foot pressures (VHR Walkway 4 pressure mat, Tekscan) and a 60 Hz video (1080P HD Webcam, SVPRO) of motion in the sagittal plane. Immediately prior to testing, we shaved both hindlimbs and marked the approximate joint centers of the metatarsophalangeal, ankle, and knee joints with black ink. Since our set-up permitted measurements from only one hindlimb at a time, we prompted the rabbits to hop across the track ten times in each direction. We extracted the vertical ground reaction force (vGRF) of the contact foot from the pressure recordings. Using morphology-based marker tracking in MATLAB (Mathworks, Natick, MA), we calculated the ankle angle and foot angle (i.e. the angle between the foot and ground) from the videos. We compared the magnitudes of angles and the vGRFs during stance phase between the left and right hindlimbs.

### Results and Discussion

Both the foot and ankle angles were similar between hindlimbs (Fig. 1), showing no statistical differences through statistical parametric mapping (SPM) [2]. This indicates that rabbits exhibit symmetric ankle kinematics during locomotion. Future post-intervention testing should analyse both limbs to evaluate if changes in one limb also affect contralateral locomotor function.

Unlike humans, who transition from a negative foot angle during initial contact to a positive angle at toe off [3], rabbits maintain a positive foot angle throughout stance. The ankle dorsiflexed during the loading response phase as the vertical ground reaction force increased. Plantar flexion during terminal

**Figure 1:** (Top) Sagittal plane joint angles during stance show the foot angle relative to the ground and the ankle angle. Joint angles were similar between limbs. (Bottom) vGRF during stance phase. The right hindlimb hadd qualitatively higher vGRFs. Joint angles and vGRFs are segmented into phases with mid-stance occurring at the lowest ankle angle.

stance coincides with and likely contributes to forward propulsion.

The right hindlimb produced a qualitatively higher vGRF throughout stance. However, SPM revealed that significant bilateral differences occurred only at 48% of stance ( $p = 0.047$ ). Previous studies observed similar vGRF magnitudes and bilateral differences [1], though the cause of bilateral differences is unclear. A limitation of the pressure mat was that we could only measure the vertical force component. Future testing should be conducted with force plates to quantify forces and moments along all six degrees of freedom.

### Significance

In this study we quantified healthy rabbit hindlimb ankle kinematics during locomotion based on a noninvasive motion capture approach, the first of its kind reported in rabbits. The data adds to previous data [1] to more fully characterize healthy rabbit hindlimb biomechanics and serve as a baseline for quantifying function following interventions. Noninvasive motion capture is relatively straightforward to implement, which should encourage more researchers to quantify locomotor function in future studies.

### Acknowledgments

We thank the Office of Laboratory Animal Care at UTK for providing veterinary care for the rabbits used in this study.

# Gestational Lumbopelvic Postural Changes and Joint Loads in Standing and Walking

Robert D. Catena, W. Connor Wolcott  
Washington State University  
Email: \*[robert.catena@wsu.edu](mailto:robert.catena@wsu.edu)

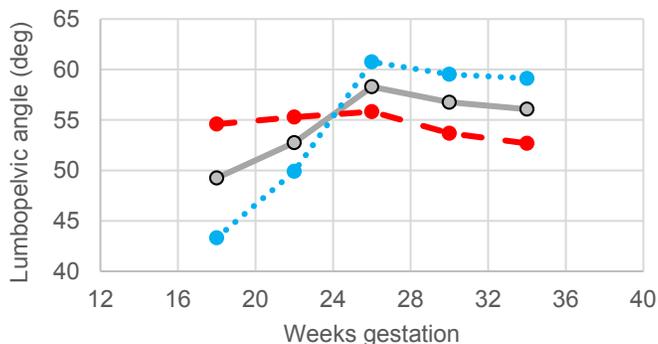

## Introduction

Human females have evolved with lumbopelvic morphology that allows them to self-select a more curved spinal posture. These may (contradicting research exists) include such sexual dimorphisms as greater vertebral body wedging ratio<sup>1</sup>, lower spinal levels of maximum curvature<sup>2</sup>, and zygapophyseal orientations to resist shear forces<sup>3</sup>. These morphological differences were previously hypothesized to mechanically balance the body while carrying a growing abdominal ventral load (fetus during pregnancy) by allowing for gestational-related repositioning of the center of mass over the hip joints<sup>3</sup>. This *Balancing Hypothesis* indicates that lumbopelvic morphology evolved for gestational balance control in standing and walking, which has distinct implications on the evolution of hominin bipedalism. Also based on the *Balancing Hypothesis*, all pregnant women would choose a more curved spinal posture, which isn't the case from our lab observations. The purpose of this study was to determine biomechanical changes associated with self-selected gestational lumbopelvic postural change in both standing and walking. We hypothesized that women with more lumbopelvic curvature change (as compared to those with less change) would benefit most with reduced joint loading during gait.

## Methods

Twenty participants were tested in four week intervals between 18 and 34 weeks of gestation. Lumbopelvic angle (LP), the sum of standing pelvis anterior(+) tilt and lumbar lordotic extension(+) angles, was measured at each testing and used as the main independent variable. Joint moments, dynamic balance, and mechanical energy during quiet standing and self-selected pace walking were measured as dependent variables. Dynamic balance and mechanical energy were calculated from center of mass motion, determined from individual center of mass anthropometry for each pregnant woman<sup>4</sup>. Multivariate ANOVAs and hierarchical regressions were employed to test relationships while controlling for confounding variables.

## Results and Discussion

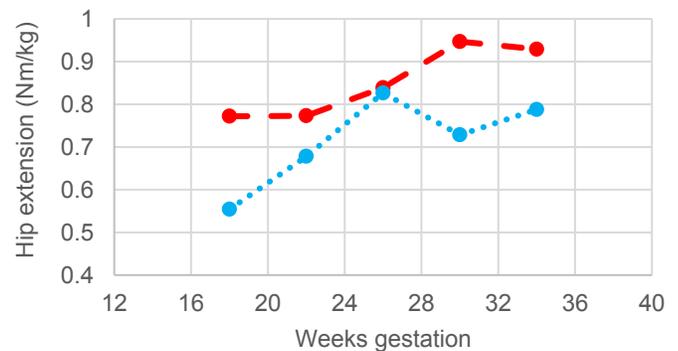

**Figure 1:** Average lumbopelvic angle (anterior pelvic tilt + lumbar extension) change through gestation. Grey solid line is the average of all participants. Dashed red line (=LP) is the average of the half of the group with the greatest LP beta value. Dotted blue line (ΔLP) is the average of the other half of the group, those with the lowest LP beta value.

On average, LP angle increased through gestation by 8°, but the amount of change is starkly different between pregnant women, with  $\pm 30^\circ$  change through gestation ( $p < 0.001$ ) (Fig 1). The two groups (=LP and ΔLP) did not start with different BMIs, nor did they experience different weight gains through pregnancy or have different BMI change through pregnancy, but the ΔLP group was 6cm shorter than the =LP group ( $p < 0.001$ ).

There were little significant effects of LP on standing joint loads, standing balance or walking balance.

In walking, LP was positively correlated to walking speed and stride length. Additionally, LP was negatively correlated with torso center of mass motion in the sagittal plane. These indicate a possible positive effects of LP on energy conservation.

The effects of LP change were most apparent during walking in the stance hip (Fig 2), but also seen in the low back, swing hip and swing knee, with joint loads significantly (20-25%) lower in the ΔLP group, even while controlling for body height or normalizing by weight. Increasing LP angle resulted in reduced joint loads in the third trimester of pregnancy. Our results seem to indicate that spinal sexual dimorphisms likely evolved for kinetic aspects of walking rather than balance control.

**Figure 2:** Average hip extension moment (as a percent of body mass at first testing) in loading response phase. Similar significant interaction in midstance phase. Dashed red line is =LP. Dotted blue line is ΔLP.

## Significance

This research could have significant impacts on current obstetrics practices and ergonomic product development targeting low back pain during pregnancy. Natural spinal posture changes benefit other joints during walking. We will continue to explore the effects of LP change for groups that can't self-select LP change like pregnant women with pregravid back conditions that prohibit lumbar extension, or with lower extremity conditions that may prohibit anterior pelvic tilt. Our findings may also lead to better understanding of the evolution of hominin sexual dimorphisms, intermediate bipedalism, and dispersal of different hominins.

## The effect of active shortening velocity on the ratio of muscle stiffness to muscle force

Siwoo Jeong<sup>1</sup> and Kiisa C. Nishikawa<sup>1,\*</sup>

<sup>1</sup>Department of Biological Sciences, Northern Arizona University, Flagstaff, AZ USA

Email: \*kiisa.nishikawa@nau.edu

### Introduction

It is widely accepted that the ratio of muscle stiffness to muscle force should be relatively constant during isometric contraction at a given muscle length and activation level [1], because both isometric force and stiffness are linearly related to the number of attached cross-bridge [2]. However, Julian and Morgan (1981) found that the stiffness to force ratio was altered during isometric force redevelopment after active shortening at the same muscle length and activation level [3]. Though their study shows the stiffness to force ratio can be altered by active shortening, it remains unknown whether shortening at different velocities affects the ratio. Furthermore, there is no generally accepted mechanism for the difference in the stiffness to force ratio between isometric contraction before vs. after active shortening.

To systematically investigate the effect of active shortening on the ratio of muscle stiffness to muscle force, we designed an experiment in which muscles first develop force isometrically, and are then shortened at different velocities, followed by a period of isometric force development at the same muscle length. If the stiffness to force ratio is determined only by the number of attached cross-bridges, then muscle stiffness should increase linearly with muscle force, with an intercept of zero stiffness at zero force, as observed during force development in a purely isometric contraction,

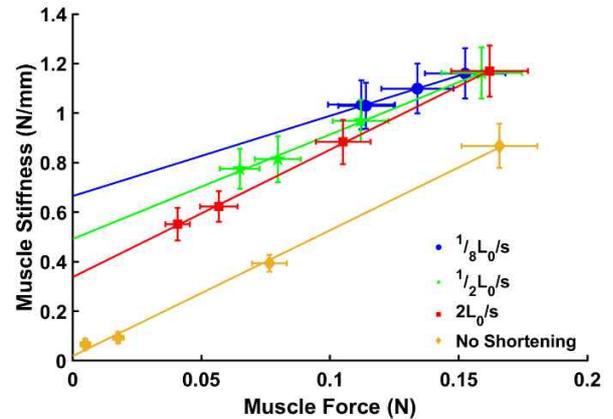

### Methods

Maximal isometric force at  $1.05 L_0$  was established for whole soleus muscles isolated from wild-type mice ( $n = 7$ ). The muscles were actively shortened to  $L_0$  at three velocities ( $1/8L_0/s$ ,  $1/2L_0/s$  and  $2L_0/s$ ) and then held isometrically for four pause durations which allowed isometric force redevelopment (10, 20, 80 and 1000ms). Instantaneous muscle stiffness was measured at the end of the pause by a quick stretch ( $0.9\%L_0$  stretch at a speed of  $3L_0/s$ ). For comparison, the muscle stiffness was also measured during isometric contractions at  $L_0$  without active shortening at similar durations after the onset of stimulation (10, 20, 80 and 1000ms).

ANCOVA was used to compare muscle stiffness and muscle force among different shortening velocities. Shortening velocity was the main effect, individual was a random effect nested within shortening velocity, and muscle force was the covariate.

### Results and Discussion

During isometric contraction, the stiffness to force ratio was constant with an intercept of zero stiffness at zero velocity as expected (Fig. 1, Yellow). In contrast, significant differences were found for the slopes ( $p < 0.01$ ) and y-intercepts ( $p < 0.001$ ) of the relationship between muscle stiffness and force at different shortening velocities (Fig. 1). At the fastest shortening velocity (red), the slope was similar to that of the purely isometric contraction, but with a larger intercept. The slope decreased with slower shortening velocities. The different slopes and y-intercepts indicate that the ratio of muscle force to muscle stiffness during the isometric for redevelopment period depends

**Figure 1. Force vs. Stiffness at different active shortening velocities ( $n=7$ ).** Data points shown are means across mice, with error bars representing SD.

on the velocity of active shortening for a same muscle length and activation level.

'Stress-induced inhibition' has been invoked to explain the reduction in force that occurs after active shortening [4]. The hypothesized mechanism postulates that weakly bound cross-bridges form in the new overlap zone between myosin and actin filaments that is created during shortening. Although the weakly bound cross-bridges would not produce force, they would contribute to muscle stiffness [5]. Therefore, it contributes to the change in the stiffness to force ratio caused by active shortening.

Another possible explanation of our result is a change in titin stiffness. If muscle stiffness depends exclusively on cross-bridge stiffness and constant titin stiffness, then the ratio after active shortening should be constant at same muscle length. This is due to a muscle having the same titin-actin binding location and the same overlap between myosin and actin filaments at a given length regardless of shortening velocity. Our results cannot be explained solely by cross-bridge and constant titin stiffness. Therefore, it is possible that titin stiffness could be changed by active shortening.

### Significance

This study shows that the velocity of active muscle shortening affects the stiffness to force ratio. The sliding filament theory cannot explain the results reported here, Constant titin stiffness in active muscle is also insufficient to explain the observed changes in the stiffness to force ratio of active muscle.

## Introduction

Male bighorn sheep (BHS) participate in seasonal ramming bouts that can last for several hours, yet they do not appear to suffer major brain injuries from these violent battles [1]. It has been suggested that motion of the horn or its distal portion during and directly following impact plays a significant role in reducing translational brain cavity accelerations, with up to a 50% increase in these accelerations when the distal portion is removed [2]. While the etiology of concussions is not fully understood, translational accelerations of the brain cavity have been correlated with concussion occurrence [3]. The current study aimed to quantify horn shape metrics and their variability from one animal to another to provide insights regarding the role of horn shape in mitigating brain cavity accelerations during impact [2]. We hypothesized that bighorn sheep horns exhibit a transition from having no directional bending preference near the base of the horn to a medial-lateral bending preference at the horn tip to facilitate side-to-side oscillations, which would reduce brain cavity translational accelerations by damping.

## Methods

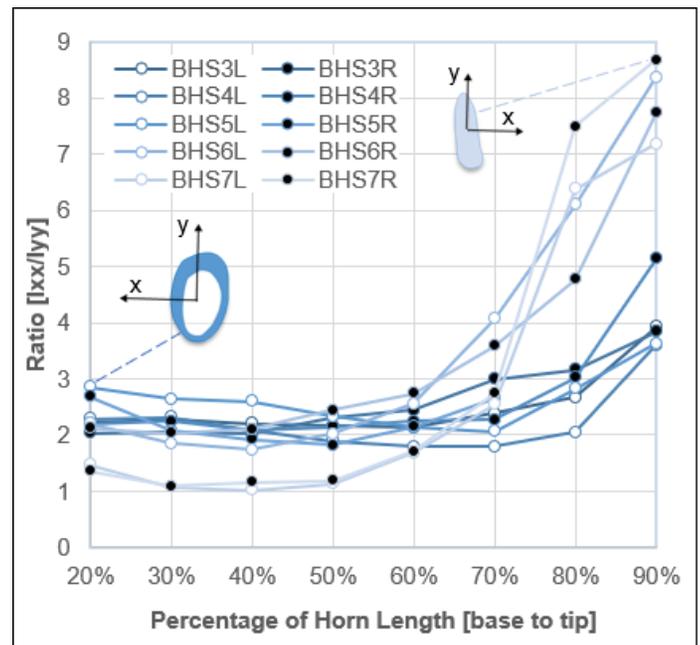

Seven male bighorn sheep skulls provided by The Colorado Division of Parks and Wildlife were scanned using x-ray computed tomography (CT). CT images were segmented with a custom MATLAB script, manually edited and verified as needed, and then converted into a surface geometry (.stl) with open source image processing software (Seg3D, sci.utah.edu). All horn shape characterizations were completed in SolidWorks. Three orthogonal horn views were used to trace an exterior horn shape and to define a horn centerline. The centerline provided a representation of the path of each horn's helicoidal shape from which evenly spaced cross sections were generated. For each cross section, a local coordinate system was defined with a point on the centerline as the origin, a local x-axis parallel to the medial-lateral direction, and a local y-axis perpendicular to the medial-lateral direction and in the plane of each cross section (Fig. 1). Second moment of area was calculated for cross sections about local coordinate systems.

**Figure 1:** Horn cross section and cross section plane with respective x and y axes. A second moment of area ratio  $[I_{xx} / I_{yy}]$  greater than 1 indicates a medial-lateral bending preference (ie about y-axis) promoting oscillations of the horn tip.

## Results and Discussion

Male BHS horns exhibit a medial-lateral bending preference throughout their length that increases toward the tip, reaching a maximum value at 90% of total length (Fig. 2). The medial-lateral bending preference measured in this study supports medial-lateral oscillations of the horn tip observed in a finite element model of the BHS skull and horns [2]. This model also suggested that removing the horn tip increased brain cavity accelerations during impact [2]. We propose that the gradual cross-sectional variations measured here act to mitigate brain cavity accelerations by inducing damped medial-lateral oscillations.

**Figure 2:** Ratio  $[I_{xx}/I_{yy}]$  of second moment of areas for all bighorn sheep cross sections. R/L = right/left horn.

## Significance

To the best of our knowledge, we have measured bighorn sheep horn second moment of area as a function of horn length for the first time. Results from this study may be used to guide future modeling efforts to better understand the relationship between horn shape, energy dissipation, and reduction of brain cavity accelerations during impact.

Email: bh558@nau.edu

### Introduction

In skeletal muscle, the molecular motors actin and myosin interact to generate force for joint movement and locomotion. Many experiments refer to the classic force-length relationship to predict muscle behavior in a wide variety of conditions<sup>1-3</sup>, which states that optimal force is produced at an intermediate muscle length, where overlap of actin and myosin is optimal and peak isometric force is produced. However, muscle performance is known to deviate from the classic muscle force-length relationship under physiologically relevant conditions, such as varying activation level<sup>4,5</sup> and changes in muscle length during contraction<sup>6</sup>.

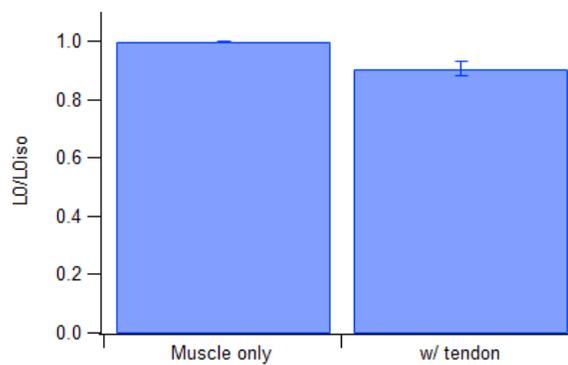

This study looks at the effect of imposing a length change to muscles during fixed-end contractions by adding an elastic element in-series to muscle. If the optimum length of a muscle changes as a result of adding series compliance and the subsequent shortening that the muscle undergoes, then this would suggest that muscle shortening against a compliant element induces an activation-dependent contractile history, which is not currently well understood.

### Methods

Sartorius muscles were excised from *R. catesbeiana*, bathed in an isotonic Ringer's solution, and tied fixed-end to a force transducer either without a series elastic band (isometric "muscle only" condition), or with ("w/ tendon" condition, allowing muscles to shorten approximately 15% of their starting length before reaching isometry). Muscles were stimulated tetanically at various starting lengths and differences in optimum length (LO) and peak force (FO) between "muscle only" (iso) and "w/ tendon" conditions were found and plotted. Differences between tetanus and twitch stimulation will also be found in both conditions to quantify the amount of force-length shift that is due to the activation-dependent contractile history rather than a calcium-dependent shift.

### Results and Discussion

Preliminary results suggest that adding an artificial tendon in-series with skeletal muscle causes a decrease in both optimum length ( $0.91L_{0iso} \pm 0.06$ ,  $n=4$ ) and peak force ( $0.62F_{0iso} \pm 0.08$ ,  $n=4$ ). The observed shift in optimum length and peak force support that the classic force-length relationship of skeletal muscle may not always be reliable when predicting muscle behavior *in vivo*, where elastic connective tissue interactions are common. When muscles actively shorten against an in-series compliant element, they are subjected to contractile history that causes a decrease in optimum length and

**Figure 1.** Adding compliance to the muscle setup causes an approximate 9% decrease in optimum length.

peak force, and this activation-dependent contractile history is hypothesized to change the force and length properties of muscle at the sarcomere level. This sarcomere-level change is hypothesized to increase with additional compliance.

### Significance

Many clinical and biomedical applications rely on the accuracy of theories in muscle physiology. Muscle modelling, robotic exoskeletons, and powered prosthetics are emerging as some of the most rapidly advancing technologies in biomedicine, but their advance is being slowed by outdated muscle theories. Research like ours brings attention to the need for updates to our understanding of muscle physiology so we can enhance treatment for disabled individuals and reach a better understanding of biological systems as a whole.

Email: [chri4094@vandals.uidaho.edu](mailto:chri4094@vandals.uidaho.edu)

### Introduction

For terrestrial organisms, the ability to navigate complex environments is critical to survival. As habitat conditions vary, animals must modify speed, angle, and direction of travel. These deviations are inherently linked to changes in mechanical demand, providing downstream insight into the functional plasticity of vertebrate muscle. As limb performance fluctuates, it remains unclear whether mechanical demands are satisfied via differential coordination across muscle groups, or if individual muscles vary in their mechanical roles. In the present study, we explore this idea through quantifying the contractile behavior of two hindlimb muscles from *D. deserti*, a bipedal rodent, when hopping on surface inclines of 0°, 10°, and 20°.

### Methods

Data were collected as animals ( $n = 3$ ) hopped at 1.6 m s<sup>-1</sup> on a motorized treadmill. Electromyography (EMG) and sonomicrometry (SONO) were used to reveal patterns of muscle activation and fascicle strain in the lateral gastrocnemius (LG), a biarticular ankle extensor and knee flexor, and the vastus lateralis (VL), a knee extensor. Video data were recorded at 200 frames s<sup>-1</sup> with a high-speed camera (Xcitex Inc, Woburn, MA, USA) and digitized using DeepLabCut [1]. EMG, SONO, and kinematic data were analyzed with a customized MATLAB script (2015a, MathWorks, Natick, MA, USA).

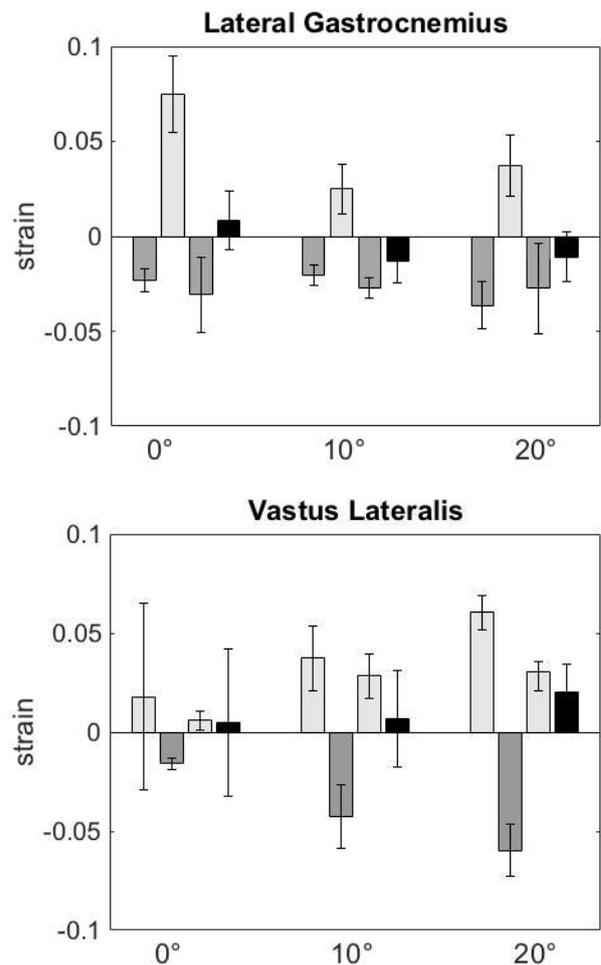

### Results and Discussion

The LG exhibited similar strain and EMG activation patterns across grades, undergoing low-magnitude shorten-stretch-shorten cycles during stance (Figure 1). Alternatively, a stretch-shorten-stretch cycle was seen during stance in the VL. Unlike the LG, the VL expressed fascicle strain variation across grades, with an increase in both lengthening and shortening strain during incline hopping. As surface grade increased, VL strain fluctuations were accompanied by a decreased period of EMG activity, as well as a delayed onset time.

The strain patterns seen in the VL, particularly the increase in net lengthening, highlight its role in energy absorption as well as its capacity for functional modulation in response to a shifting environment. On the other hand, the statistically homogeneous behavior of the LG across experimental conditions suggests the muscle is not involved in balancing the increased work requirements of incline locomotion. Additional research involving a broader range of *D. deserti* hindlimb muscles, as well as assessments of regional variation within these muscles, will provide further insight into the undefined mechanisms accommodating mechanical demand variance during natural locomotion.

### Significance

By determining *in-vivo* patterns of functional deviation across locomotor conditions, we can begin to outline the adaptability of vertebrate muscle in response to variable mechanical demands. Subsequently, a concrete definition of this environment-dictated plasticity will provide a foundation on which to advance navigation capability in legged robotic models.

**Figure 1.** Mean ( $\pm$  s.e.m.) lengthening (light grey), shortening (dark grey), and net (black) strains recorded in the VL and LG during stance phase ( $n = 3$ ).

## Dynamic changes in force modulate pennate muscle architecture

Jarrod C. Petersen and Thomas J. Roberts  
Brown University, Providence, RI, USA  
Email: [jarrod\\_petersen@brown.edu](mailto:jarrod_petersen@brown.edu)

### Introduction

Muscles change shape and experience an array of dynamic forces during a contraction. In pennate muscles, the oblique orientation of the muscle fibers is important in determining the force and speed output of the muscle. Recent studies have shown the important functional implications of this oblique orientation and changes in muscle thickness with a phenomenon known as muscle gearing [1, 2]. Muscle gearing describes the observation that a pennate muscle belly can achieve higher velocities than the fibers, and that this phenomenon is variable depending on the load [1].

While several studies highlight the importance of load for muscle shape change and gearing during a contraction, few show the effect of variable force. Here we use an *in-vitro* isolated muscle prep in conjunction with high speed videography and marker tracking to demonstrate the effects of variable force on pennation angle and muscle thickness. We show that dynamic changes in force result in corresponding changes in pennation angle and muscle thickness and these changes may act on elastic elements located within the muscle belly [3] (Fig. 1). Our results suggest that dynamic force modulates muscle shape change and pennate muscles are capable of storing and releasing internal elastic strain energy.

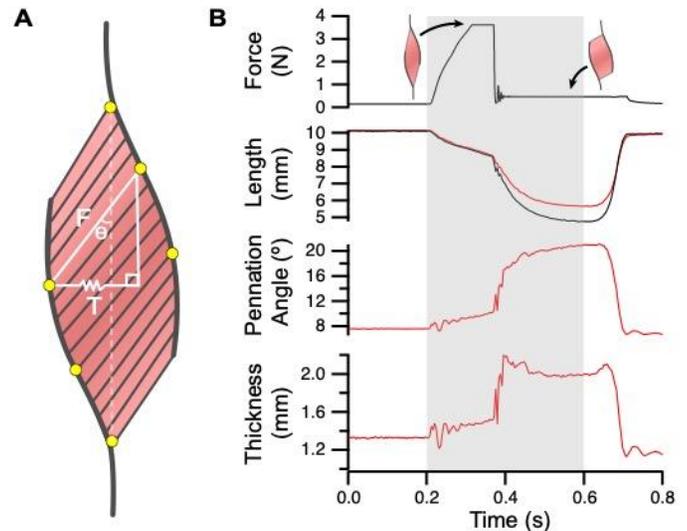

### Methods

The flexor digitorum superficialis brevis (~20mm x 10mm) was isolated from the legs of bullfrogs (*Rana catesbeiana*) and black polyethylene microspheres (350 $\mu$ m) were placed at the ends of fibers and the muscle belly (Fig. 1A). The muscle was submerged in oxygenated ringers solution, fixed to a rigid mount, and attached via stainless steel chain to a muscle servomotor within a clear rectangular housing. The muscle was filmed with one camera at 250 fps, and points were later tracked from this video in XMAlab.

### Results and Discussion

During a frog jump, as the muscles in the leg contract, the mechanical advantage at the knee joint improves, providing a latch mechanism with which stored elastic energy is released quickly [4]. We used a control signal to drop the regulated force of the muscle servomotor to mimic this latch, an exaggerated one of which, an instantaneous drop, is shown in Fig. 1. When force declined from 80% to 10% of peak isometric force, there was a concurrent and notable increase in pennation angle and thickness (Fig. 1). An increase in pennation angle is expected with fiber shortening, however, the large increase in pennation angle following the force drop was ~6X the magnitude of pennation angle change for an equivalent amount of fiber shortening prior to the force drop. Based on these observations, the large changes in pennation angle and thickness seem to correspond with the drop in force more so than fiber shortening.

A control signal inducing a more gradual decline in force, much like what typically occurs *in vivo*, also showed what we observe in the instantaneous drop. We suggest these data provide evidence that muscle thickness is modulated by force in pennate

**Figure 1:** (A) Our model of internal elastic energy storage (white) superimposed on an illustration of a unipennate muscle with markers (yellow) used to calculate fiber length (F), muscle thickness (T), and pennation angle ( $\Theta$ ) relative to muscle line of action (dashed line). (B) Experimental data shows immediate increases with pennation angle and thickness, indicators of muscle belly shape change, of the muscle fiber (red), and whole muscle (black) in response to a drop in force. Two insets on the force trace show approximate muscle shape before and after the drop in force, the duration of stimulation is highlighted (gray).

muscles. Additionally, we interpret the sharp rise in pennation angle and thickness to mean that elastic energy is being released from within the muscle belly itself, due to the rapid expansion of a transverse spring (T, Fig. 1A) which was initially compressed during force rise [3].

### Significance

The present results provide evidence that force is a determinant of pennation angle and thickness change in muscle. We find that sudden changes in muscle belly shape occur during force decline, and may allow for internal elastic energy storage and recovery in muscle. These internal elastic elements may augment muscle performance in similar ways to in-series elastic elements, and may do so through changes in muscle shape during variable force.

# Landing on Compliant Surfaces: Lessons from an animal model of landing control

Alex Duman<sup>1</sup> and Emanuel Azizi<sup>1</sup>

<sup>1</sup>Department of Ecology & Evolutionary Biology at the University of California, Irvine

Email: [aduman@uci.edu](mailto:aduman@uci.edu)

## Introduction

Locomoting in the real world requires us to interact with different surfaces that vary in height, compliance, and damping. This introduces complexity that challenges both humans and animals to modulate their motor behaviour to move effectively [1,2]. Landing and decelerating also pose a greater risk of injury to the musculoskeletal system than takeoff since muscles undergo lengthening contractions while functioning as brakes. Therefore, surface properties may dramatically alter deceleration strategy.

We are interested in exploring how organisms coordinate decelerations when landing on surfaces that differ in stiffness and damping. Toads offer a unique model to study coordinated landing as they can jump several times their own body length, producing relatively large impact forces and energy, while still landing effectively across a wide range of environmental conditions. Here we report on our findings of how joint work, key muscle activity and many other kinematic and kinetic variables change with surface stiffness and damping.

## Methods

We used the cane toad, *Rhinella marina*, as a model for probing coordinated decelerations. With high-speed videography, force plate ergometry and electromyography we collected and analyzed joint work across the forelimb using inverse dynamics and patterns of forelimb muscle activity in preparation for and during landing. Toads jumped from a rigid platform 1.5 times their body length onto a platform that recorded impact force and could be locked in place or attached to springs to test how toads responded to landing on a surfaces with varying compliance (0, 2.5, 5 or 10 mm BW<sup>-1</sup>). To include damping we altered the inertia of the platform by changing the mass from 123g to 725g.

## Results and Discussion

Our findings suggest compliance and surface damping minimally affect landing in cane toads (Fig. 1). We did observe significantly reduced impact forces and joint work on compliant surfaces. There was also a trend across compliance treatments of more proximal forelimb joints like the shoulder and elbow (as opposed to distal joints like the wrist) doing a greater proportion of work to slow the animal upon impact.

We also observed substantial variation in forelimb extension prior to impact, which lead to certain individuals crashing into the platform with their torso, or effectively coordinating a landing with their forelimbs. The crashing and coordinated landing behaviors are not only distinct in forelimb kinematics, but differ in impact force and energetics of the forelimb muscles as well. These results are highly suggestive of varying tolerances for crashing behavior and imply that there are two distinct strategies for dealing with impacts.

Our electromyographic results further support these assertions. We found that platform compliance had little impact on forelimb muscle activity, yet the amount of activity in key muscles was correlated with the use of a crashing strategy. This suggests cane toads have a robust control strategy for landing across a wide range of surface stiffnesses that is likely not influenced by proprioceptive feedback from the forelimbs.

It appears cane toads don't alter landing behavior due to varying surface stiffness and damping, unlike humans [3]. However, cane toads may be an insightful model for understanding mechanisms that coordinate robust movement in complex environments without relying on contact limb proprioceptive feedback.

## Significance

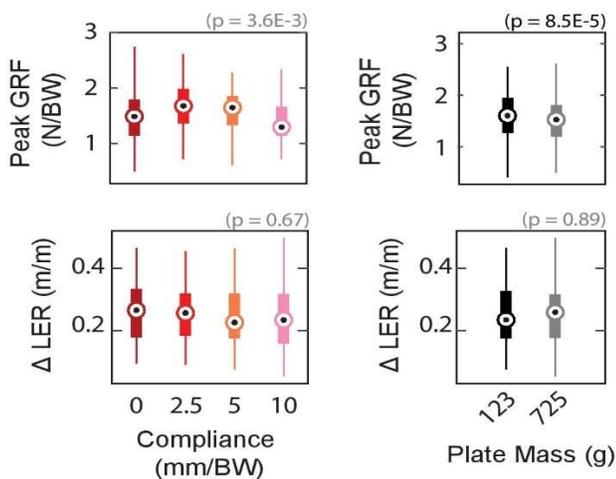

Cane toads do not seem to change their motor behaviour in response to changes in the mechanical properties of landing surfaces. While these findings suggest cane toads may not be the best model for exploring neuromuscular control of landing behaviour in humans, they do provide a system to probe control paradigms that may allow robotic devices to locomote effectively over varying terrain conditions with simple commands and without the need for real-time sensory integration.

# EXPLORING HOW FUNCTIONAL IMPROVEMENT IS RELATED TO INTERACTION BETWEEN CHILDREN WITH CEREBRAL PALSY AND HORSES DURING EQUINE-ASSISTED THERAPY: A PILOT STUDY

Yonghee Lee<sup>1</sup>, Priscilla Lightsey<sup>2</sup>, Nancy O'Meara Krenek<sup>2</sup>, and Pilwon Hur<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Texas A&M University, College Station, TX, USA

<sup>2</sup>ROCK (Ride On Center for Kids), Austin, TX, USA

Email: {yongheele87<sup>1</sup>, pilwonhur<sup>1</sup>} @tamu.edu, {priscilla<sup>2</sup>, Nancy<sup>2</sup>} @rockride.org

## Introduction

The prevalence of cerebral palsy (CP) is 3.3 per 1,000 births in the United States and is the most common cause of motor disability in children [1]. One treatment strategy that may benefit persons with CP is Equine-Assisted Therapy (EAT) utilizing equine movement controlled by the therapist [2]. A few researchers provided kinematic evidence-based effects of EAT, but no one has studied the effects of EAT on kinetics. Thus, we hypothesize the following: 1) the functional mobility of children with CP would improve as the number of EAT sessions increased, 2) there exists the kinetics-related interaction between the rider and the horse during EAT sessions.

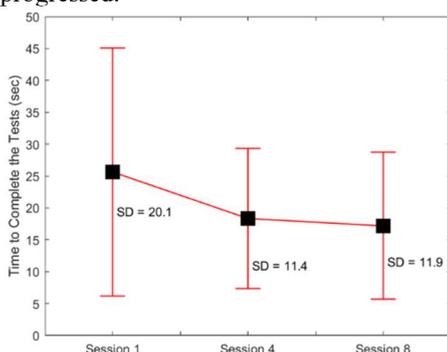

## Methods

Four children with CP aged 3 - 12 years participated. Eight 20-minute sessions of EAT treatments were conducted, with data collection on sessions 1, 4, and 8. Functional mobility was measured using the Timed Up and Go (TUG) test for 3 subjects and 10-Meter walk (10MW) test for 1 subject, all performed before and after EAT on data collection days. Kinetic measurements were done with acceleration representing force normalized by mass. The acceleration data of the children and horses during EAT sessions were measured using 6 Inertial Measurement Units (IMU). The trends of acceleration data were determined using frequency domain and time domain analyses. For frequency domain analysis, Fast Fourier Transform (FFT) was performed to display a repetitive pattern of each signal and dominant frequencies. Besides, the differences between the frequency spectrum of the horse's back and subject were calculated to study the correlation in the frequency domain. For time-domain analysis, correlation by a time shift between the horse's back and the subject's movement was studied and the time delay between their movements was characterized.

## Results and Discussion

### Functional Mobility

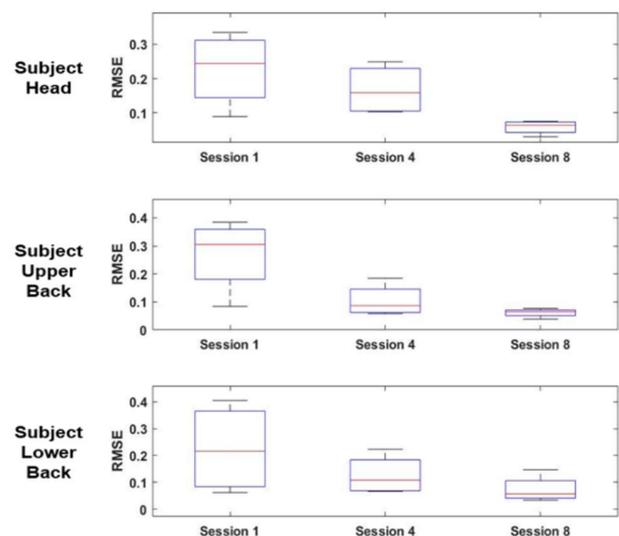

As the number of sessions increases, TUG or 10MW significantly improved over the course of the study (Figure 1). From those results, it might be said that there would be positive changes in the functional mobility of children with CP as the therapy progressed.

**Figure 1:** The outcomes of functional mobility tests with error bars. Black points indicate the means of the test results. SD stands for standard deviation- [3].

### Kinetic-Related Interaction

The mean values and variation in the difference between the frequency spectrums dropped significantly as EAT sessions progressed (Figure 2), suggesting that the dominant frequencies of the movement of children with CP synchronized with those of horses. The results of correlation by a time shift also showed that there was an increase in the correlation between the horse's back and the subject as therapy progressed.

**Figure 2:** The boxplot of difference between frequency spectrums of the horse's back and subject each session [3].

With continued EAT sessions, participants appeared to become more familiar with the horse's movement pattern. Participants seemed to learn automatic postural responses since the subject's movement tended to synchronize with the horse's movement as EAT progressed. Therefore, this study showed that positive kinetic interaction between the movements of children with CP and a horse might occur during EAT.

### Significance

This study showed : 1) that children with CP were able to produce synchronize their movement with the horse's movement and 2) the existence of kinetic interactions between the child and the horse. EAT has the potential to be a valuable treatment intervention that maximizes the functional mobility of children with CP potentially due to the progressive synchronous interaction between the rider and the horse. This study is expected to lay the foundation for a better understanding of the interaction between children with CP and horses.

## Limb joint mechanics during quadrupedal walking in alligators

Adrien A. Arias,<sup>1</sup> Alexander J. Duman<sup>1</sup>, Emanuel Azizi<sup>1</sup>

<sup>1</sup>Dept. of Ecology & Evolutionary Biology, University of California, Irvine

Email: [adriena@uci.edu](mailto:adriena@uci.edu)

### Introduction

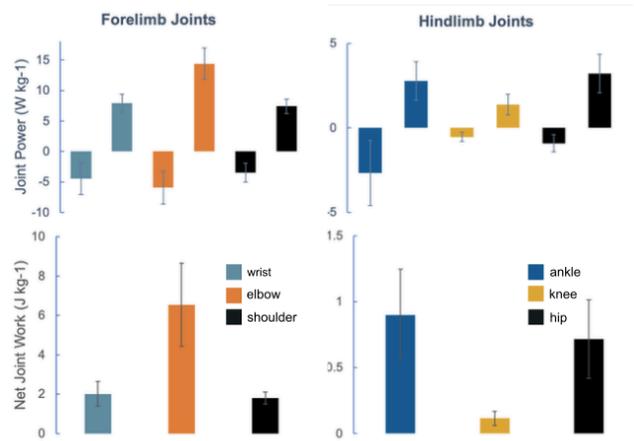

Most limb-level analyses of quadrupedal walking have focused on a small subset of animal models that are cursorial (with limbs adapted for running) and exert negligible mediolateral forces during stance phase of walking [1-3]. These studies have been instrumental in understanding the mechanics of limbed locomotion on land, but have largely ignored the more complex walking strategies used by non-cursorial animals. Previous work in alligators show they exert large laterally-directed forces [4] and have complex limb joint kinematics outside of the parasagittal plane during walking [5,6]. Therefore, the assumptions used by standard 2D inverse dynamics models (e.g. mediolateral forces are negligible, kinematics are parasagittal) are not true in alligators or other non-cursorial walkers. Here we use a quaternion-based inverse dynamics model [7] to estimate the mechanical work done by hindlimb and forelimb joints during steady-state walking in alligators. We expect hindlimb joints will perform net positive work during stance phase of walking and forelimb joints will perform net negative work, similar to other quadrupedal animals studied so far. Results from inverse dynamics and previously published anatomical data [8] will be used to identify representative hind- and forelimb muscles to examine *in situ*, in an attempt to link non-parasagittal body mechanics to the mechanical properties of limb muscles.

### Methods

Five juvenile American alligators ( $523.1 \pm 87.9$  g) were trained to walk across a custom-built trackway instrumented with two high-speed video cameras ( $200 \text{ frames s}^{-1}$ ) and a small circular force plate ( $16\text{cm}^2$ ) flush-mounted with the ground. This allowed analysis of isolated limb strikes of either the hindlimb and forelimb on a given trial. Only trials where alligators walked at a constant speed were analyzed ( $0.14 \pm 0.06 \text{ m s}^{-1}$ ). Kinematic and kinetic data were synchronized with an external trigger and imported into MATLAB (R2019b). A custom inverse dynamics script calculated instantaneous joint power and work from 3D kinematic and kinetic data using quaternion algebra and inverse dynamics.

### Results and Discussion

When normalized to mass of the functional group at each joint [8], we find that peak joint moments were greatest in the ankle joint of the hindlimb and elbow joint of the forelimb. All forelimb and hindlimb joints experienced negative and positive power, but every limb joint analysed performed positive net work during stance phase (Figure 1). Based on patterns observed in other quadrupedal animals walking, we originally hypothesized that forelimb joints would perform more negative work than hindlimb joints. Our results do not support this hypothesis, likely because the non-parasagittal forces and kinematics dominate limb joint function in alligators. We find the greatest muscle mass-specific power and work in the elbow and ankle joints, which are both associated with bipennate, biarticular, limb muscles, therefore it is possible that proximal energy transfer from larger muscles may be an important feature of non-cursorial limbed locomotion.

**Figure 1:** Average peak joint powers (top row) and average net joint work (bottom row) during stance phase of walking in alligators-- normalized to mass of the functional group at each joint. Bars represent means  $\pm$  sem.

### Significance

Detailed analyses of locomotion in a diversity of animals is necessary to understand the evolution of complex integrative movements like walking and can help us identify which components of quadrupedal walking (e.g. joint mechanics, muscle mechanics) are significant to whole-body mechanics. Alligators serve as a model organism for studying walking in non-cursorial animals because they exert large mediolateral forces and have non-parasagittal kinematics. Additionally we benefit from past research on alligator whole-body mechanics (i.e. center-of-mass dynamics in vertical and horizontal directions), musculoskeletal anatomy, and electromyographical activity during walking. This allows us to test joint-level— and eventually muscle-level— hypotheses about functional and mechanical features of locomotion in non-cursorial quadrupeds.

## Introduction

Although researchers rely on the measurement of rat locomotion to better understand injury rehabilitation, diseases and more (1-3), existing workflows present a bottleneck that reduces study sample sizes, increases costs, and slows down the scientific process. Rodents present unique challenges with regards to kinematics measurements; their loose hindlimb skin makes optically tracking skin-mounted markers inaccurate (4), and their bones are too small to track surgically implanted markers via x-ray video (5). Currently, researchers interested in whole limb kinematics of rats have two options, both of which rely upon the collection of biplanar x-ray videos: manually track skeletal landmarks (4), or align  $\mu$ CT-derived 3D bone models for each bone of interest (rotoscoping, 6). Both of these options are tremendously time consuming and require sophisticated software and expertise to implement.

We aimed to increase the efficiency of rodent kinematic analysis by combining tools created for x-ray video analysis with DeepLabCut, a deep learning-based tool for markerless body part tracking designed for use with traditional optical video (7).

## Methods

Biplanar, high speed x-ray video (41-44kV, 80mA, 5ms, 100 fps) was taken of one Lewis rat with right sciatic nerve injury performing treadmill locomotion (17 cm/s) in accordance with a protocol approved by Georgia Institute of Technology's IACUC. A total of 17 strides from two collection sessions were captured and analysed. 3D calibration and undistortion reference images were captured during each session as well (5).

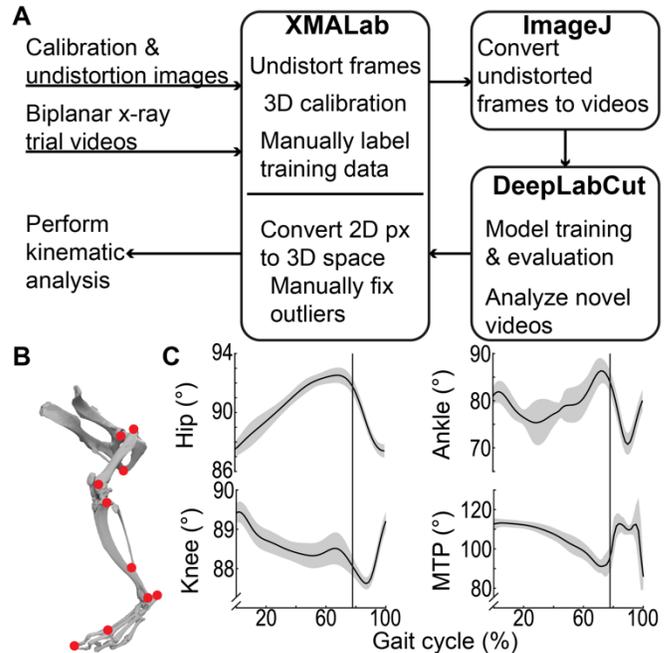

Training data was generated in XMA Lab (5) by identifying 19 skeletal landmarks (Fig 1B) in 319 pairs of x-ray video frames. Frames were randomly chosen for labelling to ensure a broad representation of the entire gait cycle. Data fidelity was maintained by minimizing the reprojection error between the paired points. Undistorted trial video frames and corresponding 2D pixel coordinates were exported from XMA Lab. ImageJ was used to losslessly convert these undistorted frames into video files to accommodate DeepLabCut's input requirements.

Model training was performed on the undistorted x-ray videos in Google Colab with DeepLabCut until performance plateaued. A single model was trained on both x-ray cameras.

Outlier machine-labelled points were identified using a combination of DeepLabCut's reported likelihood score, the jump distance to a given 3D point from its predecessor, and the reprojection error between the two cameras' points. Outliers were manually refined in XMA Lab. 3D points were low-pass filtered at 7 Hz, after which they can be exported and used for a variety of kinematic analyses (Fig 1C).

## Results and Discussion

After training for over 600,000 iterations on 95% of the labelled data, DeepLabCut reported a training error of 2.3 pixels, and a test error of 4.2 pixels.

**Figure 1:** A, flowchart of pipeline for biplanar x-ray videos. B, diagram of tracked skeletal landmarks. All landmarks are tracked on both hindlimbs except for pubic symphysis. C, Pooled data (N=17 gait cycles) of left limb sagittal plane joint angles derived from DeepLabCut and filtered at 7 Hz. SD error bars.

Previous studies measuring rat locomotion analysed kinematics at 3 time points during the gait cycle due to time and resource constraints (3). With our combination of DeepLabCut and XMA Lab, 600 frames of new video can be analysed by DeepLabCut in  $\sim 2$  minutes, and outliers can be refined in XMA Lab in roughly 30 minutes. However, performance is only as good as the training data, so generate it with care.

## Significance

Reducing the analytical burden for rodent kinematic analysis can reduce costs, increase sample sizes and expand the possibility for new research collaborations to answer new questions.

## Acknowledgments

# How do Leg Joint Stiffness Affect Dynamics of Backward Falling: A Simulation Work

Mu Qiao<sup>1,\*</sup> and Feng Yang<sup>2</sup>

<sup>1</sup>Department of Kinesiology, Louisiana Tech University, Ruston, LA 71272

<sup>2</sup>Department of Kinesiology and Health, Georgia State University, Atlanta GA, 30303

Email: \*mqiao@latech.edu

## Introduction

Falls are a serious concern among older adults. Most of the falls experienced by older adults are backward falls, which are more dangerous than other types of falls (such as forward falls and sideways falls) because the visual input cannot be used to plan quick and adequate protective reaction. Little is known about the dynamics of backward falling, such as the falling duration, the impact severity, and how the falling dynamics are affected or controlled by the lower limb joints, in particular, the stiffness. We investigated the influence of the rotational stiffness of individual leg joints on the dynamics of a backward falling after the loss of consciousness in terms of the falling duration and impact velocity.

## Methods

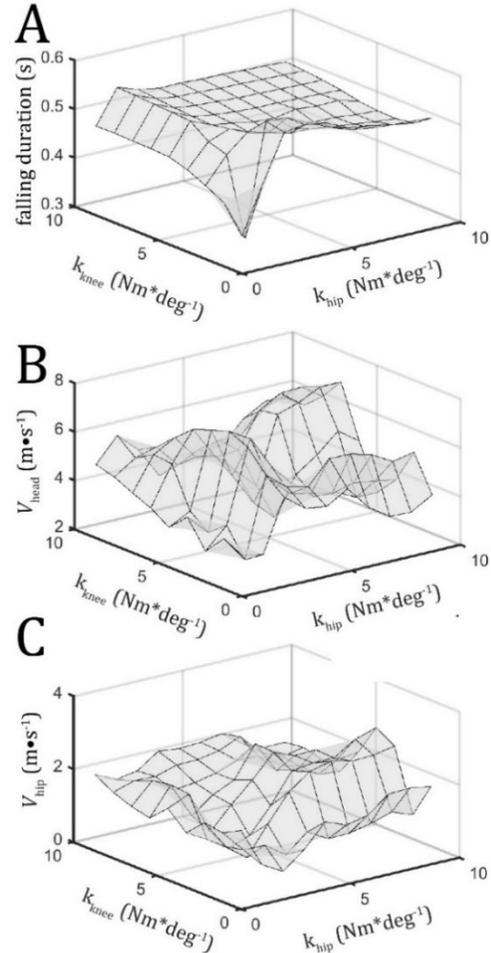

We assumed the backward falling occurs in the sagittal plane, and the movements are symmetric between left and right body sides. The same torsional spring with the same time series of angles and moments was applied to each pair of bilateral lower limb joints. We locked joints in the upper body by increasing the stiffness in its joint to a relatively large number to simplify the simulation work. We then constrained the moments at each leg joint (*i.e.*, hip, knee, and ankle) in the sagittal plane to be equal to moment generated by the torsional springs. For each joint, the stiffness of the torsional spring changed between 0 and 8.73 Nm·deg<sup>-1</sup> (*i.e.*, [0, 500] Nm·rad<sup>-1</sup>). When the joint's angle was beyond the normal range of motion, the stiffness of the torsional spring increased by 10 times pulling the joint back to its normal range.

## Results and Discussion

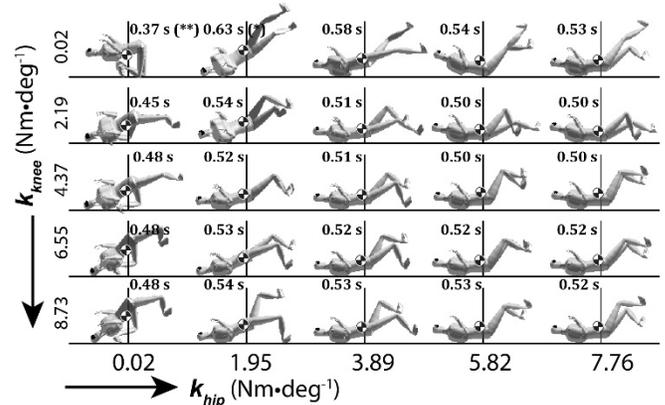

Both the falling duration and the impact speed are affected by the stiffness of lower limb joints, especially the hip and knee (Fig. 1). The falling duration, head impact speed, and hip impact speed ranged between 0.27 and 0.63 s, 2.6 and 7.9 m·s<sup>-1</sup>, and 0.35 and 3.4 m·s<sup>-1</sup> when the stiffness of leg joints changed within their limits. Additionally, hip stiffness is the most influential one affecting both variables (*i.e.*, the falling duration and impact speeds). Knee stiffness also affected both variables when < 4 Nm·deg<sup>-1</sup>. Ankle stiffness showed little influence on the falling dynamics.

## Significance

The influence of the joint stiffness on the falling dynamics (falling duration and impact speeds) is comparable between hip and knee. Whereas, ankle stiffness showed little influence on the falling dynamics. Because the hip and knee are the primary joints controlling the falling dynamics, training on proximal joints may be considered to reduce falling risks. Our findings could also inform the design of protective devices to prevent impact-induced injuries after a fall in individuals with high risk of falls.

**Figure 1:** The effect of the stiffness of knee and hip on (A) falling duration, (B) the head speed, and (C) the hip speed at impact.

**Figure 2:** Body postures at impact at selected stiffness of ankle ( $k_{ankle}$ ), knee ( $k_{knee}$ ), and hip ( $k_{hip}$ ).

# Evaluation of an app for vestibular rehabilitation of older adults with motion controlled games and remote monitoring

## Introduction

About half of people aged over 60 experience vestibular dysfunction [1]. Vestibular rehabilitation has been proven effective in reducing dizziness and falls [2]. However, adherence remains a major problem and can be below 50% [3]. Clinicians typically rely on self-reporting to assess adherence and do not know if exercises were performed correctly at-home. Therefore, this research aimed to develop an app with gaming elements and remote monitoring to improve adherence of older adults to vestibular rehabilitation.

## Methods

A mobile (smartphone or tablet) app containing games for the vestibular ocular reflex (VORx1) exercise was developed using Felgo (FELGO GmbH). The app allows exercise prescription and assesses dizziness and balance (Dizziness Handicap Inventory (DHI) [4], Activities based Balance Confidence scale (ABC) [5]; Figure 1). Games are controlled by an Inertial Measurement Unit (IMU; SensorTag, Texas Instruments) placed on the head using an elastic band. Sensor orientation (roll, pitch, yaw) was computed using the Madgwick algorithm [6]. Assessment measures are calculated using IMU data and sent to a cloud-based database for further analysis. Six females aged over 65 undergoing vestibular rehabilitation used the app after providing written informed consent (IRB approval by University of Pittsburgh). Head range of motion and velocity during VORx1 were recorded while participants performed the exercises with and without the app. Participants then answered a questionnaire to evaluate ease of use, enjoyment, motivation, use intention, and usefulness of the app.

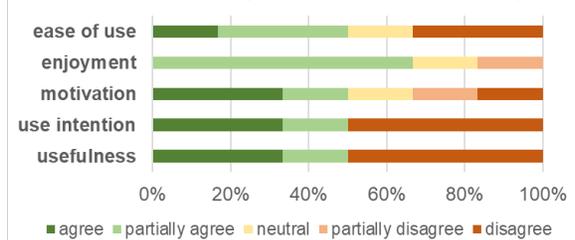

**Figure 1:** Three different levels of exercise for VORx1 in the pitch and yaw direction plus for a balance exercise. The various levels of visual stimuli are tailored to vestibular dysfunction severity.

## Results and Discussion

DHI scores ranged between 24 and 72 (mean: 46, SD: 18.5). Questionnaire responses (Figure 2) showed half the participants felt the app was useful and would motivate them to do their exercises. They reported they enjoyed the app and would use it again. The more negative responses came from the same three individuals, whose DHI scores (mean 44) did not differ from the overall group. Anecdotal feedback from these individuals

suggested the negative responses were due to frustration playing the games and not knowing what to expect. This will be addressed in the future by adding a slower speed practice game. Sensor data demonstrated participants performed exercises with similar head range of motion and velocity with and without the app (Table 1).

**Figure 2:** Overview of evaluation of the vestibular app by six older adults undergoing vestibular rehabilitation.

**Table 3:** Comparison of sensor data of the six older adults performing exercises with the app and traditionally (mean ± standard deviation).

	Angle (°)		Velocity (°/s)	
	App	Traditional	App	Traditional
<b>Flexion</b>	19±5	22±6	106±42	91±41
<b>Extension</b>	26±9	25±6	94±44	97±44
<b>Left</b>	23±6	25±1	85±31	98±45
<b>Right</b>	24±7	32±5	102±16	98±47

## Significance

This study demonstrated that patients performed their vestibular rehabilitation similarly with an app and traditional care. Evaluation highlighted areas for improvement and showed that elderly female participants enjoyed having their rehabilitation delivered in the form of a gaming app. Although some gaming approaches have been used successfully with older adults, this is the first study to demonstrate feasibility of this approach for those with vestibular problems and rehabilitation specific games.

## Introduction

Balancing a large mass over a small Base of Support (BOS) is a major challenge for humans in bipedal stance. It is important that the Center of Mass (COM) remain within the BOS in order to maintain the balance. [1] Postural stability testing provides a valuable tool for objectively evaluating the motor domain of neurologic functioning. [2] Analysis of coherence between EMG signals provides a means of examining the characteristics of common neural inputs to co-contracting muscles during voluntary contraction. EMG-EMG coherence helps to determine the oscillatory input to the muscle. [3]

The primary objective of this project was to analyze the coherence between the pairs of EMG signals from the lower leg in different frequency bands to examine the common neural input characteristics to the muscles during tandem stance balance test.

## Methods

Six healthy individuals (3 males; age: 24.1±3.5 yrs; Ht.: 167.4±5.5 cm; Wt.: 71.1±5.5 Kg) participated. Approval was obtained from the Grand Valley State University Human Research Review Committee (IRB#18-246-H). Employing a full body Plug-in-Gait model, 16 Vicon MX cameras (120 Hz) and Nexus motion capture software were used to track anatomical marker trajectories. Ground reaction forces were collected at 1200 Hz, using floor embedded AMTI force platforms. The EMG signals from the lower legs; Anterior Tibialis (AT), Medial Gastrocnemius (MG) and Soleus (SOL) were collected at 1200 Hz using Motion Lab System.

Data were collected with participants standing with arms crossed on two force plates under four different conditions – feet together eyes open (FTEO), feet together eyes closed (FTEC), tandem eyes open (TanEO) and tandem eyes closed (TanEC). The tandem standing position was done with the dominant foot (right foot dominant if right-footed) placed on a rear force plate and the non-dominant foot placed on the fore force plate with knees extended and maintaining equal distribution of weight on each force plate. Data were collected for 30 seconds and five trials were collected under each condition.

The raw EMG signals were used for further analysis to examine the intermuscular coherence between pairs of muscles in different neural frequency bands i.e. gamma (30–100 Hz), beta (13–30 Hz), alpha (8–13 Hz), theta (4–8 Hz) and delta (1–4 Hz) using wavelets and magnitude squared coherence. A time-frequency coherence analysis was performed between different muscle pairs.

## Results and Discussion

Strong coherence was found at all frequency bands between the MG and SOL muscle on the right leg, particularly in the delta band (Figure 1). The coherence between the muscle pairs from the same leg were significantly greater during the eyes closed and least stable postures. Previous research also demonstrated stronger coherence between the lower leg muscles within the same leg at the lower frequencies. [4] Dispersion (i.e., standard deviation) of mean muscular coherence was increased in the lower frequency bands and during more complex stability postures. Maximum dispersion for all muscle pairs was observed in the tandem, eyes closed condition. The time frequency analysis also showed greater coherence for muscle pairs RMG and RS in the right leg for the tandem stance posture (Figure 2).

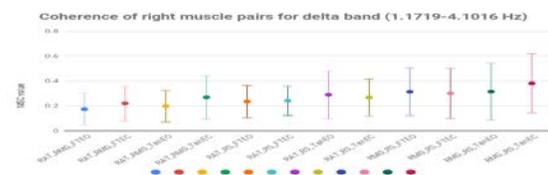

Figure 1: Mean coherence of the right muscle pairs with standard deviation for delta frequency band

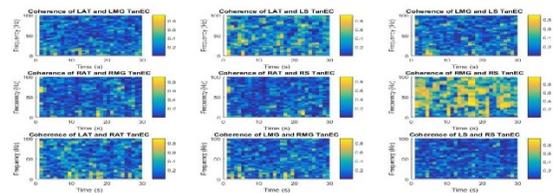

Figure 2: Time-Frequency coherence spectrogram of different muscle pairs for TanEC

## Significance

The result of this study might help to provide a benchmark to compare the neural function of athletes who have suffered from concussive damage to our normal, healthy control subjects.

## Acknowledgements

# Human-human hand interactions assist walking balance by acting more like a “brake” than a “motor”

Mengnan Wu<sup>1</sup>, Luke Drnach, Sistania M. Bong, Yun Seong Song, and Lena H. Ting<sup>1</sup>

Email: \*[mengnan.wu@emory.edu](mailto:mengnan.wu@emory.edu)

## Introduction

A human can improve another person’s balance during walking through haptic interaction by holding hands, but it is unknown *how* these interactions affect balance. The current study characterized the effects of hand contact with a partner during a balance-challenging walking task and examined how hand forces were used to assist balance.

We hypothesized that mechanical power transfer at the hands is used to assist balance during partnered beam-walking, characterized by braking or propulsion. Previous work showed that hand interaction forces were small during a partner-dance task and likely used only for communication<sup>[1]</sup>, but the task did not challenge balance and thus did not require significant physical assistance.

We further hypothesized that the forces at the hand can be directly related to the beam-walker’s balance performance through a linear mass-spring-damper model. If so, kinematics and kinetics of the interaction point at the hands could be used to predict task performance of the individual.

## Methods

We measured whole-body kinematics and hand forces in 12 pairs of healthy young adults. During the main experimental condition, one person walked on a narrow (2 cm wide) balance beam with a partner walking by their side overground (Fig. 1a). Each partner held one end of a custom handle that measured interaction forces.

We compared balance performance of the person walking on the beam during the partnered condition vs. when they walked on the beam solo. We quantified performance by the beam-walker’s lateral sway, distance completed on the beam, and mean forward walking speed.

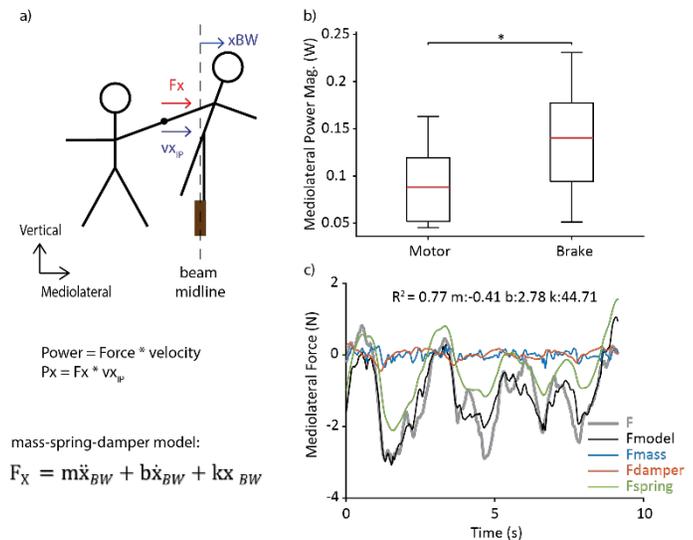

We compared force and mechanical power at the interaction point (Fig. 1a) during partnered beam-walking vs. during partnered overground walking to examine energy exchange for balance assistance.

Finally, we fit the interaction force to the beam-walker’s clavicle displacement, velocity, and acceleration as a mass-spring-damper system (Fig. 1a) in the mediolateral direction during the partnered beam-walking condition.

## Results and Discussion

Our results show that all balance performance metrics improved during partnered beam-walking vs. solo beam-walking ( $p < 0.05$ ). Lateral sway decreased by 4.2cm and mean forward walking speed increased by 0.24m/s. The mean distance completed during solo beam-walking was 1.8m while every person completed the entire beam length (3.7m) during every partnered beam-walking trial.

Magnitudes of mediolateral interaction forces and power were small during partnered beam-walking:  $\sim 2\text{N}$  and  $\sim 0.1\text{W}$ , respectively. They were, however, 1.2N and 0.073W larger, respectively, than during partnered overground walking ( $p < 0.05$ ). Mean force magnitudes during partnered beam-walking were also higher than the 1N threshold for light touch<sup>[2]</sup>

**Figure 1:** a) Partner (left) and beam-walker (right) during partnered beam-walking condition. Lateral hand interaction force ( $F_x$ ) and power exchange is calculated at the interaction point (IP). A mass-spring-damper model relates interaction force to beam-walker’s lateral displacement ( $x_{BW}$ ), velocity, and acceleration relative to the beam midline. b) Negative (“braking”) power is greater in magnitude than positive (“motor”) power for partnered beam-walking across all pairs. c) Measured force, modeled force, and force components from mass-spring-damper model for example “spring-like” pair during partnered beam-walking.

( $p < 0.05$ ). These results suggest that interactions at the hand provide mechanical support for balance assistance.

Mean negative power magnitude was greater than mean positive power magnitude during partnered beam-walking ( $p < 0.05$ ), indicating that hand contact assists balance during walking by acting more often as a “brake” than a “motor” (Fig. 1b).

Results from the mass-spring-damper model showed that the interaction forces restored balance similar to a passive spring and/or damper in the lateral direction, but some partnerships were more “spring-like” (Fig. 1c) or “damper-like” than others, suggesting different interaction strategies.

## Significance

Hand interactions with a partner have low force and affect a person’s whole-body balance performance through mechanical power transfer, which is dominated by braking energy. This principle may be used in design of devices and robotic controllers to assist walking balance. Forces at the interaction point in haptic assistance can contain sufficient information for altering balance performance of the individual.

# Dance Interventions Improving Balance in Parkinson's Disease: A Systematic Review with Meta-Analysis

Caroline Simpkins MS<sup>1</sup>, Jennifer Lees BS<sup>1</sup>, and Feng Yang PhD<sup>1</sup>  
<sup>1</sup>Georgia State University, Department of Kinesiology & Health, Atlanta, GA  
 Email: [fyang@gsu.edu](mailto:fyang@gsu.edu)

## Introduction

Parkinson's disease (PD) is a prevalent neurodegenerative disease.<sup>1</sup> Balance, gait, and postural stability impairments are common in people with PD, and this population experiences a higher risk of falling compared to their healthy counterparts.<sup>2</sup> To improve or maintain quality of life (QOL) for people with PD, reducing the likelihood of falling is vital. Dance-based interventions could be an attractive alternative to traditional exercise for people with PD and have shown promise in providing health benefits. Current information about the effect of dance interventions on balance in people with PD is limited due to the small number of articles included in previous reviews. This may negatively impact the deployment of this type of therapy. An updated meta-analysis based on a larger number of randomized controlled trials (RCT) and utilizing a rigorous calculation of effect size (ES) is necessary to advance our understanding of the influence of dance therapy on balance in this population.

The purpose of the current meta-analysis was to analyze the efficacy of dance-based interventions in improving balance among people with PD in comparison to exercise interventions or no intervention. As balance is essential to activities of daily living and closely related to falls, findings from this study could inform the design of dance interventions to reduce falls and heighten QOL among people with PD.

## Methods

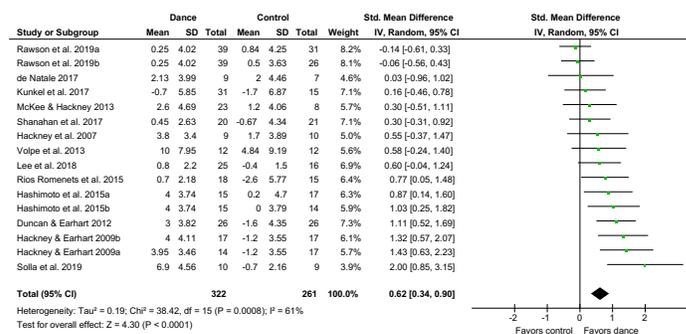

A systematic literature search was conducted in PubMed, PsycINFO, Cochrane Library, CINAHL, and MEDLINE using search terms "Parkinson" and "danc" and "balance." No restrictions were placed on type of dance or the stage of disease, sex, or age of PD participants. The initial search yielded 175 articles and 94 remained after removing duplications. Remaining studies were checked with the inclusion criteria: 1) peer-reviewed article published in English; 2) conducted among people with PD; and 3) RCT including at least one dance-based intervention arm and a control or placebo arm. Thirteen studies met the inclusion criteria.<sup>3-15</sup> Quality assessment was performed using the Physiotherapy Evidence Database (PEDro) scale.

Information about the article (author(s), publication year), the participants (sex, age, Hoehn and Yahr stage, assessed on/off medication) and interventions (dance type, control type, frequency, duration) were collected from each article. In addition, sample size and balance outcome measures were retrieved. Values for the balance measurement were extracted in the form of means and standard deviations (SD) for both the dance intervention and comparison conditions at two time points (baseline and post-intervention). Changes in balance from baseline to post-intervention and their SD were calculated from the identified means and SD if not given. A meta-analysis was conducted using a random-effects model based on data from all 13 studies within RevMan 5.3 (Denmark).

## Results and Discussion

Average PEDro value of the 13 studies was  $5.62 \pm 0.49$  (out of 10). Balance was assessed by Berg Balance Scale, Mini Balance

Evaluation System Test, or Fullerton Advanced Balance Scale among studies. The ES varied drastically from -0.14 to 2.00 (Fig. 1). Our meta-analysis on the 16 comparisons yielded a significant and medium ES indicating that dance interventions benefit people with PD to improve balance (ES = 0.62, 95% CI = [0.34, 0.90],  $p < 0.0001$ ). Our results suggest that dance therapy has the potential to safely and effectively improve balance and possibly contribute to lower rates of falls among people with PD.

**Figure 1:** Forest plot of effect sizes (the standardized mean difference) for 16 comparisons between dance interventions and control groups reported by 13 studies assessing the effect of dance-based interventions on balance in people with Parkinson's disease.

## Significance

Our findings could inform future studies for designing and deploying effective dance-based balance training and fall prevention programs specific to PD. More high-quality RCT with large sample sizes are needed to further explore the effects of various dance types in improving balance compared to other modes of exercise. The retention effects of dance-based therapies among people with PD should also be addressed in future studies.

# Margin of Stability during Tandem Stance with Dominant Limb Placed Back or Forward: A Pilot Study

Gordon Alderink<sup>1</sup>, Yunju Lee<sup>1,2</sup>, Diana McCrumb<sup>2</sup>, Samhita Rhodes<sup>2</sup>,

<sup>1</sup>Department of Physical Therapy, Grand Valley State University, Grand Rapids, MI, USA

<sup>2</sup>School of Engineering, Grand Valley State University, Grand Rapids, MI, USA

Email: [aldering@gvsu.edu](mailto:aldering@gvsu.edu)

## Introduction

Balancing a large mass over a small base of support (BOS) is a challenge for humans in bipedal stance. To maintain control of balance, the center of mass (COM) must remain within the BOS [1]. Center of pressure (COP) displacement and velocity parameters are commonly used to measure static [2], and dynamic balance [3]. Winter et al. demonstrated high correlations between net COP and partitioned right and left limb COPs during tandem standing and medio-lateral control of balance [4]. More recently, postural stability has been measured using the margin of stability (MOS), which accounts for COM velocity [5]. MOS has not been used to examine control of balance during tandem, i.e., heel-to-toe, stance. The primary objective of this project was to examine range and velocity in the COP and range of MOS under four conditions during tandem standing. We hypothesized that the COP and MOS range would increase under the eyes closed condition, but there would be no difference in COP and MOS when foot positions were changed.

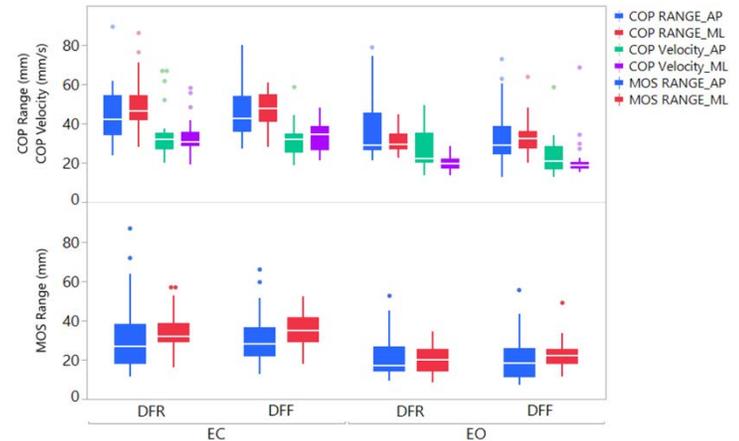

## Methods

Six healthy individuals (4 females; 24.8±3.3 yrs; 170.8±10.5 cm; 71.0±13.5 kg) participated. Approval was obtained from the Grand Valley State University Human Research Review Committee (#18-246-H). Employing a full body Plug-in-Gait model, 16 Vicon MX cameras (120 Hz) and Nexus motion capture software v2.9.2 (Oxford Metrics) were used to track anatomical marker trajectories. Ground reaction forces were collected at 1200 Hz, using floor embedded AMTI force platforms (Advanced Mechanical Technology Inc). Data were collected with participants standing, with arms flexed, hands touching shoulders, on two force plates under four conditions: 1) eyes open (EO) dominant foot on rear plate; 2) eyes closed (EC) dominant foot on rear plate; 3) eyes open dominant foot on fore plate; and 4) eyes closed dominant foot on fore plate. Participants were asked to stand with knees extended, while maintaining equal distribution of weight on each force plate. Data were collected for 30 seconds and five trials were collected under each condition. Vicon Nexus software was used to determine location of the COM. Custom MATLAB code (MathWorks) was used to determine the combined (from the rear and fore force plates) COP location and MOS [5]. A repeated measures variance of analysis (2 factor rm-ANOVA within subject) was used to test the effect of vision and foot placement ( $p < .05$ ) for range (the maximum distance between any two points) and velocity of COP and range of MOS in antero-posterior (AP) and medio-lateral (ML) directions.

## Results and Discussion

The main effect of vision on range and velocity of COP and range of MOS, in both AP and ML directions demonstrated significant differences ( $p < .001$ ) (Figure 1), i.e., increased under the EC condition. These findings are consistent with select findings from Thomson et al. [2].

The foot position affected only COP velocity in the AP direction. Interaction effects were found in range and velocity of COP and in range of MOS in ML direction. Although we instructed participants to maintain equal weightbearing on the front and back feet, we noticed a tendency to bear more weight on the rear plate regardless of dominance. It is possible that leg dominance itself is not as important as vision to control standing balance; however, leg dominance might affect tandem standing in ML direction.

**Figure 1** : COP and MOS in antero-posterior (AP) and medio-lateral (ML) directions. DFR = dominant foot rear; DFF = dominant foot fore; EC = eyes closed; EO = eyes open. Y axes include range in mm and velocity in mm/sec.

## Significance

It is clear that there are differences in COP displacement and velocity between healthy and concussed athletes in standing balance tasks when eyes are open or closed [6,7,8]. It has also been shown that MOS may better capture dynamic balance because it accounts for the inherent velocity of the COM, i.e., extrapolated COM [5]. Our results also show that both COP and MOS range are increased under EC, a less stable position. Our data suggest that MOS may also be useful to measure residual central nervous system impairment in balance following concussion.

# Coordination responses to a change in walking speed do not differ with age or knee osteoarthritis

Jocelyn F. Hafer<sup>1</sup> and Ronald F. Zernicke<sup>2</sup>

<sup>1</sup>University of Delaware, <sup>2</sup>University of Michigan

Email: jfhafer@udel.edu

## Introduction

Aging and knee osteoarthritis (OA) are associated with changes in gait. These age- or OA-related changes may coincide with altered coordination during gait, potentially indicating a limited ability to adapt to new situations. An inability to adapt to challenges during gait could partially explain the higher incidence of falls in older vs. young adults [1] and those without vs. with knee OA [2]. Testing responses to a challenge such as walking faster may reveal differences in how age or knee OA affect the motor system's ability to adapt and may indicate a need for different interventions by patient population. We sought to determine whether older adults who were asymptomatic or who had knee OA had different coordination responses to an increase in walking speed compared to each other and to young adults. We hypothesized coordination would change differently between participant groups when they walked faster.

## Methods

Three groups were recruited: young (28±5 yrs, n=10), older asymptomatic (72±3 yrs, n=10), and older with knee OA (69±5 yrs, n=9). Pelvis, thigh, shank, and foot angular velocities were collected with inertial measurement units as individuals walked on a treadmill at preferred and faster speeds (i.e., young walked faster than older and knee OA (+0.3 m/s) but all groups increased speed similarly (+0.3 m/s) from preferred to faster). Angular displacements about each segment's primary axis of rotation during gait (≈sagittal) were estimated using functional calibration and a zero-velocity update algorithm [3]. Coordination was calculated between adjacent segments using a modified vector coding technique for 100 strides of data [4]. Coordination phase angles were compared between groups and speeds across sub-phases of swing and stance using circular 2-way ANOVAs with  $\alpha=0.05$ . Post-hoc comparisons were made with 1-way ANOVAs.

## Results and Discussion

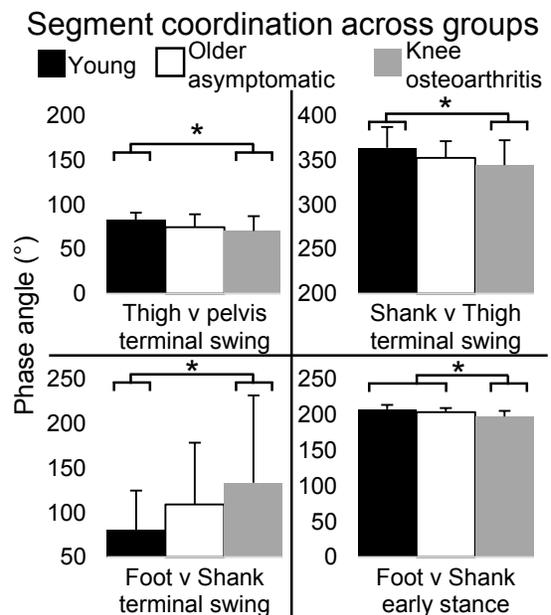

Contrary to our hypothesis, there were no significant interactions between group and speed. However, there were significant main effects of group and speed (p-values for significant group effect post-hocs and significant speed effects reported below).

During terminal swing, young adults and adults with knee OA had different phase angles for the thigh v pelvis ( $p=0.04$ ) and shank v thigh ( $p=0.05$ ) (Fig 1). Despite these differences, all groups had similar phase angle patterns for thigh v pelvis (distal segment phase) and shank v thigh (proximal segment phase) during terminal swing. For the foot v shank couple, adults with knee OA had different phase angles from young adults during terminal swing ( $p<0.01$ ) and from young and older asymptomatic adults during early stance ( $p<0.01$  and  $p=0.05$ , respectively). Here, young adults had distal phase patterns ( $81\pm44^\circ$ ) while adults with knee OA had anti-phase patterns ( $134\pm98^\circ$ ) during terminal swing, and young and older asymptomatic adults had in-phase patterns ( $208\pm6^\circ$  and  $204\pm6^\circ$ ) while adults with knee OA had proximal phase patterns ( $198\pm8^\circ$ ) during early stance.

Coordination also changed with increased walking speed for the shank v thigh and foot v shank during terminal swing, and for

the foot v shank during early stance (all  $p<0.01$ ). At the thigh v shank, phase angle patterns were the same between speeds. At the foot v shank, phase angle patterns shifted from anti- ( $140\pm79^\circ$ ) to distal phase ( $75.7\pm49.3^\circ$ ) in terminal swing and from proximal ( $201\pm7^\circ$ ) to in-phase ( $206\pm7^\circ$ ) in early stance with faster speed.

While we did not find a differential effect of walking speed on coordination across age or musculoskeletal pathology, we did identify consistent differences in coordination at the transition between swing and stance. Because this time in the gait cycle may be a naturally unstable transition, differences in coordination between groups may be an indicator of instability or fall risk.

**Figure 1.** Segment coordination phase angles averaged by group across speeds. \*Indicates significant post-hoc difference between groups.

## Significance

Differences in coordination patterns between young adults and older adults with knee OA around the transition from swing to stance phase could be an indicator of or risk factor for falls. In this study, we did not assess fall history and so we cannot determine whether differences in coordination are a predictor of future falls or a correlate of fall incidence. Interestingly, the same couples that differed by age or knee OA status shifted towards young coordination patterns with faster walking speed. Greater effort during faster walking may have required a shift to adopt younger coordination patterns. While contrary to our hypothesis that groups would respond differently to the challenge of faster walking, this response may be useful in interventions to reduce instability or falls risk.

# Effects of Sole Thickness on Recovery from an Unexpected Slip during Standing

Jiyun Ahn<sup>1</sup>, Meng-Wei Lin<sup>1</sup>, Jennifer Lees<sup>1</sup>, Kelsey Clark<sup>1</sup>, Feng Yang<sup>1</sup>

<sup>1</sup>Department of Kinesiology and Health, Georgia State University, Atlanta, GA 30303, USA

Email: jahn12@gsu.edu

## Introduction

Wearing inappropriate footwear has been identified a risk factor of falls [1]. Among the mechanical properties of shoes, the sole thickness is highlighted as a major contributor to falls. Previous studies indicated that the thicker the sole, the greater the risk of falls [2,3]. One possible explanation is that a thick sole impedes the detection of an external perturbation, delays the reactions to the balance disturbance, and thus reduces the likelihood of a successful recovery from a balance loss. Although this theory seems intuitive, no study has specifically inspected how sole thickness alters postural balance maintenance and the likelihood of falls after an unexpected perturbation. The purpose of this study was to explore how the sole thickness impacts the body's reactions to a stance-slip. It was hypothesized that increased shoe sole thickness delays the body's reactions to the slip perturbation.

## Methods

Nine young adults ( $25.3 \pm 1.5$  y/o) were recruited and evenly randomized into three groups: barefoot (0 mm sole thickness), thin (5 mm), and thick sole (10 mm). The barefoot group underwent the protocol without footwear. The thin/thick group wore a pair of 5/10 mm foamboards secured by tape to their soles during the experiment. The foamboard was individually cut to fit each participant's sole.

After about 5-min familiarization (walking with respective footwear condition over ground), each participant stepped onto the ActiveStep treadmill (Simbex). They put on a safety harness connected to overhead arch through ropes. Following five standing trials on the treadmill, each participant experienced an unexpected stance-slip [4]. The slip distance and acceleration were respectively 36 cm and  $4 \text{ m/s}^2$ . Full-body kinematics during the slip trial were captured from reflective markers attached to the body using a motion capture system (Vicon). A marker was also applied to the treadmill belt to identify the onset of the treadmill belt movement. The paths of the markers were filtered and used to determine the liftoff and touchdown of the recovery step after the slip occurrence, and three outcome variables: the step latency (the interval from the belt slip onset to the liftoff of the recovery step), step duration (from liftoff to touchdown), and step length (the anteroposterior distance between heels at recovery foot touchdown). Analysis of variance, followed by independent *t*-tests, was adopted to compare the outcomes among groups (0 vs. 5 vs. 10 mm). All analyses were conducted using SPSS 24 (IBM) with an  $\alpha = 0.05$ .

## Results and Discussion

The step latency ( $p < 0.01$ , Fig. 1a) and length ( $p = 0.01$ , Fig. 1c) showed a significant overall group-related difference. The step duration was not different among groups ( $p = 0.74$ , Fig. 1b). Post-hoc tests revealed that both the thin and thick groups exhibited a significantly longer step latency than the barefoot group. Additionally, the thick group showed a longer step latency than the thin group. Similarly, the recovery step length was significantly greater among the thin and thick groups than

in the barefoot group.

The results overall support our hypothesis that a thick sole could hinder the body's reactions to an unexpected slip perturbation. Specifically, the thicker the sole, the longer the step latency, indicating more time is needed to sense the perturbation and to plan the recovery step. The aftereffects of the same slip perturbation become more intense as sole thickness increases due to the increasingly delayed initiation of the recovery step. To arrest the backward falling trunk induced by the slip, individuals with thicker soles must take a larger recovery step to regain the body's balance, evidenced by the lengthened recovery step as the thickness of the sole rises. As timely reactions are critical for one to reestablish balance and reduce the chance of falling, thick soles could increase one's risk of falls should an external perturbation occur. Although the step duration did not differ among groups, a trend emerges that the step duration increases as the sole becomes thicker (Fig. 1b). This could be explained by the fact that individuals with thicker soles, in comparison with those with thin or no soles, need to spend longer time to execute the recovery step in order to achieve a longer step length which can effectively regain the body's balance. One limitation in our study is the small sample size. We postulate that non-significant results could be reversed with a larger sample size.

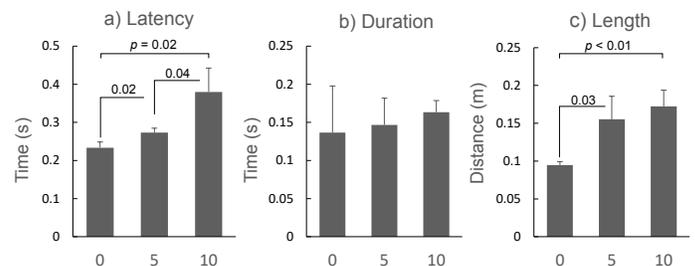

Figure 1. Comparisons of a) latency, b) duration, and c) length of the recovery step in response to an unexpected stance-slip among the three groups: barefoot (0 mm), thin (5 mm), and thick (10 mm).

## Significance

This study will enhance our understanding of the effects of the sole thickness on the risk of falls. The results could furnish some references for physicians prescribing appropriate footwear to individuals with high risk of falls. In addition, our findings could inform the design of fall-resistant footwear from the perspective of the sole thickness.

## Acknowledgments

The authors thank Shreya Kulkarni and Phum Tuntiansin for assisting with the data collections.

# Muscle activation pattern during a fall from standing height

Kwang Jun Lee<sup>1</sup>, Ki-taek Lim<sup>1</sup>, Jisoo Jang<sup>1</sup>, Woochol Joseph Choi<sup>1</sup>

<sup>1</sup>Injury Prevention and Biomechanics Laboratory, Department of Physical Therapy, Yonsei University, Wonju, South Korea

Email: [wjchoi@yonsei.ac.kr](mailto:wjchoi@yonsei.ac.kr)

## Introduction

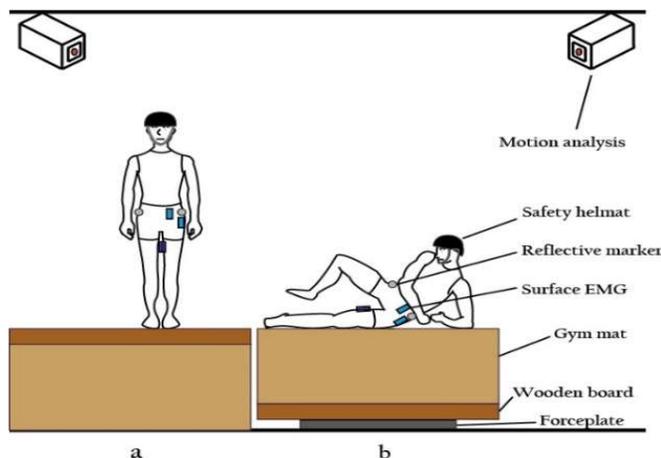

Pre-impact fall detection algorithms have been proposed based on threshold values of velocity, acceleration and/or angle changes of body segments during a fall. However, the practical use of the algorithms is limited due to incomplete sensitivity and specificity [1].

We propose to use lower extremity muscle activation pattern to detect a fall prior to impact, and the first step is to confirm whether there exists a special muscle activation pattern, which is not affected by a variety of fall kinematics. Therefore, we conducted falling experiments with humans to measure lower extremity muscle activation, and examined how this was affected by fall direction and knee position at landing.

## Methods

Twenty individuals mimicked older adults' falls and landed sideways on a 30 cm thick gymnasium mattress (Figure 1). Falling trials were acquired with three initial fall directions: forward, backward or sideways. Trials were also acquired with three knee positions at the time of hip impact, where the landing-side knee was being contacted the mat (KOM), the contralateral knee (KOK), or free of constraint (KF). Electrodes of surface electromyography (EMG) (TeleMyo DTS, Noraxon Inc., AZ, USA) were placed on the belly of iliopsoas (Ilio), adductor longus (ADDL), gluteus medius (Gmed) and gluteus maximus (Gmax). Fall kinematics and kinetics were monitored through a motion capture system (Vicon Motion Systems, Oxford, UK) and a forceplate placed under the mat (AMTI, model OR6-7-2000, Waltham, MA, USA), respectively.

Outcome variables included time to onset, activity at the time of hip impact, and timing of peak activity with respect to the time of hip impact. ANOVA was used to test if these outcome variables were associated with fall direction (3 levels) and knee position at the time of hip impact (3 levels).

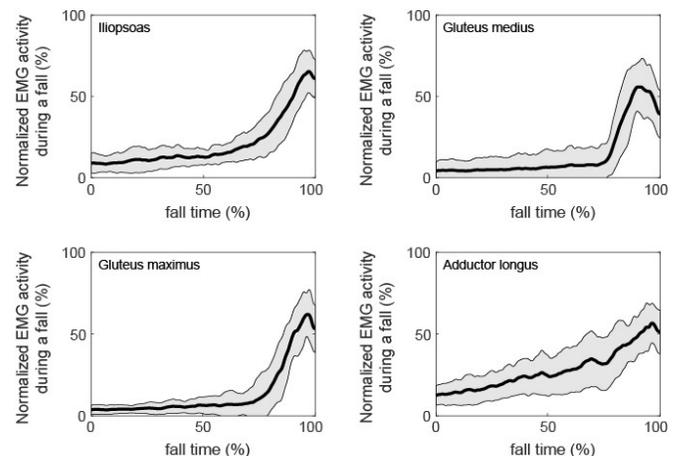

**Figure 1:** Experimental setup. (a) Participants self-initiated falls and (b) landed sideways on a 30 cm thick mattress.

## Results and Discussion

On average, given time available during a fall (941 ms, time between fall initiation and hip impact), lower extremity muscles started to contract at 393 ms after fall initiation, and reached maximum contraction at 39 ms prior to the hip impact. Furthermore, the lower extremity muscles contracted 49% of their maximum when the hip impacted the mat (Figure 2). These baseline measures should be informative for the development of myoelectric pre-impact fall detection algorithms.

For each lower extremity muscle, none of outcome variables were associated with fall direction and knee position, except activity at the time of hip impact of Gmed and ADDL, where Gmed was associated with fall direction and knee position ( $F = 5.57$ ,  $p = 0.013$ ;  $F = 4.08$ ,  $p = 0.027$ , respectively) and ADDL was associated with fall direction ( $F = 5.28$ ,  $p = 0.011$ ). This is an important finding as pre-impact fall detection through lower extremity muscle activity pattern may provide 100% of sensitivity and specificity in detecting falls, no matter how they fall and land. Since activation patterns of gluteus medius and adductor longus muscles were affected by fall types, gluteus maximus and/or iliopsoas muscles could be a good target to be used for pre-impact fall detection.

**Figure 2:** Average EMG activity (thick line) across all 540 falling trials with +/- 1 standard deviation (thin line).

## Significance

A special activation pattern of lower extremity muscles exists during a fall, informing the development of prevention strategies for fall-related injuries in older adults (i.e., pre-impact fall detection, balance recovery).

## Introduction

To maintain stability during walking, the body's center of mass (COM) must be controlled effectively within the base of support provided by the feet. In general, margin of stability (MOS) is defined as the distance between the extrapolated COM (i.e. a point on the floor at a distance from the COM that is directly proportional to the COM velocity) with respect to the limits of the base of support during walking in the anterior posterior (AP) and mediolateral (ML) directions [1, 2].

Decreased dynamic stability can be described by decreasing the mean and/or increasing the variability of MOS. During unperturbed walking conditions, dynamics of stepping are expected to result in a similar trend of stability outcomes during walking at different speeds for both overground and treadmill walking. The aim of this study is to determine if walking on a treadmill vs. overground will affect MOS at heel contact during three, speed-matched conditions.

## Methods

Twelve healthy young participants, (24.8±5.1 years; 73.0±11.8 kg; 1.74±0.07 m) without any disorders that would cause abnormal gait control were recruited to this study. Participants walked on a treadmill and overground at slow, preferred, and fast speed-matched conditions, while kinematic (marker) data were collected. Four participants' data were not included due to insufficient number of speed-matched steps across modes of walking.

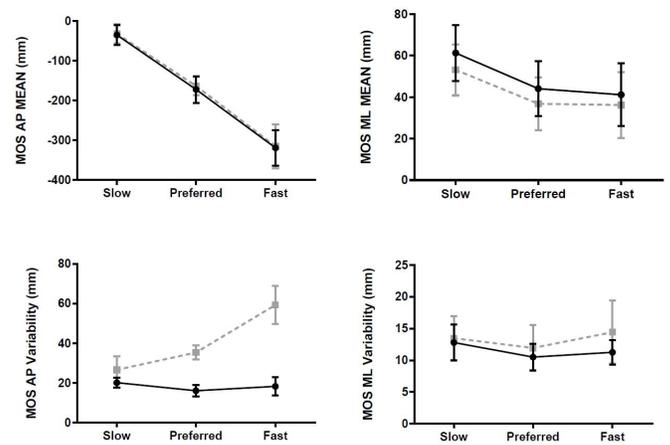

The mean and variability (standard deviation) of the MOS in AP and ML directions at heel contact were calculated for 18 right and left steps during overground and treadmill trials. All models were adjusted for preferred speed. ML mean models were adjusted for step width. AP variability models were adjusted for step speed standard deviation. ML variability models were adjusted for step width standard deviation. To identify the main effect of walking mode (treadmill vs. overground) and speed conditions (slow, preferred, fast), and the possible interaction between walking mode and speed, generalized linear model were used. The significance threshold was  $\alpha=0.05$ .

## Results & Discussion

No significant effect of walking mode was found for MOS AP mean; however, walking faster led to more negative MOS AP mean in both walking mode conditions ( $p<0.0001$ ). This indicated that the extrapolated COM was further anterior to the base of support as they walked faster, thereby reducing stability. There was a significant interaction between speed and walking mode ( $p<0.0001$ ) for MOS AP variability, where overground was more variable than treadmill walking for fast and preferred walking speeds, but not slow speeds. (Figure 1). Greater variability of MOS AP when walking faster may be the result of natural fluctuations during overground walking, while on the

treadmill, variability remained consistent due to a more repetitive pattern of stepping.

MOS ML mean during fast and preferred speed was significantly narrower compared to slow (adjusted  $p$ 's  $<0.0001$ ) indicating less stability. This could be due to maintenance of frontal plane stability in the presence of more challenges to the motor control system in the presence of increased COM displacement at slower speed [3]. MOS ML mean during treadmill walking was wider than overground ( $p=0.01$ ) indicating more stability. In the absence of natural optic flow during treadmill walking, as well as different proprioceptive input (legs being pulled back during treadmill versus remaining stationary during overground), subjects may employ strategies to increase stability. A significant interaction for MOS ML variability was found, however, no significant pairwise comparisons were found upon post hoc analysis.

**Figure 1:** MOS mean (top) and variability (bottom) values in AP (left) and ML (right) directions. Treadmill is represented by black solid lines and overground by gray dashed lines.

## Significance

Walking mode matters when we look at the variability, while the trend for absolute mean values stays the same, although they are scaled differently in the ML direction. Walking faster is more variable (overground) and less stable than slower walking (narrower MOS).

## Introduction

Falls become significant health risks of death or injury for the elderly. Although the post-fall detection system is unable to prevent falls, it can help victims quickly. The performance of post-fall detection of various classifiers could be improved by selecting feature vectors based on T-score ranking algorithm [1]., 13 ranking algorithms have been introduced and evaluated for the classification [2]. This study aimed to determine the performance of post-fall detection based on a subset of feature vectors using different ranking algorithms.

## Methods

Thirty healthy volunteers performed 9 simulated falls and 14 ADL movements (Table 1). 3-axis accelerations and 3-axis angular velocities were measured using an IMU sensor attached to the middle of LASI and RASI. ANN was applied to IMU data to determine fall and non-fall. Eight different feature vectors were introduced as shown in Table 2 and ranked using five Ranking algorithm: ReliefF[3], T-score[4], Correlation[5], Fisher Score[4] and mRMR[6]. Each ranking algorithm was evaluated by absolute errors (AE). Then, feature vector subsets were created according to the number of feature vectors and applied to the ANN classifier. Data from 10 subjects were used to train the ANN classifier and data from the remaining 20 subjects were used to test the classifier.

**Table 1:** Experimental Protocol

	Motion
Fall	slip-backward fall, walk-trip-forward fall, jogging-trip-forward fall, sit down-backward fall, sit- backward fall, forward fall, backward fall, lateral fall, and twist fall
ADL	walking, jogging, squat, waist bending, stumble while walking, Jogging in place, jumping, stairs up and down, slowly sit and up in stool, quickly sit and up in chair, trying to get up and collapse in to a chair, lying, slowly sit and up in low height mattress, and quickly sit and up in low height mattress

**Table 2:** Feature Vectors

Feature	Equation
ASVM	$C_1[k] = \sqrt{a_x^2[k] + a_y^2[k] + a_z^2[k]}$
ASVMHP	$C_2[k] = \sqrt{a_x^2[k] + a_z^2[k]}$
TA	$C_3[k] = \text{atan2}(\sqrt{a_x^2[k] + a_z^2[k]}, -a_y[k])$
Jerk	$C_4[k] = (a_x[k] - a_x[k-1]) / (t[k] - t[k-1])$
GSVM	$C_5[k] = \sqrt{w_x^2[k] + w_y^2[k] + w_z^2[k]}$
GSAM	$C_6[k] = \text{abs}(w_x^2[k]) + \text{abs}(w_y^2[k]) + \text{abs}(w_z^2[k])$
ACM	$C_7[k] = \text{nthroot}(\text{abs}(a_x[k] \times a_y[k] \times a_z[k]), 3)$
AVCM	$C_8[k] = \text{nthroot}(\text{abs}(w_x[k] \times w_y[k] \times w_z[k]), 3)$

## Results and Discussion

Figure 1.a) showed the predicted and actual rankings for 5 different ranking algorithm. 'Actual' refers to the classification performance using each feature vector ( $C_2 > C_3 > C_5 > C_1 > C_6 > C_8 > C_7 > C_4$ ).

**Figure 1:** a) Actual Ranking and Predicted Ranking  
 b) Accuracy according to number of feature vectors

Table 3 showed AE of the ranking algorithm. ReliefF inferred the best ranking and mRMR was the worst. Since ReliefF was the only time-dependent algorithm, it predicted relatively accurate ranking. On the other hand, mRMR aims to minimize redundancy and maximize relevance. Therefore, if the redundancy of the feature vector was low, the feature vector was evaluated with high rank even though the relevance was relatively lower than other feature vectors.

**Table 3:** AE of Ranking Algorithms

	ReliefF	T-score	Correlation	Fisher Score	mRMR
AE	10	14	12	14	18

Figure 1.b) showed the accuracy according to the number of feature vectors. When the actual ranking was applied, the best accuracy ( $99.86 \pm 0.65$ ) was obtained by using three characteristic vectors. ReliefF and mRMR achieved the best accuracy ( $99.86 \pm 0.65$ ) when using 5 and 6 feature vectors, respectively. mRMR showed large AE but high accuracy. This might be due to the fact that it minimized redundancy and avoided overfitting.

## Significance

The ranking algorithm showed effectiveness in clustering-based classifiers in some studies, but was not effective for post-fall detection using ANN as shown in this study. It is thought that the ranking algorithm might not be suitable for time-dependent data. In addition, it was shown that high accuracy could be obtained with smaller number of feature vectors depending on the selection of feature vectors.

## Introduction

The ability to maintain dynamic balance is critical for participating in activities of daily living. Dynamic balance in the frontal plane is largely controlled through foot placement (e.g. [1]). To compensate for imposed errors in mediolateral (ML) foot placement individuals often use a hip strategy [2, 3], a lateral ankle strategy that shifts the center of pressure (COP) [3], and/or a stepping strategy [4]. The ankle plantarflexors are important contributors to balance control during steady-state walking [5] and are used to restore balance in response to visual perturbations [6]. However, it is unclear if the plantarflexors provide a biomechanical response to foot-placement perturbations.

The purpose of this study was to identify the biomechanical response to perturbations in ML foot-placement in young healthy individuals. We hypothesized that subjects would compensate for medial (lateral) foot-placement errors with 1) a decreased (increased) hip abduction moment, 2) a lateral (medial) COP shift, and 3) an increased (decreased) ankle plantarflexion moment.

## Methods

Kinematic and kinetic data were collected from fifteen healthy volunteers (9 female, age:  $25 \pm 3$  years). Twenty 30-second walking trials were performed at a standard (1.0 m/s) and self-selected speed. Foot-placement perturbations were applied to random steps during 10 of the 20 walking trials using a custom pneumatic device, with each subject experiencing 40 perturbations. The pneumatic device used an inertial measurement unit to identify gait events and triggered a solenoid valve to release compressed air. The air applied a 15N force to the ankle to move the foot an average of 3.2 (3.7) cm medially (laterally). Participants were not aware of the perturbation timing or direction.

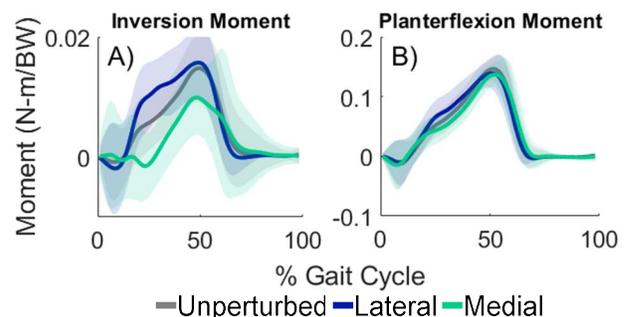

Motion capture data were processed using Visual 3D software (C-Motion, Germantown, MD) to perform inverse dynamics analyses. We used the range of frontal plane whole-body angular momentum ( $H_R$ ) to assess balance control, which was calculated by summing the angular momentum of each body segment about the body's center of mass. Differences between perturbed and unperturbed steps were evaluated using a linear mixed effects models.

## Results and Discussion

In agreement with our hypothesis and previous work [2, 3],  $H_R$  increased (decreased) following medial (lateral) perturbations ( $p < .001$ ). Hip abduction moment impulse also decreased following medial perturbations ( $p < .001$ ). Maximum COP excursion increased laterally (medially) following medial (lateral) perturbations ( $p < .001$ ), which was correlated with decreased (increased) ankle inversion moments ( $p < .001$ ,  $p = .001$ ) (Fig. 1A). We hypothesized that ankle plantarflexion moment would increase after medial perturbations to counteract increased  $H_R$ . However, peak plantarflexion moments were not

significantly different between conditions (Fig. 1B). Moreover, ankle plantarflexion moment impulse increased after lateral perturbations and decreased after medial perturbations during single leg stance ( $p = .001$ ,  $p < .001$ ). This unanticipated result may be due to ankle inverters and evertors also having plantarflexion moment arms. Thus, as the lateral ankle strategy is enacted, those muscles may have a small but significant contribution to the plantarflexor moment. Future modeling work will investigate individual muscle contributions to the 3D ankle moments.

In summary, participants used a combination of strategies to maintain balance following perturbations in medial and lateral foot-placement. Stance-leg hip abduction moment decreased after medial perturbations, and a lateral ankle strategy shifted the COP laterally (medially) after medial (lateral) perturbations. Unexpectedly, plantarflexion moment impulse decreased (increased) after medial (lateral) perturbations.

**Figure 1:** A) Average stance-leg inversion (+) and eversion (-) moment and B) Average stance-leg plantarflexion (+) and dorsiflexion (-) moment  $\pm 1$  SD for unperturbed, laterally and medially perturbed gait cycles.

## Significance

This work assessed joint-level responses to mediolateral foot-placement perturbations. Characterizing these responses to foot-placement perturbations in healthy individuals can provide a basis for comparison for those with neurological deficits and impaired balance control.

## Advancing Stages of Pregnancy on Postural Sway Range in Healthy Females

Heather R. Vanderhoof<sup>1</sup>, Christian N. Sanchez<sup>1</sup>, Jeffrey D. Eggleston<sup>1</sup>

<sup>1</sup>Department of Kinesiology, University of Texas at El Paso, TX, U.S.A.

Email: [hvanderhoof@miners.utep.edu](mailto:hvanderhoof@miners.utep.edu)

### Introduction

One in four pregnant females experience a fall while performing daily tasks, which is a rate similar to that of the elderly<sup>1</sup>. Ten percent of pregnant fallers seek medical attention due to injury and/or fetal complications<sup>1</sup>. As gestational mass gain (GMG) primarily occurs anteriorly about the torso, the center of mass (COM) shifts outside of the standing base of support (BOS)<sup>2</sup>. This may contribute to greater postural instability and increased risk of falling. GMG may also increase the moment of inertia of the body and create an imbalance in displacement between the mediolateral (ML) and/or anteroposterior (AP) center of pressure sway range displacement (COPD)<sup>4</sup>. Recent literature observed that larger COPD in the ML directions were correlated with higher incidences of falls in the elderly<sup>5</sup>. While previous research found that decreasing BOS, by narrowing stance width, created greater ML sway variables in the pregnant population<sup>4</sup>. However, research has not been performed on single-limb support in pregnant and postpartum females.

Thus, the aim of this study was to quantify COPD in ML and AP directions during bilateral standing (BL) and single-limb support (SLS) conditions when comparing 2<sup>nd</sup> trimester (2T), 3<sup>rd</sup> trimester (3T), and postpartum (POST), to non-pregnant females (NP). It was hypothesized that the 2T and 3T females would have greater AP COPD compared to NP females to compensate for the asymmetrically distributed GMG.

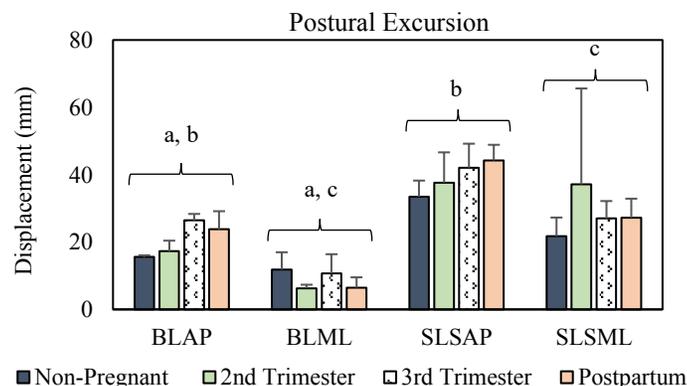

### Methods

Five females in 2T (25.6 ± 4.7 years, 1.6 ± 0.1 m, 76.3 ± 11.9 kg), three females in 3T (25.3 ± 4.2 years, 1.7 ± 0.1 m, 85.7 ± 19.2 kg), three POST (27.7 ± 2.5 years, 1.6 ± 0.1 m, 72.9 ± 16.2 kg), and two NP females (24.5 ± 0.7 years, 1.6 ± 0.1 m, 64.55 ± 14.2 kg) participated in this study. Postural stability, was quantified by examining postural sway from COPD data, wherein greater COPD correlates to decreased postural stability<sup>3</sup>. Postural sway was measured in three static standing conditions for 30s per condition: 1) BL; 2) right limb; and 3) left limb, all on a single force platform (1,000 Hz, AMTI. Watertown, MA, USA). BL width was controlled for and consistent for all groups. COPD data were exported to MATLAB and filtered with a digital low-pass Butterworth filter (12.5 Hz). Results from a pilot study revealed no SLS differences existed between right and left limbs, thus limbs were collapsed per participant across the groups in the current study. Variables of interest included: bilateral anteroposterior (BLAP), bilateral mediolateral (BLML), single-limb support anteroposterior (SLSAP), and single-limb support mediolateral (SLSML) COPD were compared to note differences created by a decreased BOS. ML and AP COPD was calculated by the absolute maximum and minimum ML (X) and AP (Y) coordinate data from the following equations: ML = (X<sub>max</sub> - X<sub>min</sub>) and AP = (Y<sub>max</sub> - Y<sub>min</sub>) in mm<sup>2</sup>.

A four (condition) by four (group) factorial ANOVA ( $\alpha=0.05$ ) was used to test for statistical significance for COPD. If no interaction was detected, variable and group main effects were examined after applying the Sidak adjustment.

### Results and Discussion

Results revealed there was not a significant group by limb condition interaction ( $F(9, 36)=0.73, p=0.68$ ), nor was there a group main effect ( $F(3, 36)=0.53, p=0.67$ ). However, there was a limb condition main effect ( $F(3, 36)=16.89, p<0.01$ ). BLAP was significantly greater than BLML (**a**;  $p<0.05$ ) and BLAP was significantly smaller than SLSAP (**b**;  $p<0.001$ ), but not significantly different from SLSML ( $p=0.17$ ). BLML was significantly smaller than SLSML (**c**;  $p<0.001$ ), however, SLSAP and SLSML were not significantly different from each other ( $p=0.173$ ) (**Figure 1**). BL conditions being characterized by smaller COPDs than SLS conditions was expected, as the BOS is greater during BL. BLAP being greater than BLML supported the hypothesis that the increased amount of GMG anteriorly could create AP imbalances. It was expected that significantly larger COPDs may occur with advancing pregnancy, however, this was not reflected in the results. Interestingly, SLS, while larger than BL, was relatively similar in both directions. While pregnant females and the elderly have similar fall rates, pregnant females are likely not falling due to static standing balance tasks. SLS being uniform in AP and ML directions may be important when conducting daily tasks, such as stair locomotion, that rely heavily on SLS.

**Figure 1:** Means and standard deviations for COP displacement (mm) by limb condition and direction (bilateral anteroposterior, bilateral mediolateral, single-limb support anteroposterior, and single-limb support mediolateral) between groups. a, b, c indicates  $p < 0.05$ .

### Significance

The reason behind high fall rates during pregnancy is still not well understood. The current study aims to understand adaptations to static postural control throughout pregnancy prior to considering dynamic postural control. Additionally, it provides evidence of evenly distributed postural stability during SLS which may correlate to dynamic functional movements.

Email: \*twood1@niu.edu

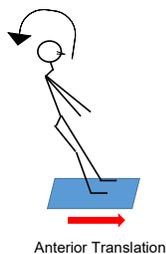

## Introduction

Traumatic brain injuries (TBIs) are a major cause of morbidity and mortality in adults over the age of 75 years [1,2]. It is estimated that  $\geq 80\%$  of TBIs in this population are attributed to head impact during same level falls [2]. Fall-related TBIs are a serious health concern for older adults, and there is a need for investigation of potential modifiable risk factors.

A potential modifiable risk factor may be neck muscle activation in response to prelibation [3,4]. In a recent study, older adults were found to have significantly greater neck muscle activation latency than young adults in response to a postural perturbation [4]. These findings suggest older adults may have reduced ability to support the head during a fall leading to head impact and consequently are at a greater risk of fall-related TBIs [4]. However, it remains to be seen if the neck muscles' response to perturbation can be changed with repeated exposure to perturbations. Thus, the purpose of this study was to examine the effect of repeated postural perturbation on co-contraction index between the right sternocleidomastoid (SCM) and right upper trapezius (UPT).

## Methods

Adults between the age of 18 – 30 years and 70 – 90 years were recruited; participants were grouped based on age. Participants were excluded if they reported any history of neck or back pain or dysfunction. Participants underwent dynamic posturography on the Smart Equitest Research System (Natus Medical Inc. Pleasanton CA, USA) with wireless electromyography (EMG) sensors (Trigno wireless system, Delsys Inc, Natick MA, USA) affixed to the right SCM and right UPT. EMG sensors were affixed per manufacturer instructions. Participants stood with their feet shoulder-width apart while staring straight ahead and arms at their side. Participants were exposed to 3 unexpectedly timed anterior translations of 6.35 cm at a velocity of 20 cm/sec on the Equitest System (Figure 1). Participants were not given practice tests.

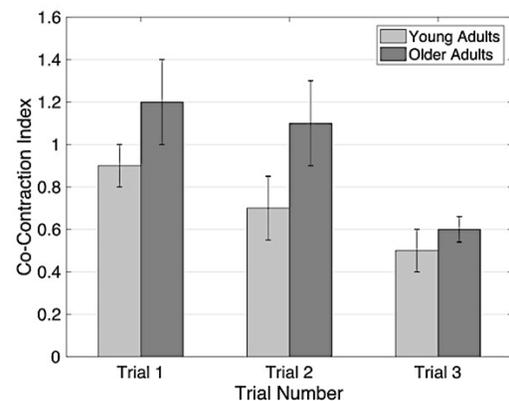

**Figure 1:** Illustration of anterior translation with body movement.

EMG data was processed using the Teager-Kaiser Energy Operator, followed by a high-pass 6th order Butterworth filter, a low-pass 2nd order zero phase shift Butterworth filter, and full wave rectified. Co-contraction index was calculated using the following equation:  $EMGS/EMGL * (EMGS+EMGL)$ , where EMGS is the mean muscle activity of the muscle with the least activity and EMGL is the mean muscle activity of the muscle with the highest activity [5].

## Results and Discussion

12 young adults (age  $22.4 \pm 1.6$  years; 7 females) and 12 older adults (age  $79.7 \pm 1.6$  years; 8 females) were included in this study. Co-contraction index for each of the three trials are displayed in Figure 2. Repeated-measures ANOVA revealed a significant effect of time; both groups displayed decreases in co-contraction index over the trials ( $F(2,44)=3.702, p=0.033$ ). Yet, there was no significant interaction between time and group ( $F(2,44)=0.558, p=0.576$ ).

**Figure 2:** Co-Contraction Index per trial as a function of group.

The lowered co-contraction indexes with each subsequent trial suggest a more selective activation of the muscles [5]. The more selective muscle activations may indicate the ability of the neck muscles to change control strategy with repeated exposures.

## Significance

Current fall-prevention exercise programs do not target the neck muscles. However, the decrease in co-contraction index with repeated exposure to postural perturbation may indicate an ability of the neck muscles to be trained. These results have further implications which suggest a potential effectiveness of rehabilitation protocols to improve neck activation during falls. With the ability to appropriately activate during falls, the neck muscles may have the capability to prevent head impact and ultimately prevent fall-related TBIs. Nevertheless, more research is needed to understand the direct effects of neck activation on the head kinematics during a fall.

# The Effect of a Reduced Marker Set on the Margin of Stability During Gait

Michael S. Christensen<sup>1</sup>, James B. Tracy<sup>1</sup>, and Jeremy R. Crenshaw<sup>1</sup>

<sup>1</sup>University of Delaware, Newark Delaware, USA

Email: [crenshaw@udel.edu](mailto:crenshaw@udel.edu)

## Introduction

The margin of stability (*MoS*) is a measure of dynamic gait stability that considers the position and velocity of the whole-body center of mass ( $COM_{body}$ ) relative to the edge of the base of support [1]. This measure is proportional to the perturbing impulse that causes a loss of stability, and it is altered in populations at risk of falling [2,3,4]. Typically, the *MoS* is calculated using a  $COM_{body}$  determined from a full-body marker set. However, in clinical gait laboratories, lower-limb marker sets are often used. If an accurate *MoS* can be calculated from a partial marker set, then we may evaluate stability in clinical contexts using an extensive dataset of past gait analyses.

The purpose of this study was to evaluate the agreement between using a full-body marker set and partial-body marker set to calculate the *MoS*. We hypothesized that *MoS* values will show acceptable levels of agreement.

## Methods

Fifteen unimpaired participants (6M/9F, mean (SD) Age: 21.0 (3.2) years; BMI: 21.3 (2.5) kg/m<sup>2</sup>) were recruited to walk at a self-selected, preferred speed while wearing a full-body marker set. The COM was determined from all segments ( $COM_{body}$ ), only the lower body segments ( $COM_{lower}$ ), and the pelvis center ( $COM_{pelvis}$ ) [6]. Each COM variant was used to determine (1) the anterior *MoS* at midswing ( $AMoS_{midsw}$ ), defined as the anterior distance between the stance toe and the extrapolated COM when the contralateral limb was in midswing and (2) the minimum lateral *MoS* ( $LMoS_{min}$ ), defined as the minimum lateral distance between the stance toe and the extrapolated COM. Each *MoS* value was averaged across limbs.

Previous studies have identified several sources of bias associated with using partial marker sets to determine *MoS* [5]. Notably the pendulum height was one of the largest sources of bias, as the height of the COM is affected by using a reduced marker set. We addressed this bias by estimating pendulum height as a ratio of leg length [1].

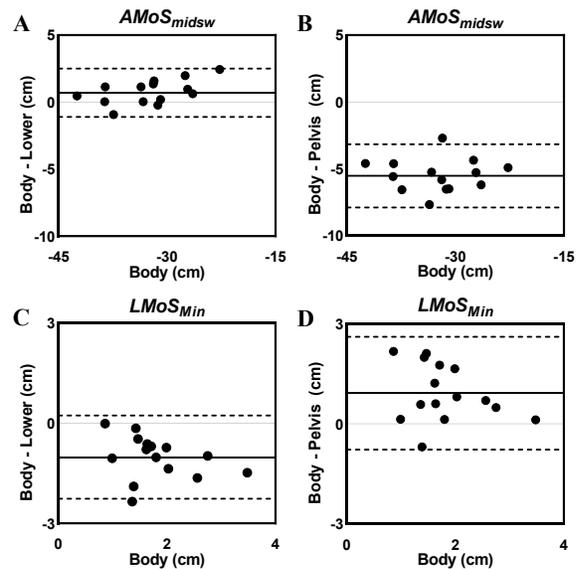

Using Bland-Altman plots (mean [limits of agreement]) and intraclass correlations ( $ICC_{2,1}$ ), the *MoS* values from the reduced marker sets were compared to those from the full-body marker set (representing the “gold standard”) to assess validity.

## Results and Discussion

For  $AMoS_{midsw}$ ,  $COM_{lower}$  was slightly biased towards less stability (0.71 [-1.10 to 2.51] cm) (Fig. 1A) and showed excellent agreement ( $ICC = 0.98$ ), while  $COM_{pelvis}$  was biased towards more stability (0.39 [-0.68 to 1.46] cm) (Fig. 1B) with less desirable agreement ( $ICC = 0.64$ ). For  $LMoS_{min}$ ,  $COM_{lower}$  was biased towards more stability (-1.01 [-2.27 to 0.24] cm) (Fig. 1C), while  $COM_{pelvis}$  was biased towards less stability (0.92 [-0.77 to 2.61] cm) (Fig. 1D). Both methods showed poor agreement to the gold standard ( $ICC = 0.46$ ).

Our results indicate that a simplified predictor of the COM, using lower-extremity segments, may have utility in estimating anterior *MoS*. Models from the lower-extremities had better validity than models using only the pelvis. This disparity is likely

the result of the velocity component of the swing limb not being accounted for by  $COM_{pelvis}$ , as evidenced by the bias of the  $COM_{pelvis}$  calculation towards less stability.

**Figure 1:** Bland Altman plots showing limits of agreement for  $COM_{lower}$  (A & C) and  $COM_{pelvis}$  (B & D) for the variables  $AMoS_{midsw}$  (A & B) and  $LMoS_{min}$  (C & D).

Reduced-model estimates of  $LMoS_{min}$  had poor agreement with full-body calculations. This result is likely due to the minimum being determined at different temporal points of stance between conditions. For example,  $COM_{body}$  identified  $LMoS_{min}$  earlier (25.54 (5.09) %Stance) than  $COM_{lower}$  (35.05 (8.30) %Stance). We suggest that lateral stability values at distinct timepoints in the gait cycle (e.g. foot strike) may have better agreement. Further assessment of lateral *MoS* during midswing and at ipsilateral heelstrike supported this. At midswing, both  $COM_{lower}$  and  $COM_{pelvis}$  showed strong agreement ( $ICC = 0.85$  and  $ICC = 0.79$ ). At ipsilateral heelstrike, both  $COM_{lower}$  and  $COM_{pelvis}$  also showed improved agreement ( $ICC = 0.59$  and  $ICC = 0.76$ ).

## Significance

Clinical gait laboratories often use a lower-extremity marker set, limiting estimations of the COM used to evaluate dynamic stability. Anterior *MoS* values and lateral *MoS* values occurring at a specific gait event, can be accurately estimated using lower-extremity marker sets. This validation informs the manner in which retrospective analyses of gait data may assess the effects of impairment, rehabilitation, or surgery on gait stability.

## Introduction

Parkinson's disease (PD), which commonly affects people between the ages of 50 and 60, is a progressive and neurodegenerative disorder associated with the dysfunction of dopamine-producing neurons in the substantia nigra pars compacta of the midbrain [1]. Dopamine acts as a lubricating oil in the neural circuits that coordinate exercise; when an 80 percent or greater of the dopamine-producing neurons (dopaminergic neurons) are depleted, the resulting symptoms of dyskinesia, such as tremor, rigidity, stiffness, bradykinesia, and postural instability, interfere with walking, climbing stairs, etc [2]. Thus, neurologists recommend exercise on a daily or weekly basis to help people with PD reduce dyskinesia and possibly delay the progression of PD [3]. In this study, we tracked the physical activity (i.e., number of steps) of people with PD for 10 weeks, used the Activities-specific Balance Confidence (ABC) scale and the Dynamic Gait Index (DGI), and assessed their physical activity. The objective is to understand the relationship between stepping as a representative physical activity and the ABC and DGI scores.

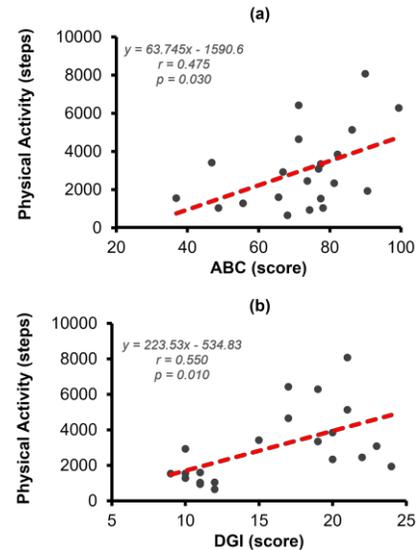

## Methods

Seven individuals (age  $68.57 \pm 12.47$ ; 6 males and 1 female) with PD were recruited. The inclusion criteria were: age between 50 and 75 years and a diagnosis of idiopathic PD (stages 2 to 4 of the Hoehn and Yahr scale). The study protocol was approved by the University of Houston Institutional Review Boards Prior to the study, a written consent form was obtained from each participant.

The experimental protocols consisted of three laboratory-based assessments of the first, sixth, and tenth weeks. The ABC scale and the DGI, standard clinical tools for assessing gait, balance, and fall risks, were used to assess participants' physical activity. Participants wore a smartwatch (Versa 2, Fitbit, Inc., San Francisco, CA) every day for ten weeks to track daily physical activity (steps). Statistical analyses were conducted with SPSS 21.0 software (IBM Corp., Armonk, NY). Pearson's linear correlation coefficients were used to measure the relationship between the ABC and DGI scores and physical activity.

## Results and Discussion

Figure 1 shows that higher physical activity positively correlated with higher ABC ( $r = 0.475$ ,  $p = 0.030$ ) and higher DGI ( $r = 0.550$ ,  $p = 0.010$ ) scores, respectively. Although there were only seven participants, the results imply that people with PD who have higher physical activity may have higher balance control ability and/or lower risk of falling during daily life.

**Figure 1:** Scatterplots of the relationship between seven participants' physical activity. (a) Activities-specific Balance Confidence (ABC) scale. (b) Dynamic Gait Index (DGI). Red dashed lines indicate the linear regression fits.

## Significance

Increased daily physical activity (stepping) may reduce the symptoms of dyskinesia and possibly delay the progression of PD. Physical activity enhancement is expected to be an effective strategy to delay the decline of physical/motor functions and decrease the risk of falling in individuals with PD.

# The Effect of Advancing Pregnancy on Postural Sway Velocity in Bilateral and Unilateral Standing

Bianca Tovar<sup>1</sup>, Heather R. Vanderhoof<sup>1</sup>, and Jeffrey D. Eggleston<sup>1</sup>  
<sup>1</sup>Department of Kinesiology, University of Texas at El Paso, TX, U.S.A.  
Email: [btovar1@miners.utep.edu](mailto:btovar1@miners.utep.edu)

## Introduction

One in four females fall during pregnancy, which may result in maternal or fetal injury and/or fetal death<sup>1</sup>. During pregnancy, the female body undergoes many hormonal and anatomical alterations, correlating to musculoskeletal adjustments which may affect postural stability<sup>2</sup>. If static posture is altered during pregnancy, then daily activities may be impaired and risk of falling may increase<sup>2</sup>. The utilization of force-plate posturography, such as postural sway velocity (SV), can accurately assess postural instability<sup>3</sup>. Previous research found that greater SV during static posture relates to a decreased balance ability<sup>4</sup>, thus leading to an increased incidence of falls<sup>5</sup>. Examining the safety of single-limb dependent activities (e.g., stair locomotion, walking, running) is of importance in pregnant females as these activities may pose an increased risk of falls due to the decreased base of support and increased single-limb support time.

The present study aims to analyze static SV across pregnancy stages (2<sup>nd</sup> trimester, 3<sup>rd</sup> trimester, and postpartum) during bilateral (BL) and unilateral (UL) conditions when compared to non-pregnant females. This study further addresses the following research questions: will postural sway velocity be different throughout advancing pregnancy during 1) BL static standing and 2) UL static standing? We hypothesized that SV would be greatest in the third trimester group and the least in the control group for both standing conditions. Furthermore, we expected postpartum SV to be similar to that of the non-pregnant control group for both standing conditions.

## Methods

Five 2<sup>nd</sup> trimester (25.6 ± 4.7 years, 1.6 ± 0.1 m, 76.3 ± 11.9 kg), three 3<sup>rd</sup> trimester (25.3 ± 4.2 years, 1.7 ± 0.1 m, 85.7 ± 19.2 kg), three postpartum (27.7 ± 2.5 years, 1.6 ± 0.1 m, 72.9 ± 16.2 kg), and two non-pregnant (24.5 ± 0.7 years, 1.6 ± 0.1 m, 64.55 ± 14.2 kg) females participated in this study. Postural SV was measured in three conditions, 30 seconds per condition: 1) bilateral; 2) right limb; and 3) left limb. Data were obtained with one force platform (1,000 Hz, AMTI, Watertown, MA, USA) and filtered with a digital low-pass Butterworth filter (12.5 Hz).

Pilot data supported that right and left limb single-limb stance were not significantly different from one another. Therefore, right and left limb data were collapsed across participants for UL stance trials. SV was calculated as the time-derivative of center of pressure excursion (COPE).

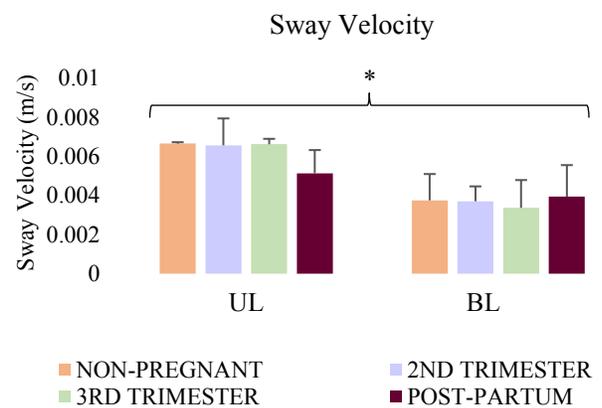

A two (condition: BL, UL) by four (group: NP, 2T, 3T, POST) factorial ANOVA ( $\alpha=0.05$ ) was used to test for statistical significance for SV. If no interaction was detected, variable and group main effects were examined after applying the Sidak adjustment.

## Results and Discussion

There was no significant group by condition interaction ( $F(3, 18)=0.96, p=0.43$ ), nor was there a group main effect ( $F(3, 18)=0.41, p=0.75$ ), however there was a condition main effect

( $p<0.001$ ). When comparing the two standing conditions (UL vs. BL), UL SV was significantly greater than BL SV across all groups ( $p<0.001$ ) (**Figure 1**).

The results did not support the stated hypothesis due to SV being similar among the stages of pregnancy. Furthermore, there were no significant differences created by a reduction in base of support between the four groups. Therefore, from these results, pregnant and postpartum women displayed similar sway velocities to non-pregnant women in both limb conditions, indicating no significant alterations in stability throughout advancing pregnancy.

**Figure 1:** Means and standard deviations for sway velocity (m/s) between group (non-pregnant, 2<sup>nd</sup> trimester, 3<sup>rd</sup> trimester, and postpartum) and limb condition (unilateral, bilateral). \* indicates  $p<0.001$ .

## Significance

The current study's findings were aimed to gain insight on the relationship between postural control (via SV) in pregnant and non-pregnant women and the size of base of support. This study infers that postural control of pregnant women did not significantly change across pregnancy stages nor significantly differ from non-pregnant women despite a reduction in base support by standing on a single limb. Thus, SV may not be a key factor in determining the safety (i.e., risk of falls) of single-limb support activities in later stages of pregnancy. Additionally, it can be inferred that physical changes during pregnancy do not pose a significant decrease in balance ability in pregnant females. Hence, the reason behind high fall rates during pregnancy remains unknown.

## Behavioral risk predicts maximum lateral reach during a roof gutter clearing task

### Introduction

Ladder falls are a problem in the domestic setting with injury rates highest among older adults [1]. Ladders aid individuals in completing tasks at elevated levels (e.g. clearing a roof gutter), but individuals often overreach during ladder use. Overreaching has been reported to cause the majority of ladder falls that occur while an individual is working from the ladder [2]. Lateral reach on a ladder is influenced by environmental factors, that is, ladder use acclimation and task motivation [3]. However, there is a lack of knowledge on individual factors that influence lateral reach on a ladder. Understanding individual characteristics that influence lateral reach can assist in identifying individuals at risk of overreaching on a ladder, particularly among older adults.

Similar to ground level reaching [4], lateral reach distance on a ladder may be dependent on the behavioral risk the individual is willing to accept to complete a task. In addition to behavioral risk, greater grip strength and better balance may provide a higher capacity for reaching. Thus, grip strength and balance may also predict how far an individual is willing to reach. We hypothesized that everyday risk-taking behavior, grip strength and balance would predict an individual's maximum lateral reach distance during a roof gutter clearing task on a straight ladder.

### Methods

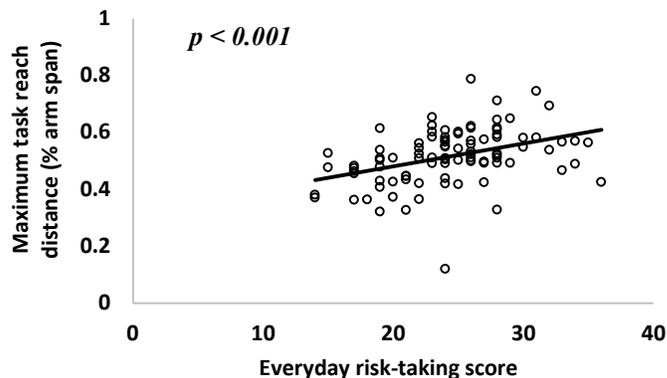

Lateral reach was assessed from 94 healthy older adults (73.0 ± 5.6 years old; 49 females) during a roof gutter clearing task on a straight ladder. Individuals were asked to climb to the third step of a straight ladder to clear a 5.8 m long gutter completely filled with tennis balls as quickly and as safely as possible. Individuals were allowed to reposition the ladder as often as needed to clear the length of the gutter. Maximum reach during the task was the calculated distance in the medial-lateral direction from the distal end of the 3<sup>rd</sup> metacarpal to the center of the ladder. Maximum task reach was normalized to arm span length. Behavioral risk was assessed from an everyday risk-taking questionnaire [5], where a higher score was associated with greater behavioral risk. Maximum grip strength was assessed from a hydraulic hand dynamometer. Balance was assessed from quiet standing sway: eyes open, on foam. Human research ethics approval and informed consent was obtained.

A multiple linear regression was performed with maximum task reach as the dependent variable. Everyday risk-taking, grip strength, sway, age and gender were entered into the model as predictor variables. A square root transform was performed on grip strength and sway to ensure a skewness of < 1.

### Results and Discussion

The mean (standard deviation) maximum task reach was 51.8 (9.7) % of arm span. Greater everyday risk-taking was associated with a farther maximum task reach (standardized  $\beta = 0.423$ ;  $t_{87} = 4.16$ ;  $p < 0.001$ ) (Figure 1). Thus, individuals who take greater everyday risks, may be taking greater risks during ladder use by

reaching farther. This suggests risk-takers to be at greater risk of a ladder fall due to overreaching. Grip strength (standardized  $\beta = 0.046$ ;  $t_{87} = 0.32$ ;  $p = 0.750$ ) and sway (standardized  $\beta = -0.151$ ;  $t_{87} = -1.35$ ;  $p = 0.180$ ) were not associated with maximum task reach. This suggests that individuals do not adjust their amount of reach based on their grip strength and balance capabilities during a roof gutter clearing task. Furthermore, maximum task reach was not significantly influenced by age (standardized  $\beta = 0.161$ ;  $t_{87} = 1.33$ ;  $p = 0.187$ ) and gender (standardized  $\beta = -0.084$ ;  $t_{87} = -0.61$ ;  $p = 0.546$ ).

**Figure 1:** Maximum task reach distance by everyday risk-taking score.

Maximum task reach was predicted by behavioral risk, but not grip strength, balance, age and gender. Behavioral risk is a potential predictor of ladder fall risk if a greater maximum task reach increases ladder fall risk. Furthermore, maximum reach during ladder use may be dependent on an individual's perception of risk more than physical ability. Additional work is needed to investigate the influence of other psychological (e.g. anxiety, fear) and physical (e.g. proprioception, reaction time) factors on maximum reach during ladder use.

### Significance

This study found that a simple risk-taking screen predicted reaching behavior during a common ladder task among older adults. The use of this screen, along with educational programs may help prevent ladder falls due to overreaching in this population.

# Characterization of posturography and sensory loss in lower-limb amputees.

Bailey A. Petersen<sup>1</sup>, Patrick Sparto<sup>1,2</sup>, and Lee Fisher<sup>1,3</sup>

## Introduction

An estimated 1.5 million people in the United States are living with a lower-limb amputation<sup>1</sup>. These individuals can suffer from a wide variety of functional deficits and, consequently, a higher risk of falls than the average population. In fact, 52.4% of community dwelling adults with lower-limb amputation reported a recent fall<sup>2</sup>. Determining the factors that influence fall risk in this population is critical. One theory is that lack of sensory feedback from the amputated limb, and the contralateral limb in the case of peripheral neuropathy, may contribute to abnormal postural control. **The purpose of this study is to determine the extent to which impaired sensation affects postural control in individuals with lower-limb amputation.**

## Methods

In this study, we collected measures of sensory impairments and balance control in fifteen lower-limb amputees, regardless of level or nature of amputation. Somatosensory integrity of both the intact and residual limb was assessed by a trained physical therapist. These tests included monofilament threshold, light touch and protective (pinprick) sensation, vibration sense, two-point discrimination and joint position sense.

To quantify balance, we used the Sensory Organization Test (SOT) using the NeuroCom Equitest. In the SOT, participants stand on a force platform while either visual (eyes closed, sway-

referenced surround rotation) or somatosensory feedback (sway-referenced platform rotation) are altered across six conditions. Each condition consists of three 30-second trials. Standard measures of posturography (excursion, sway velocity, 95% confidence interval ellipse of sway area and sample entropy) were calculated for each trial. In addition, clinical measures including equilibrium scores and somatosensory ability (ratio of equilibrium scores in conditions with and without vision) were recorded. Equilibrium scores indicate a participant's ability to stay within a normative 12° anteroposterior sway envelope. Regression analyses were performed across all measures of sensation and balance.

## Results and Discussion

From our preliminary results, lower-limb amputees have significantly lower equilibrium scores across all conditions than controls, and this difference is most pronounced in the static condition without vision (80.1±6.6 vs 92.0±2.9 respectively). Despite the clear balance impairments in this group, we have found no significant relationship between quantitative measures of sensory impairment (monofilament threshold) and posturography measures across all conditions of the SOT.

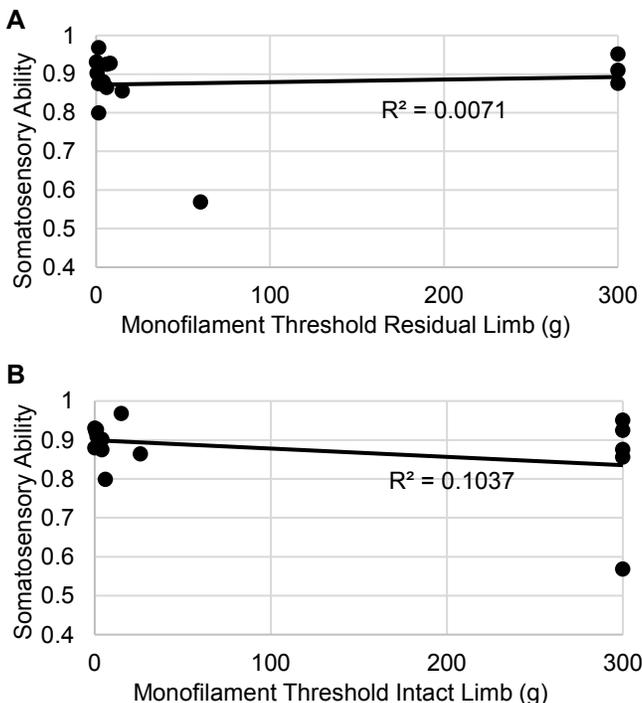

As expected, area of sway and sample entropy both increased without visual feedback, as was seen in previous studies. However, these changes showed no significant correlation to any measures of severity of sensory impairment ( $p < 0.05$ ). In addition, the ratio of sway with vision to without vision (somatosensory ability) shows no correlation with clinical tests of sensation (Figure 1). This lack of correlation could be due to the ceiling effect (maximum 300g) in monofilament testing, especially with the bimodal distribution of sensory loss in our data (Figure 1) or may indicate that lower-limb amputees are able to compensate for loss of tactile sensation in the limbs in static balance.

## Significance

This lack of relationship between tactile sensation and balance is surprising, given the spinal reflexive pathways that are activated by tactile stimuli when balance is perturbed. With respect to assessing sensory loss, the ceiling effect seen here calls for a more robust measure of sensory ability across impairments or an alternative test of balance that is sensitive to sensory impairments. On a broader scale, the question of the effects of sensation for postural control remains and, as a field, we may need to shift our focus to tasks that can demonstrate the relative importance of proprioception versus tactile sensation in balance.

## Introduction

Each year between 700,000 and 1,000,000 patient falls occur in U.S. hospitals, with 33% resulting in injury [1]. Most efforts directed at reducing patient falls have focused on bed alarms, monitoring, and education to raise awareness. Longer term interventions have focused on exercise and balance training [1]. Aspects in room design and environment, often referred to as extrinsic risk factors for falls, have been identified based on fall incident reports [2]. The limited research that exists related to fall risk and room design has focused on individual factors such as flooring and lighting, [3, 4] often missing the complex interactions between the patient and environment.

The purpose of our survey was to investigate how healthcare professionals view object characteristics and their influence on patient safety and stability during ambulation.

## Methods

A diverse group of 66 healthcare professionals completed our voluntary online survey (IRB #00099410). Study data were collected and managed using REDCap electronic data capture tools hosted at the University of Utah [5, 6]. In order to participate in the survey, respondents must have interacted with individuals with mobility impairment in a place of employment in the last 5 years. All potential respondents were recruited by email.

The survey presented the following 5 scenarios describing individuals with mobility impairments ambulating without assistive devices: proactively seeking out objects for support during walking (**PW**), reaching for objects after becoming unstable during walking (**RW**), proactively seeking out objects for support during a 180-degree turn (**PT**), reaching for objects after becoming unstable during a 180-degree turn (**RT**) and, completing a sit-stand-sit (**STS**).

Respondents were asked to assign a score between 1 (low) and 5 (high) to the level of influence an object characteristic has on a patient's safety and stability during each scenario. General object characteristics included: Height, Movability, Grasp-ability. Sub-characteristics included: Compliance of Surface (**COS**), Resistance to Movement (**RTM**), Type of Grasp (**TOG**), Smoothness of Grasp (**SOG**), Seat-pan Height (**SH**), Armrest/rail Height (**AH**) and Backrest Height (**BH**).

Wilcoxon signed-rank test, with an alpha of 0.01 was used to compare scores between characteristics. Only characteristics in the same group were compared.

## Results and Discussion

Table 1 summarizes the distribution of healthcare professionals who responded to the survey. Based on the preliminary results and an  $\alpha$  level of 0.01, Wilcoxon signed-rank test showed no significant difference ( $p > 0.01$ ) between Height/Grasp-ability, Height/Movability, and Grasp-ability/Movability for PW, RW, PT, and RT, suggesting that Height, Movability and Grasp-ability characteristics are equally important for tasks involving gait.

For STS, the Wilcoxon signed-rank test indicated that Movability ( $4.05 \pm 1.01$ ) and Height ( $4.29 \pm 0.74$ ) were

significantly different than Grasp-ability ( $3.17 \pm 1.16$ ),  $p < .001$ , suggesting that Movability and Height are more influential in providing safety and stability than Grasp-ability. Additionally, the SH ( $4.56 \pm 0.64$ ) and AH ( $4.05 \pm 0.77$ ) ratings were significantly different from BH ( $2.67 \pm 1.07$ ),  $p < .001$ , and SH was also statistically different from AH,  $p < .001$ . Therefore, SH may be the most important characteristic contributing to a patient's safety and stability during STS.

For all scenarios TOG was statistically different than SOG,  $p < .01$ , and RTM was significantly different from COS,  $p < .001$ . Therefore TOG, and RTM may be more influential in providing safety and stability than SOG and COS respectively.

**Table 1.** Distribution of survey respondents

Profession	% Response	Count
Physical Therapist	50.0	33
Physician/Medical Doctor	15.1	10
Nurse/Nurse Assistant	13.6	9
Occupational Therapist	9.1	6
Other Healthcare Professional	12.1	8

## Significance

Based on the preliminary results there appears to be a consistent trend in ratings across walking and turning scenarios (PW, RW, PT, RT), suggesting that tasks involving gait require similar object characteristic for safety and stability. Tasks involving sitting, may require slightly different object characteristics.

The results from this survey will provide valuable insight into the way healthcare professionals perceive how different object characteristics influence the safety and stability of a patient with mobility impairment. This insight will provide a starting point for future research into object characteristics, and their influence on safety and stability during ambulation. These data may also impact the future of fall prevention research, shifting the focus more towards room design. Data collection for the survey will continue until 100 responses have been achieved.

## Acknowledgments

### Introduction

The Four Square Step Test (FSST) assesses dynamic balance with predictive validity for fall risk in a variety of clinical populations<sup>1</sup>. The FSST was previously used to assess changes in fall risk in a multi-site study aimed at utilizing a training program to decrease fall incidence in Service members (SM) with severe lower extremity (LE) trauma<sup>2</sup>. This secondary study of a larger intervention evaluated the use of the FSST to assess fall risk during a clinically-focused fall prevention program. It was hypothesized that SMs who successfully completed the program would show faster FSST times.

### Methods

SMs (n=24) with major LE trauma who utilize an Intrepid Dynamic Exoskeletal Orthoses (IDEO) or prosthesis for high level activities were recruited across three Medical Treatment Facilities (MTFs) and signed informed consent approved by the NMCS D IRB (NMCS D.2016.0077). Subjects (Age: 35.1±8.7 years, time since injury: 5.0±4.2 years) completed a total of 5 FSST as described previously<sup>3</sup> (Baseline; Two-week Baseline Retest; Post-Training; 3Mo; and 6Mo Follow-up) over a 7-month period in conjunction with a training program designed to improve their ability to recover from falls. After the completion of the training program each subject reported any falls via an electronic survey distributed every 2 weeks during the 6 months following training completion. Patients who reported one or more falls post-training were categorized as fallers (F) (n=14), those that reported no falls were categorized as non-fallers (NF) (n=10). A two-way repeated measures ANOVA was used to determine the effect of the training program on FSST times and the tests ability to predict falls in the following 6 months ( $\alpha=0.05$ ).

### Results and Discussion

Mean FSST at Baseline was 6.2 ± 1.4 s for all participants. The average reduction in time for all participants was 0.90 ± 0.93s. There was no decrease across all time points in the FSST score times ( $Power=0.81$ ). Neither the completion of the training program nor time reduced the FSST scores. Furthermore, F reduced their FSST time by 0.89 ± 1.1s and NF reduced their FSST time by 0.88 ± 0.72s; there were no differences ( $p>0.05$ ) in FSST times between F and NF, nor at any time point (Table 1).

It has been reported that a threshold of 8.49s can differentiate fallers and non-fallers<sup>4</sup>. However, all subjects were below this threshold time at the completion of the training program and yet 14 (58%) still reported falling post-training. This may be indicative of a ceiling effect in the FSST in this population as these participants performed similarly to uninjured military controls<sup>6</sup>. Additionally, the reduction in mean FSST group scores was not greater than the minimally detectable change of 1.41s for either F or NF<sup>5</sup>. SM participating in this study do not represent the typical LE injury patient seen in the civilian sector. Of the 24 participants, 67% reported a walking capacity of more than 5 miles and an additional 13% could walk between 2 -3 miles indicating a high level of fitness. There was also no difference in the time since injury between either F and NF group. SM have greater access to rehabilitative services compared to civilian counterparts which may contribute to lower FSST scores. Other tests, such as the Narrowing Beam Walking Test, have been shown to be a valid measure in similar populations and may be a more appropriate test for this population<sup>6</sup>.

### Significance

Historically, the FSST has been used to assess fall risk in some populations with LE trauma. This study has demonstrated that high-performing individuals may require a different assessment tool due to a possible ceiling effect. When evaluating fall risk in highly functional patients with lower extremity trauma, test selection is an important and evolving process.

## Introduction

When perturbed by unpredictable backward support-surface translations during upright standing while trying to keep the feet in place, healthy older adults (OA) step more frequently than young adults (YA). Different possible causes for the increased step frequency in OA compared to YA have been suggested. First, alterations in the musculoskeletal system are thought to underlie this increased step frequency. Reduced plantarflexor strength and rate of force development might reduce the potential to use the ankle strategy to restore balance. Use of the ankle strategy can be quantified by observing the shift of the center-of-pressure (COP) within the base-of-support (BOS, defined by the feet) following a perturbation. However, the relation between muscle strength and stepping frequency is unclear [2]. Other changes in the musculoskeletal system (e.g. reduced hip and lumbar mobility/flexibility) impair performing hip strategies to counteract the effect of a perturbation. Use of the hip strategy can be quantified by observing the trunk lean trajectories during the postural response. Second, the initial COP position is related to the occurrence of stepping responses [3], and therefore increased postural sway in OA might explain increased stepping incidence. Third, a change in neural control strategy might favor stepping strategies at less threatening situations in OA, leading to initiation of a step strategy at lower extrapolated center-of-mass (xCOM) deviations. We confirm that (a) OA step more frequently than YA at the same perturbation magnitude and we test three hypotheses about increased step frequency in OA: (b) COP movement is altered due to less effective use of the ankle strategy in OA, (c) anterior initial COP increases step incidence and is more prevalent in OA, (d) older adults initiate steps at lower xCOM.

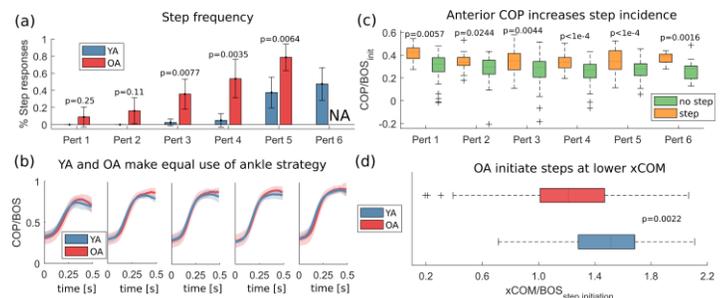

## Methods

We measured the kinematic response of 10 healthy young (20-27y) and 14 healthy older adults (72±3.13y) standing on a movable platform. Subjects were instructed to maintain balance without taking a step. Backward support-surface translations with six different magnitudes were administered randomly five times each within a set of multi-directional perturbations. Motion capture and force plate data was processed to analyze the trunk lean angle, the body COM kinematics, the COP motion and the step incidence during the responses to backward translations. We compared (a) step incidence between YA and OA (t-test), (b) COP trajectories and trunk lean trajectories between YA and OA (statistical parametric mapping; t-test), (c) initial COP location between stepping and non stepping responses (t-test) and between YA and OA (t-test) and (d) xCOM position at step initiation (instant at which at least one foot leaves the ground) between YA and OA (t-test).

## Results and Discussion

OA stepped more often than YA (Fig. 1a). The most plausible hypothesis for this increased step incidence in OA is that OA shift to a stepping strategy at less balance threatening conditions, i.e. at lower xCOM (Figure 1d). OA shift their COP similar to

YA, and thus the increased step incidence is not a coping mechanism for a reduced ability to perform an ankle strategy (Fig. 1b). We confirmed that the mobility to properly use a hip strategy is intact in OA as trunk lean trajectories do not differ between OA and YA (not shown). Overall, initial COP is more anterior for step responses (Fig. 1c), but OA do not exhibit higher variability in initial COP (not shown in figure;  $p>0.1$ ). An important finding is that variability in OA COP trajectories, xCOM at step initiation and trunk lean trajectories (not shown) is higher.

**Figure 1 - (a) OA step more often than YA, (b) COP/BOS trajectories are not different for OA and YA. (c) Initial COP is more anterior for step responses. (d) xCOM at step initiation is lower in OA than in YA.**

The initial response to the perturbation, which relies on the development of ankle torque to move the COP within the BOS is similar in OA and YA. Yet, OA step more often and our results suggest that this is due to an altered strategy where steps are initiated at a more stable position. The underlying reasons for this shift in strategy needs further investigation. Increased movement variability, originating from sensorimotor noise at different levels of the neuromotor system, might play a role in selecting a more robust strategy. But alternative explanations, such as increased fear of falling are plausible as well.

## Significance

OA might adapt movement strategies in order to cope with subtle changes in neuromotor function rather (e.g. increased sensorimotor variability) than with obvious specific declines (e.g. reduced muscle strength) if these don't limit the performance of a specific task. We believe that further research is necessary that focusses on causal interaction between changes in the neuromotor system and adaptations of the central nervous system to cope with these. We will do this by combining simulations with experiments as this is a valuable approach to understand causalities.

## Introduction

Falls pose a significant health risk to persons with major lower limb loss throughout the rehabilitation process, commonly resulting from trips [1]. Fall risk is already elevated for older individuals due to neuromotor decline [2], and so risk is of greater concern for older lower limb prosthesis users (PUs). Characterizing the motor response of persons to gait disturbances is a useful methodology to understanding the factors related to falls [3]. While this technique has been applied to younger PUs [4], it has not been implemented with their older counterparts. The study aim was to characterize the locomotor response of older PUs to a trip disturbance and compare this response to able-bodied controls. As analysis is ongoing, we present initial results from two age-/gender-matched control and PU participants.

## Methods

After obtaining written informed consent, lower extremity muscle strength was measured with a handheld dynamometer (Lafayette Systems, IN). Participants then completed two trials of steady-state data collection while walking on a custom-built treadmill (Motek Forcelink, the Netherlands) at their self-selected speed and 0.8 m/s (steady-state speed used for perturbation trials). Following baseline collections, participants completed 12 perturbation trials. For each perturbation trial, participants first achieved steady-state walking at 0.8 m/s, then at the moment of foot initial contact received a rapid, symmetric treadmill belt acceleration and deceleration ( $6.5 \text{ m/s}^2$ ) back to 0.8 m/s. The perturbation occurred at a random stride ( $n=11-20$ ) after reaching steady-state walking. The trial ended 20 strides after the perturbation occurred. Six trials for each foot side (right, left) initial contact were collected in a randomized order. Participants were instructed to recover from the disturbance and continue walking. Kinematic data were collected with an optical motion capture system (Motion Analysis, CA) and custom marker set. Visual 3D (C-Motion, MD) was used to estimate sagittal-plane whole-body angular momentum (*WAM*), trunk inclination (*TI*), and trunk inclination velocity (*TV*) *PRE*- and *POST*-perturbation.

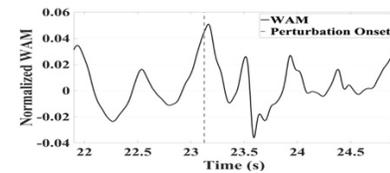

## Results and Discussion

The control participant (70 years, 173.0 cm, 82.8 kg, male) and PU participant (69 years, 180.5 cm, 78.8 kg, male) completed all trials and successfully recovered from the perturbations without a fall (partial harness arrest). A representative temporal WAM profile is displayed in Fig. 1, and Table 1 reports *PRE* and *POST* values for maximum WAM (normalized by subject mass, height, and treadmill speed), *TI*, and *TV* across trials for each limb side.

*PRE* *TI* and *TV* were similar for both participants, but the PU displayed a higher maximum WAM during steady-state walking at baseline. As expected, WAM increased *POST*-perturbation, but the control participant experienced a greater increase relative to their *PRE* levels than the PU, as well as greater WAM on both limb sides respectively compared to the

PU. This result suggests greater postural control demands of the control participant to regulate higher WAM post disturbance.

Maximum *TI* and *TV* increased *POST*-perturbation as participants rotated their trunk forward during recovery, which may help explain the increase in *POST* WAM (Fig. 1). However, while *POST* *TI* was nearly equivalent for both participants and limb sides, maximum *TV* was noticeably different. *TV* increased *POST*-perturbation for controls in a way that aligned with the relative increase in WAM (higher non-dominant than dominant), this trend was the opposite for the PU. Furthermore, the sound-side *POST* *TV* was considerably higher than control values, while prosthetic-side *TV* was lower than control values. Even though *POST* sound-side *TV* was the largest, the WAM was the smallest. Results suggest different postural control strategies between the control and PU to regulate WAM during perturbation response. Future work will assess contributions of other body dynamics.

**Figure 1:** Representative graph of PU normalized WAM approximately one stride pre-perturbation onset and two strides post-perturbation.

**Table 1:** Maximum WAM, *TI* and *TV* (mean $\pm$ SD) across trials for each perturbed side, control Non-/Dominant and PU Sound/Prosthetic.

Perturbed Limb side	WAM (PRE)	WAM (POST)	TI (°) (PRE)	TI (°) (POST)	TV (°/s) (PRE)	TV (°/s) (POST)
Control, Dom	0.033 $\pm$ 0.001	0.053 $\pm$ 0.005	6 $\pm$ 1	16 $\pm$ 3	21 $\pm$ 1	73 $\pm$ 27
Control, Non-Dom	0.034 $\pm$ 0.001	0.065 $\pm$ 0.005	6 $\pm$ 1	17 $\pm$ 2	19 $\pm$ 2	90 $\pm$ 15
PU, Sound	0.038 $\pm$ 0.002	0.050 $\pm$ 0.005	7 $\pm$ 3	18 $\pm$ 2	20 $\pm$ 4	113 $\pm$ 17
PU, Prosthetic	0.037 $\pm$ 0.001	0.053 $\pm$ 0.003	7 $\pm$ 3	17 $\pm$ 2	22 $\pm$ 4	67 $\pm$ 5

## Significance

Initial results suggest different motor control strategies between older able-bodied individuals and PUs when recovering from a trip. This work will help understand mechanisms underlying fall risk in older PUs, and potential strategies to minimize this risk.

# Balance Control and Muscle Asymmetry in Persons with Lower-limb Amputation During Yoga Poses

Nicole M. Stoehr, Pranavi Depur, Andrew St. Julien, Rosa M. Angulo-Barroso Ph.D. and Jacob W. Hinkel-Lipsker Ph.D.  
Move-Learn Lab, Department of Kinesiology, California State University, Northridge  
Email: Nicole.stoehr.721@my.csun.edu

## Introduction

People with lower limb amputation (LLA) commonly experience chronic orthopedic disabilities (e.g. low back pain) and comorbidities (e.g. obesity) partially due to reduced activity levels<sup>1</sup>. Yoga could potentially improve quality of life by increasing muscular strength, flexibility, and overall activity levels<sup>2</sup>. However, the poses commonly performed during general yoga practices are designed for healthy individuals, without considering the compromised balance and musculature for those with LLA.<sup>3,4</sup> Therefore, we seek to assess how individuals with LLA maintain balance during static yoga poses. We hypothesize that people with LLA will experience greater balance challenges, as demonstrated by an increased center of pressure (COP) sway in the medio-lateral (ML) and anterior-posterior (AP) directions. We further hypothesize that these balance challenges will be accompanied by heightened asymmetric behaviors in the trunk and hip muscles.

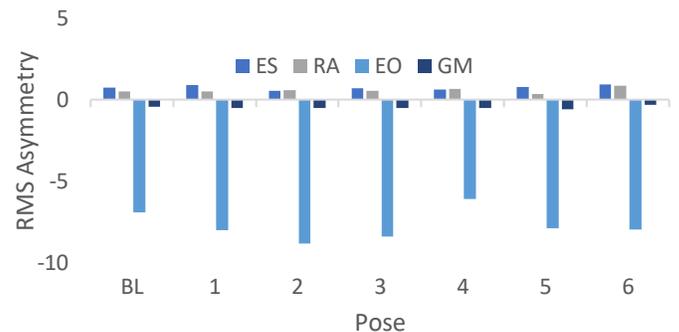

## Methods

Five individuals with LLA and five healthy matched control participants (able-bodied; AB) are being recruited in this ongoing study. Pilot data for n=1 for each group are presented here. Participants were instrumented with eight electrodes placed bilaterally on the belly of the lower rectus abdominus (RA), external obliques (EO), erector spinae (ES), and gluteus medius (GM) for collection of electromyographic data (EMG). They were also fitted with six reflective markers placed on the feet to define their base of support (BOS). Participants partook in a yoga warm-up, followed by a randomized sequence consisting of seven poses that required neutral pelvic orientation and parallel feet, each foot on top of a force plate. Each pose was held for 50 seconds and the sequence was repeated three times. During the sequence, EMG data were recorded at 2000 Hz, COP data were collected using two force plates at 2000 Hz and 3D marker coordinate data were collected at 100 Hz using a 10-camera motion capture system. The root mean square (RMS) for each EMG signal was normalized to the dominant side during standing in anatomical pose (baseline; BL) and the difference between the right and left side was computed as a measure of muscle asymmetry. Using the measured vertical ground reaction force and COP from each force plate, we implemented a novel approach that expresses a combined center of pressure (COPc) from both feet in the global coordinate system. Lastly, we expressed COP sway in each direction (ML, AP) as a percentage of the corresponding BOS width for each direction.

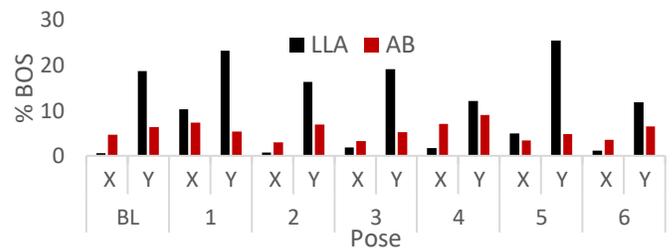

## Results and Discussion

Preliminary results from one participant with and one without amputation are presented here. The LLA participant has a unilateral transfemoral amputation (left) but is otherwise healthy. Compared to the AB participant, this individual experienced greater difficulty maintaining balance in the AP direction, with the greatest difficulty in poses with flexed knees (chair and back bend) (Figure 2). In addition, the LLA participant had a pattern of muscle activation across all poses that showed heightened

muscle activity towards the amputated side only in the EO group (Figure 1). Such results potentially indicate that the LLA may be using the left EO to stabilize the trunk and may be compensating for the missing lower extremity muscles on the amputated side. These results partially support our hypotheses as asymmetry was only observed on one set of muscles. Furthermore, sway was only increased in the AP direction and decreased in the ML direction for some poses. Data collection is in process and will help to further elucidate these findings.

**Figure 1:** RMS EMG Asymmetry for a single unilateral transfemoral LLA participant. (+)= greater activation on intact side and (-)= greater activation towards amputated side.

**Figure 2.** COP sway in the ML (X) and AP (Y) directions as a percentage of BOS across yoga poses.

## Significance

Findings from this study indicate that the LLA has increased AP instability while performing common yoga poses. Practitioners and clinicians should be mindful of this additional challenge when prescribing these poses to those with LLA. The noted muscle recruitment asymmetries from the LLA demonstrate that the more proximal trunk musculature on the amputated side compensate for the lack of lower limb muscles—indicating that static exercises may be beneficial for training of core stabilization muscles. Further study is warranted to determine how these strategies differ across various subcategories within the LLA population (e.g. type of amputation). In total, performance of these yoga postures were feasible and has the potential to improve quality of life for individuals with LLA.

## Introduction

People with a transtibial amputation (TTA) have difficulty regulating angular momentum compared to people without amputation during straight-line walking [1], suggesting decreased balance control. In daily life, ~35% of indoor steps are turns [2]. Turns may pose a greater risk for loss of balance as they require greater generation of segment angular momentum compared to straight-line walking in people without amputations [3]. Further, the inability to actively control the ankle in people with TTA may result in altered strategies to regulate segment angular momenta used during turning. The purpose of this study was to compare upper and lower limb segment angular momenta during 90° turns between people with and without TTA and determine the influence of turn direction.

## Methods

Eight people with TTA (1F/7M; 52±15 years; 99.5±17.9 kg; 1.77±0.08 m) and 8 controls (2F/6M; 39±15 years; 80.7±19.5 kg; 1.77±0.09 m) performed left and right 90° step turns. Full body kinematics were tracked at 120 Hz using a 20-camera motion capture system. Kinematics were low-pass filtered using a 4<sup>th</sup>-order Butterworth filter ( $f_c = 6$  Hz). A 13-segment model was developed in Visual3D; the mass and inertial properties of the prosthesis were adjusted for people with TTA [4]. We summed the foot, shank, and thigh, and separately, the upper arm and forearm angular momenta about the body center of mass to calculate the angular momentum ( $\mathbf{H}$ ) for each limb (Outside Leg, Inside Leg, Outside Arm, Inside Arm). We normalized limb  $\mathbf{H}$  by body height, mass, and speed across each stride.  $\mathbf{H}$  was defined in the center of mass reference frame. We divided the turn into initiation and termination strides. Turns for people with TTA were grouped for analysis by whether the prosthesis was on the inside ( $P_{in}$ ) or outside ( $P_{out}$ ) of the turn. The dependent measures were the four average limb  $\mathbf{H}$  values. We compared measures between groups and turn direction using a doubly multivariate analysis. Significant main effects and interactions were explored using Estimated Marginal Means with a Bonferroni correction.

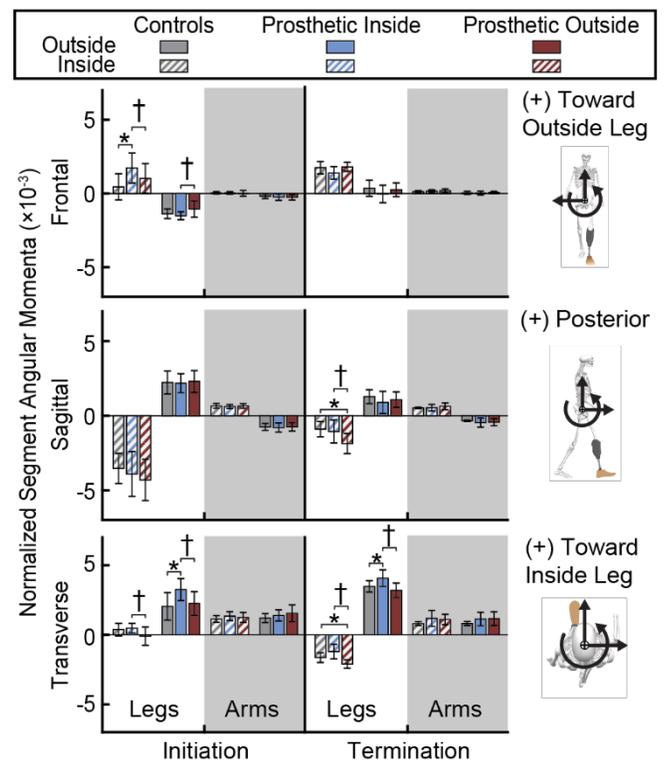

## Results and Discussion

There were group  $\times$  turn interactions for limb  $\mathbf{H}$  during initiation in the frontal plane and during termination in the sagittal plane ( $p < 0.009$ ). Here, we focused on significant interactions in the transverse plane as this plane is critical for turning and there were differences during both initiation and termination.

During initiation and termination in the transverse plane, the  $P_{in}$  condition had greater outside leg  $\mathbf{H}$  toward the inside of the turn compared to controls ( $p < 0.037$ ) and  $P_{out}$  ( $p < 0.001$ ). Also during initiation, the  $P_{in}$  condition had greater inside leg  $\mathbf{H}$  toward the inside of the turn compared to  $P_{out}$  ( $p < 0.001$ ). During termination, the  $P_{in}$  condition had smaller inside leg  $\mathbf{H}$  toward the outside of the turn compared to  $P_{out}$  ( $p < 0.001$ ) while the  $P_{out}$  condition had greater  $\mathbf{H}$  compared to controls ( $p = 0.013$ ).

For people with TTA, the  $\mathbf{H}$  generated by the leg to complete the turn depended on whether the prosthesis was on the inside or

outside of the turn. Overall, outside leg  $\mathbf{H}$  values were greater during  $P_{in}$  relative to  $P_{out}$ . Reduced muscle control and range of motion on the prosthetic leg may require greater velocities (and therefore momentum) from the outside leg to complete the turning task. While people with TTA were able to complete 90° turns, greater  $\mathbf{H}$  generation compared to controls suggest that the regulation of  $\mathbf{H}$  between limbs during turning may be more challenging for people with TTA. In addition, prostheses capable of transverse plane movement [5] may influence turning strategy and the associated limb  $\mathbf{H}$ .

**Figure 1:** Average limb  $\mathbf{H}$  over the initiation and termination strides. (\* $p \leq 0.05$  between groups; † $p \leq 0.05$  between turn types)

## Significance

Turning with the prosthesis on the inside may be more challenging for people with TTA as it requires greater leg angular momentum. Thus, prosthetic rehabilitation should focus on generating momentum with other segments to regulate outside leg momentum when turning with the prosthesis on the inside. Future work should explore the role of other body segments and different types of prostheses on angular momentum during turns.

# Relationship Between Postural Control and Lower Body Physical Function in Children with Cerebral Palsy

Sydni Wilhoite<sup>1</sup>, Katelyn S. Campbell<sup>1</sup>, Li Li<sup>2</sup>, Karl M. Newell<sup>1</sup>, Gavin Colquitt<sup>2</sup>, Barbara Weissman<sup>3</sup>, Joshua Vova<sup>3</sup> and Christopher Modlesky<sup>1</sup>

## Introduction

Cerebral palsy (CP) is a neurological disorder often characterized by deficits in postural control.<sup>1</sup> The deficits are often assessed by center of pressure (COP) motion during quiet stance using a single force platform. However, assessing COP motion of each limb using two separate platforms might be beneficial due to the asymmetrical nature of the pathology.

Balance impairments may cause limitations in functional mobility; however little is known about the relationship between balance measures and functional movement measures in children with CP. The purpose of this study was to assess the relationship between COP motion of individual limbs and combined limbs during quiet stance and measures associated with lower body physical function. We hypothesized that compared to COP movements of combined limbs, COP movements of the individual limb will exhibit a stronger association with lower body physical function.

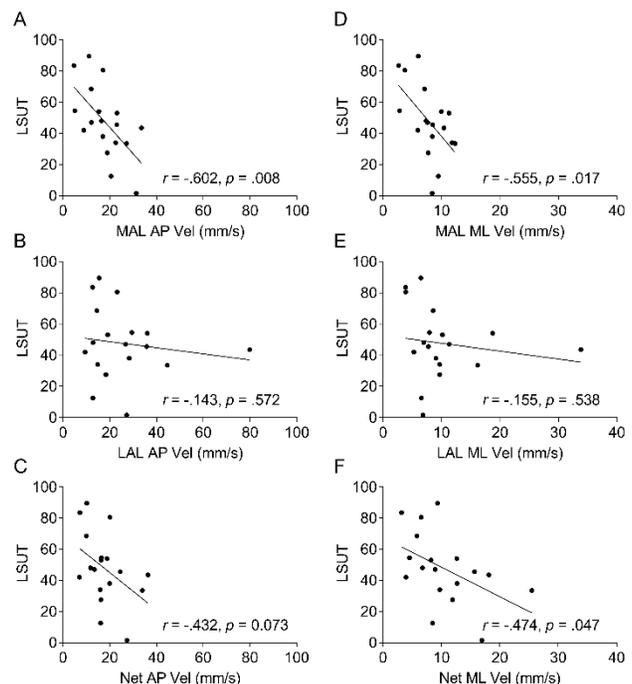

## Methods

Eighteen ambulatory children (5-11 y; Gross Motor Function Classification System I-II) with spastic CP were studied. Two force platforms (Bertec, Columbus, OH, 100 Hz) were used to assess COP from more (MAL) and less affected limb (LAL) during quiet stance. Net COP was calculated by combining MAL and LAL data from both platforms.<sup>2</sup> Participants completed 3 trials of quiet stance for 30 seconds each. COP data were filtered using a 5 Hz 8<sup>th</sup> order Butterworth low pass filter. Linear (i.e., sway distance and velocity) and nonlinear (i.e., sample entropy (sampEn)) COP variables were calculated for both anteroposterior (AP) and mediolateral (ML) directions. Outcome variables presented as the average of the 3 trials. A progressive lateral step up test (LSUT) was conducted to assess lower body physical function. The test consisted of 3 trials of with the MAL on the step and the LAL raised onto and lowered off the step as many times as possible in 20 seconds. Each trial corresponded with an increase in step height (i.e., 10, 15, and 20 cm). A composite score was calculated based on step height and the number of steps completed. Pearson correlations were used to assess the relationship between COP variables for individual and combined limbs and LSUT score.

## Results and Discussion

The MAL's AP and ML sway velocity were inversely related to LSUT score ( $r=-.602$ ,  $p=.008$  and  $r=-.555$ ,  $p=.047$ , respectively; Figure 1A and D). However, none of the LAL's COP variables were significantly related with LSUT score ( $r$  range $-.255$  to  $.139$ ,  $p>.30$ ). The Net AP and ML sway velocities were inversely related to the LSUT score, although the relationships were weaker ( $r=-.432$ ,  $p=.073$  and  $r=-.474$ ,  $p=.047$ , respectively; Figure 1C and F) than the relationships observed with the more affected limb.

The relationships between sway velocity and LSUT score suggest that assessment of COP using a single force platform may predict lower body functional ability on the more affected side in children with CP. However, the prediction may not be as robust as an assessment of COP using 2 force platforms. Further research should be conducted to examine the relationship between individual limb COP measures and measures of physical function beyond LSUT for individuals with CP and other conditions that may lead to more prominent effects on one side.

**Figure 1.** Relationship between COP sway velocity in the anteroposterior (AP) and mediolateral (ML) directions for the more (MAL) and less affected limb (LAL), and combined limbs (Net) and lateral step up test (LSUT) score.

## Significance

Postural control assessment using a single force platform is common, but compared to postural control assessment using dual force platforms is likely less representative of the functional deficits in children with CP.

## Acknowledgments

### Introduction

Various structural components of the human foot stabilize the body during upright standing to maintain postural control. Center of pressure (COP) is often used as an index of postural stability in standing [1]. Previous studies have found associations between static foot structural measures and plantar pressures in healthy individuals, but to date no study has investigated the associations between foot structure and metrics of COP motion [2].

This study sought to determine if there is an effect of foot structure on postural stability in healthy young individuals. It was hypothesized that foot structure has an effect on postural stability in this population.

### Methods

Measurements of foot structure and postural stability were measured for 10 subjects (5 male, 5 female; age  $21.5 \pm 0.5$  yrs; mass  $71.4 \pm 19.8$  kg; height  $1.70 \pm 0.11$  m) who gave informed consent to procedures which had been approved by the institutional review board.

The subtalar joint of participants' dominant foot was placed in subtalar neutral position defined as equal palpation of the medial and lateral talar head in the frontal plane. Measurements of navicular height (NH), medial longitudinal arch angle (LAA) and Feiss line (FL) were made using an ink pen, a six-inch plastic ruler, and a six-inch plastic goniometer. FL was measured as the perpendicular distance from the navicular tuberosity to a line connecting the medial malleolus to the medial aspect of the first metatarsal head [3]. If the navicular tuberosity was above the line, FL was positive; if below, FL was negative. Measurements were repeated with the foot in subtalar resting position. Differences between neutral and resting measures were used to calculate range of motion (ROM). Foot arch and ROM measurements were then classified using cut-off values from Nilsson et al., 2012 [4].

Indices of COP motion from a force plate were measured at 100 Hz during quiet standing for four trials of 30 seconds each under each of three conditions: eyes open normal (EON) stance, eyes closed normal (ECN) stance and eyes open tandem (EOT) stance (one foot directly in front of the other).

Each COP measurement was modelled, by condition, as a function of foot structure, trial and their interaction via a mixed

model employing an unstructured covariance structure to accommodate within subject effects. Hochberg's multiple comparison adjustment was applied to accommodate multiplicity of statistical inference within each condition.

### Results and Discussion

The COP metrics produced values comparable to values in the literature [1]. Analysis of the effect of foot structure on COP metrics indicated significant relationships. Incidents of significant interaction effects were found; therefore, Hochberg's multiple comparison adjustments were made (Table 1). Adjusted values show no statistically significant relationships between any of the foot measures and COP metrics (Table 1). These findings do not support the original hypothesis that foot structure has an effect on postural stability in healthy young individuals.

Significant interactions across condition and trial may exist between foot structure and postural stability such that metrics of COP motion are not uniform across trials but rather change over time. Future studies may want to examine two groups with extreme differences in foot structure (e.g. severely high arch vs low arch) to expand upon these findings.

### Conclusions

These results suggest that when comparing postural stability between individuals of varying foot structure there is no need to account for foot structure in healthy young individuals.

### Introduction

Within a golf swing, one aspect that stands out in each phase is the ability to maintain balance. Previous reports suggest that extrinsic factors such as footwear and intrinsic factors such as muscular exertion level have detrimental effects on human postural control. However, no studies have examined the effects of modern golf footwear on muscle activity of the lower extremity. Thus, the purpose of this study was to examine differences in muscle activity when walking for extended durations in golf footwear

### Methods

Six healthy male adults completed the study (age: 23.4±2.2 years; height: 181.5±9.0 cm; mass: 95.8±18.6 kg). Participants were tested in three types of golf-specific footwear including the dress shoe (DS), tennis shoe (TS), and casual spike-less shoe (CAS), as well as a barefoot condition (BF). Participants were instructed to walk at their self-selected walking speed and path throughout a 4 hour testing duration on the artificial turf that was laid throughout the lab. Reactive balance was assessed prior to the start of walking, and again every hour for 4 hours using the Motor Control Test (MCT), that can translate in the backward and forward directions to create two testing conditions, which include backward translations [medium (BWM)/large (BWL)] and forward translations [medium (FWM)/large (FWL)]. During balance tests, muscle activity was examined for two lower extremity muscles of the right leg: the tibialis anterior (TA), and the medial gastrocnemius (MG). Raw EMG data were collected at 1,500 Hz, band-pass filtered (20-250Hz) and rectified prior to analysis. Peak EMG, and time-to-peak (TTP) EMG were calculated for each muscle of interest. The EMG parameters were analysed using a 4 x 5 [4 (Footwear – DS, TS, MIN, BF) x 5 (Time – Pre, 60, 120, 180, 240)] repeated measures analysis of variance (ANOVA) independently for each of the MCT tests. Post hoc pairwise comparisons using a Tukey's LSD were performed if main effect significance was found for footwear types, and simple effects were calculated if significant interactions were found. Partial eta squared ( $\eta^2$ ) effect size and F statistic are reported. For all analyses, significance was set at an alpha level of  $p < 0.05$  and all statistical analyses were performed using the SPSS 22 statistical software package.

**Figure 1:** Time to peak EMG in the MG during the FWM condition. Bars represent stand error.

### Results and Discussion

A significant interaction was found for the MG peak EMG during the BWL condition ( $F(12,60) = 2.016, p = 0.03, \eta = 0.207$ ), suggesting that at hour 4, TS peak EMG was greater than the CAS. Time main effect for the TA TTP in the BWL condition ( $F(4,20) = 3.62, p = 0.02, \eta = 0.420$ ), with increased TTP at hours 3 and 4 compared to hour 2. Finally, a footwear main effect was found for MG TTP in the FWM condition ( $F(3,15) = 4.16, p = 0.025, \eta = 0.454$ ), suggesting that the DS and TS had increased TTP compared to the CAS.

The findings herein suggest, as expected, that reactive balance decrements would present over time. Specifically, decrements were observed after the second hour of standing and walking. Primarily, footwear differences were observed as decrements in muscle activity wearing the dress shoe and tennis shoe styles relative to the casual styles. Our findings over time corroborate with previous work, where balance deficits are observed after 2 hours of an extended workload (1). While footwear differences are likely due to structural differences between footwear. Previous work has suggested an increase in footwear mass, causes an increased workload in the lower extremity, and may lead to increased muscle activation and balance decrements (2). Currently, the TS and DS, both had a higher mass than the CAS, possibly explaining the balance decrements observed.

### Significance

These findings are important, because, while maintaining postural control is a relatively simple process for the CNS under healthy conditions, when alterations to sensory input begin to disrupt the postural control system this task becomes more difficult. Further, as maintaining postural control becomes more difficult, it can affect any second tasks that are being done (3), such as the golf swing. Therefore, if footwear are causing adverse effects on postural control, it could also lead to decrements in golf performance. Based on the current findings, golfers should seek footwear that is lightweight and has relatively thin sole/midsole thickness in order to mitigate postural control deficits and decrease workload on the lower extremity.

## Preliminary Investigation of Limb Load Symmetry During Quiet Stance & Sit-to-Stand

### Introduction

Understanding human postural control is critical to assessing musculoskeletal and neurological pathologies. Postural control can be characterized by quantifying limb symmetry during various tasks [1]. Thus, limb symmetry is an important factor in evaluating balance performance of numerous populations such as those with Parkinson's Disease [2], or patients who have undergone knee anterior cruciate ligament reconstruction [3] and ankle arthroplasty [4]. Limb symmetry is also affected by everyday, environmental disturbances, and hence performing asymmetry assessments in non-research settings is important to capture a realistic perspective on human balance.

The purpose of this study was to examine load asymmetry during quiet stance in a healthy population, and if that relates to a functional, sit-to-stand, task in a non-laboratory environment.

### Methods

This institutional review board approved study was conducted at the Biomedical Engineering Society annual meeting (2019, Philadelphia, PA). Participants were included based on criteria in self-reported questionnaires that looked for injuries or conditions that may affect their ability to balance or load symmetrically. Each participant completed a quiet stance (QS) task and five sit-to-stand (STS) trials. Two PASCO force platforms (Roseville, CA) recorded vertical ground reaction forces during 30 second, eyes open, bilateral QS and STS.

In MATLAB, load symmetry was quantified using the Normalized Symmetry Index (NSI) [5]. The NSI performs best with multiple trials. Consequently, the middle 20-second interval of the QS task for each participant was broken up into three sub trials, and the five STS trials were used to calculate the NSI. Both calculations were computed with reference to the subjects dominant leg, as self-reported by answering "Which leg would you kick a soccer ball with?". Symmetry differences between tasks was assessed using a paired t-test and the association between tasks was determined using Pearson's correlation ( $p < 0.05$ ).

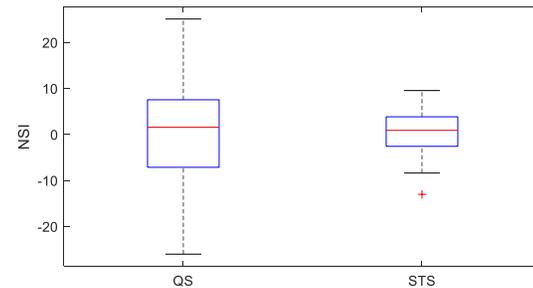

### Results and Discussion

Data from sixty-three healthy, adults ( $25.9 \pm 6.8$  years old,  $170.3 \pm 9.1$  cm,  $68.0 \pm 14.3$  kg, 34 females, 29 males) were collected and analysed. Despite a visually large difference in the range of NSI between that for QS ( $0.692 \pm 10.7$ , mean  $\pm$  s.d.) and STS ( $0.824 \pm 4.45$ ) as indicated by the standard deviations, the values were not statistically different between tasks, suggesting a similar magnitude of asymmetry between the tasks. (Figure 1,  $p = 0.9191$ ).

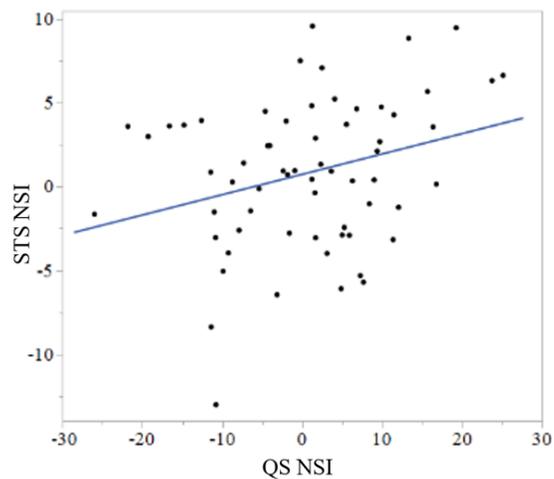

This is further confirmed through the Pearson's correlation and the correlation plot (Figure 2). The NSI of QS and STS demonstrated a weak significant positive correlation ( $r = 0.291$ ,  $p = 0.021$ ).

One goal of this study was to collect asymmetry data in real-world settings, which could also be considered a limitation of this work. The testing took place in a noisy, visually stimulating conference environment disturbing subjects' performance, with

limited control over clothing or shoes worn, which restricts capturing the maximum bounds of human balance.

**Figure 1:** Boxplot comparing NSI values for QS and STS tasks;  $p$ -value 0.9191.

**Figure 2:** Correlation plot for the QS and STS tasks.

### Significance

This study demonstrated that limb load asymmetry was consistent between QS and STS. The large range in asymmetry of QS has been found in a similar study [6]. Compared to NSI of STS, this difference is hypothesized to be associated with the ease of the balance task. QS requires less muscle activation and postural control to maintain balance than a five-time STS, and subjects may displace their weight more asymmetrically due to the reduced risk of falling. Hence, in a healthy population, asymmetry is to be expected within a relatively large range in typical, non-research settings. Future studies should seek to verify load asymmetry in relation to ease of task, and aim to establish the normal bounds of balance in larger populations.

# Physical and Perceived Abilities and Motor Planning of Older Adults During A Virtual Beam-Walking Task

Meghan E. Kazanski<sup>1\*</sup>, Jonathan B. Dingwell<sup>1</sup>

<sup>1</sup>Department of Kinesiology, The Pennsylvania State University, University Park, PA, USA

Email: \*[mek79@psu.edu](mailto:mek79@psu.edu)

## Introduction

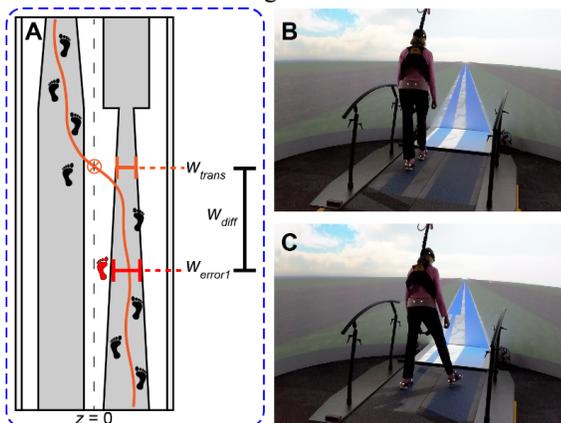

Lateral balance control is critical to remaining upright while walking and maneuvering [1, 2]. In addition to physical stepping ability, we must also consider how perceived ability and motor planning impact responses to lateral balance challenges. Older adults demonstrate discrepancies between perceived and actual balance ability [3] and motor planning ability degrades with age [4]. Older and younger adults respond similarly to continuous lateral perturbations [5]. However, lateral balance challenges that require more motor planning and highlight discrepancies between actual vs. perceived ability may more-comprehensively demonstrate how age-related deficits impact lateral balance.

Here, young and older adults faced competing lateral balance challenges: stay on a continually narrowing beam or make a lateral transition to an adjacent wider beam. We hypothesized that older adults' physical and perceived abilities to beam walk would be less than those of younger adults, and that older adults would require more motor planning to execute lateral transitions.

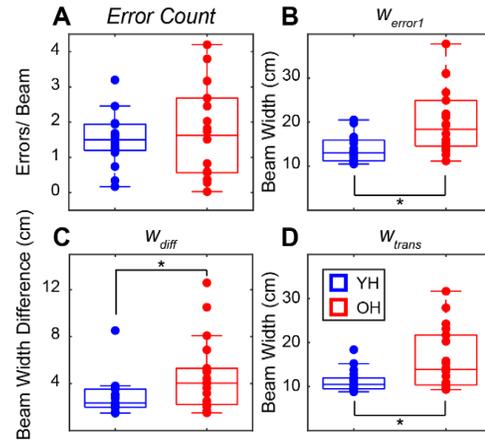

## Methods

Eighteen healthy older (OH; ages 65+) and 18 younger (YH; ages 18-27) adults performed 35 repetitions of treadmill walking on virtual beams. They began each repetition walking on a constantly-narrowing beam, and chose when to transition to an adjacent, wider beam, trying to avoid stepping errors (Fig. 1). Participants received auditory feedback of stepping errors that occurred whenever a foot landed outside of the beam boundaries. Transitions from the narrowing beam were identified when the center of mass (COM) crossed the z-axis.

For each beam, the number of errors made prior to transition (*Error Count*) quantified task compliance (to minimize step errors). At narrower beam widths, more stepping accuracy is required to stay within the beam bounds. Thus, beam width at the first error instance ( $w_{error1}$ ) quantified the physical ability to maintain stepping accuracy. The beam width at transition ( $w_{transition}$ ) quantified perceived ability. The change in beam width between first error and transition ( $w_{diff}$ ) quantified motor planning ability, as it directly related to the time and distance required to execute the transition following the first error.

**Figure 1:** COM trajectories (orange) and first stepping errors (red foot) were recorded (A) as participants walked on a narrowing beam (B) and transitioned to a wider beam (C).

**Figure 2:** Task compliance (A), stepping accuracy (B), motor planning (C) and perceived abilities (D) were compared between groups.

## Results and Discussion

Young and older adults made  $1.50 \pm 0.71$  and  $1.65 \pm 1.29$  errors prior to transition ( $p=0.662$ ), respectively (Fig. 2A). Thus, participants in both groups generally followed task instructions.

OH adults made initial stepping errors ( $w_{error1}$ ) at greater beam widths ( $13.8 \pm 3.1$ cm) than YH adults ( $20.2 \pm 7.5$ cm), respectively ( $p=0.003$ ; Fig. 2B). OH adults required wider beams to retain their stepping accuracy. This was expected, as older adults generally prefer wider steps and age reduces step accuracy [6].

Beam width changes ( $w_{diff}$ ) between first error and transition were higher for OH ( $4.7 \pm 3.1$ cm) than for YH adults ( $2.9 \pm 1.2$ cm), respectively ( $p = 0.031$ ; Fig. 2C). OH required slightly more time and distance to respond to errors, likely for processing and motor planning. This was predicted, as these increase with age [4].

OH adults transitioned from the narrowing beam ( $w_{trans}$ ) at greater beam widths ( $16.1 \pm 7.0$ cm) than YH adults ( $11.3 \pm 2.5$ cm), respectively ( $p = 0.011$ ; Fig. 2D). Thus, OH adults not only demonstrated a reduced physical ability to maintain stepping accuracy, but also appeared to perceive this reduced ability.

## Significance

Responses to lateral balance challenges not only require the physical ability to execute walking and maneuvering tasks, but also rely on perceived ability and motor planning. Further, age-related deficits reduce the physical and perceived abilities and increase the motor planning required to execute lateral balance challenges, such as narrow beam walking and lateral transitions.

# Step Width Variables are not Meaningfully Correlated with Stumble or Fall Incidence in a High Functioning Population with Lower Limb Trauma

Riley Sheehan<sup>1,2</sup>, Mark Grabiner<sup>3</sup>, Trevor Kingsbury<sup>4</sup>, Brad Hendershot<sup>5</sup>, and Kenton Kaufman<sup>6</sup>

<sup>1</sup>Henry Jackson Foundation, <sup>2</sup>Center for the Intrepid, <sup>3</sup>University of Illinois at Chicago, <sup>4</sup>Naval Medical Center San Diego, <sup>5</sup>Extremity Trauma and Amputation Center of Excellence, <sup>6</sup>Mayo Clinic

Email: riley.c.sheehan.crt@mail.mil

## Introduction

Individuals with lower limb trauma (LLT) have an elevated risk of falling<sup>1</sup>. Fall risk is the intersection of the likelihood of stumbling and the likelihood of successfully recovering from a stumble. While both of these factors contribute to overall fall risk, the underlying causes and potential interventions are different. It is important to be able to assess these different fall risk features in order to determine the specific stability deficits and most effective interventions.

Individuals with LLT often walk with a wider, more variable step width. A wider step width increases the frontal plane base of support and potentially reduces the likelihood of balance loss. Step width variability has been related to balance control<sup>2</sup> and, thus, may be associated with the likelihood of recovering from a stumble.

The purpose of the study was to determine if step width and step width variability assess different aspects of fall risk. Specifically, we hypothesized that step width would be correlated with the incidence of balance loss and step width variability would be correlated with the stumble recovery rate.

## Methods

This is a secondary analysis of fourteen Service Members (age: 35±6 yrs, height: 1.81±0.06 m, mass: 92.1±13.7 kg, 13 males) with LLT who participated in a larger trip-prevention training study. For this analysis, all data are collected prior to receiving any training. Participant's injuries included limb preservation for which custom ankle foot orthoses were worn (4), unilateral below-knee amputation (7), and bilateral below-knee amputation (3). Participants completed a questionnaire that reported the number of stumbles, uncontrolled falls, and controlled falls during the previous four weeks. The total number of balance losses (stumbles plus falls) reported was used as our measure of incidence of balance loss. The stumble recovery rate was calculated as the number of stumbles divide by the total number of balance losses.

Participants walked on a treadmill for 10 minutes at a speed scaled to leg length and injury severity. The position of markers on the heels was used to calculate the step width mean and variability (standard deviation) over the trial. Spearman correlations were used to separately characterize the relationships between the step width variables (mean and variability) and the fall variables (incidence of balance loss and recovery rate).

## Results and Discussion

Contrary to our hypotheses, there were no significant correlations between step width or step width variability and the reported balance and fall variables. The strongest correlations were with stumble recovery rate for both step width (Rho=0.19, p=0.51) and step width variability (Rho=0.31, p=0.28). The average step width (160±36 mm) was 66% greater than

previously reported able-bodied individuals evaluated at the same facility (96 mm)<sup>3</sup>. However, the step width variability (29±7 mm) was comparable (30 mm) to those same able-bodied individuals<sup>3</sup>. Notably, the study cohort was comprised of individuals with LLT, who are young Service Members with an overall high level of fitness and function that may decrease the extent to which they are representative of the typical civilian LLT population. For example, two participants reported the ability to walk a mile and the remainder reported the ability to walk greater than 5 miles. This suggests an overall high level of function for these participants.

Despite the overall high level of physical ability, the participants still reported losing balance and falling. On average, over the previous four weeks, participants reported balance losses 8±5 times, reported having fallen 2±3 times, and had a stumble recovery rate of 77±20%. While the small size and diverse makeup of our sample may have limited our ability to identify a significant correlation, the results may also be related to a limitation of the step width variables characterizing fall risk. Many falls occur as a result of trips or slips (balance loss in the sagittal plane) and measures of step width and step width variability may not be associated with the capacity to perform compensatory stepping responses following typical balance loss. Further, many of the participants reported that they fell the most on challenging surfaces (e.g. high curbs, uneven terrain, wet floors). Thus, for this more high functioning LLT population, it may be more relevant to look at measures relating to step length and foot clearance in order to more accurately evaluate fall risk.

## Significance

This study was not able to identify a meaningful relationship between typical step width metrics and stumble and fall incidences in a high functioning LLT population. However, the high reported stumble and fall incidences suggests the need to evaluate other measures that may be more associated with fall risk in this population.

Email: MTillman@stevens.edu

## Introduction

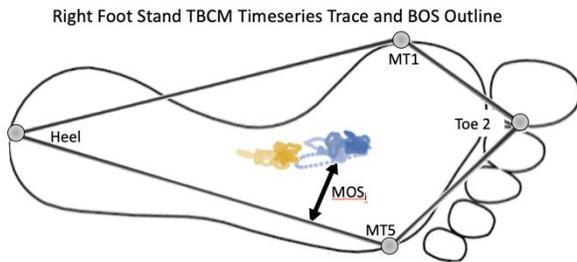

Fall-related injuries due to loss of balance are a leading cause of injury and mortality for older adults [1]. For those with compromised balance abilities, balance training can be assisted with external biofeedback. An emerging area of biofeedback for clinical applications is called sonification, which maps real-time measurements through sound. Existing systems have been shown to assist balance in static upright stance using an inverted pendulum model [2]. We are in the initial stages of developing a task-independent balance training sonification system, building on previous works [2,3]. This system sonifies margin of stability (MOS) [4], base of support (BOS) area, and total body center of mass (TBCM) location. We hypothesize that sonified biofeedback of balance metrics will increase the MOS in single leg stance compared to before biofeedback in young healthy adults.

## Methods

Five participants (two female; age  $24 \pm 2.65$  yrs) volunteered for this study after providing informed consent. They performed five repetitions for one minute each of a single leg stance task, alternating between left and right for five trials. They repeated this in blocks, Before and During sonified biofeedback. Time to move freely and verbal instructions were provided for participants to become familiar with the sound design.

Optical motion capture (Optitrack, OR), Matlab (Mathworks, MA) and MaxMSP (Cycling '74, CA) enabled real-time sonification of three metrics: TBCM location within or outside of the BOS boundaries (boolean value), BOS convex hull area (defined by foot markers in contact with the ground; Fig. 1), and MOS (horizontal distance from the TBCM position to the closest edge of the BOS). The sonification design consisted of a synthesizer that produced continuous oscillatory pulsing sounds (shown [here](#)) [adapted from 3]. Decreasing MOS increased pulse speed. Decreasing BOS area increased brightness. Dissonance was added if the TBCM was outside of the BOS.

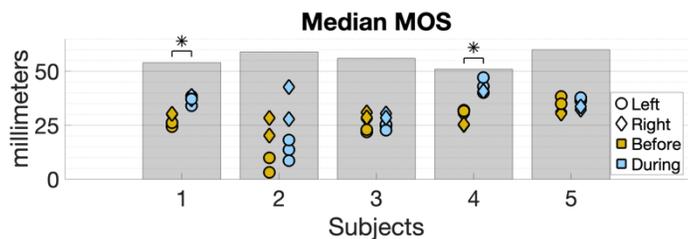

Within-subject, Cliff's analog of the Wilcoxon-Mann-Whitney test was used to compare mean, median, and max MOS Before vs. During biofeedback ( $\alpha=0.05$ ).

**Figure 1:** Representative (Subject 4) TBCM trajectories Before (yellow) and During (blue) sonified biofeedback, shown on a right foot BOS convex hull. Light to dark indicates forward progression of time. MOS is labelled at one timepoint. Labelled gray circles are motion capture markers; foot illustration is included for reference.

## Results and Discussion

During biofeedback, two of five participants significantly increased their maximum, mean, and median (Fig. 2) MOS vs. Before biofeedback ( $p=0.032$  for all three metrics and both subjects). No subjects displayed the opposite trend between conditions. BOS area was constant throughout given the nature of the single leg stance task. Additionally, the TBCM was only outside of the BOS boundary at any time for Subject 2.

**Figure 2:** Median MOS in Before (yellow) and During (blue) sonified biofeedback conditions for each subject during single leg stance of the left (circles) and right (diamonds) legs. Gray bar displays the range of possible MOS values per subject-specific base of support geometry.

Due to the differences observed between right and left stance legs (Fig. 2 circles vs. diamonds), future single leg balance research will be restricted to comparisons of the right or left leg support separately. We also acknowledge that our current BOS model is biased medially relative to the foot surface (as in Fig. 1).

Our hypothesis was partially supported by significant changes in two of five subjects' median, mean, and maximum MOS. However, it is unclear whether these changes are practically significant as the TBCM movement is small relative to the BOS size (Fig. 1). Further, maximizing MOS in single-leg stance may not be functionally helpful. Despite the maximum MOS decreasing, posterior TBCM placements can take advantage of underlying musculoskeletal structure that may reduce the need for active balance control.

## Significance

This work shows promise towards developing a task-independent optical motion capture-based sonified biofeedback system to assist balance training. We are developing practices to inform future experiments including ways to analyze cognitive load and psychosocial aspects of human computer interaction that can affect who learns most from this biofeedback modality. Next, we will expand towards sonification of balance metrics during dynamic over-ground movements. Our long-term goal is to assist clinical practice to remediate balance deficits.

## Introduction

Postural imbalance and falls increase with age and disease, incurring substantial social, economic, and medical costs. A key impediment to preventing falls is insufficient understanding of the foundational coordination mechanisms that enable humans to remain upright while standing. Measures of balance ability, such as those related to the center of pressure (CP) of the ground on foot force (F), demonstrate changes with age- and disability-related declines in balance, but are inadequate to quantify angular momentum control, a primary aspect of maintaining one's balance. Also, imprecision in joint torque and muscle activity estimations are unable to capture the subtle adjustments that maintain posture.

Our approach relates directly to sagittal-plane translational *and* angular body motion. We quantify the relationship between CP and the ratio of F horizontal to F vertical as the height of an emergent intersection point (zIP)<sup>1</sup>.

Hypotheses:

1. zIP is a more consistent and repeatable metric within a subject compared to traditional measures of balance.
2. zIP has higher discriminatory value across age than traditional measures.

## Methods

We examined standing trials from a public dataset of human posturography assessments to analyze force of the ground on the feet during quiet standing on a rigid horizontal surface (3 60s trials)<sup>3</sup>. Subjects were divided into two groups: young (n = 86) and old, defined as >60 years (n = 72). Ground on feet forces in the anterior-posterior horizontal (Fx) and vertical (Fz) directions were bandpass filtered in 0.2 Hz wide bands centered every 0.2 Hz from 0.4 to 7.2 Hz. The slope of the relationship between the bandpass filtered xCP and Fx/Fz was determined with principal components analysis to calculate zIP according to this formula:

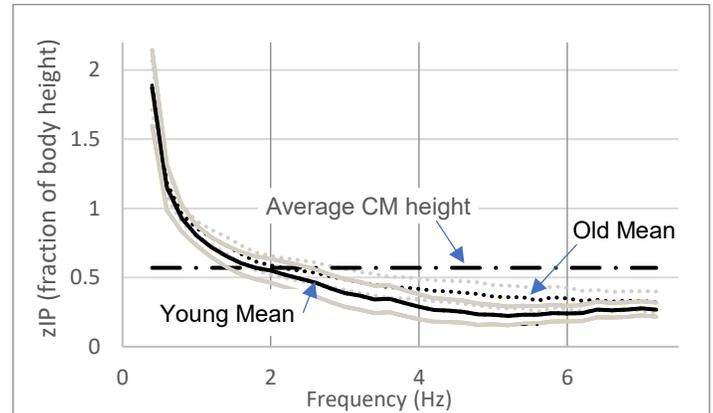

$$\frac{1}{zIP} = \frac{(Fx/Fz)}{xCP}$$

For each frequency bin, we used Student's t-tests to compare the mean zIP of the two samples using a Bonferroni correction.

## Results and Discussion

Clustering analysis showed that the function of zIP across frequency had a high degree of similarity within the multiple trials of a subject relative to the trials of other subjects, which exceeded that observed for the traditional measures of: variance of (CM acceleration, Fx, & CP), root-mean-square of CP velocity, and CP path length (p < 0.001). The zIP in the old was found to be elevated compared to the young (p<0.0001). Traditional measures failed to show an age difference.

Standing requires coordinated activation of muscles across multiple joints (sagittal plane). Previously described muscle

**Figure 1:** Older individuals have a higher zIP at most frequencies.

synergies during standing support the concept of fixed weightings<sup>4</sup> that produce IP's appropriate for the various kinematic modes of falling<sup>5</sup>. Our results of conserved zIP across an individual subject's multiple trials is consistent with fixed weightings of the synergies. zIP is shown to have higher discriminatory value across age than traditional measures.

An elevated IP provides a greater moment about the CM that induces more angular acceleration toward the desired upright posture. This could be a compensation for aging-related deficits in other components of the postural control system (e.g. sensory degradation, processing delays, modified muscle properties).

## Significance

Our findings suggest that zIP is a metric of balance capacity that could have clinical value as a screening and therapeutic feedback tool. A next step is to determine the extent to which IP is associated with fall risk and is able to track balance training improvements in older individuals and those with neurologic impairment. Assessment of zIP can be performed in under a minute with only a force plate and thus could be deployed broadly.

## Acknowledgments

Support was provided by the NSF (NRI 1830516), Virginia Horne Henry Fund, and the UW School of Education Grand Challenges Award.

## Introduction

Robust bipedal locomotion is required to traverse the unpredictable and non-uniform environment that exists outside of the lab. However, we know much less about locomotion in these kinds of non-steady-state environments in comparison to steady-state ones. Previous studies have used perturbations to cause instability during gait, revealing information about recovery strategies, step responses, and muscle contributions used to maintain balance [1]. However, much of this work has not evaluated the interplay between many independent variables, which would improve our understanding of highly unpredictable reactions to gait perturbations that occur in real-world environments. In this study, we establish an experimental protocol to investigate how perturbation *magnitude* and *direction* affect locomotion stability. Specifically, we focus here on how perturbation magnitude and direction affect step response.

## Methods

One subject walked at 1.25 m/s on a treadmill mounted on a Stewart platform and we applied translational perturbations in the mediolateral and anteroposterior directions. We applied 288 perturbations that varied in direction (8 directions, 45° increments) and magnitude (5, 10, 15 cm), creating 24 conditions. We collected lower body motion capture.

We lowpass filtered marker data at 6 Hz. We identified gait events using a kinematic coordinate method [2]. We identified the step length (SL) and step width (SW) at the heel contact at the beginning of each step using the distance between heel markers, shown in Figure 1. We examined the mean SL and SW for each of the 24 conditions for the perturbed step ( $S_0$ ) and the five subsequent steps ( $S_1$ - $S_5$ ), shown in Figure 1.

## Results and Discussion

The steady-state SL and SW were 0.661 m and 0.096 m, respectively. SL was affected by perturbation direction, but only for a single step after the perturbation. In the  $S_1$  step, platform

movement lateral or posterior to the stance foot resulted in a SL decrease. Similarly, platform movement medial or anterior to the stance foot resulted in a SL increase. These changes in SL also increased with the magnitude of the perturbation. Following the  $S_1$  step, magnitude and direction do not appear to influence SL. SW was also affected by direction, with effects lasting for three steps following the perturbation. Platform movement medial to the stance foot caused a SW decrease in the  $S_1$  step and a SW increase in the  $S_2$  and  $S_3$  steps. Similarly, platform movement lateral to the stance foot caused an SW increase in the  $S_1$  step and a SW decrease in the  $S_2$  and  $S_3$  steps. Similar to SL, perturbation magnitude also scaled the severity of SW changes. The simultaneous influence of both perturbation magnitude and direction on SL and SW responses confirm the importance of considering both of these independent variables when analyzing locomotion stability. Future work will also evaluate the interplay between perturbation timing and the two independent variables tested here.

## Significance

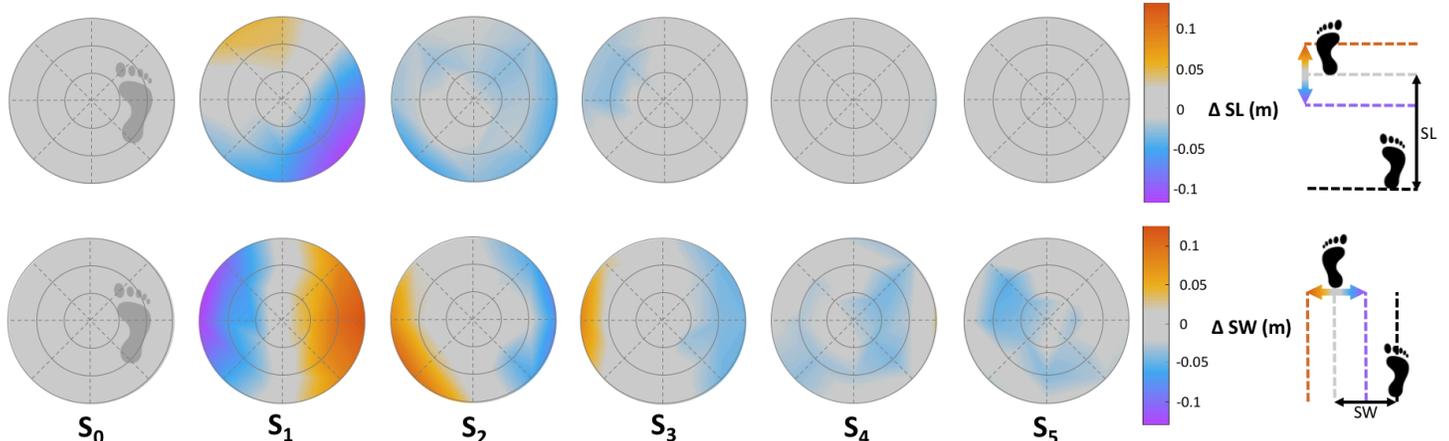

Understanding how balance during bipedal locomotion is resilient to unsteady environments is imperative for designing rehabilitation therapies, assistive devices, and bipedal robots. Our results provide a foundation to understand how a diverse set of perturbations affect locomotion dynamics. Additionally, these data provide a biomechanical reference for researchers and engineers who are designing advanced devices for use in non-steady-state environments.

**Figure 1:** Circular axes represent perturbation magnitude (5, 10, 15 cm) and radial axes represent the direction of platform movement. Perturbations on the right or left foot are normalized and displayed as though the right foot was the perturbed step ( $S_0$ ), shown by the footprint. The colors show the mean SL and SW deviations from steady-state for each step.

# Implementing A Double-Limb Slip Training Protocol To Reduce Falls And Improve Slip Recovery: A Pilot Study

Abderrahman Ouattas<sup>1</sup>, Corbin M. Rasmussen<sup>1</sup> & Nathaniel H. Hunt<sup>1</sup>

<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE USA

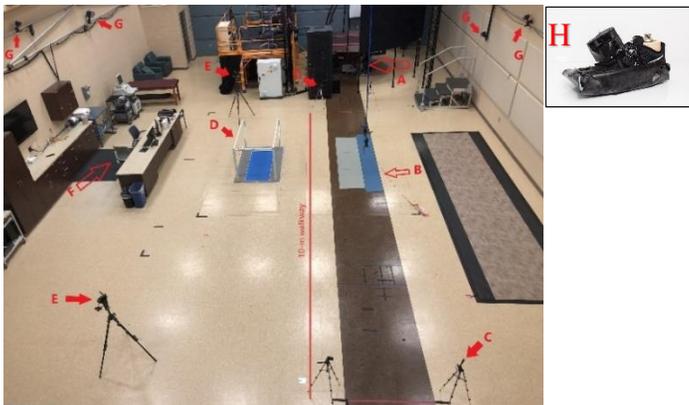

Email: [\\*aouattas@unomaha.edu](mailto:*aouattas@unomaha.edu), web: <https://www.unomaha.edu/college-of-education/cobre/>

## Introduction

Falls are the second leading cause of accidental death in older adults, and account for 17 million serious injuries worldwide, e.g. bone fractures, head trauma, and bruises<sup>1</sup>. Slips alone account for 25% of overall falls<sup>2</sup>. Traditional fall prevention exercise interventions peak at 30% reduction in falls<sup>3</sup>, possibly due to lack of transfer to motor tasks such as trips and slips. Slip training has been previously addressed and shows high promise in reducing falls during slips in the short (1-week) and long term (12 months)<sup>4</sup>. Yet, such methods still lack two factors that may hinder clinical improvement and further reduction in overall falls: 1) laboratory induced slips that mimic slips in real world environments (e.g. unknown slip time and location, low friction surface, double limb slips); 2) identifying reliable biomechanical variables that predict the causation or prevention of falls. This study aims to investigate the aftereffects of a 3 session double-limb slip training protocol (12 slips/session) on reducing falls and describe the specificity of reactive responses to slips in younger and older adults using a novel slipping method. We hypothesized that 1) participants who will experience falls in the first session will not experience falls in the last session, and 2) their reactive response will significantly improve.

## Methods

Two young adults ( $28.5 \pm 0.7$  years;  $85.82 \pm 8.47$  kg,  $1.75 \pm 0.04$  m) participated in the study. The study is a registered clinical trial and we anticipate collection 21 participants in each group (old & young). The study is approved by the University of Nebraska Medical Center IRB. Participants completed 3 sessions of 12 double limb slips each within one week (36 slips in total) that were triggered using an in-lab built Wearable Apparatus for Slip Perturbations (WASP)<sup>5</sup> (Fig 1-H). The WASP induced slips to both limbs simultaneously while participants walked at a fixed gait speed of  $1.3 \pm 0.2$  m/s on a 10 m walkway (Fig 1). Slips were delivered to the dominant foot at 3 separate slip onsets; 1) early stance, 2) mid-stance, 3) late stance. Falls were identified if participants applied more than 30% of body weight to the harness, which was measured using a load cell<sup>6</sup>. Full body kinematics were recorded using a 17-camera motion capture

**Figure 1:** A. Harness and load cell. B. 10-m walkway and force plates. C. Dashr timing. D. AMTI Treadmill. E. Cameras. F. Control Station. G. 17-Camera Motion Capture. H. WASP

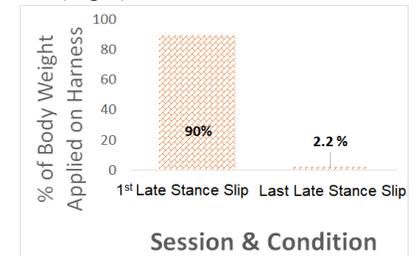

system (Motion Analysis Corp., Santa Rosa, CA) and sampled at 100 Hz.

All data were analysed from slip onset until feet reached a velocity of 0, except for shank angle, which was measured at slip onset. Anteroposterior (AP) and mediolateral (ML) minimum Margin of stability ( $MOS_{min}$ )<sup>7</sup> were used to analyze dynamic stability. Peak shoulder and trunk angles were used to quantify upper body slip recovery. Slip velocity and displacement, in addition to shank angle relative to the floor were used to quantify slip severity. A simple paired t-test was used for each outcome variable to measure the differences between the first and last slips for each slip incidence.

## Results and Discussion

Only late stance slip incidence on the dominant leg yielded a fall in the first slip trial of the 2<sup>nd</sup> participant, and the last slip showed reduction in harness assistance (Fig 2).

Interestingly,  $MOS_{min}$  increased to reach positive values during all subjects and slip incidences after the slip training protocol (Table 1), which indicates that participants became more stable as negative values indicate instability which requires a compensatory mechanics to recover stability. All other variables did not show any significant differences.

**Figure 2:** Load Cell results for 2<sup>nd</sup> participant.

## Significance

Based on these preliminary findings, one can conclude that our novel method is a valid tool in disrupting dynamic stability in both legs, but late stance slips induced to the dominant leg may yield more severe balance disruptions compared to other slip incidences. However, more data is needed to support these conclusions, specifically since covariables such as muscle strength or activation may change the recovery behaviour.

# Acute Effects of Virtual Reality Treadmill Training on Gait and Cognition in Older Adults

Lisa A. Zukowski<sup>1</sup>, Faisal D. Shaikh<sup>1</sup>, Alexa V. Haggard<sup>1</sup>, and Renee N. Hamel<sup>1,2</sup>

<sup>1</sup>Department of Physical Therapy, High Point University, High Point, NC

<sup>2</sup>School of Physiotherapy, University of Otago, Dunedin, NZ

Email: lzukowsk@highpoint.edu

## Introduction

Older adults commonly fall while walking in everyday life, which involves simultaneous performance of cognitive tasks (i.e., dual-tasking). Conventional fall prevention interventions aim to improve strength, gait speed, and/or coordination but not impaired cognition. Interventions that incorporate simultaneous physical and cognitive training demonstrate improved dual-task walking performance and reduced fall prevalence.<sup>1-3</sup> Further, a single cognitively-demanding, visually-interactive exergaming session can result in acute cognitive performance enhancement.<sup>4</sup> An exercise intervention utilizing immersive virtual reality on a treadmill may be especially beneficial in mimicking the distractions and demands of everyday walking, but cognitive benefits of this training have not been explored.

The purpose of this study was to identify the acute effects of a single session of immersive virtual reality treadmill training (IVRTT) on cognitive and gait performance. We hypothesized that compared to a single session of conventional treadmill training (CTT), after a single session of IVRTT, older adults would demonstrate greater improvements in reaction time and accuracy on cognitive tasks, and greater reductions in dual-task costs on gait and cognition relative to pre-training performances.

## Methods

Sixty healthy older adults were recruited and randomized to complete a single IVRTT (experimental) or CTT (active control) exercise session. Participant demographics, baseline cognition, motor abilities, and community participation were assessed.

Exercise sessions were 30 minutes and completed on a treadmill with integrated, immersive virtual reality (GRAIL, Motek). IVRTT incorporated audiovisually-interactive self-paced and set-pace walking challenges. CTT required participants to perform similar motor tasks, but with oral instructions rather than audiovisual components. Participants performed 3 trial conditions before and after the exercise session: 1) single-task walking (ST<sub>gait</sub>), 2) dual-task walking (DT), and 3) single-task cognitive (ST<sub>cog</sub>). Gait was recorded with 6 Opal sensors (128 Hz, APDM). A visuospatial reaction time test was utilized for the cognitive test. Stimuli were produced and recorded using DirectRT (Empirisoft) via wireless headphones.

The dependent variables were cognitive response reaction time (ST<sub>cogRT</sub> and DT<sub>cogRT</sub>), cognitive response accuracy (ST<sub>cogAcc</sub> and DT<sub>cogAcc</sub>), gait speed (ST<sub>gait</sub> and DT<sub>gait</sub>), DT effect on gait speed (DTE<sub>gait</sub>, % = 100\*[ST - DT]/ST), and DT effect on cognition (DTE<sub>cog</sub>, combined reaction time and accuracy). An independent samples t-test was used to compare demographics and baseline abilities of the groups. A multivariate repeated measures ANOVA was used to compare the dependent variables before and after the exercise session for each group (Time x Group).

## Results and Discussion

The groups did not differ in demographics, baseline cognition, motor abilities, or community participation (all p>0.05). In

accordance, there was no Group effect (p>0.05) on measures of gait or cognition. Therefore, differences in gait and cognitive performances can be attributed to the exercise interventions.

Both IVRTT and CTT groups improved performances from pre- to post-exercise session. There was a main effect of time (p<0.001) with both groups exhibiting an 81.1 ms quicker ST<sub>cogRT</sub> and 314.2 ms quicker DT<sub>cogRT</sub>, 0.04 m/s faster ST<sub>gait</sub> and 0.09 m/s faster DT<sub>gait</sub>, 14.5% less DTE<sub>cog</sub>, and 3.9% less DTE<sub>gait</sub> during post-exercise testing, relative to pre-exercise testing. ST<sub>cogAcc</sub> and DT<sub>cogAcc</sub> did not change from pre- to post-exercise testing. These results provide evidence that both exercise interventions acutely improved visuospatial reaction time and gait speed in ST and DT trial conditions and align with previous research providing evidence of improvements in cognitive performance with a single session of dual-task exergaming and aerobic exercise.<sup>4,5</sup>

Contrary to our hypothesis, there was no Group x Time interaction effect (p>0.05). The CTT in this study may have been equally cognitively-demanding as IVRTT and more cognitively-demanding than typical exercise because it required participants to interact with instructions from a trainer. Therefore, both exercise interventions may have resulted in gait and cognitive improvements, only differing in terms of the audiovisual input and feedback. Although these results do not provide evidence for the superiority of IVRTT relative to CTT, they still support that IVRTT can result in key acute improvements in gait and cognition. This is important because if IVRTT were administered in a multi-week exercise program, it could result in significant, more permanent improvements in gait and cognition.<sup>1</sup>

These results support that IVRTT is effective in acutely improving gait and cognition in older adults. IVRTT is a safe way to execute a multimodal exercise intervention that combines simultaneous motor control, attention, planning, visual input, and auditory processing. Results of this study may be used in the design of a multi-week exercise training aimed to safely increase physical activity and reduce fall prevalence in older adults.

## Significance

This study is the first analysis of the benefits of IVRTT. The results of this study lay the foundation for the development of a new fall prevention exercise program that aims to address the safe performance of motor tasks in real-life situations with the associated cognitive distractions that contribute to many falls.

## Identification of specific somatosensation and location to predict postural control outcomes

Riley J. Horn<sup>1</sup>, Meardon<sup>2</sup>, O'Brien<sup>3</sup>, DeVita<sup>1</sup>, and Lin<sup>2</sup>

<sup>1</sup>Department of Kinesiology, East Carolina University, Greenville, NC, USA

<sup>2</sup>Department of Physical Therapy and <sup>3</sup>Department of Biostatistics, East Carolina University, Greenville, NC, USA

Email: [hornr19@students.ecu.edu](mailto:hornr19@students.ecu.edu)

### Introduction

Postural control is a complex motor skill requiring interaction of dynamic sensorimotor processes receiving information from the visual, vestibular, and somatosensory systems. Somatosensation has been reported to account for 50-70% of postural control performance in older adults and 30-40% in young adults.<sup>1</sup> Deficits in somatosensation are known to reduce postural control.<sup>2</sup> Somatosensation measures such as touch pressure sensation threshold (PT) and vibration perception threshold (VT) have been used to identify people with somatosensory deficit in the clinic. However, the appropriate threshold, site on the foot, and modality has not been established in relation to postural control.

Postural control can be assessed using the sensory organization test (SOT) and the motor control test (MCT) using the EquiTest platform.<sup>3</sup> The SOT weighs the individual's use of the visual, vestibular, and somatosensory inputs for postural control through manipulation of the individual's visual surrounding and support surface to determine an equilibrium score. The MCT computes the time for postural recovery after backward and forward translations to determine a latency score. Studies have shown people with postural control deficit have lower equilibrium and latency scores.<sup>4</sup> The purpose of this study was to identify the most relevant sites of somatosensation for postural control. We hypothesized that specific sites of the foot and ankle would have significant associations with equilibrium and latency scores.

### Methods

In this study, 49 healthy adults (22M, 27F; mean age  $42.0 \pm 13.8$  (SD) y.o.) were evaluated for postural control and somatosensory measures. Subjects with fall history, vestibular, orthopedic, or neurological disorders, knee or hip replacement, abnormal dizziness, low visual acuity, or using an assistive device for ambulation were excluded from this study. Subjects with abnormal SOT scores were excluded from this preliminary analysis.

PT was evaluated using a set of Semmes Weinstein graded monofilaments (Touch-Test Sensory Evaluator, North Coast Medical Inc., Morgan Hill, CA, USA). VT was evaluated using a handheld biothesiometer (Bio-Medical Instrument Co., Newbury, OH, USA). PT and VT were measured at 14 sites on the foot: the plantar surface of the great toe, 1<sup>st</sup> metatarsal, 3<sup>rd</sup> digit, 3<sup>rd</sup> metatarsal, 5<sup>th</sup> digit, 5<sup>th</sup> metatarsal, medial arch, lateral arch, the mid heel; the medial and lateral malleoli; and the dorsal surface of the 1<sup>st</sup> metatarsal, between the 1<sup>st</sup> and 2<sup>nd</sup> metatarsal, and the 5<sup>th</sup> metatarsal. A Smart-EquiTest platform (NeuroCom, Clackamas, OR, USA) was used for the SOT and MCT.

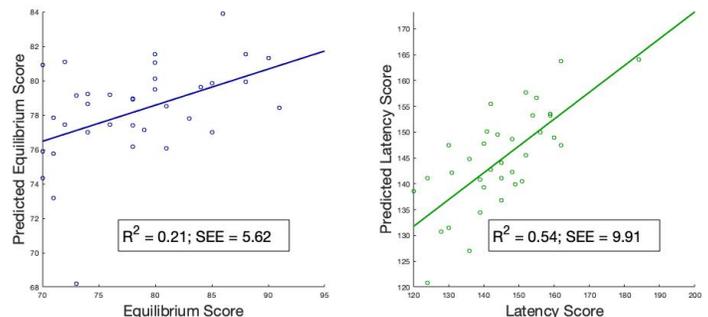

Bivariate correlations were used to quantify the relationship between postural control variables and somatosensory inputs. Linear regression modeling using the backward method was used to identify the most relevant site(s) for postural control outcomes. Data were assessed for multi-collinearity and the model that

optimized the variance accounted and standard error of the estimate was identified ( $p < 0.05$ ).

### Results and Discussion

A total of 35 subjects were included in our analysis; 14 out of 49 were excluded due to abnormal SOT scores. The final linear regression model demonstrated the PT on the right 1<sup>st</sup> dorsal metatarsal and VT on the right 3<sup>rd</sup> metatarsal predicted the equilibrium score ( $F(2, 32) = 4.28, p < .02$ ), with an  $R^2$  of .21 (Figure 1). The PT on the right 1<sup>st</sup> metatarsal, left middle toe, left medial arch, left 5<sup>th</sup> dorsal metatarsal, and the VT on the left middle toe predicted the latency score ( $F(6, 28) = 5.42, p < .01$ ), with an  $R^2$  of .54 (Figure 1).

Somatosensory thresholds were moderately correlated to equilibrium and latency scores in healthy adults. The somatosensory system is only one component in postural control and is expected to only explain a portion of variance in postural control performance. This study provides baseline data for somatosensory measures in healthy adults and gives insight to somatosensory inputs of the foot relevant to postural control.

**Figure 1:** Equilibrium Score vs. Predicted Equilibrium Score and Latency Score vs. Predicted Latency Score.

### Significance

This report is part of an ongoing study investigating the potential cut-points of PT and VT for predicting balance dysfunction in older adults and individuals with peripheral neuropathy to improve clinical fall screening algorithms. Future analyses will examine relationships in atypical populations as well as confounding influences of sensory re-weighting.

# Mediolateral Margins of Stability of Older Adults During A Virtual Beam-Walking Task

Meghan E. Kazanski<sup>1\*</sup>, Jonathan B. Dingwell<sup>1</sup>

<sup>1</sup>Department of Kinesiology, The Pennsylvania State University, University Park, PA, USA

Email: \*[mek79@psu.edu](mailto:mek79@psu.edu)

## Introduction

Mediolateral stability is critical to remaining upright while walking and maneuvering [1, 2]. Many lateral balance tasks encountered while walking, such as executing lateral maneuvers or modulating step width, require trade-offs in mediolateral stability [2,3,4].

Age-related deficits may affect how older adults adjust their mediolateral stability to successfully respond to lateral balance challenges. Here, young and older participants faced competing lateral balance tasks: stay on a continually narrowing beam or make a lateral transition to an adjacent beam. We hypothesized that older adults would adopt a more cautious transition strategy that would minimize changes in stability, with more steps required to recover stability following the transition.

## Methods

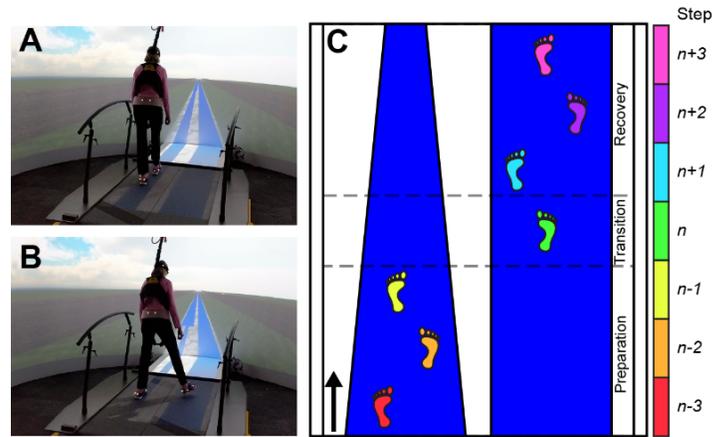

Eighteen healthy older (OH; ages 65+) and 18 younger (YH; ages 18-27) adults performed 35 repetitions of treadmill walking. They began each repetition walking on a constantly-narrowing beam, and chose when to transition to an adjacent, wider beam, trying to avoid stepping errors (Fig. 1A-B). This required participants to plan and execute a lateral maneuver while modulating step width, as both challenge mediolateral stability [2,3]. The transition step ( $n$ ) from the narrowing beam to the wider beam was identified as the first step after the pelvic centroid crossed the z-axis. The ‘transition phase’ was defined as 3 preparation steps, one transition step and 3 recovery steps (Fig. 1C). To quantify transition strategy, the mediolateral Margin of Stability ( $MOS_{ML}$ ) was calculated at the heelstrike of each step during the ‘transition phase’ for each transition, then averaged.

## Results and Discussion

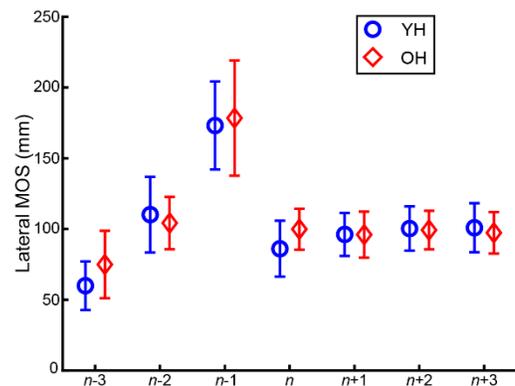

Participants modified their mean  $MOS_{ML}$  at steps within the ‘transition phase’ to perform the lateral maneuver off of a narrowing beam, onto an adjacent beam (Fig. 2). For preparation steps ( $n-3$  to  $n-1$ ), all participants increased their  $MOS_{ML}$  ( $p < 0.001$ ;  $p < 0.001$ ). From step  $n-1$  to step  $n$ , participants reduced their  $MOS_{ML}$  ( $p < 0.001$ ). Following this, the  $MOS_{ML}$  was quickly recovered and was similar for recovery steps (steps  $n+1$  to step  $n+3$ ) following the transition step ( $p = 0.465$ ;  $p = 0.327$ ;  $p = 0.860$ ).

There were no age group differences in  $MOS_{ML}$  for the preparation steps ( $p = 0.050$ ,  $p = 0.475$ ,  $p = 0.684$ ) or recovery steps ( $p = 0.978$ ,  $p = 0.841$ ,  $p = 0.536$ ). The only significant age group difference in  $MOS_{ML}$  occurred at the transition step  $n$  ( $p = 0.032$ ), where OH adults retained slightly higher  $MOS_{ML}$  ( $100 \pm 15$  mm) compared to YH adults ( $87 \pm 20$  mm).

All participants of both age groups adopted a clear strategy when performing the lateral maneuvering task. This strategy involved increases in  $MOS_{ML}$  to prepare for the transition, and a rapid return to consistent  $MOS_{ML}$  from the very first step following the transition. Similar  $MOS_{ML}$  modulation strategies have been adopted by young, healthy subjects navigating constant-width lane changes [2].

**Figure 1:** Participants walked on a narrowing beam (A) and transitioned to an adjacent, wider beam (B). A ‘transition phase’ from the narrowing beam to the adjacent beam is defined (C).

**Figure 2:** Mean  $MOS_{ML}$  plotted for steps in the ‘transition phase.’

OH adults chose to transition off of the narrowing beam sooner, at wider beam widths ( $p = 0.011$ ; see accompanying abstract). Thus, while we expected older adults to adopt a more cautious strategy reflected in *how* they modulated stability throughout the transition, it seems this caution was rather applied to *when* they performed the transition. Likely, lateral transitions were perceived as less hazardous than narrow walking.

## Significance

Here, competing lateral balance tasks provided insights into older adults’ preferences for and execution of these challenges. These preferences may emerge in an effort to retain a maneuvering strategy that modulates stability similar to that of young adults.

### Introduction

Restoration of gait performance is a major rehabilitation goal after hip fracture. Several studies have indicated that relatively high intensity exercise and endurance training beginning six-months post-fracture could benefit gait performance. However, gait characteristics of post hip-fracture recovery are still poorly understood. As an ancillary study of the Community Ambulation Project [1], this study aimed to investigate the effect of a multicomponent home-based rehabilitation training on gait characteristics quantified by spatiotemporal variables, including rhythm, phase, pace and asymmetry [2,3]. We hypothesized that, at the end of the intervention, participants in the multi-component intervention group, compared to the control intervention group, would have greater improvements in gait characteristics.

### Methods

Subjects were part of the Community Ambulation after Hip Fracture (CAP) randomized clinical trial Mechanistic Pathways (CAP-MP) ancillary study. In CAP-MP, 40 subjects with hip fracture were randomly assigned to either the multi-component home-based physical therapy intervention (PUSH) that focused on lower extremity strength, endurance, balance and function or an attention control intervention (PULSE) that included active range of motion (AROM) exercises and sensory level TENS to the lower extremity. Of these 40 participants, 27 had gait measures. There were n=14 in PUSH (9 women, mean age=77.6.5±8.1 years, days after fracture: 112±36), and n=13 in PULSE (7 women, age=79.8±6.8 years, days after fracture: 111±32). Both PUSH and PULSE groups did their respective home-based training over 16 weeks.

The GAITRite<sup>®</sup> System was used to assess gait characteristics and balance. Participants walked across an 8-meter long instrumented GAITRite<sup>®</sup> walkway under 2 conditions: preferred steady state (normal) speed and at their safe fastest speed to determine spatial and temporal parameters of gait. Each subject completed 2 trials of each condition with a short rest period between trials for a total of 4 trials (i.e., 2 trials x 2 conditions). For each condition, values were averaged over the two trials. Walking aids were permitted only when the participant was unable to walk without assistance. Data were sampled at 120 Hz and processed using GAITRite<sup>®</sup> Platinum software.

Data were analysed using SAS studio (basic version 3.8). All 27 participants with at least one baseline value were included. The effect of training on the gait outcome improvements from baseline to 16 weeks was compared between the PUSH and PULSE groups using a general linear mixed-effect model fitted by restricted maximum likelihood. Participants with partial missing data were included in the analysis.

### Results and Discussion

Overall, there was no significant difference in the measured gait parameters over the 16-week training between the PUSH and PULSE groups. Thus, our hypothesis was rejected. Results of

within group comparison are shown in Table 1. Both PUSH and PULSE groups showed significant improvements in most gait rhythm and pace parameters ( $p<0.05$ ). The normal walking speed was 0.741 m/s and 0.698 m/s for PUSH and PULSE at 16-weeks, respectively, which was much lower than age-matched healthy adults (e.g., 1.10-1.20m/s reported in the literature) [2]. The PUSH group but not the PULSE group showed improved postural control for normal speed walking and decreased asymmetry between the fractured and non-fractured sides for fast speed walking ( $P<0.05$ ).

Domain	Gait parameters	PUSH		PULSE	
		Normal	Fast	Normal	Fast
Rhythm/ pace	Walking speed (cm/s)	17.00(4.56)*	13.57(4.95)*	13.6(5.12)*	13.10(5.77)*

	Step length assymetry	-6.90(4.04)	-6.21(2.55)*	-5.87(4.24)	-4.76(2.69)

**Table 1.** Changes (standard errors) from baseline to 16-weeks for PUSH or PULSE groups at the normal and fast walking conditions. \* indicates significant change between the 16-weeks and baseline ( $p<0.05$ ).

### Significance

The effect of a 16-week multicomponent home-based rehabilitation training is comparable with active control on gait performance for people with hip fracture, starting at 3-months post-fracture. Both PUSH and PULSE interventions provided beneficial effects on gait rhythm and pace for older adults after hip fracture. Moreover, until 7-months post-fracture, the gait performance of the individuals with hip fracture was still inferior to that of age-matched healthy adults. Long-term intervention would be warranted for people to regain their ambulation function after hip fracture.

# Improvement of Shock Absorption Performance of Construction Helmet using Air-bubble Cushioning- A Preliminary Study

John Z. Wu\*<sup>1</sup>, Christopher S. Pan<sup>1</sup>, Mahmood Ronaghi<sup>1</sup>, Bryan M. Wimer<sup>1</sup>, Uwe Reischl<sup>2</sup>

<sup>1</sup>National Institute for Occupational Safety and Health, Morgantown, WV, USA.

<sup>2</sup>Boise State University, Boise, ID, USA. \*Email: jwu@cdc.gov

## Introduction

The industrial helmet is considered as the most common and effective personal protective equipment to reduce work-related traumatic brain injuries [1, 2, 3]. The Type I construction helmet is the most commonly used model in construction and manufacturing. A representative Type I helmet consists of a hard shell and a suspension system. The suspension system, which typically consists of synthetic woven webbing and bands of molded nylon or vinyl, plays an important role in shock absorption and impact force redistribution. In the current study, we tested our hypothesis that adding air bubble cushioning into the suspension system of a Type I industrial helmet will enhance its shock absorption performance.

## Methods

The current study was performed only via Type I impact tests, i.e., the impact on the top crown of the helmet shell [4]. Typical off-the-shelf Type I construction helmets were utilized in the study. Helmet drop impact trials were performed using a commercial drop tower test machine (HP, White Laboratory, MD, USA), complying with the ANSI Z89.1 standard [5]. The impactor had a mass of 3.6 kg and was dropped from six different heights from 2.00 ft (0.59 m) to 6.34 ft (1.86 m). The transmitted impact forces to the base of the headform were measured at a sampling rate of 25 kHz. The effects of the air bubble cushioning on the helmets' shock absorption performance were evaluated via two test groups: group I (unmodified helmets) and group II (helmets with air-bubble cushioning). The air-bubble cushioning consists of two layers of typical air-bubble cushioning wrap sheets (Blue Hawk, Gilbert, AZ). The air-bubble cushioning was placed between the headform and the helmet. Four replication trials were performed in each of the drop impacts. A fresh helmet and a fresh cushioning sheet were used for each replication trial.

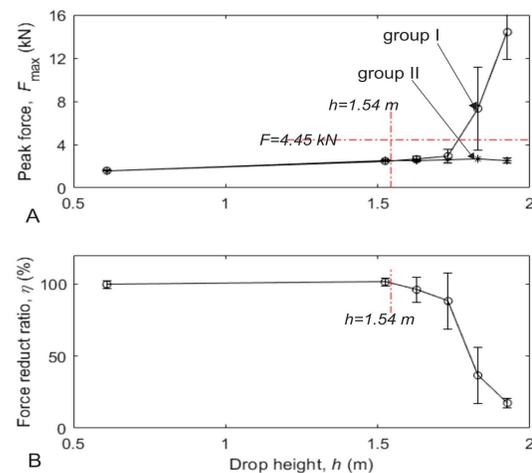

## Results and Discussion

The peak impact forces have been identified from the force-time curves of each drop impact trial. The peak impact forces as a function of the drop height for groups I and II are shown in Fig. 1A. The ANOVA analysis shows that the peak transmitted forces between the two test groups are significantly different ( $p < 0.002$ ) when  $h \geq 1.83$  m. For tests in group I, the peak force values increase gradually with the increase in drop height for  $h < 1.73$  m (5.68 ft); when  $h > 1.73$  m (5.68 ft), peak force values increase dramatically. For tests in group II, the peak force values increase gradually and evenly with the increase in drop height for the entire range of the tested drop height. The ratio of the peak force with the air bubble cushioning to that without air bubble cushioning ( $\eta = F_{\max,air}/F_{\max,no-air}$ ) is shown in Fig. 1B. It is seen that the force reduction ratio ( $\eta$ ) varies little for  $h < 1.63$  m, and it then decreases dramatically with increasing drop height. At smaller drop heights ( $h < 1.63$  m), the air bubble cushioning has little effect on the impact force reduction (i.e.,  $\eta \approx 100\%$ ), whereas for higher drop heights ( $h > 1.63$  m), adding the air

bubble cushioning to the existing suspension system substantially reduces the transmitted peak impact force (i.e.,  $\eta \ll 100\%$ ).

## Significance

Our results demonstrate that adding an air bubble cushioning layer to a basic Type I construction helmet would substantially enhance the shock absorption performance at high impact forces, providing better protection. The concept of air bubble shock reduction may be introduced to the helmet industry to improve the helmets' shock absorption performance, especially for Type I helmets.

**Figure 1.** Peak forces for test group I (without air bubble cushioning) compared with those for test group II (with air bubble cushioning). A: Peak force. B: Peak force reduction ratio.

### Introduction

Surgical training is often supplemented with simulated procedures using animal models. Representative animal models have been developed to simulate difficult procedures and prepare surgeons for real-time patient surgical operations [1]. The goal of these simulated procedures is to challenge the surgeon, both mentally and physically, above the standard, baseline procedure. Challenging surgical procedures may require additional time to complete and lead to increased muscular fatigue [2]. Muscle fatigue can be detected by quantifying muscle activity frequency. A decrease in the median muscle frequency is indicative of muscle fatigue [2]. The purpose of this study was to validate the increased difficulty of an experimental artery and vein anastomosis rat model by demonstrating that surgeons experience muscular fatigue compared to the standard, control model.

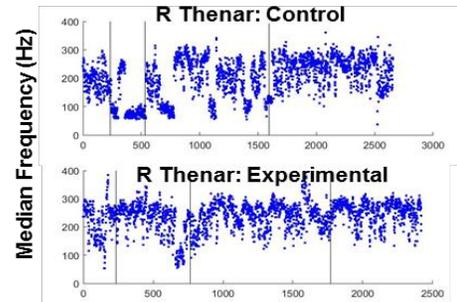

### Methods

One seventh year neurosurgery resident was evaluated. The participant performed two procedures, first with the control model followed by the experimental model. Surface electrodes were placed bilaterally on the following muscles: thenar group (TG), flexor digitorum profundus (FDP), and extensor carpi radialis (ECR). EMG signals were obtained using a standalone system (MA-720 system Motion Lab Systems Motion Lab Systems, Inc., Baton Rouge, LA) and collected at 2400Hz for 30 seconds at two minute intervals over the entire procedure. Raw data files were converted to ASCII format files (RData2, Motion Lab Systems Motion Lab Systems, Inc., Baton Rouge, LA) before processing with custom Matlab (Mathworks, Natick, MA) software routines.

For each data collection epoch, the median frequency was calculated for 500 ms blocks for each muscle using non-stationary signal analysis [3]. These slope of median frequencies over time was calculated for each 30 second data collection for each muscle. The procedure was divided into four time blocks: basic exposure, vessel isolation, clamp 1 and clamp 2. The overall slopes during each time block for each time block and condition was determined.

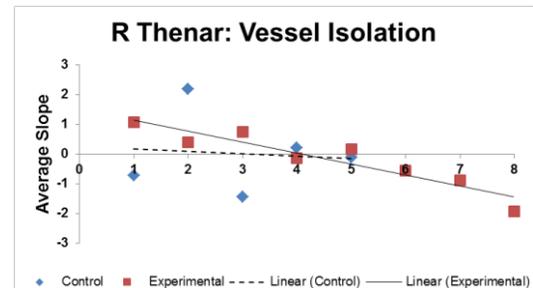

### Results and Discussion

The control and experimental procedures lasted 90 and 84 minutes, respectively. Bilaterally, the median frequency for the FDP and the ECR did not change between time blocks or across conditions, which may be due to the surgeon's posture. The forearms were supported for both procedures. Notably, for the surgeon's dominant hand (right side), there was a difference in the median frequency for the TG during the vessel isolation portion of the procedure between the experimental and control conditions (Figure 1). The experimental model was designed to be more challenging during the vessel isolation portion due to increased scaring.

**Figure 1:** Each data point represents the median frequency for a 500 ms block for right thenar group (dominant hand) for the control (top) and experimental (bottom) conditions. The vertical lines divide the procedure into time blocks (in order): basic exposure, vessel isolation, clamp 1, and clamp 2

Comparison of the slopes of the median frequency during vessel isolation between conditions (control=-0.0805,  $R^2=0.0087$ ; experimental=-0.3689,  $R^2=0.8742$ ) demonstrated a decrease in frequency during the experimental condition compared to the control condition (Figure 2).

**Figure 2:** Each data point represents the average slope of the median frequencies for 500 ms blocks during a 30 second data collection during the vessel isolation. The dashed line is the overall slope of the control condition and the solid line is the overall slope of the experimental condition during the vessel isolation.

The decrease in frequency of the TG during vessel isolation demonstrated that there was muscle fatigue during this portion of the procedure. The presence of TG fatigue supports the hypothesis that the experimental model was more challenging than the control model.

### Significance

The presence of dominant hand TG muscle fatigue demonstrated that the experimental condition was more difficult than the control condition. This technique can be used to study ergonomics during surgical procedures.

# Non-linear analysis of effects of inertial properties on hammer movement variability

Joseph E. Langenderfer<sup>1</sup>, Mara R. Thompson<sup>2</sup>

<sup>1</sup>School of Engineering and Technology, <sup>2</sup>Department of Physical Therapy

Central Michigan University, Mt. Pleasant, Michigan

Email: [j.langend@cmich.edu](mailto:j.langend@cmich.edu)

## Introduction

Hammers have different inertial properties including overall rotational inertia and the symmetry of inertia. The relationship between the overall inertia and symmetry influences object effectiveness as a hammering tool [1]. Hammering is repetitive, but with variable movement. It is unknown if how the hammer movement varies is different for different hammers.

The purpose of this study was to use recurrence quantification analysis (RQA) to quantify the non-linear dynamics of the hammer movement in order to determine if the predictability and complexity of movement variance are related to hammer rotational inertia properties. RQA has been used previously to analyse the structure of hand motion variability in experts compared to novice hammerers [2], and to analyse motion when objects were wielded with intention to perceive object dimension compared to no intention [3]. The objective here was to examine the role of hammer inertia and symmetry of inertia. The hypothesis was that hammers with greater rotational inertia symmetry would result in a swinging movement that is more regular but more complex.

## Methods

Marker data were collected with VICON from male subjects (N=23) repetitively swinging hammers (Fig. 1). Overall rotational inertia for pairs of hammers (H1-H2 and H3-H4, respectively) was approximately equal. Inertia symmetry of H2 and H4 were 3 and 7 times, respectively, the symmetry of H1 and H3 (approximately equal).

Angular velocity of the hammer swing waveform was analysed with RQA. For 3 hammer swings from each trial, the phase space was constructed using the optimal lag (4 samples) and embedding dimension ( $m=2$ ), determined from a trial-and-error process [4]. Recurrence plots were constructed using a radius of 10% of the maximum Euclidean norm between data points in the reconstructed phase space with at least two points defining a line segment required for determinism.

Recurrence plots (Fig. 1c) are created by darkening pixels when the waveform revisits the same neighbourhood in phase space. Recurrence rate (%REC), percent determinism (%DET) and Entropy measures the pattern of darkened pixels. RQA measures were assessed with ANOVA and t-tests with Bonferroni correction for pairwise comparisons.

Figure 1: Repetitive swinging (a) of hammers (b); Recurrence plot (c).

## Results and Discussion

Pairs of hammers with similar overall inertia demonstrated different RQA parameters. %REC of hammer swinging motion was different between H2 and H3 ( $p=0.0001$ ) and H3 and H4 ( $p=0.003$ ) (Fig. 2). %DET was different between H2 and H3 ( $p=0.003$ ). For Entropy, there was a difference between H2 and H3 ( $p=0.002$ ) and H3 and H4 ( $p=0.001$ ).

The greater %REC found for the more inertia symmetric but shorter handled hammers indicates that that movement is more non-linearly autocorrelated, i.e. movement is more regular. Higher %DET indicates the recurrence is more predictable. Entropy is a measure of complexity in the deterministic structure of the time series. Increased Entropy for shorter handle hammers indicates the recurrence is more disordered, with greater adaptability of the movement to meet task demands.

The movement of shorter handle, more inertia symmetric hammers was more regular, less random and of greater complexity. The lack of significant differences between H1 and any other hammer, combined with the lack of differences between H2 and H4, suggests that inertia symmetry does not uniquely affect how hammer movement varies. Rather, handle length, possibly combined with familiarity with the tool and its inertia, may be a more important influence of how the movement varies.

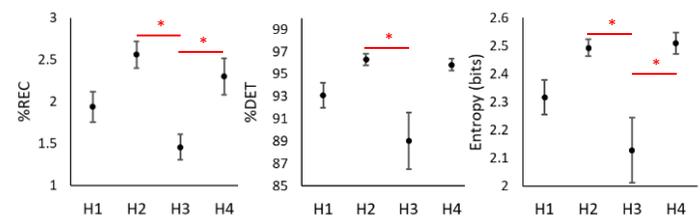

Figure 2: RQA measures for hammers 1-4. \* significant difference.

## Significance

Results suggest resiliency of motor control to altered inertial properties (overall inertia and symmetry). Handle length likely affects how the hammer movement varies more so than inertia symmetry. Similar techniques may be useful for understanding how subjects move objects differently including tools for manual labor, prostheses, or implements used in sport.

# Office Workers Maintain Decreased Sitting Time Long Term When Provided Sit-Stand Workstations

Erika Nelson-Wong, Ingrid Carlson, Jack Corrigan, Tara DiRocco, Brianna Hall-Nelson, Stephanie Kutcher, Patrick Mertz

School of Physical Therapy, Regis University, Denver, CO, USA

Email: enelsonw@regis.edu

## Introduction

Long periods of sitting have many detrimental health effects, yet American adults still spend an average of 6.4 hours/day seated [1]. Many companies have adopted sit-stand desks (SSDs) in the workplace as an attempt to promote employee health, decrease sedentarism, and reduce musculoskeletal ailments. It is unknown whether intervention approaches directed towards decreasing sedentary behaviors through SSD prescription result in long-term behavioral changes in office workers. While previous studies have noted decreases in sitting time from SSD adoption in the short term [2,3,4] whether these changes last in the long-term is ambiguous. If SSDs are poised to serve as a solution to office place sedentarism, data on long-term SSD utilization is critical.

Previous work investigated the impact of a structured program for transitioning from seated to standing work, with SSDs provided to office workers [4]. The current study seeks to explore whether participants in the previous study maintained decreased sitting time long-term through a follow-up survey. We expected participants to have similar sitting minutes/day to those reported upon completion of the previous study.

## Methods

Individuals who had formerly completed a previous study investigating effects of a targeted intervention on standing tolerance were invited to participate in the current follow-up study. Study participants were required to be employed full-time (> 32 hours/week) in an office setting at a primary desk job.

Qualtrics<sup>XM</sup> survey software (Provo, UT) was used for this study. Pattern of use information including number of hours worked and percentage of time spent sitting and standing during the previous 7 days using the Occupational Sitting and Physical Activity Questionnaire (OSPAQ) [4].

Sitting minutes per day from the follow-up survey were compared with the baseline sitting minutes and final (end-point of previous study) sitting minutes. Sitting minutes were entered into a repeated measures ANOVA for the 3 time-points with Bonferroni corrected paired *t*-tests for post hoc multiple comparisons.

## Results and Discussion

Of the 32 original participants, 20 agreed to participate and 12 were lost to follow-up for a response rate of 62.5%. One participant no longer had their SSD, this participant's data was excluded. Time since completing the original study was 19.8 ± 4.2 months (range 12-24 months).

Prior to enrollment in the original study (baseline), participants reported sitting 461.7 ± 86.6 min/day. At study completion, participants reported sitting 289.0 ± 96.3 min/day. In this follow-up survey, participants reported sitting 342.0 ± 111.9 min/day. As reported previously [4], participants in the original study

decreased their sitting time by 30-50% during the 12-week study period. While participants increased their daily sitting time 12-24 months after study completion, this was not significant ( $p = .13$ ). Sitting time at follow-up remained significantly lower ( $p < .001$ ) than participants' baseline values prior to SSD implementation.

Limitations of this study include the small sample and the low response rate/loss to follow up. Participants were also highly motivated to use SSDs and were provided the workstations as an incentive for participation in the original study. The original study included a control group and an intervention group (received a structured approach to increasing their standing time over the 12-week period and a home exercise program), however those groups are not analyzed separately here due to the small group sizes.

These findings suggest that the decreased sitting time observed when office workers are provided with SSDs persists over time, even in the absence of continued encouragement and/or structured instruction.

## Significance

While beneficial effects have been found in the short-term with standing workstation implementation in office settings, the longer term benefits have been unclear. Findings from this study demonstrate office workers maintain decreased sedentary behaviors at work for a period of 12-24 months following adoption of standing work solutions. Office workers who are motivated to try standing desks at work can be expected to benefit through decreased sitting time long-term.

## Acknowledgments

The authors would like to thank VARIDESK for providing the sit-stand desk units for this study. VARIDESK was not involved in study design, analysis, or interpretation of findings. This study was funded by the Regis University Research and Scholarship Council.

### Introduction

Development of sophisticated microsurgical skills can be obtained through training with animal models. A rodent model has been developed to simulate the physical and psychological challenges inherent to operating under subarachnoid haemorrhage conditions [1] with the goal of preparing surgeons for a high-stakes procedure at the end of a fatiguing event. Individuals with normal upper-extremity physiology will have a tremor at an 8-12 Hz frequency during times of stress, anxiety and physical exertion [2-3]. This tremor can be used to identify surgeon fatigue. The purpose of this study was to validate the increased difficulty of an experimental artery and vein anastomosis rat model by demonstrating that surgeons experience increased hand tremor compared to the standard, control model.

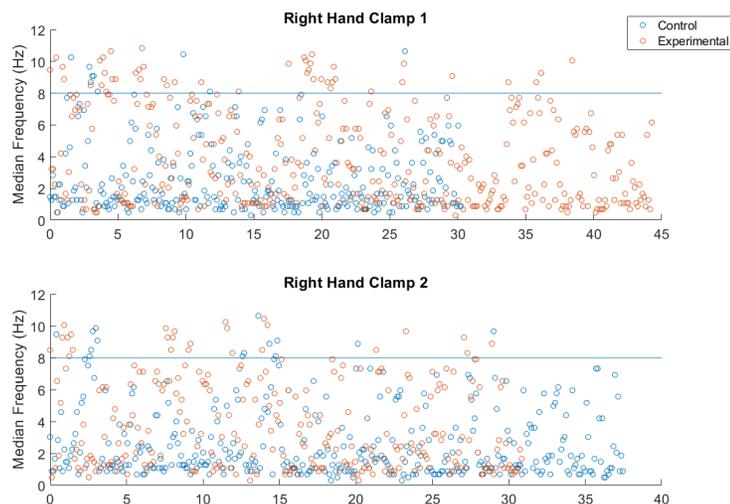

### Methods

In this pilot study, a sixth year neurosurgery resident was evaluated. The subject performed two surgeries: artery and vein anastomosis on a control and experimental rat model. Tremor measurements were acquired using two single axis piezoelectric accelerometers (Type 8640A, Kistler, Novi, MI) affixed to each thumb on the dorsum of the distal third aspect of the 1<sup>st</sup> metacarpal. The accelerometers were attached to a piezotron coupler (Type 5114, Kistler, Novi, MI) and the data was acquired continuously at 100 Hz (NI-USB-6225, National Instruments, Austin, TX).

Median and low pass filters were applied to the raw piezoelectric signals to remove noise and separate the acceleration components due to gravity and bodily motion (BA) [4]. The BA was low-pass filtered at 20Hz and a 512-point Fast-Fourier transform (FFT) was calculated. Power spectral densities (PSD) were calculated from the FFT and median frequency was found for each data block. The procedure was divided into four categories: basic exposure, vessel isolation, clamp 1 and clamp 2. The median frequencies for both left and right hands were assessed over time for the control and experimental condition. For each surgical category, the proportion of time above 8Hz was calculated. A Z-test statistic was calculated to determine if there was a difference in the portion of time between the experimental and control procedures. Significance was set to  $p < 0.05$ .

### Results and Discussion

The experimental procedure lasted longer than the control (93 and 71 minutes, respectively), with the vessel isolation portion taking 4 times longer in the experimental procedure (28 and 7 minutes, respectively). The surgeon experienced tremor bilaterally, with tremors occurring during the vessel isolation, clamp 1 and clamp 2 portions for both surgeries. There was a statistically significant increase in the median frequencies above 8Hz during the experimental conditions for the surgeon's dominant hand (right) during the clamp 1 ( $p < 0.00001$ ) and clamp 2 ( $p = 0.005$ ) portions of the surgery (Figure 1).

**Figure 1:** Median frequency of thumb tremor over time for control and experimental conditions. Each data point represents the median frequency for a 512 ms block for the Clamp 1 and 2 portions of the control (blue) and experimental (red) surgeries. Frequencies above the vertical line at 8 Hz indicate fatigue induced tremor.

The experimental model increased scar tissue formation, resulting in more challenging vessel isolation, indicated by the increased time spent on this portion of the procedure. While differences in median frequencies were not found during vessel isolation, the increased scarring of the experimental model acted as a fatiguing event for the subsequent Clamp 1 and Clamp 2 steps.

### Significance

An experimental animal model has been design to replicate the physical and psychological challenges to a neurosurgeon performing a high stakes surgical procedure. The efficacy of the model is documented by the increased surgeon tremor compared to the control model. The ability to quantify surgeon fatigue allows for the quantitative assessment of model fidelity and analysis of a surgeon's ergonomic profiles throughout surgical tasks.

# Verifying Joint Space-Based Metabolic Energy Expenditure Models

Jazmin M. Cruz<sup>1</sup> and James Yang<sup>1\*</sup>

<sup>1</sup>Department of Mechanical Engineering, Texas Tech University, Lubbock, TX, USA

Email: \*[james.yang@ttu.edu](mailto:james.yang@ttu.edu)

## Introduction

Walking, running, sitting, and sleeping all require some amount of metabolic energy consumption in humans. Naturally, humans prefer to optimize their energy consumption when performing a task because doing so means less energy is required, thus allowing the human to maximize the available energy they have left.

In the past half century, metabolic energy expenditure (MEE) models that estimate energy expenditure have been developed by either using muscle states or by using joint dynamics [1,2]. A recent comparison between energy models was performed by Koelewijn et al. (2019) and found that muscle-state-based models performed better than the joint-based model [3]. It appears that the muscle-based metabolic models are more reliable, but they require muscle information.

If muscle information is not available, the joint space-based MEE offers a more convenient option when calculating energy consumption. Therefore, the objective of this work is to compare the energy consumption calculation accuracy among two versions of a joint-based energy consumption model. It is expected that the latest model will perform better than its predecessor.

## Methods

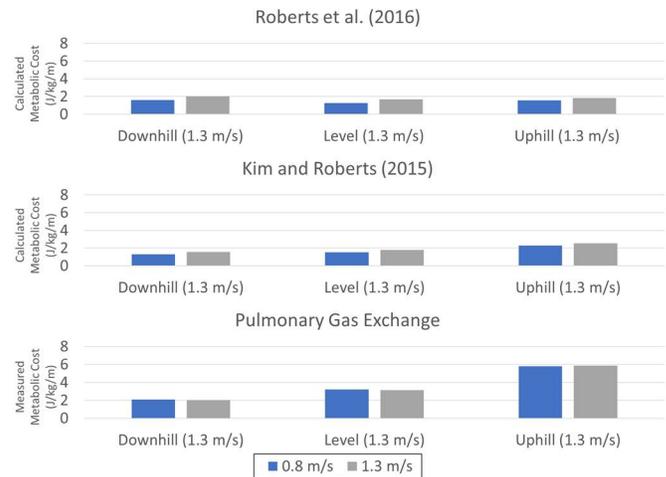

This study uses experimental data provided by Koelewijn et al. (2019). The study recruited 12 individuals (sex: 6 males to 6 females; age:  $24 \pm 5$  y; weight:  $70 \pm 12$  kg; height:  $1.73 \pm 0.08$  m) and measured metabolic cost using indirect calorimetry while walking at two paces (0.8 m/s and 1.3 m/s) during three inclines (0%, 8%, and -8%). This data is available for download online.

In the literature there are two joint space-based MEE models (Kim and Roberts, 2015; Roberts et al., 2016). In Koelewijn et al. (2019), the older joint space-based model (Kim and Roberts, 2015) calculated MEE values based on the experimental scenerios. In this study, MEE values from the new joint space-based model (Roberts et al., 2016) were also calculated. In the calculation, the following inputs are needed: task duration, joint torques, joint velocities, and maximum knee torque. All inputs were available to us except for maximum knee torque. An estimated average maximum knee torque value of 212.4 Nm and 107.6 Nm was used for men and women, respectively. The energy cost was normalized by dividing the energy cost (W) by the participant mass (kg) and speed (m/s). A root mean squared error (RMSE) calculation was used to assess how well each model performed. All scenarios used  $n = 12$ , but  $n = 11$  was used for downhill walking at 1.3 m/s because one subject did not have experimental data for this case.

## Results and Discussion

The results in Figure 1 show the calculated MEE from the two models and the measured metabolic cost. Table 1 contains the RMSE values for each model during each scenario. Kim's model is more accurate than Robert's model when performing level and uphill walking at both paces. However, when walking downhill, Roberts has a better estimation. The experimental metabolic cost

has a steady increase as the incline increases from downhill to uphill, which is intuitive. Yet, it appears that both models do not adjust well to the incline change, where each of the graphs in Figure 1 have very little difference in magnitude and do not follow the steady increase in energy cost as seen in the experimental data.

**Figure 1:** Calculated and measured metabolic cost.

**Table 1:** Root mean square error (J/kg/m) between the calculated and measured metabolic cost for both models. (The bolded numbers 0.8 and 1.3 are the speed of walking in m/s.)

Model	Downhill		Level		Uphill	
	0.8	1.3	0.8	1.3	0.8	1.3
Roberts	0.51	0.32	2.05	1.51	4.34	4.04
Kim	0.98	0.57	1.82	1.43	3.59	3.34

## Significance

The primary advantage to the joint space-based MEE approach is that there is no need for muscle information, which can be helpful when analyzing full body motion with limited muscle information. It is important to verify whether the published joint space MEE models accurately predict metabolic energy cost for various applications. The findings in this work demonstrate that there was some improvement in the joint-based MEE modelling, but there is still a need to further develop the joint space-based model which can account for incline.

## The Effects of Posterior Shank/Thigh Contact on the Knee Joint Loading during Deep Squatting

John Z. Wu\*, Erik W. Sinsel, Robert E. Carey, Liying Zheng, Christopher M. Warren, Scott P. Breloff  
National Institute for Occupational Safety and Health, Morgantown, WV, USA. \*Email: jwu@cdc.gov

### Introduction

In some occupational or sport activities, workers or athletes need to make repetitive deep squatting motions or maintain deep squatting postures for extended periods of time. These unfavourable knee postures may cause excessive loading in the knee joint, thereby leading to the initiation and development of osteochondritis dissecans (OCD) and osteoarthritis (OA) [1,2]. During deep squatting motions, the posterior aspect of the shank comes into contact with the posterior thigh, which will result in a compressive force within the soft tissues. The goal of the current study is to quantify *in vivo* knee joint loading during deep squatting using a dynamic biomechanical model that includes the effects of the interface contact between posterior thigh and shank.

### Methods

Inverse dynamical analysis was performed based on the data collected from a healthy male subject (mass 70 kg, height 1.68 m), who performed five deep, heel-up squatting tasks at a self-selected pace (Fig. 1a-b). A 14-camera system (Vicon) captured marker trajectories at 100 Hz, and the ground reaction forces were collected at 1,000 Hz via two force plates (Bertec). The interface contact pressures between the posterior thigh and shank were measured using a pressure sensor film (TekScan) (Fig. 1a). An existing, whole body model with detailed anatomical components of the knee (AnyBody v7.0) has been customized to fit the current study (Fig. 1b). The knee model includes bony segments of the tibia, femur, and patella (Fig. 1c). The motions of the tibiofemoral (TF) and patellofemoral (PF) joints are represented by 11-degrees-of-freedom (DOF), in which TF joint has six-DOF and PF joint has five-DOF. The model includes a total of 159 muscles in the lower extremity.

### Results and Discussion

The calculated normal contact forces in PF and TF joint are shown in Fig. 1d and 1e, respectively. The curves represent the average values obtained from five squatting cycles. The model prediction shows that, at the deepest squatting posture (knee flexion of 120 degrees), the maximal PF and TF joint contact forces including the posterior thigh/shank contact are approximately 58% and 43%, respectively, of those that ignore the posterior thigh/shank contact. The model prediction shows that the PF contact force, without considering the posterior thigh/shank contact effects, reached about 3.80 times BW at a deep squatting posture, which is consistent with previous studies [3]. The measured peak thigh/shank contact force at each leg was approximately 43% BW in the current study, which is comparable to a previous study [4].

There was no direct validation for the model. We tried to validate our model indirectly with the experimental observations in two aspects. First, at a static upright standing posture (i.e., knee flexion = 0 degree), the model prediction on one-leg TF contact force was about 0.5 BW, which is physiologically reasonable. Secondly, the predicted time histories of the ground reaction forces agree reasonably well with the experimental measurements (results not shown). The ground reaction force fluctuation during the squatting task is caused by the dynamic

mass inertial effects of the body segments and by the muscular forces that are needed to maintain the dynamic balance. The maximal difference between the predicted and measured ground reaction force was approximately 0.01 BW, indicating the agreement between the model predictions and the experiments.

### Significance

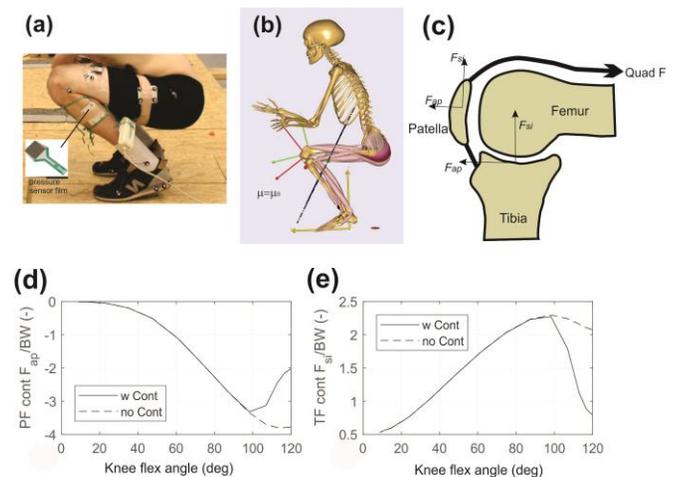

We demonstrated via the biomechanical modelling that, in a deep knee flexion posture, the contact between posterior thigh and shank will result in a compressive force within the soft tissues around the joint, substantially affecting the joint loading. The model prediction supports the epidemiological observations that occupational or sports activities that require extended squatting are associated with higher prevalence of knee OCD and ORS.

# Evaluation of a Powered Lumbar-Support Exoskeleton during a Pace-Controlled Lifting Task: A Pilot Study

Liying Zheng\*, Ashley L. Hawke, Robert E. Carey, Kevin Moore, John Z. Wu

Health Effects Laboratory Division, National Institute for Occupational Safety and Health, Morgantown, WV, USA.

\*Email: lzheng2@cdc.gov

## Introduction

Back injuries are prominent in work-related musculoskeletal disorder (MSD) cases, especially among those who regularly and manually handle materials [1]. In aim to reduce fatigue and prevent MSD-related injuries at workplace, passive exoskeletons have been developed and adopted in the industries involving material handling, while powered back-assist exoskeletons are still at the early development stage worldwide. In this preliminary study, we evaluated a Japanese powered lumbar-support exoskeleton during a pace-controlled lifting task, where the users' muscle activities, heart rate, cerebral oxygenation and rating of perceived exertion (RPE) were assessed.

## Methods

In this pilot study, two subjects (age =  $46 \pm 25$  years old; height =  $167.9 \pm 0.2$  cm; weight =  $73.4 \pm 11.9$  kg) performed 30 times of pace-controlled lifting movements—lifting a 20-lb wooden tray from ankle to hip height at a pace of one lift per 10 seconds guided by a metronome. The subject repeated the 30-lifting task for two conditions: without wearing the exoskeleton (NoExo) and while wearing the powered lumbar-support exoskeleton (Exo). The activations of 16 major leg and torso muscles (vastus lateralis, biceps femoris, semitendinosus, thoracic erector spinae, lumbar erector spinae, multifidus, latissimus doris and abdominal external oblique on both sides) were measured by a wireless surface electromyography (EMG) system (Noraxon U.S.A. Inc., Scottsdale, AZ). The heart rate was recorded by a 3-lead Biomonitor (Noraxon U.S.A. Inc., Scottsdale, AZ). The cerebral oxygenations were measured by a 8-channel functional near-infrared spectroscopy system (fNIRS) (OctaMon+, Artinis Medical Systems B.V., Netherlands). Six long fNIRS channels with 30-mm inter-optode distances were positioned over the prefrontal cortical areas according to the international EEG 10-20 system (left: Fp1, F3 and F7; right: Fp2, F4 and F8). Two short separation channels with 10-mm inter-optode distances measured solely the extracerebral signals and were used to remove the “noisy” components from the long channels. Additionally, RPE scores (0: no exertion, 10: exhausted) were collected at the end of the lifting task in each condition.

## Results and Discussion

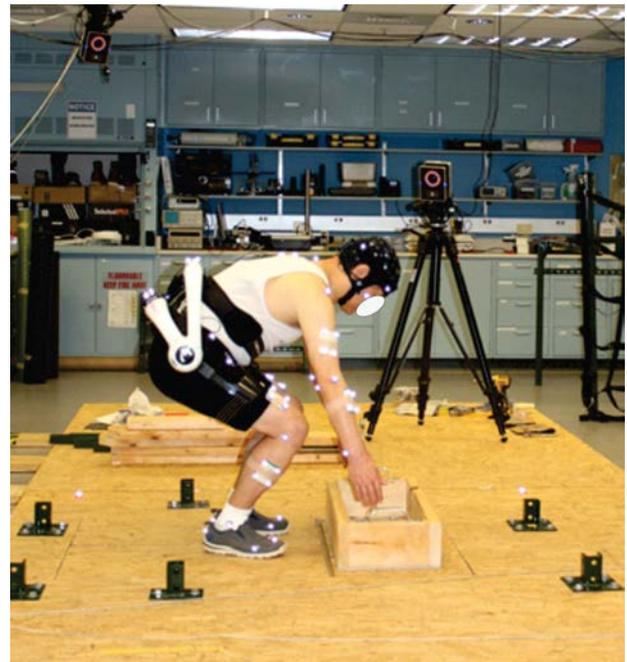

The average heart rate during the 30-lifting task was reduced 6% in the Exo condition compared to the NoExo condition for both subjects. The effects of wearing the powered exoskeleton on the users' muscle activities, cerebral oxygenation and self-reported RPE values varied between the two subjects. Although both subjects reported smaller RPE values (less perceived effort) for EXO condition compared to the NoExo condition, the reduction in the RPE scores is much larger in Subject A (4 vs. 8) than in Subject B (3 vs. 4). Compared to the NoExo condition, reductions in leg and back muscle activations were also found to be more pronounced in subject A (ranged from -3% to -26%). The oxyhaemoglobin (O<sub>2</sub>Hb) values of Subject A in the left prefrontal cortical area increased in the Exo condition compared

to the NoExo condition, while the O<sub>2</sub>Hb values decreased in the Exo condition for Subject B.

This pilot study showed promising results of using a powered lumbar-support exoskeleton during a repetitive lifting task. Besides the common evaluation measurements such as muscle activity and heart rate, the cerebral oxygenation demonstrated a possible measure to assess performance of exoskeletons. The prefrontal cortex oxygenation appeared to respond to the subject's perceived effort, which was similar to findings in a previous study [2]. The variations of the user experience and product performance were observed in this small pilot study. More comprehensive evaluations in a large subject pool are expected in the future.

## Significance

Our results demonstrate promising applications of powered exoskeletons in industries involving manual material handling. Along with muscle activity and heart rate, cerebral oxygenation manifests the potential to complement the evaluations of the effectiveness of exoskeletons.

**Figure 1.** A subject performed 30 lifts of a 20-lb box from ankle to hip height at a rate of one lift per 10 seconds. The muscle activities, heart rate and cerebral oxygenation were measured simultaneously by EMG, Biomonitor and a fNIRS system.

# Comparison of a Mid-Seated Posture with Seated and Standing Postures

Archana Lamsal<sup>1</sup>, Garrett Weidig<sup>1</sup> and Tamara Reid Bush, PhD<sup>1</sup>

Teresa Bellinger, PhD<sup>2</sup>

<sup>1</sup>Michigan State University, East Lansing, MI, USA, <sup>2</sup>Haworth, Holland, MI, USA

email: reidtama@egr.msu.edu

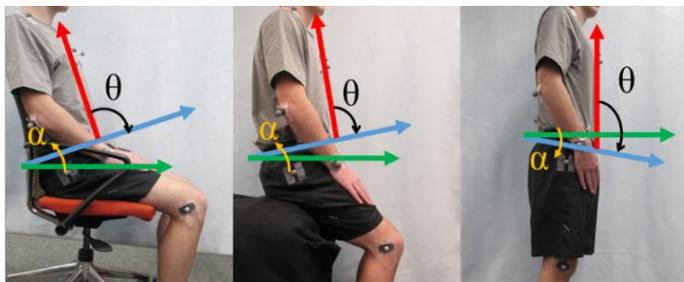

## Introduction

Prolonged inactivity during work hours is a major factor that leads to various health issues in office workers [1]. Frequent movement is essential to promote blood and nutrient flow, especially in the intervertebral discs as they are avascular organs [2]. Standing desks promote movement, however, standing for long periods of time has been associated with musculoskeletal disorders, pain, and discomfort of the feet and legs [3]. Current research suggests a need for other positions which can provide changes in body posture without subjecting the legs to large loads. The goal of this study was to compare the joint angles, joint moments and loading on the body between seated, a new type of mid-seated posture and standing.

## Methods

Twenty consenting participants (ten males and ten females) were recruited. An 11-camera motion capture system and force plate were used for this study. Reflective markers were attached on various anatomical landmarks. The participants were asked to conduct a computer task in three different postures, spending fifteen minutes in each posture. The postures were: seated, mid-seated, and standing. The mid-seated posture was with a slightly bent knee, in an elevated chair with their feet on the ground. Marker position and force data were collected for every posture and during transition between postures. Data for all postures and motions were collected for 20 participants. Additionally, a subset of three participants returned to the lab to conduct movements directly from seated to the standing position.

Pelvic tilt (angle between the pelvic plane and horizontal) and openness angle (angle between the thorax and pelvis) were calculated for all postures (Figure 1). Inverse dynamics was used to compute joint moments at the ankle, knee and hips in the sagittal plane for transition between three postures, also referred to as dynamic motions. The motions were: seated-to-mid-seated (Sit-M), mid-seated-to-standing (M-S), and seated-to-standing (Sit-S). Anthropometric data for calculating joint loads were taken from Winter [4].

**Figure 1:** Vector overlay diagram of pelvic tilt angle and openness angle in seated, mid-seated and standing postures. The angle between pelvis plane (blue) and horizontal (green) gives pelvic tilt ( $\alpha$ ) and the angle between pelvis plane and torso (red) gives openness angle ( $\theta$ )

## Results and Discussion

The average ground reaction force expressed as the percent of body weight in mid-seated posture (16.41%) was slightly higher

than the seated posture (12.55%) but significantly lower than standing (96.54%). It is interesting to note that even while “seated” in the mid posture, the pelvis was able to be moved to a point halfway between the seated and standing postures. This is shown by the change in pelvic tilt angles and also supports a change in lumbar curvature (Table 1). The openness angle was smallest in the seated posture and largest in the standing posture. Previous research has shown that a larger openness angle is correlated to an increased lordotic lumbar curvature [5]. This change in lumbar curvature is good as it promotes nutrient transport in intervertebral discs which are avascular.

All the maximum joint moments were smaller for M-S motion compared to Sit-S motion. Moving from the mid-seated position to standing put lower load on the joints than standing directly from the seated posture. The Sit-M motion had smaller joint moments in the knee and ankle joints compared to Sit-S motion. However, the hip moment was the largest in the Sit-M motion. The hip moment was largest because participants had to lean forward to move the seat into the second position, which resulted in larger moment arm for the torso weight. Although this may be similar to when people lean forward to adjust seat height.

**Table 1** Average joint angles and standard deviations in degrees across the subject pool for each posture

Angles	Seated	Mid-seated	Standing
Pelvic Tilt	15.3 (6.6)	6.3 (6.6)	-8.4 (7.6)
Openness	96.7 (15.7)	102.1 (14.0)	116.5 (17.1)

To summarize, the mid-seated posture provided a pelvic and lumbar posture closer to that of standing, while subjecting the feet to a lower load than in standing. Standing from the mid-seated posture was easier on the joints than from the standard seated posture as it produced lower moments. A mid-seated posture is another possibility for office workers who wish to achieve postural change without increasing loading on the feet or legs.

## Significance

Based on our data, one can say that the mid-seated posture provides the benefit of both sitting and standing. It reduces the load on the feet and legs in comparison to standing and is easier to stand from in comparison to the seated posture. Change of position from the seated posture to mid-seated posture also provides motion to the joints and lumbar region. Thus, the mid seated posture provides an excellent additional working posture.

## Introduction

Manual wheelchair use is associated with a high incidence of shoulder pain and pathology [1]. However, previous reports have found that children and adults with pediatric-onset SCI have less pain than adults with adult-onset SCI. Presence of pain is associated with decreased shoulder range of motion (ROM) [2,3], which may suggest why self-reported pain is less prevalent in pediatric wheelchair users than in adult wheelchair users [1,4]. Moreover, increased ROM and within-subject variability in human movement is important for improved function and reducing the risk of overuse injuries [5]; however, differences in these metrics between pediatric and adult manual wheelchair users remain unknown. The purpose of this study was to investigate differences in glenohumeral (GH) joint ROM and subject variability during propulsion in pediatric and adult manual wheelchair users with SCI.

## Methods

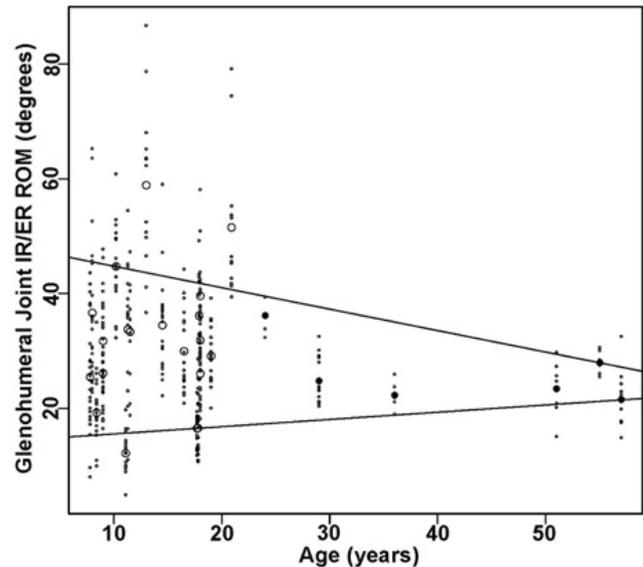

Fifteen pediatric manual wheelchair users with SCI ( $12.2 \pm 3.8$  years) and eleven adult manual wheelchair users with adult-onset SCI ( $31.4 \pm 15.8$  years) participated in this study. A 15-camera Vicon T-Series motion capture system (Vicon Motion Systems, Oxford, UK) was used to collect 3-dimensional (3D) kinematic data at 120 Hz. Twenty-seven passive markers were placed on each subject to implement our validated upper extremity inverse dynamics model [6]. Subjects performed multiple trials of manual wheelchair propulsion at a self-selected speed on a level, tile floor using their own wheelchair. Mean GH joint adduction/abduction, internal/external rotation, and flexion/extension ROM was calculated across multiple strokes for each subject. Data were plotted with respect to age using quantile regression models for 0.10 and 0.90 quantile levels to display within- and between-subject variability (Figure 1).

## Results and Discussion

GH joint ROM variability significantly decreased in the coronal and transverse planes. Pediatric manual wheelchair users exhibited greater GH joint variability in adduction/abduction and internal/external rotation ROM compared to adult manual wheelchair users (Figure 1). Findings of this study support the notion that movement variability decreases with age [5]. That is, overuse motions increase and may explain the higher prevalence of shoulder pain reported by those with adult-onset SCI compared to pediatric-onset SCI, despite controlling for age and years of wheelchair use [1,4]. Results also support previous research that found pediatric wheelchair users use highly variable upper extremity biomechanics and propulsion patterns compared to adult wheelchair users [4, 7].

## Significance

Implications of this research can be largely impactful for manual wheelchair users across the lifespan with SCI. Current

**Figure 1:** Glenohumeral joint ROM for internal/external rotation with respect to age. Each vertical scatterplot is one subject's data (each stroke is a dot and the subject's mean is the large, open circle (pediatric) and solid circle (adult)). Narrowing of 10% and 90% quantile lines demonstrates the decrease in variability with age.

recommendations for promoting the preservation of the shoulder are antiquated and are applicable only to adults [8]. This research indicates the necessity for identifying manual wheelchair propulsion best practices for children and across the lifespan to decrease the trend of shoulder pain and pathology. Research is underway with a larger population of children and adults with both pediatric- and adult-onset SCI. Ultimately this will enhance physical and occupational therapy interventions to improve mobility and quality of life for all wheelchair users with SCI.

# Neck Kinematic Differences Between Six Computer Monitor Configurations

Caleb C. Burruss, Elizabeth Bjornsen, and Kaitlin Gallagher, Ph.D.

University of Arkansas, Fayetteville, AR, U.S.A

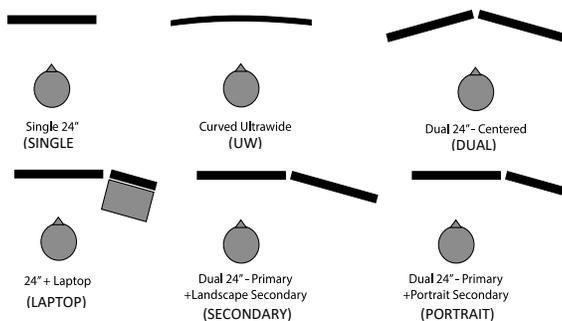

Email: [kmg014@uark.edu](mailto:kmg014@uark.edu)

## Introduction

The average size of a computer screen has increased from 19.5" in 2011 to 21.6" in 2019 [1]. A systematic review on dual monitor usage found that users strongly preferred multiple monitors; however, users may be in non-neutral neck postures while using them [2]. Biomechanics driven studies have also only looked at monitors 15-17" in size [2], which is below the average size used today [1]. The purpose of this study was to determine the effects of computer monitor configuration on neck kinematics. We hypothesized that specific monitor configurations would allow for a neutral neck posture; however, this may be task dependent.

## Methods

We recruited 17 graduate students with no current head, neck, back, or upper extremity injuries. Participants came into the lab six different days, and each day used a different monitor configuration (**Figure 1**). Each day, participants completed five tasks [3] consistent with multiple display use: copy/pasting, information comparison, referencing while preparing a document, drag/dropping (not shown), and monitoring information (not shown). Participants' neck rotation was tracked using a motion capture system (Qualysis AB) with markers placed on the head and trunk. The participant performed five 10-minute tasks that were randomized each day. Angles were calculated using Visual3D (v6, C-Motion Inc). Neck rotation angle median and range of motion were calculated using an amplitude probability distribution function. A one-way repeated measures ANOVA was conducted for each task with a factor of monitor configuration. Tukey post-hoc tests were used to evaluate significant main effects. Significance was set at  $p=.05$ .

**Figure 1:** Monitor configurations.

## Results and Discussion

There was a main effect of configuration for the median neck rotation angle ( $p<.001$ ). SINGLE, UW, and DUAL (centered monitors) were significantly different ( $p<.001$ ) than the off-center configurations (**Table 1**). The UW monitor was never significantly different from SINGLE.

There was a main effect of configuration for range of motion ( $p<.001$ ) for all tasks. SINGLE and UW had the smallest range of motions for these three tasks (**Table 1**). The other four monitors were significantly different ( $p<.001$ ) than SINGLE and UW. The UW monitor did not significantly

differ from SINGLE. UW had a similar rotation range of motions as SINGLE, and when they differed, it was by less than 5 degrees.

Our results agree with a previous systematic review [2], in that many of the monitors and tasks produced non-neutral neck postures. As hypothesized, the specific task influenced if a person was in a non-neutral neck angle when using a given monitor configuration. Interestingly, the UW monitor had similar median neck rotation and range of motions to SINGLE despite an increased screen area (33" vs. 24" diagonal). The UW monitor also reduced neck rotation median and range compared to other large screen set-ups such as dual monitors and secondary laptops.

**Table 1:** Median neck angles and neck range of motion values for compare, copy/paste, and reference tasks. Note: Mean (standard deviation) presented. For median, negative = right axial rotation. ^, \* denotes significant differences.

## Significance

A larger screen area means more area to scan while working; however, our study found that a 33" UW did not alter neck kinematics compared to a 24" single monitor. As a result, the UW monitor may be more appropriate for office workers compared to one single monitor or two dual monitors. Research on the actual implementation and effect of UW monitors on a user over the course of the day is still limited. As a result, future studies should look at the proper distance for an UW monitor and the potential increase in hand movement when operating a mouse.

## Acknowledgements

Funding was received from the Office Ergonomics Research Committee. Herman-Miller provided in-kind equipment.

## Introduction

For many years, sitting was thought to be a risk factor for low back pain development in sedentary jobs [1,2], however more recently, meta-analyses and systematic reviews have suggested that this is not the case [3]. Regardless of whether sitting is the cause of low back pain or not, some individuals will develop low back discomfort while sitting, whereas other people will not [4]. Previous studies describe the complexity of pain and have identified age, sex, and mental health [5], flexibility [6], and health status [7] as predictors of chronic low back pain development however, no study has examined which factors could be used to predict the development of self-reported low back pain in healthy, working individuals.

Therefore, the purpose of the current analysis was to determine whether onset of low back discomfort while sitting could be predicted given some personal characteristics of the worker, and to assess whether this risk could be mitigated through ergonomic recommendations.

## Methods

Fifty-four individuals (36 Female, 18 Male) who work sedentary jobs were recruited from three age groups (20 – 25 years, 40-45 years, and 60-65 years). Volunteers were excluded if they were experiencing low back pain, or if they had experienced low back pain significant enough to cause them to seek medical attention or to miss school or work in the past 12 months. Participants completed a battery of physical fitness tests and responded to a comprehensive digital survey which covered areas of health, work history, nutrition, sleep, injury history, mood, depression, anxiety, and stress. Participants sat for 60 minutes in a backless office chair, which was ergonomically adjusted to suit their stature. Every ten minutes during the seated time, the participants were asked to rate their low back discomfort on a digital visual analog scale with “No discomfort” and “Worst discomfort imaginable” as the anchors. A change in perceived discomfort of 10 units of more at any point in the hour was designated as clinically relevant pain development, and those participants were classified as “Pain Developers” (n = 29) [8].

Variables discussed previously as being predictors of pain, as well as those thought to possibly hold a strong association with spine health were selected from the database. These included: age, sex, body fat percentage, grip strength, cardiovascular health, history of joint pain, history of neck and/or back pain, hours of sleep, depression, anxiety, stress, trunk flexibility, hours of exercise per week, and sedentary time per week.

Statistical analysis consisted of binary logistic regression with pain as a binary variable (Pain Developers and Non-pain Developers), and all other variables as binary, categorical, and continuous variables as appropriate. Predicted probabilities from the logistic regressions were used to plot receiver operating characteristic (ROC) curves, and the area under these curves (AUC) identified each factor's ability to group for pain status [9].

## Results and Discussion

The binary logistic regression did not identify any significant association between any of the variables of interest and pain status. To determine whether any of these variables could discriminate between pain groups despite their inability to predict the risk of developing pain, the ROC curves were generated and AUCs were calculated. These AUCs are presented in Table 1. None of the variables of interest were found to be discriminatory as far as differentiating those who would develop low back discomfort while sitting from those who would not.

**Table 1:** AUCs and Significance for all variables of interest. Variable type is presented as: Bin = Binary, Cat = Categorical, or Cont = Continuous.

VARIABLE	AREA UNDER ROC CURVE	SIGNIFICANCE ( $\alpha = 0.05$ )
Age (Cat)	0.61	0.18
Sex (Bin)	0.51	0.88
Touch Toes Yes/No (Bin)	0.53	0.68
Percent Body Fat (Cat)	0.56	0.44
Grip Strength (Cat)	0.55	0.51
Trunk flexion (Cont)	0.57	0.41
Cardiovascular Risk (Bin)	0.61	0.17
History of Joint Pain (Bin)	0.53	0.67
Hist. Neck/Back Pain (Bin)	0.54	0.66
Hours of sleep/night (Cat)	0.51	0.87
Sedentary hours/week (Cont)	0.52	0.80
Hours of exercise/week (Cont)	0.51	0.92
DASS 21 - Depression (Cat)	0.50	1.00
DASS 21 - Anxiety (Cat)	0.51	1.00
DASS 21 - Stress (Cat)	0.49	0.94

The lack of any predictive or discriminatory variables just further reminds of the complexity of pain. Without being able to distinguish those at risk for developing low back pain while sitting from those who are less likely to, recommendations should err on the side of caution and treat all workers as possible pain developers by suggesting less time spent sitting for everyone.

## Significance

The purpose of this analysis was to identify the risk factors that could be mitigated in order to reduce the risk for developing low back pain while working in seated occupations. Rather, it appears as though, in healthy working adults with no history of chronic debilitating low back pain, the onset of low back discomfort cannot be predicted. This finding (or lack thereof) points to the complexity of pain, and further analysis is required to identify whether there are other previously overlooked factors that could predict the onset of low back discomfort while sitting.

# EMG Based Biomechanical Analysis of the Effect Different Writing Surfaces and Postures Have on Forearm Muscles

Mustafa Ozkan Yerebakan<sup>1</sup>, Boyi Hu<sup>1\*</sup>

<sup>1</sup>Department of Industrial and Systems Engineering, University of Florida, Gainesville, FL, USA

Email: \*boyihu@ise.ufl.edu

## Introduction

Writing as we know it has been changing in the past decade. With the introduction of tablet computers, it is possible to write on surfaces other than paper or whiteboards. Although it is being used by millions of people, biomechanical effect of digital device writing is not well understood. Apart from one study that compares different grasp patterns (Almeida et al., 2013), comprehensive studies aim to investigate the effects of posture on writing tasks that have been limited. These two points plus the possible effects of fatigue due to long sessions of notetaking makes it vital to investigate what posture and writing surface are the least damaging to the human body.

## Methods

A convenience sample of 5 participants was recruited in this pilot study. The main task of the study was to write randomly selected sentences that included every letter of the English alphabet. There were three writing surfaces (paper, tablet PC and whiteboard) and three writing postures (45-degree angle, horizontal and vertical). The muscle that were selected for EMG data collection were extensor digitorum (ED), extensor carpi radialis (ECR), flexor carpi radialis (FCR), flexor carpi ulnaris (FCU) and flexor digitorum superficialis (FDS). Muscle activity was measured by normalizing the EMG using the values from maximum voluntary contraction (MVC) trials. The EMG signals were recorded with a sampling frequency of 1000 Hz and they lasted for three seconds. Each participant had 9 trials and each trial lasted about 60 seconds.

After data collection was finished the raw EMG signal was pre-processed before normalization was done and median frequency was calculated. Pre-processing involved applying a 3 Hz cutoff frequency filter to the signal, rectification and smoothing by using a 2<sup>nd</sup> order Butterworth filter. Normalization was done taking the percentage value of the ratio between the average value of the EMG signal and corresponding value from the MVC trial. All of pre-processing and processing was done in Matlab (MATLAB 2019b, Mathworks, Natick, MA).

The data analysis involved a multivariate ANOVA in which the effects of device, posture and interaction was investigated for each of the five muscles. In order to determine the conditions

that result in the lowest amount of percentage muscle activation and highest frequency values and further test significance, a Tukey's Honest Significance test was conducted.

## Results and Discussion

The muscle activation level results indicate that different surfaces had a more significant effect on both carpi radialis muscles and different postures affected the FCU and FDS more. Looking at these significantly different instances it could be seen that the tablet condition and the 45° posture resulted in the lowest levels of muscle activation. The median frequency values showed the effect of posture being more significant FCR muscle, however it seems there was no significant effect of surface for this variable. A possible reason why the results are limited for the median frequency is the length of the trial.

## Significance

This study has investigated the effects of different writing surfaces by using biomechanical tools such as EMG and EMG based signal complexity measures. Although there are studies that compare different writing surfaces (Alamargot and Morin, 2015), all of them utilize kinematics or graphonomics outcomes. This study emphasizes the effects on the human body, specifically the muscles. The results from this study could be used to establish guidelines for tablet usage in both office and recreational usage. Future studies that increases the sample size and lengthen the trial to similar writing fatigue studies (Summers and Catanzaro,2003) would be useful in seeing the effect more clearly.

## Exoskeleton Usage, Arm Posture, and Tool Weight Changes Shoulder Fatigue Risk

Jason C. Gillette<sup>1\*</sup>, Shekoofe Saadat<sup>1</sup>, and Terry Butler<sup>2</sup>

<sup>1</sup>Department of Kinesiology, Iowa State University

<sup>2</sup>Lean Steps Consulting

Email: \*gillette@iastate.edu

### Introduction

In 2015, shoulder injuries resulted in 23 days median days missed for private industry, the longest recovery time of any body part [1]. It is widely accepted that repetitive overhead arm postures are associated with increased risk of shoulder overuse injuries. Threshold limit values (TLVs) for upper limb fatigue provide a relationship between percent of maximal voluntary contraction (%MVC) and duty cycle [2]. Therefore, the risk of fatigue and overuse injury may be predicted using electromyography (EMG).

The Levitate Airframe is a passive upper body exoskeleton designed to support the arms during elevated shoulder postures. Previous EMG field studies at John Deere and Toyota indicated that the exoskeleton may reduce deltoid fatigue risk [3,4]. The purpose of this study was to determine if fatigue risk changes with exoskeleton usage, arm posture, and tool weight. Our hypothesis was that the exoskeleton would reduce deltoid fatigue risk for shoulder flexion angles 90-135° and tool weights 3-7 lb.

### Methods

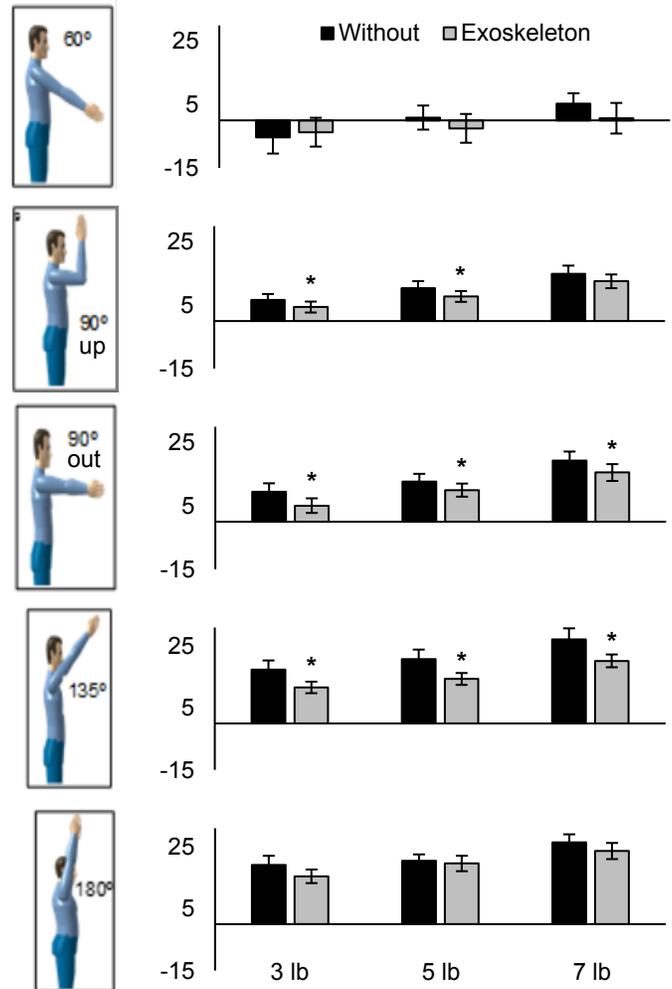

Twenty healthy young adults (10 male/10 female) participated in this study. Six shoulder flexion angles common to automotive assembly were tested: 60°, 90° up, 90° out (90° elbow flexion), 135°, and 180° (Figure 1). Three tool weights (3 lb, 5 lb, and 7 lb) were created by adding weight to a drill. A frame was adjusted so that the arm postures would be achieved by pressing a button with the drill bit. Participants repeated 4 s movements for 30 s: move to position, press button, move to neutral, and rest.

EMG sensors were placed on the anterior deltoid, biceps brachii, upper trapezius, and right/left erector spinae. Shoulder flexion, shoulder abduction, elbow flexion, and spinal extension were used as MVCs for normalization. Average EMG amplitude was determined while a muscle was active (>5% MVC), and duty cycle was set to time muscle is active divided by task time (30 s). Duty cycle was used to calculate the TLV [2], and the fatigue risk value was calculated as EMG amplitude minus the TLV.

### Results and Discussion

*Without exoskeleton.* Increasing tool weight from 3 lb to 5 lb to 7 lb increased fatigue risk values for all muscles ( $p \leq 0.001$ ). Increasing shoulder flexion from 60° to 90° up to 90° out to 135° increased fatigue risk values for the deltoid ( $p < 0.001$ ), while 135° and 180° were similar. In addition, increasing shoulder flexion from 60° to 90° up to 135° increased fatigue risk values for the trapezius ( $p < 0.001$ ), while 90° up and 90° out were similar and 135° and 180° were similar.

*Exoskeleton vs. without.* The exoskeleton reduced deltoid fatigue risk values for all tool weights with arm postures of 90° up, 90° out, and 135° ( $p < 0.05$ , Figure 1), with the exception of 90° up with 7 lb tool weight. Fatigue risk reductions were driven by reductions in EMG amplitudes ( $p < 0.04$ ) for these arm posture and tool weight combinations. With one exception, these results support the hypothesis that the exoskeleton would reduce deltoid fatigue risk for shoulder flexion 90-135° and tool weights 3-7 lb.

**Figure 1:** Deltoid Fatigue Risk Values (%MVC). \* indicates significant reduction in fatigue risk with exoskeleton ( $p < 0.05$ ).

The exoskeleton is expected to reduce shoulder fatigue for common automotive assembly postures and tool weights. Further testing with the exoskeleton high reach adaptor is recommended for the 180° posture, while the 60° posture has lower fatigue risk.

### Significance

Lab tests predict a range of arm postures and tool weights where an exoskeleton is effective for fatigue reduction, which can help ergonomists determine job tasks that may benefit from usage.

## Introduction

Many medical experts recommend the use of a footrest as an ergonomic intervention to reduce low back pain (LBP) during prolonged standing. However, previous research on the effectiveness of using the footrest for prolonged standing were insufficient due to a lack of proper scientific support.

The purpose of this study was to determine the effect of standing with a footrest compared with level standing on lumbo-pelvic-hip kinematics and kinetics, and low back visual analogue scale (VAS) scores between pain developer (PD) and non-pain developer (NPD).

## Methods

In total, 30 subjects participated in this study, including 15 classified as PDs, and 15 as NPDs. The subjects were classified as PD if they reported an increase in the low back VAS score greater than 10-mm from baseline on the 100-mm VAS scale during the 2-hour prolonged level standing.

Three-dimensional motion analysis system was used to analyze lumbo-pelvic-hip joint angles, and lumbar flexion-extension moment. The VAS was used to evaluate the degree of low back pain.

Subjects then entered into the 2-hour prolonged level standing task (Figure 1). Subjects visited the laboratory on the second day and performed standing with the footrest. The light simulated tasks, i.e., sorting coins, sorting poker chips, and a simple assembly task, were performed within the subject's shoulder width.

A two-way (2 × 2) mixed analysis of variance with standing positions (level standing, standing with the footrest) as the within-subject variable and groups (PD, NPD) as the between-subjects variable was used to assess the dependent variables.

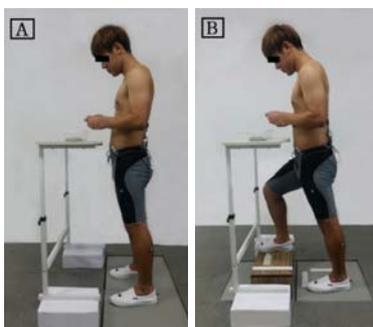

Figure 1: Standing positions (A: Level standing, B: Standing with footrest).

## Results and Discussion

The results of this study showed that lumbar flexion angle, posterior pelvic tilt angle, hip flexion angle, and the lumbar flexion moment were significantly higher in standing with a footrest than in level standing ( $p < 0.05$ ) (Table 1).

In PD the group, the low back VAS score was significantly lower during standing with the footrest than during level standing ( $p < 0.012$ ). During level standing, there was a significantly higher low back VAS score in the PD group compared with the NPD group ( $p < 0.012$ ) (Figure 2).

The results of this study indicate that prolonged standing with a footrest can be an effective ergonomic intervention because it increased the lumbar flexion angle, posterior pelvic tilt angle, and lumbar flexion moment, thereby reducing low back pain.

Table 1. Lumbo-pelvic-hip kinematic and kinetic differences

	Level standing	Standing with footrest
Lumbar flexion-extension (°)	-10.48 ± 8.14 <sup>a</sup>	-2.62 ± 9.09*
Pelvic tilt (°)	0.07 ± 1.85	-3.42 ± 3.22*
Hip flexion-extension (°)	-1.65 ± 1.99	45.25 ± 6.74*
Lumbar flexion-extension moment (Nm)	-0.02 ± 0.25	1.62 ± 0.37*

<sup>a</sup>Mean ± standard deviation.

\* $p < 0.05$  significant difference between standing positions.

Positive values indicate flexion, anterior pelvic tilt, and flexion moment whereas negative values indicate extension, posterior pelvic tilt, and extension moment.

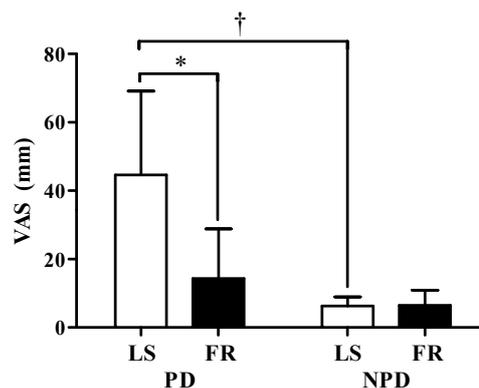

Figure 2. Low back VAS score (PD: Pain developers, NPD: Non-pain developers, LS: Level standing, FR: Standing with the footrest, VAS: visual analog scale \* $p < 0.012$  significantly different between standing positions; † $p < 0.012$  significantly different between groups).

## Significance

This study is in the field of ergonomics. Through this study, it is a study that proved the effect of the footrest as a biomechanic for people who stand for a long time.

# Biomechanics and Ergonomic Analyses of Shoulder Posture in a Seated Position Through the Use of an Avatar

Garrett Weidig<sup>1</sup>, Archana Lamsal<sup>1</sup>, and Tamara Reid Bush, PhD<sup>1</sup>

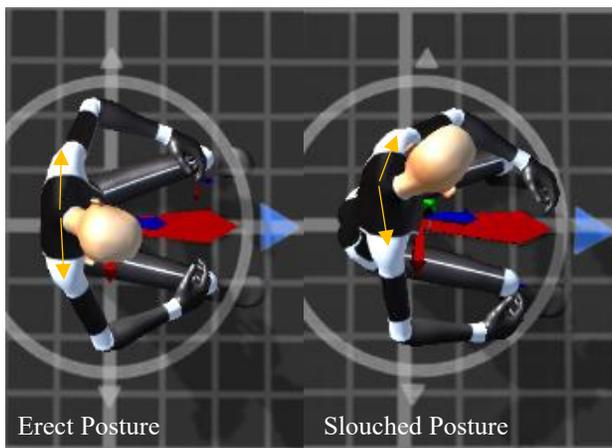

<sup>1</sup>Michigan State University, East Lansing, MI, USA

Email: [weidigga@msu.edu](mailto:weidigga@msu.edu), [reidtama@msu.edu](mailto:reidtama@msu.edu)

## Introduction

Whether it's playing video games, sitting in class, or working at the computer, posture is always a concern. With teens and young adults interacting with technology more and more, bad habits with respect to posture are perpetuated<sup>1</sup>. This increase in technology use has been shown to cause poor posture, such as slouching with the shoulders or downward neck movement<sup>2</sup>. Poor posture can then lead to back pain and general joint pain- even for teenagers<sup>3</sup>. Ergonomic standards aim to correct poor posture, suggesting that ankle, knee, and hip angles should be at 90°. However, these standards are rarely known and are followed by even fewer individuals. There is a need to quantify good and poor postures. Also, so that these postures can be communicated to others, particularly teens and young adults, a visual representation of these body positions is necessary.

One approach to visually convey biomechanical components (such as numerical data) and deviations from preferred ergonomic postures is the use of an avatar, such as the one in Figure 1. By linking motion data with a human body model, or avatar, differences in posture can be shown visually and these postures can be numerically quantified. Therefore, the goals of this study were twofold. The first was to define and identify poor posture, specifically rounding of the shoulders; and the second was to create an avatar that could serve as a communication medium for postural change.

**Figure 1:** Top view of avatar shoulder curvature in an erect, ergonomic posture (left) and a slouched, non-ergonomic posture (right). The orange arrows represent shoulder curvature.

## Methods

Reflective markers were placed on the body and movement data were recorded with an 11 camera motion capture system. Five participants (4 men, 1 woman – average age 20 years SD 1.6) were instructed to type and mouse as they would naturally. At the end of the five minute test, participants were positioned in an erect posture as defined by the ergonomic standards previously noted. The results of this study produced two outputs, the first being engineering definitions for poor posture, specifically related to shoulder curvature. Shoulder curvature was defined by the angle made by the left acromion (shoulder top), 7<sup>th</sup> cervical

vertebra (the top of the spine), and the right acromion. Poor posture was defined by the magnitude of the deviation from the erect posture. The second output from this study was the creation of an avatar from these data sets.

## Results and Discussion

The following table provides the averages for the shoulder angle of the participants and the deviation from the erect posture, while mousing, and while typing.

**Table 1.** Average shoulder angle at erect and slouched postures

Posture	Shoulder Angle(°)	Angle Deviation(°)
Erect	127	-
Slouched Mousing	112	15
Slouched Typing	111	16

The data in Table 1 show that it is possible to define poor posture as a deviation from an erect posture. As of now, there is no spectrum that defines what levels of poor posture are associated with which angles of shoulder curvature. However, these preliminary data show that there is a measurable difference between erect and slouched.

For the second goal of this work, these data were incorporated into an avatar to demonstrate shoulder rounding. Just as there is a difference in the shoulder angle calculation, there is a clear difference in the shoulder rounding appearance in the avatar between the subject's erect and slouched postures.

## Significance

The results of this study provided quantitative measures on slouched posture and provided a means to visually present these postural changes. This research has the potential to help in device design such as gaming chairs that provide more support when poor posture is engaged. This also opens up opportunities to create biofeedback devices that, based on duration and magnitude of the poor posture, will tell users how to correct their positioning. With more testing, postural changes between different demographics can be analyzed to further help office/gaming seating companies create optimized designs.

The use of the avatar reveals how people look in these poor postures and the use of the markers can verify the posture. Future work will include more participants, including more activities for participants (such as using a cell phone or playing video games), and include standing.

# Relationship between Joint Stiffness and Limb Stiffness in Running Across Speeds

Li Jin<sup>1</sup>, Michael E. Hahn<sup>2</sup>

<sup>1</sup>Department of Kinesiology, San Jose State University, San Jose, CA

<sup>2</sup>Department of Human Physiology, University of Oregon, Eugene, OR

Email: [li.jin@sjsu.edu](mailto:li.jin@sjsu.edu)

## Introduction

The lower extremity system acts like a spring in the stance phase of running. The loading and unloading characteristics of the leg spring system can be regarded as limb stiffness patterns. Among different stiffness levels, vertical stiffness ( $K_{vert}$ ) and leg stiffness ( $K_{leg}$ ) reflect whole body center of mass (COM) and leg spring system loading and response in running stance phase [1]; while joint stiffness ( $K_{joint}$ ) reflects joint level dynamic loading and response. Little is known about whether connections exist between the lower level system stiffness ( $K_{joint}$ ) and higher level system stiffness ( $K_{vert}$ ,  $K_{leg}$ ) in running across speeds.

The purpose of the study was to investigate whether  $K_{joint}$  is associated with  $K_{vert}$  or  $K_{leg}$  at different running speeds. We hypothesized that  $K_{joint}$  would have significant association with  $K_{vert}$  and  $K_{leg}$  at each running speed.

## Methods

Twenty healthy subjects ( $36.8 \pm 15.3$  years,  $171.6 \pm 11.2$  cm,  $68.5 \pm 14.1$  kg) were enrolled in the study. Subjects were asked to run on a force-instrumented treadmill (Bertec, Inc. Columbus, OH) at six different speeds, from 1.8 to 3.8 m/s (0.4 m/s intervals), for 75 seconds per stage. Kinematic data were collected at 120 Hz using an 8-camera motion capture system (Motion Analysis Corp., Santa Rosa, CA). Kinetic data were collected at 1200 Hz using the force-instrumented treadmill.

$K_{vert}$  was calculated from peak vertical ground reaction force divided by vertical displacement of the COM from initial ground contact until mid-stance.  $K_{leg}$  was calculated as peak vertical ground reaction force divided by leg-spring maximum displacement in stance phase.  $K_{joint}$  was calculated as change in sagittal plane joint moment divided by sagittal plane joint angular displacement in the first half of ground contact. Multiple linear regression analysis was conducted to determine potential associations between  $K_{vert}$ ,  $K_{leg}$  and  $K_{joint}$  (ankle, knee, hip) for each running speed, using SPSS (V22.0, IBM, Armonk, NY).

## Results and Discussion

$K_{joint}$  was associated with  $K_{vert}$  at 1.8 m/s and 2.2 m/s (Table 1). At 1.8 m/s, the model accounted for 38.4% of the variance in  $K_{vert}$  ( $R^2 = 0.384$ ,  $p = 0.046$ ), and  $K_{knee}$  had the strongest unique association with  $K_{vert}$  at this speed ( $\beta = 0.509$ ,  $p = 0.022$ ). At 2.2 m/s, the model accounted for 49.8% of the variance in  $K_{vert}$  ( $R^2 = 0.498$ ,  $p = 0.014$ ), and  $K_{knee}$  again had the strongest unique association with  $K_{vert}$  at this speed ( $\beta = 0.553$ ,  $p = 0.011$ ).

Additionally,  $K_{joint}$  was associated with  $K_{leg}$  among most speeds, except at 3.0 m/s and 3.8 m/s (Table 1).  $K_{knee}$  had the strongest unique association with  $K_{leg}$  at 1.8, 2.2 and 2.6 m/s ( $p = 0.014$ ,  $p = 0.0004$ ,  $p = 0.04$ ).  $K_{hip}$  also had strong unique association with  $K_{leg}$  at 2.2 and 3.4 m/s ( $p = 0.001$ ,  $p = 0.009$ ).

## Significance

$K_{joint}$  was associated with both  $K_{vert}$  and  $K_{leg}$  in the multiple linear regression models at slow speeds (1.8 and 2.2 m/s) and  $K_{knee}$  had a significant unique association with  $K_{vert}$  and  $K_{leg}$  at these speeds.  $K_{joint}$  was associated with  $K_{leg}$  at a wider range of speeds and  $K_{knee}$  had a significant unique association with  $K_{leg}$  among most speeds. This may be attributed to the observation that in the human leg spring system, under similar loading conditions, the spring with the lowest stiffness ( $K_{knee}$  in this case) will undergo the largest displacement and this would have the most influence on the overall leg-spring system stiffness [2]. These findings built a connection between joint stiffness and limb stiffness within certain range of running speeds.  $K_{knee}$  may need to be considered as an important factor in future limb stiffness optimization and general running performance enhancement.

# Lower Extremity Support Moment and Distribution of Joint Moments during Sloped Running

Yo Shih, Kathleen Stone, Kai-Yu Ho  
Department of Physical Therapy, University of Nevada, Las Vegas

## Introduction

Running is a popular exercise for fitness and recreational purposes. However, running injuries are also prevalent and are the main reason a runner temporarily or permanently discontinues to run.<sup>1</sup> Previous studies show that runners change their step frequency, step length, lower extremity energetics, and joint moments to adapt to upslope or downslope running surfaces.<sup>2-4</sup> However, how sloped running affects runners' lower extremity loading profiles has not been thoroughly examined. This study aimed to examine the 1) peak total support moment, a variable that incorporates hip, knee and ankle joint moments, and the 2) joint contributions of ankle, knee and hip to the total support moment during level, upslope and downslope running. The data obtained from this work will inform clinical decision making for training lower extremity musculature and/or preventing joint injuries in runners.

## Methods

Twenty recreational runners (10 females, age:  $24.9 \pm 2.4$  years, body height:  $1.70 \pm 0.07$  m, body weight  $67.0 \pm 9.7$  kg) were recruited in this study. Each participant ran under three different conditions, including level,  $6^\circ$  upslope and  $6^\circ$  downslope at a standardized speed of 2.3 m/s. Data was collected during three, 20 s trials on an instrumented treadmill. Reflective markers were attached to the trunk and lower extremities. Hip, knee and ankle joint moments were calculated using an inverse dynamics method. Total support moment was calculated as the sum of the hip, knee and ankle joint moments during the stance phase of the running cycle. Each joint's contribution to the support moment was analyzed and presented as a percentage of the total support moment. The primary variable of interest was peak total support moment and the secondary variables of interest were hip, knee and ankle joints' contributions to the support moment at the time of peak total support moment. All variables were examined on the right leg. A one-way ANOVA with repeated measures and post-hoc pairwise comparisons were used to compare the variables among the three running conditions.

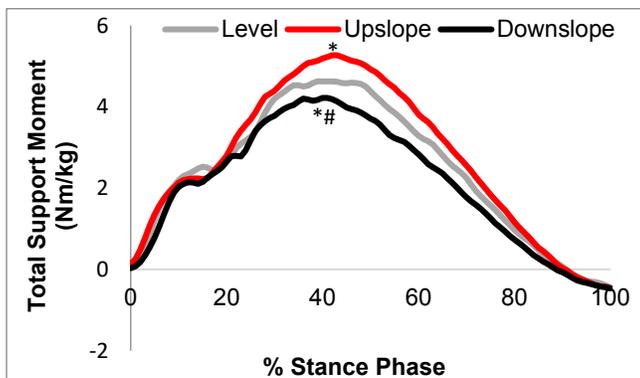

Figure 1. Total support moments of the three running conditions during the 100% stance phase of the running cycle. (\* indicates a significant difference from Level; # indicates a significant difference from Upslope)

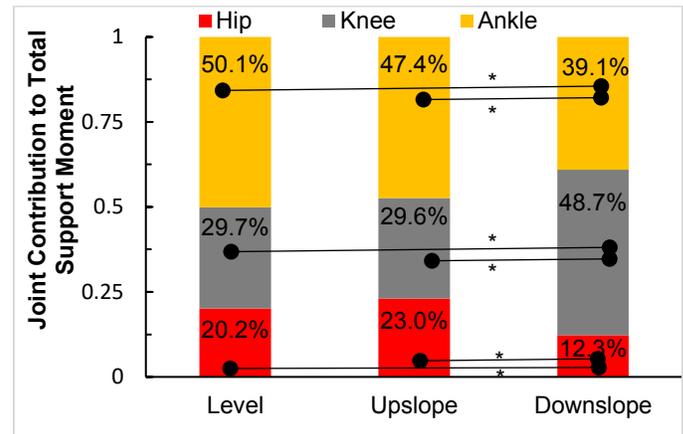

Figure 2. Hip, knee and ankle joint contributions of the three running conditions at the time of peak total support moment (\* indicates a significant difference between conditions)

## Results and Discussion

Peak total support moment was significantly different among the three running conditions ( $p < 0.05$ ). The post-hoc analyses showed that the peak total support moment during upslope running was significantly larger than level and downslope running ( $p < 0.05$ ). Also, the peak total support moment during level running was significantly larger than downslope running ( $p < 0.05$ ) (Figure 1).

During upslope running, the participants demonstrated no significant difference in ankle, knee, or hip joint contribution to total support moment compared to level running. During downslope running, the participants demonstrated significantly larger knee contribution and significantly less ankle and hip contributions to the total support moment compared to level and upslope running (Figure 2).

Our data suggests that running upslope increased the overall loading of the lower extremity joints, while the increased loading was evenly distributed among the three joints. Running downslope decreased the loading of the lower extremity joints in total as well as the hip and ankle joint contributions. However, the knee joint contribution during running downslope increased 64 % compared to level and upslope running.

## Significance

This study shows that different lower extremity loading profiles were used in runners when running on different sloped surfaces. Clinicians and coaches may consider the training slopes for runners based on the training purposes and/or joint conditions of the runners to prevent running injuries.

## Training effects on frontal plane kinematics and coordination in novice runners

<sup>4</sup>Nike Sport Research Lab

Email: kate.harrison@boatechnology.com

### Introduction

Novice runners appear to be at particularly high risk for knee injury.<sup>1</sup> Position and motion of the hip and ankle in the frontal plane have been linked to development of knee injury,<sup>2,3</sup> potentially because they influence the position and loading of the knee joint.<sup>4</sup>

It could be that runners improve their kinematics over time, leading to reduced risk of knee injury. However, the effect of training on kinematics is not well understood. Further, it is unclear how the ankle and hip may contribute to knee positioning in novice runners. The purpose of this study was to assess changes in frontal plane kinematics as well as ankle and hip coordination in novice runners.

### Methods

Eight healthy adult females (30±10 yrs, 28±6 kg/m<sup>2</sup>) with no previous running experience performed 8 weeks of walking, followed by 8 weeks of run training. Before and after run training, kinematic data were collected using a 3D motion analysis system while participants ran on an instrumented treadmill at 2.67 m/s. The current analysis compared kinematics immediately before and after the run training period.

Mean frontal-plane ankle, knee, and hip joint angles were calculated throughout the stride for each participant and modelled using cubic splines. The resulting models were compared between pre- and post-training timepoints using a generalized linear model ( $\alpha=0.05$ ). Confidence intervals (95%) of the mean change in joint angles across the stride were constructed to identify periods where a significant change in joint angle occurred. A modified vector coding technique was used to assess changes in coordination of the ankle and hip in the frontal plane.<sup>5</sup>

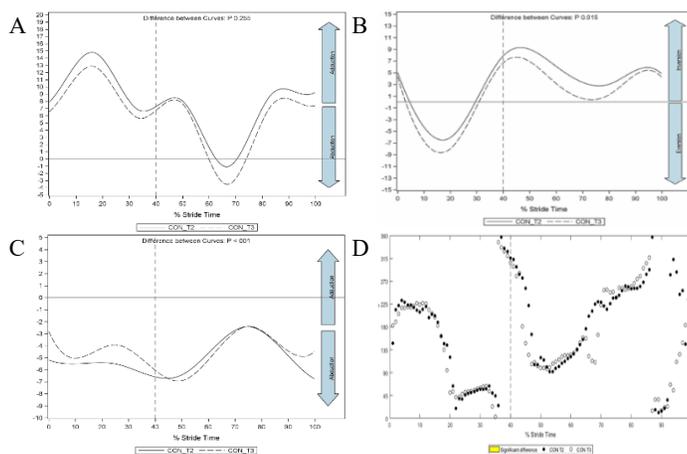

We hypothesized that run training would lead to decreased hip adduction, increased ankle eversion, and knee abduction. Further, we expected that training would lead to improved synchronization of hip and ankle motion in the frontal plane.

### Results and Discussion

After run training, participants displayed less hip adduction during early and midstance (Figure 1A). This is counter to what has been observed in a cross sectional study,<sup>6</sup> suggesting a prospective design may be more powerful in detecting biomechanical changes with training.

Participants also displayed greater ankle eversion during midstance after training (Figure 1B). Increased eversion has been proposed as injurious to the knee,<sup>7</sup> however the relation between peak eversion and injury is equivocal.<sup>3,8</sup>

The combination of decreased hip adduction and increased ankle eversion appeared to result in less knee abduction during early and midstance (Figure 1C). This may have reduced patellofemoral joint contact force and compression of the medial compartment of the knee.

**Figure 1:** A) Frontal plane hip motion. B) Frontal plane knee motion. C) Frontal plane ankle motion. D) Frontal plane hip-ankle coordination angles. CON\_T2=before running, CON\_T3=after running.

There was no significant change in relative motion of the hip and ankle (Figure 1D). Similarly, it was previously found that coordination of lower extremity joints in the sagittal plane did not differ between novice and experienced runners.<sup>9</sup>

### Significance

Run training appeared to alter kinematics related to knee injury, without instruction or supplementary exercise. A reduction in hip adduction and knee abduction during stance may help to explain why experienced runners are at lower risk for knee injury than novice runners. Changes at both the ankle and hip appeared to contribute to improved knee kinematics, and thus may be worth considering in future research.

# HOW DO NET MECHANICAL JOINT WORK & STIFFNESS CHANGE ON SLOPES DURING RUNNING

Caelyn Hirschman<sup>1</sup> & Alena M. Grabowski<sup>1,2</sup>

<sup>1</sup>Applied Biomechanics Lab, University of Colorado Boulder, CO USA

<sup>2</sup>Eastern Colorado Healthcare System, Department of Veterans Affairs, Denver, CO USA

email: [Caelyn.Hirschman@colorado.edu](mailto:Caelyn.Hirschman@colorado.edu)

## Introduction

The spring mass model describes the mechanics of running on level ground, where body mass is represented as a point mass and the legs as massless linear springs [1]. Further, the ankle and knee joints can be characterized as springs with angular stiffness [2], yet the ankle generates net positive mechanical work and knee absorbs net negative mechanical work during level ground running [3].

When running uphill, the leg muscles produce net positive work to lift the center of mass (COM) and overcome gravity [3], mainly due to positive work produced by the muscles surrounding the hip [4]. When running downhill, the leg muscles absorb net negative work to lower and decelerate the COM [5].

We determined ankle and knee net mechanical work and joint stiffness during running on level-ground and uphill/downhill slopes to provide insight into the biomechanics of running and inform the design of running specific leg prostheses (RSPs). We hypothesized, similar to Roberts et al. [4], that the net mechanical work done by muscles surrounding the ankle and knee would not change across slopes during running and that ankle stiffness would increase during uphill and knee stiffness would decrease during downhill compared to level ground running.

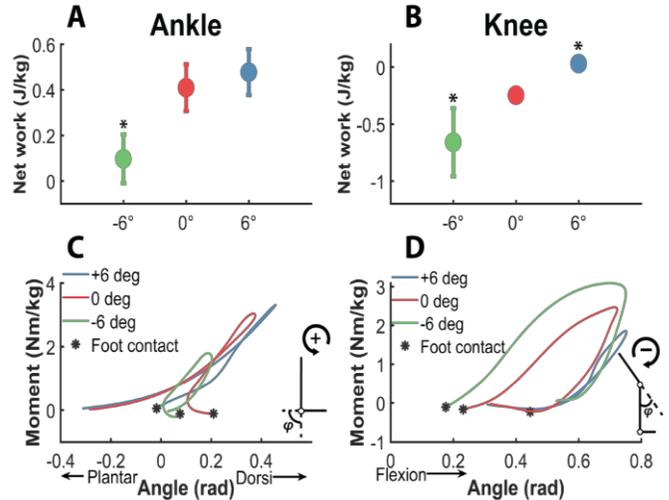

## Methods

16 runners (11M, 5F; mean  $\pm$  SD: age 25 $\pm$ 5 yrs; 69 $\pm$ 7.9 kg; 176 $\pm$ 8 cm) provided written informed consent. Subjects reported no cardiovascular, pulmonary, or neurological disease or disorder, or musculoskeletal injuries. Participants ran on an instrumented treadmill (Treadmetrix, Park City, UT) at -6° and 0° at 3 m/s and +6° at 2 m/s. We measured ground reaction forces (GRFs) at 1000 Hz and motion at 200 Hz (Vicon, Centennial, CO) from markers placed bilaterally on the lower extremity. We used a 20 N vertical GRF threshold to determine ground contact and analyzed  $\geq 15$  steps from both legs. We used a low pass 4<sup>th</sup> order Butterworth filter with a 15 Hz cutoff on kinematic and kinetic data. We calculated joint angles ( $\theta$ ) and moments (M) during ground contact using Visual 3D (C-Motion, Germantown, MD). We calculated initial stiffness (K) prior to mid-stance and final stiffness after mid-stance as average  $\Delta M/\Delta \theta$ . We used a one-way ANOVA and Bonferroni post hoc analyses to determine significant differences.

## Results and Discussion

Net positive ankle work decreased during -6° ( $p < 0.01$ ) and trended towards increasing during +6° ( $p = 0.06$ ) compared to 0° running (Fig. 1). The magnitude of net negative knee work increased during -6° ( $p < 0.01$ ) and decreased during +6° ( $p < 0.05$ ) compared to 0° running. Thus, we reject our hypothesis that ankle and knee net mechanical work would not change on slopes. Initial  $K_{\text{ankle}}$  trended towards decreasing at +6° ( $p = 0.21$ ) and final  $K_{\text{ankle}}$  trended towards increasing at -6° ( $p = 0.20$ ) compared to 0°.

Initial  $K_{\text{knee}}$  increased at +6° ( $P < 0.01$ ) and final  $K_{\text{knee}}$  increased at -6° ( $p < 0.01$ ) compared to 0° (Table 1).

**Figure 1.** Ankle (A) and knee (B) net mechanical work during running at 0° and  $\pm 6^\circ$  (\*  $p < 0.05$ ). Moment versus angle at the ankle (C) and knee (D) during running at 0° and  $\pm 6^\circ$  for a representative subject. The area within the curve indicates net mechanical work. Positive ankle angles indicate dorsiflexion. Static knee angle is 0 rad and a positive angle indicates flexion. \* in (C) and (D) indicates foot contact and the arrow shows the direction of net mechanical work.

**Table 1.** Ankle and knee joint stiffness (K in N\*m/kg/rad) during running at 0° and  $\pm 6^\circ$ . \* indicates  $p < 0.05$  compared to 0°.

	-6°		0°		+6°	
	Initial	Final	Initial	Final	Initial	Final
$K_{\text{ank}}$	10.4 $\pm$ 4.6	6.7 $\pm$ 1.9	10.6 $\pm$ 3.6	5.8 $\pm$ 1.3	8.3 $\pm$ 4.2	5.2 $\pm$ 2.3
$K_{\text{knee}}$	6.3 $\pm$ 1.3	11.2 $\pm$ 4.8 *	6.6 $\pm$ 1.3	6.4 $\pm$ 1.4	10.4 $\pm$ 2.9 *	4.2 $\pm$ 1.4

## Significance

Our results suggest that during downhill running, a prosthetic knee should absorb more negative work but be stiffer after mid-stance than on level ground and during uphill running, a prosthetic ankle should generate more positive work and be less stiff prior to mid-stance than on level ground. Moreover, joint mechanics and stiffness change on slopes. Future work will determine hip net mechanical work and stiffness on slopes.

# Beat the Streets: Music-based Stride Length Intervention to Decrease Injury Risk in Runners

Mikaela A Smith<sup>1</sup>,  
Allison R. Altman-Singles<sup>1,2</sup>

<sup>1</sup>Kinesiology, Penn State Berks, Reading, PA, USA

<sup>2</sup>Mechanical Engineering, Penn State Berks, Reading, PA, USA

Email: mas7377@psu.edu

## Introduction

Each year nearly 20 million people participate in running and 65% suffer from an overuse injury due to running mechanics [4]. High impact loading increases the likelihood of injury and overstriding is one factor that contributes to high impact loading [1].

Overstriding is characterized by an increased stride length (SL). At a fixed speed, cadence can be increased to decrease SL. Prior interventions have used a metronome as a cue for foot contact and found it was a good way to decrease SL. One study found that a 5% increase in cadence, decreased impact peak by 34% [2], another found a 15% increase in cadence reduced joint loading by 18% [3]. This study used a controlled music tempo as a cue to increase cadence. As cadence increased and SL decreased it was expected that impact loading characteristics would decrease. Ultimately, this reduction in impact loading could help to reduce running overuse injury risk.

## Methods

Active, uninjured runners aged 18-55 were recruited to complete a three-week intervention. Participants were required to run a minimum of 10 mi/wk prior to the study. Participants ran on a treadmill at 2.9m/s to collect cadence. Reflective markers were fixed to the foot to determine SL and impact loading variables overground using a floor-embedded Bertec force plate (Columbus OH) surrounded by the Vicon Bontia camera system (Vicon, Boulder, CO, USA), sampled at 1000 Hz and 200 Hz, respectively. Force data were filtered with a 50 Hz low pass filter.

Cadence from the treadmill was used to determine the target cadence for each week of the intervention. An increase in cadence of 5%, 7.5%, and 10% was targeted each week. Each cadence corresponded to the beats/min of a variety of music. Participants were asked to listen to the music during all runs throughout the intervention, while maintaining their normal mileage.

Cadence, SL, and impact loading characteristics were collected pre and post intervention. Impact peak (IPz), average load rate (ALRz), and instantaneous load rate (ILRz), were extracted from the vertical ground reaction force curve. A paired T-test was used to compare the variables.

## Results and Discussion

12 participants entered the study, however, only 11 completed the study. Participants were 29±13 years old, 1.723±0.105 m tall, and 72.2±18.1 kg.

After the intervention, overground SL decreased 3% due to the intervention ( $p=0.09$ ). 8 out of 11 participants responded positively to the intervention showing a 12% decrease in SL, the remaining participants had no change or a small increase. This decrease was associated with a 4% increase in cadence post-intervention ( $p=0.012$ ) measured on the treadmill at a fixed speed (Figure 1). In contrast to the SL, all participants displayed increased cadence on the treadmill after the intervention. Impact characteristics all decreased, but did not reach significance (Figure 1). Among the 8 responders to the study there were decreases in ALRz (12%,  $p=0.041$ ) and IPz (10%,  $p=0.073$ ).

There were some discrepancies between cadence and SL. Speed was fixed on treadmill, but when running over ground, a self-selected speed was used. While SL was trending toward an overall reduction, only 8 participants reduced SL due to the intervention. Compliance and exposure to the intervention were not monitored, and may have limited the effectiveness of the intervention. There was no overall decrease in impact characteristics, however in those who reduced SL, ALRz and IPz were reduced, indicating the intervention was effective for reducing some aspects of impact loading.

Studies using a metronome found 17.6-33.8% reductions in loading with a 5-15% increase in cadence when done at a controlled speed. The current study showed only a 3% reduction in SL overground, which was associated with a non-significant 6.65% reduction in impact loading. In contrast, the 8 responders displayed a 12% reduction in SL, which was associated with a 10.9% reduction in impact loading, which is more similar to the results found in previous studies. It is possible that controlling the overground running speed, increasing compliance, and adding additional participants will yield similar results.

## Significance

This intervention was fun for the runners. The use of phone apps encourages ease and compliance. The apps can be used by runners, coaches, trainers, and rehabilitation professionals alike to maximize the potential benefit of the intervention.

## Long term training on sand changes foot posture and running kinetics in active individuals with over-pronated feet

AmirAli Jafarnezhadgero<sup>1</sup>, Seyed Hamed Mousavi<sup>2</sup>, Amir Fatollahi<sup>1</sup>

<sup>1</sup> Department of Physical Education and Sport Sciences, Faculty of Educational Sciences and Psychology, University of Mohaghegh Ardabili, Ardabil, Iran.

### Introduction

Running is one of the most popular sporting activities, but running-related injuries (RRIs) are a major drawback of running which are increasingly ongoing [1]. About 87% of RRIs occur in the knee, lower leg, foot and ankle, with abnormal foot posture as one of the main causes of those injuries [2]. The foot is the only part of the body which is in contact with the ground while running and it is responsible for shock absorption and dispersal of ground reaction force (GRFs) across the foot. Foot overpronation affects running kinetics which is also considered a risk factor for RRIs. Running on sand could be a promising exercise intervention to treat foot pronation because it is easy-to-access worldwide and produces hardly any costs. The present study aimed to evaluate the long-term effect of running on sand on foot overpronation, impact vertical ground reaction forces (GRFs), loading rate, and anteroposterior impulse (impulse y) in active male adults with over-pronated feet compared with controls.

### Method and Discussion

Thirty active over-pronated feet male adults as experimental group (EG) and 30 active over-pronated male adults as control group (CG) were enrolled in this study. Participants ran barefoot at pre-defined speed (3.3 m/s) over the level stable ground during both before and after running on sand training protocol. The running training protocol on sand includes continuous jogging, striding, bounding, galloping and short sprints [3]. The CG performed the training protocol for eight weeks (three sessions per week). The training protocol was done during barefoot condition. Each session was started with a warm-up and stretching session for five minutes and ended with a warm-down session for five minutes. Training duration was 50 minutes per session. Foot pronation was measured using navicular drop test. A force plate was included in the 18-m runway to collect GRF data.

### Results

In the CG, navicular drop was decreased after running on sand training protocol ( $p < 0.001$ ;  $d = 2.06$ ). The statistical analysis showed significant group by time interactions for impact vertical ground reaction forces ( $p < 0.047$ ,  $d = 0.71$ ). In the EG but not the CG, significantly lower  $F_{Z_{HC}}$  ( $p = 0.026$ ;  $d = 0.86$ ) was observed during post-test than that in the pre-test. Also, the statistical analysis showed significant group by time interactions for impulse y and loading rate ( $p < 0.032$ ;  $d = 0.57-0.77$ ). In the EG but not the CG, significantly lower Impulse y ( $p = 0.032$ ;  $d = 0.39$ ) and loading rate ( $p = 0.004$ ;  $d = 0.45$ ) were observed during post-test than pre-test. Both the magnitude and rate of loading have been identified as risk factors for RRIs [4]. Our results show that long-term running on sand resulted in lower navicular drop, impact vertical GRF and lower loading rate. This is in line with a previous study showing that running on sand produces low impact forces [4].

### Significance

The results of the current study suggest that running on sand can be considered a training base to modify over-pronated feet and running kinetics. This might lead to reducing the risk of RRIs.

### Introduction

Even though multiple factors are involved in running economy and performance, recent World Record performances and research findings from high-calibre runners indicate beneficial effects of the Nike Vaporfly footwear range in runners. In the last year, this particular footwear range has sparked debate regarding whether its use constitutes ‘technology doping’ and has led to the World Athletic revising their footwear guidelines. It has been proposed that recreational runners might reap greater benefits from wearing the Nike Vaporfly shoes than elite runners; however, laboratory-based data are not available to support this proposition.

Our aims were hence to compare running economy (RE) at relative running speeds and 3-km time-trial (TT) performances of male recreational runners wearing the commercially available Nike Vaporfly 4% (NIKE), Saucony Endorphine Racer 2 lightweight racing flats (FLAT), and their habitual footwear (OWN).

### Methods

Eighteen male recreational runners [age: 33.5 (11.9) y,  $\dot{V}O_{2peak}$ : 55.8 (4.4) mL·kg<sup>-1</sup>·min<sup>-1</sup>] attended four treadmill-based laboratory sessions. A minimum of four and maximum of seven days separated each session. In the first session, runners completed a  $\dot{V}O_{2peak}$  to set RE speeds at 60, 70, and 80% of the speed eliciting  $\dot{V}O_{2peak}$ . Treadmill RE and 3-km TT performances were examined in the three footwear in a randomised, counterbalanced crossover design in the second, third, and fourth session (**Figure 1**). The two experimental footwear were spray-painted black to minimise the potential for a placebo effect.

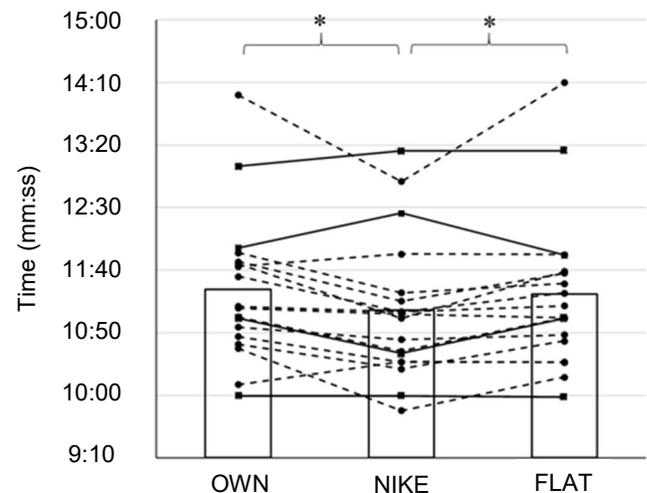

**Figure 1:** Experimental study design. ↔, randomized; FLAT, racing flats; NIKE, Nike Vaporfly; OWN, habitual shoes; RE, running economy; TT, time trial;  $\dot{v}VO_{2peak}$ , speed that elicited  $VO_{2peak}$ .

### Results and Discussion

RE was improved in NIKE (3.6 to 4.5%,  $p \leq 0.002$ ) and FLAT (2.4 to 4.0%,  $p \leq 0.042$ ) compared to OWN across intensities, with no significant difference in RE between NIKE and FLAT (1.0 to 1.6%,  $p \geq 0.325$ ). NIKE 3-km TT (11:07.6 ± 0:56.6

mm:ss) was superior to OWN (+16.6 s, 2.4%,  $p = 0.005$ ) and FLAT (+13.0 s, 1.8%,  $p = 0.032$ ), with no significant difference between OWN and FLAT 3-km TT times (**Figure 2**). Only five runners, all of whom were rearfoot strikers, were more economical across intensities and faster in NIKE. The four non-rearfoot strikers in our cohort appeared to respond less favourably to NIKE.

**Figure 2:** 3-km time-trial time (mm:ss). Bars represent means; circles joined by dashed lines, rearfoot runners; squares joined by black lines, non-rearfoot runners; and asterisks (\*),  $p \leq 0.05$  during post-hoc tests (significant main effect of footwear). NIKE, Nike Vaporfly; OWN, habitual shoes.

Overall, our findings indicate that NIKE could benefit RE and performance in male recreational runners. However, the high variability in individual RE (-3.1 to 12.1%) and TT (-3.8 to 8.2%) shoe-responses suggests that individualisation of running footwear prescription is warranted. Furthermore, RE was also improved in FLAT versus OWN, consistent with the ~0.7 to 1.0% improvements in RE for each 100 g of lighter mass per shoe<sup>1,2</sup>.

### Significance

This study provides evidence that NIKE is a viable ergogenic aid in recreational runners; but only 29% of runners were more economical across intensities and faster in NIKE. Given the considerable individual responses, our data does not support a generalised NIKE performance benefit in male recreational runners. Certain runners were more economical or performed better in FLAT. The injury risk associated with changing biomechanical patterns in uninjured runners<sup>3</sup> and transitioning to novel footwear without proper adaptation should also be considered.

# Coordination Variability in Injured and Uninjured Runners: A Systematic Review

Heather M. Hamilton, DPT,<sup>1</sup> Collin D. Bowersock, M.S.<sup>1</sup>

<sup>1</sup>Old Dominion University

Email: hmcco006@odu.edu

## Introduction

The study of dynamic systems theory has shown movement variability to be an important characteristic of biological systems, representing the ability for individuals to adapt and respond to environmental changes.<sup>1</sup> Further, decreases in movement variability may be indicative of pathology.<sup>1</sup> Coordination variability, or joint coupling variability, refers to the variability in coordination between joint segments over time and can quantify dynamic coordination throughout the gait cycle.<sup>1</sup> It has been suggested that movement variability is essential for the ability to adapt in a dynamic environment and to decrease the risk for overuse injuries in runners.<sup>2,3</sup>

The purpose of this systematic review was to determine the relationship between coordination variability and overuse injuries in runners. Identifying the association between coordination variability and running injuries may provide information to assist with evaluation, treatment, and prevention of overuse injuries.

## Methods

The electronic databases PubMed, CINAHL Plus, and SPORTDiscus were systematically searched in November 2019. The terms “runners” OR “running” AND “coordination variability” OR “joint coupling variability” were used. Reference lists of each included article were hand searched to identify any other appropriate studies. Studies were included that met the following criteria: (1) compared an injured to a healthy control population, (2) measured segmental coordination variability, and (3) included running as the main task. Methodological quality of the included articles was assessed with the Modified Downs and Black Index independently by two reviewers.<sup>4,5</sup>

## Results and Discussion

A total of 11 articles met all inclusion criteria and were included in the narrative synthesis. Based on the results of the Modified Downs and Black Index, 2 articles were identified as high quality,<sup>7,12</sup> 7 as moderate quality,<sup>1,3,6,9-11,13</sup> and 2 as low quality.<sup>2,8</sup> There were 3 primary overuse injuries that were reported: patellofemoral pain,<sup>2,6,10</sup> iliotibial band syndrome,<sup>7,9,12,13</sup> and low back pain.<sup>1,11</sup> Of the 11 included studies, 4 studies reported that the injured group demonstrated decreased coordination variability,<sup>1,2,6,8</sup> 2 studies reported that the injured group demonstrated increased coordination variability,<sup>10,13</sup> and 5 studies reported similar levels of coordination variability between the injured and healthy runners.<sup>3,7,9,11,12</sup> The 2 studies with the lowest methodological quality reported decreased coordination variability in the injured group,<sup>2,8</sup> and the studies with the highest methodological quality reported equivocal results between the injured and healthy runners.<sup>7,12</sup>

Overall, moderate quality evidence does not consistently demonstrate altered coordination variability in injured runners compared to healthy controls. Several limitations may affect the interpretation of these results, including inconsistencies in calculating coordination variability, participants running under different conditions, measurement of different joint couplings,

and measurement of coordination variability at different points in the gait cycle.

## Significance

It is unknown if an optimal amount of coordination variability exists, and whether deviations in either direction are detrimental to performance. There have been no prospective studies to determine if differences in coordination variability lead to injury, or if an injury causes a modification to running mechanics that then alters coordination variability. Further exploration is needed to clarify the role of coordination variability in overuse injuries.<sup>10</sup>

## Acknowledgments

No acknowledgements to report.

# EVALUATING RUNNING MECHANICS OF SOLDIERS IN VARIOUS ATHLETIC FOOTWEAR

Kari L. Loverro PhD, Victoria Bode MS, Kevin O'Fallon PhD, Jessica Schindler MS

<sup>1</sup>Combat Capabilities Development Command Soldier Center (CCDC SC) Natick, MA USA

Email: [\\*kari.l.loverro.civ@mail.mil](mailto:kari.l.loverro.civ@mail.mil)

## Introduction

US military recruits are issued a single pair of athletic shoes for initial entry training (IET) and used throughout their training timeline (8-22 weeks). These shoes are used across a variety of activities including running, strength training, ruck marching, and fitness evaluation testing as well as on a range of surfaces including gym floors, pavement, grass, sand and gravel. The athletic shoes currently issued are classified as "road running shoes" [1] aimed to reduce running related injuries. The question of whether road running shoes are the proper type of athletic shoe to distribute has arisen, given the breadth of activities being during IET. This program aims to determine if different athletic shoe types effect performance on a variety of activities experienced during training and if the use of a single athletic shoe would effect performance across the training timeline. The preliminary analysis described here aimed to determine if athletic shoe type affects vertical and anteroposterior ground reaction forces (GRF) during running. Future analyses will include the effect of shoe type on performance of other training activities.

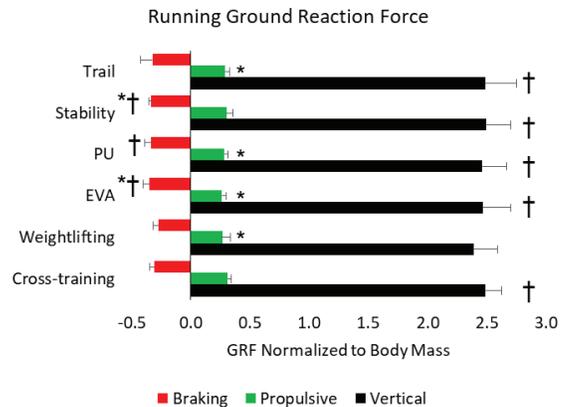

## Methods

Seven US Army Soldiers (5M, 2F, age: 20.6±3.3 yrs, mass: 70.0±3.1 kg, height: 1.70±0.08 m) completed three running trials in six different athletic shoes: a stability road running, a cushioning road running with an ethyl vinyl acetate (EVA) midsole, cushioning road running with a polyurethane (PU) midsole, trail running, a cross-training and a weightlifting shoe. Soldiers ran an 18m runway at a predetermined speed (4.0±5% m/s) and were positioned to strike a force plate with their dominant limb. Vertical and anteroposterior GRFs were time normalized to the stance phase of each stride and averaged across trials. Peak vertical, braking, and propulsive GRF (normalized to body mass) of the dominant limb were used for analysis. Separate Generalized Linear Models with Generalized Estimating Equations were used to evaluate the affect of shoe type on each dependent variable. Post-hoc pairwise comparisons were performed if factors were significant. (SPSS, IBM Inc.)

## Results and Discussion

Shoe type had a significant main effect on all GRF variables ( $p \leq 0.002$ ). Pairwise comparisons indicate that GRF variables of the weightlifting and cross-training shoes differed significantly from the other shoe types. (Figure 1) Running in the weightlifting shoes significantly decreased peak vertical GRFs compared to all other shoe types ( $p \leq 0.026$ ). While peak braking GRFs were decreased in the weightlifting shoes compared to the cushioning EVA, cushioning PU and stability shoes ( $p \leq 0.009$ ), peak propulsive force was only decreased compared to the cross-training shoes ( $p = 0.024$ ). Running in the cross-training shoes also produced greater peak propulsive GRFs than running in the cushioning EVA, cushioning PU, and trail running shoes ( $p \leq 0.033$ ). When running in the cross-training shoes, peak braking GRFs were significantly decreased compared to the cushioning EVA and stability shoes ( $p \leq 0.041$ ). The differences detected between the weightlifting and cross-training shoes compared to the running shoes tested is most likely due structural design differences. The weightlifting shoes have a higher drop

height and more rigid sole construction, while the crosstrainers have lower drop and stack heights than the running shoes. The increased drop height of the weightlifting shoes may have forced participants to adjust their foot strike pattern to a more midfoot or forefoot strike, decreasing both the peak vertical and braking GRFs. The flatter construction of the cross-training shoes may have caused the heel to be lower to the ground during the stance phase, resulting in increased propulsive GRFs required to push the foot up into toe-off position.

**Figure 1:** Running GRFs for vertical and anteroposterior directions across shoe type. \*Significant difference from the cross-training shoes  $p < 0.05$  †Significant difference from the weightlifting shoes  $p < 0.05$ .

## Significance

When evaluating footwear to be distributed to Soldiers in IET, all aspects of performance must be considered for a variety of tasks. This study is a first step to understanding the influence of different footwear types. Other studies have identified that shoe type can affect GRF parameters during running [2], and our results contribute to this body of knowledge. Running in weightlifting shoes is not frequently evaluated because they are not designed for running activities, but when advising if a single pair of shoes should be distributed in IET it is important to characterize all aspects of the relevant footwear types. Yet it is not surprising that most differences detected were between the weightlifting shoes and the other shoe types. Further analysis of these differences should be conducted to understand any other effects on body mechanics. It is also important to consider the differences identified here when evaluating cross training shoes for IET. This shoe type may seem the natural choice for the diverse activities that Soldiers perform in this environment, but a more complete understanding of the changes in running mechanics demonstrated here is still necessary. Overall, this work makes a start on identifying the ideal footwear for optimal performance or injury mitigation during the diverse tasks of IET.

## Novice runners maintain cumulative loads during steady-state running

Jessica G. Hunter<sup>1</sup>, Ross H. Miller<sup>1</sup>, Irene S. Davis<sup>2</sup>

### Introduction

Previous studies on running injuries have mostly considered training habits and mechanical loads separately. However, an interaction between these two factors leading to running injuries is likely [1,2]. A recent investigation found that cumulative loads associated with tibial stress fracture injuries are higher at slow running speeds than at fast running speeds [3], which may have implications for stress fracture injury risk since popular training programs recommend high proportions of slow running [4]. Prolonged running causes fatigue-induced modifications in running mechanics that may affect the load accumulated throughout a single run or over a volume of running [5]. Therefore, the purpose of this study was to determine if there is a relationship between run distance and cumulative vertical instantaneous loading rate (VILR), run distance and cumulative axial tibial load (TL), and run distance and step frequency (SF) during steady state running to fatigue. The hypothesis was that cumulative loads would increase as running distance increased.

### Methods

Twenty novice female rearfoot strike runners ran until they felt they needed to stop at a constant self-selected speed on an instrumented treadmill. Sixteen seconds of kinematic and ground reaction force data were collected at 3 minutes and the end of each kilometer. Data were processed using Visual3D to determine R and L step SF, VILR, and TL. VILR was measured as the greatest change between data points from 20 to 80% of the time between initial contact and impact peak and scaled by body weight. TL was the combined proximal ankle force and Achilles' tendon force. Achilles' tendon force was calculated as the sagittal ankle moment divided by the ankle moment arm, estimated as 5% of foot length. Cumulative load of each kilometer was estimated for VILR and TL by multiplying the number of steps x mean value. A Wilcoxon test determined that outcomes on the dominant vs. nondominant sides were similar, therefore only the dominant side was analyzed further. Spearman's rho was calculated to determine the relationship between run distance and cumulative loads, and run distance and SF.

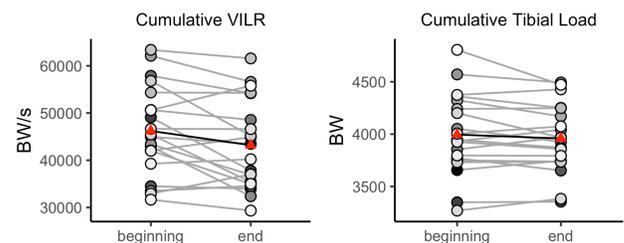

### Results and Discussion

Details on participant demographics and running metrics are shown in Table 1. There was no relationship between run distance and per-kilometer cumulative VILR ( $r_s = -0.09$ ), cumulative TL ( $r_s = -0.04$ ) or SF ( $r_s = 0.04$ ). Figure 1 shows cumulative loads at the beginning to the end of the run. The hypothesis that cumulative loads would increase with run distance was not supported. There was no relationship between run distance and cumulative VILR, cumulative TL, or SF. These results indicate there were no substantial changes to peak loads or the number of loading cycles. Novice runners may be more sensitive to other manifestations of fatigue

(physiological or perceptual) and cease running before gait adjustments occur.

**Table 1.** Participant demographics and run metrics

	mean (SD)	Min.	Max.
age	25 (6)	18	38
miles/wk	12.7 (6.1)	4.5	25
experience (months)	16 (9)	3	36
run speed (mph)	6.1 (0.7)	5	8
run distance (km)	5 (2)	3	8

**Figure 1:** Cumulative loads at the beginning and end of a fatiguing run. Circles show individual subjects, red diamonds show the mean.

### Significance

Cumulative load did not increase with run distance, which may be related to differences between the laboratory and runners' typical running environment. Cumulative damage to tissues and subsequent injury risk is not linearly proportional to cumulative load [1] and may be more sensitive to non-significant changes in SF and peak loads. Whether the lack of increase in cumulative load with fatigue translates to an absence of elevated injury risk is unknown. Future studies are required to determine the utility of cumulative load in running injury risk applications.

# Effects of Experimental Anterior Knee Pain on Running Neuromechanics: A Pilot Study

Matthew K. Seeley<sup>1</sup>, Justin T. Barker<sup>1</sup>, Sunku Kwon<sup>1</sup>, Dillon Kunz<sup>1</sup>, Hannah Coombs<sup>1</sup>, Aubrey R. Odom<sup>2</sup>, Shane Huang<sup>2</sup>, William F. Christensen<sup>2</sup>, and J. Ty Hopkins<sup>1</sup>

## Introduction

Patellofemoral pain (PFP), or anterior knee pain (AKP), alters running biomechanics [1]. Altered running biomechanics might affect knee cartilage health [2]. It is difficult to distinguish the independent effects of AKP during running from other simultaneous PFP factors (e.g., joint effusion). The purpose of this pilot study was to test the feasibility of using experimental AKP during a 60-min run in order to clarify the independent effects of AKP during distance running on neuromechanical variables associated with knee cartilage health. We hypothesized that (1) an experimental AKP model could effectively induce perceived AKP throughout a 60-min run and (2) the experimental AKP would alter vertical ground reaction force (vGRF) and quadriceps muscle activation.

## Methods

Ten healthy volunteers (5 females; Age =  $24 \pm 2$  yrs; Height =  $173 \text{ cm} \pm 11 \text{ cm}$ ; Mass =  $68.4 \text{ kg} \pm 10.3 \text{ kg}$ ) ran for 60 min on a force-instrumented treadmill on 3 different days. Each day corresponded to a different experimental condition: control, sham, and pain. The pain and sham sessions involved a 75-min hypertonic and physiological saline infusion, respectively, into the right infrapatellar fat pad [3]; this duration included the 60-min run. Surface electromyography (EMG), normalized to reference value specific to each subject and session, was used to quantify activation of the vastus lateralis (VLA) muscle. vGRF and VLA EMG data, during the stance phase of running, were collected and averaged across six 30-s durations (at the end of each 10-min duration throughout the run). Perceived AKP was quantified every 3 min using a 100-mm visual analog scale. vGRF and VLA EMG during the stance phase of running were compared between sessions using a functional data analysis approach. Mean perceived AKP levels were compared between sessions using a mixed-model ANOVA.

## Results and Discussion

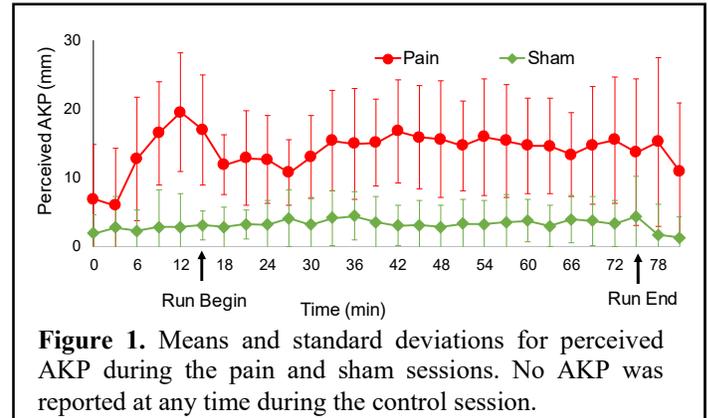

As hypothesized, mean perceived AKP was greater ( $p < 0.01$ ) during the painful session relative to the control and sham sessions (Figure 1). This is the longest duration (75 min) we have ever utilized this experimental AKP model. As hypothesized, the experimental AKP altered running vGRF and VLA EMG (Figure 2); although Figure 2 does not depict the sham session, to increase clarity. The experimental AKP decreased vGRF as much as 4% of body weight (BW) between 2-9% of stance, and as much as 5% of BW between 27-78% of stance (Figures 2A & 2C). The experimental AKP resulted in decreased and delayed VLA activation: VLA EMG was decreased during the pain session as much as 1 times the EMG reference value during the first 60% of the stance phase, but increased as much as 0.5 times the reference value during the last 40% of stance (Figures 2B & 2D).

These findings fit with previously stated ideas that clinical AKP causes quadriceps weakness [4]. These results show that AKP can independently inhibit quadriceps muscle activation and decrease associated running vGRF during a 60-min run. In

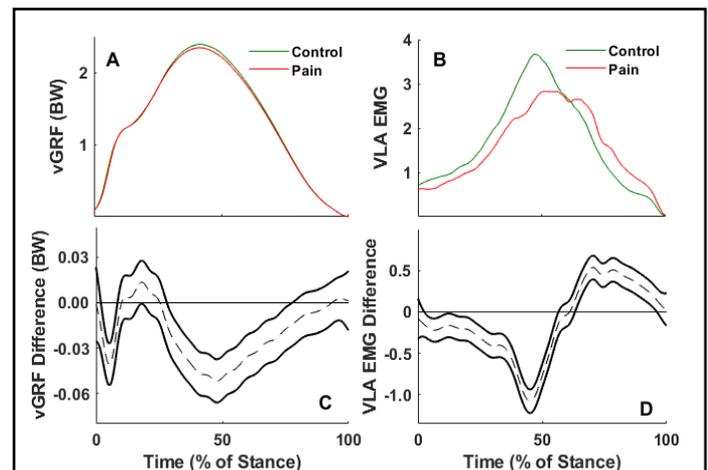

combination with previous findings from our laboratory [2], these results also indicate that experimental AKP may influence the acute effects of running on knee articular cartilage; our previous research has shown that altered walking and running biomechanics alter knee cartilage biomarkers [2]. In the future, we plan to observe effects of experimental AKP during distance running on articular cartilage biomarkers, and direct measures of knee articular cartilage morphology and composition.

# Relationship Between the Single-Leg Step-Down and Lower Extremity Loading in Adolescent Runners

Allison Hoffee<sup>1</sup>, Scott Monfort<sup>2</sup>, and James Becker<sup>1</sup>

<sup>1</sup>Department of Health and Human Development, <sup>2</sup>Department of Mechanical and Industrial Engineering, Montana State University, Bozeman, MT, USA

Email: james.becker4@montana.edu

## Introduction

Previous studies have shown associations between movement screen performance and running kinematics [1]. However, it is still unclear whether movement screen performance is related to injury mechanisms, and by extension, whether they can be used to identify individuals at risk of developing common injuries. Therefore, the purpose of this study was to determine the relationship between performance on the single leg step down (SLSD) movement screen and Achilles tendon (AT) and patellofemoral (PF) joint loads. It was hypothesized that poor performance (i.e. more motion) on the SLSD would be associated with higher AT and PF loads.

## Methods

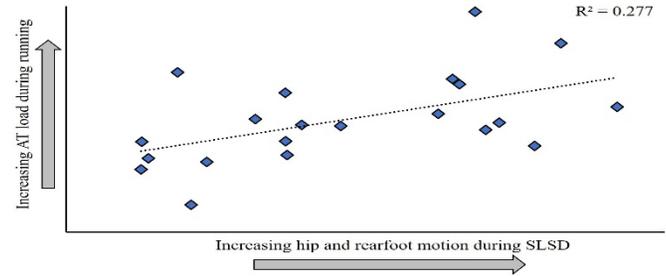

Twenty-one adolescent runners participated in this study (12 M/9 F; age:  $12.38 \pm 0.79$  years; weekly mileage:  $23.2 \pm 6.4$  miles; easy training run pace:  $3.25 \pm 0.17$  m/s). Participants ran for 5 minutes on an instrumented treadmill, after which 10 SLSD trials were performed. 3D motion capture recorded kinematics and kinetics during both running and SLSD. Kinematics during SLSD and kinetics in AT and PF joint were calculated based on previously describe models [2] (Table 1). Principal component analyses were performed for SLSD, AT, and PF variables. Factor loadings were interpreted to create surrogate variables [3] and regressions were performed to determine whether SLSD surrogates predicted AT or PF surrogates.

## Results and Discussion

Descriptive statistics for SLSD, AT, and PF loads are shown in Table 1. Three principal components were extracted for SLSD: 1) a hip-rearfoot component, 2) a tibia internal rotation component, and 3) a pelvis-knee component. A single principal component was extracted for AT and PF variables, respectively.

A regression model containing the hip-rearfoot SLSD surrogate predicted AT loading surrogate ( $R^2 = 0.277$ ,  $p = 0.014$ , Figure 1). Each one unit increase in the hip-rearfoot surrogate resulted in a 3.26 unit increase in AT loading (95% CI 0.73 – 5.79). The tibia rotation ( $p = .300$ ) and pelvis-knee ( $p = .447$ ) surrogates were not significant predictors. None of the SLSD surrogates predicted the PF the surrogate.

Our hypothesis was partially supported as higher SLSD hip-rearfoot surrogate scores predicted higher AT loading surrogate scores. This means adolescent runners with higher hip adduction, hip internal rotation, and rearfoot eversion during the SLSD experience higher AT tendon loads while running. Previous studies have suggested that neuromuscular control at the hip

**Figure 1.** Relationship between SLSD hip-rearfoot surrogate and AT surrogate. The hip-rearfoot motion surrogate is the average of hip adduction, internal rotation, and rearfoot eversion during SLSD. The AT loading surrogate is the average of the peak AT force, loading rate, impulse, and cumulative impulse.

during running is altered in individuals with Achilles tendinopathy [4]. Since the SLSD assesses neuromuscular control of the hip it may be a useful assessment for identifying runners at risk of developing Achilles tendinopathies. Indeed, as we followed this cohort over the course of their running season, the two individuals who performed worst on the SLSD were the ones who developed Achilles injuries. However, future prospective studies are needed to confirm this relationship.

SLSD performance was not, however, associated with PF loads. This is contrary to previous studies that show increases in PF stress in individuals who also have increased hip adduction and internal rotation during both running and SLSD [5]. Whether this is due to the adolescent participants or other factors requires further research.

## Significance

This is the first study to show a relationship between performance on a common movement screen and tissue loading parameters related to the development of common running injuries. This relationship supports the hypothesis that movement screen performance may be beneficial for identifying individuals at risk of developing running overuse injuries.

# Effect of Increasing Running Cadence on Impact Force in an Outdoor Environment

Taylor L. Musgjer<sup>1</sup>, Jacob D. Anason<sup>1</sup>, Thomas W. Kernozek<sup>1</sup>, Drew N. Rutherford<sup>1\*</sup>

<sup>1</sup>Department of Health Professions, Physical Therapy Program, University of Wisconsin-La Crosse, La Crosse, WI

Email: \*[drutherford@uwlax.edu](mailto:drutherford@uwlax.edu)

## Introduction

Running-related injury prevalence has been reported between 56-80% in U.S. runners (van Gent et al., 2007). A proposed mechanism is high impact loading. Reducing impact forces may be an effective intervention to reduce injury rate (Davis et al., 2010).

Cadence modification was reported to decrease peak vertical ground reaction forces (vGRF) in laboratory settings (Schubert et al., 2014). Increasing cadence while maintaining running pace generally decreases a runner's stride length. Heiderscheit et al. (2011) reported reduced impact loading due to cadence modification during treadmill running (Heiderscheit et al., 2011); however, running over-ground in an outdoor setting may be different.

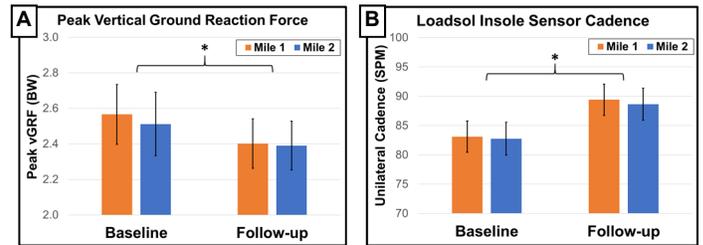

The goal of this study was to quantify decreases in peak vGRF associated with cadence modification in outdoor running. Additionally, we sought to evaluate the compliance of running cadence modification using an auditory metronome cue.

## Methods

Fifteen recreational runners (female n=8 ; male n=7), ages 18-26 (mean=23.5 yrs), with an average mileage of at least 8 miles/week participated. Each completed two outdoor running sessions  $\approx$  1 week apart. Runners wore wireless sensor insoles (Loadsol, novel gmbh, Munich, Germany) in both shoes interfaced with an iPod Touch for recording data and administering auditory cueing. Vertical ground reaction forces (vGRF) were sampled at 100 Hz and smoothed with a dual-pass Chebyshev filtered with a 30 Hz low-pass cutoff frequency. A GPS watch (Forerunner 25, Garmin International Inc., Olathe, KS) recorded distance and cadence and provided pacing information during runs. Runners utilized their own footwear.

During their Baseline run, participants ran a 2.4 mile (3.9 km) course on a straight, flat asphalt road under their preferred, training pace and cadence. All were instructed to maintain a consistent pace using the GPS watch. During the Follow-up session, runners ran at +10% of their Baseline cadence (Heiderscheit et al., 2011), measured via the GPS watch at the same preferred pace as Baseline. Auditory cueing was provided from the iPod speaker with a metronome application (MetroTimer version 3.3.2, ONYX Apps, US).

Peak vGRF in bodyweight (BW) and cadence data were extracted from one unilateral vGRF time-series for each run. Sensor insole-based cadence data in steps/minute (SPM) were obtained from peak-to-peak timing of vGRF data. Peak force and cadence data were collapsed to mile 1 (1.6 km) and mile 2 (3.2 km) for averages. Two 2x2 repeated measures ANOVA's were performed on time (Baseline, Follow-up) and distance (Mile 1, Mile 2) using IBM SPSS (version 25, Armonk, NY). A separate ANOVA was used for cadence on time and device (Insole, GPS watch). Post hoc testing was performed using Bonferroni correction.

**Figure 1:** Effects of auditory metronome cueing on peak vGRF (A) and cadence from the pressure insole sensor (B) from Baseline to Follow-up for Mile 1 and Mile 2.

## Results and Discussion

Participants demonstrated moderate compliance with the iPod auditory metronome cueing via a 7.3% cadence increase from Baseline to Follow-up ( $p < 0.001$  ; Cohen's  $d = 1.24$ ). Unilateral peak vGRF decreased 0.15 BW during Follow-Up compared to Baseline (-5.9% ;  $p = 0.029$  ; Cohen's  $d = 0.56$ ). Treadmill-based studies with cadence increases have reported smaller impact reductions  $\approx$  2.5% (Heiderscheit et al., 2011; Lenhart et al., 2014); The present study utilized different force sensor technology. Peak vGRF and cadence did not deviate between the first and second mile within each outdoor run.

Cadence reported from the insoles and the GPS watch data showed the two devices were similar ( $p > 0.05$  ; 0.5% difference). This may suggest that a commercially available GPS watch can effectively measure cadence while enforcing pace during outdoor running scenarios.

## Significance

Runners seeking to lower their impact forces may benefit from the auditory metronome cues for increased cadence and GPS watch to enforce pace. These data support use by clinicians to alter running cadence in an effort to prevent impact-related injury during outdoor running.

## Acknowledgments

The authors wish to thank the University of Wisconsin-La Crosse Graduate School for a graduate student research grant funding this work.

## Biomechanics during running in Vaporfly shoes with intact vs. cut carbon-fiber plates

Laura A. Healey<sup>1\*</sup>, Justin Angelo O. Ortega<sup>1</sup>, Dale Haavind-Berman<sup>1</sup>, and Wouter Hoogkamer<sup>1</sup>

Email: \*[laurahealey@umass.edu](mailto:laurahealey@umass.edu)

### Introduction

Performance running shoe technology has recently become a polarizing topic, most notably due to the use of carbon-fiber plates. While small benefits of carbon-fiber plates in footwear have been shown before (Roy & Stefanyshyn, 2006), Nike Vaporfly 4% (VF) shoes, which utilize a curved carbon-fiber plate embedded in a compliant and resilient midsole, have been shown to improve running economy by as much as 4% compared to two popular marathon racing shoes (Hoogkamer et al. 2018). In a biomechanical analysis of the VFs, Hoogkamer et al. (2019) determined the clever lever and the stiffening effects of the plate are likely among the main contributors to the 4% energy savings. However, that study compared shoes that differed in both geometry (taller stack height), foam properties (more compliant and resilient) and longitudinal bending stiffness (stiffer; carbon-fiber plate). Understanding how the VFs' carbon-fiber plate affects running mechanics is critical to informing optimized shoe design.

Therefore, the aim of this study was to determine how the carbon-fiber plate in the VFs affects ankle and metatarsal-phalangeal (MTP) mechanics. We hypothesized that decreasing the longitudinal bending stiffness would (1) increase MTP angle, moment, and power, (2) decrease ankle angle and moment and (3) increase positive distal rearfoot power.

### Methods

To reduce the effectiveness of the carbon-fiber plate six medio-lateral cuts were made in the forefoot of a pair of new VFs through the carbon-fiber plate (Figure 1). Nine male runners (size M9.5, 23±4 years, 67.2±4.7 kg, 174±3 cm) ran over ground across a 100ft runway at 14km/h ± 4% five times in the cut VFs (CVF) and intact VFs (VF). Force plate data (AMTI 2000Hz) and 3D positional data (Qualisys 200Hz) were collected for the right leg and foot. We calculated joint angles, moments, and powers during the stance phase for the ankle and MTP joint, as well as distal hindfoot power (DHFP) (Zelik & Honert, 2018) using a custom Python script. To analyze the entire stance phase, we used one dimensional spatial parametric mapping (SPM) to conduct two-tailed paired t-tests ( $\alpha = 0.05$ ).

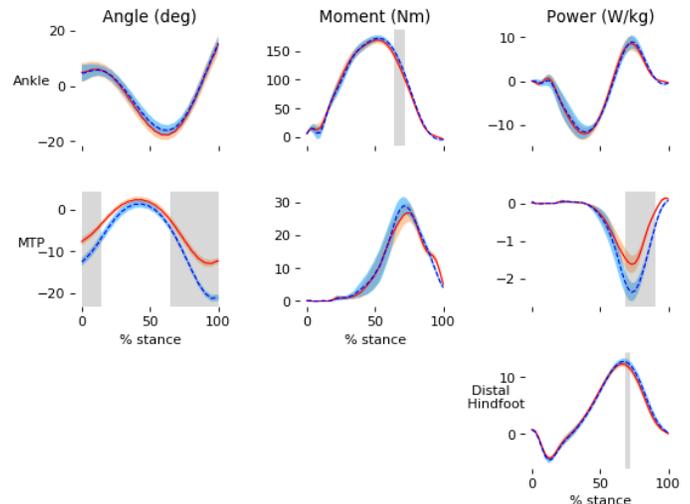

**Figure 1:** Shoe conditions: VF (baseline), CVF (decreased longitudinal bending stiffness)

### Results and Discussion

Most differences were found in MTP mechanics, with small changes in ankle moment and distal hindfoot power (Figure 2). MTP angles were more dorsiflexed ( $p=0.038$ ) in the CVF between 0-14% and 72-100% of the stance phase. This was accompanied by increased ( $p<0.001$ ) negative MTP power in the

CVF compared to the VF from 68-90% of stance phase. Ankle moment was significantly higher ( $p<0.001$ ) in the CVF from 64-72%. Finally, positive distal hindfoot power was significantly higher ( $p=0.027$ ) in the CVF from 69-72%.

**Figure 2:** Angle (deg), moment (Nm), and power (W/kg) for the Ankle, MTP, and distal hindfoot in the VF (orange line) and CVF (dashed blue line). Grey areas indicate regions where shoe conditions differ significantly ( $p<0.05$ ).

The results partially support our first hypothesis, that decreasing longitudinal bending stiffness would increase MTP angle and power, however no differences were seen in MTP moments. Interestingly, these differences in MTP mechanics did not translate to the ankle, as few changes were observed. DHFP was calculated to better understand the power contribution from the shoe, including the plate and the foam. In this method only the power fluctuations between the calcaneus and the ground are considered, as treating the whole foot as a rigid segment has been found to be less accurate (Zelik & Honert, 2018). Only a small difference in DHFP was found, suggesting that the carbon-fiber plate does not substantially change the combined power absorption and generation from the shoe foam, plate and foot structures. Overall, our results suggest that the carbon-fiber plate in the VFs has the most influence on the MTP joint.

### Significance

As carbon-fiber plates become increasingly popular in running shoe innovation, it is important to understand how they affect joint mechanics, and how this could contribute to improved performance. Outside of performance running, shoes that alter joint mechanics may be beneficial to specialized populations such as older adults or individuals with reduced muscle function.

# The Effect of Carbon-Fiber Plate Racing Shoes on Running Biomechanics

JJ Hannigan & Luisa Westley  
San Jose State University, San Jose, CA  
Email: [jj.hannigan@sjsu.edu](mailto:jj.hannigan@sjsu.edu)

## Introduction

Maximal running shoes are loosely defined as shoes that contain greater midsole cushioning from heel to toe compared to a traditional shoe. The effect of maximal running shoes on biomechanical measures related to running injury risk have only recently been investigated, with some studies finding elevated loading rates, impact forces [1,2] and prolonged eversion [2,3] in maximal shoes compared to traditional footwear.

While maximal running shoes were initially designed for training on the road or trails, a new type of maximal shoe has recently become popular for road racing, containing a carbon-fiber plate in the midsole as well as a proprietary new midsole material with high compliance and resilience. Initial findings have demonstrated that shoes in this category may reduce the energetic cost of running by ~4% [4], possibly due to changes in ankle and metatarsophalangeal joint biomechanics [5]. These shoes are in stark contrast to lightweight minimally cushioned shoes that had generally been worn for road racing.

While many running shoe companies have since released a shoe in this category, Nike's Vaporfly 4%, and subsequently the Vaporfly Next%, were the first shoes in this category on the market, and remain the most popular option among runners. While predominately used for racing, these shoes are becoming increasingly popular for use in training, leading to the question of the effect of these shoes on common biomechanical injury risk factors during running. Therefore, the purpose of this study was to compare hip, knee, and ankle biomechanics during running between the Nike Vaporfly Next% and a common minimal shoe.

## Methods

Twelve healthy competitive distance runners (age =  $21.0 \pm 2.5$  yrs) participated in this study. Twenty-one reflective markers and six marker clusters were placed on subjects who ran overground in the lab at their marathon pace wearing the a) Nike Vaporfly Next% (NP), and b) New Balance Minimus (NB) in random order. Five successful running trials for each shoe were collected at 200 Hz with a 16-camera 3D motion capture system (Vicon Motion Systems, Oxford UK). Two force plates collected ground reaction forces and were used to determine initial contact and toe-off (Kistler Instrument Corp., Novi MI).

Kinematics were calculated using Visual3D software (C-Motion, Germantown MD). Variables of interest included peak angles and excursions at the ankle (dorsiflexion and eversion), knee (flexion and valgus), and hip (adduction and internal rotation) as well as peak internal moments at the ankle (plantar flexion and inversion), knee (extension and valgus), and hip (abduction and external rotation). Data were compared using paired t-tests with the alpha-level set to 0.05.

## Results and Discussion

No significant differences were found between peak angles or excursions at the hip and knee ( $p > .05$ ). At the ankle, peak dorsiflexion (NP:  $19.0 \pm 3.8^\circ$ , NB:  $25.3 \pm 3.7^\circ$ ,  $p < .001$ ) and dorsiflexion excursion (NP:  $21.6 \pm 4.3^\circ$ , NB:  $25.6 \pm 4.2^\circ$ ,  $p < .001$ ) were both significantly lower in the Nike Next% (Figure 1). While there were no differences in peak eversion, eversion

excursion was significantly higher in the Nike Next % shoe (NP:  $15.1 \pm 2.6^\circ$ , NB:  $12.9 \pm 2.6^\circ$ ,  $p = .001$ ).

At the ankle, the internal plantar flexion moment was significantly lower in the Next% shoe (NP:  $2.4 \pm 0.5$  Nm/kg, NB:  $2.9 \pm 0.5$  Nm/kg,  $p = .001$ ). At the knee, the internal extension moment was significantly higher in the Next% shoe (NP:  $4.4 \pm 0.7$  Nm/kg, NB:  $4.0 \pm 0.9$  Nm/kg,  $p = .01$ ). Differences between shoes for the internal hip extension moment were close to achieving significance (NP:  $1.3 \pm 0.6$  Nm/kg, NB:  $1.1 \pm 0.7$  Nm/kg,  $p = .06$ ). No other differences were observed for kinetics.

The kinematic results indicated few differences between shoes for important injury risk factors for injury. Greater eversion excursion was observed in the Next% shoe which has been linked to injury, however, these differences were largely driven by slightly greater inversion at initial contact and toe-off.

While not commonly linked to injury risk, less dorsiflexion excursion and peak dorsiflexion were observed in the Next% shoe (Figure 1) in addition to a smaller peak internal plantar flexion moment, which agrees with previous research [5] and may help explain the performance benefits of the shoe. However, this appears to come at a cost, as the internal knee extension moment was significantly higher in the Next% shoe.

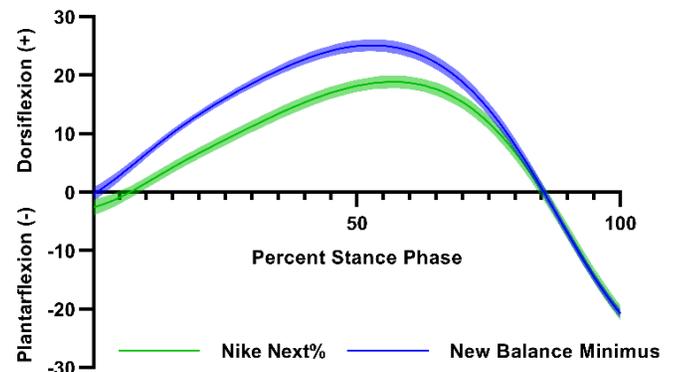

Figure 1. Ensemble curves of sagittal plane ankle kinematics.

## Significance

While greater ankle eversion excursion is noteworthy in the Next% shoe, no other kinematic or kinetic risk factors for injury were observed in this shoe, indicating this carbon-fiber plate racing shoe may not substantially increase injury risk. Differences between shoes in ankle biomechanics agree with previous research and may explain the performance benefits.

# Application of automatic segment filtering procedure to the kinematics of running

Daniel J Davis, and John H Challis

Biomechanics Laboratory, The Pennsylvania State University, University Park, PA

Email: djd426@psu.edu

## Introduction

The processing techniques used on biomechanical signals can often be as important as the experimental paradigms. The filtering methods of motion capture signals have received considerable attention with respect to estimating signal derivatives in particular. Recently, an automatic filtering procedure which applies a Butterworth low-pass filter with different cut-off frequencies specific to signal sections was proposed [1]. This technique aimed to better filter time-series signals with varying frequency content. It is not clear, however, how this approach would compare to typical filtering procedures when applied to a set of common biomechanical measures which comprise multiple signals. Therefore, the purpose of this investigation was to explore the application of the automatic segment filtering procedure (ASFP) to a publicly available simulated running stride [2].

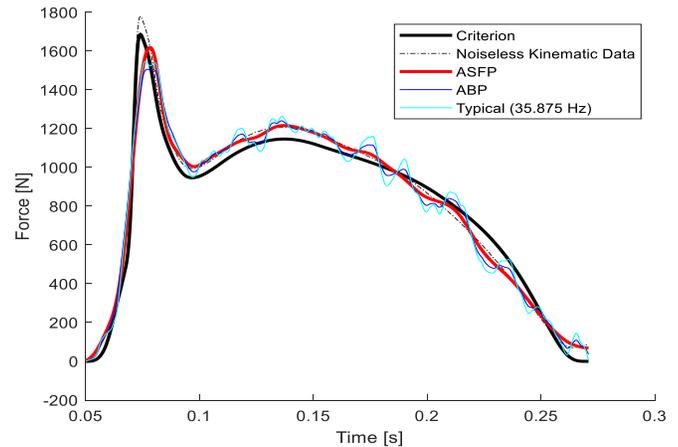

## Methods

The test data of van den Bogert & de Koning (1996) were used as criterion data [2]. This data set consists of lower body segment kinematics and ground reaction forces from computer simulations of running gait. To illustrate the influence of filtering multiple signals in a signal section by section manner, the vertical ground reaction force (vGRF) was estimated from the computed vertical center of mass (COM) acceleration of lower limb segments throughout the stance phase after adding noise to the limb segment coordinates.

Body segment COM displacements and accelerations were estimated ten times using noiseless kinematic signals, and after the addition of noise (0.1 mm root mean square) using three signal processing techniques. 1) The “typical” technique in which all kinematic signals were filtered at a single filter cut-off frequency (the mean of the autocorrelation-based procedure [ABP; 3] cut-off frequencies for the body segment COM displacements), 2) a whole signal ABP technique which saw each body segment COM displacement signal filtered with a cut-off frequency specific to that segment, and 3) the segment filtering technique (ASFP) where the segment COM signals were broken into sections based on the variation in the Teager-Kaise Energy Operator (TKEO) of the estimated vGRF from the “typical” filtering method above [1,4]. In brief, this previously developed segment filtering technique applied the ABP to each section of the given signal to produce a whole signal displacement estimate corresponding to each signal section. These estimates were then joined together such that each section of the final signal contained the acceleration estimate derived from applying the ABP to that signal section.

## Results and Discussion

The ASFP was better able to match the impact peak of the simulated vertical ground reaction force than both a typical approach and the ABP as demonstrated by a reduced absolute peak error (Table 1). This was accomplished by allowing for a filter with a higher cut-off frequency during the impact portion of stance. Additionally, the ASFP better attenuated oscillations in lower frequency portions of the signal (Figure 1).

**Figure 1:** Vertical ground reaction force and estimates from noiseless kinematic signals and three filtering techniques.

## Significance

When accurate magnitudes of kinetic and kinematic derivatives are of interest in impact-like biomechanical tasks, removing the appropriate amount of noise in measured signals is of great importance. Commonly, multiple signals are processed with a common Butterworth filter cut-off frequency, potentially inappropriately handling the variation in signal to noise ratio between body segments and signal sections therefore poorly estimating the magnitudes of interest. By implementing processing techniques which are sensitive to changing frequency content, such as the ASFP, more accurate estimation of common measures such as vGRF are attainable.

# Visualizing Variation in Vertical Ground Reaction Forces During Running

Bryan P. Conrad<sup>1</sup>, Alison L. Sheets-Singer<sup>1</sup>

<sup>1</sup>Nike Sport Research Lab, Nike, Inc.

Email: [bryan.conrad@nike.com](mailto:bryan.conrad@nike.com)

## Introduction

Ground reaction forces (GRF) provide valuable information about running biomechanics. Variations in speed, foot contact pattern, incline, footwear, etc.[1] can produce a number of distinct patterns. With the many potential variations in the force signal, researcher often aim to find the features that are best able to discriminate different running techniques. Many of the parameters commonly reported from ground reaction forces can be correlated, thus a way to express these differences and their correlations by reducing the dimensionality of the data can be helpful.[2] Using principal component analysis, we aim to quantify the variations in force time series data across a large population and create visualizations that can help researchers understand how these patterns manifest in healthy runners.

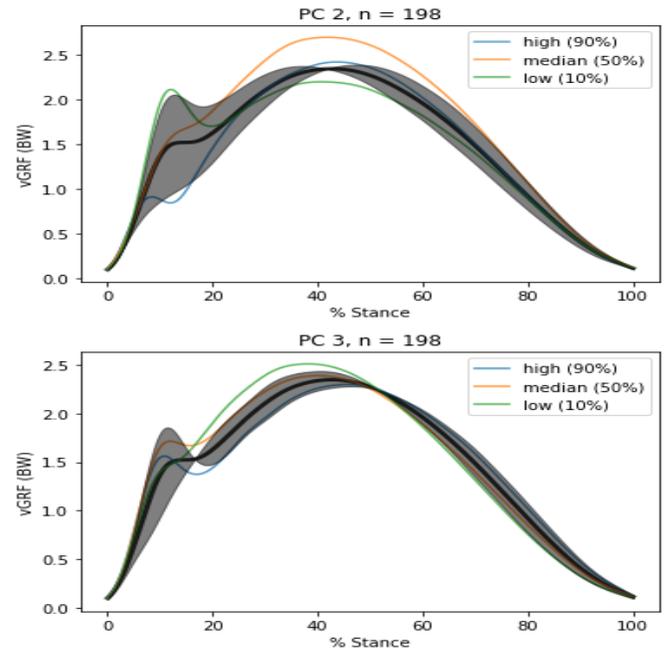

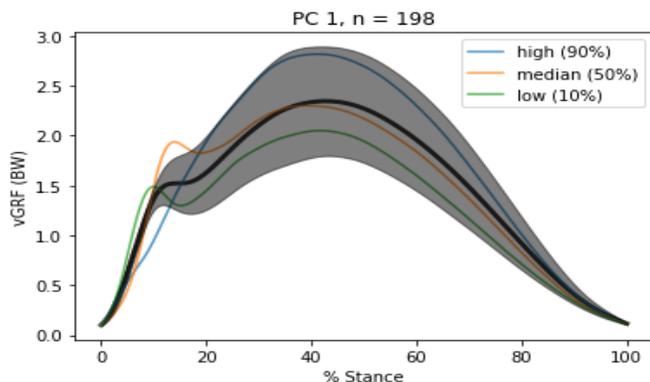

## Methods

Ground reaction forces were measured for 198 participants (86 F: mass =  $65.2 \pm 10.5$  kg, age =  $33.5 \pm 8.7$  yrs; 111 M: mass =  $78.1 \pm 10.8$  kg, age =  $34.0 \pm 6.6$  yrs) while running on a Bertec treadmill in neutral running shoes. Data used in this analysis were collected as part of multiple studies implementing different protocols regarding running speed, experimental shoe condition, and treadmill incline. For most of the subjects, multiple conditions were evaluated and included in the analysis. The final data set included a total of 877 trials each consisting of an average of 377 steps. Before data collection, athletes provided informed consent to participate in the research study.

Ground reaction forces were recorded at 1200Hz or higher, and filtered using a low pass Butterworth filter with a 50 Hz cut off. Vertical ground reaction force (vGRF) was normalized to body weight (BW), and stance time was interpolated to 0-100% using 1000 points. Principal component analysis (PCA) was run on the normalized vGRF. Considering the principal components (PCs), the modes of variation can be visualized across the population by transforming PC scores back into GRF space.

## Results and Discussion

The first 3 principal components explain over 90% of the variance between runners. PC 1 predominantly describes the magnitude of the peak GRF (64% variation explained). PC 2 primarily captures differences in the loading rate of the GRF curve during impact (19% variation explained).

**Figure 1:** Principal Components 1-3. The black line is the mean ground reaction force (normalized to BW) and the gray band is +/- 2 standard deviations of each Principal Component. Thin lines are representative trials for high and low PC scores.

PC 3 describes the height of the heel impact transient (9% variation explained). Standard deviations for the PC 2-3 are largest during the first 30% of stance. Alternately, after weight acceptance and through push off, standard deviations are smaller. This may indicate that while there are numerous ways to contact the ground during impact (differences in foot strike type being the most obvious), the requirement during mid-stance and push off is more universal: support body weight and propel the body into the air to take the next step. Other factors that affect impact forces include footwear, slope of running surface, and speed, which all also have interactions with foot strike type. Using similar approach, Kiernan showed significant correlations between PC scores and number of running injuries.[3]

## Significance

GRF patterns from a wide range of runners can be predominantly described by a small number of features. Researchers can gain a more intuitive understanding for how specific kinetic features relate to running by visualizing PC differences in the time domain.

# Maximum voluntary ankle joint moments are unaffected by extension of the metatarsophalangeal joints

Justin C. Wager<sup>1</sup>, John H. Challis<sup>2</sup>

<sup>1</sup>Department of Physical Therapy and Human Movement Science, Sacred Heart University

<sup>2</sup>Biomechanics Laboratory, The Pennsylvania State University

Email: [wagerj4@sacredheart.edu](mailto:wagerj4@sacredheart.edu)

## Introduction

During the push-off phase of walking and running, the ankle plantarflexor muscles provide a large portion of the positive lower-limb power. This power is influenced by the force-generating capacities of the ankle plantarflexors, which are affected by the ankle and knee joint positions and, potentially, the metatarsophalangeal (MTP) joints. The MTP joints may influence the force-generating capacities of the ankle plantarflexor muscles through two possible mechanisms: 1) the multiarticular flexor hallucis longus (FHL) and flexor digitorum longus (FDL), which contribute to ankle plantarflexion and cross the MTP joints, and 2) connections (both anatomical and mechanical) between the plantar aponeurosis and Achilles tendon<sup>1-3</sup>, which is a pathway for MTP joint extension to influence the Achilles tendon and triceps surae muscle fibers. As the MTP joints extend during the push-off phase of walking and running, interactions between MTP joint extension and ankle plantarflexion strength could influence the understanding of mechanical power generation during push-off. It was hypothesized that maximum voluntary ankle plantarflexion moments would increase with the MTP joints positioned in extension.

## Methods

Eight healthy subjects exerted maximum voluntary isometric ankle plantarflexion contractions on a dynamometer (Biodex Medical Systems, Shirley, NY) in 16 different combinations of knee, ankle, and MTP joint position. The MTP joints were held statically in either a neutral or fully extended position while the knee joint (2 positions: 90 degrees flexion or fully extended) and ankle joint (4 positions: -10, 0, 10, and 20 degrees of plantarflexion) positions were systematically varied. A 3-way repeated measures ANOVA was used to test the effect of the MTP, ankle, and knee joint angles on the maximum voluntary ankle plantarflexion moment. Significance level was set at 0.05.

## Results and Discussion

No statistically significant effect of MTP joint extension on the maximum ankle plantarflexion moment was detected (Figure 1). The mean difference between the MTP neutral and MTP joint extended positions (across all knee-ankle configurations) was  $2.6 \pm 12.8$  N·m ( $p = 0.41$ ). Expectedly, statistically significant effects of ankle joint angle and knee joint angle on the maximum ankle plantarflexion moment were found ( $p < 0.001$ ).

These results do not support our hypothesis that ankle plantarflexion moments would increase when the MTP joints were extended. Further, the results suggest that: 1) the FHL and FDL contribute little to the maximum ankle joint moment, 2) the force-generating capacities of the FHL and FDL are unchanged by MTP joint extension, and/or 3) MTP joint extension has a negligible influence on the force-generating

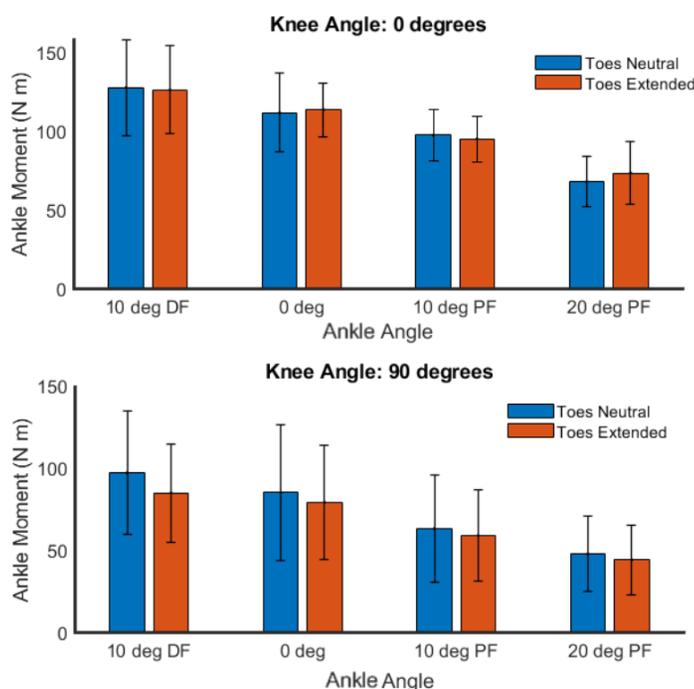

capacities of the gastrocnemius and soleus muscles. While mechanical connections between the toes and the ankle plantarflexors have been shown<sup>3</sup> and the fibers of the plantar aponeurosis seem to continue on to the Achilles tendon in young individuals<sup>1</sup>, there does not seem to be an influence of toe position on the strength of the ankle plantarflexor muscles.

## Significance

This finding increases understanding of locomotion mechanics by suggesting that if extension of the toes during late stance affects the triceps surae, it is not through direct alterations to the muscle's moment-generating capacity. This understanding may be important clinically, for toe or partial foot amputation, and in sport, for footwear that alters MTP joint mechanics (e.g., by increasing forefoot bending stiffness).

### Introduction

The goal of post-stroke locomotor therapy is to help individuals return to activities of daily living. Straight-line walking has been the primary focus of gait and rehabilitation studies. However, turning steps represent 35-45% of all steps taken during activities of daily living [1]. In addition, nearly four times as many individuals post-stroke report falling while turning compared to healthy adults [2]. Falling while turning can be extremely dangerous, with 70% of those falls leading to injury [3]. Currently, there are no specific exercise protocols for improving turning performance [4]. Thus, there is a need to provide clinicians with evidence-based rehabilitation to improve turning performance for individuals post-stroke. The purpose of this study was to identify relationships between turning performance and muscle coordination, with a focus on two types of turns involved in activities of daily living: 90-degree and 180-degree turns. We hypothesize turning performance will decline for subjects with impaired muscle coordination.

### Methods

EMG and full body 3D kinematic data were collected from 20 chronic hemiparetic stroke subjects (20 left hemiparesis) and 20 healthy age-matched controls. Subjects performed 3 tasks including straight over-ground walking, 90-degree turns, and 180-degree turns. For the turning trials, stroke subjects were instructed to turn as quickly as possible towards their paretic side.

Turning performance was defined using two measures: the time to complete the turn and turning smoothness. Time to

complete the turn was defined as the time it takes to return to a constant forward velocity. Turning smoothness was assessed using a Velocity Peaks Metric, which was defined as the number of body center of mass (COM) forward velocity peaks over the course of a turn normalized by the number of steps taken. Smoother movement is represented by fewer periods of acceleration and deceleration, leading to fewer peaks in COM velocity. For each subject, muscle coordination was assessed using the number of muscle modules during the straight overground walking task determined by non-negative matrix factorization [5]. We determined differences in turning performance between individuals post-stroke with different number of muscle modules and the age-matched controls.

One-way ANOVAs were used to test for significant differences in the turning performance measures. Tukey's post hoc tests were used to test for differences between each group (controls and individuals post-stroke with 2 modules, 3 modules, 4 modules, and 5 modules).

### Results and Discussion

Differences between groups were only seen in the 180-degree turning performance measures (Fig. 1). Subjects with 2 modules took a significantly longer time to complete the 180-degree turn (Figure 1b) and had a significantly larger velocity peak metric (i.e., were less smooth) during 180-degree turns (Figure 1d). This suggests merged muscle activity is predictive of poor 180-degree turning performance. This is consistent with studies showing the merging of modules leads to impaired walking performance [6] and planar reaching studies showing a lack of smoothness is characteristic of upper limb motor impairment [7]. These results suggest that obtaining independent modules should be an important aim in turning rehabilitation.

### Significance

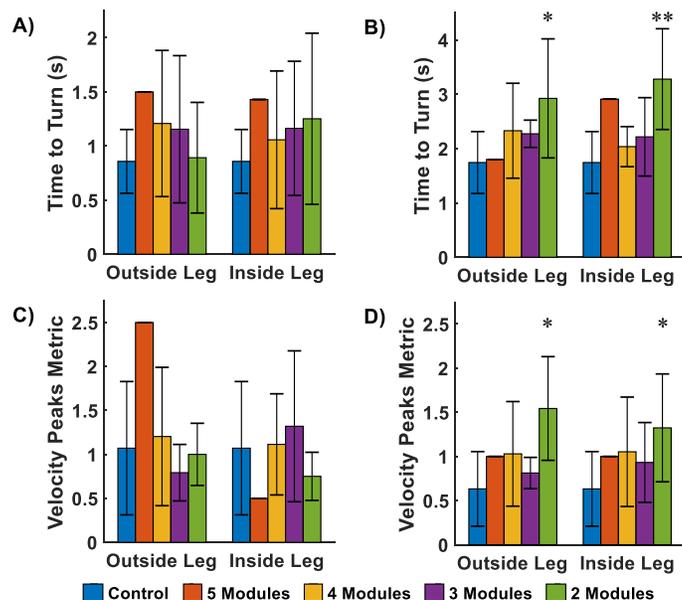

Turning therapy is needed to help individuals post-stroke navigate the complex environments encountered during activities of daily living. These results highlight the relationships between turning performance and impaired muscle coordination and that the time it takes to complete a 180-degree turn is a promising clinical assessment measure of muscle coordination and could be used to help identify impairment levels post-stroke.

## Introduction

Stroke causes spastic foot deformity, equinus foot, which has a foot with more dorsiflexion and inversion at resting condition [1]. It significantly impairs gait and increases trip-related fall risk in chronic stroke. Three dimensional(3D) laser scanning technology is accurate and more economical to identify kinematic differences in clinics compared to magnetic resonance imaging or even x-ray[2].

We investigated novel hemiparetic foot parameters that were acquired from 3D laser scanned foot images with non-paretic feet or age-matched normal healthy feet. Several kinematic foot biomarkers were proposed. We hypothesized that there are significant difference in proposed foot parameters between paretic and non-paretic sides.

## Methods

Total 30 chronic stroke patients (F/M: 11/19; Age: 65.6±8.7years; Onset: 10.2±8.8years) and 11 age-matched healthy controls(F/M: 7/4; Age: 62.9±5.7years) participated in this study.

Using commercial 3D scanner (Artec Eva, Artec3D, Luxemburg), 3D foot images were acquired from 41 subjects and converted to stl files to measure dimension. Figure 1 shows the definitions of lengths( $L_{100F}$ ,  $L_{10F}$ ,  $L_{66F}$ ), heights( $H_{MM}$ ,  $H_{LM}$ ) and angles( $\theta_{HC}$ ,  $\theta_{MMC}$ ,  $\theta_{LMC}$ ,  $\theta_{MS}$ ,  $\theta_{LS}$ ) in given foot images.  $\theta_{HC}$  denotes the angle between horizontal line in coronal plane and the line connecting medial and lateral malleoli. After scanning, subjects repeated walking on 10 meter even and uneven surfaces for three times at their self-selected comfortable speed. The gait kinematics were recorded using VICON motion capturing system (Vicon Motion Systems Ltd, United Kingdom). The paired t-test was used to compare between paretic and non-paretic parameters and the t-test with independent samples was used for between group statistic.

**Figure 1:** Definitions of foot kinematic parameters: (Lengths:  $L_{100F}$ ,  $L_{10F}$ ,  $L_{66F}$ ; Heights( $H_{MM}$ ,  $H_{LM}$ ) and Angles( $\theta_{MH}$ ,  $\theta_{LH}$ ,  $\theta_H$ ,  $\theta_{ML}$ ,  $\theta_{LL}$ )

## Results and Discussion

The horizontal tilt angle in coronal plane( $\theta_{HC}$ ) in paretic foot( $17.3^\circ \pm 5.7$ ) was significantly greater than both non-paretic foot( $14.6^\circ \pm 5.7$ ,  $p=0.004$ ) and dominant foot in healthy controls ( $13.9^\circ \pm 1.3$ ,  $p=0.024$ ).  $\theta_{LMC}$  was significantly bigger in paretic side ( $31.0^\circ \pm 4.4$  vs  $28.3^\circ \pm 2.7$ ,  $p=0.007$ ). Foot kinematic parameters showed significant changes in sagittal and coronal planes on paretic foot ( $H_{MM}$ : $p=0.027$ ;  $\theta_{MMC}$ :  $p=0.001$ ;  $q_{MS}$ :  $p=0.001$ ). Table 1 summarizes the kinematic differences in foot parameters between chronic stroke and healthy controls or between paretic and non-paretic sides.

We showed that 3D surface scanning technology is useful to identify the foot kinematic differences using proposed foot kinematic parameters between chronic stroke patients and healthy controls. The proposed foot parameters are possible to be used as foot kinematic biomarkers that may be applied to evaluate the capability to conduct activities of daily livings. Thus further investigation is necessary on the relationship with the proposed foot parameters and gait impairments in chronic stroke.

	Chronic Strokes			Healthy Controls	
	Paretic	Nonparetic	vs NP	Dominant	vs HC
$H_{MM}$	<b>90.4 ± 10.5</b>	<b>89.3 ± 6.9</b>	<b>0.027</b>	82.6 ± 6.7	0.627
$H_{LM}$	68.6 ± 7.4	69.9 ± 5.5	0.303	66.1 ± 5.8	0.472
$\theta_{HC}$	<b>17.3 ± 5.7</b>	<b>14.6 ± 3.1</b>	<b>0.004</b>	<b>13.9 ± 1.3</b>	<b>0.024</b>
$\theta_{MMC}$	<b>18.3 ± 5.3</b>	<b>20.6 ± 3.8</b>	<b>0.001</b>	22.8 ± 2.2	0.057
$\theta_{LMC}$	31.0 ± 4.4	28.3 ± 2.7	0.094	<b>28.6 ± 2.4</b>	<b>0.007</b>
$\theta_{MS}$	<b>63.3 ± 4.8</b>	<b>64.2 ± 4.1</b>	<b>0.001</b>	69.0 ± 3.9	0.451
$\theta_{LS}$	73.1 ± 5.5	72.4 ± 3.9	0.092	76.2 ± 3.7	0.556

**Table 1:** Comparisons in foot parameters with paretic foot (vs NP indicates p-values in non-paretic foot parameters; vs HC indicates p-values in healthy controls foot parameters)

## Significance

This study showed potentially useful in clinical fields including physical medicine, orthopaedics etc., to identify pathological conditions that bring kinematic changes in body parts. Especially in the rehabilitation hospital, proposed parameters are used to apply more effective footwears for patients with stroke including ankle foot orthosis.

## Introduction

Traumatic brain injuries (TBIs) can occur during many types of activities and in different populations. As part of recovery, gait intervention may be necessary for patients who have experienced TBI. However, literature on consistently successful techniques is scarce, possibly due to the heterogeneity of the TBI-affected population [1]. More in-depth analysis of gait characteristics could be essential to finding successful intervention techniques. Continued improvements in analysis of gait may better inform and compare intervention techniques for patients who have experienced TBI. Non-linear analysis shows more qualitative aspects of data sets that are missed in typical gait characterization. This abstract uses recurrence quantification analysis (RQA), a non-linear method, to look at center of mass (COM) movement during preferred gait and an interventional gait in TBI patients when compared with a control group.

## Methods

Motion capture data was collected at 100 Hz, using a 12-camera Vicon T160 system and standard marker set, from 18 subjects (8 with previous TBI, 10 control). Subjects were directed to walk at their preferred pace and stride length for one of the analyzed trials (Preferred condition). For the Narrow condition, subjects were directed to walk by placing their next foot in a straight line in front of the other, but not required to touch the heel of the front foot to the toe of the standing foot. The COM was calculated by the Vicon Nexus software from collected marker data and anthropometrics (Fig. 1a). RQA measures were calculated for the COM virtual marker trajectories for 6 steps in the medial-lateral and superior-inferior directions, using Norbert Marwan's MATLAB CRP Toolbox [2]. Movement in the anterior-posterior direction was not analyzed as it only represents the forward walking of the patients.

RQA measures are quantitative values for data visualization from recurrence plots (Fig. 1b). Recurrence plots show points, known as *recurrent points*, where the 2-D data reenters a section of the phase space. Determinism (%DET) is the percentage of these recurrent points that form diagonal lines in the plot and maximum line length (LMax) is the inverse of the positive maximal Lyapunov exponent. Paired *t*-tests were performed on the data groups and condition and the critical *p*-value was corrected for multiple comparisons.

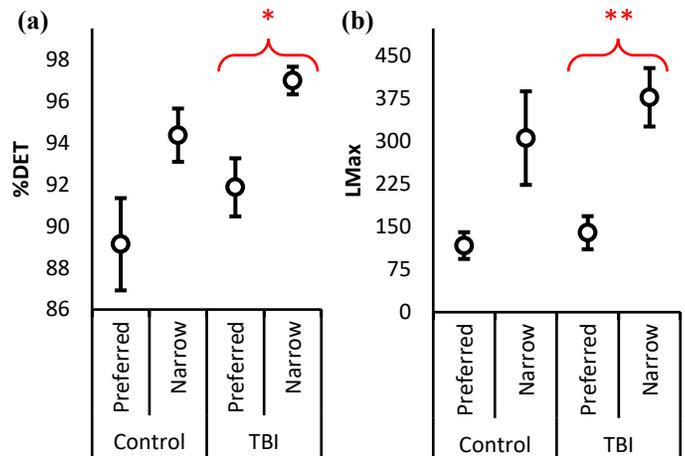

**Figure 1:** (a) Motion capture markers with COM (white marker) (b) recurrence plot

## Results and Discussion

%DET between conditions was not significantly different for the Control group, but a statistically significant difference ( $p=0.0032$ ) was found within the TBI group (Fig 2a). The same is true for LMax with a significant difference ( $p=0.0011$ ) for the TBI group (Fig2b).

%DET measures the predictability of a trajectory and is highest for periodic functions. The predictability of COM movement significantly increased for the TBI group during Narrow walking, showing an improvement in consistency and periodicity across the individual steps. This result may be interpreted as the TBI group gaining better control during narrow walking compared to preferred stride. LMax is a measure of mathematical stability of the data, and larger values show less sensitivity to perturbation [3]. In this case, TBI subjects may have benefited from walking narrowly by decreasing unnecessary movement.

**Figure 2:** (a) Average determinism values with standard error bars, separated by group and then condition. \*Red bracketed pair shows significant difference in mean. (b) Average maximum line length values with standard error bars, separated by group and then condition. \*\*Red bracketed pair shows significant difference in mean.

## Significance

Continued research on gait intervention techniques and improved analysis of their success is important to better understand and facilitate the gait recovery process in patients with a history of TBI. Further research could continue to inform clinical practices and help improve quality of life for individuals who have experienced TBI.

## Introduction

The corticospinal tract (CST) is the major descending motor pathway involved in mediating muscle coordination of skilled movements, but it is possible that CST may not be necessary to control steady-state walking. Previous animal studies support involvement of corticoreticular pathway (CRP) during steady state walking, and CST as well as CRP during skilled movements<sup>1</sup>. It is not clear how damage to the CST post-stroke affects muscle coordination and walking ability. The CRP likely plays an important role in locomotor recovery following stroke when there is CST damage<sup>2</sup>. However, CRP produces mass flexion and extension muscle activation patterns (fewer muscle modules) and fewer modules post-stroke is correlated to poor walking performance. **Therefore, to understand the altered neural control of modules on walking ability, we investigated the relationship of module composition and walking ability of stroke survivors with CST and CRP recovery.**

## Methods

We recruited 33 stroke survivors and 17 healthy controls. We collected lower extremity Fugl-Meyer Assessment (FMA), Functional Gait Assessment (FGA), six-minute walk test (SMWT), over-ground self-selected (SS) walking speeds from stroke survivors. Paretic leg EMG data were collected at self-selected walking speeds to compute number of muscle modules using non-negative matrix factorization (Fig 1A). Imaging data for all subjects included T1 and T2-weighted images, and diffusion kurtosis imaging (DKI). Tractography was estimated using FSL's FMRIB's Diffusion Toolbox to evaluate the CST and CRP recovery based on number of streamlines (Fig 1B). Spearman's correlation was used to identify the relationship between motor pathways recovery and functional walking ability. One-way ANOVA was used to identify differences in CST and CRP recovery between stroke survivors with 2, 3, and 4 modules (typically healthy individuals have 4 modules).

between cortex and midbrain cerebral peduncle) and CRP (streamlines between cortex and midbrain reticular formation).

## Results and Discussion

We found a positive correlation between CST from the lesioned hemisphere and FGA ( $r=0.39$   $p<0.05$ ); and FMA ( $r=0.36$   $p<0.05$ ). We found a negative correlation between CRP from the non-lesioned hemisphere and FMA ( $r=-0.43$   $p<0.05$ ); and SMWT ( $r=-0.37$   $p<0.05$ ). This suggests that poorer walking ability is related to increased reliance on the non-lesioned CRP following damage to CST. We did not see any significant relation between module number and CST or CRP. However, there was a trend suggesting more CST streamlines on the non-lesioned hemisphere maybe associated with fewer modules ( $r=-0.29$   $p=0.09$ ). There was also an asymmetry in number of streamlines between the hemispheres in stroke population compared to healthy individuals computed as ( $Assym_{Stroke} = Lesioned/Non-lesioned$ ;  $Assym_{Healthy} = Right/Left$ ), ( $CST_{Healthy}: 1.47$ ,  $CST_{Stroke}: 0.44$ ,  $p<0.001$ ;  $CRP_{Healthy}: 1.28$ ,  $CRP_{Stroke}: 0.69$ ,  $p<0.01$ ). In summary, non-lesioned CST and CRP may compensate for the lesioned CST. Furthermore, greater reliance on the motor pathways from the non-lesioned hemisphere is associated with greater impairment of walking ability and poor muscle coordination (fewer modules).

## Significance

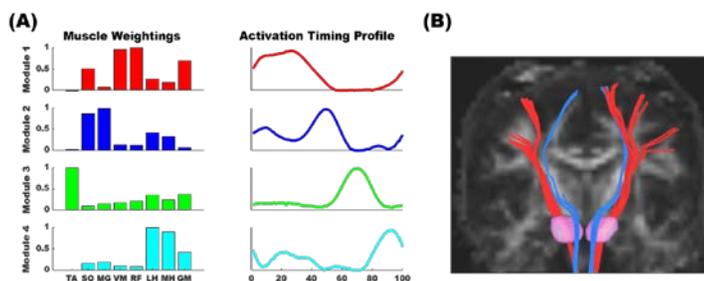

The current work seeks to extend the understanding of the associations between recovery of motor pathways and steady-state muscle coordination to more complex tasks fundamental to household and community walking, such as speeding up, slowing down, starting, stopping and turning. Results from this work will be used to identify patient-specific deficits in muscle coordination and their impact on limiting household and community walking. We expect clinicians will use this information to understand mobility task requirements and develop individualized targeted therapies.

# Verbal Instructions and Feedback Enhance Motor Learning During Post-Stroke Gait Retraining

Nicole K. Rendos, Laura Zajac-Cox, Rahul Thomas, Sumire Sato, Steven Eicholtz, Trisha M. Kesar  
Emory University School of Medicine, Department of Rehabilitation Medicine, Atlanta, GA  
Email: [nrendos@emory.edu](mailto:nrendos@emory.edu)

## Introduction

Restoration of walking function is an essential component of neurorehabilitation in individuals who have survived a stroke. Post-stroke gait deficits include reduced paretic propulsion during terminal stance, foot drop during swing, and inter-limb asymmetry with a reduction in gait speed. FastFES, a post-stroke training intervention that combines functional electrical stimulation (FES) delivered to the paretic ankle dorsiflexor (DF) and plantarflexor (PF) muscles during fast treadmill walking, has been shown to induce long-term improvements in gait speed and reduce the energy cost of walking,<sup>1</sup> yet the motor learning processes underlying FastFES are currently poorly understood.

During neurorehabilitation, verbal instructions and feedback regarding motor performance are commonly used to promote motor learning.<sup>2-4</sup> Feedback provides information based on previous movement attempts with the intent to decrease movement errors and facilitate achievement of accurate movement goals.<sup>2</sup> Instructions include statements about how to perform a motor task and/or its desired outcome.<sup>2</sup> The purpose of the study was to determine whether the addition of verbal feedback and individual-specific instructions, which are commonly incorporated during clinical gait training, would augment motor learning of gait patterns induced by FastFES.

## Methods

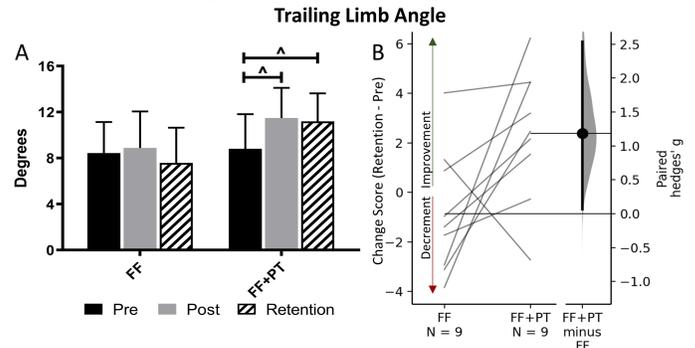

Nine individuals with post-stroke hemiparesis (4 M, 59.0 ± 7.4 y, 35.9 ± 21.1 months post-stroke) completed a crossover study comprising exposure to 2 types of gait training sessions with > 3 weeks between sessions. The first training session involved five, 6-min bouts of FastFES (FF). The second training session was conducted ≥ 3 weeks after FF. Procedures were identical to FF but included the addition of individualized verbal instructions and feedback regarding gait performance from an experienced physical therapist (FF+PT). Non-scripted, individual-specific feedback focused on the variables targeted by FF was provided in a faded schedule throughout the training session.

Gait biomechanics data were measured before (Pre) and immediately after each training session (Post) to evaluate within-session changes, and during a Retention test conducted 24 hours after the training session to evaluate motor learning. A 7-camera Vicon system and a Bertec instrumented treadmill were used for gait analysis. Dependent variables included push-off integral (POI), trailing limb angle (TLA), and ankle angle at initial contact (AAIC) of the paretic limb. Within-Session (Post-Pre) and Retention (Retention-Pre) change scores were calculated to assess online performance and motor learning. Repeated measures ANOVAs examined the effects of training type and time on each variable. Paired samples t-tests were conducted to examine the effects of training type on change scores.

## Results and Discussion

For POI, we observed a significant main effect of training type ( $F_{(1,8)} = 6.93, p = .030, \eta_p^2 = .464$ ), and a significant training type x time interaction ( $F_{(2,16)} = 4.66, p = .025, \eta_p^2 = .368$ ). Compared to Pre, TLA was significantly greater at Post ( $M_{diff} = 2.69, SE = .0741, p = .007, g = .30$ ) and Retention ( $M_{diff} = 2.39, SE = .90, p =$

$.029, g = .28$ ) for FF+PT. TLA retention change scores were greater for FF+PT compared to FF ( $t(8) = 2.41, p = .043, g = 1.19$ ). At Post, AAIC were more plantarflexed than Pre for both FF and FF+PT ( $M_{diff} = -1.60, SE = 0.62, p = .033$ ).

**Figure 1.** (A) During FF+PT, we found increase in TLA at both Post and Retention compared to Pre, indicating online improvements and motor learning (B) TLA retention change scores were significantly greater for FF+PT versus FF.

Addition of individualized verbal instructions and feedback by a physical therapist (FF+PT) resulted in greater online improvements and motor learning (Retention) of improved gait biomechanics in response to a single training session. Though 12 weeks of FastFES training have been shown to improve walking speed, endurance, energy efficiency, and gait biomechanics post-stroke,<sup>1,5,6</sup> a single session of FF did not induce significant within-session improvements or across-session retention. However, a single session of FF+PT induced significant within- and across-session improvements in TLA and POI, suggesting that addition of individualized verbal instructions and feedback may augment motor learning processes during gait training.

Interestingly, AAIC displayed a within-session decrement for both types of training, which may be related to DF muscle fatigue, further accentuated by non-physiological activation during FES.<sup>7</sup> AAIC is primarily controlled through eccentric contraction of the ankle DF.

## Significance

With insurance payers limiting the dosage of gait training sessions, developing clinical strategies to maximize motor learning within each treatment will have significant clinical impact.

## Introduction

Nearly 800,000 people experience a stroke annually in the US alone [1], and frequently survivors are left with the sudden onset of difficulties completing daily motor tasks [2]. Of particular concern are the dynamic changes that occur to a stroke survivor's gait pattern. Walking is the primary locomotion strategy used by individuals to navigate their environments, and when this ability is compromised, so is the overall quality of life. Gait impairments reflect motor control changes, where unimpaired gait motions are produced by more complex control schemes than impaired ones [3-6]. Unlike common measures of performance following treatments, such as walking speed, step-length symmetry, paretic propulsion, etc., the Dynamic Motor Control (DMC) Index provides insight about the effect of the treatment at the neural level on motor control complexity, and it has successfully been used for analyzing gait in individuals with cerebral palsy [3, 8].

In this study, we sought to answer two questions: 1. "How does FastFES treatment (combined Fast treadmill walking and Functional Electrical Stimulation) impact post-stroke motor control, as measured by the DMC Index?" and 2. "What are the distinguishing pre-treatment gait features between those that responded to treatment and those that did not?"

## Methods

Using OpenSim 3.3, we created forward dynamic simulations tracking gait data of 8 individuals post-stroke [7] with patient-specific musculoskeletal models having 23 degrees-of-freedom and 92 muscles. Computed Muscle Control determined muscle activations of paretic lower-limb muscles, which were then used as inputs to non-negative matrix factorization where only a single module (group of co-activated muscles) was considered [6]. The DMC index is based on the variance accounted for (VAF) by this module in reproducing the original activations signal. A DMC index value of 100 is equal to that of an average unimpaired individual, and smaller DMC index values represent decreased motor control complexity. Following FastFES treatment, individuals were grouped as a *responder* if their DMC index values increased after treatment, and a *non-responder* otherwise.

Distinguishing pre-treatment gait features between the two groups were identified with Statistical Parametric Mapping (SPM), which reduces errors associated with discretized analysis (i.e. selection of instances such as "peak knee flexion") of time-varying data by regarding this data as a single observation [9, 10].

## Results and Discussion

The FastFES treatment increased the DMC index in 5 of the 8 individuals (Fig. 1a, green). Interestingly, the 3 non-responders (Fig. 1a, red) had the highest pre-treatment DMC index values. These results suggest that the treatment *is* effective at increasing motor control, but *only if the individual's motor control is sufficiently impaired*. Individuals with moderate motor control impairment may not benefit from this treatment. Furthermore, we identified larger ( $p < 0.001$ ) pre-treatment knee flexion during 20-40% of gait (Fig. 1b, blue) and smaller ( $p < 0.001$ ) support

moment (sum of the sagittal-plane moments of the hip, knee, and ankle) [11] between 30-40% of stance (Fig. 1c, blue) in the responders.

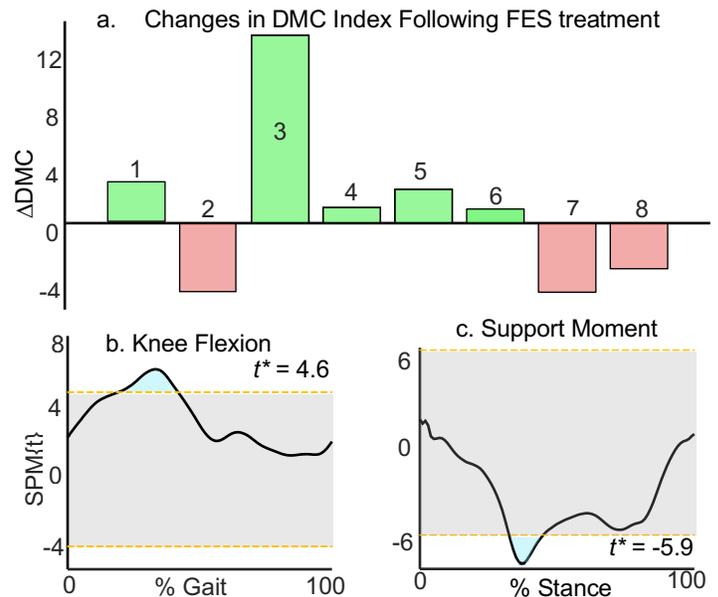

Figure 1: Variation in treatment response and distinguishing pre-treatment gait features. a. responders exhibit  $\Delta DMC > 0$  and non-responders  $\Delta DMC < 0$ ; b. Responders have larger knee flexion during 20-40% of gait; c. Responders have smaller support moments during 30-40% of stance.

## Significance

While our findings are specific to one treatment for post-stroke gait, the approach may be extended to other treatments and disorders. Quantifying treatment response in terms of motor control complexity provides useful information on whether the treatment is targeting the source of the impairment at the neural level. Identifying pre-treatment gait features that distinguish responders and non-responders not only allows for treatment outcome predictions, but clinicians can also learn about what areas to target for specific cases.

## Acknowledgments

We would like to acknowledge NIH NR 010786 for funding the collection of the FastFES data.

## Introduction

Determining readiness for duty after mild traumatic brain injury (mTBI) is essential for the safety of service members (SM) and their units. Though the ability to perform warrior tasks and battle drills, such as moving under fire while maintaining situational awareness, reacting to contact, and establishing security are critical components of combat effectiveness and survival [1], these aspects are not currently assessed after mTBI. Return-to-duty decisions are based on self-reported symptoms and single-domain clinical tests of function. There is a need for objective tests that are sensitive to mTBI-related deficits, and a need to understand how mTBI affects functional performance in theater.

Turning is an ecologically-relevant task involving coordinated movement of the head and body that can be objectively quantified using inertial measurement units. We have previously found people with mTBI turn slower and have more variable head-body coordination patterns than healthy controls during a clinical turning task [2]. However, the implications of these results remain unclear. Therefore, the purpose of this study was to examine turning behaviour during a task representative of the complex demands a SM may face in theatre. We expected individuals with mTBI to turn slower and to perform significantly worse compared to healthy control subjects.

## Methods

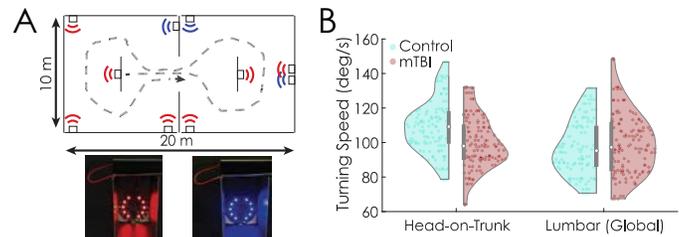

Participants included 44 individuals with mTBI [34F/10M, mean age (SD) 33 (10) yrs] and 40 healthy controls [28F/12M, mean age (SD) 31 (10) yrs] across three sites. All mTBI participants were greater than 3 weeks post-injury and reporting residual symptoms. All participants provided informed written consent in accordance with this IRB approved study.

Participants completed a simulated urban patrol task (SUP) that consisted of navigating a small room containing LED targets representing hostile (red) and friendly (blue) targets. Using a laser-tag weapon, participants were instructed to clear all hostile targets as quickly as possible without tagging friendly targets. Three SUP trials were completed; hostile and friendly targets were changed between trials. Performance was quantified using a hit score (total points / total time).

Inertial measurement units (APDM Opals, Portland, OR) on the lumbar, sternum, and forehead collected angular velocity data at 128 Hz. A  $\pm\pi/4$  rad/s threshold identified head, trunk, lumbar, head-on-trunk, and trunk-on-lumbar yaw turns. For each turn, the peak angular rate for each turn was determined. The median of turning speeds at each segment were calculated within a trial and were compared across groups using linear mixed effects regression with random intercepts by subject. Additionally, outcomes were averaged across trials and linear regression models compared the association between turning metrics and task performance after controlling for group using  $R^2$  values.

## Results and Discussion

Head-on-trunk ( $p = 0.007$ ) and head-on-lumbar ( $p = 0.012$ ) turns were significantly slower in the mTBI group compared to healthy controls. No between-group differences were observed in other metrics of turning. Compared to controls, the mTBI group completed the task slower ( $p = 0.022$ ) and had lower hit scores ( $p = 0.027$ ). Across all turning measures, slower turning speeds were associated with lower hit rates; lumbar turning speed (adj.  $R^2 = 0.37$ ), head-on-lumbar turning speed (adj.  $R^2 = 0.24$ ), and head-on-trunk turning speed (adj.  $R^2 = 0.21$ ) were most associated with hit rate after adjusting for group.

**Figure 1:** A. Schematic of the testing set-up with sample target configuration. B) Selected results of head-on-trunk and lumbar turning speeds for each group. Head-on-trunk turns were slower in the mTBI group, but lumbar turning speeds did not differ between groups.

The group differences in segmental head-on-trunk and head-on-lumbar turning speeds are consistent with previous reports of slower head turns in acute mTBI [3], but we were surprised overall turning speeds at the trunk and lumbar were not different given previous studies [2]. The group-difference in hit rate suggests the ability to freely move one's head are important for this warfighter tasks and may be impaired in those with mTBI. Future work should examine whether the poorer performance and slower completion times in mTBI participants stem from decreased perceptual awareness due to slower independent head motion.

## Significance

Individuals with persisting symptoms after mTBI exhibited performance deficits and slower intersegmental head rotations in a high-fidelity, ecologically relevant task for SMs.

# Is Faster Always Better? A Subgroup Analysis of the Effects of Walking Speed on Post-Stroke Gait Biomechanics

Hannah Christianson, Payton Sims, Justin Liu, Brandon Choi, Carol Ann Elliott, Alex Schilder, Benjamin Koke, Trisha M. Kesar

Email: tkesar@emory.edu

## Introduction

Restoration of walking function is an essential component of stroke rehabilitation. Common post-stroke gait deficits include decreased paretic leg push-off during late stance, foot drop, and inadequate hip, knee and ankle flexion during swing. These deficits lead to compensations such as hip circumduction or pelvic hiking, as well as reduced gait speed, endurance, and energy efficiency, contributing to diminished community participation and quality of life post-stroke<sup>1</sup>.

During stroke rehabilitation, clinicians commonly rely on treadmill-based gait training due to the ability to modulate speed and inclination, promote mass stepping practice, and encourage faster walking on a safe, predictable terrain<sup>2</sup>. Previous research suggests that training at faster speeds is an evidence-supported strategy to improve post-stroke gait deficits and function<sup>3-5</sup>. However, gait speed and gait quality may interact in complex ways, which warrants investigation. Here, we comprehensively examined the effect of speed on biomechanics of the paretic leg, non-paretic leg, and inter-limb asymmetry post-stroke.

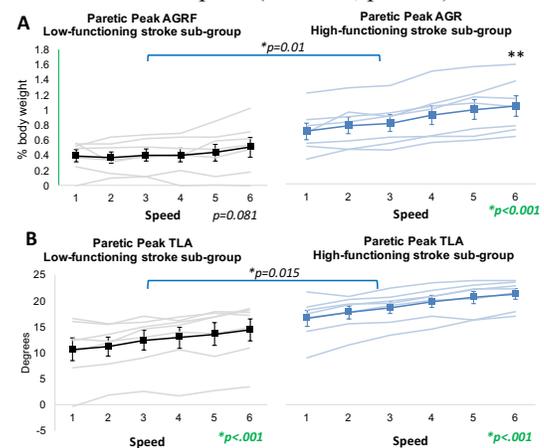

## Methods

Fourteen individuals post-stroke (10 males, 60 ± 11 years, 41 ± 32 months post-stroke) participated in one session of treadmill walking on a dual-belt treadmill embedded with force platforms to enable collection of ground reaction force (GRF) data from each limb. Reflective markers were attached to the trunk, pelvis, and bilateral thigh, shank, and foot segments. Marker data were collected via a 7-camera Vicon system and processed in Visual 3D. Kinematic and kinetic gait biomechanics parameters were measured at 6 different speeds ranging from each individual's self-selected to their fastest walking speed. Dependent variables included ankle push-off (anterior or AGRF), trailing limb angle (TLA), ankle angle at initial contact, peak ankle moment, ankle power, hip power, circumduction, and pelvic hiking. Participants were further sub-grouped into low or high-functioning using gait speed of 0.4 m/s as a cutoff. For each dependent variable, 2-way between-within ANOVAs evaluated the effect of speed (6 speeds ranging from SS to Fast), sub-group (high-functioning, low-functioning), and interaction effects. Planned post-hoc independent t-tests compared each variable between the high- and low-functioning sub-groups at the Fast and SS speeds. Repeated measures ANOVAs were performed to assess the effect of speed separately within each sub-group.

## Results and Discussion

For paretic leg push-off, we found a significant main effect for speed ( $F=12.312$ ,  $p<0.001$ ), sub-group ( $F=8.833$ ,  $p=0.012$ ), and a significant interaction ( $p=0.001$ ). A significant main effect of speed for paretic push off occurred in the high-functioning sub-group ( $F=21.013$ ,  $p<0.001$ ), but not the low-functioning sub-group ( $F=2.198$ ,  $p=.081$ ). For TLA, both sub-groups showed a main effect of speed, with TLA being greater for the high- than low-functioning sub-groups at both Fast ( $p=.012$ ) and SS speeds ( $p=.049$ ). For ankle moment and power, both groups showed a main effect of speed ( $p<0.001$ ). Ankle

moment, ankle power, and hip power were significantly larger for high-functioning versus low-functioning sub-group for both Fast ( $p<0.01$ ) and SS speeds ( $p<0.02$ ). There was no main effect of speed for either sub-group on ankle angle at initial contact ( $F=1.249$ ,  $p=.240$ ), but an interaction was present ( $p=0.042$ ). Circumduction worsened as speed increased for both sub-groups ( $F=5.690$ ,  $p=.001$ ), ( $F=2.595$ ,  $p=.046$ ). The high-functioning sub-group failed to show a significant main effect of speed on pelvic hiking ( $F=.703$ ,  $p=.625$ ), but the low-functioning sub-group showed a main effect of speed ( $F=3.464$ ,  $p=.014$ ).

**Figure 1.** Group (bold lines and symbols) and individual subject data for the 2 stroke sub-groups at 6 different speeds. (A) Peak paretic AGRF did not increase with faster speeds (x-axis) in the low-functioning group ( $p=0.081$ ), but speed did induce AGRF increases in the high-functioning group ( $p<0.001$ ). (B) Both low- and high-functioning individuals increased TLA with faster speed ( $p's<0.001$ ). Both AGRF ( $p=0.01$ ) and TLA ( $p=0.015$ ) showed a main effect of group.

Interestingly, when stroke survivors were stratified into sub-groups using baseline walking speed, unlike the high-functioning group, for lower-functioning post-stroke individuals, faster gait speeds were not accompanied by improved paretic leg pushoff, and worsened asymmetry and compensatory patterns (circumduction and pelvic hiking).

## Significance

We evaluated gait biomechanics across multiple speeds with systematic increments to assess interactions between stroke gait biomechanics and gait speed. Our results demonstrate that baseline walking function influences the effects of gait speed on gait quality (biomechanics). Our findings may have implication for developing individual-specific, data-driven criteria for the selection of training speeds for post-stroke gait rehabilitation.

# Simulation-based Predictions of Gait Patterns with Muscle Strength Asymmetries

Russell T. Johnson and James M. Finley

Division of Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, CA

Email: rtjohnso@usc.edu

## Introduction

Many neuromuscular impairments occur after an individual has a stroke, such as muscle weakness, spasticity, overactivity, and paresis, most of the time primarily affecting one side of the body. These impairments can impact gait performance, as people post-stroke walk slower than controls and display spatiotemporal and kinematic asymmetries [1]. However, since various combinations of these neuromuscular impairments are often present in people post-stroke, it is difficult to determine the relative contributions of these impairments to gait performance.

Musculoskeletal modeling and predictive simulation provide an opportunity to investigate how specific neuromuscular impairments affect gait performance. Our aim was to quantify the spatiotemporal asymmetries and changes in metabolic cost of transport (COT) that emerge from predictive simulation when muscle strength is unilaterally reduced in a musculoskeletal model. This study will allow us to better understand how muscle strength impairments impact gait performance, independent of other neuromuscular changes that occur post-stroke.

## Methods

A 2-D musculoskeletal model with 11 degrees-of-freedom and actuated by 42 muscle-tendon units (modified from [2]) was used within OpenSim. The base model was modified by uniformly reducing the peak isometric muscle force in all muscles on the left side of the model by 10, 20, 30, 40, 50, and 60 percent. Optimal control simulations of walking were generated at 1.0 m/s under these seven different conditions using direct collocation with IPOPT [3]. The optimization allowed stride time and length to vary while generating solutions at the set walking speed. The unilateral reduction in muscle strength was intended to model the asymmetry in force generation measured between limbs in people post-stroke. The objective of the optimizations was to minimize the sum of the cubed muscle activations across all muscles, chosen based on its proxy to muscle fatigue.

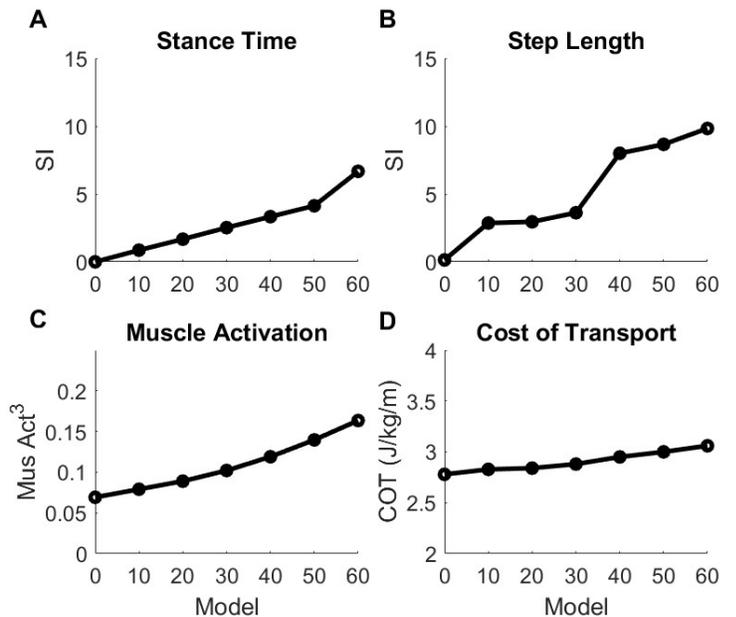

Outcome measures included asymmetry indices (Asym) for stance time and step length, and were calculated as follows:

$$Asym = \frac{X_{NW} - X_W}{(|X_{NW}| + |X_W|)}$$

Where  $X_{NW}$  is the variable for the non-weak limb, and  $X_W$  is the variable for the weak limb. Positive values of Asym indicate greater values on the non-weak than the weak side. The other outcome measures were muscle activation cubed (objective function value) and predicted COT based on the Umberger 2010 probe built into OpenSim. The COT was calculated while holding muscle mass constant throughout the conditions.

## Results and Discussion

In the optimal control result with the base model (with no strength asymmetry), the model walked with symmetrical stance time and step length. With greater strength asymmetry, the model walked with greater spatiotemporal asymmetry (Fig. 1A, B). The optimal solutions had greater overall muscle activation with greater muscle weakness asymmetry (Fig. 1C), and the metabolic COT

**Figure 1:** Asymmetry indices (Asym) for the A) Stance Time Asymmetry, B) Step Length Asymmetry. Positive values indicate greater values on the non-weak side than the weak side. C) The sum of muscle activations cubed. D) Cost of transport (COT) computed using OpenSim Umberger probe. Model 0 is the base model, and Model 60 represents a 60% decrease in muscle strength on the left limb.

gradually increased throughout the conditions. The COT for the model 60 solution was about 10% greater when compared to the solution from the base model.

Our results suggest that the expected level of spatiotemporal asymmetry observed during walking should scale with muscle strength asymmetry. This suggests that independent of other post-stroke impairments, common clinical goals of rehabilitation, which may aim to restore step length and step time asymmetry to patients, may not be energetically optimal if the patient has a lingering strength asymmetry. Furthermore, a unilateral loss in force generating ability may partially explain increases in COT observed in people post-stroke relative to controls [4].

## Significance

The most optimal way for people with muscle strength asymmetries to walk is likely not symmetrical, and the level of optimal spatiotemporal asymmetry depends on the level of muscle strength asymmetry between limbs.

## Introduction

Lower limb loading and weight transfer abilities are associated with walking speed and risk of falling in individuals post-stroke (Hsiao et al., 2017; Pavol et al., 2007). Functional weight transfer requires coordination between multiple joints to regulate impact force, prevent limb collapse, and support body weight during loading impact. The ankle joint plays a major role during ground impact energy absorption (Farley et al., 1998). After stroke, deficits in ankle muscle activation and torque production have been documented (Kitatani et al., 2016). It is unclear how these deficits affect loading reactions. Studying lower limb loading capacity in individuals post-stroke is limited partly due to the tendency to avoid fully loading the paretic limb during voluntary movements. Accordingly, a novel perturbation was used to induce rapid loading of the lower limbs in this study. The primary purpose of this study was to characterize the ankle joint torque/power generation capacity and neuromuscular activity during impact absorption in response to imposed unilateral loading in individuals post-stroke compared to able-bodied age-matched controls.

## Methods

Fifteen individuals with chronic stroke and fifteen age-matched able-bodied controls participated in this study. Participants stood with each foot on top of a perturbation platform. Five unilateral support surface lowering perturbation trials were delivered at an unpredictable time to each leg in a randomized order.

Kinematic data were collected via a 10-camera motion analysis system (Vicon, UK). Following perturbation onset, sagittal plane average ankle joint torque, angular velocity, power, and work were calculated from maximum plantarflexion to maximal dorsiflexion (impact absorption phase).

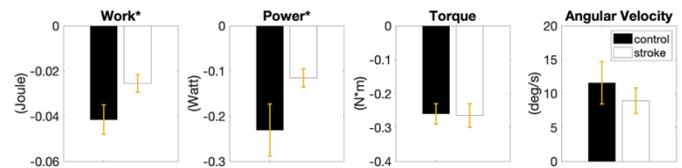

Electromyographic data were collected via surface electrodes (Noraxon, US) placed on the Tibialis Anterior (TA) and Medial Gastrocnemius (MG) muscles. Baseline muscle activity is acquired from 200ms - 300ms before perturbation onset, and muscle activation is defined by 3 standard deviation over baseline. Data were averaged across trials for each subject and data from the paretic limb in stroke were compared with non-dominant limb in controls using 2-tailed t-tests.

## Results and Discussion

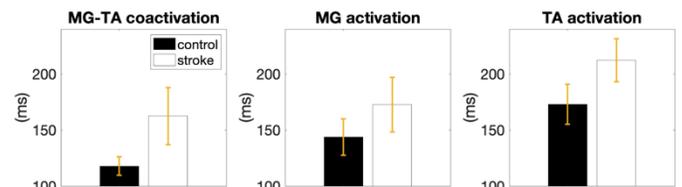

Preliminary results for 11 individuals post-stroke (64.7±8.3 yrs old, 4 females, time since stroke 16.1±13.9 yrs) and 9 controls (66.2±7.0 yrs old, 4 females) were analyzed to date. The duration of impact absorption phase was not different between groups (214.7±75.6 ms in control and 247.5±84.3 ms in stroke). During impact absorption, the stroke group showed reduced ankle work and power production compared to controls (Fig.1), indicating reduced energy absorption by the ankle joint. Ankle

plantarflexion torque and angular velocity were similar between groups.

A trend of longer muscle co-activation duration between TA and MG was observed in stroke compared to controls ( $p = 0.10$ ). The prolonged muscle co-activation was likely due to longer activation duration of the TA ( $p = 0.12$ ), while the activation duration of MG was similar between groups (Fig.2). Prolonged co-activation of the ankle muscles may reduce the power production and limit energy absorption ability in the ankle joint after stroke.

**Figure 1:** Between-group comparisons of kinetic and kinematic measurements of the ankle joint. For joint torque and angular velocity, negative values indicate ankle plantarflexion. \* indicates  $p < 0.05$ .

**Figure 2:** Ankle muscle activation duration during impact absorption.

## Significance

A novel approach was used to characterize ankle joint power generation and neuromuscular activity following rapid unilateral lower limb loading. Preliminary results suggest that when impact loading was induced to the paretic limb, individuals post-stroke showed reduced ability to absorb energy with the ankle joint. In addition, prolonged ankle muscle co-activation may have contributed to limited energy absorption. We anticipate that these trends differentiating those with chronic stroke from healthy controls, will be sustained and achieve statistical significance when additional data are analyzed. Future research will determine whether these abnormalities could be modulated through repeated induced limb loading training.

### Introduction

Stroke is the primary cause of long-term adult disability in the United States [1]. Walking is a major goal of rehabilitation, and a common intervention is increasing paretic (weak side) propulsion [2]. During rehabilitation, assistive devices such as treadmill handrails or a cane are commonly utilized. Research has demonstrated that these devices alter biomechanics such as step symmetry [3] and energy cost [4] when using handrails, and braking assistance when using a cane [5]. How functional ability affects the interaction of assistive device and propulsive impulse is unknown, and subsequently, there are no quantitative guidelines on how to utilize these devices to maximize a patient's paretic propulsion. Therefore, the purpose of this study is to determine the effect of assistive device use, such as cane or handrails, on propulsive impulse in individuals post-stroke with varying functional levels and experience with assistive devices. We hypothesized that individuals dependent on assistive devices will have increased propulsive impulse with the assistive device and those not device dependent will have increased propulsive impulse without the device. We further hypothesize that assistive device anterior impulse generated on a handrail will be greater than on a cane.

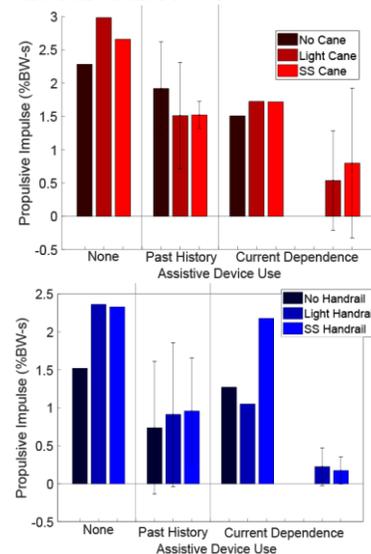

### Methods

Six participants (3M, 3F; age  $63.33 \pm 14.01$  yrs.;  $1.07 \pm 1.00$  yrs. since stroke) from an ongoing study with different levels of function were included in this analysis: no history of assistive device use (N=1), past history of an assistive device use (N=2), and current dependence on an assistive device (N=3). Inclusion criteria included: age 19-80, single-chronic stroke, and ambulatory. Motion capture analysis using a full-body, 65-marker set was done both overground, using in-ground force plates and an instrumented cane, and with an instrumented treadmill and handrails. For the treadmill trials, subjects walked for three walking conditions (3 minutes each): no handrail use, light support handrail use and self-selected handrail device use. For the overground trials, subjects completed three conditions: walking with no cane, walking with a cane using light pressure and walking with a cane comfortably. Real-time feedback of the cane and handrail forces were displayed for the light-support condition on a screen in front of the participant. Two subjects, who were dependent on an assistive device, were only able to complete the handrail and cane conditions. The average paretic propulsive GRF impulse and assistive device anterior force impulse were calculated and were normalized to body weight.

### Results and Discussion

The self-selected walking speed was  $0.55 \pm 0.31$  m/s for the overground conditions and  $0.38 \pm 0.26$  m/s for the treadmill conditions. Individuals with a past history of assistive device use tended to produce the most propulsive impulse without a cane, but no assistive device use or current dependence on an assistive device produced more propulsive impulse with the cane (Figure 1). The propulsive impulse generated on the handrail

( $0.69 \pm 0.63\%$  BW) was significantly more than on the cane ( $0.17 \pm 0.12\%$  BW) ( $p=0.008$ ). For 5 out of 6 subjects, the ratio of cane impulse to propulsive impulse was less than 22%. Conversely, 3 out of 6 subjects (2 device dependent, 1 past history) produced more anterior impulse on the handrails than propulsive impulse from their paretic leg, suggesting these individuals may be utilizing handrails to compensate or replace lower propulsive forces on the paretic limb. These preliminary results suggest that an individual's functional level and experience with the assistive device will change how use of an assistive device will affect propulsive impulse. Further work will include additional subjects and regression modelling based on walking speed and functional level.

**Figure 1:** Positive propulsive impulse for assistive device use category, for the overground conditions (red, top) and treadmill conditions (blue, bottom). None (N=1), Past History (N=2), Current Dependence (N=3). Current Dependence are separated because 1 currently dependent subject was able to complete all three conditions, and the other 2 could not complete the no assistive device condition.

### Significance

This study aims to provide insight on how best to utilize assistive devices to maximize walking functional recovery for individuals after stroke. Preliminary findings suggest that the amount of propulsive impulse that can be generated with and without an assistive device can inform the amount of assistive device use.

## Introduction

Stroke is the leading cause of adult disability in the United States [1]. Robotic rehabilitation with self-initiated and assisted movements is a promising technology for upper limb stroke rehabilitation [1]. We have developed a novel tongue-operated robotic system (TDS-KA) for stroke rehabilitation that integrates the tongue drive system (TDS) [3] and a bimanual upper extremity exoskeleton KINARM (BKIN, Canada) [4]. Our working hypothesis is that the voluntary initiation and control of movement in the paretic arm by the normally functioning tongue may help improve arm motor function. The close proximity of brain representations of the tongue and arm may also contribute to arm functional recovery [5]. In order to design appropriate rehabilitation interventions with the TDS-KA system, we characterized arm reaching kinematics of healthy subjects in 4 modes of TDS-KA operation.

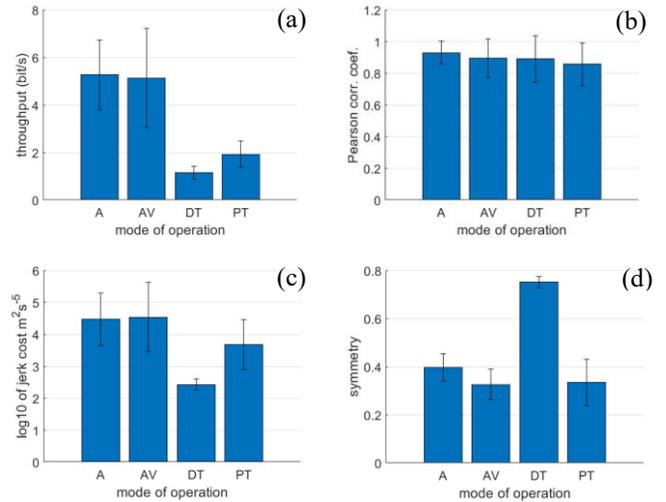

## Methods

All experimental procedures were approved by the Georgia Tech Institutional Review Board. A group of healthy participants (n=10) of both sexes were instructed to perform multiple accurate and fast unidirectional left-right reaching movements between two antero-posterior lines with different width and inter-line distances. Four movement modes were tested: (A) the dominant right arm movement (active control), (AV) active control with viscous resistance, (DT) the relaxed arm moved by the TDS-KA system via the tongue motion (discrete tongue control) and (PT) proportional tongue control. Mode A corresponds to a normal arm movement. In mode AV, the robot generates resistive force as a function of the arm endpoint velocity. In mode DT, a discrete command (left or right) is issued by the tongue and the robot moves the arm endpoint in the corresponding direction with an average velocity of 0.1 m/s and bell shaped velocity profile to the end of movement range. When the command is interrupted, the robot will come to a stop as velocity decreases linearly. In mode PT, the instantaneous tongue position is mapped to the force applied to the endpoint of exoskeleton arm.

We recorded tongue tip kinematics using a disk-shaped magnetic tracer glued to the tongue tip and magnetic sensors mounted on a headset. For each subject, a total of 18 trials were collected for each of 4 modes and each reaching distance-target width pair: 24 cm-3 cm, 24 cm-1.5 cm, 12 cm-3 cm, and 12 cm-1.5 cm. Hand kinematics were characterized by throughput [7], arm endpoint jerk cost, conformity to Fitts' Law [7] and symmetry of the arm endpoint velocity profile.

## Results and Discussion

The throughput and jerk cost in PT mode were greater than in DT mode and closer to those in A and AV modes although still smaller ( $p < 0.05$ , Figure 1 a, c). The Pearson coefficients of correlation between indexes of difficulty and average movement times were between 0.86 and 0.93 for all modes of operation,

**Figure 1:** Hand kinematics during reaching movements generated by four control modes of the TDS-KA system. (a) Throughput, (b) Pearson correlation coefficient between indexes of difficulty and average movement times, (c) jerk cost, and (d) hand velocity profile symmetry.

confirming Fitts' Law (Figure 1b). Velocity profile of PT mode was comparable to A and AV modes with symmetry relatively close to 0.5 (equal times of the velocity increase and decrease), whereas DT profile was highly asymmetric ( $p < 0.05$ , Figure 1d).

## Significance

In this study, we have characterized arm reaching kinematics in 4 modes of TDS-KA operation. We found that the PT mode is more similar to A and AV modes compared to DT. This result indicates that the PT control strategy is a better candidate than the DT for the tongue assisted rehabilitation. This study also provides initial insights into possible kinematic similarities between tongue-operated and voluntary arm movements. Furthermore, the results show that the viscous resistance to arm motion does not affect significantly kinematics of arm reaching movements.

In the future studies, we plan to increase the accuracy of the TDS-KA system and to develop a new operation mode of the two-dimensional proportional control by a combination of hardware and algorithm improvements. In addition, we will develop new rehabilitation interventions based on the TDS-KA system and test them in stroke survivors with severe paresis.

# Abnormal coordinataion of the multiple upper-limb joints during passive movement

Kyung Koh<sup>1</sup>, Dongwon Kim<sup>1</sup>, Giovanni Oppizzi<sup>1</sup>, Li-Qun Zhang<sup>1</sup>

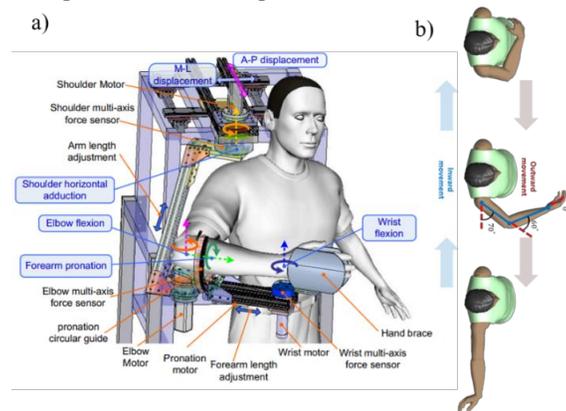

<sup>1</sup>Physical Therapy and Rehabilitation Science, University of Maryland, Baltimore, MD, USA  
Email: l-zhang@som.umaryland.edu

## Introduction

Motor impairment in upper limb (UL) is one of the most common deficits after stroke. Even though understanding of UL coordination deficits in persons with strokes are crucial for better identification of motor recovery as well as rehabilitation, it is still not clear how stroke affects coordination patterns of multi-joint movements in UL<sup>1</sup>. Here, we investigated kinematic and kinetic coordination patterns of UL after stroke during passive arm movement. We hypothesized that abnormal coordination patterns would be more severe during outward movement (i.e. away from the body) as compared to inward movement (i.e. toward the body) due to stroke accompanied by flexor spastic hypertonia of UL.

## Methods

10 stroke survivors (sex (F/M): 2/8; impaired side (L/R): 7/3) and 10 age-matched control subjects (sex (F/M): 2/8) were recruited for this study. All the control subjects were right-handed. Using the rehabilitation robot called IntelliArm, all subjects were asked to sit upright comfortably, and to put the upper arm, forearm and hand on IntelliArm (Fig. 1a)<sup>2</sup>. IntelliArm produces simultaneous passive movements at shoulder, elbow, and wrist joints during inward and outward directions. Each joint was moved until it reaches pre-specified limits for either the joint resistance torque or angular position. Torque and angular position limits were set to be  $\pm 3$  N·m and  $0^\circ$  to  $120^\circ$  for shoulder horizontal adduction,  $\pm 2$  N·m and  $10^\circ$  to  $90^\circ$  for elbow flexion/extension, and  $\pm 1.5$  N·m and  $-45^\circ$  to  $45^\circ$  for wrist flexion/extension, respectively. There was 3 seconds holding time at initial position and all movements were performed for 8 repetitions.

**Figure 1:** A multi-joint intelligent rehabilitation robot, called IntelliArm was used to control the shoulder, elbow and wrist simultaneously (a). IntelliArm produced simultaneous movements at shoulder, elbow, and wrist joints, starting to outward direction followed by inward direction.

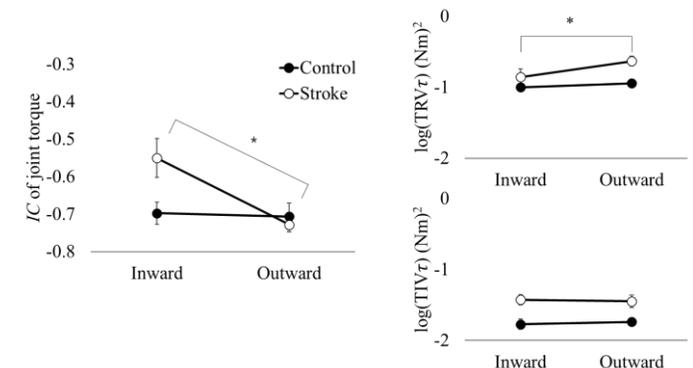

The uncontrolled manifold (UCM) analysis was used to assess multi-joint coordination patterns in a redundant system by quantifying variability of elemental variables (i.e. joint angles or torques) with respect to changes in performance variable (i.e. position or force or the tip of the end-effector). Using the UCM analysis, we examined how the multiple joints interacted with each other to stabilize the actions of the end-effector in terms of kinematics and kinetics. variability of joint angle and torques

were decomposed into task-relevant variability ( $TRV$ ) and task-irrelevant variability ( $TIR$ ), respectively. An index of coordination ( $IC$ ) was defined as  $IC=(TIV-TRV)/(TIV+TRV)$ .

## Results and Discussion

We found no significant  $IC$  of joint angles between the groups. However, we found that  $IC$  of joint torques in Stroke group significantly decreased during outward movement as compared to during inward movement ( $p=0.003$ ) while  $IC$  in Control group remained unchanged between movement directions, which was supported by a repeated measures ANOVA significant interaction  $Direction \times Group$  ( $F_{1,17} = 5.99$ ;  $p=0.026$ ) (Fig. 2). The decreased  $IC$  in Stroke group was mainly due to the increased TRV of joint torques ( $TRV_\tau$ ) ( $p=0.001$ ) which was supported by a repeated measures ANOVA significant interaction  $Direction \times Group$  ( $F_{1,17} = 5.011$ ;  $p=0.038$ ). This result indicates that during passive movement, joint torques were generated in a way that force at the end-effector (i.e. hand) became more variable or less inconsistent during outward movement than inward movement.

In summary, our findings clearly demonstrate that passive UL movements in stroke individuals induces abnormal coordination patterns especially in outward direction. Therefore, the abnormal coordination patterns provide important information for understanding of the motor deficits during passive movements post stroke.

**Figure 2:** Index of coordination ( $IC$ ), logarithm of task-relevant variability ( $TRV_\tau$ ) and task-irrelevant variability ( $TIV_\tau$ ) of joint torque of during inward and outward directions were compared between stroke group (open dot) and control group (closed dot). The asterisk indicates a significant difference (\*:  $<0.05$ ) between directions in stroke group.

# Humeral Energy Transfer and Glenohumeral Rotation Strength in Adolescent Baseball Pitchers

Kyle W. Wasserberger, Kevin A. Giordano, Jessica L. Downs, and Gretchen D. Oliver  
Sports Medicine and Movement Laboratory, School of Kinesiology, Auburn University, Auburn, Alabama, USA  
Email: [goliver@auburn.edu](mailto:goliver@auburn.edu)

## Introduction

During the baseball pitch, the glenohumeral (GH) joint is responsible for transferring large amounts of energy from the trunk to the upper extremity [1]. Due to a lack of bony stability at the proximal end of the humerus, optimization of this energy transfer (ET) is largely dependent on active stabilization provided by the musculature surrounding the GH joint [2]. If weakness of the GH musculature is present, pathological humeral arthrokinematics may develop during arm cocking and arm acceleration; potentially leading to unnecessary increases in ET as pitchers attempt to maintain performance [2].

Active stabilization of the GH joint in baseball pitchers is often assessed in clinical settings using internal (IR) and external (ER) rotation strength tests [3]. Several authors have proposed weakness or imbalance between these muscle groups as a warning sign of future injury [3, 4]. However, the association between clinical GH strength tests and pitching mechanics is still largely unknown. Further investigation into the relationships between clinical strength measures and pitching ET may help elucidate how GH strength impacts the risk of pitching-related injury. Therefore, the purpose of our study was to examine the association between the clinical GH strength and ET to and from humerus during the pitching motion. We hypothesized that increased GH strength would allow pitchers to minimize humeral ET while maintaining a given ball speed.

## Methods

A convenience sample of 88 (1.7±0.2m; 59.5±12.9kg; 13.1±2.1yrs) healthy adolescent baseball pitchers were recruited to participate. The Institutional Review Board of Auburn University approved all testing protocols.

Throwing-arm IR and ER strength was assessed using isometric dynamometry in the supine position with the arm abducted 90 degrees in the frontal plane and was normalized to body weight before analysis. Following strength testing, four electromagnetic sensors were affixed to the thorax (T1), throwing arm upper arm, forearm, and hand. A fifth sensor was attached to a moveable stylus for the digitization of bony landmarks consistent with the International Society of Biomechanics recommendations [5]. Participants pitched three fastballs to a catcher at a regulation distance. Kinematic data were collected at 100 Hz using an electromagnetic tracking system.

Energy transfer between the thorax, proximal humerus, and distal humerus was calculated using a segment power analysis similar to that of Howenstien et al [1]. To calculate the total ET, segment power curves were integrated over specific time intervals relevant to the theoretical proximal-to-distal ET patterns of overhead, open-chain, athletic tasks.

Multi-step linear regression was used to estimate the effects of GH strength on predicted humeral ET after accounting for the effects of ball speed. Separate regression equations were developed to estimate ET from the thorax to the proximal humerus during arm cocking (proximal inflow; pIF) and ET from the distal humerus to the forearm during arm acceleration (distal outflow; dOF). Arm cocking was defined as the time between

stride foot contact and maximal shoulder external rotation. Arm acceleration was defined as the time between maximal shoulder external rotation and ball release. Statistical analyses were performed in RStudio (R version 3.6.1).

## Results and Discussion

Regression analysis showed that pIF was predicted by a linear combination of ball speed and IR strength; accounting for 75% of the variance in pIF. Similarly, dOF was predicted by a linear combination of ball speed and ER strength; accounting for 24% of the variance in dOF. Regression coefficients for pIF and dOF can be found in Table 1.

Table 1  
Variables Included in Regression Analyses

		B	$\Delta r^2$	p
Proximal IF	Ball Speed	5.93 (0.37)	.73	<.01
	IR Strength	-1.40 (0.59)	.02	<.05
Distal OF	Ball Speed	1.42 (0.29)	.18	<.01
	ER Strength	-1.18 (0.53)	.06	<.05

Glenohumeral IR and ER strength exhibited a small ability to predict pIF and dOF, respectively. In both regression models, GH strength negatively predicted humeral ET, suggesting that, for a given ball speed, increased GH strength may reduce necessary ET. Both models supported our hypothesis that increased GH strength would minimize the amount of ET needed to achieve a given ball speed. This reduction of predicted ET may indicate a protective effect of increased GH strength against unnecessary increases in ET during the pitch.

Although increasing IR and ER musculature strength has long been recommended by the coaching community, data concerning specific mechanisms by which increases in strength may benefit pitchers has been lacking. These data provide initial evidence for reducing ET as a potential mechanism behind the benefits of GH musculature strengthening. Reducing ET is likely to decrease joint loading during the pitch which, in turn, may decrease the risk of mechanical overload to vulnerable tissues in the upper extremity such as the glenoid labrum, rotator cuff musculature, and ulnar collateral ligament.

## Significance

Clinically assessed GH strength showed a small ability to predict humeral ET. Our results not only support previous research suggesting strengthening of the IR and ER musculature as a method of decreasing the risk of injury to the throwing arm [4] but also add insight by purposing reduction in ET as a potential mechanism behind the potential benefits of GH muscle strengthening.

## Introduction

How pitching velocity relates to shoulder and elbow joint loading is not well understood<sup>1,2</sup>. Since medial elbow injuries are linked to excessive elbow valgus torque<sup>3</sup> and peak shoulder distraction force may contribute to rotator cuff injuries<sup>4</sup>, understanding the relationship between pitching velocity and upper extremity kinetics can aid in better identification of pitchers at risk for upper extremity injury. Further, these data can provide a foundation for throwing and pitching loading strategies for rehabilitation and return to sport programs following upper extremity injuries. Therefore, the purpose of this study was to determine the relationship between baseball pitching velocity, shoulder distraction force, and elbow valgus torque.

## Methods

Data from reports generated as part of a 3D biomechanical pitching evaluation were retrospectively reviewed. A total of 70 baseball pitchers (College: n = 23; High School: n = 47) participated in a pitching evaluation. Inclusion criteria consisted of baseball players, from all competition levels, whom pitcher is their primary or secondary position.

Variables extracted from the pitching reports included pitching velocity, shoulder distraction force, and elbow valgus torque. Shoulder distraction force and elbow valgus torque were normalized by body weight (N) and body weight times height (Nxm), respectively.

Each pitch was considered an individual observation. Multivariable linear regressions with fractional polynomial regressions were used to investigate the relationship between pitch velocity, shoulder distraction force, and elbow valgus torque. Subgroup analyses were then performed for college and high school pitches, and then for pitches that were thrown above 85 mph. R squared ( $r^2$ ) were utilized to assess model fit.

## Results and Discussion

A total of 273 pitches were included in this study. There was a positive linear relationship between pitch velocity and shoulder distraction force ( $r^2 = 0.21$ ,  $p < 0.001$ ) and between pitch velocity and elbow valgus torque ( $r^2 = 0.32$ ,  $p < 0.001$ ) for the entire sample (Figure 1).

Separately, college and high school pitches both exhibited a positive linear relationship between pitch velocity and shoulder distraction force (College:  $r^2 = 0.09$ ,  $p < 0.001$ ; High School:  $r^2 = 0.32$ ,  $p < 0.001$ ), and between pitch velocity and elbow valgus torque (College:  $r^2 = 0.16$ ,  $p < 0.001$ ; High School:  $r^2 = 0.32$ ,  $p < 0.0001$ ).

In pitches that were thrown above 85 mph, there was no relationship between pitch velocity and shoulder distraction force ( $r^2 = 0.005$ ,  $p = 0.500$ ), nor between pitch velocity and elbow valgus torque. ( $r^2 = 0.002$ ,  $p = 0.712$ ). Neither college nor high school pitches thrown above 85 mph exhibited a relationship between pitch velocity and shoulder distraction force (College:  $r^2 = 0.004$ ,  $p = 0.606$ ; High School:  $r^2 = 0.13$ ,  $p = 0.117$ ). College

pitches thrown above 85 mph also did not exhibit a relationship between pitch velocity and elbow valgus torque ( $r^2 = 0.007$ ,  $p = 0.476$ ). However, high school pitches thrown above 85 mph exhibited a positive linear relationship between pitch velocity and elbow valgus torque ( $r^2 = 0.27$ ,  $p = 0.020$ ).

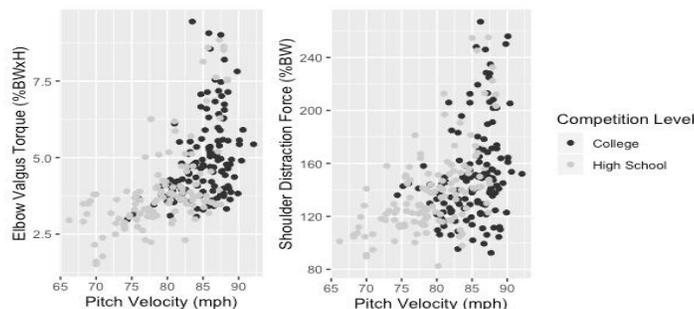

Figure 1: Elbow valgus torque vs pitch velocity and shoulder distraction force vs pitch velocity

Both the high school and college pitchers exhibited significant positive linear relationships between pitching velocity and shoulder distraction force and pitching velocity and elbow valgus torque. After stratification, high school pitchers who threw the fastest experienced greater elbow and shoulder torques. However, this trend did not hold true among the college pitchers. These findings may indicate a survival effect among the elite college pitchers compared with the elite high school pitchers.

It has been shown that pitchers from higher competition levels produce greater pitching velocity and joint forces; but, also have greater pitching mechanical efficiency and skill. These competition level discrepancies between pitching velocity and biomechanical efficiency may potentially attenuate a linear increase between pitch velocity and upper extremity kinetics. The results of this study suggest that these age discrepancies continue to exist, and are more pronounced, among elite or highly skilled pitchers.

## Significance

These findings suggest that high school pitchers that throw at high velocities may be more susceptible to pitching injury. There were many successful high velocity pitches from college pitchers who were able to limit stress on the elbow and shoulder. Identifying the mechanics and other meaningful contributors to pitch velocity and arm kinetics among this subgroup would help inform throwing and pitching loading strategies.

### Introduction

At the instant of lead foot contact, a variety of biomechanical parameters are associated with an increase in upper extremity kinetics and kinematics [1]. Some of these kinematic parameters include front foot position, shoulder horizontal abduction, and shoulder abduction [1]. While previous studies have indicated that changes in the lead foot position have led to an increase in kinetics and kinematics, minimal studies have investigated the implications of the rear foot placement on the pitching rubber. Therefore, the purpose of this study was to investigate the effects of the rear foot placement on the pitching rubber in relation to both kinematic and kinetic parameters. Our hypothesis was that there would be a significant difference in the kinematics (motions) and kinetics (torques & forces) when pitching from the third base side and first base side of the pitching rubber.

### Methods

This was a retrospective review of the American Sports Medicine biomechanics database where four hundred and thirty-three right-handed professional baseball pitchers were determined to fit the criteria for this study. Shoulder and elbow passive range of motion were measured on the participant's dominant and non-dominant arms.

A total of twenty-four kinematic and kinetic parameters were calculated using methods that have already been previously described [2] [3]. All the pitchers were first divided by their third base side or first base side rear foot position. Second, they were sub-divided into having an open or closed front foot position. From these two distinctions, each pitcher was grouped into the following four possible combinations: first base closed (FBC), first base open (FBO), third base closed (TBC), and third base open (TBO). An Analysis of variance (ANOVA) was utilized to detect significant differences among the location of the lead and rear foot placement on the pitching mound.

### Results and Discussion

Significance was found in the follow five variables, trunk forward tilt at ball release, trunk forward tilt at maximal internal rotation, shoulder abduction, arm slot, and wrist flexion torque. Our hypothesis was supported that there were significant differences found in the biomechanical parameters between the front foot placement and rear foot location on the pitching rubber. As a baseball pitcher improves their skill, they are better able to adjust their pitching mechanics [5] [7]. Front foot placement on the mound has been shown to increase the coordination and stability of the pitching arm [8]. Although pitch type deception may be improved with a change in foot placement on the pitching rubber, recent research has shown implications of injury to the ulnar

collateral ligament with a change of the release point, in relation to the movement on the pitching rubber [9].

Before the conduction of the study, it was thought that when the pitcher had FBO the elbow was put in a compromised position. It was also thought that with a TBC the shoulder would be placed in a compromised position. The results did indicate that there was a significantly lower arm slot (p-value 0.02) for a pitcher who has a TBC position when compared to an TBO, however no significant kinetic differences were found. There were no significant findings in relation to the kinematics or kinetics of the elbow with the placement of either the front or rear foot. The implications of this study for baseball coaches will help to increase the ability to change rear foot placement on the pitching rubber with hopes of decreasing the potential incident of injury. Rear foot and lead foot placement drills can be established as part of a training and practice schedule for baseball pitching coaches.

### Significance

This study aimed to bring the gap between the incident of injury and foot placement on the pitching mound closer together. The goal for all baseball coaches and pitchers is to stay healthy and decrease the potential risk of injury. Both pitching coaches and players will be better able to adjust their pitching location to increase their likelihood of staying healthy and adjust the above-mentioned biomechanical parameters.

## The Effect of Pronation on Break of The Curveball

Megan Stewart, Alek Diffendaffer<sup>1</sup>, Jon Slowik<sup>1</sup>, Karen Hart<sup>1</sup>, Glenn Fleisig<sup>1</sup>  
The American Sports Medicine Institute, Birmingham, Alabama, USA

### Introduction

Previous research has indicated that the movement of the wrist and the forearm may have significance on the location of the pitch [1], however, there is no indication of the significance of the amount of wrist supination or pronation with respect to vertical or horizontal break of the baseball. Therefore, the purpose of this study was to investigate the relationship between wrist pronation of a curveball and the horizontal and vertical break.

### Methods

This was a retrospective review of the American Sports Medicine database where forty-three baseball pitchers were determined to be eligible. Shoulder and elbow passive range of motion were measured on the participant's dominant and non-dominant arms by the research staff.

Each participant was tested throwing five full-effort curveballs to a target located behind home plate, 18.44 m from the rubber. Horizontal break of the baseball was defined as the maximal horizontal variation from a straight-line path between the release point of the baseball and the point where the baseball crossed the back edge of home plate. Vertical break was defined as the maximal vertical variation from a straight-line path between the release point of the baseball and the point where the baseball crossed the back edge of home plate. A linear regression was utilized to investigate the relationship between forearm pronation and the baseball kinematics (ball velocity, horizontal and vertical break).

### Results and Discussion

A statistically significant relationship was found between forearm pronation at foot contact, forearm pronation at foot contact and vertical break, and forearm pronation at ball release, and the velocity of the baseball on both the vertical and horizontal break. These results indicate that the ball velocity (mph) will have a significant effect on the vertical break (up and down) location and horizontal break (side to side) location for the baseball. It was also indicated that the amount of forearm pronation at the instant of foot contact, will significantly affect the amount of pronation at the instant of ball release and the vertical break location. Figure 1 is showing the effect of forearm pronation at foot contact and the vertical break of the baseball.

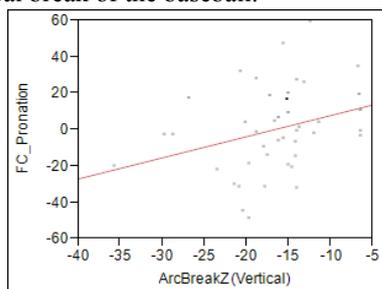

Figure 1: The Relationship Between Pronation at Foot Contact and Vertical Break

Previous research has determined that a baseball pitchers' dominant forearm will have 5° more of pronation when compared to their non-dominant forearm [2]. It has been discussed that the ability of greater pronation is a persisting structural difference between position players & pitchers [2]. Even with pitchers having an increase in forearm pronation, it has been seen in some research that the vertical control and horizontal control of the baseball increase with the ability for a pitcher to alter their forearm pronation [2].

There was no significant relationship between the horizontal break of the baseball and the pronation of the forearm at foot contact. However, there was a significant relationship between the velocity of the baseball and the horizontal break. Furthermore, it was found that the amount of forearm pronation at foot contact had a significant relationship (p-value = 0.04) with the amount of forearm pronation at the ball release and the amount of vertical break of the baseball (p-value = 0.05). There is a positive linear relationship between the amount of forearm pronation at foot contact and the location of the vertical break of the baseball. Therefore, as the foot contact pronation at the forearm increases, the vertical break of the curveball increases.

The results of this study indicate that when the velocity of a pitcher is higher there is a significant increase in the horizontal break of the baseball (p-value = 0.02) and the vertical break of the baseball (p-value < 0.001). The amount of forearm pronation at the instant of foot contact will have a significant effect on the amount of forearm pronation at the instant of ball release (p-value = 0.04) and the location of the vertical break of the baseball (p-value = 0.05).

### Significance

With the ability to manipulate the amount of forearm pronation at foot contact to affect the amount of forearm pronation at ball release, coaches and pitchers will be better adept to adjust their mechanics. The practical applications for coaches and pitchers to implement a training program for foot contact and pronation drills will help to increase the amount of pitch type deception and allow for the potential increase in vertical break of the baseball, which will help to increase the time for the baseball to change positions from the release of the hand. This increase in time and deception will help to generate the potential for more strikeouts and variation in pitch location.

# The Relationship between Fastball Velocity and Elbow Varus Torque in Professional Baseball Pitchers

Jonathan S. Slowik, Kyle T. Aune, Alek Z. Diffendaffer, E. Lyle Cain, Jeffrey R. Dugas, and Glenn S. Fleisig

American Sports Medicine Institute, Birmingham, AL

Email: jons@asmi.org

## Introduction

Baseball pitching is a highly dynamic task that involves extraordinary velocities, requiring potentially damaging torque levels, especially in the throwing arm. However, previous studies have been unable to find a strong relationship between ball velocity and elbow varus torque, possibly due to the confounding effects of between-subject differences (e.g., detailed anthropometrics and pitching mechanics) [1,2]. Therefore, the purpose of this study was to examine the relationship between fastball velocity and elbow varus torque in professional pitchers, through both across-subject and within-subject statistical analyses. We hypothesized that ball velocity explains 1) only a small percentage of the across-subject variance in varus torque, but 2) a much higher percentage of the within-subject variance in varus torque.

## Methods

From a database of previously collected biomechanical data of baseball pitchers [e.g., 3], we identified 64 professional pitchers meeting the following criteria: 1) threw at least 5 fastball trials, 2) exhibited a velocity range of at least 2.2 m/s (5.0 mph), and 3) had no single pitch trial that accounted for over half of the velocity range. These criteria enabled both within-subject and across-subject statistical analysis methods. We then performed a retrospective review of their fastball data (e.g., ball velocity and inverse-dynamics-based elbow varus torque). We established the across-subject relationship between ball velocity and normalized maximum elbow varus torque using simple linear regression between each subject's mean ball velocity and mean normalized maximum elbow varus torque value. Similarly, we established the within-subject relationship between ball velocity and normalized maximum elbow varus torque using a mixed linear model with random intercepts. An  $R^2$  statistic was calculated for this model by comparing its residual variance against the residual variance of the random intercept alone:

$$R^2 = (ResidualVar_{int} - ResidualVar_{model}) / ResidualVar_{int}$$

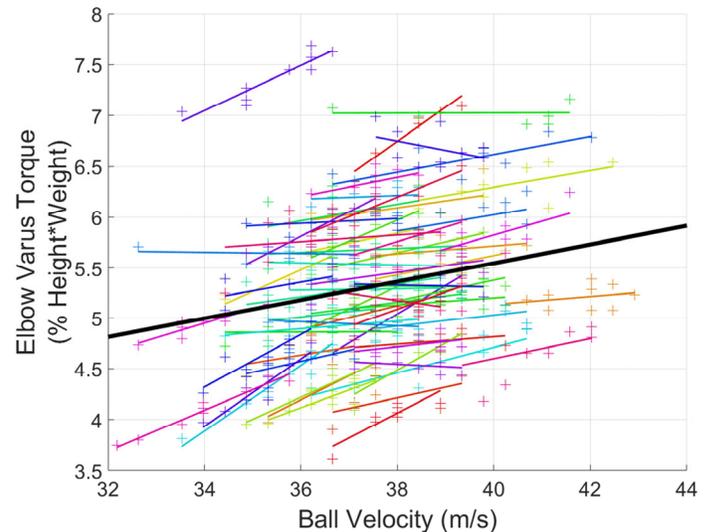

The significance level  $\alpha$  for all tests was set a priori at 0.05.

## Results and Discussion

Across all subjects, the mean fastball velocity was  $37.6 \pm 1.5$  m/s ( $84.1 \pm 3.5$  mph) and the within-subject range of fastball velocity was  $2.8 \pm 0.7$  m/s ( $6.4 \pm 1.6$  mph). The across-subject mean value for normalized maximum elbow varus torque was  $5.33 \pm 0.74$  % body weight\*height. The simple linear regression model indicated a statistically significant, but weak positive association between ball velocity and varus torque at the across-subject level ( $p=0.03$ ,  $R^2=0.08$ ). The linear mixed model (with random intercepts) indicated a considerably stronger positive association between ball velocity and varus torque when performing within-subject comparisons ( $p<0.001$ ,  $R^2=0.96$ ). Plots of within-subject normalized maximum elbow varus torque vs. ball velocity are provided in Figure 1.

These results suggest that when comparing two individual professional pitchers, higher velocity may not necessarily indicate higher elbow loading. However, within an individual pitcher, higher ball velocity is strongly associated with higher

elbow varus torque. Furthermore, the model suggests that for every 1.0 m/s increase in ball velocity, varus torque increases by 0.092% (body weight\*height). For a pitcher with the mean height (1.90 m) and mass (94.6 kg) of the participants, this would equate to a 1.62 Nm increase in varus torque for every 1.0 m/s increase in ball velocity.

**Figure 1:** Plot of normalized maximum elbow varus torque vs. ball velocity. Each individual pitcher is represented by a series of points and the best-fit line in one color, while the regression line from the linear mixed model is represented by the thick black line. This model suggested a strong positive within-subject relationship between varus torque and velocity ( $R^2=0.96$ ).

## Significance

The results of this study suggest that while between-subject comparisons are obscured by subject-specific attributes, a deliberate reduction in velocity (without compromising mechanics) will likely reduce the load on an individual pitcher's elbow. Considering the fact that many professional pitchers throw over 3000 in-game pitches each season, as well as the extensive research on the dangers of pitch volume and the resulting accumulated load, these results suggest that a pitcher may be able to reduce his elbow injury risk by deliberately varying his velocity from pitch to pitch. Thus, we believe that pitchers should focus on using good mechanics, developing command, determining the minimum level of pitch intensity necessary to obtain the outcome they desire for each of their pitches, and learning to recognize the situations when success requires maximum velocity. Furthermore, professional baseball teams with the ability to recognize when pitchers lack these attributes (i.e., pitchers who require "maximum effort" for success) may be able to avoid potentially costly mistakes by either correcting this weakness, limiting their pitch count, or avoiding signing these players altogether.

Email: jons@asmi.org

## Introduction

Baseball coaches and trainers frequently summarize a pitcher's delivery by subjectively classifying his arm slot (i.e., orientation of his arm in the frontal plane, at the time of ball release). Arm slots are commonly categorized into one of three groups: overhand (OH), three-quarter (TQ), and sidearm (SA) (Fig. 1). Previous studies have examined quantities that are related to arm slot (e.g., lateral trunk tilt, shoulder abduction), but conflicting results have led to confusion and inconsistent recommendations within the literature [e.g., 1,2]. Therefore, the purpose of this study was to objectively quantify the arm slot angles of professional pitchers, and then investigate the differences in pitching biomechanics between these three arm slot groups.

## Methods

From a database of previously-collected biomechanical data of baseball pitchers [e.g., 3], we identified 378 professional pitchers meeting the following criteria: 1) threw at least 5 full-effort fastball trials from the windup position, 2) were healthy at the time of testing, and 3) had not undergone shoulder or elbow surgery in the previous 18 months. Arm slot angle was defined as the angle between a vertical vector and a vector connecting the throwing shoulder joint center to the hand, when viewed from behind the mound (Fig. 1). Three arm slot groups were then defined as follows: OH ( $\leq 40^\circ$  arm slot angle), TQ ( $50^\circ$  to  $60^\circ$  arm slot angle), and SA ( $\geq 70^\circ$  arm slot angle). Differences in 37 pitching biomechanics variables were then assessed using a one-way ANOVA. If a significant main effect was found, pairwise comparisons were performed using student t-tests with a Bonferroni correction. The uncorrected significance level for all tests was set at  $\alpha=0.01$ .

## Results and Discussion

There were no significant between-group differences in age, body mass, body height, or ball velocity. There were significant differences found for 14 biomechanical variables (Table 1). There were large between-group differences in lateral trunk tilt, with OH>>TQ>>SA. A similar trend was seen in shoulder abduction but with smaller differences (OH>TQ>SA). Overall,

the kinematic differences between groups suggest that OH moved most in the vertical plane, while the SA moved most in the horizontal plane. In addition, SA had less shoulder anterior force than TQ, while OH had less elbow flexion torque than either TQ or SA.

**Table 1:** Biomechanical variables (mean  $\pm$  standard deviation) with statistically significant differences <sup>a</sup>between OH and SA, <sup>b</sup>between TQ and SA, and <sup>c</sup>between OH and TQ.

## Significance

The results of this study suggest that arm slot is primarily driven by lateral trunk tilt, with a secondary contribution from shoulder abduction. The greater elbow flexion torque and shoulder external rotation exhibited by SA pitchers may increase their risk of labral injury. Conversely, the lower shoulder anterior force in SA pitchers may indicate lower stress on shoulder joint capsule and rotator cuff.

## Introduction

Baseball pitching requires a rapid sequencing of body segment rotations from the windup through ball release. Subtle variations in pitching mechanics may negatively result in decreased ball velocity, increased joint stress, and decreased accuracy. Previous literature has extensively investigated the relationships between pitching mechanics, ball velocity, and joint kinetics [1,2]; however, there has been limited research investigating the relationship between consistency of pitching mechanics and pitch location. Therefore, the purpose of this study was to assess the relationship between variability in pitching mechanics and pitch location. It was hypothesized that lower variability in pitching kinematics would be associated with increased consistency in pitch location.

## Methods

From a database of previously-collected biomechanical data, 47 baseball pitchers were identified as meeting the following criteria: 1) threw at least 8 full-effort fastball trials with 3D motion capture and PITCHf/x data being successfully collected and 2) were healthy at the time of testing. For each pitch thrown, vertical and horizontal coordinates of the baseball as it crossed homeplate were measured via the PITCHf/x system. From these coordinates, each pitcher's mean pitch location was calculated. The distances from each pitch location to the mean pitch location were found. A consistency metric was then calculated for each pitcher by averaging these distances. Twenty kinematic parameters were calculated from the motion capture data for each pitch tracked by the PITCHf/x system, which has been previously described [3]. Variability was defined as the standard deviation among the pitches thrown and was calculated for each of the 20 kinematic parameters. A stepwise linear regression analysis using backwards elimination was performed to assess the relationship between kinematic variability and pitch location consistency.

## Results and Discussion

At the end of the backwards elimination process ( $p < 0.1$ ), only five parameters remained in the model (Table 1). Three kinematic

parameters occurred at foot contact (upper trunk tilt, shoulder abduction, and shoulder horizontal abduction), while two occurred at the time of maximum shoulder external rotation (maximum shoulder external rotation and maximum shoulder horizontal adduction) (Figure 1). The model accounted for 58% of the variance in the consistency metric ( $R^2 = 0.58$ ).

**Table 1:** Multiple linear regression model resulting from a stepwise linear regression using backward elimination. For each parameter, variability is the standard deviation for the pitches thrown by a pitcher. (B = unstandardized coefficients; SE = standard error, Beta = standardized coefficients)

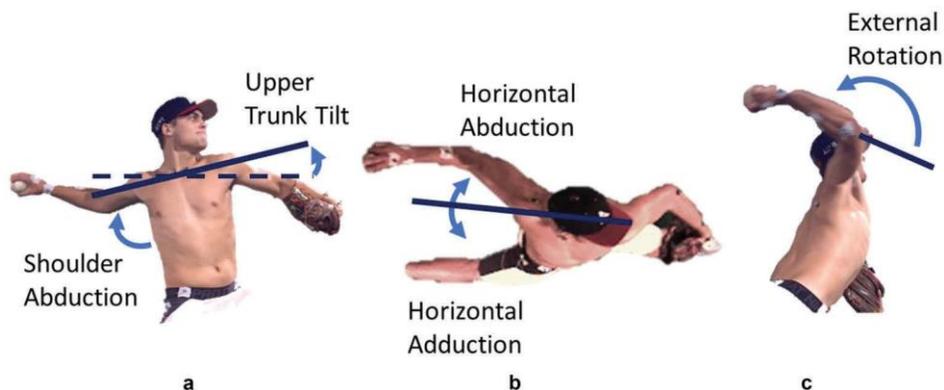

Parameter	B	SE	Beta	p-value
Constant (cm)	10.08	4.15	-	0.020
Upper Trunk Tilt	2.24	0.78	0.33	0.007
Shoulder Abduction	3.03	1.31	0.26	0.026
Shoulder Horizontal Abduction	-1.64	0.69	-0.29	0.023
Max Shoulder External Rotation	8.86	2.54	0.40	0.001
Max Shoulder Horizontal Adduction	7.71	2.46	0.35	0.003

## Significance

The results of this study suggest that a pitcher's ability to locate the baseball is directly dependent on his ability to pitch with consistent kinematics. Four of the above-mentioned parameters involved variability in shoulder kinematics, which has also been proven to significantly contribute to ball velocity and injury risk. In general, pitchers should strive for consistency in shoulder motion and upper trunk tilt to optimize their ability to locate pitches.

# Hip Range of Motion and Isometric Strength Differences Between High and Low Batted Ball Velocity Hitters

Jessica L. Downs, Nicole M. Bordelon, Kenzie B. Friesen, Gretchen D. Oliver

Sports Medicine and Movement Laboratory, School of Kinesiology, Auburn University, Auburn, Alabama, USA

Email: jzd0075@auburn.edu

## Introduction

Hitting performance is essential to offensive success in baseball and softball. Specifically, bat speed and batted ball velocity (BBV) are variables coaches analyze when predicting hitting success. Previous hitting research has focused on kinetics and kinematics associated with hand velocity as an indicator of BBV [1,2]; however, there are little to no data regarding the relationship between clinical measures and BBV.

Defensively, hip and shoulder range of motion (ROM) and strength have been correlated with kinetic chain energy transfer, altered throwing mechanics, ball velocity, and potential predictors of injury during the overhand throw [3]. Investigating the relationship between BBV, hip ROM, and hip strength will give coaches and clinicians a field measurement to identify potential musculoskeletal deficits that may influence hitting performance. Therefore, the purpose of this study was to investigate potential differences in hip ROM and strength between low and high BBV hitters in adolescent baseball and softball athletes. It was hypothesized that high BBV hitters will have greater hip ROM than low BBV hitters and that there would be no significant differences between baseball and softball athletes

## Methods

Forty-three right-handed adolescent baseball and softball athletes (13.7±2.6yrs, 165.5±15.0cm, 67.2±19.8kg) participated. All participants were deemed free of injury and surgery for at least the past six months.

Passive hip internal rotation (IR) and external rotation (ER) ROM and isometric strength (ISO) of the lead and back leg were collected prior to warm-up. Hip ROM and ISO were measured with a digital inclinometer and a handheld dynamometer, respectively, while the participant was seated with knees flexed at 90°. Isometric strength was normalized to individual participants' body mass.

Participants were given an unlimited amount of time to warm-up from a tee. Once deemed warm, the participants were instructed to execute game effort swings from a tee at a self-selected height and placement for 10 trials. A trial was saved if the hit resulted in a line-drive and if the participant gave verbal feedback that they felt it was a good swing. At least three saved trials were needed for the participant to be included in the analysis. Batted ball velocity was assessed using a radar gun placed behind the participant. The average BBV of the saved trials were used for analysis. Participants were divided into high BBV and low BBV groups. Groups were assigned based on whether their average BBV was above (high) or below (low) the group mean. Participants were also coded based on sport (baseball or softball).

Due to non-normally distributed data, a Mann-Whitney-U test was used to determine differences in IR/ER hip ROM and/or ISO between BBV groups and between sports. To minimize chance of type 1 error, alpha level was set *a priori*,  $\alpha = .006$ .

## Results and Discussion

Results revealed a statistically significant difference in BBV groups for back hip IR ROM ( $U = 107.50$ ,  $p = .003$ ,  $effect\ size = .274$

0.46), with the low BBV group having significantly greater back hip IR than the high BBV group. There were no other significant differences between BBV groups (Table 1 and 2). When analyzing sport differences, the test revealed a statistically significant difference in lead hip ER ISO ( $U = 86.00$ ,  $p = .001$ ,  $effect\ size = 0.52$ ). Specifically, baseball athletes had significantly greater lead hip ER ISO than softball athletes. However, the current study did not control for age. Controlling for age is a limitation and may produce different results [4]. There were no other significant differences between sports.

Table 1: Range of Motion Descriptives

Group	n	Batted Ball Velocity	Lead Hip IR	Back Hip IR	Lead Hip ER	Back Hip ER
High	22	33.60	28.04	*25.88	34.68	34.33
Low	21	23.18	33.07	*34.11	36.15	36.67

Note: n=number of participants, IR=internal rotation, ER=external rotation, \* denotes significant difference between groups, all range of motion values are reported in degrees, velocity is reported in m/s

Table 2: Isometric Strength Descriptives

Group	n	Batted Ball Velocity	Lead Hip IR	Back Hip IR	Lead Hip ER	Back Hip ER
High	22	33.60	2.21	2.09	2.06	2.03
Low	21	23.18	2.27	2.23	1.94	2.14

Note: n=number of participants, IR=internal rotation, ER=external rotation, all isometric strength values are reported in N/kg, velocity is reported in m/s

The result of increased back hip IR ROM in the low BBV group compared to the high BBV group was not hypothesized. In overhead throwing, there is an optimal range for hip ROM where too little or too much ROM can contribute to increased injury risk [5]. Based on the results of the current study, the same concept of an optimal range may hold true for hitting. It is worth noting however that hip ROM was assessed passively and different results may be found when assessing dynamic hip ROM during the swing.

## Significance

The results of this study are important as they are one of the first to analyze the association between hitting performance indicators with passive hip ROM and ISO. These results provide clinical measures that can potentially be used to predict BBV in adolescent baseball and softball athletes. Future research should be done to investigate if these differences hold true in a collegiate population in addition to the association between dynamic hip ROM and hitting performance.

## Introduction

Due to the high forces involved, shoulder injuries are common in baseball pitchers. Despite a number of studies on youth pitching kinematics and kinetics, there is little information about techniques that maximize ball speed and minimize joint loads. Previous work indicates that the sequence of discrete torso movements influence upper extremity joint loading (3). It would also be beneficial to know if dynamic time-series patterns of torso movements relate to pitching performance and joint loads.

One method of analysis that is often used to quantify sport techniques and dynamic movement patterns is principal components analysis (PCA) (2). PCA involves analyzing time series as opposed to discrete values. In the context of pitching, PCA may facilitate a better understanding of how movement patterns throughout the entire pitching motion relate to performance and shoulder joint loads rather than discrete variables at distinct time points. The purpose of this study was to investigate the associations between torso movement patterns extracted via PCA, and shoulder forces, moments, and ball speed.

## Methods

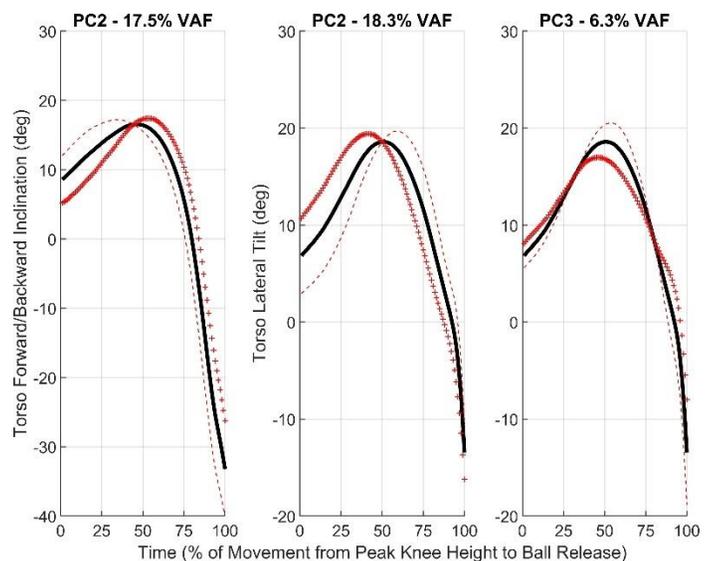

Twenty-four little league pitchers were fitted with a full-body marker set consisting of 32 individual markers and 7 marker clusters. Kinematic and kinetic data were recorded at 250 Hz and at 1000 Hz, respectively. Kinetic data were recorded with a two force plates that were built into a pitching mound. A 4<sup>th</sup>-order, 14 Hz, zero-lag, low-pass Butterworth filter was used on the marker data, while a 4<sup>th</sup>-order, 300 Hz, zero-lag, low-pass Butterworth filter was used on force plate data. Inverse dynamics equations were used to calculate net joint force and moments (NJM) at the shoulder, and normalized to body mass.

Data from 23 youth pitchers (five trials each) were used for analysis (range: 9-13 years, height:  $1.55 \pm 0.12$  m, body mass:  $46.0 \pm 11.9$  kg). Torso segment orientation data were time-normalized from peak knee height to ball release in three planes and input to a PCA. PC scores for torso forward/backward inclination, lateral tilt, and transverse rotation were calculated for each individual trial, with within-subject averages of PC scores, ball speed, and peak shoulder kinetics (e.g. DistractF: distraction force, HorizAbM: horizontal abduction moment, AdM: adduction moment) analyzed via correlational analysis. Due to the violation of normality, Spearman's rho correlations were used, along with 1,000 replicate sample bootstrapping to increase robustness of the analyses.

## Results and Discussion

Mean pitch velocity was  $51.6 \pm 7.5$  mph. The PCA was able to explain 98% of the variance in torso forward/backward inclination angle. PC2 of these data exhibited a significant positive correlation in that a phase shift and delayed transition from backward to forward inclination relates to increased distraction force (Table 1). The PCA accounted for 96.7% of the

variance in torso lateral tilt angle, and 96.8% in torso rotation angle. A phase shift to an earlier contralateral tilt (PC2) was related to a greater horizontal abduction moment, and a smaller magnitude of lateral tilt change throughout the movement (PC3) was associated with a greater adduction moment (Table 1). Lastly, a smaller degree of torso rotation for the majority of the movement (PC1) was correlated to reduced ball speed, though the confidence interval for this significant result includes zero ( $\rho = -0.456$ ,  $p = 0.029$ , 95% C.I. =  $-0.832, 0.037$ ).

**Figure 1:** Ensemble average (black line) of time-normalized torso time series data along with the variance accounted for (VAF) and effects of principal components (PC) on the shape of the curves (effects of positive and negative PC scores are illustrated with +/- symbols, respectively).

**Table 1: Spearman's Rho Correlations**

Torso PCA	PC	Variable	$\rho$	Sig.
Forward/Backward Incl.	PC2	DistractF	0.432	0.040
Lateral Tilt	PC2	HorizAbdM	0.455	0.029
Lateral Tilt	PC3	AddM	0.481	0.020

## Significance

Since the kinematic patterns associated with joint loads were not associated with ball speed it may be possible to alter pitching technique to decrease joint loads and retain pitching performance. Future research should investigate this conclusion with an interventional study.

# Shoulder External Rotation ROM During Physical Exam Is Related to the Joint Loading During Baseball Pitching

Hannah L. Stokes<sup>1</sup>, Nigel Zheng<sup>1</sup>, Koco Eaton<sup>2</sup>

<sup>1</sup>University of North Carolina at Charlotte, NC, <sup>2</sup>Tampa Bay Rays and University of South Florida, FL  
nzheng@unc.edu

## Introduction

Baseball pitching is demanding on the shoulder and it is common for injuries to occur. Higher joint loading has been shown to lead to more injury incidences (1). The relationship of shoulder range of motion (ROM) and injury has been studied (2). The shoulder ROM is checked by team physicians regularly.

The purpose of this study is to investigate how shoulder external rotation (SER) ROM measured during a physical exam is related to the shoulder joint loading during pitching. This connection could allow for correction of baseball mechanics and ultimately reduce the risk for injuries. We hypothesize that SER ROM during a physical exam is not related to shoulder forces or torques during baseball pitching.

## Methods

The study included 177 college pitchers (height: 186±7.2 cm and weight: 188±19.6 lbs). The study protocol was approved by an institutional board, and all participants gave written informed consent. The maximum SER ROM was previously defined as the end-point angle (EPA), which was recorded during a physical exam using a custom-made wireless device (3). The pitchers were grouped into low (<mean-SD, n=33), medium (mean±SD, n=114), and high EPA (> mean+SD, n=30).

Ten fastball pitching motions were collected at 240 Hz using a motion capture system. Three best pitches were analyzed. A custom MATLAB program was created to calculate: anterior/posterior (AP) force, proximal/distal (PD) force, superior/inferior (SI) force, abduction/adduction (AA) torque, internal/external (IE) torque and horizontal abduction/adduction (HAA) using an inverse dynamics model. One-way analysis of variance (ANOVA) with Tukey pos-hoc tests were performed using SPSS with an alpha set to 0.05. The maximum, minimum and range values and timings or duration of these shoulder kinetics variables were compared among three EPA groups.

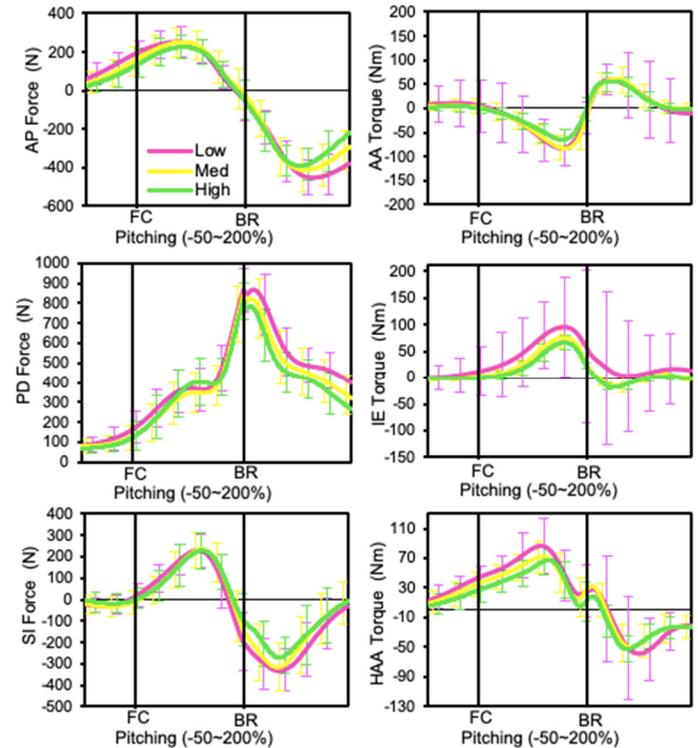

**Table I:** Results p-values for one-way ANOVA, bolded indicates significant, a: Low vs Medium, b: Low vs High, c: Medium vs High (F/T: force/torque, R: Max-Min, %: timing during pitching cycle).

F/T	Max	Max %	Min	Min %	R	R %
AP	0.472	0.432	<b>0.027<sup>b</sup></b>	0.072	0.082	<b>0.007<sup>ab</sup></b>
PD	0.093	<b>0.004<sup>ab</sup></b>	<b>0.001<sup>ab</sup></b>	0.250	0.374	<b>0.028<sup>ab</sup></b>
SI	0.885	0.641	0.087	0.167	0.374	0.147
AA	0.144	0.869	<b>0.005<sup>bc</sup></b>	0.622	<b>0.015<sup>b</sup></b>	<b>0.032<sup>b</sup></b>
IE	<b>0.035<sup>b</sup></b>	<b>0.030<sup>a</sup></b>	0.325	0.403	<b>0.026<sup>b</sup></b>	<b>0.000<sup>ab</sup></b>
HAA	<b>0.024<sup>ab</sup></b>	0.798	0.243	<b>0.000<sup>ab</sup></b>	0.067	<b>0.039<sup>b</sup></b>

## Results and Discussion

There was no significant difference in ball speed (Low: 75.7±5.1, Medium: 76.9±4.6, High: 77.7±4.9 mph). The shoulder forces and torques were significantly different among the three EPA groups (Table I). The primary differences appeared in the IE and HAA torque (Fig. 1). The IE torque was significantly different in the maximum value, timing of the maximum value, range and duration between the maximum and minimum values. The HAA torque was significantly different in the maximum value. The PD

force was significantly different in the timing of the maximum value.

**Figure 1:** Forces and torques during pitching (mean±SD) normalized from foot contact (FC: 0%) and ball release (BR: 100%).

These findings bridge the gap, showing that SER ROM during exam is related to shoulder joint loading during baseball pitching, aligning with previous work (4). The differences found in the maximums show that lower EPA was associated with higher shoulder forces or torques. The differences found for max, min and range and timings could be contributed to different pitching styles or mechanics, which was similar to a previous study (5). In conclusion, SER ROM during a physical exam is related to shoulder forces and torques during baseball pitching.

## Significance

Higher shoulder joint loading leads to more injury incidences. These results show that high EPA is advantageous because it reduces the shoulder joint loading during baseball pitching. The measurement of SER ROM allows team physicians to address and correct those with limited EPA to prevent throwing injury.

## Acknowledgments

# External Shoulder Flexibility During Physical Exam Is Related to Shoulder Joint Loading During Baseball Pitching

Hannah L. Stokes<sup>1</sup>, Nigel Zheng<sup>1</sup>, Koco Eaton<sup>2</sup>

<sup>1</sup>University of North Carolina at Charlotte, NC, <sup>2</sup>Tampa Bay Rays and University of South Florida, FL  
nzheng@unc.edu

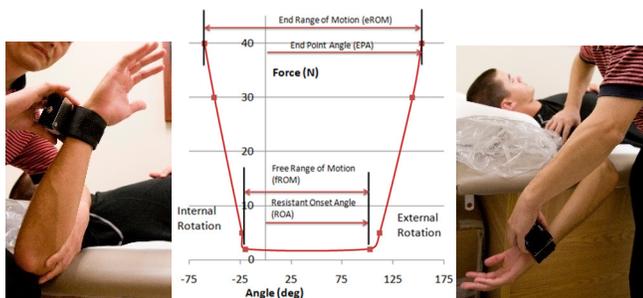

## Introduction

Increased throwing arm flexibility in baseball pitching increases performance but is also a risk factor for throwing-related injuries. A study showed when shoulder laxity worsens then instabilities develop and increase injury incidences (1). Shoulder pain in youth baseball pitchers was shown to be caused by forces and torques on the shoulder joint (2).

The purpose of this study is to investigate how shoulder flexibility measured during a physical exam is related to the shoulder joint loading. This connection could serve as a link between clinical examinations and shoulder joint loading. We hypothesize that shoulder flexibility is not related to the shoulder joint loading during baseball pitching.

## Methods

The study included 177 college pitchers (height:  $186 \pm 7.2$  cm and weight:  $188 \pm 19.6$  lbs). The study protocol was approved by an institutional board, and all participants gave written informed consent. The resistive onset angle (ROA) and shoulder rotational flexibility (SRF) during passive ROM exam were previously defined (3). They were measured and calculated during a physical exam using a custom-made wireless device (Figure 1). The pitchers were grouped into low ( $< \text{mean} - \text{SD}$ ,  $n=23,26$ ), medium ( $\text{mean} \pm \text{SD}$ ,  $n=126,121$ ), and high ( $> \text{mean} + \text{SD}$ ,  $n=28,30$ ) SRF and ROA respectively.

**Figure 1:** Shoulder rotational laxity test performed during an exam. ROA and EPA were measured and SRF is the slope between the two (3).

Ten fastball pitching motions were collected at 240 Hz using a motion capture system. Three best pitches were analyzed. A custom MATLAB program was created to calculate: anterior/posterior (AP) force, proximal/distal (PD) force, superior/inferior (SI) force, abduction/adduction (AA) torque, internal/external (IE) torque and horizontal abduction/adduction torque (HAA) using an inverse dynamics model. One-way analysis of variance (ANOVA) with Tukey post-hoc tests were performed using SPSS with an alpha set to 0.05. The maximum and minimum values of these shoulder kinetic variables were compared among the three SRF and ROA groups.

## Results and Discussion

The maximum value AP force was significantly different among the three SRF groups (Table 1). High SRF leads to low joint loading in PD force, AA torque, and HAA torque at maximum

values and AP force, PD force, IE torque, and HAA torque at minimum values. The maximum value IE torque was significantly different among the three ROA groups. High ROA leads to low joint loading for all variables at maximum and minimum values.

**Table I:** Maximum shoulder forces (N) and torques (Nm) for both SRF and ROA (mean $\pm$ SD). For post-hoc tests  $p < 0.05$ , a: Low vs Medium, b: Low vs High, c: Medium vs High.

		Maximum			Minimum

	HAA	92 $\pm$ 44 <sup>b</sup>	81 $\pm$ 20	76 $\pm$ 15 <sup>b</sup>	-78 $\pm$ 79	-60 $\pm$ 21	-63 $\pm$ 16
SRF	AP	266 $\pm$ 59	265 $\pm$ 70 <sup>c</sup>	301 $\pm$ 76 <sup>c</sup>	-468 $\pm$ 82	-450 $\pm$ 98	-434 $\pm$ 85
	PD	874 $\pm$ 107	859 $\pm$ 127	853 $\pm$ 128	74 $\pm$ 23	63 $\pm$ 30	64 $\pm$ 21
	SI	238 $\pm$ 59	255 $\pm$ 79	261 $\pm$ 92	-329 $\pm$ 80	-365 $\pm$ 103	-390 $\pm$ 113
	AA	74 $\pm$ 17	71 $\pm$ 32	65 $\pm$ 27	-83 $\pm$ 23	-90 $\pm$ 39	-90 $\pm$ 32
	IE	75 $\pm$ 16	82 $\pm$ 73	83 $\pm$ 25	-24 $\pm$ 6	-22 $\pm$ 13	-20 $\pm$ 6
	HAA	90 $\pm$ 17	82 $\pm$ 26	76 $\pm$ 22	-63 $\pm$ 19	-64 $\pm$ 40	-60 $\pm$ 24

This emphasizes that shoulder flexibility should be measured and monitored in order to reduce shoulder joint loading during baseball pitching. Both ROA and SRF contribute to the results of shoulder joint loading for EPA. Loss of shoulder flexibility leads to increased shoulder joint loading, aligning with previous work (4). Further, a study showed in youth baseball pitchers that increases in forces and torques of the shoulder can lead to deformation of soft tissue leading to injury over time (5). These differences could be contributed to different age populations and pitching styles or mechanics. In conclusion, shoulder external rotation flexibility measured during physical exam is related to shoulder joint loading during baseball pitching.

## Significance

High shoulder flexibility is advantageous in baseball pitchers because it lowers the forces and torques on the shoulder joint. High shoulder external rotation range before any resistance (ROA) may reduce the risk of injury during baseball pitching. Shoulder flexibility could serve as a screening that could aid clinicians and coaches in prospectively identifying players at risk for developing arm injuries during the season.

# Shoulder Rotational Properties During Physical Exam Are Related to Performance and Injury During Baseball Pitching

Hannah L. Stokes<sup>1</sup>, Nigel Zheng<sup>1</sup>, Koco Eaton<sup>2</sup>

<sup>1</sup>University of North Carolina at Charlotte, NC, <sup>2</sup>Tampa Bay Rays and University of South Florida, FL  
nzheng@unc.edu

## Introduction

Increasing both shoulder external rotation and angular velocity during baseball pitching improves performance but also increases the risk for injury. Developing the kinetic chain increases both the shoulder external rotation angle and shoulder angular velocity which increase ball speed and performance (1). A study showed that increasing ball speed also increased the risk for injury (2). Improving performance and reducing injuries are a focus for both coaches and players.

The purpose of this study is to investigate how shoulder rotational properties measured during a physical exam are related to performance and injury during baseball pitching. This connection could create a quantitative measurement and predictor for baseball performance and injury. We hypothesize that shoulder rotational properties during physical exam are not related to shoulder kinematics during baseball pitching.

## Methods

The study included 177 college pitchers (height:  $186 \pm 7.2$  cm and weight:  $188 \pm 19.6$  lbs). The study protocol was approved by an institutional board, and all participants gave written informed consent. Self-reported injury questionnaires were filled out when pitchers were tested and then during follow-ups (95 of them were followed at least for one year). The following shoulder rotational properties: end-point angle (EPA), shoulder rotational flexibility (SRF), and resistant onset angle (ROA) were previously defined (3). They were measured and calculated during a physical exam using a custom-made wireless device.

Ten fastball pitching motions were collected at 240 Hz using a motion capture system. A custom MATLAB program was calculated the following shoulder kinematic variables: maximum external rotation angle (ERA), timing of ERA (PERA), maximum internal rotation angular velocity (IRV) and timing of IRV (PIRV) throughout the pitching cycle. Timing variables PERA and PIRV were normalized based on the lead foot contact (0%) and the ball release (100%). One-way analysis of variance (ANOVA) with Tukey post-hoc tests were performed using SPSS with an alpha set to 0.05. The chi-squared test was performed on the follow up injury questionnaires.

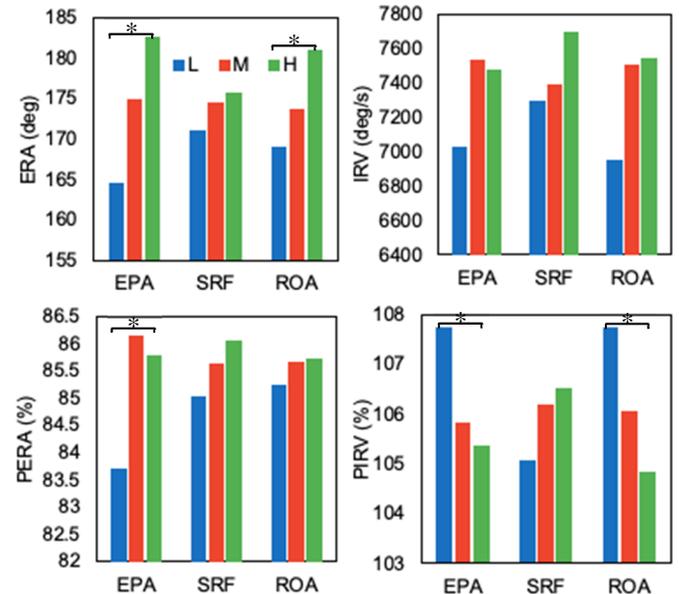

**Table I:** Results from gun speed (mph) of baseball pitch and follow-up injury questionnaires (total number of elbow and shoulder surgeries).

Group	EPA			SRF			ROA		
	L	M	H	L	M	H	L	M	H
n	33	114	30	23	126	28	26	121	30
Gun Speed	76 $\pm 5$	77 $\pm 5$	78 $\pm 5$	77 $\pm 4$	77 $\pm 5$	78 $\pm 5$	77 $\pm 4$	77 $\pm 5$	78 $\pm 5$
Surgery	0	12	2	0	9	5	3	10	1
NoSurgery	19	58	18	14	71	10	11	67	17

## Results and Discussion

Shoulder ERA, PERA, and PIRV were significantly different among the three EPA groups (Figure 1). Shoulder ERA and PIRV were significantly different among the three ROA groups. No significant difference was found among the three SRF groups. There was no significant difference in gun speed (Table 1). There

was a significant difference in follow up surgeries among SRF groups ( $p=0.02$ ). There was no significant difference in follow-up surgeries among EPA ( $p=0.13$ ) or ROA ( $p=0.41$ ) groups.

**Figure 1:** Shoulder rotational properties versus the ERA and IRV values and timings during baseball pitching (\* indicates  $p < 0.05$ ).

Findings of this study emphasizes that shoulder rotational properties should be measured and monitored in order to improve performance and reduce injury during baseball pitching. Increased shoulder range of motion increases both ERA and gun speed, aligning with previous work (4). Our results showed many factors influence the incidence of injury, including the following: joint loading, flexibility, experience of pitcher and pitching styles or mechanics, aligning with previous work (5). In conclusion, shoulder rotational properties measured during physical exam are related to both performance during baseball pitching and risks for injuries.

## Significance

Greater shoulder external rotation is advantageous in baseball pitching because it reduces joint loading and increases ball speed. Shoulder rotational properties during physical exam should serve as a screening that could aid clinicians and coaches in prospectively identifying players who will perform best and reduce injury throughout the season.

## Acknowledgments

This study is funded by a Clinical Research Grant from Major League Baseball.

# Knee Kinetics in Baseball Hitting and Their Implication for Return to Play After Anterior Cruciate Ligament Reconstruction

Kevin A. Giordano<sup>1</sup>, Meredith Chaput<sup>2</sup>, Adam Anz<sup>3</sup>, James Andrews<sup>3</sup>, Gretchen D. Oliver<sup>1</sup>  
<sup>1</sup>Sports Medicine and Movement Laboratory, Auburn University School of Kinesiology, Auburn, AL  
<sup>2</sup>Ohio University, Athens, Ohio  
<sup>3</sup>Andrews Research and Education Foundation, Gulf Breeze, FL  
 Email: KAG0070@auburn.edu

## Introduction

Anterior cruciate ligament (ACL) tears are the most common injury requiring surgery among high school athletes.<sup>1</sup> In baseball, ACL tears are more prevalent in position players than pitchers.<sup>2</sup> Position players are required to complete short bursts of maximal exertion from a static position, often including high rotary movements, like hitting. However, kinetics at the knee in hitting have not been described in the literature.

Despite the large incidence of ACL tears and ACL reconstruction (ACLR), there are very few sport specific measures for return to play (RTP). Therefore, the purpose of this study was two-fold (1) to describe knee kinetics in baseball hitting and (2) to provide clinicians a tool to predict knee kinetics based on easily accessible information to help individualize rehabilitation protocols for safe RTP.

## Methods

Nineteen high school baseball athletes (16.3 ± 0.8 yrs, 180.6 ± 5.7cm, 78.4 ± 10.8kg) participated. Participants completed a self selected independent warm up in preparation to give game-effort swings. Participants took ten swings off a tee. The swings with the top three exit velocities were included for analysis. Kinetic data were recorded using an electromagnetic tracking system, normalized to participant mass, and reported as external moments. Position and orientation data were obtained using Euler angle sequences consistent with ISB recommendations.<sup>3</sup>

Linear regressions were used to determine if height, mass, age and exit velocity could predict bilateral knee net, extension, internal (IR) and external (ER) rotation, valgus and varus moments and anterior force. Backwards regressions were chosen to analyse data due to the nature of the predictors being easily accessible by clinicians, who may discard unneeded information.

**Table 1:** Descriptive Statistics of Maximum Knee Kinetics

Front Knee	
Net Torque	0.32 ± 0.10
Internal Rotation Torque	0.08 ± 0.05
External Rotation Torque	0.09 ± 0.04
Extension Torque	0.20 ± 0.08
Valgus Torque	0.14 ± 0.07
Varus Torque	0.16 ± 0.06
Anterior Force	1.10 ± 0.31
Back Knee	
Net Torque	0.41 ± 0.17
Internal Rotation Torque	0.15 ± 0.09
External Rotation Torque	0.16 ± 0.07
Extension Torque	0.14 ± 0.10
Valgus Torque	0.13 ± 0.06
Varus Torque	0.10 ± 0.06
Anterior Force	0.75 ± 0.20

Torques given in Nm/kg body mass, forces given in N/kg body mass

## Results and Discussion

Descriptive statistics of selected kinetic variables are displayed in Table 1 and regression equations in Table 2. Kinetic variables chosen for inclusion were based on their directionality mechanically stressing the ACL.<sup>4,5</sup>

**Table 2.** Backwards Regression Equations

	F	R <sup>2</sup>	p
<b>Front Knee</b>			
(IR) <sup>'</sup> = -0.268 + 0.027(age)	4.51	.163	<b>0.049</b>
(ER) <sup>'</sup> = 1.243 - .007(cm) + .002(kg)	4.74	.294	<b>0.024</b>
(Ext) <sup>'</sup> = 2.371 - .018(cm) + .005(kg) + .043(age)	5.49	.427	<b>0.010</b>
(Var) <sup>'</sup> = 1.331 + .002(EV) - .009(cm) + .003(kg)	3.59	.301	<b>0.039</b>
(Ant) <sup>'</sup> = 10.692 - .082(cm) + .026(kg) + .194(age)	10.44	.611	<b>0.001</b>
<b>Back Knee</b>			
(Net) <sup>'</sup> = 0.588 - .016(cm) + .169(age)	3.57	.313	<b>0.019</b>
(Vlg) <sup>'</sup> = 1.552 - .012(cm) + .006(kg) + .020(age)	3.66	.307	<b>0.037</b>

<sup>'</sup> denotes predicted value, IR = internal rotation torque, ER = external rotation torque, Ext = extension torque, Vlg = valgus torque, Var = varus torque, Ant = anterior force, EV = exit velocity in MPH, cm = height in cm, kg = mass in kg, age = age in years

Using predictors age, height, mass and ball exit velocity, we were able to predict IR, ER, extension and varus torques and anterior forces in the front knee. This is clinically meaningful, because our strongest predictor, anterior force, most directly stresses the ACL.<sup>4</sup> In the back knee, we were able to predict net and valgus torques. This is clinically significant as valgus stress is a commonly known risk factor for ACL injury.<sup>6</sup>

To our surprise, ball exit velocity was seldom a predictor of knee kinetics, and height was a negative predictor. Age and mass were positive predictors as expected. These equations can be used by clinicians to predict knee kinetics in baseball players after ACLR and compare to kinetic values of traditional ACL rehabilitation exercises, to safely initiate hitting programs.

## Significance

To the author's knowledge, this is the first study describing knee kinetics in baseball hitting. These values can be used by clinicians to determine when it is safe to initiate hitting after ACLR, and adds sport specific measures to general ACLR rehabilitation protocols.

## Introduction

Softball hitting initiates proximal to distal kinetic chain sequencing by transferring mechanical energy sequentially from the lower extremities to the trunk, humerus, forearm, and hand [1]. Based on the summation of speed principle, hand velocity is maximized just before ball contact and is therefore used as an indicator of hitting performance [1, 2]. Although efficient energy transfer is essential to maximizing hand velocity, previous softball hitting research has yet to examine the association between patterns of mechanical energy transfer and hitting performance.

Energy flow analysis can be used to provide a deeper understanding of how energy flows throughout the kinetic chain during hitting. Recent studies examining the baseball pitch and tennis serve have reported relationships between the magnitude of energy flow into the upper extremity and ball velocity [3, 4]. Therefore, the purpose of this study was to investigate the relationship between humeral segment energy flow during the acceleration phase of the softball swing and lead hand angular velocity at ball contact. It was hypothesized there would be a relationship between net and maximum rates of segment energy inflow (IF) and outflow (OF) with hand velocity.

## Methods

Twenty-five female collegiate softball athletes (20.4±1.7yr; 166.7±22.0cm; 74.9±15.9kg) participated and were currently active on a playing roster as well as injury free for the past six months. Participants performed three maximum effort swings off a stationary tee placed in the middle of the strike zone. An electromagnetic system and force plate were used to collect kinematic and kinetic data during each swing. Data were analyzed during the acceleration phase, defined as the period from stride foot contact to ball contact.

The rate of work done on or by the humerus at the distal (elbow) and proximal (shoulder) joints were calculated using equations 1 and 2, respectively. The individual joint force power (JFP) and segment torque power (STP) terms were summed to calculate total humeral segment power (SP) using equation 3.

- (1)  $JFP = (\text{joint reaction force}) \cdot (\text{linear joint velocity})$
- (2)  $STP = (\text{joint moment}) \cdot (\text{humeral angular velocity})$
- (3)  $SP = (JFP_{\text{distal}} + STP_{\text{distal}}) + (JFP_{\text{proximal}} + STP_{\text{proximal}})$

Total SP was integrated over the acceleration phase to calculate net segment energy transfer. Further, SP was separated into positive (IF) or negative (OF) components to determine net energy gained and transferred out of the humerus, respectively. Pearson product-moment correlations were used to determine relationships between humeral segment IF and OF during the acceleration phase with angular hand velocity at ball contact.

## Results and Discussion

The results support the hypothesis indicating a relationship between humeral energy OF and angular hand velocity. Significant negative correlations between humeral OF and hand velocity ( $r=-.72, p<.01$ ) along with maximum rate of humeral OF and hand velocity ( $r=-.69, p<.01$ ) (Figure 1a, 1b) were observed. Angular hand velocity increased with increased magnitude of humeral OF. However, the hypothesis for energy IF was not supported.

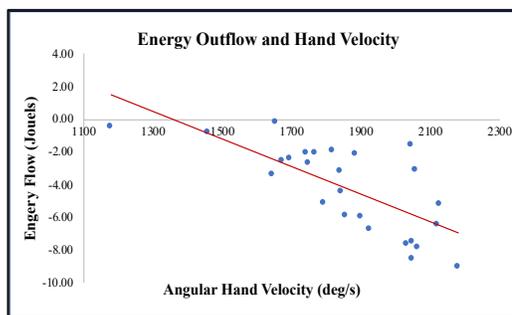

Figure 1a. Outflow and hand velocity

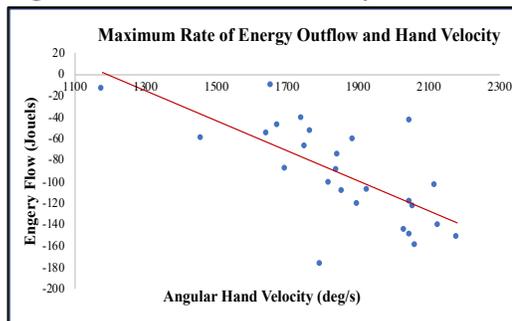

Figure 1b. Maximal OF and hand velocity

## Significance

Softball hitting performance is strongly associated with humeral segment energy OF. However, future studies should examine JFP and STP components to more precisely isolate energy IF and OF at the segment's proximal and distal ends in addition to determining the relative linear and angular contributions towards humeral OF.

Efficient energy flow through the kinetic chain is essential to optimizing performance during hitting [1]. This study illustrated a strong relationship between humeral OF and hand angular velocity at ball contact; therefore, energy flow analysis can be used as an additional tool to provide a deeper understanding of how energy is generated, absorbed, and transferred through body segments during softball hitting.

# Segmental components of induced velocity and power of a pitched baseball in collegiate baseball players

Arnel Aguinaldo,<sup>1</sup> Kristen Nicholson,<sup>2</sup> Gordon Alderink<sup>3</sup>

<sup>1</sup>Department of Kinesiology, Point Loma Nazarene University, San Diego, CA, USA

## Introduction

In an open kinetic chain such as baseball pitching, the velocity of the throwing arm is affected by the mechanical power through the chain via coordination of proximal-to-distal segmental motion, where muscular torques can induce accelerations of anatomically remote segments through dynamic coupling [1,2]. However, traditional inverse dynamics approaches are insufficient in decomposing the components of segmental motion that contribute to the forward velocity of the pitched ball [3]. Previous researchers have implemented induced acceleration analysis (IAA) models to perform this decomposition in baseball pitching but did not include lower body contributions [1,4]. Hence, the purpose of this study was to use a full-body IAA to examine how muscular and non-muscular torques contribute to the forward velocity of a pitched ball off a mound in collegiate baseball players. A secondary aim was to examine how these components contribute to the induced power of the throwing arm.

## Methods

This retrospective study was approved by the institutional review board at Wake Forest University. Data from 17 collegiate pitchers (age =  $20.4 \pm 1.2$  years, height =  $1.87 \pm 0.05$  m, mass =  $94 \pm 7$  kg) were examined from in-season pitching analyses. Each participant threw 12 various types of pitches to a catcher at a regulation distance (18.4 m) away from a mound instrumented with three force platforms (AMTI, Watertown, MA). One representative fastball was extracted for this analysis in which 3D motion data were captured at a sampling rate of 400 Hz using a marker-based motion analysis system (Qualisys, Göteborg, Sweden) [1]. Ground reaction force (GRF) data were collected at sampling rate of 1000 Hz. Ball speed was recorded with a pitch flight analysis device (Rapsodo, Brentwood, MO).

A 14-segment model was configured and implemented in Visual 3D (C-Motion, Germantown, MD). The joint accelerations were estimated using the following IAA equation:

$$\ddot{\theta} = I^{-1}(\theta)[\tau + V(\theta, \dot{\theta}) + g(\theta)]$$

where  $\ddot{\theta}$  = generalized accelerations vector,  $I^{-1}$  = inverse of the system inertia matrix,  $\tau$  = vector of the net muscular torques,  $V(\theta, \dot{\theta})$  = vector due to velocity-dependent (Coriolis, centripetal) forces, and  $g(\theta)$  = gravitational force. By taking the product of each force or torque component and the corresponding velocity vector, an induced power analysis (IPA) of the throwing arm was performed [1]. All IAA equations were derived in SD/Fast (PTC, Cambridge, MA) and implemented in Visual 3D.

The induced ball velocity was calculated by time-integrating the induced acceleration of each source between the instants of maximum knee height in the stride phase and ball release. Likewise, the mechanical work of the throwing arm was computed via time integration of the induced power between these events. The concurrent validity of the IAA model was estimated with the Spearman rho ( $\rho$ ) coefficient ( $\alpha = 0.05$ ) by

comparing the induced ball velocity with the ball speed obtained from the pitch flight device.

## Results and Discussion

The results of this IAA indicated that the largest contribution to ball velocity came from the shoulder torque followed by velocity-dependent forces (Figure 1).

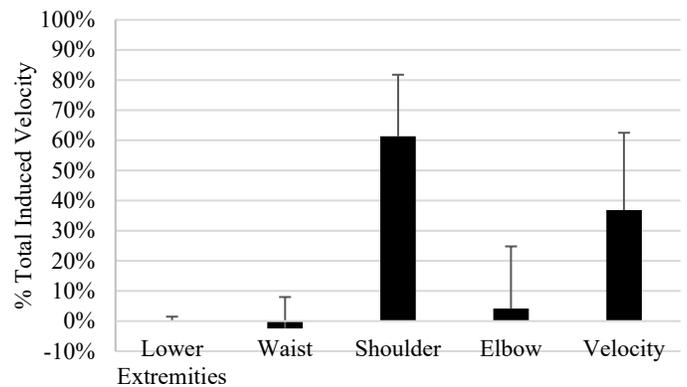

Figure 1: Mean contributions (%) to the induced ball velocity (n=17).

Similarly, the IPA showed that the velocity-dependent torque represented the largest proportion (60%) of the energy transferred to the arm at  $-0.93 \pm 0.62$  J/kg. This finding aligns with previous IPA studies which showed how pelvis and trunk motion indirectly accelerate the throwing arm via the velocity-dependent torque [1,3].

The forward velocity of the ball estimated by the IAA model was  $32.9 \pm 5.4$  m/s ( $73.5 \pm 12.1$  mph) while the recorded flight speed of the ball was  $39.1 \pm 0.9$  m/s ( $87.5 \pm 2.1$  mph), indicating an underestimation error of 16% with low concurrent validity ( $\rho = -.177$ ,  $p = .498$ ). This error could be due to the IAA model, which defines the hand and ball as one rigid segment when the ball most likely moves relative to the ball.

## Significance

These findings may challenge conventional wisdom regarding training and rehabilitation methods that are based on the current understanding of pitching biomechanics.

## Acknowledgements

The authors thank Tom Kepple of C-Motion for the development of the IAA plug-in and for his technical contributions.

## Proximal to Distal Sequence is Predicted by the Fibonacci Sequence

<sup>2</sup>Other affiliations are optional for the abstract, but will be entered into the submission portal and will be searchable

Email: weimawh@auburn.edu

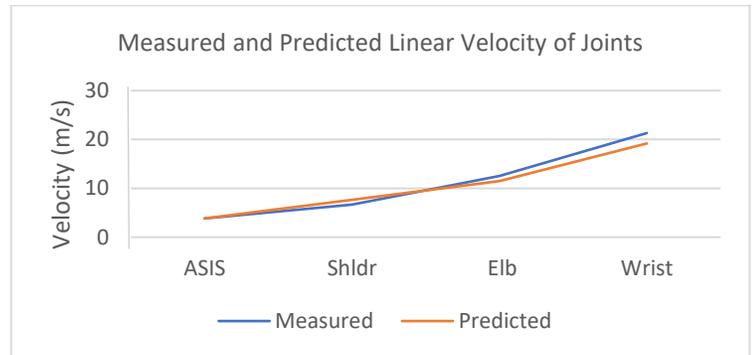

### Introduction

Proximal to distal sequencing is a method of understanding the summation of speed principles proposed by Bunn in 1971. The premise of proximal to distal sequencing is that human limbs will begin in a position that provides for a decreased mass moment of inertia. As the performer progresses through the motion, in this case the overhand throw, the adjacent, more distal segment will extend, thus adding the velocity of the more proximal segment. This progressive increase from proximal segments to distal segments can be seen in many different movements and many theories have been proposed to explain this successive increase in speed, yet a definitive explanation eludes researchers.

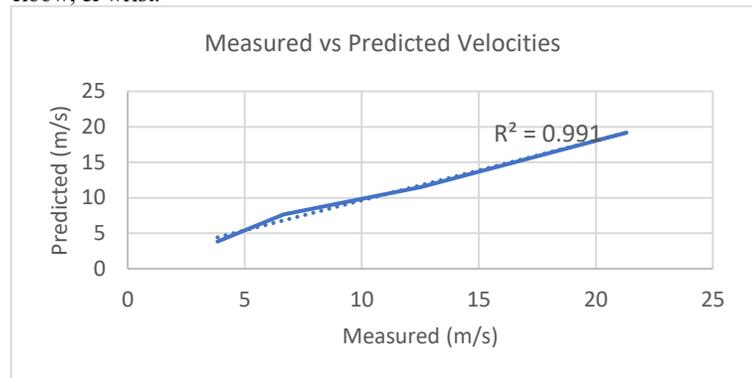

In considering an explanation for this increase in speed progression, a mathematical sequence was sought. The sequence that was first to mind was the Fibonacci Sequence as its pattern has been found in other areas of nature. The Fibonacci Sequence starts with the number 1 and proceeds as the sum of the previous two numbers. In this manner, it starts with 1, the second entry is  $1+0=1$ , the third entry is  $1+1=2$ , the fourth entry is  $1+2=3$ , and so on. Fascinatingly, the ratio of the adjacent pairs is equivalent to the Golden Ratio which has been identified throughout nature including in the relationship between the variations of lengths of several anatomical segments, such as the length of the upper arm to the forearm. This relationship has also been found in the temporal components of the human gait cycle. However, the correlation of this sequence to velocities remains limited. Therefore, the purpose of the present project endeavoured to determine if the increases in speed associated with proximal to distal sequencing could be predicted by the Fibonacci Sequence.

### Methods

Kinematic data collected for an unrelated project on overhand throwing was acquired and served as the measured data for this project. Ten right handed male collegiate baseball pitchers served as participants and kinematic data were captured with a 3D automated tracking system (Motion Analysis Corp.). The right Anterior Superior Iliac Spine (ASIS) was chosen as the beginning of the Fibonacci proximal-to-distal sequence of linear velocities in the direction of throw. As a result, the velocity of the right ASIS formed the initial number in the sequence (the initial "1's" of the previously mentioned sequence). Predicted right shoulder velocity was calculated as the sum of right ASIS and right ASIS. The right elbow predicted velocity was the sum of the velocities of the ASIS and the shoulder. Last, predicted right wrist velocity was calculated as the sum of the shoulder and elbow predicted velocities. A regression analysis was then conducted on the predicted and measured velocities.

**Figure 1:** Measured versus predicted velocities of the ASIS, shoulder, elbow, & wrist.

**Figure 2:** A scatter plot of the predicted values of velocity vs the measured values of velocity for the ASIS, shoulder, elbow and wrist.

### Results and Discussion

Figures 1 and 2 present the relationship between the two data sets. The value of Figure 1 is in the pictorial relationship between the two data sets. The value of Figure 2 is in the presentation of the coefficient of determination. Based on the strength of the coefficient of determination, it is clear that there is a strong relationship between the measured and calculated values. Under further scrutiny, two participants deviated from the predicted values to a greater extent than the other participants (not enough to be outliers) and it was revealed that these participants were recovering from injuries. The primary finding of this project is two-fold: (1) the velocity of the wrist can be predicted from the velocity of the ASIS; (2) there is a strong relationship between the peak linear velocity of the ASIS and the wrist velocity of the overhand pitch.

### Significance

From a training perspective, the importance of being able to develop pelvic girdle velocity cannot be overstated. Further, the anecdotal finding of being able to identify injured throwers from this analysis may have implications for the prevention of injuries.

# Using IMUs to Quantify Throw Counts and Intensities in Youth Baseball Players

Michael J. Rose<sup>1</sup>, Katherine A. McCollum<sup>1</sup>, Michael T. Freehill<sup>2</sup>, and Stephen M. Cain<sup>1\*</sup>  
<sup>1</sup>University of Michigan, Ann Arbor, MI, USA, <sup>2</sup>Stanford University, Palo Alto, CA, USA  
Email: smcain@umich.edu \*corresponding author

## Introduction

Injuries to the throwing arm, specifically the elbow, in baseball players has reached an epidemic across many age groups [1]. Of particular concern is the frequency of these injuries in younger players who have not reached musculoskeletal maturity. The rise of arm injuries has led to pitch count recommendations and guidelines by age, however, they are made on in-game pitches only and ignore the importance of warm-up throws before the game or at the start of each inning [2]. Further, current methods treat each pitch as equal intensity.

Increased measurement precision of stress on musculoskeletal structures may be possible with recent advances in wearable sensor technology. Small wearable inertial measurement units (IMUs) make it possible to capture every throw during games and practices and utilize IMU-derived data to estimate the amount of musculoskeletal stress via the level of intensity of each throw. The purpose of this pilot study was to develop a methodology to capture total throw count and to estimate the intensity of each throw accrued by adolescent (competitive) baseball players over a season of baseball.

## Methods

In our IRB approved study, a local travel 11U baseball team of 11 players (11 males, age 10-11yrs) was recruited for participation in this study. All participants provided informed consent. An inertial measurement unit (GT9X, Actigraph, LLC) and charging station were distributed to each player on the team. IMUs were configured to collect both acceleration ( $\pm 16$  G) and angular rate ( $\pm 2000$  deg/s) continuously at a sampling rate of 100 Hz. IMUs were secured 3-5 cm above the lateral epicondyle of the throwing arm of each participant using a modified protective wrist/forearm guard (EvoCharge, EvoShield, LLC). Participants were instructed to wear their IMUs during any baseball activity (*i.e.* practice and games). Every 1-2 weeks, the IMUs were collected by a study team member to download the data and reinitialize the IMUs.

We developed custom algorithms in MATLAB (The MathWorks, Inc.) to identify and classify the intensity of each throw. Two structured workouts were carried out to develop the throw identification and intensity classification algorithms.

Table 1. Participant data collection and throw data.

Participant ID	Total Days of Data	Days with Throwing	Number of Throws
01	56	30	5,110
02	35	17	3,942
03	14	8	1,020
04	34	13	1,274
05	16	7	759
06	26	5	790
07	15	5	288
08	22	7	660
09	53	18	1,240
10	24	11	2,155
11	8	3	497
		<b>Total</b>	<b>17,735</b>

We found that features of the angular velocity signal could be used to accurately distinguish throws from other common baseball movements. For the intensity classification algorithm, a collection of acceleration metrics were calculated for each throw.

## Results and Discussion

We were able to successfully utilize wearable IMUs to quantify throw counts and throw intensities over a spring/summer season of baseball. Throughout the study, we identified 17,735 throws from the 11 participants (Table 1). Compliance issues arose as participants were required to keep their own IMUs charged, and many throws were not captured because the IMUs stop collecting data when their battery is depleted.

A linear support vector machine, created from the preliminary structured workout to classify throw intensity, was applied to classify the season-long collection data (Figure 1). The results of this classification in combination with data for when participants pitched during the season suggest counting and assessing the intensity of all throws is more valuable than simply counting in-game pitches in determining player workload and thus mandating rest periods between activities.

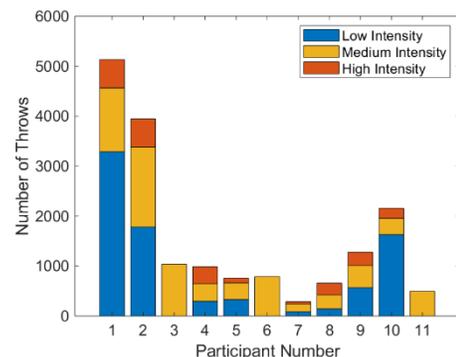

Figure 1: Intensity classification results for full-season data collection.

## Significance

A wearable inertial measurement unit (IMU) placed on the throwing arm can be used to more precisely determine musculoskeletal stress (throw count and throw intensity) during a baseball season, which is necessary to reduce injury frequency and severity, particularly in youth athletes. These data can be used to explore the relationship between musculoskeletal stress and structural changes about the elbow joint (measured via clinical tests and imaging).

## Acknowledgments

This project was supported by a grant from Major League Baseball. We thank Bethany Ruffino for helping facilitate data collections and thank the participants for diligently wearing the sensors throughout the season.

# Effect of Real-Time Feedback on Baseball Pitching Mechanics Using Inertial Measurement Units

Andrew P. Oliver<sup>1</sup> and Michelle B. Sabick<sup>1</sup>

<sup>1</sup>Saint Louis University, St. Louis, MO

Email: [andrew.oliver@slu.edu](mailto:andrew.oliver@slu.edu)

## Introduction

Overuse injuries in youth pitchers are prevalent and increasing, so prevention is a pressing concern (1). Performing an efficient pitching motion requires optimal activation of musculature and timing of major steps in the motion (2). Correcting flaws in the pitching mechanics could reduce the stress on the elbow and shoulder and possibly prevent many overuse injuries.

This study is important because it collected lower extremity kinetic data in the field using IMUs and it evaluated the effectiveness of real-time feedback given to pitchers. Pitchers threw with increased stride length, decreased stride length, and increased pelvis angular velocity in response to verbal cues. The effect of condition on velocity, ground reaction force, and kinematic measures was quantified. The use of IMUs in the field, the focus on lower extremity contributions to pitching, and the evaluation of real-time feedback are all novel aspects of the study.

## Methods

Eleven male baseball pitchers (age: 22.1±1.6ys, ht: 1.8±0.1m, mass: 85.9±12.5kg) were recruited for this study. Kinematic data were recorded with inertial measurement units (IMUs) at 200 Hz, kinetic data of the drive (rear) leg (DL) and stride (front) leg (SL) were sampled at 1000 Hz, and pitch velocity was recorded by a radar gun. Four conditions were tested: baseline (no cue, BL), increased stride length (ISL), decreased stride length (DSL), and increased pelvis angular velocity (PAV). Subjects were told to alter stride length by 10% (~6 inches) and were told to rotate pelvis as hard as was feasible for the PAV condition. The three fastest pitches for each condition were analyzed. Ground reaction force (GRF) data was normalized to body weight (BW). The components of force in the direction of home plate and in the vertical direction were recorded. Variables were compared using Pearson correlation coefficients with the p-value set at 0.05 for all statistical comparisons.

## Results and Discussion

The pitch velocity, ground reaction force values (Table 1), trunk angular velocity values, stride length (Table 2), and drive leg impulse values all significantly changed as a result of the real-time feedback cues given to the subjects. This showed that subjects were able to respond to feedback and alter their mechanics in real-time. Many of the ground reaction force variables were highly correlated to increased pitch velocity, increased peak trunk angular velocity, and increased peak pelvis angular velocity (Table 2). In some cases, individual outliers overshadowed the overall trends.

The main takeaways are that feedback can be incorporated in real-time to impact pitching performance and that there are significant differences as a result of this feedback. In addition, pitch impulse was utilized with kinematic variables to better understand the contribution of the lower extremities to pitch velocity in a more holistic way. Drive leg impulse varied significantly among three of the four pitch conditions.

GRF Variable	BL	DSL	ISL	PAV
DL Plate Dir.	56.0 ± 13.3	47.4 ± 9.6	61.3 ± 12.4	57.6 ± 12.3
DL Vertical Dir.	128.4 ± 12.4	120.4 ± 11.6	130.9 ± 12.6	128.7 ± 15.9
SL Plate Dir.	79.8 ± 13.5	84.6 ± 9.5	89.3 ± 19.2	87.3 ± 8.5
SL Vertical Dir.	144.2 ± 27.9	152.5 ± 19.2	160.7 ± 30.5	160.7 ± 26.3
Drive Impulse Plate Dir.	-15.7 ± 4.7	-13.8 ± 3.4	-17.8 ± 4.1	-16.3 ± 3.5

**Table 1.** Mean (±SD) GRF Values for each Condition (%BW).

PAV Vertical Direction	<b>0.714</b>	0.474	0.226

**Table 2.** Correlations between Normalized Drive Leg GRF and Other Pitch Variables. (**Bold** = statistically significant).

## Significance

This study demonstrates that simple verbal feedback cues can be used to significantly alter pitching performance, at least over the short term. Most subjects were able to adjust their stride length or pelvis angular velocity, which in turn affected pitch velocity. Therefore, coaches should consider telling pitchers to increase stride length and PAV as two ways of increasing pitch velocity. Significant differences were found in the stride length and pelvis angular velocity when the respective cues were given, showing that pitchers can respond to simple feedback to change their motions. This is one of the first studies to incorporate real-time feedback and its effects on pitching performance.

This study was also conducted completely in the field using IMUs. These versatile tools detected differences in lower extremity mechanics and can be valuable for collecting data outside a typical motion capture laboratory.

In addition, this is one of the first studies to utilize ground reaction force impulse values with other kinematic variables to get a more complete picture of how velocity is generated by pitchers. Future studies should investigate the same variables with a larger subject pool of high level college or professional pitchers to further understand the lower body contributions to pitch velocity.

# Utilizing Kinematic Motion Capture Data to Visually Improve Lower Extremity Mechanics of a Pitching Motion

Andrew E Bryan<sup>1</sup>, Jennifer Mathews, Jacob Howenstein, Michelle Sabick

<sup>1</sup>Biomedical Engineering, Parks College of Engineering, Aviation and Technology, Saint Louis University, St. Louis, MO

Email: andrew.bryan@slu.edu

## Introduction

Most adolescent baseball pitchers depend on their coaches and trainers to correct their throwing mechanics. Often, these instructors must rely on visual methods to identify weaknesses and suggest modifications in pitching mechanics. Three easily identifiable variables in a pitching motion are foot placement, pelvis position and pelvis rotation. With maximum shoulder anterior force shown to increase 3.0 N for every centimeter the stride foot lands towards an open position, the need to efficiently and permanently correct stride angle is imperative.<sup>1,2</sup> This study examined the relationship between pelvis orientation at the instant of stride foot ground contact, the change in orientation of the pelvis during the pitch, and the angle between the stride foot and the drive foot, referred to as stride angle. By examining kinematic data obtained from a motion capture system, thoughtful instruction can be relayed to these coaches, so that they have proper and inciteful knowledge as to how to correct potentially long lasting damage to the young athlete or uncover a more efficient manner of pitching.

## Methods

After sufficient warm-up, twenty-four male, adolescent baseball players (age:  $11.1 \pm 1.3$  yr) threw 15 fastballs at maximum effort towards a target.<sup>3</sup> Each subject was instrumented with a 32 marker, full-body marker set<sup>3</sup> and threw from a pitching mound. The three fastest pitches thrown for strikes were analyzed. Marker trajectories were tracked using Vicon Nexus Software (Vicon Corp, Oxford, UK) and filtered using a fourth-order, zero-lag, Butterworth filter with a cut-off frequency of 18 Hz using Visual 3D (C-Motion, Germantown, MD). Subjects were modelled using an eleven-segment model to compute kinematics and kinetics of each joint. The data were time-normalized to standardize the four critical phases of the pitching motion; maximum knee height of the stride leg (MKH), ground contact of the stride foot (SFC), maximum external rotation of the throwing shoulder (MIR), and maximum internal rotation of the throwing shoulder (MER). Mean values for the three trials per subject were used for all analyses. Pelvis axial rotation was calculated relative to the home plate direction.<sup>3</sup> The stride foot angle ( $\theta$ ) was calculated using the angle between the two ankles at SFC.

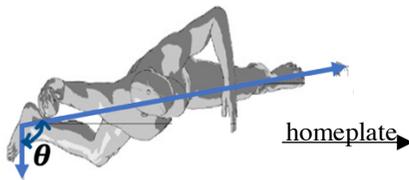

Figure 1: Measuring the stride angle using both ankle joint positions.<sup>1</sup>

## Results and Discussion

We hypothesized that the change in axial orientation of the pelvis from MKH to SFC and the final axial angle of the pelvis at SFC would be related to stride angle. Of the 24 subjects, two presented with a  $\theta$  larger than  $90^\circ$  upon SFC and three were inconsistent within their own trials. For those five subjects, average stride angle was  $95.5^\circ \pm 4.6$ . Those with a closed stance averaged a

stride angle of  $79.0^\circ \pm 5.5$ . A Pearson correlation coefficient ( $\alpha = 0.05$ ) was calculated for both the change in pelvis orientation from MKH to SFC (Fig. 1) and the pelvis orientation at SFC with respect to the stride angle (Fig. 2). The correlation between the change in pelvis orientation and stride angle was 0.358 ( $p=1.55 \times 10^{-14}$ ) while the correlation between the pelvis orientation and stride angle was 0.017 ( $p=3.21 \times 10^{-6}$ ). Therefore, both correlations were statistically significant, but practically very weak.

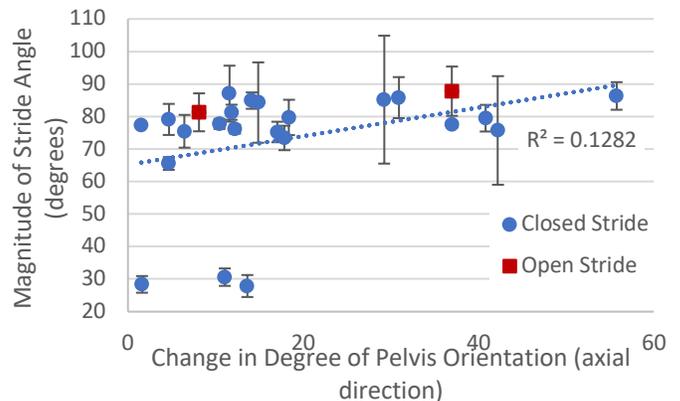

Figure 2: The magnitude of the stride angle compared to the change in pelvis orientation from MKH to SFC yields a weak correlation.

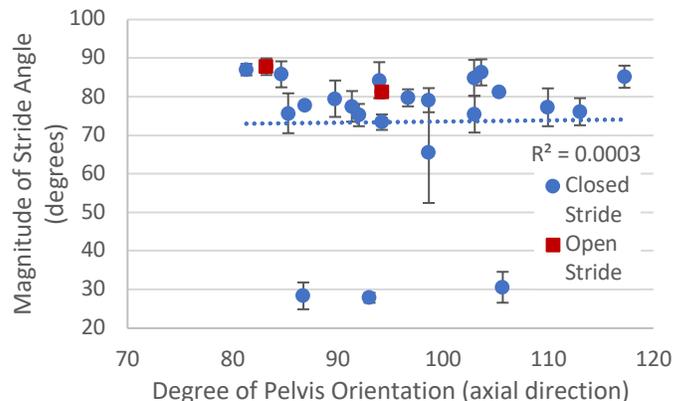

Figure 3: Comparison of the pelvis orientation at SFC and the stride angle yields a weak correlation.

## Significance

Observing the change in axial orientation of the pelvis through MKH to SFC or pelvis orientation at SFC is not strongly correlated with the stride angle; therefore, it is not advisable for coaches of the sport to solely fixate on pelvis rotation when trying to correct an inappropriate stride offset. Until future work is completed, instructors of the sport must continue to make direct adjustments to the position of the stride foot at SFC as opposed to observing prior cues and revising those preceding mechanics.

## Introduction

Injuries between the L4-S1 vertebrae are extremely common in the golfing community. This is due to a four times larger compressive load being applied to the L4-L5 during each swing. Sean Foley, world renowned golf coach has reported seeing lower back issues in 80% of his students and claims lower back injuries lead to secondary injuries in the shoulders, wrists, and elbows (Floey,2010). Such injuries are common among those who play a draw-shot due to increases in pelvic angles combined with rotation. Therefore, it is our goal to create a musculoskeletal (MSK) model and simulation of an elite golfer to analyze the golf mechanics during a standard swing to grasp a better understanding of how the lumbar moves through its range of motion. The results from this case study will be used to develop a patient-specific protocol that will be later used to develop a database of relationships between lateral and anterior pelvic tilt with the rotational moments of the L4-L5 vertebrae.

## Methods

The subject, a 20 year old male (57.6 kg) collegiate golfer with an official United States Golf Association (USGA) handicap of +1, performed three repetition draw shot swings barefooted. The elimination of shoes was enforced to limit the effects of shoes on the ground reaction forces.

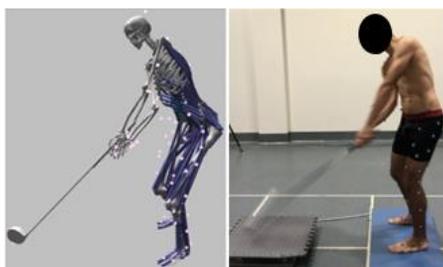

Figure 1: left: OpenSim MSK Model. Right: Subject within the motion capture lab.

Kinematic and kinetic data obtained from the dynamic swing trial was recorded using motion capture system (VICON Nexus, version 2.7; Oxford Metrics Ltd.) and two force plates ((OR6 2000 series; 1000 Hz; Advanced Medical Technologies Inc.). This data was then applied to a modified computational MSK model (Raabe,2016). Within this model, a driver was added as a segment to help scale the virtual driver to the experimental driver (Mahadas,2018). Most drivers are cut to different lengths to accommodate different players so it is important for this segment to be scaled properly. Marker placements followed the marker set from the Raabe model (Raabe,2016). Each segment is defined using 2-3 landmark markers and between 5-6 tracking markers with very heavy focus on the lower extremities given that is where the power is generated in a golf swing. Furthermore, the most common spinal injury for golfers occurs between the L4 and S1 vertebrae. Therefore, additional markers were added to the T10, T12, L3, and L5 vertebrae. The T10 and T12 were chosen since they are the lower portion of the thoracic spine closer to the lumbar. More specifically, the T12 since it is what connects the thoracic to the lumbar regions of the spine. The L3 and L5 were chosen since they are the midpoint and endpoints of the region of interest. The driver also had two markers: one on the driver's grip and the other on the head to aid in scaling. Inverse kinematics and

dynamics were then performed to calculate joint angles and joint moments at each instant during the swing cycle. The subject naturally hits a draw shot shape in turn designating him a draw shot player. Although this makes him inherent to injuries between the L4-S1 vertebrae, he is currently free of all known musculoskeletal disorders.

## Results and Discussion

A correlation between pelvic tilt and the moments at L4-L5 vertebrae was observed: as pelvic tilt increases the L4-L5 moment also increases as seen in Figure 2. In addition, this same correlation was observed between lateral pelvic tilt and L4-L5 moment. These correlations suggest that the angles of the pelvic griddle in the setup and throughout the swing have an effect on the loads being applied to the lumbar spine.

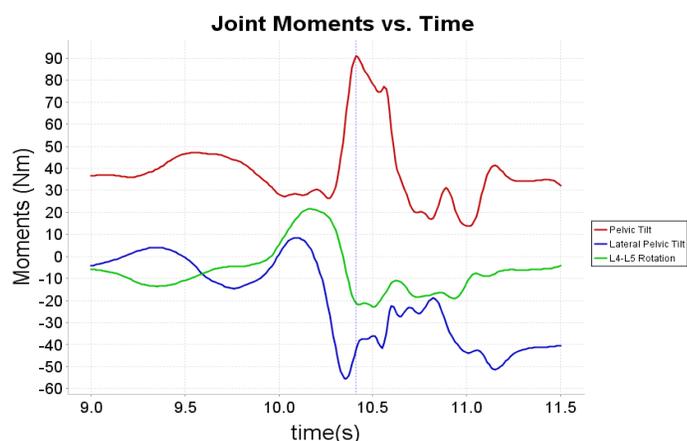

Figure 2: Shows the pelvic tilt and lateral tilt moment, and the L4-L5 rotational moment vs. time during one golf swing.

## Significance

The importance of this case study is that it shows the potential for reduction in injuries of the lumbar spine through precision treatment. There is a potential to use these results to reposition the athlete in a less anterior and lateral pelvic tilt. If justified, this could be used by medical professionals, and athletic coaches to prescribe biomechanical adjustments in the golf swing in order to reduce the number of lumbar injuries around the world.

## Acknowledgments

This study was conducted in the Embry-Riddle Biomechanical Analysis Laboratory under the assistance of graduate students Yeram Lim Sr. and Tyler Farnese.

# A Comparison of Filtering Techniques applied to Baseball Pitching Data

Stephen M. Cain

University of Michigan, Ann Arbor, MI, USA

Email: smcain@umich.edu

## Introduction

In traditional, lab-based, biomechanics analyses, positions of optical markers on body segments of interest are measured and used to calculate segment positions, orientations, and joint angles. Body segment linear accelerations, angular velocities, and angular accelerations required to estimate joint kinetics via inverse dynamics must be calculated through numerical differentiation of position and orientation data. Position data must be smoothed before differentiation because differentiation can amplify small errors in position data [1]. Proper data smoothing can attenuate the noise content while leaving the true data signal unaffected, whereas improper signal processing can result in large errors in the kinematics calculated by differentiation [2].

Inertial measurement units (IMUs) enable direct measurement of the linear acceleration and angular velocity of any rigid body to which they are attached and therefore provide ideal measurements for evaluating position data filtering techniques. In this study, data collected during a baseball pitch by a wrist-mounted IMU is used to generate position data, which is then used to evaluate common data smoothing approaches.

## Methods

In this IRB approved study, a wrist-mounted IMU (Opal, APDM, Inc.) measured the linear acceleration ( $\pm 200$  g) and angular velocity ( $\pm 2000$  deg/s) of the participant's throwing arm using a sampling rate of 800 Hz while the participant (an elite pitcher) completed a 32-pitch bullpen session. Angular velocities that exceeded the measurement range were extrapolated using cubic splines. Position data for a triad of simulated optical markers rigidly attached to the forearm IMU were generated from the measured acceleration and angular velocity by using inertial navigation techniques [3]. The primary marker was placed in the same location as the IMU; the other two markers were placed 0.1 m proximal and lateral from the primary marker, respectively. These noise-free position data were sampled at a range of common motion capture sampling rates (240, 300, and 500 Hz, [4-6]). White Gaussian noise (mean = 0, standard deviation = 0.001 m) was added to the sampled position data to simulate real data. These data were smoothed using 4<sup>th</sup> order Butterworth low-pass filters with set cut-off frequencies (6, 13.4, and 18 Hz, [4-6]) and a cut-off frequency determined from an autocorrelation-based procedure (ABP [7]), a generalized cross-validated quintic spline (GCV [8]), and a predicted mean squared error quintic spline (MSE [8]). The smoothed position data were used to estimate the original IMU-measured linear acceleration ( $a$ ) and angular velocity ( $\omega$ ). The error was quantified by the magnitude of the difference between estimated and measured values starting 200 ms before and ending 100 ms after ball release.

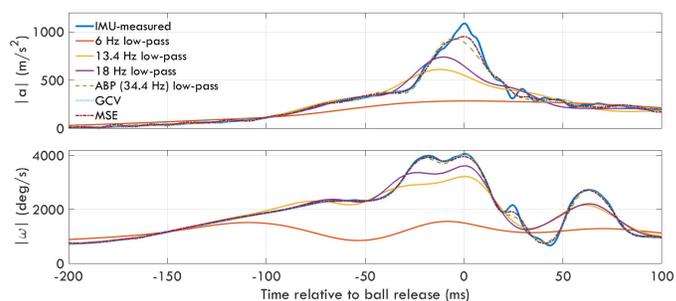

## Results and Discussion

Table 1 provides summary data for a simulated motion capture sampling frequency of 500 Hz; lower sampling rates resulted in larger errors. Data from a representative pitch (Figure 1) illustrates the significant errors in estimates of linear acceleration

and angular velocity that are created by improper data smoothing. No filtering technique resulted in estimates that were in full agreement with the original IMU-measured data. The results here suggest that employing a quintic spline smoothing algorithm (GCV or MSE) will yield the most accurate estimates of linear acceleration and angular velocity. Other filtering techniques should be explored with the approach above to identify a superior filtering technique for pitching and similar dynamic movements.

**Table 1:** Root mean squared (RMS) and maximum errors due to data smoothing across 32 pitches for a simulated motion capture sampling frequency of 500 Hz (values = mean (standard deviation)).

Filter	RMS Error		Maximum Error	
	$ a $ ( $m/s^2$ )	$ \omega $ ( $^\circ/s$ )	$ a $ ( $m/s^2$ )	$ \omega $ ( $^\circ/s$ )
6 Hz	258 (13)	1502 (71)	851 (40)	3432 (252)
13.4 Hz	183 (12)	647 (76)	581 (40)	1723 (182)
18 Hz	157 (13)	454 (51)	480 (40)	1307 (138)
ABP	72 (7)	128 (19)	270 (34)	438 (69)
GCV	55 (6)	68 (6)	206 (32)	244 (39)
MSE	55 (5)	69 (6)	206 (30)	239 (33)

**Figure 1:** Acceleration (top) and angular velocity magnitudes (bottom) versus time relative to ball release (defined by the time of maximum forearm linear velocity) for one pitch (2-seam fastball, 90.4mph).

## Significance

Accurate measurements of body segment linear accelerations, angular velocities, and angular accelerations are critical for calculating joint kinetics dominated by large body segment kinematics. IMUs can provide ideal measurements for accurately calculating joint kinetics as long as the detrimental effects of soft tissue motions between IMUs and bone can be minimized.

# Comparison of Hip Biomechanics During a Half and Full Golf Swing in Male Amateur Golfers

Christopher S. Wendt<sup>1</sup>, Audrey L. Millar<sup>1</sup>, Kelly Boss<sup>1</sup>, and Chloe Gilgannon<sup>1</sup>  
<sup>1</sup>Department of Physical Therapy, Winston-Salem State University, Winston-Salem, NC  
Email: [wendtc@wssu.edu](mailto:wendtc@wssu.edu)

## Introduction

Golf has become a very popular sport worldwide, recently growing to approximately 33.5 million participants in the United States alone.<sup>1</sup> According to the National Golf Foundation's 2019 Participation Report, an estimated 15% of beginners in 2018 were over the age of 50. With an increase in middle-aged, committed participants, so does the risk for lower extremity pain, injury and/or surgery. Research has shown that though some participants report hip pain following golfing activities, most are eager to continue to play.<sup>2</sup> This presents a challenge for clinicians to determine the best protocol and progression to allow the patient to safely return to golf.

A common recommendation for those wishing to return to golf after a lower extremity injury or surgery is to use a half swing, however, there is little evidence to support that this significantly reduces the motion or muscular torque at the hip. The purpose of this study was to compare and evaluate the positions and internal torques of the hip during a half and a full golf swing in male amateur golfers.

## Methods

Eleven healthy, amateur golfers volunteered to participate in this study. All participants were right-handed males, with a reported handicap of less than 20. Each golfer completed 10 full swings, followed by 10 half swings, instructed by a standardized script. Kinematic and kinetic data was recorded by a 10-camera motion capture system with a force platform under each lower extremity collecting ground reaction forces. A launch monitor recorded ball impact characteristics including club head velocity (CHV).

A 3-D modeling program was used for swing phase identification, data reduction, and standard inverse dynamic calculations to determine internal net joint torques. Participant demographics, internal hip torques (Nm; normalized by %BW\*Ht) and hip positions (degrees) in all 6-degrees-of-freedom were analyzed in SPSS (v25). Repeated measures ANCOVAs (full swing CHV in mph as the covariate) and Pearson-Product Correlations were used to compare hip biomechanics during half and full golf swings, with significance level set at  $p < .05$ .

## Results and Discussion

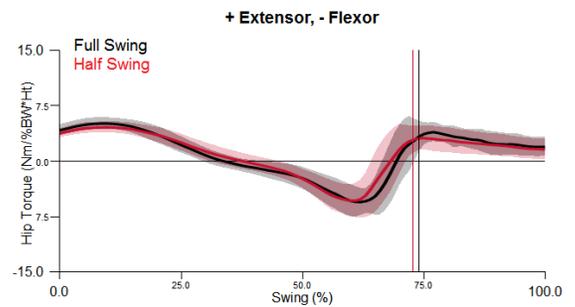

Participants ( $44 \pm 16$  years) reported an average handicap of  $13 \pm 6$ . Full swing CHV averaged  $91 \pm 12$  mph, consistent with average male amateur golfers. Peak trail hip extensor torque [Figure 1] was the largest internal torque produced in both half ( $12.04 \pm 2.07$  Nm/%BW\*Ht) and full swings ( $12.02 \pm 1.97$  Nm/%BW\*Ht). Peak lead hip flexor and abductor, and trail hip abductor torques were next largest, respectively, in both swing styles.

There were no statistically significant differences found in peak internal hip torque production between half and full golf swings when controlling for CHV. With respect to peak hip position, there were no significant differences found between half and full swings, with the exception of peak lead hip flexion ( $p = .017$ ). Correlational analysis showed strong, statistically significant correlations between each half and full swing peak hip

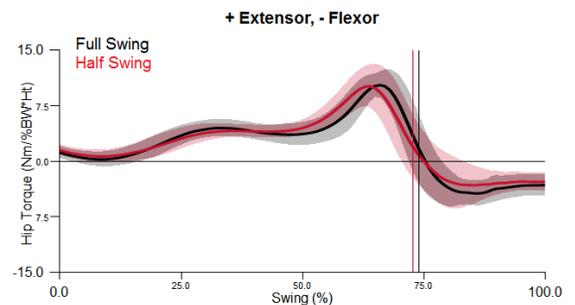

torque (ranging from  $r = .71$  to  $r = .98$ ) and position (ranging from  $r = .85$  to  $r = .99$ ).

Overall, peak hip joint torques and positions during a half golf swing were found to be comparable to those in a full golf swing. This suggests that reducing the length of the backswing may have minimal effect on demands at the hip in male amateur golfers.

## Lead

## Trail

**Figure 1:** Mean sagittal hip torques (Nm/%BW\*Ht) of the lead and trail limbs in a full (black) and half (red) golf swing.

## Significance

In the present study, our data revealed no significant reductions in internal torque at either the lead or trail hip when performing a half golf swing, as compared to a full golf swing. Peak muscular torque production around the hip in both swing styles were much higher than reported hip torques for activities of daily living, such as level-walking.<sup>3</sup> These findings suggest that clinicians should use caution in recommending a half versus a full swing for those returning to golf following an injury or surgery.

## Acknowledgments

# Problem-based Learning Improves Student Learning in Undergraduate Biomechanics

Brian J. Wallace<sup>1</sup>, Duane Knudson<sup>2</sup>, and Naghmeh Gheidi<sup>3</sup>

<sup>1</sup>Department of Kinesiology, University of Wisconsin Oshkosh, USA, <sup>2</sup>Department of Health and Human Performance, Texas State University, USA, <sup>3</sup>Department of Exercise & Sport Science, University of Wisconsin-La Crosse, USA  
Email: wallaceb@uwosh.edu

## Introduction

Student's anxiety toward the difficult, but important, subject matter of biomechanics requires instructors to develop teaching methods that allow students to most effectively learn course concepts and content. Problem-based learning (PBL) is a primarily concepts-based form of active learning (AL), and closely matches the inquiry-based process of clinicians and researchers in this area of study. It has been successfully utilized in a variety of other subject areas. No studies, however, have quantitatively investigated the effect of PBL on student learning in an undergraduate biomechanics course for kinesiology or exercise and sport science students. Therefore, the purpose of this study was to objectively quantify the effect of PBL on student learning in such a course. A secondary aim was to identify student perceptions of the PBL technique's implementation. We hypothesized that PBL would increase student learning to a similar degree as other AL techniques and that students would view the PBL approach positively.

## Methods

Students (n=109) in three introductory biomechanics classes at two comprehensive universities participated. The courses were three credit-hours of effort including lab. The content taught in each class was similar. Ethics approval was obtained prior to any student participation in concurrence with the Declaration of Helsinki and students provided written Informed Consent.

Students took a pre-test consisting of the original Biomechanics Concept Inventory (BCI) (Knudson et al., 2003) on the first day of class, and a post-test on the last day of class. The post-test consisted of the BCI and eight additional questions on student perceptions of the PBL activities.

We implemented PBL assessments as part of the classes across seven different course topics: motions and planes, linear kinematics, angular kinematics, linear kinetics, angular kinetics, mechanics of the skeletal system, and the muscular system. A small number of low-tech AL supplemented PBL. All of the PBL assessments were based off of one or more 2D videos of: depth jumps (drop, land, rebound) and/or drop jumps (drop, land) from 12", 24", and 36" heights.

Gain scores (g), a measure of student learning that incorporates the increase in correct responses between BCI pre and post-tests, were calculated. Descriptive statistics were calculated for the eight questions of student perceptions of PBL. Descriptive statistics of BCI pre-test and learning (g) were calculated for each university, and analyzed with t-tests to compare with data from previous studies. Alpha was set at 0.05.

## Results and Discussion

Pre-test, post-test, and gain scores are in Table 1. Student learning (g) was not different (p=0.19) between the two universities (university 1: 0.23 ± 0.11, university 2: 0.26 ± 0.14). The mean (g) scores for all three classes combined were 0.25 ± 0.14, with a 95% CI of [0.22, 0.28]. Student ratings of PBL as helpful in aiding learning were also primarily (83%) positive, however 17%

of students disagreed. 95% of students believed that they worked moderately to extremely effectively together in PBL.

Table 1: Pre-test, post-test, and learning scores

	University 1	University 2	Combined
Pre-test*	8.0 ± 1.5	9.5 ± 2.6	8.9 ± 2.4
Post-test*	11.6 ± 2.0	13.4 ± 2.7	12.7 ± 2.6
Learning (g)	0.23 ± 0.11	0.26 ± 0.15	0.25 ± 0.14

Values reported as Mean ± SD. University 1 = University of Wisconsin Oshkosh (n=38), University 2 = University of Wisconsin-La Crosse (n=71); Pre-test and post-test scores are out of 24 points maximum, g range is between 0 and 1; \*Significant difference between universities (pre-test p = 0.002, post-test p = 0.009).

Learning was greater with the implementation of PBL than what has previously been reported with low-tech AL in similar courses (g=0.15 – 0.22) (Knudson, 2019a,b; Knudson & Wallace, 2019). The PBL exercises by both instructors in this study took up approximately 30 minutes of class time per topic, on average. Reducing low-tech AL and adding PBL increased student learning by 53% with the same instructor (Knudson & Wallace, 2019). PBL seems to have a disproportionately large positive effect on student learning of biomechanical concepts.

Approximately 85% of students "strongly agree(d)" to "agree(d)" that the four individual PBL exercises surveyed (linear and angular kinematics and kinetics) aided their learning of biomechanical concepts, with the rest "disagree(ing)." Students' overall impression of PBL were similarly positive. These results are encouraging in that not only did students think the PBL aided their learning, they did so even though they required some additional work outside of class with other students.

## Significance

PBL was shown to be a highly effective teaching technique for increasing student learning in undergraduate biomechanics. Students also had positive perceptions of the PBL exercise implementation, and thought that it aided in their learning of biomechanical concepts.

## Acknowledgments

We thank the students who participated.

Email: \*kfrisch@georgefox.edu

## Introduction

Project Based Learning (PBL) is a curricular structure that frames students' learning in the context of a real (ill-defined) problem, and then provides resources and guided progression through the relevant information. [1] Used extensively in medical education and increasingly in engineering, it has few application (to date) in undergraduate biomechanics classrooms. [2,3]

## Methods

### *Enrolment & Implementation*

During the F2019 semester, 22 mechanical engineering students (with previous course work in dynamics) enrolled in a senior engineering elective course on biomechanics at a teaching-focused university. Groups of 4-5 students completed the project together, submitting team deliverables and receiving a team grade, (individually modified if necessary).

### *The PBL Statement*

The challenge statement was aimed at teaching students do a biomechanical motion analysis:

One of the "hot topics" at ISB 2019 was wearable sensors as a way to capture motion "in the wild" (e.g. runners on city streets as opposed to on a treadmill in a lab). There is lots of appeal to the idea of being able to do biomechanics analysis in a natural environment but, as with any new technological advance, you need to be sure that you are getting equivalent (or relatable) data and that if you're not the benefits of the tech outweigh the loss. I am very interested in using these sensors in my research studying the swinging motions of volleyball athletes, but I want to know that my set of inertial sensors produce equivalent results to the "gold standard" techniques for a variety of motions (e.g. walking, running, throwing a baseball and hitting a volleyball).

### *Project Structure & Activities*

At the beginning of the 8-week unit, students generated a set of questions based on the PBL statement [4], including two key ones that motivated the learning experience: "what is the "gold standard"?" and "what are IMUs?" These motivated a sequence of class and lab activities to learn the basics of acquiring and analyzing force plates, motion capture, and IMU data. Once familiar with the data they could collect in the lab, students were presented with the requirements for their research project and (with instructor guidance) chose a motion to study. Each group had two 1-hour data collection sessions.

### *Project Deliverables*

The final deliverables were an ISB 2019-style abstract and a "conference" poster (presented in 5-minute quick-talks to a class conference). Scaffolding towards the final deliverables consisted of a literature review, homework on the learning the lab basics activities, and (during the data collection/analysis) group weekly progress reports (including individual learning logs for each member).

## Results and Discussion

End-of-semester responses (Table 1) show a favourable student view of PBL as a tool for learning biomechanics. Students felt prepared with adequate foundational knowledge and supported by the assignment framework. Most importantly, based on oral interviews, both students and the instructor believe they learned the subject material.

**Table 1:** Student responses (N=15) from the end-of-course feedback survey questions relating to the project.

	S.A./A	Neut	D./S.D.
The project created an effective opportunity to learn biomechanics	93%	0	7%
I felt prepared with the knowledge and tools I needed for the IMU project	80%	7%	13%
I had sufficient guidance and resources to complete the IMU project.	93%	0	7%
This course improved my ability to find and interpret information about engineering mechanics from a diverse set of sources.	80%	13%	7%
This course improved my ability to analyze biological problems, particularly relating to human movement and tissue mechanics, using basic mechanics principles.	87%	0%	13%
This course improved my ability to make meaning from a data set	93%	0	7%
Writing the abstract about our data was a valuable learning experience for me and my group.	80%	13%	7%
Creating the poster about our data was a valuable learning experience for me and my group.	67%	27%	7%
My group wrote the abstract before creating the poster.	67%	27%	7%
The in-class peer-review process was valuable for the poster and abstracts.	80%	13%	7%

## Significance

This project provides one example of what PBL might look like in a university-level biomechanics course. As with all education innovations, adaptation for other contexts will require flexible use of local resources, however, this case-study shows that the project can be done with a modest number of students, and that all parties believe that the students learned biomechanics from the experience. It is the hope of the author that this example will inspire others to dream about what project-based learning might look like in their classrooms.

## Acknowledgments

Thank you to students in ENGB 420 (F19) for experimenting, my dean, Bob Harder for funding, Robin Dorociak for lab facilitation, and the GFU DPT program for access to their lab.

# The Impact of National Biomechanics Day on Student Perceptions toward Biomechanics: A Multisite Pilot Study

Scott M. Monfort<sup>1\*</sup>, Kimberly E. Bigelow<sup>2</sup>, Srikant Vallabhajosula<sup>3</sup>, and Paul DeVita<sup>4</sup>  
<sup>1</sup>Montana State University; <sup>2</sup>University of Dayton; <sup>3</sup>Elon University; <sup>4</sup>East Carolina University  
Email: \*[scott.monfort@montana.edu](mailto:scott.monfort@montana.edu)

## Introduction

National Biomechanics Day (NBD) is a worldwide celebration of biomechanics that has exposed over 29,000 high school students to biomechanics from 2016 through 2019 [1]. Some initial evidence suggests NBD positively impacts interest, excitement, and perceived importance of biomechanics among the students [2]. These findings were however generated from a single NBD event and their generalizability is unknown in terms of different geographic locations, NBD designs, or assessment tools. We propose that while reaching large student populations is indicative of success, the educational value of NBD needs to be assessed through direct, quantitative tools.

The purpose of this study was to quantify changes in high school students' perceptions toward biomechanics after participating in NBD events held at multiple locations. Our hypothesis was that NBD would increase interest, excitement, and perceived importance of biomechanics.

## Methods

High school classes were invited to participate in independent NBD events at two biomechanics laboratories at institutions with different geographical and institutional characteristics (Montana State University and Elon University).

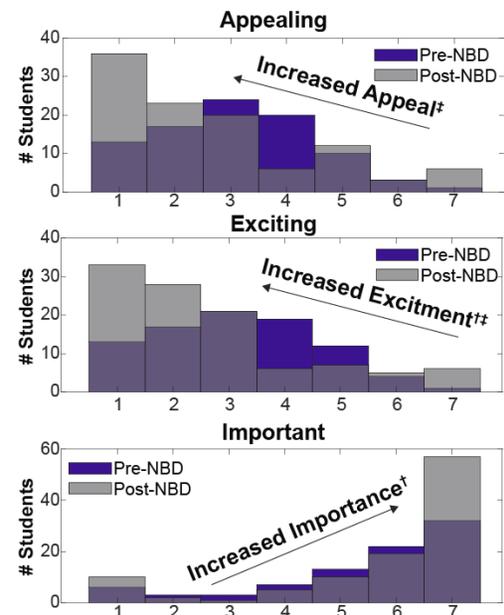

We adapted questions from the STEM Semantics Survey to develop a tool to characterize biomechanics-specific outcomes [3]. Specifically, students were asked to respond to the question "To me, biomechanics is," for four pairs of adjectives: 'appealing vs. unappealing', 'exciting vs. unexciting', 'unimportant vs. important', 'boring vs. exciting', with the last question serving as a reverse-coded validation check. Responses were on a 7-point Likert scale, and students were also given the choice of responding with 'I don't know enough about biomechanics to answer' (IDK), as we anticipated NBD was often students' first exposure to biomechanics. Students also answered questions about their interest in biomechanics-related careers and enjoyment/learning from the NBD event. A combination of Sign Tests (contrast of paired pre-post data) and Chi-Squared tests (unpaired data) were used. Missing and IDK responses were omitted from pairwise comparisons.

## Results and Discussion

Data were collected from 112 high school students, although only 109 students (16.5±1.0yr; 63/38 f/m) were included in our analyses as three surveys did not have matched pairs. Ten students provided no or partial demographic information.

Our hypothesis was largely supported as students perceived biomechanics as more exciting and important following the events compared to their paired pre-event responses (all  $p < 0.015$ ). The magnitudes of the shift in perceptions were moderate, as paired and unpaired assessments suggested a positive shift in medians of these questions of  $\leq 1$  on the 7-point Likert scale. Chi-squared analysis echoed the positive impact of NBD (Figure 1). Additionally, number of IDK responses decreased from 114 across the four adjective pairs to a total of one following NBD, which suggests that NBD was effective at

helping students form opinions toward biomechanics. While students also seemed more informed regarding biomechanics-related careers (decrease in IDK from 18 to 1), no change was observed in students seeing themselves in a biomechanics career (median = 4). Notably, students resoundingly enjoyed NBD (6.3±1.4 [7 being highest]).

**Figure 1:** Survey responses from students (omitting IDK) taken before (blue) and after (gray) NBD events (note: dark gray regions reflect overlap in pre/post bars). † indicates  $p < 0.05$  for paired Sign Test. ‡ indicates  $p < 0.05$  for Chi-Squared test.

The findings of our multi-site pilot study support the generalizability of recent findings by Teeter et al. regarding the positive impact of NBD on student perceptions of biomechanics [2]. Not only did students enjoy NBD, but the event generated excitement and perceived importance in the STEM sub-discipline. The lack of change in perceptions regarding biomechanics-related careers may mark a potential point of emphasis for future NBD events.

## Significance

Strengthening the future STEM workforce is a national priority that relies on exciting young students about STEM fields. Our research provides quantitative evidence across two institutions that NBD is well-positioned to support this goal.

## Acknowledgments

We would like to thank the many volunteers that contributed to vibrant 2019 NBD events at MSU and Elon University.

## Teacher Content Knowledge and Confidence in Youth Biomechanics Education

Amelia S. Lanier<sup>1</sup>, Anne Karabon<sup>2</sup>, Michelle Friend<sup>2</sup>, Neal F. Grandgenett<sup>2</sup>

<sup>1</sup>Department of Biomechanics University of Nebraska at Omaha

<sup>2</sup>Department of Teacher Education, University of Nebraska at Omaha

Email: alanier@unomaha.edu

### Introduction

Biomechanics plays a prominent role with young children through body and sports connections [1,2] and provides opportunities to teach STEM concepts. To enhance youth STEM education, faculty in Teacher Education and Biomechanics organized a 2-week biomechanics focused professional development (PD) workshop for middle and elementary school STEM teachers followed by a 1-week student academy. The student academy introduced students to STEM concepts through the lens of biomechanics. Student participants of the 1-week academy, hosted by the teacher participants, exhibited significant improvements in scientific inquiry skills through the use of a novel assessment tool [3]. This improvement may be due to teacher content knowledge and confidence, which is a crucial factor in student learning, especially in STEM fields [4]. Thus, the purpose of this work was to evaluate teacher STEM self-efficacy and biomechanics content knowledge over the course of the PD. We hypothesized the teachers would exhibit increases in both STEM self-efficacy and biomechanics content knowledge.

### Methods

Teacher participants included 13 teachers with elementary teaching licenses from public and private districts. The PD included biomechanics sessions, inquiry based pedagogy sessions, and biomechanics research lectures.

Teachers completed a pre and post PD Teacher Efficacy and Attitudes toward STEM (T-STEM) Survey [5] and pre and post PD interviews. Audio-recorded interview data were transcribed and biomechanics knowledge analysed using NVivo software. Efficacy measures were based on the Personal Teaching Efficacy and Beliefs construct of the T-STEM survey. Eleven questions addressed teachers' confidence in teaching science, on a scale from 1 to 5. A Wilcoxon signed rank test demonstrated significant differences in average self-efficacy score from pre- to post-PD.

### Results and Discussion

Findings from this study indicate that teachers' self-efficacy about their ability to teach science significantly increased over the course of PD (Table 1,  $p=0.006$ ). However, a review of transcribed interview data revealed limited changes to teachers' biomechanics definition pre vs. post PD. Almost all teacher participants focused on "body movement" or "how the body moves" in both pre and post responses while a limited number indicated mechanics connections through specific mechanical vocabulary in post responses.

**Table 1:** Individual T-STEM Efficacy Scores for teacher participants Pre and Post PD.

Teacher	1	2	3	4	5	6	7	8	9	10	11	12	13	Mean $\pm$ STD
Pre	3.64	2.82	4.27	3.82	3.73	4.18	3.73	3.45	3.55	3.55	3.55	3.73	4.27	3.71 $\pm$ 0.39
Post	3.55	2.73	4.36	4.36	3.82	4.82	4.18	3.82	3.55	4.00	3.82	4.00	4.36	3.95 $\pm$ 0.51

Ideally, teachers would gain both confidence in teaching science and biomechanics content knowledge through this PD, however, this was not the case. Contextual review and analysis of interviews may not be an ideal measure of biomechanical content knowledge for this particular group. Previous work indicates an increase in biomechanics and STEM inquiry skills, which can be related to biomechanics knowledge, post PD using a novel assessment tool [3]. We believe teachers are still gaining biomechanics knowledge which may not be reflected in the interviews and so additional measures will be explored.

Through this biomechanics-focused PD experience teachers gained confidence in teaching biomechanics. These preliminary results from teachers, in combination with previous results showing student learning gains, indicate continued success of the PD model and the ability to integrate biomechanics into elementary and middle school classrooms.

### Significance

Biomechanics offers teachers diverse and rich applications to teach STEM concepts in elementary and middle school classrooms. Teachers with pedagogical and scientific confidence engage students in high-quality, child-centered inquiry-based learning experiences. The first steps in integrating biomechanics learning experiences into the classroom must focus on teachers confidence in teaching and knowledge of the field. Through a 2-week PD we are confident in our ability to improve STEM efficacy and hope that this model will be utilized at additional sites.

### Acknowledgments

NSF ITEST #1759000 and RMC for evaluation of this project.

## Introduction

The STEM Early College at N.C. A&T is an early college designed to serve high-performing students with an interest in science, technology, engineering, and math. In contrast to traditional high school, the STEM Early College exposes students to engineering, technology, and advanced math courses. However, up until their senior year, STEM Early College Students have not applied what they've learn to a real-world problem. Therefore, to address this gap, our lab volunteered to assist students apply their knowledge to an interdisciplinary area of biomechanics. Research in our group includes finite element analysis (FEA) based topographical optimization, soft tissue analysis, and ACL interference screw evaluation. The purpose of this study is to describe the approach used to teach and mentor STEM Early College Students to perform FEA on human gastrocnemius for the investigation of mechanical properties in partial fulfillment of the Senior Internship Graduation Research Project.

## Methods

The Senior Research Project equips students with critical, analytical, and problem-solving skills, thus preparing students for post-secondary educational success. Students are expected to participate in Senior Seminars, which cover topics on project deliverables (e.g. annotated bibliography, research paper, oral presentation, and peer review editing). Our lab was entrusted with mentoring students achieve these deliverables. All STEM Early College Students ranked three research topics most suited for their interest. Then based off student's interest, the lab director and manager identified which of the lab's graduate students would be qualified to manage the STEM Early College Student's Senior Research Project. A mechanical engineering graduate student was selected to mentor and teach a STEM Early College Student who identified FEA of soft tissues as their research interest. The central objective of the FEA project was to determine the mechanical properties of human gastrocnemius, which was accomplished using SolidWorks, MATLAB, Excel, and Ansys. A project management sheet via Excel and Monday.com were utilized to identify and assign deliverables needed to complete FEA. The mentor provided references and instructional time to help the student become acclimated with the previously mentioned software products. References included in person step-by-step and video walkthroughs, engineering textbooks, peer reviewed articles, software help websites, and YouTube videos. The purpose of the references was to provide tips for analyzing and interpreting results, performing hand calculations (e.g. normal stress, principal stresses), creating, exporting, and importing gastrocnemius specimen models, techniques for FEA validation (e.g.  $\Sigma F = 0$ ), applying boundary conditions, and generating appropriate meshes.

**Figure 1:** Screenshot of a walkthrough video on how to probe results for normal stress in Ansys as a form of FEA postprocessing.

## Results and Discussion

Finite element analysis results of human gastrocnemius were communicated via the research paper and oral presentation for the Senior Research Project. The mentor provided the student references needed to illustrate background knowledge using peer reviewed articles on the mechanical properties and material behavior of calf muscles. The mentor also provided the student with techniques on how to visualize and extract data via contour plots, Excel spreadsheets of hand calculations, and Ansys generated data tables.

## Significance

The collaboration between our lab and the STEM Early College intends to encourage more students, particularly minority and female students, to pursue higher education in STEM. Moreover, it challenges instructors and mentors to create rudimental teaching methods that introduce high school students to in depth topics of engineering, such as FEA. Furthermore, the collaboration shows students that a career in the STEM field is attainable for people who do not identify with the majority.

## Acknowledgments

We would like to acknowledge B.I.O.F.A.B.B and the STEM Early College at N.C. A&T.

## Biomechanics On Our Minds (BOOM): Learnings from a biomechanics podcast

Johanna J. O'Day<sup>1\*</sup>, Melissa A. Boswell<sup>1\*</sup>, Scott L. Delp<sup>1</sup>, Joseph Hamill<sup>1</sup>  
<sup>1</sup>Department of Bioengineering, Stanford University, Stanford, CA, USA

\*These authors contributed equally to this work

Email: [odayj@stanford.edu](mailto:odayj@stanford.edu)

### Introduction

Biomechanics is an interdisciplinary field, which is full of diverse perspectives and ideas, both technical and non-technical. Conferences facilitate the exchange of these perspectives and ideas, connect us with the people behind the research, and remind us that science is a human endeavor. Attending conferences is fantastic but requires resources for travel and conference fees and expertise to understand the research. We created the podcast Biomechanics On Our Minds (BOOM) for students and researchers. BOOM was developed with three main goals: increasing access, building community, and improving scientific culture. We discuss our learnings from BOOM and their applicability to other contexts.

### Methods

We chose the podcast platform due to its increasing popularity and ability for listeners to learn from any place in the world.

Each episode has three parts: 1) "A Bit of BOOM", which is an overview of new research findings in biomechanics; 2) an interview with a person on a specific topic (Table 1); and 3) "Research Fails," in which we share recent mistakes as learning experiences. Melissa Boswell and Johanna O'Day conduct the interview together starting with the interviewee's path to biomechanics, then exploring the specific topic, and ending with their perspective on the future of biomechanics.

BOOM has included a wide range of topics across biomechanics, career, research, diversity, and support. Running over 2 years, we have released 33 episodes of 45-60 minutes in length. BOOM has had over 16,000 total listens for an average of around 500 listens per episode. It is freely available on Spotify, iTunes, and SoundCloud [1].

Categories	Specific Topics
Biomechanics	exoskeletons, wearables, rehabilitation, prosthetics, orthopedics, impacts, bone, muscle, dinosaur biomechanics, breast biomechanics
Career	paths to biomechanics, academia, industry, graduate school, non-profits, conferences
Research	needs finding, patient-centered research, ambiguity, open-science, collaboration, positive-results bias
Diversity	women in biomechanics, developing countries, internationalization, LGBTQ+
Support	mentorship, mental health, overcoming failure, impostor syndrome

Table 1. Categories and specific topics of BOOM episodes.

### Results and Discussion

We discuss our learnings with regard to BOOM's three main goals.

ACCESS. The podcast has been a useful platform for expanding awareness of biomechanics research. One listener shared, "Thanks to BOOM I've been able to hear from researchers and professors ... who I wouldn't otherwise have the opportunity (or know-how) to approach."

In addition, our conversations provide information that is not typically included in graduate education, such as mental health. We have found that fostering an empathetic and positive environment allows us to navigate sensitive but salient topics. These learnings are transferable; we empower students to conduct interviews with a similar environment and share them through our "Student Voices" series.

COMMUNITY. By leveraging the extensive community already established by the International Society of Biomechanics, we have connected with listeners worldwide; a Dutch listener shared, "The BOOM podcast has been like a real friend! I literally talk with you guys as I bike across the city."

CULTURE. Sharing failures and stories of overcoming adversities as learning experiences have proven encouraging and empowering; one student shared, "My perspective on failing changed as I understood that experts fail." Another student shared that, "Failure makes research successful and meaningful." These stories have expanded our perspectives and given us a more holistic picture of the researcher.

We think the most important learnings from BOOM are: empathetic conversations open the door to a wide range of topics, building upon existing communities enables far-reaching impact, and sharing adversities makes us more connected and resilient. These learnings can be applied to other contexts. For the largest positive impact, we encourage listeners to continue these conversations throughout their communities so as to improve our culture.

### Significance

BOOM uses the podcast platform to expand awareness of biomechanics research and positively impact accessibility, community, and culture. It has attracted listeners inside and outside of the biomechanics community and serves as an inspiration for others to initiate similar deep, meaningful conversations in their fields

### Acknowledgments

The BOOM podcast was started through the International Society of Biomechanics (ISB). We thank the ISB for their continued support, Peter Washington for BOOM's music, and Sanford Health for supporting the Student Voices initiative.

## Effects of assistive devices on postural sway during a simulated forward fall

Yunju Lee<sup>1,2</sup>, Meri Goehring<sup>2</sup>, Rachel Badr<sup>2</sup>, Brianna Bove<sup>2</sup>, and Patrick Jewett<sup>2</sup>

<sup>1</sup>School of Engineering, Grand Valley State University, Grand Rapids, MI, USA

<sup>2</sup>Department of Physical Therapy, Grand Valley State University, Grand Rapids, MI, USA

Email : [leeyun@gvsu.edu](mailto:leeyun@gvsu.edu)

### Introduction

Assistive devices are utilized to provide balance and stability to those that may require extra base of support, especially during ambulation or essential functional tasks in activities of daily living [1, 2]. In assistive device use, postural sway is a major factor to consider in the prevalence and prevention of falls [3, 4]. There is a lack of research on assistive devices, such as walkers, regarding measurable outcome variables related to fall risk. Few studies have assessed the effectiveness between walker types on stability during a forward fall [2]. The purpose of this study was to determine how much the postural sway in single limb stance during a simulated forward fall is affected by utilizing three different walker types designed to promote stability.

We hypothesized that the lowest amount of postural sway will be with the standard walker (W1), followed by the front wheeled walker with straight wheels (W2), and the greatest amount of postural sway will be with the front wheeled walker with caster wheels (W3).

### Methods

Twenty-three healthy adults (13 females, 10 males;  $26.1 \pm 4.2$  yrs;  $76.9 \pm 16.3$  kg) participated and gave consents. The NeuroCom® SMART EquiTest® system was utilized to simulate forward falls via its moving force plate quickly tipped backward in order to measure postural stability in single limb stance. Each participant experienced a total of 18 simulated falls while the subject was asked to maintain balance. Each trial was completed utilizing random assignment of three different walker types and leg dominance as a standing leg with perturbation. Three trials were collected per condition with two 1-minute seated rest breaks taken every six trials to prevent the fatigue effect.

The two-way repeated measures variance of analysis (rm-ANOVA) were performed to test effect of walker type and leg dominance in SAS JMP ( $p < .05$ ) for the center of pressure's (COP); maximum distance (mm), velocity (mm/sec) in antero-posterior (AP) and medio-lateral (ML) directions. If p value was less than 0.05, we applied Tukey's HSD as post-hoc tests.

### Results and Discussion

The ANOVA table 1 showed that the type of walker and the leg dominance in standing limb significantly affected postural sway in a simulated forward fall. The COP maximum distance in AP direction was significantly different under walker type as a main effect however, the rest of variables did not show differences among three walkers in AP direction. As expected, we found that the effect of leg dominance was significant in all variables except velocity in ML direction. There was no interaction effect between walker and stance leg. The post-hoc tests revealed that the standard walker (W1) had the smallest significant maximum distance in AP direction compared to two front wheeled walkers (Fig. 1 left shown as \*) while there were no differences between two front wheeled walkers (W2 vs. W3).

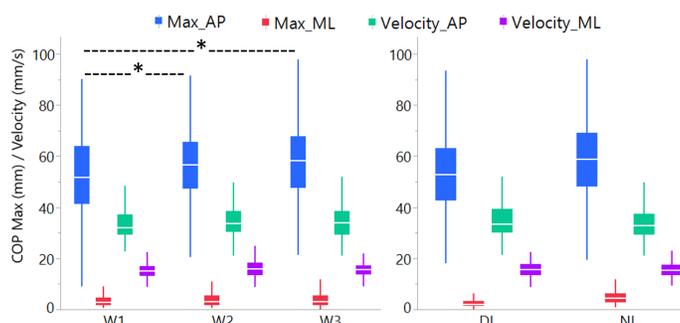

The result supported the hypothesis of the relationship between the postural sway and three different walkers during a

simulated forward fall. Moreover, the findings provided the evidence to support that a standard walker had best stability when compared to the other two front wheel walkers with wheels.

**Table 1.** ANOVA table of COP outcome variables.

COP	AP direction		ML direction	
	Max	Velocity	Max	Velocity
Walker type (W1, W2, W3)				
<i>F</i>	6.316	2.348	.856	2.514
<i>p</i>	<b>.002</b>	.097	.426	.082
Stance leg (DL vs. NL)				
<i>F</i>	10.797	5.651	122.001	2.795
<i>p</i>	<b>.001</b>	<b>.018</b>	<b>&lt;.0001</b>	.095
Walker x Stance leg				
<i>F</i>	1.239	.837	.336	1.485
<i>p</i>	.291	.434	.715	.228

Significant *p*-values ( $p < .05$ ) are indicated in bold. Key: W1 = Standard Walker; W2 = front wheeled walker with straight wheels; W3 = front wheeled walker with caster wheels; DL = dominant leg; NL = non-dominant leg for a standing limb.

**Figure 1:** COP Maximum distance and velocity shown by 3 different walker types (left: W1 vs. W2 vs. W3) and leg dominance in standing limb (right: Dominant leg (DL) vs. Non-dominant leg) in AP and ML directions.

### Significance

By investigating the effectiveness of three walker types on postural sway during a simulated forward fall, health care professionals will be provided with clinically relevant information to aide in prescribing appropriate assistive device options for patients that specifically tailor to their stability needs. This is especially important for those who are at a high risk for falls [2, 3]. In addition, walkers are often used for patients who are limited or non-weight bearing on one lower extremity after a lower extremity injury or surgery [1, 2]. Prescribing assistive devices with appropriate stability for a patient's presentation will assist in the effort to decrease falls and therefore minimize fall-related injuries.

### Acknowledgments

We thank the study participants for their cooperation.

# Gait Event Specific IMU-Based Kinematic Metrics are able to Identify Balance Control Deficits in Acutely Concussed Young Adults

Will Pitt<sup>1,2</sup>, Suz-Hua Chen<sup>2</sup>, and Li-Shan Chou<sup>2,3</sup>

<sup>1</sup>Baylor University – KACH D1 Sports Physical Therapy Fellowship, West Point, NY

<sup>2</sup>Department of Human Physiology, University of Oregon; <sup>3</sup>Department of Kinesiology, Iowa State University

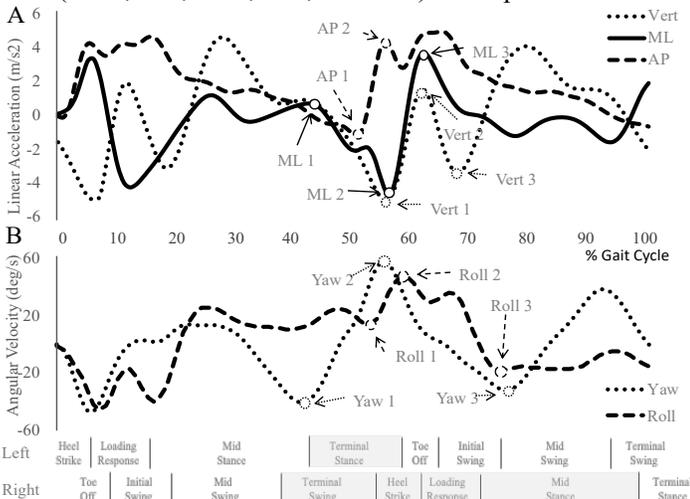

Email: William.j.pitt6.mil@mail.mil

## Introduction

Concussed individuals often present with persistent gait balance deficits, identifiable with whole body center of mass (COM) kinematic analysis[1]. Inertial measurement units (IMUs) offer a promising method for clinical assessment of COM-based metrics. Examination of IMU accelerations and angular velocities is necessary to identify metrics indicative of balance control impairments. The purpose of this study was to identify IMU-based kinematic metrics capable of distinguishing concussed from healthy individuals across a two month post-injury period. We hypothesize multiple gait event specific accelerations and angular velocities will be able differentiate healthy from concussed individuals across a two-month post-injury period.

## Methods

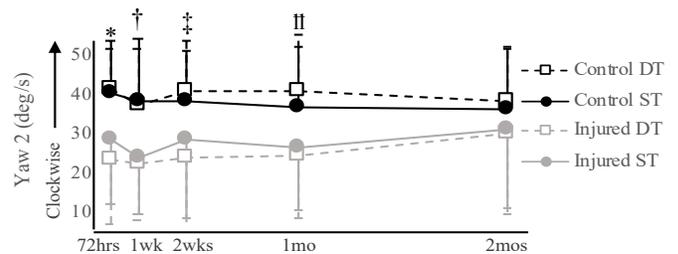

Eleven acutely concussed individuals (within 72 hours of injury) were matched to 11 healthy controls by sex, age, height, and weight. Individuals with an injury affecting normal gait, a history of permanent memory loss or concentration abnormalities, or who had impaired hearing were excluded. A gait balance control assessment [2] was performed in both single- (ST) and dual-task (DT) conditions at five time points: within 72 hours of injury (72hrs), at one week (1wk), two weeks (2wks), one month (1mo), and two months (2mos) post-injury. Healthy participants were assessed at similar intervals. Participants walked over a seven meter straight level path at a self-selected pace, performed a 180° counter clockwise turn, and returned to the start position. During the DT condition, participants responded to an auditory Stoop task in which the words “high” and “low” were presented in either congruent or incongruent word/pitch combinations. Kinematic data were collected from a single IMU (APDM, Portland, OR) placed over the L5 vertebra. Data were sampled at 128Hz and filtered with a 2<sup>nd</sup> order low-pass Butterworth filter with a 12Hz cutoff. All IMU measures were analyzed with a 3-way analysis of variance with group (concussed, healthy), condition (ST, DT), and time (72hrs, 1wk, 2wks, 1mo, and 2mos) as independent variables.

**Figure 1:** (a) Vert, ML, AP acceleration and (b) Yaw and Roll angular velocity profiles.

## Results and Discussion

Eight consistent gait event specific peak accelerations along the medial-lateral (ML), anterior-posterior (AP), and vertical (Vert) axes and six peak angular velocities about the AP (roll) and Vert (yaw) axes were identified. Accelerations and angular velocities were referenced to a left heel strike initiated gait cycle, and occurred at right terminal swing, left terminal stance, right heel strike, right single- to double-support transition (loading response), and right mid-stance (**Fig. 1**). Concussed individuals produced a smaller downward acceleration (Vert2) during loading response, which increased over time in both groups (interaction effect;  $p=.04$ ), and smaller upward acceleration (Vert3) at the end of terminal stance than healthy participants (main effect of group;  $p=.02$ ). They also had a slower clockwise angular velocity (Yaw2) at right heel strike which increased over the five assessments (interaction effect;  $p<.001$  [**Fig. 2**]). Non-significant trends of smaller ML accelerations toward the left at right heel strike (ML2) and to the right during loading response (ML3), and a greater peak posterior acceleration from right heel strike to loading response (AP2) were identified in concussed individuals (main effects of group;  $p=.06$ ,  $p=.06$ , and  $p=.07$ ).

**Figure 2:** Peak yaw angular velocity (Yaw2). Significant follow-up comparisons (Tukey) between healthy and concussed at 72hrs (\* $p<.01$ ), 1wk († $p=.04$ ), 2wks (‡ $p=.01$ ), and 1mo (¶ $p=.02$ ).

## Significance

Multiple gait event specific peak accelerations and angular velocities collected from a single L5 place IMU were able to detect gait imbalance up to two months post-injury. The timing and magnitude of the metrics suggests a momentum control strategy in which health individuals generate a greater braking acceleration along the AP axis during the loading response phase, resulting in an off-axis shift in energy into the ML and Vert axes. This ability is diminished in concussed individuals suggesting adoption of a more conservative balance control strategy, offering a promising method for identifying individuals with impaired dynamic gait balance control with a clinically feasible instrument.

# An Investigation of Rambling-Trembling Sway Trajectories with Simulated Somatosensory Deficit

Eryn D. Gerber<sup>1</sup>, Camilo Giraldo<sup>2</sup>, Paris Nichols<sup>2</sup>, Logan Sidener<sup>1</sup>, Dr. Carl Luchies<sup>1,2</sup>

<sup>2</sup>Department of Mechanical Engineering, University of Kansas, Lawrence, KS

Email: [cryngerber@ku.edu](mailto:cryngerber@ku.edu)

## Introduction

Falls in older adults are often multifactorial, but can be primarily attributed to diminished sensation abilities and lowered processing rates due to age-linked neural degeneration.<sup>1,2</sup> A novel method for center of pressure (COP) analysis, called rambling-trembling (RM-TR) decomposition, seeks to understand the underlying feedback loops that modulate balance and has potential to provide new, valuable information about postural sway.<sup>3,4</sup> The purpose of this study is to investigate the effects of simulated somatosensory deficit on RM-TR-derived measures of the COP during quiet standing. It was hypothesized that RM and TR parameters would show similar trends across deficit severity, but with different magnitudes, and present greater sensitivity to deficit detection compared to traditional COP measures.

## Methods

Fifty-two healthy young adults (aged  $22.10 \pm 1.88$  years, 29 male, 22 female) participated in the study. Participants were asked to stand on two force plates (AMTI, Watertown, MA) with a standardized stance and eyes closed. Five randomly-ordered foam thickness conditions (0", 1/8", 1/4", 1/2", and 1", corresponding to F0, F1, F2, F3, and F4, respectively) were used to simulate varying degrees of somatosensory deficit experienced during natural aging. Three 60-second trials were completed for every foam thickness. Foot-floor kinetic data were collected and analyzed using MATLAB software (Mathworks, Natick, MA). Force and moment data were filtered using a 10Hz lowpass Butterworth filter and used to calculate COP, RM, and TR time series, as detailed by Zatsiorsky & Duarte (1999).<sup>3</sup> Velocity, acceleration, and jerk in the mediolateral (ML) and anteroposterior (AP) directions were calculated for RM, TR, and COP time series. In this study, measure sensitivity was used to describe the relative percent change from baseline (F0). MATLAB software was used to perform analyses of variance (ANOVA) with Tukey's HSD post hoc tests with  $p < 0.05$  to determine statistical significance.

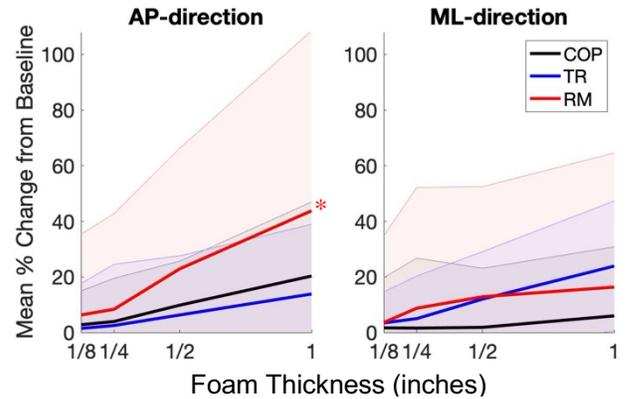

## Results and Discussion

Condition F4 showed greatest percent changes from baseline for all assessed parameters, with an upward trend in mean values from F1 to F4 in all measures. In general, standard deviations were very large, likely due to the large sample size and inherent variability in postural sway between healthy young subjects.

**Table 1.** Mean % change in velocity (vel), acceleration (acc), and jerk from baseline to F4. P-values describe the difference between COP and RM or TR. Significant differences ( $\alpha=0.05$ ) are bolded.

	COP	RM	p-value	TR	p-value
VEL <sub>AP</sub>	43.186	48.687	0.7086	40.766	0.9355
VEL <sub>ML</sub>	46.526	48.011	0.9776	45.712	0.9932
ACC <sub>AP</sub>	24.043	<b>42.380</b>	<b>0.0255</b>	20.425	0.8653
ACC <sub>ML</sub>	22.009	24.260	0.9376	26.059	0.8118
JERK <sub>AP</sub>	20.329	<b>43.779</b>	<b>0.0161</b>	<b>13.860</b>	<b>0.0013</b>
JERK <sub>ML</sub>	5.987	16.344	0.2756	<b>23.905</b>	<b>0.0218</b>

## Changes in Normalized Jerk Across Foam Thickness

**Figure 1.** Mean percent changes in normalized jerk across foam thickness. Bold lines represent measurement means with shaded regions depicting the standard deviations.<sup>6</sup> Significant differences between COP and RM or TR are shown with an asterisk (\*).

Statistically significant differences between COP and RM or TR acceleration and jerk were found in the F3 and F4 conditions (Table 1). These findings support the hypothesis that COP, RM, and TR measures would show similar trends with variable magnitudes, and RM and TR acceleration and jerk exhibited greater sensitivity to F4 compared to COP.

Much debate surrounds the attribution of physiological mechanisms to RM and TR, but a leading theory suggests that RM trajectories are controlled centrally, while TR trajectories are peripherally-controlled.<sup>5</sup> RM and TR measures showed different behavior in the AP- and ML-direction, with RM greater than COP and TR in the AP-direction, and TR greater than COP in the ML-direction (Figure 1). This result is particularly interesting when considering the physiological mechanisms attributed to RM and TR, as these results may suggest that movement is more heavily controlled centrally in the AP and peripherally in the ML.

## Significance

Results of this study suggest that RM-TR derived measures may: (1) provide greater deficit detection abilities than traditional COP measures, and (2) reveal previously unknown mechanisms of postural control. Broadening our understanding of postural sway has the potential to alter the way we measure, analyze, and modify balance. From a clinical standpoint, our findings could be used to develop methods that more accurately detect fall risk, inform prevention strategies, and maintain high quality of life with age.

## Introduction

Postural control is regulated by the visual, vestibular, and somatosensory system. During static standing, augmented somatosensory feedback stimulates the mechanoreceptor to deliver information on bodily position, improving the postural control [1]. The various types of such feedback include ankle-foot orthoses (AFOs) and vibration. The optimal feedback to mitigate postural sway remains unclear, as does the effect of augmented somatosensory feedback on muscle co-contraction. We have compared the effects of feedback-free, AFOs, and vibration on postural sway and muscle co-contraction.

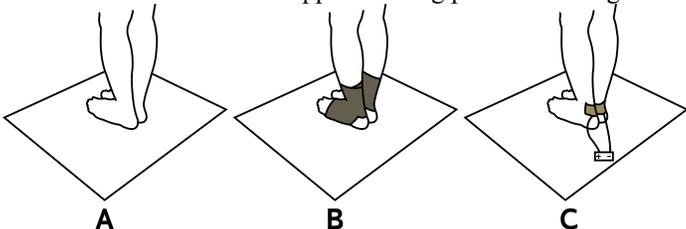

## Methods

Fifteen young adults (11 males and 4 females) aged between 21 and 24 participated. The study protocol was approved by the Institutional Review Board at Yonsei University Wonju Campus. The participants stand on the force platform with their feet together and their arms relaxed on both sides of the body. They were instructed to try not to sway during measurements taken over 60 s during all tests.

There were two treatment factors: augmented somatosensory feedback (feedback-free, wearing the AFOs, vibrators on both Achilles tendon) and sensory conditions (eyes open, eyes closed with the head tilted back). Each participants was tested under all six combinations of the two treatment factors in random order. Postural sway was measured using a force platform (FDMS; Zebris Medical GmbH, Isny, Germany); the mean sway area of the 95% confidence ellipse (AREA) and the mean velocity of the center-of-pressure displacement (VEL) were assessed.

Tibialis anterior (TA) and gastrocnemius (GCM) muscle activities was measured using electromyography (EMG). Co-contraction of TA and GCM converted into a co-contraction index (CI). The CI was calculated using the method of Falconer and Winter (1985) [2].

The two-factor within subjects ANOVA was used to determine the difference in the postural sway and CI among augmented somatosensory feedback (feedback-free, AFOs, vibration). the Bonferroni correction was applied during post-hoc testing.

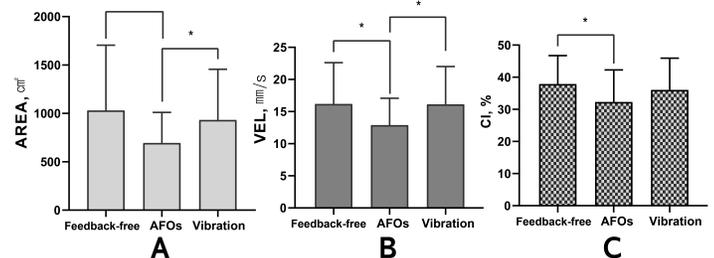

**Figure 1:** The augmented somatosensory feedback (A: feedback-free, B: ankle foot orthoses, C: vibration).

## Results and Discussion

We found significant main effects of the augmented somatosensory feedback on AREA ( $F=1.004$ ,  $p=0.002$ ), VEL ( $F=2.380$ ,  $p<0.001$ ) and CI ( $F=0.747$ ,  $p=0.002$ ). The sensory conditions exerted significant main effects on AREA ( $F=0.680$ ,

$p=0.005$ ) and VEL ( $F=1.061$ ,  $p<0.001$ ). In AREA and VEL, AFOs resulted in significantly more reduced postural sway than feedback-free ( $p=0.014$ ,  $p<0.001$ ) and vibration ( $p=0.024$ ,  $p<0.001$ ) (Figure 2A,B). In CI, AFOs had significantly better than feedback-free ( $p=0.004$ ). But vibration had not significantly difference with feedback-free in AREA, VEL and CI (Figure 2C). Our results conflicts with a previous finding that vibration reduce the postural sway [3]. In previous studies, the frequency of the vibration to affect the postural sway was 80-100 Hz, whereas in our study, the frequency of the vibration was 1-100 Hz. It is important to set a specific frequency for the vibration to affect the postural control. Our finding that AFOs were better than vibration to improve the postural sway support the previous finding [4]. As the AFOs contact greater proximal stimuli were more effective in reducing postural sway. In addition, We examined that AFOs reduced the CI. During static standing, the plantarflexor are continuously activated and the dorsiflexors are rarely activated, but people with impaired postural control frequently engage the dorsiflexors. AFOs provide adequate somatosensory cues to the ankle dorsiflexors, so the dorsiflexor and the plantarflexor activated properly.

**Figure 2:** Post-hoc comparison of the effects of the augmented somatosensory feedback (feedback-free, AFOs, vibration) on the AREA, VEL, and CI values during static standing. (AREA: the mean sway area of the 95% confidence ellipse, VEL: the mean velocity of the center-of-pressure displacement, CI: co-contraction index).

## Significance

Our finding suggests that AFOs of the somatosensory feedbacks improve postural sway and reduce ankle muscle co-contraction. Such feedback stimulates muscle mechanoreceptors to enhance somatosensory awareness, rather than inducing excessive muscle contractions, and it is particularly sensitive to changes in body movements and position. Therefore, static balance training using flexible AFOs would effectively improve postural control while preventing excessive ankle muscle co-contraction during static standing.

# Effects of vibration training in reducing falls in people with multiple sclerosis

Meng-Wei Lin<sup>1</sup>, Jiyun Ahn<sup>1</sup>, Feng Yang<sup>1</sup>

<sup>1</sup> Department of Kinesiology and Health, Georgia State University, Atlanta, USA

Email: mlin10@student.gsu.edu

## Introduction

Multiple sclerosis (MS) is a chronic central nerve system disease resulting from demyelination. The disease affects both the sensory and motor systems and increases the risk of falls. Numerous efforts have been devoted in developing interventions to reduce falls in people with MS (PwMS). Controlled whole-body vibration (CWBV) training has recently emerged as an alternative fall prevention modality. Previous studies reported that CWBV may reduce the risk of falls by improving body balance, lower limb strengths, mobility, and sensation level (Yang et al., 2016; Yang et al., 2018). As these factors closely relate to falls among PwMS (Finlayson et al., 2006), improving them could lower the likelihood of falls. However, falls in everyday living were not used as an outcome in the previous studies. In addition, prior studies adopted a single-group design. It is impossible to eliminate the potential confounding effects from other factors. The purpose of this study was to further examine the effects of an 8-week CWBV program in reducing falls among PwMS based on a randomized controlled trial. We hypothesized that CWBV reduces falls among PwMS.

## Methods

Thirty-one individuals with MS were recruited. They had a less than 7 Patient Determined Disease Steps (PDDS) score, no experience with CWBV training, and no significant relapse within the past 8 weeks. All participants provided a written consent approved by the Institutional Review Board.

**Table 1 Between-group comparison of demographic and disease information prior to training**

Group	Intervention	Control	<i>p</i> value
Number	24	7	
Males (%)	8 (33%)	0 (0%)	0.081
Age (years)	55.69 ± 14.11	54.63 ± 15.56	0.865
MS duration (years)	10.14 ± 8.57	15.58 ± 10.68	0.228
PDDS (/8)	3.56 ± 1.77	3.93 ± 1.37	0.618

The participants were randomized into two groups: intervention and control groups. The intervention group underwent an 8-week CWBV program on a side-alternating vibration platform (Galileo, Med-L). The vibration frequency and amplitude were 20 Hz and 2.6 mm, respectively. During training, participants were required to stand on the platform with knee bent at 20° and the trunk held upright. Each training session consisted of five CWBV training bouts each followed by a 1-minute rest. The same training session was repeated three times a week over eight weeks. The control group followed the identical protocol except for a 0-mm amplitude. Before the training, the fall incidence in the past year was collected by using a falls-questionnaire. During 12 months following the first training session, each participant was contacted by research staff members once a month to track whether they have had falls in the past month. Independent *t*-test and chi-square test were used to compare the demographic and disease information between

groups prior to the training. Generalized estimating equation (GEE) analysis, with group (CWBV vs. control) and falls data collection period (retrospective vs. prospective) as the two factors in the model, was used to compare the fall incidence between groups over the two 12-month periods. SPSS 24 (IBM) with a significance level of 0.05 was used.

## Results and Discussion

The demographic and disease information of the two groups were comparable before the training (Tab. 1). GEE results revealed that the two main factors and their interaction had little effect on the fall incidence: group ( $p = 0.716$ ), session ( $p = 0.556$ ), and group by session ( $p = 0.283$ ) on the fall incidence. Although our results did not support our hypothesis, the prospective fall rate over the 12 months after the first training session for the CWBV group was about 17% less than the one for the control group (71% vs. 86%, Fig. 1). Such a reduction could be contributed to the CWBV-induced improvements in fall risk factors as reported by previous studies (Yang et al., 2016; Yang et al., 2018). Our finding may indicate that CWBV training is a clinically-meaningful modality to reduce falls in PwMS. The non-significant results could be due to the small and imbalanced sample size between groups. A larger scale trial is needed to further confirm the efficacy of CWBV in reducing falls in PwMS.

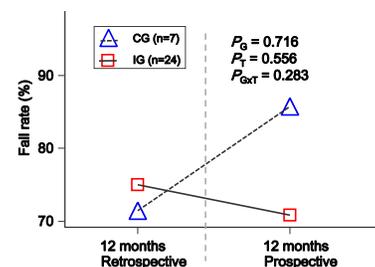

Figure 1. Comparison of the fall rate (12-month retrospective report vs. 12-month follow up) between the intervention (IG) and control groups (CG).  $p_G$ : *p* value for the main factor of group.  $p_T$ : *p* value for the main factor of time (retrospective vs. prospective).  $p_{G*T}$ : *p* value for group by time interaction effect.

## Significance

CWBV is an easy, safe, and cost-effective approach to reduce the risk of falls. In addition, it is less physically-demanding in comparison with other traditional exercise-based intervention for preventing falls. Therefore, CWBV could be an encouraging alternative program to reduce falls in PwMS.

Email: [p153n802@ku.edu](mailto:p153n802@ku.edu)

### Introduction

During quiet stance the human body is unstable and requires constant adjustment from the central nervous system (CNS) to remain upright. Somatosensory deficits, caused by aging, diabetes, or stroke, can create an increased risk of falling which often results in injury or potentially death.<sup>1</sup> Improving our ability to clinically detect these deficits allows for a better understanding of a patient's need and timing for an intervention.

The center of pressure (COP) time series during quiet stance has been used to detect changes in balance through a variety of parameters.<sup>2</sup> Entropy, a measure of signal predictability, has shown success as one of these parameters.<sup>3</sup> The algorithm used to calculate entropy compares vectors within a signal using the Heaviside function to estimate probability of their occurrence. Approximate Entropy (AppEn) and Sample Entropy (SampEn) are two common measures of entropy.<sup>4,5</sup> Recent studies replaced the Heaviside function with fuzzy sets (variation between 0 and 1) leading to the development of Fuzzy AppEn (FAppEn) and Fuzzy SampEn (FSampEn).<sup>6,7</sup> This study tests the hypothesis that fuzzy entropy will improve sensitivity to sensory deficits in COP.

### Methods

**Testing Procedure:** Fifty-two healthy, young subjects (aged  $22.10 \pm 1.88$  years, 29 male, 22 female) stood on two force plates (AMTI, Watertown, MA) with a standard stance and their eyes closed for all trials. Sensory deficits were simulated using five foam thickness conditions (no foam, 1/8", 1/4", 1/2", 1" corresponding to F0, F1, F2, F3, & F4, respectively) applied in a random order. Three 1-minute trials were taken at each condition.

**Data Analysis:** A subset of ten randomly-selected subjects were used in a parameter study to compare AppEn, SampEn, FAppEn, and FSampEn. MATLAB (Mathworks, Natick, MA) was used to calculate COP in the anteroposterior (AP) from force plate data.<sup>2</sup> All entropy measures were calculated for each trial at varying input parameter, R (0.01 to 1 at a 0.01 step size).<sup>4,5,6,7</sup>

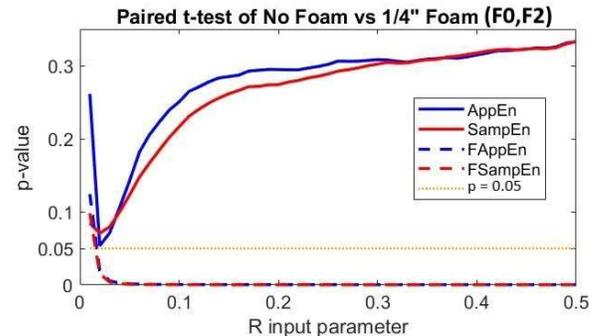

**Statistics:** Entropy values were averaged across each three-trial set of foam conditions and R input parameter. A paired t-test was run for three pairs of foam condition: (F0,F2), (F0, F4), and (F2,F4). Statistical significance was set at  $p < 0.05$ .

### Results and Discussion

All four entropy measures produced significantly different values in the (F0,F4) and (F2,F4) tests at each R. The (F0,F2) test, however, showed varied statistical significance across entropy measures. *Figure 1* demonstrates a trend with AppEn and SampEn p-values  $> 0.05$  (likely due to the large variations seen in *Table 1*) while the FAppEn and FSampEn p-values were  $< 0.05$  as a function of R. Fuzzy entropy values were much smaller in magnitude, but varied less between subjects. The hypothesis was upheld, as both fuzzy entropies studied showed more sensitivity to sensory deficits compared to AppEn and SampEn (due to their statistical significance across almost all values of R).

The results show that there are limitations to the sensitivity of AppEn and SampEn in detecting sensory deficits. Both

detected a significant difference on the 1" foam, but the subtle deficit created by the 1/4" foam is only found using the fuzzy entropy values. The difference is likely due to the use of fuzzy sets which create a robustness to random noise. FAppEn and FSampEn were initially developed for use with electro-myography (EMG) signals and successfully reduced the influence of random noise in those signals.<sup>6,7</sup>

**Figure 1.** Results of paired t-test (F0,F2). Significance is indicated by the yellow dots at 0.05.

mean $\pm$ stdev	R = 0.1		R = 0.3		R = 0.5	
	No Foam	1/4" Foam	No Foam	1/4" Foam	No Foam	1/4" Foam
<b>AppEn</b>	0.379 $\pm$ 0.193	0.347 $\pm$ 0.172	0.086 $\pm$ 0.041	0.081 $\pm$ 0.036	0.046 $\pm$ 0.020	0.043 $\pm$ 0.018
<b>SampEn</b>	0.338 $\pm$ 0.177	0.309 $\pm$ 0.153	0.081 $\pm$ 0.040	0.076 $\pm$ 0.034	0.043 $\pm$ 0.020	0.041 $\pm$ 0.018
<b>FAppEn (x10<sup>-3</sup>)</b>	1.95 $\pm$ 0.257	2.03 $\pm$ 0.317	0.689 $\pm$ 0.087	0.717 $\pm$ 0.108	0.419 $\pm$ 0.053	0.435 $\pm$ 0.065
<b>FSampEn (x10<sup>-3</sup>)</b>	1.92 $\pm$ 0.272	2.02 $\pm$ 0.293	0.688 $\pm$ 0.088	0.722 $\pm$ 0.101	0.419 $\pm$ 0.053	0.439 $\pm$ 0.061

**Table 1.** Mean and standard deviation (stdev) values for all four entropy measures at select R input parameter values.

### Significance

The results of this study demonstrate the potential that fuzzy entropy measures have in detecting postural sway deficits. Potential clinical uses include tracking COP entropy changes over time to track the progression of declining balance. Further analysis is required to understand the relationship between changes in entropy and increased fall risk.

This study shows the versatility of fuzzy entropy for use across a variety of biosignals. It has the potential to improve the sensitivity of analysis outside of EMG and COP signals, uncovering information in biological data that conventional entropy measures cannot detect.

## Gait changes in young onset Parkinson's disease before and after medication

<sup>1</sup>Klein, S., <sup>2</sup>Savica, R., <sup>1</sup>Kaufman, K.

<sup>1</sup>Motion Analysis Laboratory, Department of Orthopedic Surgery

Mayo Clinic, Rochester, MN

Klein.sara@mayo.edu

### Introduction

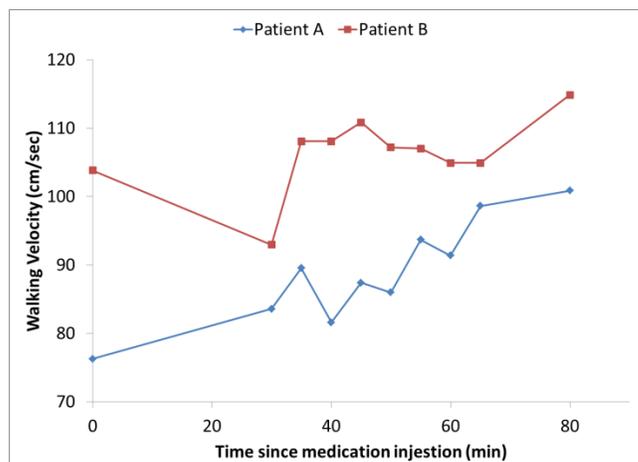

Young onset Parkinson's disease (YOPD) occurs in people who are between 20 and 50 years of age. Of the one million people with PD in the US, an estimated 4% of them are affected by YOPD [1]. There is a paucity of studies on YOPD available to healthcare providers, leading to poorer patient outcomes. This study was performed to provide objective evidence of changes in the patients' gait patterns with medication.

### Methods

Two male patients, ages 48 and 43, were recruited for this study. One patient had been diagnosed with YOPD a year and a half prior, the other six months prior to the study. Both patients were un-medicated for at least seven hours upon arrival for testing. They reported similar impairments, including slowness of movement and difficulty controlling unilateral lower extremity movements. Prior to data collection, a set of 41 retro-reflective markers were placed with respect to bony landmarks on the trunk, pelvis, and extremities using a modified Helen-Hayes marker set. One gait trial was collected prior to the patients orally administering their medication. Thirty minutes were allowed for medication absorption. Then gait trials were collected every five minutes, totaling eight trials. A fifteen minute rest was provided to eliminate the effect of fatigue before a final trial was collected.

### Results and Discussion

Each patient demonstrated significant improvements in temporal distance (TD) factors (Figure 1) as a result of subtle improvements in gait kinematics and kinetics. The more involved lower extremity for each patient demonstrated greater improvements than the less involved side. These gait improvements created greater symmetry in support times and step lengths. Overall, the kinematics demonstrated improved muscular control of the limb and foot when on medication, with greater improvement on the more involved side. This was especially apparent in the sagittal plane for both patients, demonstrating increased joint range of motion with longer steps. Similarly, the moments tended toward normal when on medication, with greater improvement on the more-involved side leading to improved gait symmetry. Furthermore, the more-involved side powers were closer to normal on medication, with very little change on the uninvolved side. The improvements in gait kinematics and kinetics resulted in improvements in TD factors including increased velocity (Fig.1), normalized step widths, increased single support times, and increased step lengths. These changes in TD factors, are associated with improved lower extremity support and balance for reduced fall risk [2, 3, 4]. Additionally, the patients' subjective reports of maximal improvement aligned with the time of improved TD measures. Understanding that subjective patient report aligns with objective improvements in gait mechanics is powerful information for practitioners to better manage medications. Overall, TD factors represented medication efficacy and correlated with subjective report.

**Figure 1:** Gait velocity changes over time after administration of PD medication.

### Significance

This report is the first to quantify the gait changes of patients with YOPD while off- versus on-medication, and revealed the most important changes were TD measures. This study demonstrates that objective gait measures should be utilized to improve clinical decision making, including medication management. The gait data was used to adjust medication profiles for improved functional outcomes for these patients. Medication adjustments based upon objective measures become especially important in the long term pharmaceutical management of this neurologic disorder where medication intolerance is common. This study provided patient education opportunities, including teaching the patients about their individual gait improvements and the importance of medication adherence to reduce fall risk. There are implications for other healthcare providers as well. With objective gait data, therapists can teach their patients how their PD medications affect their gait, fall risk, and create individualized exercise programs to target patient specific impairments in the off-medication state. Therapists can also use gait data to educate patients and families on activity planning within medication timelines to improve quality of life. Objective gait data should be a standard of clinical practice when treating YOPD for best outcomes.

### Introduction

Traumatic brain injury (TBI) is relatively common and often results in debilitating conditions experienced by military personnel. TBI can negatively influence postural control, which we define as one's ability to maintain a stable posture with their center of mass vertical to their center of support. TBI impairs a patient's ability to maintain this stability which may lead to difficulties during activities of daily living. After recovery from the acute symptoms of TBI, an individual's altered performance may persist. Previous studies have shown that postural control measures are useful in detecting deterioration of balance function following a TBI in the short-term [1,2], however little work has been done on detecting lingering effects outside of this initial timeframe.

The goal of this investigation was to compare linear metrics characterizing postural control between patients with and without a lifetime history of TBI. Significant differences between the two groups may identify lingering effects in postural control due to TBI. This detection would enable clinicians to differentiate between acute effects of a TBI and lingering effects from previous injury.

### Methods

253 individuals, 41 with a history of TBI (TBI\_hist -age:  $18.8 \pm 1.1$  yr, height:  $1.75 \pm 0.09$  m, mass:  $75.3 \pm 14.6$  kg) and 212 who have no history of TBI (no\_TBI - age  $18.8 \pm 1.1$  yr, height:  $1.75 \pm 0.09$  cm, mass:  $75.8 \pm 12.8$  kg) participated in the IRB-approved protocol. For the subjects with a history of TBI, injury occurred at least 6 months before testing. Patient's center of pressure (COP) position data were collected over the course of a Sensory Organization Test (SOT). A SOT consists of six conditions that are a combination of eyes open/closed, platform fixed/sway referenced, and visual surround fixed/sway referenced. This test was performed on a NeuroCom Balance Master [Natus, Pleasanton, CA] which outputs a score representing balance function for each trial based off proprietary algorithm. Raw COP position data were collected at 100 Hz during three trials of each of the six SOT conditions and smoothed with a window size of 10 samples (0.1 seconds).

**Figure 1:** COP Path overlaid with 95% Confidence Ellipse over a 20 second trial of a Sensory Organization Test (SOT)

We then calculated the following linear metrics: path length, 95% confidence ellipse area, average speed, average acceleration, and root mean squared medial lateral displacement. Figure 1 shows an example of COP path during a trial and the corresponding ellipse area. After removals for incomplete and repeated tests, 702 trials of patients with a history of TBI and 4680 trials of never-concussed patients were analyzed. A two-sample T-test was then performed to identify differences between the TBI\_hist and no\_TBI groups for every metric across each of the six SOT conditions, at a significance level of  $\alpha < 0.05$ . Due to the exploratory nature of this research, a multiple-comparison correction was not applied.

### Results and Discussion

No significant differences were observed between subjects in the history of TBI and no history of TBI groups for any of the variables of interest. Table 1 shows results for SOT Condition 1. These findings are in line with work by Buckley et al. that did not observe lingering deficits in postural control characterized by linear metrics outside of the initial post-injury recovery phase from TBI. [2]

**Table 2:** Postural control metrics between participants with and without a lifetime history of TBI across all 20 second trials of the Sensory Organization Test (SOT) Condition 1

Metric	History of TBI	No History of TBI	P-Value
	Mean $\pm$ STD	Mean $\pm$ STD	
NeuroCOM Score	83.0 $\pm$ 14.7	82.7 $\pm$ 15.7	0.81
Path Length	35.6 $\pm$ 27.4	37.9 $\pm$ 31.2	0.48
95% Ellipse Area	2.30 $\pm$ 3.50	2.72 $\pm$ 6.55	0.51
Average Speed	1.87 $\pm$ 1.52	1.93 $\pm$ 1.62	0.72
Average Acceleration	26.7 $\pm$ 19.5	27.9 $\pm$ 20.1	0.56
RMS Medial-Lateral Displacement	9.91 $\pm$ 4.90	10.7 $\pm$ 6.85	0.23

### Significance

No differences in NeuroCOM functional score or other postural control metrics were observed between individuals with and without a history of TBI. A limitation of this research is that all participants were cadets at the United States Military Academy and passed a comprehensive physical before admittance. Additionally, severity of TBI was not considered in our analysis. Future work should investigate individual SOT conditions and the potential of non-linear metrics to detect lingering deficits between individuals with and without a history of TBI.

### Introduction

Traumatic brain injury (TBI) is relatively common among military personnel and may result in debilitating conditions. TBI can negatively influence postural control, which we define as one's ability to maintain a stable posture with their center of mass vertical to their center of support. TBI impairs a patient's ability to maintain this stability which may lead to difficulties during activities of daily living. Current clinical evaluations of postural control rely heavily upon qualitative assessments [1], however these tend to be unreliable and subjective. While commercial computerized posturography systems are becoming more common, they are often cost-prohibitive for widespread use.

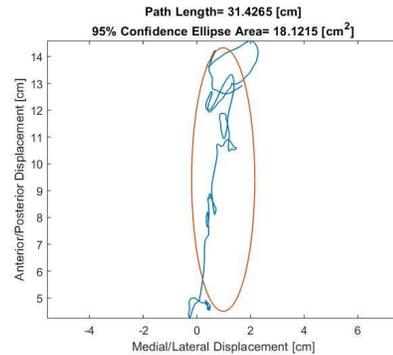

The goal of this investigation was to develop metrics to characterize relevant measures of postural control and identify correlations to proprietary commercial posturography output. The non-proprietary algorithms developed from this research would serve as the basis for an inexpensive and effective device to assist clinicians in making return-to-duty decisions for soldiers with TBI.

### Methods

253 individuals, 70 females (age:  $18.77 \pm 1.00$  yr, height:  $173.55 \pm 9.86$  cm, mass:  $74.89 \pm 13.74$  kg) and 183 males (age  $18.85 \pm 1.12$  yr, height:  $175.66 \pm 9.05$  cm, mass:  $76.07 \pm 12.81$  kg) participated in the IRB-approved protocol. Patient's center of pressure (COP) position data were collected over the course of a Sensory Organization Test (SOT). A SOT consists of six conditions that are a combination of eyes open/closed, platform fixed/sway referenced, and visual surround fixed/sway referenced. This test was performed on a NeuroCom Balance Master [Natus, Pleasanton, CA] which outputs a score representing balance function for each trial based off a black-box algorithm. Raw COP position data were collected at 100 Hz during three trials of each of six SOT conditions and smoothed with a window size of 10 samples (0.1 seconds). We then calculated the following linear metrics: path length, 95% confidence ellipse area, average speed, average acceleration, root mean squared medial lateral displacement and average rate of heading change. After removals for incomplete and repeated tests, 4240 trials were analyzed. Pearson-R correlations were then calculated to find relationships between the linear metrics and the numerical function score for as determined by the NeuroCom for data in each condition and across the whole SOT (significance level  $\alpha < 0.05$ ). Strong correlations identified where  $R > 0.7$ .

### Results and Discussion

All correlation data between linear metrics and NeuroCom function are shown in Table 1, for each individual condition of the SOT and the combination of all conditions, along with scatter plots for select conditions. The strongest correlation was identified between the NeuroCom function scores and the 95% confidence ellipse area across combined conditions, ( $R=-0.87$ ;  $p<0.001$ ). This negative correlation indicates that a larger area covered by the COP during a given trial, is related to a worse NeuroCom function score.

**Figure 1:** COP Path overlaid with 95% Confidence Ellipse over a 20 second trial of a Sensory Organization Test (SOT)

Path length ( $R=0.81$   $p<0.001$ ), average speed ( $R=-0.81$   $p<0.001$ ), average acceleration ( $R=-0.73$   $p<0.001$ ), and RMS ML ( $R=-.70$   $p<0.001$ ) may be considered as complementary surrogates for the NeuroCom score. Heading change yielded weak correlations indicating that there is little relation between that metric and NeuroCom balance score ( $R=0.02$   $p=0.29$ ). Individual condition correlations are less than the total due to the massive number of data points across all conditions. Strong correlations between linear metrics and Neurocom function suggest the possibility of a less expensive system to identify postural control deficits.

### Significance

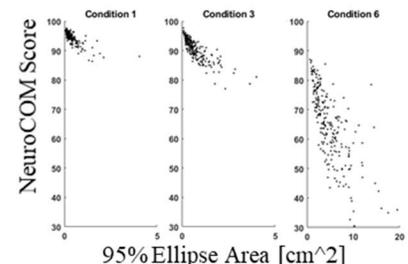

Less expensive, quantitative testing of postural control may assist clinicians in making more informed decisions for TBI patients in smaller clinics. This study laid the groundwork for improving clinical care of TBI without expensive computerized posturography equipment.

## Walking Balance Control is Delayed in Children with Cerebral Palsy.

Ashwini Sansare, Hendrik Reimann, Samuel C.K. Lee, John Jeka

University of Delaware, Newark, DE, USA

Email: [ashwini@udel.edu](mailto:ashwini@udel.edu)

### Introduction

Children with CP are known to be heavily reliant on visual input compared to other sensory modes, as evidenced by increased errors in proprioception when their vision was perturbed in standing<sup>1</sup> and during single plane lower extremity movement<sup>2</sup>. However, it is not known how children with CP use visual information for sensorimotor feedback during walking, an activity where the threat to balance is higher. The aim of this pilot study is to assess how children with CP react to visual perturbations compared to children with typical development (TD). Our hypothesis, based on previous studies on older adults<sup>3</sup>, was that children with CP would demonstrate a delayed response to visual perturbations.

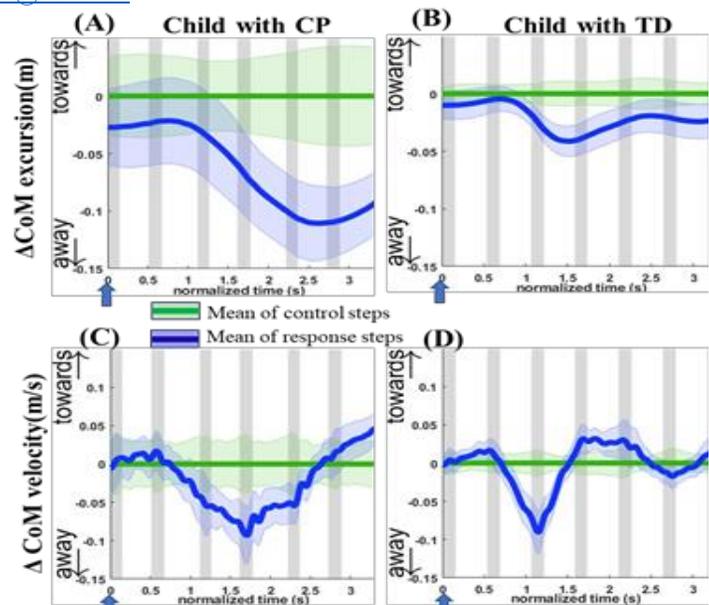

### Methods

Four subjects with CP between the age of 8-18 years (2 with hemiplegia, 2 with spastic diplegia), Gross Motor Function Classification System (GMFCS) level I-II, were recruited along with four age-matched controls. Subjects walked on a self-paced treadmill in a virtual reality environment. They received a visual fall stimulus in the medio-lateral plane toward the triggering heel strike of either foot, with 12-13 steps intervening steps between stimuli. Randomly determined triggers without stimulus served as controls in the analysis. Each trial lasted two minutes, and was repeated ten times, with intermittent rest breaks. Our primary outcome variables were center of mass (CoM) excursion and velocity.

### Results and Discussion

Subjects in both groups reacted to the visual fall stimuli by moving their CoM away from the direction of the perceived fall. The TD group reached the peak average CoM excursion of  $5.2 \pm 1.7$  cm in away direction typically at the 4th post-stimulus step while the CP group demonstrated a more magnified but delayed shift in CoM, with the peak average CoM excursion of  $8.3 \pm 3.3$  cm occurring on the 5th post-stimulus step (Fig 1). The average CoM velocity for the TD group peaked during the 3rd post-stimulus step while that for the CP group peaked during the 4th post-stimulus step. The magnitudes of both peak average CoM excursion and velocity were higher in CP vs. TD group, as evidenced by large effect sizes (Table 1).

Our results suggest that compared to typically developing peers, our cohort of children with CP demonstrated a delayed but magnified balance response to sensory perturbations while walking. This might be suggestive of delayed neural processing and poor sensory integration abilities in children with CP. Previous studies<sup>4</sup> suggest there is a shift from visual dominance towards kinesthetic inputs while mediating postural responses by 6 years of age. A magnified CoM response in an older cohort of children with CP may be indicative of over-reliance on vision, a characteristic seen in younger TD, thus suggesting that CP group's response may not have matured to the level of TD peers. Future research efforts with larger sample size and a wider age range for both CP and TD groups is needed to provide stronger support to the findings of this pilot study.

**Figure 1.** Medio-lateral center of Mass (CoM) excursion and velocity trajectories in response to visual fall stimuli in one representative subject with CP (A & C) and with TD (B & D) respectively. Green lines indicate the mean of control steps (no fall stimulus) steps, which is subtracted from stimulus data, and resulting response is depicted as blue lines. Shaded areas around each line represent one standard deviation. X axis shows 6 steps, time-normalized to 100 timepoints, with double-stance periods shaded gray and single-stance periods white. Arrows at the beginning of each curve mark the triggering visual fall stimulus.

	Peak $\Delta$ CoM excursion(m)		Peak $\Delta$ CoM velocity(m/s)	
	Mean	SD	Mean	SD
TD	0.05	0.02	0.03	0.02
CP	0.08	0.03	0.04	0.02
Effect Size	1.36		1.03	

**Table 1.** Mean, standard deviation (SD) and effect sizes for  $\Delta$ CoM excursion (meters) and velocity(meters/sec) for TD and CP group.

### Significance

While most assessments and treatments in CP address motor-related deficits such as weakness, flexibility and spasticity, our results underscore the role of sensory regulation in balance control during walking. These findings are relevant in developing targeted sensory-based treatment protocols to enhance balance control not only in children with CP but also other neurodevelopmental disorders that could benefit from augmented sensory input during walking.

## Introduction

Multiple sclerosis (MS) affects more than 2.3 million people worldwide and 1 million people in the United States (US) [1]. Symptoms of MS include muscle weakness, poor cognition, and decreased alertness, all impacting upright posture.

The purpose of this study is to examine postural stability mechanisms of MS patients across tasks of increased cognitive demand. Previous work examined the cognitive effects of these tasks [2], but not the dynamic stability effects.

Stability mechanisms were examined through the Hurst exponent (H), a statistical parameter defining long-term correlations in moving systems. H is defined from  $0 \leq H \leq 1$ , where  $H < 0.5$  indicates stability and  $H > 0.5$  indicates instability [3]. H values were calculated with wavelet analyses because this approach can characterize non-stationary signals and provide time-frequency localization of a signal [3,4].

## Methods

Four test conditions were: (1) quiet eyes-open standing (EO), (2) quiet eyes-closed standing (EC), (3) perturbed standing with participants leaning to their limits of stability (PRT-LOS), and (4) perturbed standing in a comfortable stance (PRT-STA).

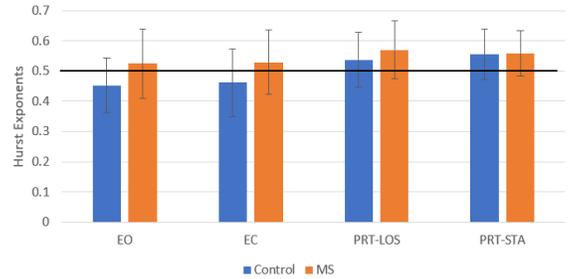

During EO and EC conditions, participants were instructed to stand comfortably for 30s. During the PRT conditions, 20 auditory cues (beeps) were given during each task. Participants were asked to respond as quickly as possible by saying “pop” out loud. They were instructed to maintain their balance on both tasks. Ages for controls (n=33) and MS (n=16) were  $62.6 \pm 9.1$  years and  $55.3 \pm 11.1$  years, respectively.

Anterior-posterior (AP) center-of-pressure (CoP) values were analyzed by a level 12, Symlet 2 wavelet decomposition. To obtain H, log-log plots of the average wavelet coefficients at each decomposition level versus  $2^j$  (j = number of levels) were plotted [3,4]. H values are then calculated as  $H = \text{slope} - \frac{1}{2}$  [3,4]. Average H values were calculated for both groups.

## Results and Discussion

In the AP direction, control  $H_{\text{PRT-LOS}}$  values were significantly higher than  $H_{\text{EO}}$  and  $H_{\text{EC}}$  ( $p < 0.001$ ). Similarly, control  $H_{\text{PRT-STA}}$  values were higher than  $H_{\text{EO}}$  and  $H_{\text{EC}}$  ( $p < 0.001$ ). (Figure 1)

MS did not display significant differences in the AP-directions between conditions. MS were significantly less stable than controls in both the EO ( $p = 0.019$ ) and EC condition ( $p = 0.026$ ). MS displayed instability on all four conditions ( $H > 0.5$ ), whereas controls displayed stability ( $H < 0.5$ ) for EO and EC, but instability ( $H > 0.5$ ) for PRT-LOS and PRT-STA.

**Figure 1:** AP Hurst Exponents for Controls and MS. The black line indicates  $H = 0.05$

Controls became less stable on PRT-STA than PRT-LOS, even though the difficulty decreased. MS became more stable on PRT-STA than PRT-LOS. Controls are considered “high hazard estimate, high postural reserve” meaning they are cognitively sound, and have control over their motor output [5]. MS are considered “high hazard estimate, low postural reserve” meaning they are cognitively sound but have poor motor output control [5]. For PRT-STA, controls most-likely spent more time focusing on the cognitive task, as they were more confident in their postural control. As a consequence, their balance suffered. MS participants on the other hand had to focus more on maintaining postural control, and spent less time focusing on the cognitive task as a way to maintain their balance.

## Significance

Using wavelets to obtain Hurst exponents allows for the analysis of non-stationary time-series data. Examining dynamic postural changes in neurological disorders is important as it provides information that cannot be seen through cognitive tasks alone. The combination of dynamic and cognitive information can be used by clinicians to enhance rehabilitation methods for patients. The way these different cohorts (control vs. MS) respond to cognitive tasks is connected to their amount of hazard estimate versus postural control.

# Leg Joint Mechanics When Hopping at Different Frequencies

Mu Qiao\*

Department of Kinesiology, Louisiana Tech University, Ruston LA, 71272, USA

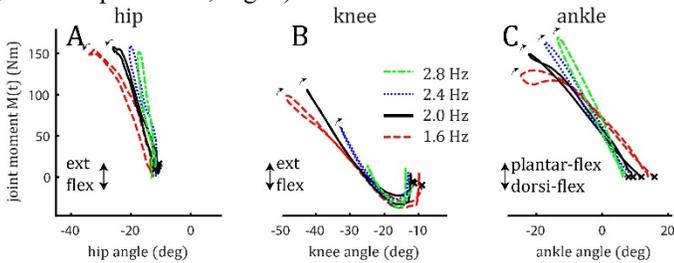

Email: [\\*mqiao@latech.edu](mailto:*mqiao@latech.edu)

## Introduction

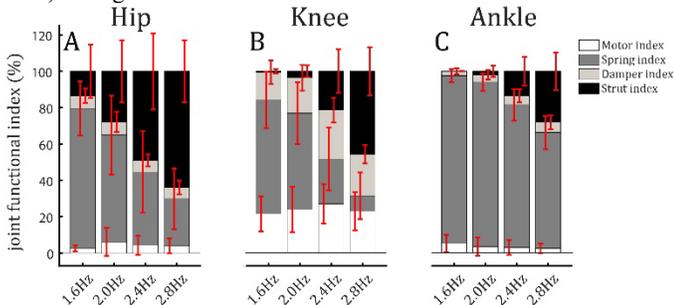

Although the dynamics of the center of mass (COM) can be accounted for by a spring-mass model during hopping, less is known about how each leg joint (i.e., hip, knee, and ankle) contributing to the COM dynamics during hopping. This study investigated the function of individual leg joints when humans hopped vertically and unilaterally at four different frequencies (i.e., 1.6, 2.0, 2.4, and 2.8 Hz) (1). I hypothesized that 1) all leg joints (i.e., hip, knee, and ankle) maintained the functional as torsional springs and increased their stiffness when hopping frequency increased, and 2) the leg joints are controlled to maintain the same mechanical load when hopping at different frequencies.

## Methods

A 3D motion capture system (12 cameras, model Miquis M3, Qualisys, Göteborg, Sweden) was used to record full body kinematics at 120 Hz. A force platform (600 × 900 mm, model 6090-15, Bertec Corp., Columbus, OH, USA) acquired ground reaction forces (GRFs) at 1440 Hz. The stance phase from touchdown (TD) to takeoff (TO) of the left foot on the platform during all cycles in each trial was analyzed. To characterize the leg joint function during hopping, I used previously developed indices decomposing the function of a leg joint into four mutually exclusive and exhaustive components (i.e., strut-, spring-, motor-, and damper- index, Fig. 2).

**Figure 1:** The work loop formed by each leg joint (i.e., hip, knee, and ankle) during stance.

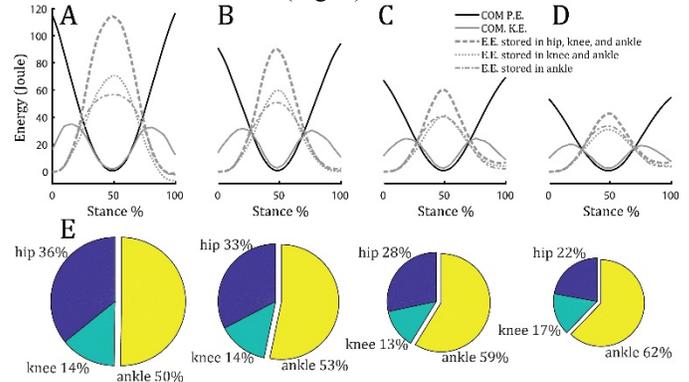

**Figure 2:** The % of the motor, spring, damper, and strut indices during stance phase of hopping for (A) hip, (B) knee, and (C) ankle.

## Results and Discussion

Decomposing the mechanics of leg joints into functional roles supported that, in slow hopping, all leg joints behaved like a spring. The spring indices for the hip (76%), knee (63%), and

ankle (93%) were the largest index among motor, spring, damper, and strut indices at 1.6 Hz (Fig. 2).

**Figure 3:** The flow of different mechanical energy during the stance phase of hopping (A) 1.6 Hz, (B) 2.0 Hz, (C) 2.4 Hz, and (D) 2.8 Hz. (E) The % of each leg joint in storage and return mechanical energy in the stance phase.

As hopping fast, leg joints changed their functional roles differently. Specifically, the hip's spring index decreased from 76% at 1.6 Hz to 26% at 2.8 Hz. The decrease of hip's spring index was mainly compensated for by the increase of strut index from 14% at 1.6 Hz to 64% at 2.8 Hz. For the knee, fast hopping required spring index decreased from 63% at 1.6 Hz to 9% at 2.8 Hz and strut index increased from 1% at 1.6 Hz to 45% at 2.8 Hz. Therefore, faster hopping requires hip and knee to change functional roles from spring to strut (Fig. 2). For the ankle, hopping fast mainly decreased the ankle's spring index from 93% at 1.6 Hz to 64% at 2.8 Hz while increased strut index from 0% at 1.6 Hz to 28% at 2.8 Hz. Therefore, hopping fast only required ankle to reduce its primary role as a spring.

For the relative amount of COM mechanical energy's storage and return, the ankle dominated in all hopping frequencies. When hopping frequency increased, the system's mechanical energy decreased (Fig. 3), but ankle's dominance of energy storage and return increased (i.e., from 51% at 1.6 Hz to 65% at 2.8 Hz).

## Significance

Understanding the function and control of leg joints in hopping could provide insight into the fundamental principles of legged locomotion of humans. Human hopping is not passive because the functional roles of each leg joints change at different hopping frequencies. The functional change of leg joints could help to understand how the muscles are controlled to achieve task goals.

## Methods of Estimating Foot Power in Takeoff Phase of Standing Vertical Jump

Kundan Joshi and Blake M. Ashby

School of Engineering, Grand Valley State University, Grand Rapids, MI, USA

Email: [joshik@mail.gvsu.edu](mailto:joshik@mail.gvsu.edu)

### Introduction

Experimental motion capture studies have commonly considered the foot as a single rigid body despite the presence of numerous internal joints and deformable soft tissue. Various approaches have been used to quantify the internal foot power due to rigid body deviations of the foot. Two strategies that can be used with a traditional rigid foot are distal foot power (DFP) [1] and foot power imbalance (FPI) [2] techniques. Another approach for modeling the non-rigid nature of the foot is with a multisegment foot [3]. The purpose of the present study was to compare the internal foot power and work in the takeoff phase of the standing vertical jump (SVJ) using DFP and FPI on a single rigid foot and using a two-segment foot model separated at the metatarsophalangeal (MTP) joints.

### Methods

The right-sided lower limb model devised for this study contained a shank and a two-segment foot divided at an MTP joint. A 16-camera motion capture system (Vicon Motion Systems Ltd., Los Angeles, CA) was used to record six physically active participants performing six SVJs from two adjacent force platforms (Advanced Mechanical Technology Inc., Watertown, MA). The participants positioned their feet so that the ground reaction forces (GRF) acting on the foot could be divided at the MTP joints consistent with the protocol introduced by [3].

Using inverse dynamics with a two-segment foot, the total 6DOF power at the MTP joint was calculated and integrated to get MTP work. Using inverse dynamics on a single rigid foot, DFP and FPI were calculated using the equations shown below and integrated to get foot work:

$$DFP = \mathbf{F}_{GRF} \cdot (\mathbf{v}_G + \boldsymbol{\omega}_{foot} \times \mathbf{r}_d) + \mathbf{M}_{free} \cdot \boldsymbol{\omega}_{foot}$$

$\mathbf{F}_{GRF}$  is the GRF acting on the foot at the center of pressure (COP),  $\mathbf{M}_{free}$  is the free moment acting on the foot,  $\boldsymbol{\omega}_{foot}$  is the foot angular velocity,  $\mathbf{v}_G$  is the foot mass center (COM) velocity, and  $\mathbf{r}_d$  is the position vector from the COM to the COP.

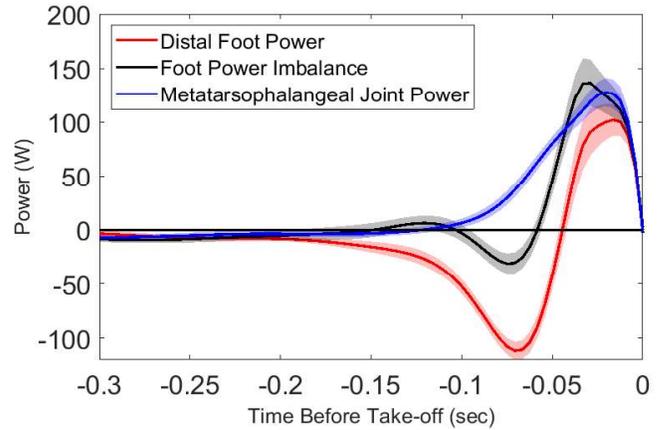

$$FPI = \frac{dE_{foot}}{dt} - \mathbf{M}_{ank} \cdot \boldsymbol{\omega}_{foot} - \mathbf{F}_{ank} \cdot \mathbf{v}_{ank}$$

$E_{foot}$  is the foot mechanical energy, and  $\mathbf{M}_{ank}$ ,  $\mathbf{F}_{ank}$ , and  $\mathbf{v}_{ank}$  are the net ankle moment, intersegmental force, and velocity, respectively.

Descriptive statistics for foot power and work were generated. To compare the three methods, one-way within repeated measures ANOVA was implemented (alpha value 0.05).

### Results and Discussion

MTP power was basically zero or positive (Figure 1). DFP showed significant power absorption, followed by power generation that peaked lower than the other two. FPI showed lesser power absorption than DFP, with power generation peaking about the same as MTP. The work values were  $-4.0 \pm 1.0$  J for DFP,  $1.8 \pm 1.1$  J for FPI, and  $5.1 \pm 0.5$  J for the MTP joint (all significantly different from each other with  $p < 0.0001$ ).

**Figure 1:** Comparison of least square mean values for DFP versus FPI versus MTP joint power (with 95% confidence interval bands)

All three approaches demonstrate positive power contributions right before takeoff due to structures internal to the foot. The two-segment foot model only calculated the power at the MTP joint, which was almost all positive. The other two approaches, DFP and FPI both demonstrated periods of negative power indicating that areas of the foot other than the MTP joints were absorbing power. The difference between DFP and FPI might be explained by understanding that DFP represents the power due to deviation from the rigid body state only for the portion of the foot between the COM and the COP [4], whereas theoretically, FPI captures the internal power throughout the foot. For both methods, errors can arise from the assumption that the angular velocity of the foot is the same throughout and that the COM can be accurately determined.

### Significance

Any of these three methods may be used to quantify internal foot power, but it is important to properly understand the limitations of whichever method is used. Using a multisegment foot may seem like a better approach, but more than two segments is probably required to capture all the internal foot power. Moreover, apportioning the GRF across multiple segment is rarely practical. DFP and FPI are relatively simple ways of quantifying the power contributions of the foot that can be used with a traditional rigid foot model. The results motivate further research to compare and understand the relative merits of the two methods for movements besides jumping, as well as investigating how to quantify kinetics of a foot model with three or more segments.

### Introduction

For individuals with unilateral lower limb loss, single-leg hopping is often a convenient method of ambulation. However, large and unusual forces presented during single-leg hopping may accelerate degeneration of joint health and integrity compared to walking itself [1]. Therefore, the purpose of this study was to identify the forces and movement patterns used by individuals with unilateral transfemoral (TF) and transtibial (TT) limb loss. With a smaller residual leg, we hypothesize TF vs. TT participants will exhibit larger hip motions.

### Methods

Thirty-two males with unilateral lower limb loss (22 TT and 10 TF) participated, with mean (SD) age=36.7 (7.4) yr, height=178.8 (5.0) cm, body mass=88.7 (13.1) kg. Each hopped on one leg along a 15m walkway, at a self-selected pace. Full-body kinematics were tracked using a motion capture system; ground reaction forces were simultaneously sampled via force platforms.

Kinetic outcomes included features of the knee adduction (KAM) and flexion (KFM) moments; impulse was calculated as the integral of the moment-time series; LR as the slope between 20% and 80% of the time from heel strike to the first KAM peak; and the per-unit-distance (PUD) KAM as the average joint moment across all strides divided by the average stride length[2]. Kinematic outcomes included features of knee, hip, and trunk angles; trunk-pelvic coordination was quantified using continuous relative phase (CRP), computed as the difference between the normalized phase angles of the trunk and pelvis segments [3]. All outcomes were averaged across hops, and kinetic outcomes scaled by body weight and height. Unpaired t-tests assessed differences between TT and TF participants ( $p < 0.05$ ).

### Results and Discussion

There were no differences in kinetic outcomes between TT and TF participants (Table 1). Although slightly different movement patterns were observed between TT and TF participants, differences in forces applied are compensated with different movement strategies.

Table 1. Single-leg hopping kinetics

	TT (n=22)	TF (n=10)	p(sig)
Peak KAM (BW·Ht)	4.4±2.0	4.4±1.4	0.99
KAM Impulse (BW·Ht)	0.5±0.4	0.5±0.3	0.76
KAM Loading Rate (BW·Ht·s <sup>-1</sup> )	0.5±0.3	0.5±0.3	0.73
Peak KFM (BW·Ht)	14.6±3.4	12.9±3.2	0.19
KAM PUD (BW·Ht·m <sup>-1</sup> )	6.2±2.9	7.9±2.9	0.15

<sup>a</sup>-Values are expressed as mean±SD

\*- Statistically significant difference between groups ( $p < 0.05$ )

TF participants hopped with increased hip abduction at foot-contact (FC; Table 2). This increased hip abduction indicates dependence on their intact leg for stability, but may also suggest that a longer limb (apparent with TT limb-loss) may provide for

counter-weight support during single-leg ambulation. Larger CRPz is indicative of more out-of-phase (or less in-phase) movement, suggesting TF participants are increasing the relative (axial) rotation between the trunk-pelvis to assist with forward propulsion during their hop.

Table 2. Single-leg hopping kinematics.<sup>a</sup>

	TT (n=22)	TF (n=10)	p(sig)
Hop Speed (m/s)	0.50±0.07	0.46±0.04	0.10
Hop Length (m)	0.77±0.24	0.58±0.09	0.02*
Vertical COG Displacement (cm)	1.2±0.1	1.3±0.0	0.08

### Significance

Identifying movement patterns and associated forces during hopping, unique to the level of limb loss, facilitate development of clinical/movement recommendations and rehabilitative efforts. Future research can utilize the differences in movement patterns to potentially associate them with the high prevalence of knee degeneration in the limb loss population. Moreover, larger axial motions seen in TF may also inform future investigations into other highly prevalent musculoskeletal conditions following limb loss, such as low back pain.

# Shorter Muscle Activation Time Increases the Metabolic Cost of Cyclic Force Generation

## Introduction

The biomechanical basis for the metabolic cost of terrestrial locomotion is elusive. That is partly because many parameters change in the same direction as locomotion tasks vary, making it difficult to separate the independent contributions to metabolism. Muscle force generation is presumed to exact a metabolic cost. Yet, it remains unclear how the time-course of force generation affects metabolism [1]. Filling this gap in our understanding is important because reducing the metabolic cost of locomotion may improve performance, mitigate fatigue, and promote physical activity. Thus, we sought to reveal if the time-course of muscle force generation affects the metabolic cost of producing a fixed force-time integral (analogous to stride-Avg muscle force) over periodic activation-deactivation cycles; emulating muscle contractions during steady-state locomotion.

## Methods

11 participants performed 6 x 5-minute fixed-end plantar flexion trials on a dynamometer with their right knee and ankle secured at 130° and 90°, respectively. In this position, plantar flexion torque is primarily provided by the soleus. During each trial, participants cyclically generated plantar flexion ankle torque on the fixed-position dynamometer pedal at the downbeat of an audible metronome and then relaxed at the subsequent upbeat (metronome frequency: 0.75 Hz): downbeat-activate, upbeat-deactivate, repeat. During each trial, participants generated a predetermined dynamometer torque (10-30 Nm) over a set duration ( $\bar{4}$ - $\bar{8}$  s) with the goal of achieving 3 higher and 3 lower torque-time integrals over 3 different activation durations each (Fig. 1). We recorded instantaneous soleus fascicle length and pennation angle, dynamometer torque, muscle activity, joint kinematics, and metabolic data.

## Results and Discussion

Consistent with our study design, soleus activation time did not affect total activation-deactivation cycle time-integrated soleus force ( $p=0.483$ ). Greater time-integrated soleus force increased net metabolic power ( $p<0.001$ ). The three higher time-integrated ankle moment trials (Fig. 1: purple symbols) elicited a 51% increased time-integrated soleus force and a 64% greater net metabolic power compared to the targeted lower time-integrated ankle-moment trials (Fig. 1: green symbols). When controlling for time-integrated soleus force, shorter soleus activation time increased net metabolic power ( $p=0.002$ ): every 0.4 s decrease in soleus activation time increased net metabolic power 15.2 Watts.

Greater soleus force-time integrals were associated with increased average and maximum soleus fascicle pennation angles ( $p\leq 0.029$ ) and shorter minimum soleus fascicle lengths ( $p=0.025$ ). While controlling the soleus force-time integral, shorter soleus activation times were associated with greater peak soleus fascicle pennation angles ( $p\leq 0.018$ ), shorter average and

minimum fascicle lengths ( $p\leq 0.031$ ), and faster peak fascicle shortening velocities ( $p\leq 0.005$ ).

We utilized the relationship between muscle force magnitude and the time-course thereof during steady-state locomotion to study how the time of generating muscle force affects metabolic cost. While controlling other biomechanical parameters that may affect metabolism (e.g. activation-deactivation time [2]), the metabolic cost of cyclically generating force depends on the corresponding muscle activation time. Specifically, shorter muscle activation times

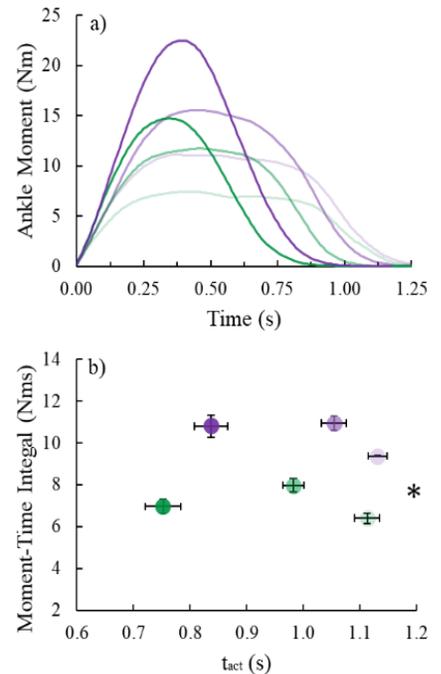

increase the metabolic cost of generating a force-time integral. This study suggests that when linking biomechanics and metabolism during human locomotion, scientists should consider the time-course of force generation.

## Significance

This study emulated muscle dynamics during steady-state locomotion, controlled for multiple potential co-variables, and revealed that shorter muscle activation times increase metabolic cost. These results may help scientists better link biomechanics to metabolism, which is essential for understanding animal behavior, developing evolutionary hypotheses, and informing interventions that reduce metabolic energy expenditure during terrestrial locomotion (e.g. assistive devices, surgical techniques, and training regimens).

### Introduction

Elderly adults are at an increased risk of falls. A return to sit (RTS) is one of the activities of daily living that is associated with falls and accounting for 12% of falls in elderly at long-term care facilities.<sup>1</sup> Proper quadriceps function are required for efficient RTS completion. A study indicated that experimentally induced muscle damages was found to result in increased knee joint power without differences in knee moment during RTS.<sup>2</sup> Consequently, an altered speed for knee motions relative to the force output should be related to the risk of falls. Considering the sustainability of quadriceps activations during RTS are more inconsistent compared to STS<sup>3</sup>, examining movements during RTS should provide clinical insights of alternated performance related to functional limitations. Therefore, the purpose of this study was to investigate biomechanical variables that lead to the decrease in performance during RTS for individuals with and without functional limitations as diagnosed by the Stand-Up Test (SUT). We hypothesized that biomechanical differences in movements during RTS will be revealed in individuals with and without functional limitations as diagnosed by SUT. These differences were not found in our previous analysis for STS despite finding significantly different clinical impairments.<sup>4</sup>

### Methods

We analyzed 15 independent community dwelling adults (mean age: 56 years old) who participated in the previously reported study.<sup>5</sup> The participants

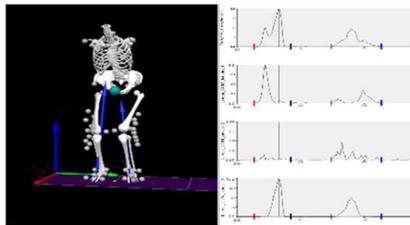

Figure: Typical Patterns for Kinetic Energy

were categorized into two groups using the SUT: Group 1: non-functional limitations (n=6) and Group 2: the beginning of mobility decline (n=9). Motion data was captured using a 3D Vicon Motion Capture System with 2 AMTI force platforms. The 6-degree of freedom model with using the V3D Composite Pelvis were applied to calculate kinetic energy previously published as a risk of falling. Due to the limited sample size, effect sizes were calculated for between group comparisons.

### Results and Discussion

Despite our hypothesis, the group differences in kinetic energy were larger in STS (Cohen's  $d=0.47-1.84$ ) as compared to RTS (Cohen's  $d=<0.01-2.68$ ). The remarkable differences for STS and RTS between groups were shown in the anterior/posterior (AP) direction. During the RTS, an extremely large effect size ( $d=2.68$ ) was noted in the linear kinetic energy in the AP direction. A small effect size ( $d=0.24$ ) was found for differences in the linear kinetic energy in the upward/downward (Vertical) direction. For Group 2, a 49% increase in the AP direction and a 45% decrease in the vertical direction for the kinetic energy was found in RTS when compared to STS. These changes in the kinetic energy distribution could represent altered joint strategies to complete RTS. The overall between-group effect size for the RTS was negligible ( $d\leq 0.01$ ) when compared to STS ( $d=0.53$ ). This may be related to varied patterns of RTS resulted from inconsistent muscle activities or joint-movements strategies when lowering against the gravitational forces.<sup>2,3</sup> Further investigations are needed to explain how muscle functions affect the altered kinetic energy.

### Significance

Individuals with subtle functional limitations demonstrated altered RTS by distributing more kinetic energy in the anterior/posterior direction. This altered kinetic energy distribution may improve stability by prolonging the duration of the COG over the feet during RTS. The findings may provide insights to the reasons behind an increased risk of injury and falls due to changes in velocity of a RTS.

# Performing Multi-Terrain Transient Locomotion Influence Changes in Joint Coordination of Individuals with Early-Stage Parkinson's Disease

Emma J. Neuendorff<sup>1</sup>, Staci M. Shearin<sup>2</sup> and Nicholas P. Fey<sup>1,2</sup>  
<sup>1</sup>The University of Texas at Dallas, <sup>2</sup>UT Southwestern Medical Center  
 Email: emma.neuendorff@utdallas.edu

## Introduction

Parkinson's disease (PD) is a neurodegenerative disorder that progressively weakens motor function resulting in symptoms such as tremors, limb stiffness and impaired balance [1]. Daily movement is commonly presented with complex motor tasks, such as changing directions or avoiding an obstacle. Individuals with PD tend to have more difficulty planning and executing these tasks due to lower motor dexterity as the disease progresses. Early detection is important for slowing the progression of PD by beginning exercise programs and other therapeutic interventions [2]. PD is currently diagnosed based on medical history and through an examination performed by a neurologist, but there is no quantitative test for PD diagnosis. Gait analysis using an optical motion capture system is a high-resolution method to examine motor impairments. Detecting changes in gait kinematics in individuals with little to no outward signs of PD relative to control subjects may provide insight into the early signs of disease and promote earlier detection [3]. In this study, we analyzed joint ranges of motion (ROM) of the hips, knees and ankles of individuals with early-stage PD compared to healthy control subjects as they walked continuously on a varying terrain circuit that integrated a level ground walkway, staircase, turn, and ramp. This study hypothesized that since individuals with PD are challenged by self-regulation of their mechanics when presented with complex terrains, subsequent analysis of underlying joint kinematics would reveal differences relative to control subjects, during transitional events between multiple terrains.

## Methods

This study consisted of five individuals with PD, Hoehn and Yahr Stage 1 or 2, and five healthy controls that walked on a terrain circuit of a ramp, turn, and four-step staircase. Each subject was equipped with 66 reflective markers attached to 12 body segments of the arms, legs, and trunk. Optical motion data was captured for each subject as they walked through the circuit, performing a total of ten trials each moving from stair ascent to ramp descent and from ramp ascent to stair descent. Lower body joint angles and ranges of motion were calculated for eight transitional terrain events for the ramp and stairs: level-walking to ramp ascent (LW/RA), ramp ascent to turn (RA/T), level-walking to stair ascent (LW/SA), stair ascent to turn (SA/T), turn to ramp descent (T/RD), ramp descent to level-walking (RD/LW), turn to stair descent (T/SD), and stair descent to level-walking (SD/LW). Unpaired, two-sample t-tests were performed across both groups for the transitions ( $\alpha=0.05$ ).

## Results and Discussion

Knee ROM when approaching turns displayed significant differences between PD subjects and controls. PD individuals exhibited less motion in their knees for RA/T and SA/T. Hip ROM was also significantly different for RD/LW. Table 1 reports the ROM and p-values for these transitions. Figure 1 reports knee angle for the SA/T transition.

Terrain Event	PD ROM	Control ROM	p-value
RA/Turn	64.06 (6.48)	68.47 (5.91)	1.91%
SA/Turn	66.92 (6.69)	76.37 (9.91)	0.06%
RD/LW	34.32 (5.81)	42.21 (8.94)	0.08%

Table 1: PD and control ROM with p-values.

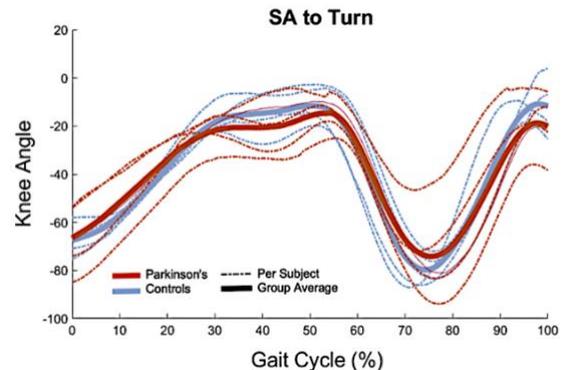

Figure 2: Knee angle during one gait cycle for SA/T. Each subject is shown for PD and control groups, along with an overall group average.

PD subjects decreased their stride length, taking more steps when moving towards the turn, consistent with a festinating gait pattern. We also found that moving from the ramp to level-walking requires a more arbitrary method for task completion compared to moving from the stairs. This is emphasized through decreased hip ROM during RD/LW. We suggest the neuromotor impairment associated with PD is exacerbated by the spatially unconstrained manner of the ramp that presents a less consistent terrain for task planning, evidenced by relatively few changes in coordination during transitions involving the stairs.

## Significance

Studying transient locomotion of individuals with mild PD could help diagnose the disease in its early stages, when impairment is not particularly evident during isolated modes of ambulation. Early diagnosis could allow PD individuals to begin therapy to slow the progression of the disease, increasing their chance of continuing to live independently and resume daily activities. The study is also the first to highlighted a significant reduction in joint range of motion when approaching a turn from the stairs or ramps, and even when moving off ramps to level-ground straight-line walking. This suggest that the varying mechanical demands of each task are not necessarily as challenging for these individuals as the issue of neuromotor task planning.

## Effects of Gravitational and Inertial Forces on Determinants of Gait Transitions

Nathan G. Frakes<sup>1</sup>, Courtney A. Perry<sup>1</sup>, and Justus D. Ortega<sup>1</sup>

<sup>1</sup>Department of Kinesiology, Humboldt State University, Arcata, CA, USA

### Introduction

Gait transitions refer to the changing from one mode of locomotion to another [1], e.g., the walk to run (WRT) or the run to walk transitions (RWT). Prior research suggests that gravitational force is pivotal in determining preferred transition speed (PTS) for both WRT and RWT [2], though not much has been researched about the effect of inertial forces on the PTS. By utilizing four key criteria to identify a determinant of the PTS [1,3], prior research suggests that PTS may be triggered across varying conditions by a change in lower limb kinematics [1]. Specifically, it is suggested that when a lower limb kinematic variable adheres to all four criteria, that variable should be considered a key determinant of the PTS.

The purpose of this study was to investigate possible kinematic determinants of PTS for both WRT and RWT across differing levels of gravitational and inertial forces.

### Methods

Twelve healthy adults (9 male, 3 female) completed WRT and RWT trials on a motorized treadmill across seven conditions of altered body weight (BW) and body mass (BM) including: 1.0 BM / 1.0 BW; 0.70 and 0.85 BW / 1.0 BM (-GF); 1.15 and 1.30 BM / 1.0 BW (+IF); 1.15 and 1.30 of both BW and BM (+GF+IF) using previously established methods [4]. For each condition, we determined PTS (m/s) by increasing speed (from 1.34 m/s for a WRT) or decreasing speed (from 2.68 m/s for a RWT) 0.09 m/s every 30 sec until a gait transition was achieved. A 9-camera motion analysis system (Vicon) was used to collect (120 hz) lower limb kinematics for each condition. This data was used to calculate the average and peak hip, knee, and ankle joint kinematics (acceleration- $\alpha$ , velocity- $\omega$ , and angle- $\theta$ ) during the gait cycle over the course of 20 strides.

We evaluated three of the four key criteria used to identify if a variable is a determinant of the PTS including 1) an abrupt change in the value of a variable before and after gait transition, 2) a return of the variable to values seen at initial speeds in the previous gait (i.e., at slower walking speeds for WRT or higher speeds for RWT), and 3) the variable reaches a shared critical value just prior to the PTS for all conditions [1]. We assumed that all kinematic variables met the fourth criteria of “needing to act on proprioceptive feedback” [1].

We performed repeated-measures MANOVAs to assess the effects of gravitation force, inertial force and combined forces on determinants of the PTS. We then conducted planned contrasts between speeds of each condition to determine if the variable increases/decreases between speeds and then changed abruptly from before to after transition (Criteria 1). We also used planned contrast to determine if the variable returned to a level observed at a previously slower (WRT) or faster speed (RTW) (Criteria 2). We compared the value of each variable just before transition between all conditions to determine if the transition happened at a similar critical value (Criteria 3). An effect size of  $<.1$  was used to identify a “negligible” difference and thus similar critical value between conditions [1].

### Results and Discussion

#### *Walk to Run Transition (WRT)*

*Criteria 1:* In all the WRT conditions,  $\alpha_{\text{dorsi-peak}}$ ,  $\omega_{\text{dorsi-peak}}$ , and  $\theta_{\text{hip-peak}}$  increased between initial and final (before transition) walking speeds ( $p < .05$ ). After the WRT, both  $\alpha_{\text{dorsi-peak}}$  and  $\theta_{\text{hip-peak}}$  abruptly decreased ( $p < .001$ ) in gravitational and inertial conditions with no significant change in  $\omega_{\text{dorsi-peak}}$ .

*Criteria 2:* Following the WRT, both  $\alpha_{\text{dorsi-peak}}$  and  $\theta_{\text{hip-peak}}$  returned to values observed at initial speeds in the previous gait ( $66 \pm 14\%$  and  $77 \pm 7\%$  respectively).

*Criteria 3:* Although each variable ( $\alpha_{\text{dorsi-peak}}$ ,  $\omega_{\text{dorsi-peak}}$ ,  $\theta_{\text{hip-peak}}$ ) shared a similar critical value just prior to the PTS, only  $\alpha_{\text{dorsi-peak}}$  and  $\omega_{\text{dorsi-peak}}$  had “negligible” effect size (ES) across all conditions (ES = .03;  $p = .826$  and ES = .06;  $p = .544$  respectively).

*WRT Summary:* Only  $\alpha_{\text{dorsi-peak}}$  met the three key criteria used to identify a determinant for the WRT. However,  $\theta_{\text{hip-peak}}$  was close to meeting all key criteria. Surprisingly,  $\omega_{\text{dorsi-peak}}$  did not meet the criteria required of a determinant for the PTS, contrasting with results found in prior literature [1].

#### *Run to Walk Transition (RTW)*

*Criteria 1:* In all of the RWT conditions,  $\alpha_{\text{dorsi-peak}}$  and  $\theta_{\text{hip-peak}}$  decreased between initial and final running speeds ( $p < .01$ ). After the RWT, both  $\alpha_{\text{dorsi-peak}}$  and the  $\theta_{\text{hip-peak}}$  abruptly increased ( $p < .0001$  and  $p < .02$  respectively) in gravitational and inertial conditions with no significant change in  $\omega_{\text{dorsi-peak}}$ .

*Criteria 2:* Following the RWT, both  $\alpha_{\text{dorsi-peak}}$  and  $\theta_{\text{hip-peak}}$  returned to similar values observed at initial speeds in the previous gait ( $150 \pm 23\%$  and  $131 \pm 11\%$  respectively).

*Criteria 3:* All evaluated variables ( $\alpha_{\text{dorsi-peak}}$ ,  $\omega_{\text{dorsi-peak}}$ ,  $\theta_{\text{hip-peak}}$ ) shared a similar critical value just prior to the RWT across all conditions (ES  $< .1$ ;  $p > .30$ ).

*RTW Summary:* Both  $\alpha_{\text{dorsi-peak}}$  and  $\theta_{\text{hip-peak}}$  met the three key criteria used to identify a determinant for the RWT while  $\omega_{\text{dorsi-peak}}$  only met one of the criteria.

### Significance

Of the kinematic variables evaluated in this study, only  $\alpha_{\text{dorsi-peak}}$  met the three criteria used to identify if a variable is a determinant of PTS for both WRT and RWT while  $\theta_{\text{hip-peak}}$  met the criteria for the RWT only. Our results suggest that there are potential differences in mechanical determinant/triggers of gait transition for the RWT compared to the WRT. These results can be used to support the hypothesis that gait transition may occur to prevent overexertion of hip and ankle musculature working maximally at speeds at or near PTS [1].

### Introduction

The intricate and adaptive structure of the medial longitudinal arch (MLA) has a pivotal role in the development of propulsive mechanics during locomotion. Structural alterations within the MLA (i.e. arch type) have been shown to induce maladaptive kinematics and kinetics that modify the generation of adequate foot function and predispose individuals to injury in forward directional movement tasks [1-3]. However, altered bony alignments of lower MLAs may produce biomechanical advantages for locomotive tasks in the mediolateral direction and such investigations remain limited. Thus, the purpose of this study was to examine the influence arch height has on the propulsive phase of directionally specific jumping tasks.

### Methods

Twenty-two Division I collegiate male athletes (height:  $1.84 \pm 0.06$  m; mass:  $88.4 \pm 12.1$  kg) were recruited to participate in this study. All participants indicated their voluntary involvement by signing an informed consent approved by the university's Institutional Review Board. Inclusion criteria for the study included good self-reported health, absence of a lower extremity injury within the last six months, and without any surgical procedure to the foot and ankle.

Prior to completing the locomotive tasks, foot anthropometric measurements were obtained to classify the different arch types [4]. Peak ground reaction forces (GRFs) of the dominant limb were collected with a force platform (Advanced Mechanical Technology, Inc., Watertown, MA, USA), sampling at 1000HZ, during the unilateral stationary hopping (SH), unilateral forward hopping (FH), and lateral jumping (LJ) tasks. The tasks were conducted in a randomized order. During the SH task, the participants performed nine continuous hops. The three middle repetitions were analyzed to minimize the influence of the initiation and cessation of the task. The FH task consisted of three trials of three consecutive forward hops. The second hop, in which the foot made contact with the force platform, was used for analysis. Within the LJ task, participants began with their dominant foot on the force platform. Participants were then instructed to complete three trials of jumping in the following rhythmic sequence: from the dominant leg to the non-dominant leg, to the dominant leg and back to the non-dominant leg. During this jumping sequence, the participants were instructed to strike the force platform when jumping from the non-dominant leg to dominant leg. Analysis of the foot strike of the dominant leg, back on the force platform was chosen to minimize the influence of initiation and cessation on the data.

Kinetic data were imported into Visual3D (C-Motion, Germantown, Maryland, USA) for the reduction of maximum vertical, anteroposterior, and mediolateral GRFs during the propulsion phases of the jumping and hopping tasks. Data were

then transferred to SPSS (IBM SPSS Inc., version 26.0, Chicago, IL, USA) for statistical analysis.

### Results and Discussion

The results of the mixed-factorial ANOVAs yielded differences in vertical, anteroposterior, mediolateral GRFs between the LJ, FH, and SH tasks. Specifically, the LJ significantly produced the greatest mediolateral GRFs ( $F(1.295, 25.890) = 72.135$ ,  $p < 0.05$ ,  $\eta^2 = 0.783$ ), the FH significantly produced the greatest anteroposterior GRFs ( $F(2, 40) = 51.883$ ,  $p < 0.001$ ,  $\eta^2 = 0.722$ ) and the least vertical GRFs ( $F(1.536, 30.723) = 8.308$ ,  $p < 0.05$ ,  $\eta^2 = 0.293$ ). Additional findings demonstrated lower arches produced significantly greater mediolateral GRFs in the LJ ( $F(1, 20) = 4.502$ ,  $p = .047$ ,  $\eta^2 = .184$ ).

The contributive efforts of the lower extremity during the propulsive phase of locomotion are complex in nature. While the MLA acts a mediator for foot function, skeletal alterations are often deemed pathological. Specifically, changes in the skeletal framework produce modified propulsive mechanisms that provide directional-specific leverage and are often corrected to mend this anatomical dysfunction [3,5]. However, the use of such corrective measures can provide a great hindrance to the overall outcome of the motion. Specifically, the findings of this study suggest that the everted positioning of low arches and production of increase mediolateral GRFs provide a mechanical advantage during propulsion. The novel approach associated with this study suggests the structural alignments and nature of the tasks should be considered when investigating human movement patterns.

### Significance

This study demonstrated the complexities of the human body during the propulsive phase of locomotion. More specifically, the arch type differences can induce directional differences in force production during the propulsive phase of locomotive tasks and highlights alternative movement patterns that may be beneficial for movement.

## Introduction

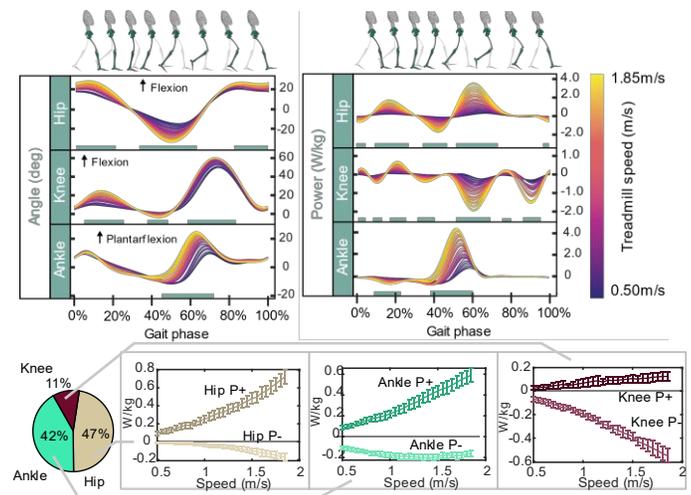

The biomechanics of locomotion have been profusely studied, establishing many standards in the field. Winter[1], is the seminal reference of motion capture data used as the standard of biomechanics analysis of walking. Other sources provide insight about the power and torque contribution to locomotion at the joint level [2], [3], [4]. This standard has extended towards other modes of locomotion where ascending and descending stairs and ramps have a major subset of biomechanics research [5], [6]. However, there is a scarcity of databases of locomotion that provide access to raw information from individual trials. Recent efforts have directed towards generating open benchmark datasets that are accessible to public. Hu et al. [7] released the first benchmark database of simultaneous kinematic and EMG data as able-bodied individuals transition between locomotor activities in a circuit consisting of a single of staircase and ramp. Following this established database, we contribute a novel dataset that extends the report of kinematics results by including the joint level moments and powers processed using inverse dynamics from the open-source biomechanics software OpenSim. In addition, we provide access to the kinematics, kinetics and joint power data in conjunction with the data from multiple sources of wearable sensors, including EMG, goniometer, accelerometer and gyroscope signals. The availability of open datasets that link wearable signals to the biomechanics will aid the development of better locomotion assistance techniques.

## Methods

The experimental collection consisted of N=22 young healthy adults, age  $21 \pm 3.4$ yr, height  $1.70 \pm 0.07$ m, weight  $68.3 \pm 10.83$ kg, instrumented with 32 motion capture reflective markers. (Vicon Motion Systems Inc, Los Angeles, CA, USA). Ground reaction forces were recorded from an instrumented treadmill (Bertec Corporation, Columbus, OH, USA) and forceplates located in level with the floor, ramp and stairs. In addition, subjects were instrumented unilaterally with 11 EMG (electromyography) 3 goniometers, and 4 six-axis inertial measure units (IMU). The study, approved by the IRB at Georgia Institute of Technology, consisted of subjects performing locomotion tasks in four different terrain types: treadmill, level ground, ramp and stairs. Treadmill walking data was collected at 28 different speeds ranging from 0.5 to 1.85m/s with increments of 0.05m/s. Level ground walking was also collected at three speeds relative to the subject's preferred speeds (slow, normal and fast), and including turns in counterclockwise and clockwise directions. Stairs at four different step heights within the range of ADA accessibility Guidelines [8] 10.16cm (4in), 12.70cm (5in), 15.24cm (6in), 17.78cm (7in). Ramp inclinations corresponded to  $5.2^\circ$ ,  $7.8^\circ$ ,  $9.2^\circ$ ,  $11^\circ$ ,  $12.4^\circ$  and  $18^\circ$ . Average profiles are computed from time series data segmented by gait strides. The effect of the terrain context is evaluated at each instant of the gait phase, using linear regression model ( $p < 0.01$ ).

## Results and Discussion

Kinematic and kinetic profiles for each ambulation are generated, reporting averages at each condition and marking the regions where the context has significant effects ( $p < 0.01$ ). For this short abstract, we present the kinematics and joint power for locomotion on treadmill at different speeds, the contribution of energy and the influence of the speed in the modulation of joint power.

**Figure 1:** Joint kinematics and instant power during a stride at different walking speeds (0.5m/s – 1.85 m/s). The pie chart represents the contribution of each joint to the average positive power. The sensitivity of joint power is presented as a function of the walking speed, with error bars showing  $\pm$ std.

## Significance

Open biomechanics datasets are beneficial to researchers interested in the development of controllers for assistive devices, where information of joint level state is required to accomplish biomimetic assistance. For this, the access to joint level moment and power at different conditions of locomotion can inform the design of controllers that accommodate for terrain conditions

### Introduction

Loaded marches are an important component of military training and operations, and involve carrying combat loads ranging from 20-60+ kg over long distances.<sup>1</sup> Previous studies have identified increases in plantar contact pressure during footstrike while walking with carried loads.<sup>2</sup> Research is required which examines regional plantar forces during the impact phase of loaded walking, running, and forced marching (walking at a velocity above gait transition velocity [GTV]), to further identify potential injurious motion patterns. The purpose of this study was to determine the effect of load magnitude and locomotion pattern on regional plantar forces. It was hypothesized that peak regional force would increase across all regions while running and forced marching compared to walking and with increased carried load.

### Methods

Eight healthy physically active females (24.5±2.4 years) participated in this IRB-approved study. Participants wore standard issue military combat boots with Pedar pressure-sensing insoles (Novel Electronics Inc, St. Paul, MN) and an evenly distributed anterior/posterior weight vest. Plantar pressure was recorded during trials of walking, running and forced marching (FM) on a treadmill while unloaded and while carrying an additional 25% and 45% of their bodyweight (+25%: 15.2±1.7 kg +45%: 27.4±3.1 kg). Walking was performed at a velocity 10% below an individuals' GTV and running and forced marching was performed at 10% above GTV. Plantar pressures from the dominant foot (right foot, 23-33 steps) were converted to force, normalized to participant bodyweight, and divided into nine foot regions (medial/lateral heel, medial/lateral arch, medial/mid/lateral forefoot, and greater/lesser toes).<sup>3</sup> Peak regional force (PRF) was determined for each region. Two-way repeated measures ANOVA with post hoc Bonferroni corrections were used to analyze the within-subjects effects of load (no load, +25%, +45%) and locomotion (walk, run, FM) on PRF across the nine foot regions ( $\alpha=0.05$ ).

### Results and Discussion

**Effect of load:** Additional load increased PRF compared to the unloaded condition at the medial and lateral heel (+25%:  $p<0.001$ ,  $p=0.042$ ; +45%:  $p<0.001$ ,  $p=0.001$ ) and +45% increased PRF compared to +25% ( $p<0.001$ ) (Figure 1). Similarly, additional load increased PRF for both the medial and lateral arch regions (+25%:  $p=0.002$ ,  $p=0.001$ ; +45%:  $p<0.001$ ,  $p<0.001$ ). For the forefoot, +45% increased PRF for the mid-forefoot ( $p=0.040$ ) and +25% increased PRF for the lateral forefoot ( $p=0.044$ ). For the greater toes, an additional +45% increased PRF ( $p=0.044$ ). Overall, the PRF at the heel was the most sensitive to an increase in carried load. This supports the hypothesis of an increase in plantar forces with increased load, although increases from +25% to +45% were not always significant.

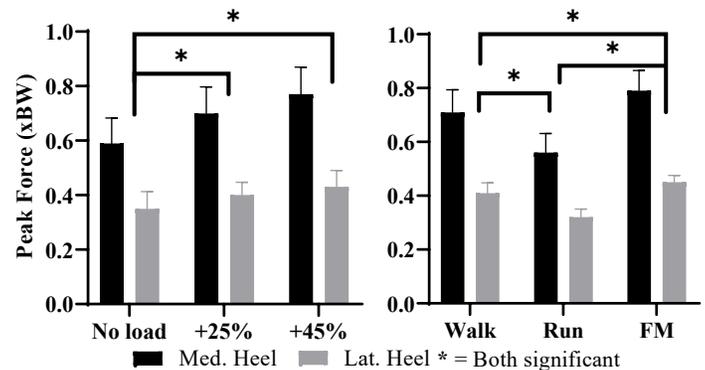

Figure 1: Average normalized peak force for the heel regions.

**Effect of locomotion:** For the heel, walking increased PRF compared to running (Medial:  $p=0.010$ ; Lateral:  $p=0.016$ ), and FM increased PRF compared to run and walk (Medial:  $p<0.001$ ,  $p=0.001$ ; Lateral:  $p=0.002$ ,  $p=0.001$ ) (Figure 1). For the arch, running and FM increased PRF compared to walking (Medial:  $p<0.001$ ,  $p=0.002$ ; Lateral:  $p=0.001$ ,  $p=0.006$ ). For the forefoot, running increased PRF compared to walk and FM (Mid:  $p=0.004$ ,  $p=0.002$ ; Lateral:  $p=0.014$ ,  $p=0.002$ ). Significant interaction between load and locomotion were identified for the medial forefoot and lesser toes ( $p=0.037$ ,  $p=0.018$ ). At the medial forefoot, running significantly increased PRF compared to walking ( $p=0.014$ ,  $p=0.006$ ) and FM increased PRF compared to running ( $p=0.010$ ,  $p=0.027$ ) for the unloaded and +25% conditions. Changes in locomotion type did not affect PRF at the greater toes. Overall, a running gait pattern resulted in higher PRF for the arch and mid/lateral forefoot regions, while forced marching increased the peak forces in the heel, arch, and medial forefoot compared to walking and running.

### Significance

This preliminary data suggests that a forced march with additional carried load increases peak force in the heel compared to walking and running. These greater forces during forced marching may increase the risk of injury and long term joint degeneration. The observation that the heel region is most sensitive to increased carried load suggests the heel region is a potential target for intervention such as an orthotic or novel shoe design to reduce heel loading during loaded locomotion.

# Young Adults Recruit Similar Motor Modules Across Walking, Turning, and Chair Transfers

Hannah D. Carey, Daniel Liss, and Jessica L. Allen\*  
West Virginia University, Morgantown, WV  
Email: \*jessica.allen@mail.wvu.edu

## Introduction

Navigating daily life requires performing diverse movement behaviors. How the nervous system coordinates muscles to successfully perform these behaviors is unknown. We recently showed that recruiting a common set of motor modules (i.e., motor module generalization) across walking and standing balance behaviors is important for successful mobility [1,2]. Here, we investigated whether motor modules are also generalized across walking, turning and chair transfer behaviors using the Timed-Up-and-Go (TUG) test. The TUG test is a common mobility assessment often executed while performing a secondary cognitive task (i.e., counting backwards) [3]. As a first step towards understanding if module generalization across walking, turning, and chair transfers underlies successful daily life mobility, we examined motor modules recruited by young adults in the TUG test. Understanding modular control strategies in young adults will provide a basis for investigating impairments due to aging, disease, and injury.

## Methods

Nine young adults (4M, 21.4±1.7 yrs) performed the TUG test with and without a cognitive distraction task (i.e., counting backwards by 3's; avg 18±3.6 trials per condition). To investigate module generalization, we divided the TUG test into 4 subtasks: sit-to-stand, walk, turn, and stand-to-sit. Motor modules from each sub-task were extracted from electromyography collected from 12 muscles spanning the hip, knee, and ankle using non-negative matrix factorization as in [1]. For each subject, modules recruited across subtasks were pooled and clustered using a k-means algorithm to identify the number of unique modules recruited across all TUG subtasks. Motor module generalization was quantified as  $(1 - \frac{U-M}{S}) \times 100\%$ , (U: number of clusters, M: smallest number of modules recruited in any subtask, and S: sum of all module numbers) and compared between TUG and TUGC using a paired t-test. To examine whether the cognitive distractive task affected motor module structure, TUG and TUGC modules were compared using Pearson's correlation coefficients.

## Results and Discussion

Young adults recruited a small number of structurally similar motor modules across TUG subtasks. Subjects recruited 3-5 motor modules in each subtask (avg 5.3±0.8; Fig. 1a) that were structurally similar across subtasks, illustrated by their high generalization (Fig. 1b). These results suggest that young adults draw upon a small library of motor modules to execute basic actions, such as plantarflexion and stabilization, that are required of walking, turning, and chair transfers. Based on our prior work examining walking and balance [1,2], we expect that motor impaired populations will recruit more task-specific modules across TUG subtasks, contributing to their reduced mobility.

Motor module structure was not affected by concurrent performance of a cognitive task. Neither performance time ( $t=-1.84, p=0.10$ ) or motor module number (Fig 1c) differed in TUG vs. TUGC. Further, motor modules recruited in TUG vs. TUGC were strongly correlated (Fig. 1d) and generalization

across subtasks remained high in TUGC (Fig. 1b). Since motor impaired populations are more affected by dual-task demands than young adults [3], we expect module structure in these populations will exhibit less similarity in TUG vs. TUGC.

Here, we follow-up on our prior studies [1,2] demonstrating the importance of motor module generalization across walking and balance behaviors for daily-life mobility and show that young adults also generalize motor module recruitment across walking, turning, and chair transfer behaviors. Together, these results suggest that young adults recruit a small number of structurally similar motor modules across movement behaviors important for daily life that are unaffected by secondary cognitive demands.

## Significance

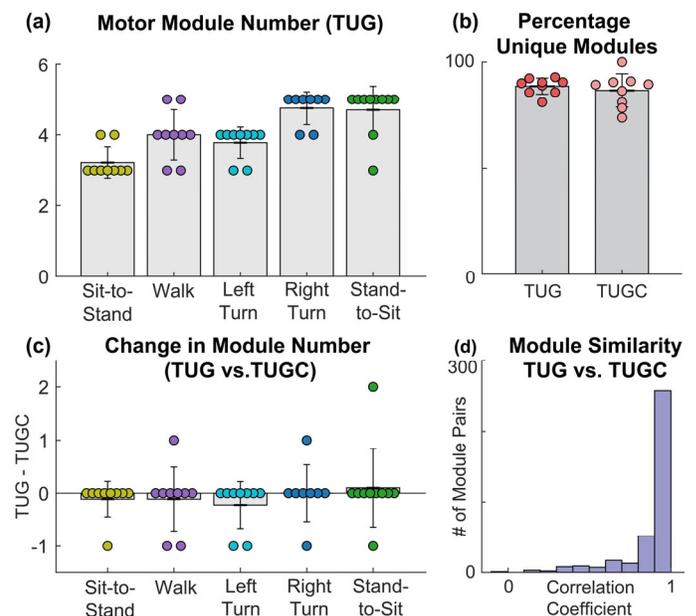

Identifying how young adults recruit motor modules during walking, turning, and chair transfers is a step towards understanding how motor control strategies are executed across a variety of movements required of daily life. Characterizing modular control strategies in young adults will allow us to more effectively identify deficits resulting from aging and impairment, which may guide the development of more effective and targeted rehabilitation treatments to improve daily life mobility.

## Association between Foot Thermal Responses and Shear Forces during Turning Gait

Angel E. Gonzalez<sup>1</sup>, Ana L. Pineda Gutierrez<sup>1</sup>, Andrew M. Kern<sup>1</sup> & Kota Z. Takahashi

<sup>1</sup> Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE USA  
Email: [agonzalez@unomaha.edu](mailto:agonzalez@unomaha.edu)

### Introduction

Thermoregulation is a vital function of the nervous system in response to cold or heat stress. Previous studies have demonstrated that foot temperature can significantly increase from pre- to post locomotor activity [1, 2]. Though these temperature fluctuations may not be a problem for healthy individuals, negative consequences may arise for individuals that are unable to properly thermoregulate, such as foot ulcer formations in patients with diabetes [3].

Shear forces have been proposed as potentially having a direct influence in foot temperature responses during walking. Technical challenges associated in measuring shear have hampered further research [4], where adjacent segments within the foot can experience simultaneous opposing shear forces that cannot be measured through a standard force plate. Recent studies utilizing custom shear-sensing force plates have revealed the influence of shear on temperature responses within localized regions of the foot [5]. Another method of potentially exploring this relationship is through curved-path walking, which has been shown to have higher magnitudes of shear compared to straight line walking [6]. Toe-walking on a standard force plate, in particular, may be one method of exploring the shear-thermal relationship while reducing the presence of opposing shear forces from adjacent segments within the foot.

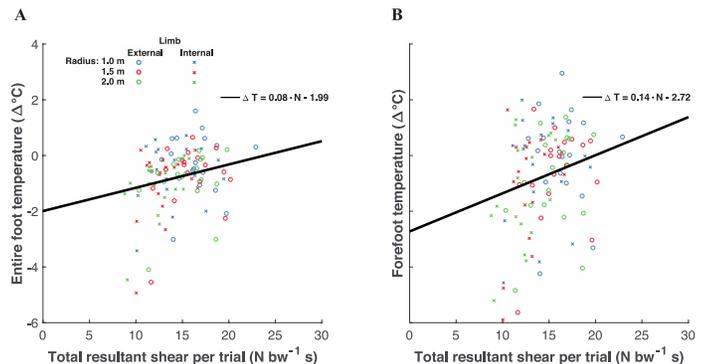

The purpose of this study is to investigate the thermal response of the foot to varying magnitudes of shear forces during barefoot curved-path toe-walking. Due to the mechanical requirement of the task, greater shear forces were expected when turning with a smaller radius, and greater shear was expected on the external foot compared to the internal foot [6]. It was hypothesized that foot temperature increase would be related to a greater shear force. It was also hypothesized that the external foot, due to greater shear forces, would experience higher temperature increase compared to the internal foot.

### Methods

14 retroreflective markers were placed on the feet to quantify motion. 18 healthy subjects (9 females) walked barefeet, on their toes for 5 minutes at a speed of 1.0 m/s in three radii of curvature (1.0, 1.5, and 2.0 m in a randomized order). A ground-mounted force plate (AMTI) was used to estimate magnitudes of medial-lateral and anterior-posterior shear forces encountered at the foot. Immediately before and after each trial of walking, we obtained thermal imaging data to quantify changes in foot temperature ( $\Delta T$ ). Using a software (FLIR ResearchIR), we manually traced thermal images with outline of the entire foot, as well as the forefoot region (encapsulating the toes, the first and fifth metatarsal heads). Each trial was separated by 20 minutes of rest.

To compare shear force and  $\Delta T$  across various radii and between feet, a two-factor repeated measures ANOVA was used. A linear mixed effects (LME) model analysis was used to determine the relationship between shear and  $\Delta T$  ( $\alpha=0.05$ ). In order to account for ground contact time, shear impulse (integral of shear force) was extrapolated to the entirety of the 5-minute

trial. The LME analysis was thus performed on  $\Delta T$  as a function of the accumulated shear impulse.

**Figure 1:** Resultant shear impulse (extrapolated to the 5 minute walking trial) was a significant predictor of entire foot  $\Delta T$  (Fig. A,  $p < 0.001$ ) and forefoot  $\Delta T$  (Fig. B,  $p < 0.001$ ). A greater sensitivity of  $\Delta T$  to shear was found for the forefoot (where shear forces were presumably encountered during toe walking) compared to the entire foot, indicated by the greater slope of the regression line. Walking data were obtained from external (x) and internal (o) limbs, as well as the three different radii: 1.0m (blue), 1.5m (red), and 2.0m (green).

### Results and Discussion

Curved-path walking with smaller radius of curvature increased the magnitude of shear impulse ( $p < 0.0001$ ) and increased  $\Delta T$  of the entire foot ( $p < 0.01$ ) and forefoot region ( $p < 0.01$ ). In support of our hypothesis, shear impulse was positively associated with entire foot  $\Delta T$  ( $p < 0.001$ ), and forefoot  $\Delta T$  ( $p < 0.001$ ), in which every unit of increase in shear impulse (normalized to body weight) increased the entire foot and forefoot temperature by 0.08 °C and 0.14 °C, respectively (Figure 1). Also consistent with our hypothesis, the external foot experienced greater  $\Delta T$  in both the entire foot ( $p < 0.01$ ) and forefoot region ( $p < 0.01$ ). Our findings about shear-temperature relationships are consistent with a prior study that used a specialized shear-sensing force plate [5].

### Significance

Using readily available standard force plate, we found a direct link between shear-thermal relationships within the foot. This study may provide a rationale for using turning gait as a simple assessment tool in predicting an individuals' susceptibility to foot temperature elevation due to shear forces, which may inform future diagnoses and/or prevention strategies for diabetic ulcer formations [3].

# Are biceps femoris muscle length changes influenced by in-series compliance across locomotor demand?

Pawel R. Golyski<sup>1,2</sup> & Gregory S. Sawicki<sup>1,2,3</sup>

<sup>1</sup>Parker H. Petit Institute for Bioengineering and Biosciences, <sup>2</sup>The George W. Woodruff School of Mechanical Engineering

<sup>3</sup>School of Biological Sciences, Georgia Institute of Technology, Atlanta, GA, USA

Email: [pgolyski3@gatech.edu](mailto:pgolyski3@gatech.edu)

## Introduction

The field of neuromechanics' current view is that terrestrial mammals' lower limbs exhibit a proximal to distal morphology gradient – proximal joints have long parallel muscle fascicles with short, stiff tendons, while distal joints have short pennate muscle fascicles and long, compliant tendons [1]. However, within humans the extent to which in-series compliance (i.e. tendons and aponeuroses) of proximal muscle-tendon units (MTUs) influences muscle and joint mechanics has not been directly quantified during locomotion. This in-series compliance has implications for where on the force-length curve a muscle operates and thus its force generation. We investigated the coupling of ultrasound-measured biceps femoris longhead (BFlh) muscle velocities and OpenSim-generated BFlh MTU velocities across different biomechanical demands (i.e. speeds and slopes) to test the hypothesis that BFlh muscle velocities would be highly positively correlated with MTU velocities, as expected from low BFlh in-series compliance across all locomotor demands.

## Methods

One healthy participant (28 yrs, 74.3 kg) completed 2 minute trials at 26 walking and running speed-slope combinations in a randomized order, with motion capture, ground reaction forces, and B-mode ultrasound data collected during the last 20 seconds of each trial. The speeds collected were walking at 1.25 and 2.0 m/s, as well as running at 2.0 and 3.25 m/s. The slopes collected were  $\pm 15\%$  grade in 5% grade increments. We did not collect the 3.25 m/s conditions at  $+15\%$  and  $-15\%$  grade. BFlh muscle lengths were measured as the product of extrapolated hand-tracked fascicle lengths and cosine of pennation angle. BFlh MTU velocities and joint moments were calculated using OpenSim. A Pearson correlation coefficients quantified coupling between MTU and muscle velocities over the entire gait cycle [2].

## Results and Discussion

Loads on the BFlh (approximated by peak hip extension moment) were generally larger with faster speeds and more extreme inclines (Figure 1a). Correlations between BFlh muscle and MTU velocities were generally largest for the slowest walking speed at

small slopes, as well as intermediate speed and high slopes, and were smallest for the fastest speed and level slopes (Figure 1b). This suggests that the in-series elasticity of the BFlh may allow for appreciable decoupling between muscle and MTU lengths, in contrast to our hypothesis. Thus, functionally, the in-series compliance of proximal musculature may not always act as a strut in humans during walking and running. Recent experimental work on the human vastus lateralis (VL) may further support this claim – during the period when the VL was active during running, VL fascicles remained approximately isometric while the MTU lengthened, attributable to either series elasticity or changes in pennation [3]. In all, the decoupling of BFlh muscle from MTU we observed during locomotion conditions indicate that in-series compliance of the hamstring group may have real, unappreciated functional implications for human movement, particularly under conditions of high load.

## Significance

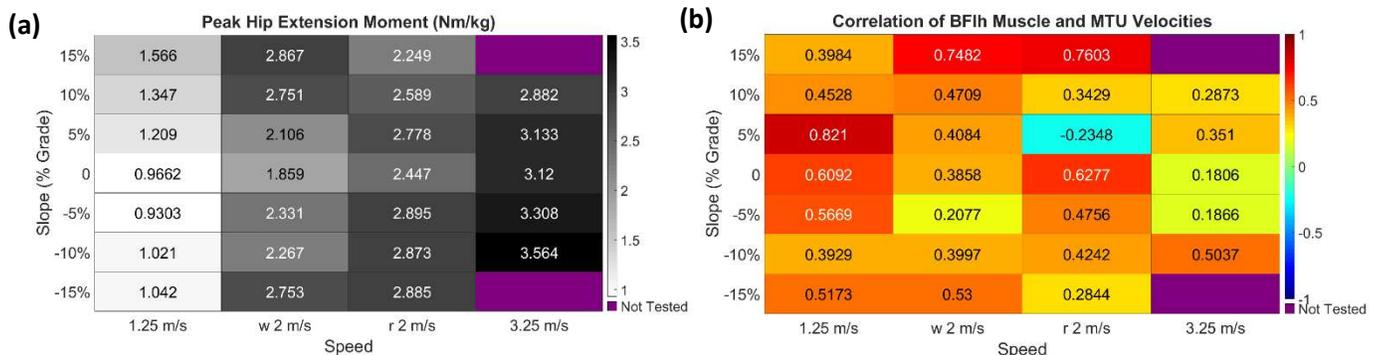

This is the first direct experimental measurement of BFlh muscle lengths during locomotion in humans. The observed decoupling influence of BFlh series elasticity at high loads suggests: 1) series elasticity of proximal muscles should be carefully reconsidered in musculoskeletal models of movement, 2) the concept of muscle-tendon tuning in elastic exoskeleton design at the ankle may also be useful at the hip, 3) proximal joints may generate force at slower, more economical velocities than previously realized, and (4) since intrafusal fibers may be decoupled from movements of the entire muscle-tendon, the proprioceptive pathways of proximal muscles should be further explored.

## Acknowledgments

## Introduction

Augmentation-based exoskeletons have traditionally addressed the biomechanics behind steady-state locomotion and repetitive tasks; however, rapid and transient human motion has rarely been studied. As environments become more dynamic, so does the type of movement exhibited by the user [1]. Previous work in steady-state walking, running, and sprinting has been a reliable foundation to analyze more targeted, reactive movements. These existing analyses do not address or quantify the kinematic and kinetic behavior employed in quick response time and dynamic movements in all directions, which will be this work's main contribution [2].

This study investigates the biomechanics in escaping threats, or quickly dodging starting from rest. Quantifying this behavior can aid in controlling an agility-enhancing exoskeleton by providing information about user intent and actuation profiles.

## Methods

Subjects provide written informed consent for this study that was approved by the Georgia Institute of Technology Institutional Review Board. An experiment is being conducted where subjects, beginning at rest, must escape a pre-defined circle ( $r = 80$  in.) in randomly-chosen directions (8 directions at 45° increments) given a visual instruction, shown in Figure 1. Ground reaction forces and lower limb motion are measured with six force plates (Bertec, Columbus, Ohio, USA) and motion capture (Vicon, Oxford Metric, Oxford, UK).

## Results and Discussion

The forward escaping motion (0° direction) was examined for three subjects who exhibited similar escape strategies. The escape strategy is the trailing limb swinging back, making foot contact, and then pushing off. The leading limb swings forwards, makes foot contact, and pushes off. Joint kinematics and kinetics were determined using OpenSim v4.1 and normalized by weight [3]. Figure 2 illustrates subjects' hip, knee, and ankle kinetic results for the trailing limb throughout the described escape strategy. 0% corresponds to when the visual instruction is given and 100% corresponds to the trailing limb's push-off for escaping after the first step. Peak moments and joint speeds, shown in Table 1, were determined during the escape strategy for each limb.

**Table 1:** Design requirements were found for each limb. Absolute peak values are annotated.

	Trailing Limb		Leading Limb	
	Peak Torque (Nm/kg)	Peak Speed (deg/s)	Peak Torque (Nm/kg)	Peak Speed (deg/s)
Hip	1.11	175	2.19	402
Knee	1.93	373	1.17	390
Ankle	2.96	619	2.33	620

Referring to the peak torques, the dominant limb during quick, transient motions is the trailing limb, where the knee and ankle contribute more than the hip. Regarding joint speeds, the leading limb was uniformly the fastest. These discoveries provide vital information when designing an agility-enhancing exoskeleton by providing peak torque and speed information, and contribute to the understanding of rapid, short movements to assist people in escaping real-world environmental threats. Future work includes completing the experiment and analyzing the 7 other directions.

## Significance

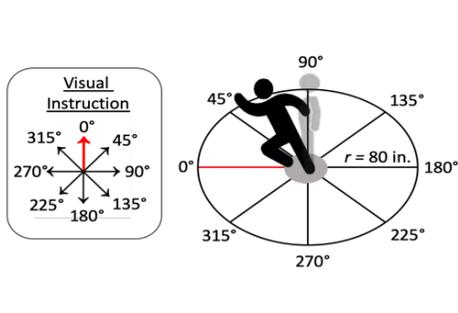

This work quantifiably distinguishes kinematic and kinetic behaviors for quick movements from steady-state locomotions and further diversifies what the field traditionally knows about the biomechanics of various locomotion. This effort will heavily contribute to the design of agility-enhancing exoskeletons for use in unstructured environments with dynamic, quick assistances.

### Introduction

Traditional manual wheelchairs commonly place the axle of the push rims directly below the user's shoulders. This setup requires users to repetitively move their shoulders through low angles of arm elevation to propel the chair. Concerningly, recent research has found that the subacromial space is smaller in these lower ranges of shoulder elevation compared to higher angles of elevation [1]. Reduced subacromial space may compress the rotator cuff tendons, leading to subsequent tendon degeneration, and development of shoulder pain or rotator cuff tears.

A theorized optimal push rim placement would require the push rim to be placed such that the top dead center of the rim is anterior to the user's shoulder [2]. In a traditional wheelchair, this push rim placement requires the drive wheel to be placed anterior to the user's center of mass, creating posterior instability of the chair. A new wheelchair design - the ergonomic wheelchair - decouples the push rim from the drive wheel, so the push rim can be placed independently without altering stability of the chair. The purpose of this study is to determine how shoulder kinematics and subacromial compression are affected by the wheelchair push rim position.

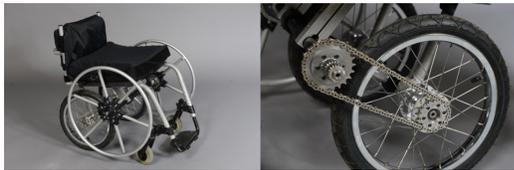

Figure 1: Prototype of the ergonomic wheelchair

### Methods

Thus far, data have been collected on four participants without spinal cord injury (SCI) who are not full-time manual wheelchair users. Upper extremity and trunk motion during wheelchair propulsion were captured using an 8-camera Vicon optical motion capture system. The variables of interest were: humerothoracic flexion and abduction; glenohumeral flexion, abduction, and axial rotation; and scapulothoracic internal rotation, upward rotation, and tilt. Data were collected using a custom wheelchair simulator that allowed for individualized placement of the push rims and individualized resistance to replicate the expected amount of inertia the user would experience while propelling overground. The simulator allowed participants to propel without moving out of the capture volume, and a hand switch was used to identify hand-to-push rim contact.

Shoulder motions were collected during 10 propulsion cycles in each of the three push rim positions: standard (push rim axle directly below the shoulder), anterior (the theoretical optimal position with the push rim axle anterior to the shoulder), and posterior (push rim axle posterior to the shoulder). For each push rim position, the middle three propulsion cycles were averaged and analysed at three points: initial hand-to-push rim contact, hand at top dead center, and push rim release. Data were analysed using two-way repeated measures ANOVAs.

### Results and Discussion

No differences were found in shoulder kinematics across push rim positions. These findings indicate that the theorized optimal anterior push rim position does not alter shoulder kinematics compared to the standard position or even a position in which the push rim is placed posterior to the user's center of mass. However, there were no constraints on hand placement on the push rim. Therefore, rather than altering shoulder kinematics across push rim positions, participants may have altered their push angle - or the arc that the hand travels on the push rim. Despite non-significant results and potential changes in push angle, the anterior push rim position generally had more humerothoracic and glenohumeral flexion and less scapular anterior tilt than the standard or posterior positions. Increased flexion and decreased anterior tilt may increase the subacromial space and reduce rotator cuff compression [1,3].

These results reflect the propulsion techniques used by a small number of individuals who are not full-time manual wheelchair users. Upcoming collection will include individuals with SCI who are full-time manual wheelchair users. Additionally, the subacromial space will be quantitatively analysed - using the minimum distance between the coracoacromial arch and the supraspinatus as well as the magnitude of compression when it occurs - through 2D/3D shape matching of subject specific MR bone models on biplane radiography captured during propulsion. This additional data collection will increase our power to detect differences across push rim positions, and the assessment of subacromial space will provide more specific insight into rotator cuff tendon compression than kinematics alone.

### Significance

Over 60% of individuals who use manual wheelchairs as their primary mode of mobility report having shoulder pain [4]. Shoulder pain can be devastating for these individuals, as they rely on their upper extremities for critical activities, including wheelchair propulsion. Thus, the design of manual wheelchairs should be updated to protect the user's upper extremities. The results of this study will help guide the redesign of future wheelchairs by describing shoulder kinematics, and eventually subacromial space, while using multiple push rim positions.

### Acknowledgments

## Introduction

Human locomotion on sand requires a higher gross metabolic cost than over hard terrain, however, to date, little has been done to quantify these energetic differences in a laboratory setting [1]. Typically, this metabolic penalty is attributed to the dissipation of mechanical energy into the sand itself during stance, and the added metabolic power required by the muscle-tendon units (MTU's) in the human leg to overcome this extra power requirement [1,2]. As such, this study aimed to quantify the energetic effects of locomotion in sand through the use of a comparative hopping study as a simplification of bouncing gaits. It has been shown that energy consumption of human hopping on hard ground follows a U-shaped relationship, with an energetic minimum between 2.5-2.8 Hz [3]. Due to its highly nonlinear, non-newtonian behaviour, the energy dissipated in a loading cycle on sand depends on the magnitude and rate of the applied ground reaction force as well as the kinematics and surface geometry of the foot. This makes it difficult to predict how metabolic cost of hopping changes on sand. Here, we pose the null hypothesis that hopping in sand would yield a consistent metabolic penalty, shifting the cost up by a fixed amount over a range of frequencies.

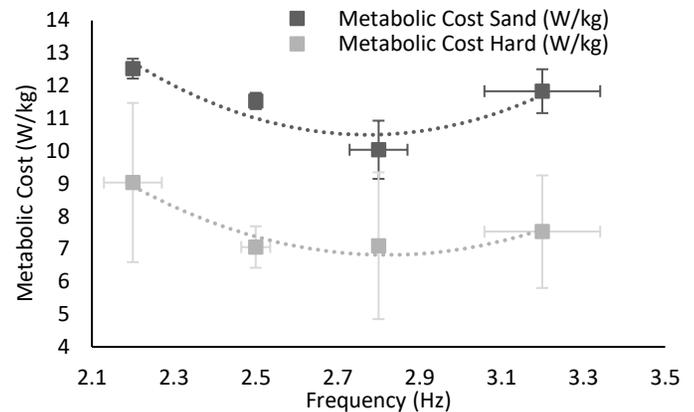

## Methods

Two male participants (mean  $\pm$  SD, age =  $21.5 \pm 0.7$  yr, height =  $1.82 \pm 0.07$  m, mass =  $80 \pm 17$  kg) completed two sessions of 4 trials, one on hard ground and one on. Participants were asked to hop to a metronome at four different frequencies (2.2, 2.5, 2.8, and 3.2 Hz), to preferred heights. Gross metabolic power was measured using indirect calorimetry, while hopping frequency and center of mass position were measured using motion capture. Each trial lasted 4.5 minutes, with each ground condition tested on a separate day in order to minimize fatigue effects due to the physically demanding nature of the protocol. Metabolic data were averaged over the last minute of each trial. The order of conditions and frequencies was randomized. Hard ground hopping was performed over a split belt instrumented treadmill, and sand hopping was performed over a custom built sand pit. The sand pit uses dry, loose packed poppy seeds as simulated sand, and allows for self-leveling through a combination of pivot enabled shaker panels that push the sand back toward the middle of the testbed, and airflow to maintain a constant sand depth.

## Results and Discussion

We found a U-shaped metabolic curve for the hard ground trials, in agreement with literature (Figure 1; [3]). A quadratic fit to the metabolic data revealed a minimum in metabolic power at 2.7 Hz. This agrees with the findings of Farris et al. which showed that intermediate hopping frequencies values between 2.5-2.8 Hz allow for the lowest level of metabolic power.

Analogous to the hard ground trials, we also found that hopping on sand followed a similar U-shaped curve, with a minimum

**Figure 1:** Graph showing metabolic power (W/kg) and frequency relationship for hopping in hard ground and sand. We found a consistent relative increase in metabolic power of  $50.1 \pm 12\%$  across participants for frequencies from 2.2 Hz to 3.2 Hz

value of approximately 2.8 Hz. Participants reported increased difficulty in trials at 2.2 Hz due to longer ground contact times allowing for significant sinkage and energy dissipation into the sand before the next flight phase. Participants also reported increased sense of effort at 3.2 Hz due to difficulty in achieving a flight phase at all. In this case, brief stance times were not long enough to drive the foot surface into the granular substrate and gain upward momentum. The sinkage time was found to be a constant  $0.11 \pm 0.14$ s across frequencies.

Additionally, we found that the best fit metabolic cost curve for sand displayed a constant increase of approximately  $50.1 \pm 12\%$  from hard ground across frequencies. This is consistent with the initial findings of Lejeune et al, who reported approximate energy expenditure increases of 60% for running on a sand track [1]. Flight time remained consistent across ground conditions for each frequency, ( $SD \pm 0.092$ s), indicating that hop height from rest across conditions was fairly consistent. Thus, the offset may be due to increased muscle activation to overcome excess dissipation while maintaining comparable flight times across variable terrain.

## Significance

This experimental protocol is the first frequency-based analysis of the comparative energetics of hopping for sand versus hard ground. It outlines the first step toward the development of a generalized energetic relationship for bouncing gait over complex media. Through this study we begin to develop a more complete understanding of the metabolic effects of locomotion over complex, non-linear substrates. These insights can now be leveraged to design wearable devices that are better suited to “real-world” use over challenging terrain.

# Predicting Human Bouncing Behavior from Trajectory Optimization of Minimal Models

Zachary W. Mercer and Christian Hubicki

## I. INTRODUCTION

Robotic assistive devices hold enormous promise for augmenting and rehabilitating human locomotion (e.g. exoskeletons). However, existing control techniques are heavily dependent on human-in-the-loop optimization [1]. We seek a modeling-driven approach for predicting how human behavior will adapt to forcing from external devices - thereby enabling model-based exoskeleton control. Specifically, we take a reduced-order modeling approach in an effort to find a generalizable framework that is less dependent on subject-specific parameters. This work investigates the efficacy of a variety of minimalistic math models and objective functions of reproducing experimental human behaviors under external forcings. Using trajectory optimization techniques, we systematically examine the effects of differing objectives and mechanical properties on the optimal strategies for completing a model task: human bouncing.

## II. METHODS

### A. Muscle Models

We want to create a general muscle model that can be applied to a variety of specific tasks, constraints, and objectives. Our muscle model is based on a modified Hill-Type structure utilizing a unidirectional contractile element with parallel damping and elasticity in series with an elastic element. This muscle model is structured as the plantar flexor in a 2D bouncing task. We vary the mass of the model to observe trends in optimal bouncing frequency.

### B. Locomotion Task Model

Human bouncing, *i.e.* hopping without flight [2], is a simple yet highly constrained movement making it well-suited for generalized analysis. By developing a bouncing optimization problem, we create an optimal control model which can be compared to published human data. Specifically, we task our model to bounce at a series of prescribed frequencies (ranging from 0.5-3 Hz). The optimization solves for the most cost-efficient actuation strategy that bounces at the commanded frequency. Here we analyze the trends in costs as functions of frequency and further pinpoint optimal bouncing strategies which we can compare to human data.

## III. RESULTS AND DISCUSSION

We implemented a reduced-order muscle model and commanded it to perform a simple bouncing task. Trajectory optimization solved for optimal control strategies over a set

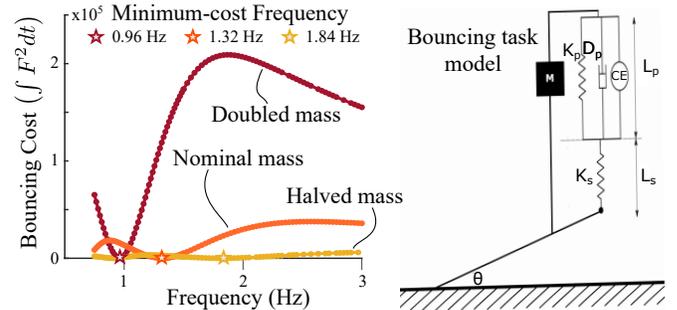

Fig. 1: (Left) Energetic cost of the bouncing model across frequencies. (Right) A schematic of the bouncing model.

of prescribed frequencies and with various changes in physical characteristics (e.g. added external mass). Specifically, the optimization solved for control strategies that minimized energetic cost (“force-squared cost” in presented result). The minimum-cost frequencies indicate the optimal bouncing strategy for each physical parameter set (e.g. added mass). In the presented results, increasing the body mass consequently shifted optimal bouncing to lower frequencies - a behavior observed qualitatively in human bouncing [2].

## IV. SIGNIFICANCE

These preliminary results validate a reduced-order model capable of predicting optimal actuation patterns for human movement tasks. This simple model can be freely modified to include external forcing devices (e.g. controlled exoskeletons), with the intention to guide future research into engineering assistive devices aiding human locomotion.

## V. ACKNOWLEDGEMENTS

Supported by Laksh Kumar for advice on the manuscript and technical methods and by the FAMU-FSU Mechanical Engineering Department.

# Quantification of Spatiotemporal Parameter Behavior During Walking Speed Transitions

Claire H. Rodman<sup>1</sup> and Anne E. Martin<sup>1</sup>

<sup>1</sup>Mechanical Engineering, Penn State University Park, State College, PA, USA

Email: chr33@psu.edu

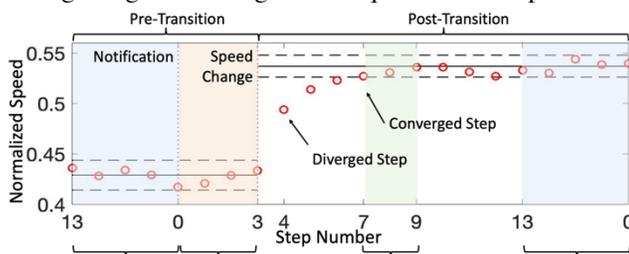

## Introduction

Constant speed walking has been rigorously investigated, but healthy humans often walk in short bouts, transitioning between speeds [1]. Starting, stopping [2] and walking to running transitions [3] have been studied, but little is known regarding walking speed transitions and the effect of speed transition magnitude on transition behavior. This work quantified spatiotemporal behavior (step period, length, and speed) in walking speed transitions. We hypothesized that the transition magnitude affects whether divergence occurs only in step period, only in step length, or in both step period and length (H1) and that the transition magnitude affects the number of steps required to perform the transition (H2).

## Methods

10 male and 13 female healthy adults (18 to 62 years old, height  $163.5 \pm 34.4$  cm, mass  $67.6 \pm 11.7$  kg) walked on a split-belt, instrumented treadmill at five height-normalized speeds spanning a comfortable walking range (about 1.2 to 1.6 m/s) for one minute each. They then performed ten speed transition trials, in which they walked on the treadmill as it transitioned between the five speeds for a total of 20 transitions. Every 17 steps the treadmill accelerated to the post-transition speed during single support. Three steps prior, subjects were notified of the post-transition speed via a bar chart.

When analyzing the data, to allow for transition behavior after notification but before the speed change, the notification step was step 0, speed change step 3, and so on (Fig. 1). The mean and standard deviation were calculated from the five steps prior to notification to quantify the pre- and post-transition converged states. Independent-sample t-tests were used to determine if the pre- and post-transition converged means were significantly different, indicating that divergence occurred for a given parameter. Number of steps to converge was calculated by subtracting the diverged step (in which the parameter value was beyond two standard deviations of the pre-transition mean) from the converged step (first of three consecutive steps in which the parameter values were within two standard deviations of the post-transition mean). Linear mixed effect models were used to test the significance of transition magnitude on parameter divergence and steps to convergence with fixed and per-subject random effect slopes. Transitions were also grouped into small, medium, and large magnitude categories for qualitative comparisons.

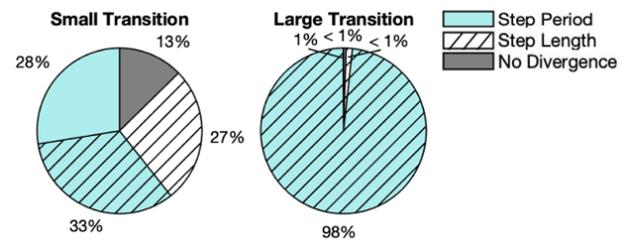

**Figure 1** Representative plot of one speed transition showing the average speed (circles), pre- and post-transition means (solid lines), and two standard deviations surrounding the means (dashed lines).

## Results and Discussion

Because speed was prescribed, essentially all transitions of every magnitude exhibited divergence in speed, as expected. This was not true for step period and length. As transition magnitude increased, the percentage of transitions that diverged in both step period and length increased ( $p < 0.001$ , Fig. 2). For small transitions, three divergence behaviors were observed: (1) step period diverged in most transitions, with fewer instances of step length divergence; (2) the converse was true; and (3) divergence in step period and length occurred roughly equally. For large transitions, divergence in both step period and length occurred overwhelmingly. These divergence rates varied across subjects ( $p < 0.001$ ). Thus, both transition magnitude and subject preference influenced divergence behavior.

Small, medium and large transitions resulted in medians of approximately 0, 1, and 2 steps to converge for step period and length and 2, 3, and 3 for speed. At all magnitudes, speed required a greater number of steps to converge compared to step period and length ( $p < 0.001$ ). The transition magnitude fixed effect slope was significant ( $p < 0.001$ ). Across subjects, the effect of transition magnitude on steps to converge for all parameters varied significantly ( $p < 0.05$ ), but all subjects exhibited positive trends with increasing magnitude. So, there is likely a relationship with increasing transition magnitude and steps to converge.

**Figure 2** Percentage of small and large transitions that diverged in step period and/or length. The overlap between transitions that diverged in both step period and length increased with increasing transition magnitude ( $p < 0.001$ ).

## Significance

This work begins to address the question: what biomechanical behaviors do healthy humans exhibit when transitioning between speeds? Beyond the fundamental understanding gained by pursuing this query, knowledge of desired healthy gait transitions could be applied to improve rehabilitation and assistive technologies for correcting gait impairments.

### Introduction

With the accelerated timeline for NASA's Artemis program, Lunar analog environments are being developed at Johnson Space Center to provide high fidelity extravehicular activity (EVA) simulations and to enable engineering evaluations. The Neutral Buoyancy Lab (NBL) simulates lunar gravity by altering buoyancy and adding weight to subjects underwater to achieve the equivalent ground reaction force of 1/6-G. Another environment, the Active Response Gravity Offload System (ARGOS), uses a computer controlled overhead suspension system programmed to continuously offload a percentage of a subject's weight to simulate partial gravity. The aim of this study is to compare gait characteristics between the EVA training facilities using wireless inertial measurement units (IMUs).

### Methods

A subject performed walking tasks in 3 environments: (1) 1-G ground with scuba mask; (2) 1/6-G NBL with scuba equipment; (3) 1/6-G ARGOS with the Mark III spacesuit. The subject was assisted with donning 3 Opal™ IMUs (APDM, USA); 1 on the chest and 2 on the lateral sides of both ankles. For the NBL environment each IMU was inserted in a GoPro waterproof housing and affixed to the subject using an elasticated strap. Before going underwater, the subject walked a measured distance of 10 meters at a self-selected speed on the pool deck (Figure 1). Data were collected at 120 Hz, and the middle 6 meters were analyzed. The subject was then equipped with diving gear and then descended underwater with diver assistance in weighing out subjects to 1/6-G. Once adapted to the 1/6-G weigh-out subjects executed a 10-meter walk on the pool floor at a depth of 12 meters. In the 1/6-G ARGOS environment, 3 IMUs were positioned to the same body segments while wearing the Mark III spacesuit attached to ARGOS via a modified Extravehicular Mobility Unit (EMU) gimbal. Due to the confined testing area, ambulation was performed on a treadmill at 2.0 mph speed for 1 minute and 10 steps were collected in the middle of the trial.

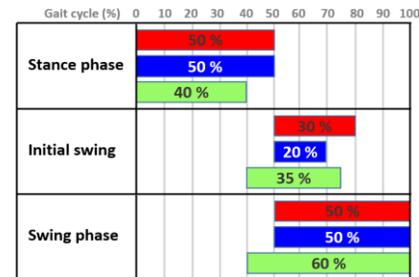

The peaks and troughs of the angular velocity waveform in the sagittal plane (measured from both ankle IMUs) have been associated with specific gait events [1]. Using detected gait events, we segmented the sagittal plane angular velocities into right and left strides (i.e., heel-strike to heel-strike), averaged the segmented gait stride, and normalized to percent gait cycle to compare gait performance between testing environments [2]. The chest IMU measured the torso tilt angle in the sagittal plane [3]. The chest IMU also used to calculate the gait speed [4].

**Figure 1:** (left) 1-G ground with scuba mask, (middle) 1/6-G NBL with scuba equipment, (right) 1/6-G ARGOS with the Mark III spacesuit.

### Results and Discussion

Figure 2 shows the summarized percent gait cycle between testing environments. Table 1 shows the overall gait speed and the averaged trunk tilt angle in the sagittal plane during walking.

**Figure 2:** Comparison of percent gait cycles including initial swing, swing phase, and stance phase between the EVA training facilities (red: 1-G ground, blue: 1/6-G ARGOS, green: 1/6-G NBL).

**Table 1:** Comparison of gait speed and trunk tilt angle.

Variable	1-G ground	1/6-G ARGOS	1/6-G NBL
Gait speed (mph)	2.3 (preferred)	2.0 (prescribed)	0.9 (preferred)
Trunk tilt angle (degree)	6.0	3.1	18.7

The differences in gait strategy found in 1/6-G NBL walking (e.g., forward trunk lean, increased swing phase, reduced gait speed) confirmed the expectation of gait adaptation to increased movement resistance because of underwater drag. At ARGOS, subjects displayed more erect upper bodies and shortened initial swing phases that may be the result of a more realistic 1/6-G environment than NBL. The added support from the offloading system and/or the treadmill could also be contributing factors.

The subject did show the same proportions of swing and stance phases between the 1-G ground and 1/6-G ARGOS conditions. In our previous work with a preceding system, the Partial Gravity Simulator (POGO), an unsuited subject in simulated 1/6-G offload displayed a shorter stance phase than that in 1-G offload that may indicate that the unsuited body may have been relying on the vertical offload forces to assist their upward movement and not producing the necessary propulsive forces in the forward direction [5]. In this study, the increased propulsive force because of the resistance to lower-limb movements of the pressurized suit may be related to the increased stance phase in the ARGOS environment.

### Significance

Walking and exploring will be one of the most common tasks during Lunar EVAs for the Artemis program. These Lunar EVA simulations and analog environments enable us to provide potential for developing training protocols and improve the current knowledge of testing environments and limitations in suited Lunar EVAs.

# Step Length Asymmetry is Associated with Gait Efficiency in Older Women with Hip Osteoarthritis

Chun-Hao Huang<sup>1\*</sup>, Kharma C. Foucher<sup>1</sup>  
<sup>1</sup>University of Illinois at Chicago, Chicago, IL  
Email: \*chuan26@uic.edu

## Introduction

Both aging and hip osteoarthritis (OA) can reduce gait efficiency [1-3]. Consequences may include reduced activity levels to conserve energy and minimize fatigue [4-6]. Only 30% of people who have hip osteoarthritis meet physical activity recommendations [7]. Thus, it is important to understand how hip OA associated factors affect the efficiency of gait so that more effective rehabilitation strategies to improve physical activity for this group. The purpose of this study was to determine how gait efficiency is influenced by step length asymmetry in older women with hip OA. We hypothesized that people with hip OA have statistically significant step length asymmetry which is associated with worse mechanical energy exchange and higher oxygen consumption during walking. We also explored interrelationships among these factors.

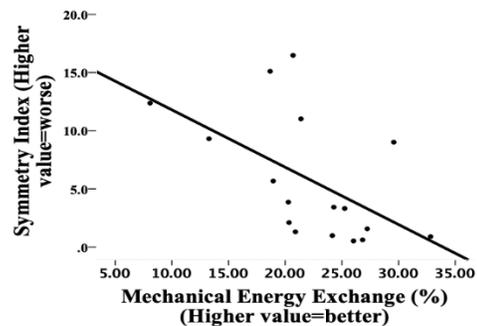

## Methods

**Subjects:** Participants gave informed consent to participate in this IRB approved study. 17 women with hip OA (age  $59.2 \pm 8.6$ , and BMI  $30.6 \pm 6.3$ ) were included in the study. **Data collection and processing:** Gait analysis was conducted using standard methods. 2.5 minutes of walking on a treadmill at each subject's self-selected walking speed was analyzed. Oxygen consumption was measured at the same time using indirect calorimetry.  $O_2$  rate and  $O_2$  cost was extracted from the cardiopulmonary diagnostic software. Step length was determined by the distance between two heel markers. We used Symmetry Index (SI):  $[(X_{uninvolved} - X_{involved}) / X_{uninvolved}] * 100\%$  to determine step length asymmetry [8]. We extracted center of mass (COM) by the segmental analysis method [9]. Next, the potential ( $E_p$ ) and kinetic ( $E_k$ ) energy were calculated by the equations:  $E_p = M_{tot} * 9.81 * COM(z)$ ,  $E_k = 1/2 * M_{tot} * (V_x^2 + V_y^2 + V_z^2)$  [10]. Finally, mechanical energy exchange, the percent of center of mass energy recovery was calculated by the equation:  $\%Recovery = [\Delta^+ E_p + \Delta^+ E_k - \Delta^+ E_{tot}] / [\Delta^+ E_p + \Delta^+ E_k]$  [11].  $\%Recovery$  is the pendulum-like transfer between  $E_k$  and  $E_p$  and can be considered a measure of gait efficiency. **Statistical analysis:** To test our hypothesis, we used a one sample T-test to determine whether the symmetry index was significantly different from 0, and Pearson correlations to determine whether it was associated with mechanical energy exchange,  $O_2$  rate, and  $O_2$  cost during gait. Next, we used Pearson correlations to evaluate the relationships among mechanical energy exchange,  $O_2$  rate, and  $O_2$  cost during gait.

## Results and Discussion

SI for the step length was  $5.7 \pm 5.4$  and was statistically significantly different from zero ( $p < 0.001$ ). Mechanical energy exchange was  $22.3 \pm 5.9\%$ . Higher (more asymmetric) SI for the step length was statistically significantly correlated with lower (worse) mechanical energy exchange ( $R = -0.542$ ,  $p = 0.024$ ) (Fig 1). The  $O_2$  rate was  $9.6 \pm 2.9$  ml/kg/min and the  $O_2$  cost was  $0.3 \pm 0.1$  ml/kg/m. However,  $O_2$  rate was not statistically significantly correlated with mechanical energy exchange ( $R = 0.44$ ,  $p = 0.079$ ) or SI ( $R = -0.34$ ,  $p = 0.186$ ). Additionally,  $O_2$

cost was not statistically significantly correlated with mechanical energy exchange ( $R = 0.24$ ,  $p = 0.347$ ) or SI ( $R = 0.18$ ,  $p = 0.481$ ).

**Figure 1:** More symmetric step lengths were associated with better mechanical energy

Our hypotheses were partially supported. Statistically significant step length asymmetry was present in hip OA patients. This asymmetry was associated with worse mechanical energy exchange. SI for the step length was significantly lower than the asymptomatic group that has been evaluated using the same method ( $SI = 2.89$ ) ( $p = 0.044$ ) [12]. Contrary to our hypothesis, oxygen consumption ( $O_2$  rate and  $O_2$  cost) was not related to step length asymmetry and mechanical energy exchange. However the  $O_2$  rate was close to significance, with a medium effect size. This was similar to results by Burdett et al. [13], who reported linear relationships between mechanical work energy exchange and energy consumption. More research is needed to explore possible strategies to increase the mechanical energy exchange by modifying step length asymmetry.

## Significance

Gait efficiency may be a barrier to physical activity in people with hip OA. This study points to a potential rehabilitation strategy to improve gait efficiency by modifying step length asymmetry.

# Zero power but positive acceleration at the end of a single-support phase in human walking

Seyoung Kim<sup>1\*</sup>, Cheolhoon Park<sup>1</sup>, and Chanhun Park<sup>1</sup>

<sup>1</sup>Department of Robotics and Mechatronics, Korea Institute of Machinery & Materials (KIMM)

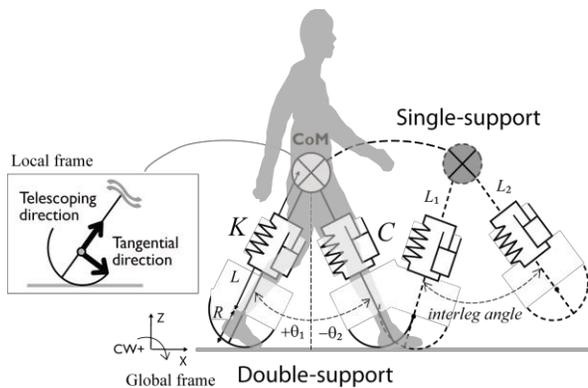

Email: [\\*seyoungkim@kimm.re.kr](mailto:*seyoungkim@kimm.re.kr)

## Introduction

Human walking naturally consists of single- and double-support phases. Although there have been many studies regarding basic understanding of each stage, how the two major sequential phases of walking interact with each other still remains to be clarified. In this study, we investigated the change in walking strategy with increasing walking speed on a local reference frame defined with respect to the direction of a telescoping leg (Fig. 1); we expect that the telescoping directional outcomes (e.g., force and power) at the end of a single-support phase change with walking speed to facilitate the modulation of the push-off work during a double-support phase.

## Methods

The telescoping directional force and power are calculated using the compliant walking model shown in Fig. 1 [1,2]. The empirical human walking data for eight healthy young subjects and the corresponding model parameters emulating the human data were used to examine the changing trend of each factor (i.e., force and power) with the increase in speed.

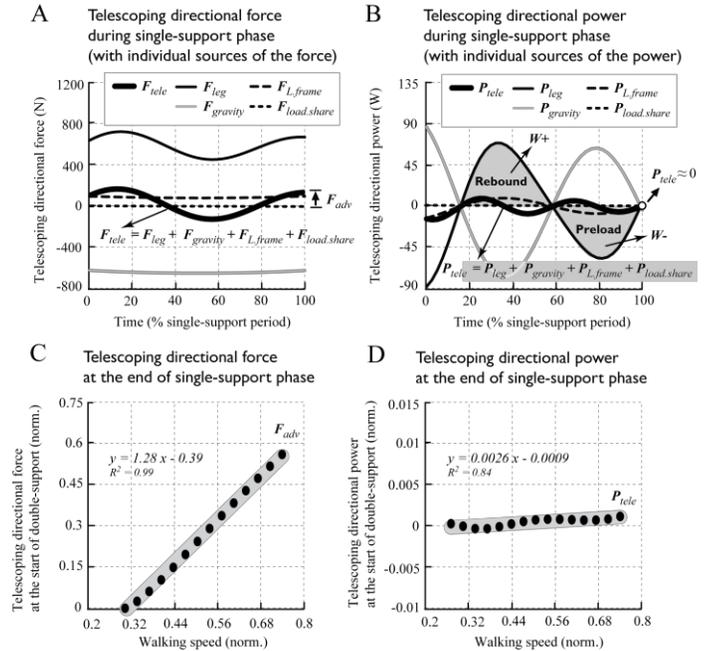

**Figure 1:** Schematic of the compliant walking model. The human body was modeled as a simple lumped mass with two massless, telescoping legs with curved feet. A local reference frame with telescoping and tangential axes was located at the center of the curved foot (inset).

## Results and Discussion

The telescoping directional force ( $F_{tele}$ ) at the end of the single-support phase significantly increased with walking speed (Fig. 2C), whereas the telescoping directional power ( $P_{tele}$ ) remained nearly unchanged at zero for the entire range of walking speeds (Fig. 2D). The positive amount of the telescoping directional force ( $F_{tele}$ ) (i.e., the acceleration force) at the end of the single-support phase (Fig. 2A and C) is a certain preparation for the double-support phase, which can contribute to a larger push-off. Starting with the supportive acceleration force (i.e.,  $F_{adv}$ ; force advantage in Fig. 2A and C) in the telescoping direction may help to efficiently increase the total push-off work during the double-support phase in a limited time, when the telescoping directional center of mass (CoM) velocity at the end of the single-support phase is nearly zero (i.e., zero power). Moreover, it is naturally preferable to have a larger force preparation to reach the

increased walking speed because of the CoM velocity redirection cost unavoidably increasing with the speed increase.

Consequently, “zero power (or zero velocity) but positive acceleration depending on the walking speed” would be one possible candidate for describing human-walking strategy during the switching procedure between the single- and double-support phases.

**Figure 2:** Telescoping directional (A) force ( $F_{tele}$ ) and (B) power ( $P_{tele}$ ) during single-support phase at a walking speed of 1.4 m/s, shown with four individual components. (C) Telescoping directional force ( $F_{tele}$ ) and (D) power ( $P_{tele}$ ) at the end of the single-support phase, with increasing walking speed.

## Significance

This study may contribute to the novel understanding of the human-walking strategy in terms of the role of the phase switching in the telescoping direction, and also can be applied to the clinical measures of walking ability modulating the force advantage with the speed increase.

# Gait Balance Control After Fatigue: Effects of Age and Cognitive Demand

Szu-Hua Teresa Chen<sup>1</sup> and Li-Shan Chou<sup>1,2,\*</sup>

<sup>1</sup>Department of Human Physiology, University of Oregon, Eugene, OR USA

<sup>2</sup>Department of Kinesiology, Iowa State University, Ames, IA USA

Email: \*[chou@iastate.edu](mailto:chou@iastate.edu)

## Introduction

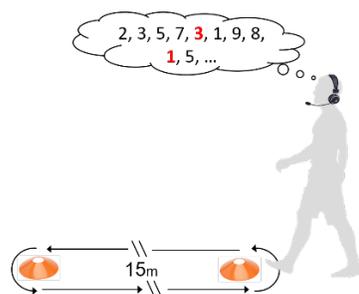

Studies have reported effects of either fatigue or cognitive demand on gait performance in both young and older adults. However, the study examining how fatigue and cognitive demand interact to affect gait balance control is still lacking. Distracted walking is commonly observed during our daily life and can happen with the presence of fatigue, especially at the end of work or sport activity. Therefore, the purpose of this study was to examine how fatigue affects walking balance control with and without performing a concurrent cognitive task.

## Methods

Seventeen young (age:  $26.0 \pm 5.8$ ) and 17 older (age:  $69.5 \pm 5.4$ ) adults were tested. Participants were asked to perform three tasks in a random order: 1) walking continuously with a self-selected speed, 2) performing a 3-back task while seated, and 3) walking and concurrently performing the 3-back task (**Figure 1**). During the 3-back test, participants were required to identify the repeated number that was presented three digits before in the sequence of random numbers. Each task lasted for two minutes and these tasks were performed again immediately after finishing a fatigue protocol. A 12-camera motion analysis system was used to record the whole body movement during walking.

A repetitive sit-to-stand (STS) task was selected as the fatiguing protocol [1]. Participants were asked to sit on a regular wooden chair without armrest and perform repetitive STS movements at their comfortable and fixed paces up to 30 minutes. The fatiguing protocol was terminated when 1) participants cannot continue due to exhaustion, 2) when the movement frequency fell below prescribed pace after encouragement, or 3) after reaching 30 minutes. Rating of perceived exertion (RPE) and maximal isokinetic contraction of right knee extensor were examined using a Borg Scale 6-20 scale and a dynamometer, respectively, before and after the fatiguing protocol.

Outcome variables included 1) the medial-lateral center of mass displacement during a gait cycle (*M-L CoM*), 2) *gait velocity*, and 3) *accuracy and reaction time* of 3-back. A 3-way mixed-effect ANOVA was used for statistical analysis with Group (age), Fatigue and Task (single vs. dual) as factors.  $\alpha = .05$ .

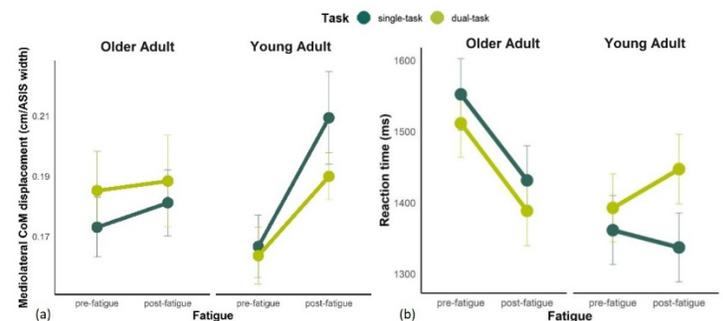

**Figure 1:** Illustration of dual-task walking (walking task + 3-back test).

## Results and Discussion

No significant age-group differences were found for the fatiguing protocol performance in terms of the fatiguing duration (19.2 mins), muscle strength reduction (18%), and increase in RPE

(from 7 to 18). From pre- to post-fatigue, a faster gait velocity (103%) was observed during dual-task walking regardless of age,  $p = 0.02$ , which may be postulated as a strategy to improve stability since the gait stability was shown reaching the best when walking at 100-110% of regular velocity [2]. For M-L CoM, we found an increased body sway at post-fatigue in young but not older adults regardless of task condition (**Figure 2a**). Older participants may have developed adaptability to fatigue, therefore are less susceptible to the fatiguing protocol. Our findings may also be reflective of healthy volunteer effect. Lastly, it is possible that our healthy older adults walked with the body sway closer to their maximum capacity, thus perturbation could not be manifested in the form of M-L CoM after fatigue.

**Figure 2:** Changes in M-L CoM (a) and reaction time (b) from pre-fatigue to post-fatigue among two age groups (mean  $\pm$  SEM).

The older adults also improved their cognitive function after fatigue (**Figure 2b**). The result maybe attributed, in part, to learning effect. The differential changes between older and young adults may be speculated from neural substrates for activity-elicited activation, in which older adults dominantly recruit frontopolar area (excitatory) after exercise instead of DLPFC (inhibitory) in young adults [3].

## Significance

We found that 1) older adults improve reaction time from pre-fatigue to post-fatigue while maintaining the mediolateral body sway, 2) balance control in young adults become deteriorated at post-fatigue and 3) fatigue effects are not exacerbated during dual-task condition. The results could serve as a scientific evidence and point out another prospective when it comes to prevention of fall accidents in workers whose job requires high physical and/or mental demand.

# Treadmill Walking Does Not Elicit Increased Tripping Risks in Children with Autism

Emily A. Chavez<sup>1</sup>, Alyssa N. Olivas<sup>2</sup>, Patrick A. Cereceres<sup>1</sup>, Pearl Quintero<sup>1</sup>, and Jeffrey D. Eggleston<sup>1</sup>

<sup>1</sup>Department of Kinesiology, The University of Texas, El Paso, TX, USA

## Introduction

Children with Autism Spectrum Disorder (ASD) experience obesity at an increased rate (30.4%) compared to controls with neurotypical development (NT; 23.6%) [1]. With the prevalence of ASD increasing to 1 in every 59 children, [2] further research is needed to identify methods aimed at decreasing obesity rates and increasing physical activity in this population. Treadmill (TM) implementation may be a viable option to do so, as previous findings suggest, metabolic requirements were 23% higher in TM walking than overground (OG) walking [3]. However, literature examining gait mechanics while on a TM in children with ASD is lacking. Specifically, investigating tripping risk or other adverse gait-related events to assess safety and efficacy of TM-use before metabolic measures can be considered. Thus, the purpose of this study was to examine lower extremity (LE) tripping descriptors in children with ASD during OG and TM walking conditions compared to NT controls. It was hypothesized that significant differences will not be identified in the ASD population between OG and TM conditions.

## Methods

Two children diagnosed with ASD (1 male [11 yrs], 1 female [10 yrs]) and two age- and sex-matched NT controls were recruited to participate in this study. Participants were outfitted with retroreflective markers on their lower extremities then were instructed to walk over a 10m walkway at a self-selected pace for 12 trials in the OG condition. Afterwards, participants were instructed to walk on a TM at a self-selected pace for a total of five-minutes. Three 30s intervals of three-dimensional LE motion capture data were collected (200 Hz, Vicon Nexus, Ltd., Oxford, UK) following the initial minute on the TM. Raw trajectory data were exported to Visual 3D for processing where a digital low-pass Butterworth filter was applied (6 Hz). The Model Statistic technique ( $\alpha=0.05$ ) [4] was used to test for statistical significance for tripping descriptors [5]: toe clearance (TC) and peak knee flexion (PKF) in both limbs. Each variable was tested during the OG condition versus the TM condition for each participant.

**Figure 1:** TC values displayed for one matched pair. \* denotes significant difference from OG to TM condition;  $p < 0.05$ .

## Results and Discussion

Mean and standard deviation values are displayed in Figure 1. Findings suggest that all ASD and NT individuals displayed more statistically significant differences between OG and TM conditions. Notably, TC in both limbs was significantly larger during the TM condition compared to the OG condition for all participants. Right PKF significantly decreased during TM condition in three individuals with the exception of one participant with ASD, who displayed no significant differences between conditions. Left PKF also significantly decreased during the TM condition compared to the OG condition for three participants with the exception of the same ASD participant that displayed a significant increase.

Though there were significant differences observed in this study in all participants, no patterns were identified in the ASD population. This may be due to the heterogenous motor characteristics of the ASD population [6]. Additionally, the magnitude of the TC in all participants may not be considered large enough to increase tripping risk between conditions as no participant experienced an adverse gait-related event during actual data collection. Thus, TM use may be a safe option to implement within the ASD population as an efficient mean of increasing physical activity without increased tripping risks. However, a larger sample size of ASD participants with matched controls needs to be examined to potentially find discernable patterns and further determine if TM use can be utilized in this population.

## Significance

Gait mechanics of children with ASD is not fully understood as current literature has only examined overground walking in this population. This study adds to the underpinnings of how children with ASD will respond to treadmill walking and assesses the safety of TM intervention as a means to increase energy expenditure. Additionally, treadmill walking may result in reduced obesity rates as well as eliminate the social and physical barriers associated with this population. On a global scale, establishing treadmill walking as a safe intervention, will allow researchers with interdisciplinary concentrations to examine and understand the social, behavioural, neurological, and clinical effects TM walking has on the ASD population.

# Gait adaptations of individuals with limited dorsiflexion ROM during incline walking

Yujin Kwon<sup>1</sup> and Gwanseob Shin<sup>1,\*</sup>

<sup>1</sup>Department of Human Factors Engineering, Ulsan National Institute of Science and Technology, Korea

Email: ekwon@unist.ac.kr

## Introduction

It is known that individuals who have limited dorsiflexion range of motion of the ankle walk with postural adaptations such as earlier heel lift to compensate for their limited functional capacity of their ankle joints (Johanson, et al., 2006).

Such associations have been observed during level walking, but no research has yet investigated how the dorsiflexion range would affect the gait pattern during inclined walking. As larger amount of dorsiflexion is required on inclined surfaces (Leroux, Fung, & Barbeau, 2002), it is assumed that the effect of limited dorsiflexion range on gait pattern would be more pronounced compared to level walking. Thus, the current study was conducted to investigate the effects of dorsiflexion range on the gait pattern while walking on inclined surfaces.

## Methods

Fifteen healthy young participants participated (mean age = 22.2(±1.9)), and grouped into 'Limited' range of motion (ROM) group (3 females, 5 males) and 'Normal' ROM group (5 females, 3 males) by their passive ankle dorsiflexion range in the Weight-Bearing Lunge Test (Table 1).

**Table 1:** Participant information. Mean(±Standard Deviation)

	Height (cm)	Weight (kg)	ROM (deg)
Limited group (n=8)	170.5(±6.7)	75.1(±6.4)	35.1(±2.9)
Normal group (n=8)	168.6(±12.0)	58.0(±11.4)	46.2(±4.6)

Each participant walked on a treadmill at five inclined slopes (0° (level), 5°, 10°, 15°, and 20°) for 2 minutes each at a self-selected comfortable speed for 20°. During walking, the ankle joint angles of the dominant leg were quantified by tracking reflective markers at 200 Hz using a three-dimensional motion capture system (Optitrack system, USA). The electromyography (EMG) signals of the soleus muscle were also quantified using a surface EMG system at 2,000 Hz (Delsys Inc., USA). The order of the five slopes was randomized between participants.

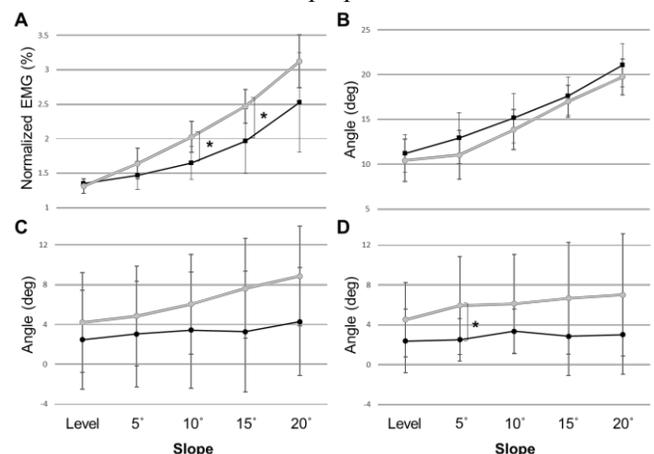

For each walking trial, the maximum dorsiflexion angle during stance, and foot external rotation and foot pronation angle at the moment of maximum dorsiflexion were identified. From the EMG signals, normalized amplitude (% of the mean amplitude during level walking) of the soleus muscle during stance was computed. The joint angle and normalized EMG data were averaged over 30 gait cycles. Two-way mixed ANOVA and a pairwise comparison with the Bonferroni correction were conducted in R (R studio, USA) to compare the variables between groups and slopes (p<0.05).

## Results and Discussion

The max dorsiflexion angle and the foot external rotation and pronation angle increased along with the slope angle (Figure 1B-D). Significant between-slope differences in the max dorsiflexion angle were found between 0°, 10°, 15°, and 20° for the limited ROM group, and between 0°, 10°, and 20° slopes for the normal ROM group. For foot rotation, significant difference was only found between 0° and 20° for the limited group. The limited

group walked with less dorsiflexion, more foot external rotation, and more pronation during stance compared to the normal group. But significance in the differences was found only at 5° for the foot pronation. The normalized EMG of the soleus muscle during stance increased as the slope angle increased, with significant differences between 0°, 10°, 15°, and 20° for the limited and between 0°, 15°, and 20° for the normal group. The limited group produced significantly higher activity than the normal group at 10° and 15° slopes (Figure 1A).

As hypothesized, the study results show the distinctive gait pattern from those who have limited dorsiflexion ROM when walking on inclined surfaces. The more external rotation and pronation at the moment of max dorsiflexion (late stance phase) would indicate the compensatory response to their limited dorsiflexion ROM when walking on inclined surfaces. The more external rotation at the later phase of stance required the soleus muscle, which is the main muscle of plantarflexion, to produce greater activation for forward propulsion.

**Figure 1:** Mean (± SD) of normalized EMG of Soleus (A), Max ankle dorsiflexion angle during stance (B), Foot external rotation angle and Foot pronation angle at max ankle flexion (C,D) of limited (gray) and normal (black) group. \*significant difference between groups (p<0.05).

## Significance

The findings of this study show that the individuals with limited dorsiflexion ROM altered their foot-ankle postures when walking on inclined slopes to compensate for their limitation, and it resulted in the greater activity of the soleus muscle. Such adaptations imply greater risk for muscle fatigue or musculoskeletal problems. The results may provide insight into the development of better walking strategy to prevent injury or exoskeletons for those with limited capacity of ankle joints.

Further research should be conducted with more participants and in more various walking conditions to quantitatively evaluate the risks associated with limited dorsiflexion ROM, and to propose proper interventions to reduce the risks.

# Older Adults Overcome Reduced Triceps Surae Structural Stiffness to Preserve Ankle Joint Quasi-Stiffness During Walking

Rebecca L. Krupenevich<sup>1\*</sup>, William H. Clark<sup>1</sup>, Greg S. Sawicki<sup>2</sup>, and Jason R. Franz<sup>1</sup>

<sup>1</sup>UNC Chapel Hill and NC State University, Chapel Hill, NC

<sup>2</sup>Georgia Institute of Technology, Atlanta, GA

Email: \*rlkrup@email.unc.edu

## Introduction

Ankle joint quasi-stiffness, the slope of the relation between ankle angle and ankle moment, is an aggregate measure of the interaction between triceps surae muscle (TS) stiffness and series elastic Achilles tendon (AT) stiffness [1]. Moreover, activation can regulate joint quasi-stiffness via changes in TS length-tension behavior [2]. However, the extent to which known age-related changes in the structure and functional behavior of the TS and AT alter ankle joint quasi-stiffness is relatively unknown. We hypothesized that, due to a more compliant AT [3], older adults would exhibit lower ankle joint quasi-stiffness than young adults during: (i) walking (Experiment 1) and (ii) isolated eccentric contractions at matched TS muscle activations (Experiment 2).

## Methods

For experiment 1, 10 young (23±2 yrs, 66.2±10.4 kg, 1.73±0.10 m, 5M/5F) and 12 older (75±5 yrs, 68.6±11.1 kg, 1.51±0.24 m, 5M/7F) adults walked on an instrumented treadmill at their preferred walking speed while we recorded lower limb kinetics and kinematics. We calculated ankle joint quasi-stiffness during the dorsiflexion, dualflexion, and plantarflexion phases of stance as the slope of the best fit line on a moment-angle plot (Fig. 1A). Two-tailed independent samples *t*-tests assessed the effect of age on ankle joint quasi-stiffness during walking. For experiment 2, 9 young (23±3 yrs, 70.7±10.4 kg, 1.76±0.12 m, 4M/5F) and 8 older (72±4 yrs, 69.1±18.6 kg, 1.68±0.09 m, 4M/4F) adults performed a series of eccentric isokinetic contractions at 30 °/s through a 25° range of motion while using biofeedback to match 75% MVIC soleus activation. Ultrasound imaging captured TS muscle fascicle length change. We calculated ankle joint quasi-stiffness and TS muscle stiffness, the latter as the slope of the best fit line on a force-length plot. We used two-tailed independent samples *t*-tests to assess the effect of age on primary outcomes and report effect sizes ( $\Delta$ ) as the difference in means divided by the standard deviation of young adults.

## Results and Discussion

Contrary to our first hypothesis, ankle joint quasi-stiffness during walking was unaffected by age [dorsiflexion ( $p=0.376$ ,  $\Delta=0.43$ ),

dual-flexion ( $p=0.96$ ,  $\Delta=0.04$ ), and plantarflexion ( $p=0.124$ ,  $\Delta=0.60$ ) (Fig. 1A)]. Our second experiment, performed at a matched activation, removed the potential for activation-dependent modulation of ankle joint quasi-stiffness that could be highly prevalent during a functional task such as walking. As hypothesized, during isolated contractions at a matched activation, older adults exhibited reduced ankle joint quasi-stiffness ( $p=0.020$ ,  $\Delta=1.04$ , Fig. 1B), soleus muscle stiffness ( $p=0.038$ ,  $\Delta=0.94$ , Fig. 1C), and gastrocnemius muscle stiffness ( $p=0.043$ ,  $\Delta=0.85$ , Fig. 1D). We offer two inter-related explanations for our findings. First, older adults likely have a scaled down length-tension curve compared to young adults due to a reduced capacity for force generation. Accordingly, we would anticipate a smaller rise in force in older than young adults across a prescribed range of motion which, thereby, would elicit reduced stiffness at the individual muscle and ankle joint levels. Second, given evidence of reduced AT stiffness with age [2], the smaller rise in force may be explained by a smaller tendon force contribution to total muscle-tendon unit force. Together, our findings suggest that during normal walking, older adults increase muscle activation to maintain ankle joint quasi-stiffness.

## Significance

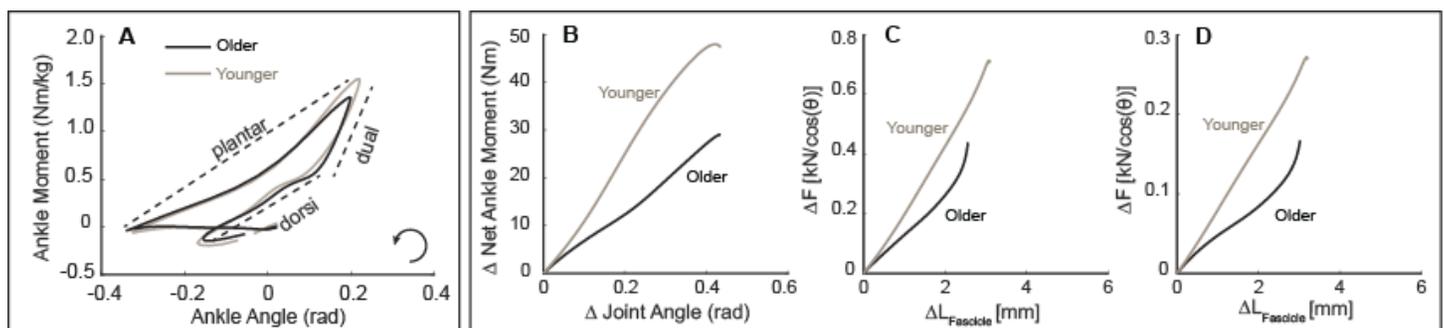

Ankle joint quasi-stiffness is preserved in elderly gait, an outcome that: (i) persists despite underlying effects of age on triceps surae muscle-tendon structure and function, and (ii) may be governed at least in part via activation-mediated increases in triceps surae muscle stiffness.

Email: [anolivas4@miners.utep.edu](mailto:anolivas4@miners.utep.edu)

## Introduction

Distinct differences in gait mechanics have been observed when comparing children with Autism Spectrum Disorder (ASD) and neurotypical (NT) peers, including hip, knee, and ankle angular joint positions, as well as vertical and anterior/posterior ground reaction forces [1]. Weighted vests (WV) are a common intervention for children with ASD to help decrease aberrant movements and behaviors linked with the disorder [2]. Recent research has demonstrated a decrease in gait coordination variability [3] and an increase in smoothness of the center of mass while wearing a WV in children with ASD [4]. Previous research analyzing WVs and their effects on movement in children with ASD have examined 15% body mass distributed in the WV; however, this load was previously established with research conducted on NT children. Consequently, a critical mass value for children with ASD has yet to be established [5]. Therefore, the purpose of this study is to investigate potential changes in spatial-temporal parameters for children with ASD during walking with 5, 10, 15, and 20% body mass distributed within the WV, compared to bodyweight. It was hypothesized that spatial-temporal parameters will change with increasing mass, similar to what has been previously observed in NT literature.

## Methods

5 children (1 female, 4 males) with a clinical diagnosis of ASD (12.7±3.1 years; 1.6±0.09m; 60.7±10.4kg) participated in the study. Participants walked over-ground for a distance of 9 m, for 12 trials at a self-selected velocity in five conditions: without a WV (baseline), with a WV at: 5, 10, 15, and 20% body mass evenly distributed posteriorly and anteriorly. During all trials, three-dimensional kinematic data were obtained using a 10-camera motion capture system (200 Hz, Vicon Motion Systems, Ltd., Oxford, UK) and exported to Visual 3D (C-Motion, Inc., Germantown, MD, USA) for analysis. Data were smoothed using a low-pass Butterworth digital filter with a cut-off frequency of 6 Hz. Mean and standard deviation values were calculated for right step length, left step length, stride width, stride velocity, and double limb support time. A repeated measures analysis of variance (ANOVA;  $\alpha=0.05$ ) was conducted to test for statistical significance between conditions. When a significant difference was detected in the omnibus ANOVA test, pairwise comparisons were interpreted after applying the Sidak adjustment.

## Results and Discussion

Analysis revealed that children with ASD displayed no statistical difference in spatial-temporal parameters among conditions (Figure 1). The repeated measures ANOVA analysis revealed: left step length:  $F(4,16)=1.564$ ,  $p=0.232$ ,  $\eta^2=0.281$ , right step length:  $F(4,16) = 1.771$ ,  $p=0.184$ ,  $\eta^2=0.307$ , stride width:  $F(4,16)= 2.101$ ,  $p=0.128$ ,  $\eta^2=0.344$ , stride velocity:  $F(4,16)= 0.929$ ,  $p=0.472$ ,  $\eta^2=0.189$ , double support time:  $F(4,16)=1.013$ ,  $p=0.430$ ,  $\eta^2=0.202$ . These findings suggest that children with ASD do not modulate their gait with increased weight, rejecting the hypothesis that the spatial-temporal parameters would change

with increasing loads. These findings may indicate that children with ASD are not appropriately interpreting the increasing mass while walking, thus, suggesting that children with ASD may not be appropriately interpreting external stimuli. While WVs have shown to decrease hyperactivity and sensory defensiveness in children with ASD [2], the individuals may not be processing the changes of the sensory input and the increasing loads are contributing to the sensory overload that is often observed in this population [6]. Previous research in gait mechanics in children with ASD has described the heterogeneous nature of ASD and how responses may be better understood through single-subject methodology, which could be applied to this project to examine if any individual changes are observed among conditions [7].

**Figure 1:** Mean (+SD) left and right step length, and stride width among conditions for children with ASD

## Significance

Understanding gait mechanics with an external stimuli present in children with ASD has not been heavily examined. The weighted vest is a common intervention for this population, and it is important to further understand how it can affect the motor deficits that have been observed. This study contributes to further discern how the weighted vest affects gait mechanics in children with ASD. On a global scale, further research in this area could provide a foundation for clinicians to recommend the weighted vest as a multi-use treatment modality for ASD.

### Introduction

Race has rarely been investigated in biomechanics studies despite racial health disparities in the incidence of musculoskeletal injuries and disease<sup>1-3</sup>. Racial differences in gait mechanics could drive disease progression and by examining them it will be possible to identify factors associated with racial health disparities. As race is a social construct, differences in gait mechanics between racial groups could be driven by specific factors other than of racial classification itself.

The purpose of this study was to (1) test the hypothesis that racial differences in fundamental gait measures between African Americans (AA) and white Americans (WA) exist and (2) that these differences would be explained by a combination of anthropometric, strength, and health status factors.

### Methods

92 participants were equally divided by gender and self-identified race. Self-selected walking speed was measured and 3D motion capture and force plate data were recorded during 7 walking trials at regular (1.35 m/s) and fast (1.6 m/s) speeds. Step length and width, peak vertical ground reaction force (pvGRF), and peak hip extension (pHEA), knee flexion (pKFA), and ankle plantarflexion angles (pAPfA) were obtained. Heart rate, blood pressure, stress questionnaires, activity level, anthropometry, lower extremity strength, and blood levels of glucose, interleukin-6, C-reactive protein, and cortisol were also assessed.

Separate multivariate ANOVA models were fit for spatiotemporal, kinetic, and angular measures in both regular and fast walking speed trials to determine main and interaction effects of gender and race (JMP Pro 15,  $\alpha=0.1$ ). For each significant MANOVA finding, post-hoc univariate ANOVA models were fit, partial eta squared effect sizes were computed for all effects, and student's T effect sizes were computed for pairwise comparisons in each interaction (Table 1). If interactions or gender effects were observed, separate analyses were run for men and women. Stepwise linear regression models were fit including race and all independent variables correlated with the outcome measure ( $p<0.2$ ) and differed between racial groups ( $p<0.1$ ); this was done for each outcome measure with an observed racial difference. If race was no longer significant in the regression model after the inclusion of the independent variable(s), those variables were considered to have explained the effect of race.

### Results and Discussion

MANOVA findings were significant for spatiotemporal ( $p<0.001$ ) and angular (regular: $p=0.001$ , fast: $p<0.001$ ) models, but no for kinetic models (regular: $p=0.895$ , fast: $p=0.200$ ). Self-selected walking speed was slower in AA ( $p=0.004$ ). Interactions between gender and race existed in step length [regular:  $p = 0.091$ ,  $\eta_p^2=0.03$ ], step width [regular:  $p=0.063$ ,  $\eta_p^2=0.04$  | fast:  $p=0.054$ ,  $\eta_p^2=0.04$ ], and pKFA [regular:  $p=0.064$ ,  $\eta_p^2=0.04$  | fast:

$p=0.015$ ,  $\eta_p^2=0.07$ ]. pHEA [regular:  $p=0.039$ ,  $\eta_p^2=0.05$  | fast:  $p=0.007$ ,  $\eta_p^2=0.08$ ] and pAPfA [regular:  $p=0.012$ ,  $\eta_p^2=0.07$  | fast:  $p<0.001$ ,  $\eta_p^2=0.14$ ] were smaller in AA. In men, larger step length during regular walking and larger pKFA during fast walking in AA were explained by larger Q-angle and lower interleukin-6 levels, respectively. In women, slower self-selected walking speed in AA was explained by larger Q-angle. Greater step widths during both walking speeds and smaller pAPfA during fast walking in AA women were explained by higher BMI and weaker ankle plantarflexion strength, respectively.

These results support our hypothesis that racial differences in gait mechanics exist and that they can be explained by a combination of anthropometric, strength, and health status factors, however, these observations were only in women. The possibility for additional factors to explain the observed racial gait differences should be investigated further, especially in men. For women, a mix of innate and modifiable factors explained racial differences. Innate metrics such as Q-angle contributing to racial differences suggests the need for racially diverse normative datasets. Modifiable factors such as BMI and ankle plantarflexion strength that are associated with racial differences could provide targets for interventions aimed at injury prevention and optimizing rehabilitation. Identified targets may also be useful in reducing or potentially eliminating racial health disparities in musculoskeletal injury and disease.

### Significance

Equivalency in gait measures between racial groups should not be assumed. Racial diversity of study samples should be a priority to enable consideration of racial differences in the development of future research and individualized treatment protocols.

## Using Movement Amplification to Explore the Effect of Walking Speed on Stability in iSCI

<sup>1</sup>Northwestern University, Physical Therapy and Human Movement Sciences, Chicago, IL, USA

\*Email: [tcornwell@u.northwestern.edu](mailto:tcornwell@u.northwestern.edu)

### Introduction

Individuals with incomplete spinal cord injury (iSCI) often walk slowly to compensate for balance deficits. Walking slowly may allow more time for corrective movements. However, iSCI gait training studies have found a positive correlation between speed and balance<sup>1</sup>, suggesting that walking faster can also positively impact balance. The effect of speed on gait stability has been studied in other populations with conflicting results<sup>2,3</sup>. Therefore, our purpose was to examine the interaction between speed and stability. We had individuals with and without iSCI walk at two speeds in a normal environment and in a force field that amplified lateral center of mass (COM) motion. Movement amplification challenges frontal plane control, potentially accentuating the impact of walking speed on stability.

We hypothesized that we would not see significant effects from speed on gait stability in the Null field because challenges to COM control during treadmill walking are relatively small. In contrast, in the Amplification field that dynamically challenges balance, we hypothesized that decreases in stability would emerge at Fast compared to Preferred speeds.

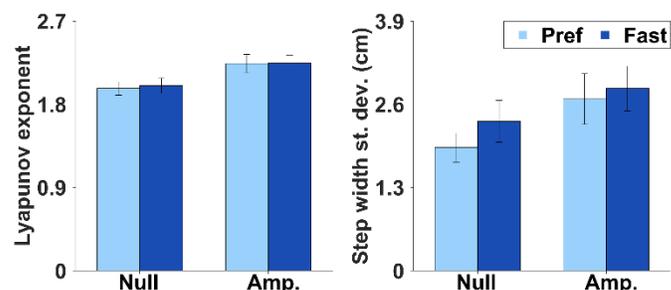

### Methods

A total of 12 adults with iSCI and 12 age- and sex-matched participants without iSCI completed the study. We recorded pelvis and foot kinematics during treadmill walking. A cable-driven robot amplified lateral motion during select trials by applying forces to the pelvis that were proportional in magnitude and in the same direction as the participant's real-time lateral COM velocity. Participants performed 4 randomized walking trials of 200 steps. The trials consisted of 2 speeds (Preferred and Fast) performed in 2 force field conditions (Null and Amplification). We calculated short-term Lyapunov exponent of frontal plane COM speed to examine local stability and step width (SW) standard deviation to probe potential control mechanisms.

To evaluate the effect of speed, we created separate linear mixed effects models of Lyapunov exponent and SW standard deviation. Speed, force field, and group were fixed effects and intercepts were random for subjects. Significance was set to  $p < 0.05$ .

### Results and Discussion

We hypothesized that individuals would maintain stability across speeds in the Null field, which was supported as there was no significant effect of speed on Lyapunov exponent ( $p = 0.240$ ). We also hypothesized that stability would decrease at the Fast speed in the Amplification field, but this was not supported as there was also no significant interaction between speed and field on Lyapunov exponent ( $p = 0.233$ ). This suggests that individuals with iSCI can maintain stability at faster speeds, even when balance is challenged. However, we did find an effect of speed on stepping with greater SW variability at the Fast speed ( $p = 0.031$ ). See Figure 1 for iSCI group data.

**Figure 1:** Data for iSCI group. At the Fast speed, Lyapunov exponent (left) did not change, but SW standard deviation (right) increased.

To better understand the significance of higher SW variability, we looked at the relationship between COM motion and foot placement (FP). Previous studies have shown that lateral COM position and speed at midstance predict >80% of lateral FP variance<sup>4</sup>. We created linear mixed effects models for lateral FP with COM position and speed as covariates. We used linear regression to fit the models' predicted values to actual FPs and recorded model fit ( $R^2$ ). Comparing model fit across trials (Table 1) may suggest a change in mechanics-dependent adjustments to stepping in order to control one's COM.

**Table 1:** Linear regression model fit values. Higher  $R^2$  values signify a better fit between actual FP and that predicted by COM motion.

Trial:	Null-Pref	Null-Fast	Amp-Pref	Amp-Fast
$R^2$	0.791	0.813	0.895	0.904

We found  $R^2$  to increase with speed, as well as from Null to Amplification field. This indicates that at the Fast speed, COM dynamics better predicted the next step, adding to a recent study that found this trend in healthy participants<sup>5</sup>. Overall, the findings suggest that individuals with and without iSCI may adapt stepping patterns to accommodate for lateral stability challenges at different speeds.

### Significance

Our findings suggest that individuals with and without iSCI can maintain lateral stability at multiple speeds, even when balance is challenged. The increase in stepping variability we observed at the fast speed may have been beneficial for COM control. This could inform iSCI gait training methods and emphasize safely increasing walking speed to encourage practice controlling one's own dynamics.

# Plantar Force During Walking Is Associated with Arch Structure and Walking Surface

## Introduction

Foot and gait pathologies may be identified by aberrant plantar pressure distribution during gait [1]. Foot pressure distribution is typically measured in clinics and gait labs using a relatively short walkway or a treadmill. It is unknown how well those clinic-based or laboratory-based measurements of plantar pressure reflect “real-world” foot loading that occurs outside the lab. One factor known to affect plantar pressure during gait is foot type (planus, normal, or cavus) [3, 4]. However, it is not clear if foot type differences in plantar pressure are consistent across different walking surfaces.

The goal of this study was to investigate the effects of foot type on plantar forces (PF) during walking on four different surfaces (lab walkway, grass, outdoor pavement, and treadmill). It was hypothesized that participants with planus feet would have higher midfoot plantar forces over all walking surfaces, and that plantar forces would be greater when walking on pavement in comparison to treadmill, grass and laboratory walkway.

## Methods

Seventy healthy subjects (41 F/29 M, 43.9±18.2 years old, 71.6±12.6 kg) with no history of foot injury or surgery provided informed written consent prior to participating in this IRB-approved study. All participants wore the same type of shoes (Nike Zoom) and walked at a self-selected pace for at least 5 minutes on four different surfaces: treadmill (TM), 7.8 m laboratory walkway (LW), 80 m outdoor pavement (OP), and 30 m grass (GS) in a random order. A Pedar insole pressure system (Novel Electronics Inc) collected bilateral plantar pressure at 100 Hz using 99 sensors per insole. Overall plantar force during each foot strike was calculated from the pressure recordings, and the first peak (P1: weight acceptance) and second peak (P2: push-off) were identified for each step and used to compare overall foot loading on each surface. The sensors were then partitioned into 9 regions [5] (Figure 1), and the Peak Regional Force (PRF), defined as the peak force within each region, was calculated for each step. These values were averaged over all steps for each surface for each participant. The arch index (AI), determined from footprints [6], was used to classify foot type as planus (low arch), normal, and cavus (high arch) [7]. A 4 way repeated measures ANOVA was utilized to identify differences among walking surfaces and foot types for P1 and P2, and for PRF within each foot region. Significance was set at  $p < 0.05$  after applying the Bonferroni correction for multiple comparisons.

## Results and Discussion

There were 43 planus, 57 normal and 40 cavus feet analyzed. An average of 140 steps per foot from each surface were analysed.

**The Effects of Foot Type:** Foot type did not affect P1 and P2 (all  $p > 0.056$ ). PRF in the heel (F1 & F2) was greatest in cavus and smallest in planus feet (all  $p < .002$ ) (Figure 2A), confirming the finding of Morag et al [8]. Midfoot PRF (F3 & F4) was greatest in planus and smallest in cavus feet (all  $p < .044$ ) (Figure 2B). Forefoot PRF (F5 & F6) was greatest in cavus and smallest in planus feet (all  $p < .031$ ) (Figure 2C). No differences in toe PRF (F8 & F9) were observed among foot types.

**The Effects of Walking Surface:** P1 and P2 were significantly higher during OP and GS than during TM and LW (all  $p < 0.01$ ). PRF was affected by walking surface in all foot regions. Differences were most apparent in the heel (F1 & F2), with all PRFs decreasing from OP to GS to LW to TM (all  $p < 0.001$ ). Midfoot PRF was greater during OP than other surfaces (all  $p < 0.024$ ). Forefoot and toe (F5 to F9) PRFs were lower during TM walking in comparison to other surfaces (all  $p < 0.003$ ).

**Interaction Between Foot Type and Walking Surface:** Significant interactions were found between foot type and walking surface in foot regions F2, F3, F4 and F7 (all  $p < 0.04$ ).

## Significance

Plantar forces measured in a controlled environment appear to underestimate peak forces experienced during outdoor walking. Lab or clinical evaluation may therefore fail to identify some potentially harmful loads on the feet. Foot type significantly affects peak regional plantar force and must be considered during any assessment of regional foot loading. Significant interactions within the midfoot suggest that the mechanical response of the arch varies among foot types and walking surfaces.

<sup>1</sup>Department of Mechanical Engineering, University of Washington, Seattle, WA, USA

<sup>2</sup>Center for Gait & Motion Analysis, Gillette Children's Specialty Healthcare, St Paul, MN, USA

<sup>3</sup>Department of Orthopedic Surgery, University of Minnesota – Twin Cities, Minneapolis, MN, USA

Email: nzaino@uw.edu

## Introduction

The time rate of energy consumption during walking in children with cerebral palsy (CP) averages approximately two times that of their typically developing peers [1]. This elevated demand impacts quality of life, participation, and walking ability [2]. The cause of elevated consumption remains a critical open question, hindering the design of effective clinical treatments. One limitation of current research is the large amount of time required to obtain accurate estimates of consumption. Typically, six minutes of data while walking is collected to obtain a steady-state (SS) measurement. However, this time requirement constrains the number of conditions or treatments that can be examined during an experiment. Future studies would benefit from a method to more rapidly estimate SS consumption.

Previous work in typically developing (TD) adults (n=10) has proposed a method to reduce the time needed to estimate SS consumption [3]. The approach uses the time constant describing the change between resting and the first portion of the transient response when someone starts walking to estimate SS consumption. A time constant of roughly  $\tau = 40$  seconds predicted the transient and SS consumption for TD adults and reduced the time required to estimate SS consumption. To our knowledge, the time constant for children with CP has not been studied. Knowing this value could greatly benefit research aimed at understanding elevated consumption in this population. The goal of this research was to determine the time constant for children with CP, and examine its variability with respect to important clinical factors such as age, sex, and functional level.

## Methods

We retrospectively identified 815 children with diplegic CP who had previously undergone gait analysis at Gillette Children's Specialty Healthcare (St. Paul, MN, USA) between 2005 and 2020. The testing protocol for each participant consisted of a 10 minute rest period followed by a six-minute over-ground barefoot walking trail at self-selected speed.

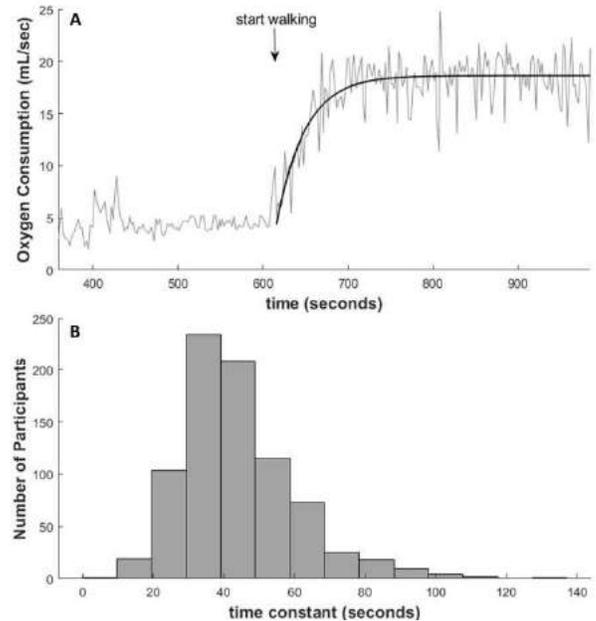

Breath-by-breath oxygen consumption was used to determine the time constant ( $\tau$ ) value for each individual according to the model:

$$E(t) = E_{walk} + (E_{rest} - E_{walk})e^{-(1/\tau)t}$$

Where  $E_{walk}$  is steady-state walking consumption,  $E_{rest}$  is steady-state resting consumption, and  $t$  is the time from the start of walking (Fig. 1a). We examined the relationship of  $\tau$  with age, Gross Motor Functional Classification System (GMFCS) level, sex, and SS consumption.

## Results and Discussion

The mean time constant for the transient portion of oxygen consumption dynamics in children with CP during walking was 44.0s (SD 16.2) (Fig. 1). These values are similar to TD adults who exhibit a mean time constant of 41.8s (SD 12.1) [3]. This indicates that CP affects SS consumption but not the transient dynamics (time constant). The time constant ( $\tau$ ) for children

**Figure 1:** (a) Example of individual breath-by-breath consumption and model prediction during last 3 minutes of resting followed by 6 minutes of walking. (b) Distribution of the time constant across children with CP.

with CP was not associated with age ( $R^2 = 0.008$ ), SS consumption ( $E_{walk}$ ,  $R^2 = 0.006$ ), GMFCS levels (GMFCS Level I 46.5(17.0), Level II 43.1(15.4)), or sex (Male 42.5(15.6), Female (46.3(17.0)).

## Significance

The time constant and its variability for children with CP was similar to TD adults. The time constant was also found to be independent of age, sex, functional level, or SS consumption. This is the first large scale exploration of the time constant for children with CP. Because the time constant matches TD adults, the results suggest that we can predict SS consumption using less than 6 minutes of walking, as shown by Selinger [3]. By reducing the required testing time for different conditions (e.g. testing various orthoses) we can gain further insight into the underlying causes of elevated consumption and potential treatments to reduce consumption in children with CP.

## It's time to start talking about timing of locomotor propulsion

Email: [dkuhman@uab.edu](mailto:dkuhman@uab.edu)

### Introduction

In human walking, the trailing limb generates large forces to propel the body's center of mass upwards and forwards during step-to-step transitions ("locomotor propulsion"). Computational models of bipedal walking suggest that timing of propulsion is crucial for mechanical efficiency [1]. It is possible then that mistimed propulsion contributes to heightened energetic costs in some populations. Propulsion timing also has important implications for designing and controlling powered lower-extremity prosthetic and exoskeletal devices. For example, optimizing actuation timing of a powered ankle exoskeleton could be important for minimizing energetic cost and maximizing user comfort [2]. Gait analyses often quantify magnitudes of propulsion (e.g., peak force or power, mechanical work) but ignore its timing, despite its potential utility for restoring/enhancing walking performance. This abstract describes our current work on propulsion timing – we hope that these data will encourage a broad discussion on this relatively unexplored gait feature at the national meeting.

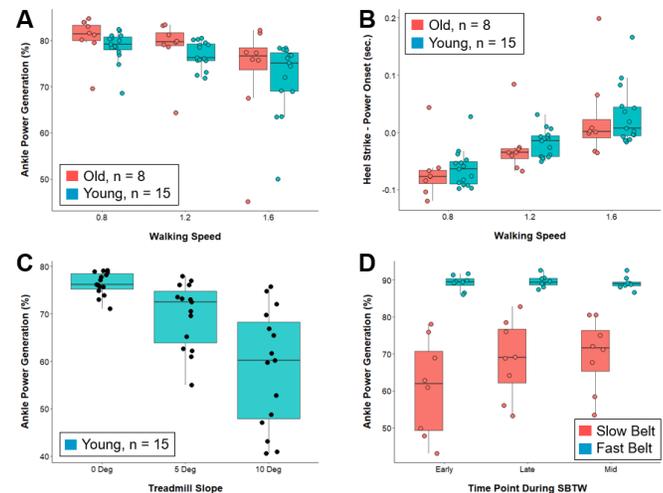

### Methods

This abstract contains data from a series of studies including healthy young ( $n = 15$ ) and old ( $n = 8$ ) adults. In both samples, propulsion timing was captured during treadmill walking across a range of speeds. For young adults, we also report propulsion timing across multiple uphill slopes ( $n = 15$ ) and during split-belt treadmill walking ("SBTW";  $n = 8$ ; right belt speed:  $0.5\text{ms}^{-1}$ , left belt speed:  $1.0\text{ms}^{-1}$  for 2-minutes). Propulsion timing was quantified using two methods: 1) timing of ankle plantarflexor positive power initiation as a percent of the support phase (%), 2) time of contralateral heel strike minus timing of ankle positive power initiation (seconds) [3]. Measuring propulsion timing relative to contralateral heel strike was inspired by the dynamic walking model [1]; positive time values indicate propulsion occurred *prior* to heel strike and negative values indicate it occurred *after* heel strike. Other measures, including timing of aspects related to ground reaction forces and total limb power, were also quantified and would be presented at the meeting (if accepted). We used a 2-way repeated measures ANOVA to compare the effects of age (young, old), walking speed (0.8, 1.2,  $1.6\text{ms}^{-1}$ ), and their interaction on propulsion timing. We used a repeated measures ANOVA to determine the effects of slope ( $0^\circ$ ,  $+5^\circ$ ,  $+10^\circ$ ) on propulsion timing in young adults. We used a 2-way repeated measures ANOVA to compare the effects of limb (fast, slow), time point (early, mid, late), and their interaction on propulsion timing during SBTW.

### Results and Discussion

We found a significant effect of walking speed on both measures of propulsion ( $p < 0.05$ ; Fig. 1A & B), but no effect of age. We found a significant effect of treadmill slope on propulsion timing measured as a percent of support (Fig. 1C)

and relative to heel strike (both  $p < 0.001$ ). Finally, we found a significant effect of limb (fast vs. slow) on propulsion timing ( $p < 0.001$ ; Fig. 1D) but no effect of time point during SBTW.

**Figure 1:** Walking speed had a significant effect on propulsion timing measured as a percentage of support (A) and relative to contralateral heel strike (B) in both young and old adults. As slope increased, propulsion was initiated earlier in support (C). During SBTW, propulsion timing differed between limbs (D).

### Significance

Although we found no age-related differences in propulsion timing, more mobility-impaired populations may exhibit mistimed propulsion. If true, interventions seeking to restore walking performance – particularly by lowering energetic cost – may consider targeting proper propulsion timing via gait retraining. We are currently collecting data in individuals with Parkinson's disease walking across a large range of speeds and will include these in the final presentation (if accepted). Altered propulsion timing in response to changes in speed, slope, and SBTW suggest that propulsion timing is an adaptable feature of gait and devices which actively provide or assist propulsion should have the capability of varying actuation timing based on the demands of the locomotor environment. Additionally, between-subject variation in timing appears to change with altered demand, suggesting the need for subject-specific control parameters in these devices. We hope that the data reported here will encourage discussion about propulsion timing at the national meeting, as we believe this gait feature has important implications for a wide range of fields (healthy and impaired gait analysis, rehabilitation, modelling and simulations of locomotion, prosthetics, exoskeletons, robotics, etc.).

## Introduction

Human walking gait can be divided into initial contact, weight acceptance, midstance, and toe-off phases. Vertical ground reaction forces (VGRF) include two local maxima separated by a local minimum, sometimes containing impact spikes during weight acceptance. Loading rate is the slope of the VGRF between initial contact and the end of weight acceptance, called the loading response (LR) phase, and it represents time between contact and maximum limb load for that phase.<sup>1</sup> Fourier analysis captures characteristic features and the sinusoidal nature of VGRFs, reflecting loads on the limb and behaviors of the leg spring.<sup>2</sup> The effect of impact spikes, which add a sinusoidal oscillation to the VGRF, has not been systematically evaluated using Fourier analysis.<sup>3,4</sup> Given their influence on lower limb and joint health, impact spike characteristics during LR have strong clinical relevance.<sup>5-7</sup> The goals of this analysis are to (1) determine the effect of leading zeros on modulating VGRF periodicity and (2) detect impact spikes and understand their influence on Fourier analysis.

## Methods

From a sample of VGRFs from habitually unshod subjects walking barefoot at self-selected speeds, we selected 10 VGRFs with and 10 without impact spikes. Data were low-pass filtered at 10 Hz with a fourth-order Butterworth filter. We zero-padded steps by appending lagging zeros equal to VGRF length.<sup>2,8</sup> We ran eight-term Fourier analyses with period equal to twice stance phase length on each variation described below.<sup>2</sup> To assess goodness-of-fit between raw VGRFs and Fourier renderings, we computed mean pointwise  $L^2$  distances and compared values with paired t-tests or ANOVAs as appropriate.

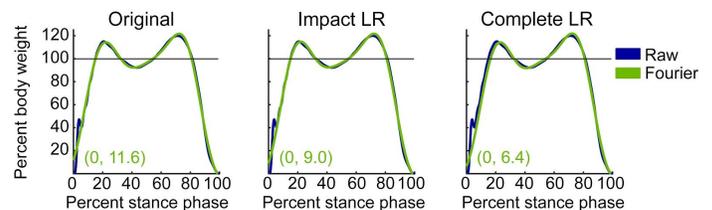

To determine how best to capture the very early loading phase, we explored varying levels of leading zero-padding from 0% to 20% VGRF length by 0.5% increments. To characterize the impact spike effect on Fourier reconstruction and facilitate comparison to original curves, we generated two LR component variants for each VGRF: impact LR and complete LR. These, respectively, are a curve with the impact spike component replaced with loading rate from origin to post-impact spike minimum and a curve that replaces LR phase with the loading rate from the origin to the end of weight acceptance (**Figure 1**).

**Figure 1:** Representative impact spike variants: “Impact LR” in left and “Complete LR” in the right panel. LR phase shaded in yellow. Replaced regions highlighted in red. Grey line is 100% body weight.

## Results and Discussion

$L^2$  distances for leading zero-padding analysis significantly increased from 0.87 (0%) to 1.04 (20%) ( $p < 10^{-8}$ ). Thus, we excluded all leading zeros from subsequent analyses.  $L^2$  distances significantly differ among normalized stance subphases, LR variations, and their interaction (2-way ANOVA,  $p < 10^{-6}$ ) (**Figure 2; Table 1**). LR of complete LR differs from that of the other two variations ( $p < 10^{-8}$ ). Impact loading rates are significantly greater than post-impact loading rates ( $p < 10^{-6}$ ). Fourier coefficients  $a_1$ ,  $a_3$ ,  $a_6$ ,  $a_8$ ,  $b_2$ , and  $b_4$  differ between original and impact LR ( $p < 10^{-2}$ ).

**Figure 2:** Fourier reconstructions (green) of Original, Impact LR, and Complete LR overlaid on representative raw data (blue). Y-intercepts for Fourier reconstructions labeled. Grey line is 100% body weight.

**Table 1:**  $L^2$  distances between LR variants and original impact spike VGRFs normalized to stance subphase duration.

	Total	LR	Midstance--toe-off
Original	0.0013	0.0045	0.0016
Post-impact LR	0.0014	0.0049	0.0018
Complete LR	0.0030	0.0111	0.0040

## Significance

Impact spikes are associated with acute injury and development of osteoarthritis.<sup>5,6</sup> Our current analysis reveals that representing the LR with a constant loading rate is insufficient and that, within the LR phase, impact spikes have higher loading rates than does the post-impact LR, a pattern that may adversely affect weight-bearing joints.<sup>1,7</sup> We further demonstrate that Fourier coefficients thought to vary with LR frequency<sup>2</sup> differ between LR variants. Standard Fourier analysis effectively models LR in the presence of impact spikes, making it a powerful method able to distinguish clinically-relevant VGRFs without preliminary adjustments to account for variations in LR.

## Introduction

The sampling rate of data acquisition has an effect on time intervals, which are required for recognizing peak points in cyclic data for event detection [1]. The sampling rates derived from the Nyquist theorem may not be appropriate for calculations that are subsequently done in the temporal domain. A low sampling rate will limit the temporal resolution by which gait events may be identified, increasing the chance for aliasing errors in timing of gait events. Low resolution leads to the timing of gait events binning into distinct bins with little variability. Reducing the sampling rate further increases the binning effect, with fewer and fewer bins for the timing of gait events available [2]. The alternative—excessively increasing the sampling rate—will prevent aliasing errors yet increase the capture of high-frequency noise. Decreasing sampling rate is expected to have a greater effect on the temporal gait measures compared to spatial measures, because spatial measures are based on coordinates in space. Coordinates are not limited in resolution based on a moment in time. The purpose of this study was to bring awareness of the effects of sampling rate on mean and regularity of gait variables. Using step time and step length, we examined the averages and sample entropy (i.e. measure of pattern regularity) of data collected from subjects walking on a treadmill.

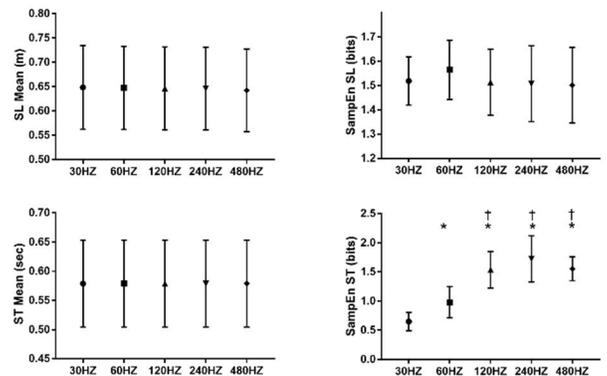

## Methods

Eleven young adults ( $24.45 \pm 2.97$  years;  $174.15 \pm 1.52$  cm;  $74.68 \pm 12.35$  kg), free from any musculoskeletal and neuromuscular disorders, participated in the study. Participants were asked to walk on a treadmill at their comfortable walking speed while lower-extremity kinematic data were recorded at 480 Hz for 10 minutes. Each walking trial was down sampled to 30, 60, 120, and 240 Hz by selecting every sixteenth, eighth, fourth, or second data points, respectively. Right and left step lengths and step times were calculated from the exact same portion of the walking trial (~9 minutes) for all of the sampling rate conditions. A combined time series of right and left SL and ST was calculated for each time series to be used for subsequent analysis. The average and sample entropy ( $m=2$ ,  $r=.35*SD$ ,  $N=756$ ) of SL and ST were then calculated for each time series. Data were inspected for normality. One-way ANOVAs ( $1 \times 5$ ) were used to compare each gait variable across the five sampling frequencies. Statistical significance was set at  $\alpha=0.05$ .

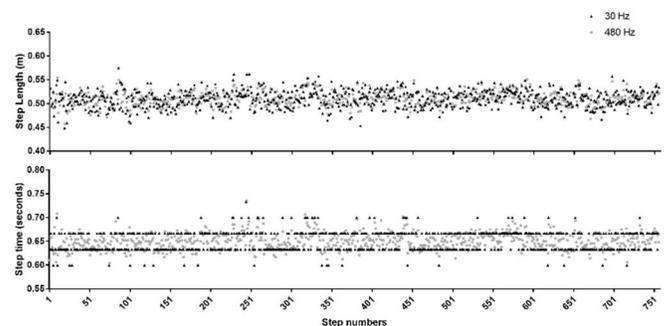

## Results and Discussion

SL and ST mean were not affected by changing sampling frequencies (Figure 1.a,b). This is credited to linear model statistics that provide us with the central limit theorem, such that 200 steps should provide the average of the population. We did not observe a significant effect of sampling frequency on the sample entropy of SL (Figure 1.c). However, by decreasing the sampling rate and thereby increasing the “binning” effect (Figure. 2), ST was restricted in the spread of values. This led to much less irregularity and a more regular ST as sampling rate decreased ( $F(1.463, 14.631)=21.812$ ,  $p<0.0001$ ). At 30 Hz and 60 Hz, the

ST was significantly more regular compared to all other sampling frequencies ( $p<0.01$ ) (Figure 1.d). When poor temporal resolution and “binning” occurs, the points will likely fall into the tolerance range ( $r$ \*standard deviation) for sample entropy calculation, and more comparisons will be counted as similar, making a time series appear more periodic.

**Figure 1.** SL and ST mean (a,b) and sample entropy (c,d), † All frequencies significantly differ from 60 Hz, \* All frequencies significantly differ from 30 Hz.

**Figure 2.** Step lengths (top) and times (bottom) for a single participant

## Significance

Sampling rates must be carefully considered when designing studies aimed at understanding regularity of patterns in walking. According to the results of this study it is recommended that gait kinematics should be collected ~ 120 Hz if entropy is to be used. This provides an appropriate compromise between event detection accuracy and processing time.

# The Cost and Spring-Like Behavior of Walking: Are Children Scaled Down Versions of Adults?

Vivian L. Rose, CPO and Christopher J Arellano, PhD  
Dept of Health and Human Performance, University of Houston, Houston, USA  
Email : vlrose@uh.edu

## Introduction

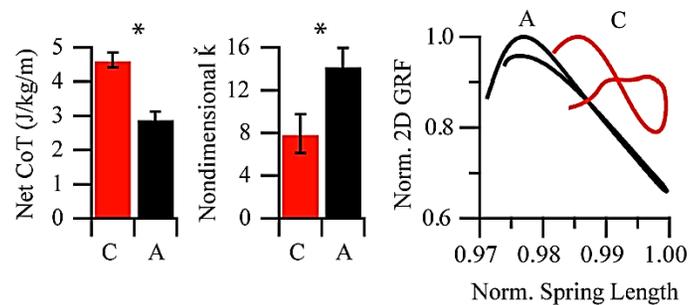

Reducing the metabolic cost of walking dysfunction is a main goal of prosthetic and orthotic devices, however, there has been limited success in achieving this goal in children for whom the cost of walking is up to 33% higher than adults, and 2-3 times more for children with a disability [1-2]. Most devices built for children are scaled down versions of adult devices, which is grounded on the assumption that children move in effectively the same way as adults—without accounting for their significant differences in cost. As a first approach in determining the mechanical factors that contribute to a higher cost, we used a simple spring-mass model [3] to compare net cost of transport (COT) and spring adaptation in typically-developing children and in young adults as they walked at their preferred speed, but at varying step frequencies. We tested the idea that when compared to adults, the higher net COT in children can be coupled to differences in how they operate the spring-like behavior of their legs. We hypothesized that when walking at their preferred speed, children would operate their leg at a different spring stiffness than adults. We also hypothesized that when varying step frequencies, children would modulate their spring stiffness in a different manner than young adults.

## Methods

Our approach was inspired by a simple bipedal spring-mass model [3], where two independent spring legs attach to the center of mass (COM). The model produces realistic ground reaction force (GRF) patterns at different speeds, which are based on touchdown angle and the leg's spring constant  $k$ . The spring constant  $k$  can be scaled to a nondimensional  $\tilde{k}$ , where  $\tilde{k} = kl_0/mg$ . To compare  $\tilde{k}$  empirically, we instructed eight children (5-6 years) and eight adults (18-30 years) to walk on an instrumented treadmill for 5 minutes at 3 step frequencies (75%, 100%, and 125% of preferred) while recording metabolic rate (Parvo Medics) and kinematics (Vicon). We defined a vector from the COM to the center of pressure to represent a 2D spring in the sagittal plane during single support, and then calculated  $k$  from the best fit slope of the 2D GRF vs. spring length curve. We used separate repeated measures ANOVAs ( $\alpha < 0.05$ ) to compare net COT,  $\tilde{k}$ , and touchdown angle between children and adults.

## Results and Discussion

Plots of 2D GRF vs. spring length during single support show typical spring-like behavior. Slopes representing  $k$  are within the range of values predicted by the model for adults. However, the spring-like behavior observed in children is less consistent and exhibits more hysteresis (Figure 1). When compared to adults,  $\tilde{k}$  in all conditions was smaller in children (age main effect,  $p < .001$ ). Our findings support our first hypothesis that children and young adults operate their legs with a different spring stiffness. We also found that children oriented their spring-like legs at higher touch down angles than adults (age main effect,  $p = .006$ ; step frequency main effect,  $p < .001$ ). However, when comparing trends across step frequency, children and adults modulated their spring stiffness and touchdown angle in a similar

**Figure 1. Left-Middle.** Data show that children walk with a higher net COT (J/kg/m) and a lower  $\tilde{k}$ . **Right.** Representative child (C) and adult (A) force-displacement curves normalized to their maximum values. Note that the slope of the curve equals  $k$ .

manner (interaction effect,  $p > 0.05$ ), meaning our second hypothesis was rejected. Consistent with previous literature, children walked with a higher net COT across their preferred and non-preferred step frequencies ( $p = .001$ ).

A spring-based model of walking recognizes the importance of storing and releasing energy in the body's elastic elements and has proven useful in scaling for robotic applications and advanced walking simulations of adults [4]. We find a child's leg spring to be more compliant, which seems to be linked to a higher net COT. A spring-based model for walking may prove useful in understanding the biomechanical factors that explain the higher cost in children, and in scaling and tuning prosthetic and orthotic devices to their unique walking mechanics.

## Significance

Despite significant differences and changes in physiological and biomechanical development in children, there remains a scientific gap in our effort to model and translate these differences to the design of devices intended to normalize movement in children. Our efforts are aimed at developing a child-specific biomechanical framework that could be used to guide the design and alignment of assistive devices, which would aid physicians, prosthetists, and orthotists in helping children achieve maximum walking function while minimizing cost.

# The effects of a 6-week horizontal impeding force training protocol on push-off intensity in older adults

Katie A. Conway<sup>1</sup>, Keyaira Crudup<sup>1</sup>, and Jason R. Franz<sup>1</sup>

<sup>1</sup>Joint Department of Biomedical Engineering, University of North Carolina Chapel Hill and North Carolina State University

Email: [kaconway@unc.edu](mailto:kaconway@unc.edu)

## Introduction

Walking ability limitations among older adults are extremely prevalent. Diminished push-off intensity, characterized in walking by reductions in peak propulsive ground reaction force (GRF) and ankle joint moment and power generation, is considered an important determinant of slower preferred speeds and thereby age-related mobility loss [1]. Strength gains following conventional intervention (i.e., resistance training) seem to convey benefits during maximum speed walking without improving habitual walking speed or movement biomechanics [2]. One explanation for these disappointing translational outcomes is that resistance training alone is unable to directly encourage access to newfound strength gains. Therefore, there is a vital need for more targeted strategies designed to purposefully enhance push-off intensity during walking. The purpose of this study was to investigate the preliminary efficacy of a 6-week impeding force training paradigm to improve calf muscle strength, walking performance (i.e. preferred and maximum speeds and 6-min walk distance) and push-off intensity (i.e. propulsive GRF and ankle moment and power) in older adults.

## Methods

11 healthy but not physically active older adults (age: 76±4 years 6F/5M) participated. Subjects were excluded if they participated in more than 150 minutes of moderate intensity or 75 minutes of vigorous aerobic physical activity per week. Subjects also had no recent neurological or musculoskeletal injuries, and could walk without an assistive device. At baseline (“Pre”), we recorded subjects preferred and maximum safe walking speeds using instrumented 30 m and 2 m walkways, respectively. Subjects then completed a 2 minute walking trial at preferred speed on an instrumented treadmill (Bertec, OH). We used motion capture (Motion Analysis, CA) and 3D ground reaction force data to estimate ankle joint kinematics and kinetics. Subjects also performed maximum voluntary isometric contractions in a dynamometer (Biodex, NY) at 10° dorsiflexion and a 6 Minute Walk Test (6MWT). After baseline testing, subjects completed 20 minute walking sessions twice per week for 6 weeks. During each session, subjects walked against horizontal impeding forces attached via wastebelt while walking at their preferred speed (Fig. 1A). Impeding forces started at 3% bodyweight (BW), and increased by 0.5% BW every 5 minutes based on Rate of

Percieved Exertion (RPE, 4-6). After 6 weeks (“Post”), subjects repeated strength, biomechanical, and walking performance testing. In addition, we monitored subjects daily activity levels before and during the 6-week intervention (Fitbit, CA).

## Results and Discussion

Subjects completed 100% of their 12 sessions across 6 weeks, and averaged 42 ± 4 days between their Pre and Post sessions. Impeding forces increased from 3% BW to 4.6±1.0% BW on average across the intervention, and subject daily activity (i.e., steps/day) outside of the lab remained relatively constant (p=0.571). Changes that follow characterize the overall effect of the 6-week intervention (i.e., Post vs. Pre). Isometric strength (1.34±0.32 vs. 1.13±0.40 Nm/kg) and maximum walking speed (2.00±0.25 vs. 1.82±0.25 m/s) increased by an average of 18% and 10%, respectively (p-values≤0.002, Fig. 1B-C). 6MWT distance also increased by an average of 46±33 m (p=0.001, Fig. 1D). Preferred walking speed was generally unaffected (1.30±0.11 vs. 1.25±0.10 m/s, p=0.095), as were habitual propulsive GRF (19.30±2.94 vs. 18.36±2.90 %BW, p=0.148) and stride length (1.37±0.14 m vs. 1.38±0.19 m, p=0.783). However, habitual peak ankle moment (1.35±0.16 vs. 1.23±0.15 Nm/kg, p=0.036) and peak ankle power (3.02±1.00 vs. 2.62±0.69 W/kg, p=0.023) increased by a significant and clinically meaningful 10% and 15%, respectively (Fig. 1E).

## Significance

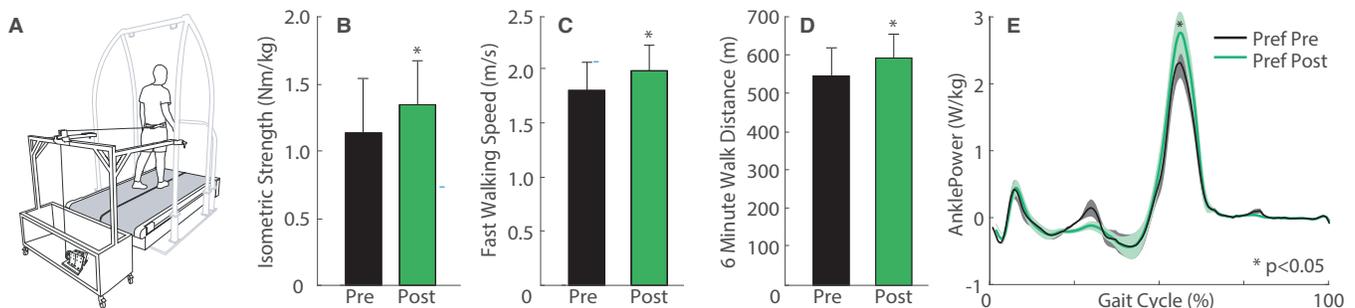

The findings of this proof-of-concept intervention study suggest that, following 6 weeks of horizontal impeding force training, older adults exhibit significant strength gains that also translate to improved maximum walking capacity (e.g., maximum speed and 6MWT distance) and habitual walking performance (e.g., greater ankle moment and power output). Moving forward, this paradigm could have broad implications for clinical populations conventionally prescribed strength-based rehabilitation programs (e.g., cerebral palsy, persons following stroke, or older adults).

# Effectiveness of a Gamification Intervention to Limit the Hawthorne Effect in Pediatric Gait Analysis

Mark Geil, Leila Rahnama, Justin Jarrells, Micah Poisal, Erica Sergeant, Kimberly Soulis  
Kennesaw State University, Kennesaw, Georgia, USA  
Email: mgeil@kennesaw.edu

## Introduction

The Hawthorne Effect occurs when individuals alter their behaviour because they are being observed.<sup>1</sup> Anecdotally, the Hawthorne Effect has been observed during gait analysis. Often called “lab gait,” individuals walk differently with markers attached and in the presence of camera arrays. Parents often encourage their children to “walk like you do at home” when they observe these atypical gait patterns.

This is problematic in both clinical and research gait analysis, since spontaneous or natural gait provides better knowledge of nervous system function and potential neuromotor abnormalities.<sup>2</sup> Cognitive distraction is sometimes used, but is challenging in many populations. This study tested a low-immersion virtual reality gamification intervention intended to produce more natural gait.

## Methods

Typically developing children between the ages of 4 and 12 were recruited to participate in this IRB-approved protocol.

Prior to motion analysis, children were provided a survey of their feelings about the study based on five emotional domains in Walden et al.<sup>3</sup> Next, a standard instrumented 3D motion analysis was conducted with a full-body Vicon Plug-In-Gait marker set during level overground walking at a comfortable self-selected speed. After ten successful trials, we displayed a virtual environment on monitors around the lab using Argonaut software (Idoneus Digital LLC). Children chose an environment (alien planet, city park, castle) and an avatar. The software couples with Vicon marker coordinates to create a real-time 3D animation. Children were free to wander the lab for about ten minutes, seeking objects and exploring the space (Fig. 1). During that time, we collected trials during any straight-line walking in the Vicon system. Next, we turned off the monitors and repeated the initial gait analysis with ten more trials. Finally, we repeated the survey on feelings. Along with survey data, we analysed walking speed, step length, Froude number, arm swing (measured as peak difference in hand bilateral marker coordinates along the axis of progression), and Gait Deviation Index (GDI).

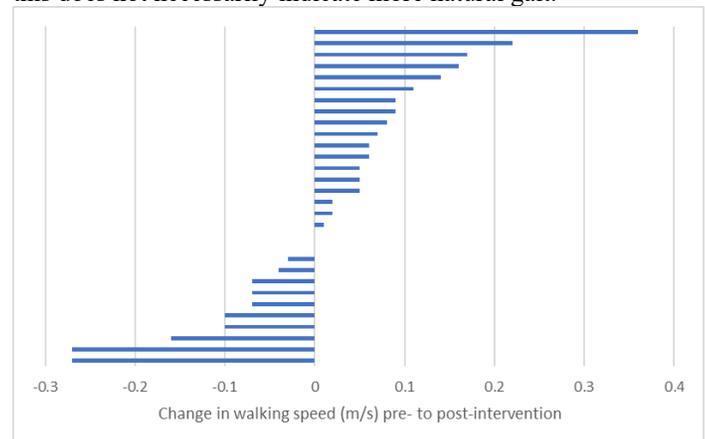

**Figure 1:** Subject moving through virtual environment and avatar displayed on monitors around laboratory walls.

## Results and Discussion

32 children participated in the study. Although the participants were typically developing children with no orthopaedic or neurological conditions, 81% expressed either diminished feelings of happiness or excitement, or increased feelings of fear in anticipation of the analysis. After the intervention, these feelings improved for 88% of those children. Across all subjects, there were significant improvements in feelings of happiness ( $p=0.001$ ), excitement ( $p=0.033$ ), fear ( $p=0.011$ ), and sadness ( $p=0.026$ ) following the intervention.

As expected, several outcome measures were significantly correlated. As walking speed increased, so did step length and

arm swing. Changes were highly variable, which is not surprising, given that the study design could only measure change and could not identify a gait pattern that was more or less “natural.” Speed results (Fig. 2) are an example of the variability. While the majority of subjects increased speed post-intervention, this does not necessarily indicate more natural gait.

**Figure 2:** Change in walking speed post-intervention

There was one significant link between changed feelings and changed gait outcomes. Point biserial correlation analysis showed a significant mild correlation between increases in excitement pre- and post-intervention and changes in GDI ( $p=0.037$ ).

Some individual cases do illustrate the potential changes in gait. Subject 25, who changed from “not at all happy” to “totally happy” and from “totally scared” to “not at all scared” post-intervention, showed a 5% increase in GDI and a 36% increase in arm swing.

In summary, the gamification intervention resulted in improved feelings about gait analysis and changed gait patterns. The latter should not be construed as more natural gait, but alterations in gait coupled with improved feelings could imply that conclusion.

## Significance

Similar to “White Coat Syndrome,” children are often nervous in a laboratory setting, which can lead to altered gait. For example, children with Idiopathic Toe Walking, who walk with initial toe contact most of the time at home, often adopt a heelstrike pattern in the lab, making it difficult to determine the severity of their condition. A simple intervention that reduces anxiety, and leverages the laboratory setting to promote, and not inhibit, natural gait could be helpful in both clinical and research settings.

# Muscle Metabolic Energy Costs While Modifying Propulsive Force Generation During Walking

Richard E. Pimentel, Noah L. Pieper, William H. Clark, and Jason R. Franz

Joint Dept. of Biomedical Engineering, UNC Chapel Hill and NC State University, Chapel Hill, NC

Email: rickypim@live.unc.edu

## Introduction

Aging and many gait pathologies are associated with an increased metabolic cost of walking, which negatively affects independence and quality of life. At least in older adults, some theories for this increased metabolic cost, such as maintaining lateral stability or higher total mechanical limb work, have been refuted [1]. Other theories, such as increased antagonist coactivation, leave roughly two-thirds of this increased metabolic cost unexplained [2]. Biomechanically, higher metabolic costs are often accompanied by smaller peak propulsive forces ( $F_P$ ) generated during push-off and a redistribution of workload from muscles spanning the ankle to those spanning the hip [3]. These are precisely the joint-level responses young adults use when responding to a real-time biofeedback paradigm designed to prescribe changes in  $F_P$  during the push-off phase of walking [4]. Indeed, our group has shown that young adults walking with decreased  $F_P$  do so by redistributing muscle workload from ankle to the hip without changing total positive mechanical work, mimicking the biomechanics of elderly and pathological gait [4]. It is not feasible to directly measure the metabolic cost of operating individual muscles during walking. Thus, our purpose was to use musculoskeletal modeling simulations to estimate how changes in  $F_P$  and changes in the relative utilization of ankle versus hip muscles for power generation in walking influence muscle metabolic cost during walking. We hypothesized that the metabolic costs of operating proximal and distal leg muscles would exhibit different responses to targeting smaller and larger  $F_P$  underlying changes in measured whole-body metabolic cost.

## Methods

12 young subjects (age:  $23.3 \pm 3.1$  years; 7 female) walked at their preferred speed on a force-sensing, dual-belt treadmill for 5 minutes. Data from the final 2 minutes was analyzed to determine subjects' habitual  $F_P$ . At this same speed, participants then completed five 5-min walking trials using  $F_P$  biofeedback, where they pushed off the ground with varying vigor to target their typical walking  $F_P$  (Norm) and  $\pm 20\%$ , and  $\pm 40\%$  of Norm in randomized order. We collected bilateral lower body kinematics, ground reaction forces, and expired gases over the final 2 minutes for each condition. For modelling, we analyzed the first left and right strides from a 10-second window with the most accurate biofeedback performance within each condition. In OpenSim,

marker trajectories and ground reaction forces drove a scaled musculoskeletal model (gait2392). After residual reductions, we performed computed muscle control and included muscle metabolic probes in our modelling pipeline [5]. Muscle metabolic costs were averaged bilaterally, mass normalized, integrated over gait cycle periods of interest, and summed for muscles spanning the hip and ankle. Repeated measures ANOVA tested for main effects of condition on metabolic cost and LSD post-hoc tests identified pairwise differences versus Norm ( $\alpha=0.05$ ).

## Results and Discussion

Measured whole-body net metabolic power increased by up to 47% and 58%, respectively, when targeting +40% and -40% vs. Norm  $F_P$  ( $p < 0.001$ ). Simulated whole-body metabolic cost positively correlated with empirical measurements ( $r^2=0.336$ ,  $p < 0.001$ ) and individual muscle outcomes supported our hypotheses (Fig. 1). When walking with smaller than usual  $F_P$ , stance phase metabolic cost increased for muscles spanning the hip ( $p \leq 0.017$ ) and decreased for muscles spanning the ankle ( $p < 0.001$ ). Conversely, when walking with larger than usual  $F_P$ , stance phase metabolic cost most consistently increased for muscles spanning the ankle ( $p \leq 0.042$ ).

## Significance

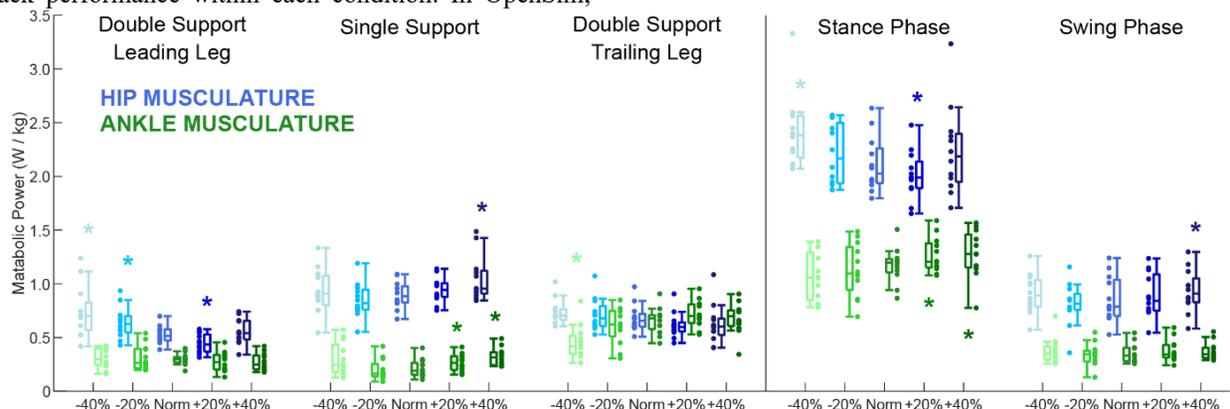

Our experimental manipulations and computational simulations suggest that an increased reliance on muscles spanning the hip, particularly the hip extensors during early stance, may independently increase metabolic cost in walking. This outcome is important for those that routinely exhibit a proximal redistribution of muscle workload (e.g., older adults).

## Introduction

Myelomeningocele (MM) is a neuromuscular disorder resulting in muscle paralysis and/or weakness. However, clinical observations suggest that some patients with low lumbar MM (MM2) are independent ambulators (IAs) with the use of orthotics, while others are non-independent ambulators (NIAs) requiring the use of assistive devices (walkers or crutches). To the best of our knowledge, currently, the information explaining the underlying cause of this variability is limited. Thus, the purpose of our study is to investigate how the ambulatory status of MM2 may be related to individual muscle groups and their associated strength.

## Methods

This is a retrospective study involving 48 patients, MM2, who underwent 3D gait analysis (3DGA), including a determination of their ambulatory status and a physical exam to assess their lower extremities joint range of motion and muscle strength (manual muscle test [MMT]). Patients were included if they were diagnosed with MM2 and could be classified as IAs or NIAs. Patients were excluded if they had a history of surgery or injury within one year prior to the evaluation.

Based on the grade given from the 5-point clinical MMT scale, muscle strength was converted to a continuous scale from 1 to 24 to allow for statistical analysis (i.e. an MMT score of 3 is a 14 on our continuous scale). Kinematic variables were determined from the 3DGA. Data collected was analyzed using an ANOVA, with  $\alpha \leq 0.05$ .

## Results and Discussion

The purpose of this study was to investigate the relationship between ambulatory status of patients with lower lumbar MM who are IAs or NIAs and their respective muscle strength.

**Table 1:** Statistical output comparing the muscle strength between patients who ambulate independently and those who do not. Muscles tested: adductors (Add); quadriceps (Quad); iliopsoas (Ilio); sartorius (Sar); gluteus maximus (Glut Max); gluteus medius (Glut Med); hamstrings (Ham). Time-distance characteristics observed: velocity (Vel); cadence (Cad); stride length (Stride Length).

Parameter	Add	Quad	Ilio	Sar	Glut Max
IA Average ± std. dev.	17.83 ± 4.85	21.13 ± 3.20	20.41 ± 3.56	18.6 ± 3.61	11.0 ± 4.22
NIA Average ± std. dev.	17.67 ± 3.98	20.50 ± 3.20	14.81 ± 3.24	14.44 ± 2.40	5.62 ± 2.25
p-value	0.9097	0.5518	<b>2.6E-05</b>	<b>0.0007</b>	<b>1.3E-06</b>

Parameter	Glut Med	Ham	Vel	Cad	Stride Length
IA Average ± std. dev.	8.11 ± 3.60	17.09 ± 2.61	0.798 ± 0.03	0.944 ± 0.02	0.852 ± 0.03
NIA Average ± std. dev.	6.46 ± 2.79	14.21 ± 1.86	0.643 ± 0.03	0.761 ± 0.17	0.833 ± 0.02
p-value	0.1046	<b>0.0002</b>	<b>0.0243</b>	<b>0.0049</b>	0.7504

**Table 2:** Comparison of the kinematics of pelvic rotation and pelvic obliquity between IAs and NIAs.

Parameter	Pelvic Protraction	Pelvic Retraction	Pelvic Obliquity Upward	Pelvic Obliquity Downward
IA Average ± std. dev.	18.26 ± 7.41	-16.70 ± 8.24	6.74 ± 3.49	-2.88 ± 4.11
NIA Average ± std. dev.	13.74 ± 5.54	-12.54 ± 6.51	8.44 ± 4.42	-6.56 ± 4.90
p-value	<b>0.0229</b>	0.0652	0.1997	<b>0.0178</b>

Of the muscle groups investigated, the iliopsoas, sartorius, gluteus maximus, and hamstrings were stronger in IAs (Table 1). Additionally, IAs demonstrated higher velocity and cadence (Table 1). Of the kinematic variables assessed, pelvic protraction was greater for IAs, while downward pelvic obliquity was greater for the NIAs (Table 2).

The stronger hip flexors and extensors seen in the IAs group can provide greater hip stability which can facilitate independent ambulation. Furthermore, the greater velocity of the IAs, which, however, appears to be a function of increased cadence, may be further reflective of the improved ability of the IAs to control their gait compared to the NIAs. The greater excursion range for pelvic rotation in the IAs group may reflect that they achieve their stride length, partly, from pelvic rotation. The assisting devices, on the other hand, may be the limiting factor for the decreased pelvic rotation seen in the NIAs group. The decreased pelvic obliquity in the cohort of IAs may suggest that they have greater pelvic control while ambulating. One limiting factor of this investigation may be the discrepancy in sample sizes between the groups (35 IAs versus 15 NIAs). It is possible, therefore, that there may be some outliers influencing the results.

## Significance

Currently, to the best of our knowledge, there does not exist any comprehensive motion analysis studies relating the ambulatory status of patients with MM2 to their muscle strength. If this information were known, then more targeted non-invasive therapeutic interventions could be identified so that NIAs can progress to IAs, a goal of any rehabilitation program.

## Acknowledgments

### Introduction

Most of us place our feet, such that we walk without falling over. What we do not fully understand, is how we achieve the required coordination between our center of mass (CoM) and our base of support (BoS). Step-by-step foot placement coordination, relative to the CoM kinematic state, is considered a dominant mechanism aimed at gait stability [1]. Foot placement can be predicted based on CoM state [2]. Such correlation could emerge from the passive dynamics of our body [3]. Yet, recent evidence points towards active control of foot placement [4-6]. CoM kinematic state predicted hip ab-/adductor activity during the swing phase preceding foot placement [4]. In turn, this activity predicted foot placement [4]. Additionally, sensory perturbations elicited predictable foot placement responses [2, 5, 6]. In this study, we identified an actively controlled step-by-step foot placement strategy during steady state walking. It is known that in response to perturbations, this foot placement strategy is complemented by a mediolateral ankle strategy [7]. Similarly, during steady state walking an inverse relationship between the two strategies has been reported [8]. Therefore, we hypothesized that, when constraining the ankle strategy, the degree of foot placement control would increase as a compensation.

### Methods

We investigated (active) foot placement control during steady state treadmill walking. We used linear regression models to predict foot placement either by CoM state or muscle activity during the preceding swing phase. We tested the regression coefficients against zero to determine whether the models were significant. We considered the  $R^2$  of the relation between CoM state and foot placement to reflect the degree of foot placement control. We intended to recruit participants until a Bayes Factor indicating strong evidence ( $BF_{10} > 10$ ) was attained. However, we did not reach this level of evidence for all our outcome measures, leaving us with our predetermined maximum sample size of 30 healthy adults. The participants walked at normal walking speed ( $1.25 * \sqrt{\text{leg length}}$  m/s). A metronome was used to impose a constant stride frequency across conditions. In the steady state walking condition, participants walked for five minutes without any constraints. In the ankle moment constrained condition, participants walked with LesSchuh. This shoe has a narrow support surface, restricting the center of pressure (CoP) shift underneath the stance foot (like a skate), while still allowing for plantar flexion. EMG of the M. gluteus medius and M. adductor longus, ground reaction forces and full body kinematics were recorded. Gait events were derived from CoP data.

### Results and Discussion

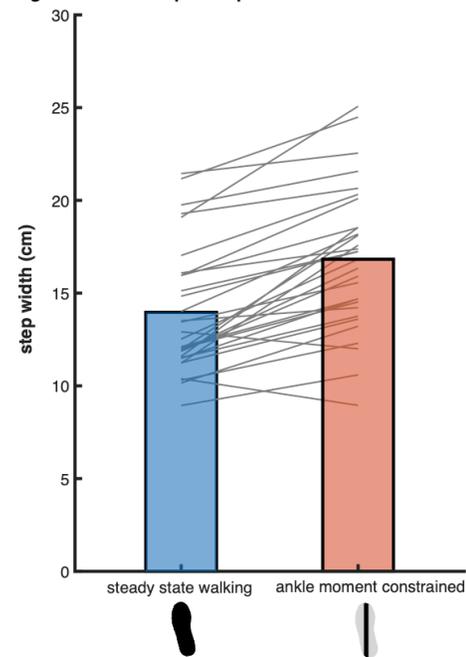

CoM state and hip ab-/adductor activity significantly predicted foot placement. As such, we identified an active step-by-step control strategy during steady state walking. The degree of foot placement control ( $R^2$ ) did not increase when the ankle moments were constrained. However, exploratory analysis revealed increased step width (figure 1), and decreased stride time as a

general compensatory strategy. Perhaps, with longer exposure to the ankle moment constraint, one can adopt tighter foot placement control and reduce step width. This is in line with repeated exposure to foot placement perturbations [9], and could potentially reduce energy cost [10].

### Significance

If training effects occur, LesSchuh could be considered a training tool to enhance the foot placement strategy and mediolateral gait stability. Apart from the foot placement strategy, other (compensatory) strategies, such as the hip strategy might play a role in stabilising gait. Insights in the complementary nature of different gait stability strategies, can help to understand and/or intervene in gait stability in elderly, pathological or prosthetic gait, and may contribute to the control of walking exoskeletons. In a fundamental context, our study contributes to our understanding of neural control of mediolateral gait stability.

Figure 1: Wider steps compensate for limited ankle moments

## Introduction

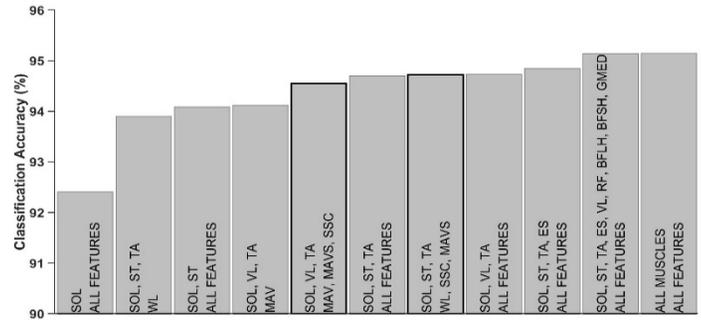

Determining the swing and stance phase of gait permits calculation of temporal parameters used to evaluate and define rehabilitation goals in clinical populations. Wearable wireless electromyography (EMG) sensors provide information regarding muscle activations during gait but their feasibility to accurately determine temporal aspects of gait is not yet established. This study aims to use machine learning to determine the optimal muscles and features to accurately classify gait phase from EMG during gait.

## Methods

Ground reaction force (2000 Hz), marker motion (whole body marker set, 250 Hz) and EMG (2000 Hz) data were recorded during 20 minutes of overground walking at an individual's preferred speed ( $1.51 \pm 0.18 \text{ m}\cdot\text{s}^{-1}$ ) from 14 healthy active males ( $25.5 \pm 2.8$  years,  $82.5 \pm 8.6$  kg,  $1.81 \pm 0.07$  m). EMG was recorded from tibialis anterior (TA), soleus (SOL), gastrocnemius lateralis (GL) and medialis (GM), rectus femoris (RF), vastus lateralis (VL), semitendinosus (ST), biceps femoris long (BFLH) and short head (BFSH), gluteus maximus (GMAX) and medius (GMED) and erector spinae longissimus (ES); locations were determined with ultrasound.

Ground contact was determined as 6 standard deviations (SD) above baseline mean from force data. EMG signals were trimmed from toe-off (TO) prior to force plate heel strike (HS) to 250 ms post force plate TO. EMG signals from 689 trials were standardised to zero mean and unit standard deviation. Signals were split into 256 ms windows with a 10 ms increment. Fifteen features were extracted within each window; mean absolute value (MAV), mean absolute value slope (MAVS), zero crossings (ZC), slope sign changes (SSC), waveform length (WL), root mean square, variance and 8 histogram bins (equal length bins with a 3 SD threshold). Features were normalised from zero to one within trials. 75% of trials were randomly selected for training data, leaving 25% for test data.

Support Vector Machine Learning (Matlab) with a radial basis function was trained to classify gait phase from the stance limb EMG features. All possible combinations of muscles and features were investigated using a 7 fold cross-validation (CV) of the training data. Algorithm parameters were optimised using the DIRECT method<sup>[1]</sup> until classification error decreased by less than 0.5% in three iterations. Mean absolute difference between test data HS, TO and ground contact time (GCT) from EMG machine learning and kinematic algorithms (TO, velocity based<sup>[2]</sup>, HS<sup>[3]</sup>) was calculated using the force plate as the ground truth.

**Figure 1:** Classification accuracy (%) for optimal muscle and feature combinations. Black outline: combination used with test data.

## Results and Discussion

The optimal two muscles with all features were SOL and ST (94.09%). SOL is a better predictor than the gastrocnemii probably due to their biarticular action as knee flexors. Addition of a third muscle improved accuracy by 0.6%. The optimal three muscles with all features were SOL, VL and TA ( $C_1$ , 94.73%) or SOL, ST and TA ( $C_2$ , 94.70%), with an accuracy less than 0.5% lower than all muscles with all features. Addition of a fourth muscle only improved accuracy by 0.15% (Figure 1).

The optimal features for  $C_1$  (MAV, 94.12%) and  $C_2$  (WL, 93.90%) were similar to Meng *et al.*<sup>[4]</sup>. Addition of MAVS and SSC to the optimal feature (features used hereafter) for  $C_1$  and  $C_2$  resulted in an accuracy of 94.68% and 94.72%, respectively.

Classification accuracy of  $C_1$  and  $C_2$  when evaluated on the test data was 97.39% and 97.58%, respectively. On average  $C_1$  and  $C_2$  predicted HS and TO time later than the force plate. Machine learning predicted HS and GCT with less mean absolute error than the kinematic algorithms (Table 1).  $C_2$  GCT error was less than half that of the kinematic algorithm.

## Significance

Machine learning can accurately predict gait phase and temporal parameters from EMG, permitting assessment of muscle activation without additional gait phase measures.

# LSTM Deep Learning and IMU Based Irregular Surface Gait Alteration Recognition

Song Li<sup>1</sup>, Boyi Hu<sup>1\*</sup>

<sup>1</sup>Department of Industrial and Systems Engineering, University of Florida, Gainesville, FL, USA

Email: \*boyihu@ise.ufl.edu

## Introduction

Falling injuries pose serious health risks to people of all ages, and knowing the extent of exposure to irregular surfaces will increase the ability to measure fall risk and human biomechanics response during locomotion (Florence et al., 2018). Current gait analysis methods require complex instrumentation and have not tested for external factors such as walking surface type in real-world settings. Artificial intelligence approaches (in particular deep learning networks) to analyze data collected from wearable sensors can be used to automatically identify irregular surface exposure. Among all deep learning models, long short term memory (LSTM) models can not only process single data inputs (e.g. images), but also entire time series of data (e.g. speech) (Hochreiter and Schmidhuber, 1997) which is well suited for human gait alteration recognition using time series data collected from wearable sensors.

## Methods

Thirty young adults participated as volunteers in this study. All participants performed 36 walking trials (6 different surfaces with 6 repetitions). Six commonly observed irregular surfaces were included: 1) an even flat surface (FlatEven), 2) cobblestone pavement (CobbleStone), 3) going up a slope (SlopeUp), 4) going down a slope (SlopeDown), 5) ascending stairs (Upstair), and 6) descending stairs (Downstair). Every participant wear six IMU sensors set on their 1) right wrist, 2) midline of the lower-back, 3-4) left and right thigh, and 5-6) left and right shank.

LSTM network (a kind of special Recurrent Neural Network (RNN) was constructed in TensorFlow. Specifically, in the current study the model first starts with the input data layer. Then add one layer of LSTM unit with 80 filters, we used Relu as activation function in the current study. We inputted the whole reshaped data and returned a sequence of data by the LSTM Unit, followed by another same LSTM layer. Dropout 50% of the neural network unit from the model was then applied. Subsequently, we added another two LSTM layers and a dropout layer but with 100 filters. The model ended with an output layer. We split 80% of the data as training data and save 20% as test data to minimize overfitting.

The performance of the model was evaluated by the result of testing data. The following metrics were used for comparison: 1) overall prediction accuracy, 2) precision, 3) recall, 4) F1-score (harmonic mean of 2) and 3)) (LeCun et al., 2015). A confusion matrix was also created.

## Results and Discussion

The accuracy of the model was 0.90. The static standing position had the best performance, with a 0.99 prediction accuracy. The Model also had a great prediction on the upstairs and slope up surface, with accuracy above 0.95. Bank left and

Bank right had the worst performance among all, with only 0.76 and 0.75 accuracy. We also repeated the test on the same model to provide a statistically stable result. The results from the repetitions demonstrated accuracy levels varying from 0.84 to 0.91.

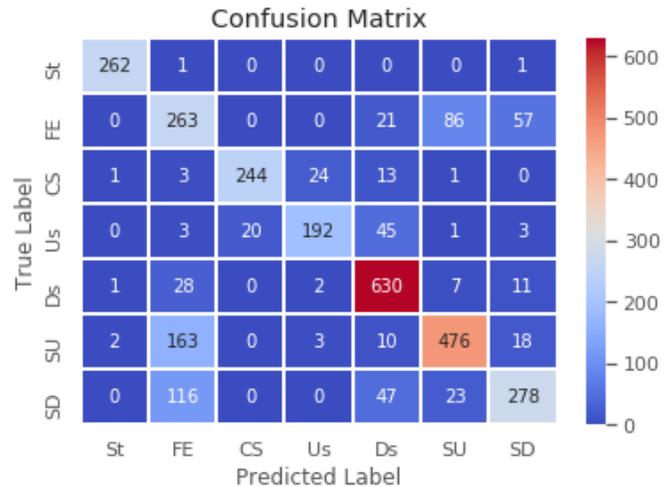

Figure 1: Confusion matrix. St: Standing, FE: FlatEven, CS: Cobble Stone, Us: Upstair, Ds: Downstair, SU: Slope Up, SD: Slope Down.

## Significance

In this study we developed deep learning LSTM models to classify human gait patterns when walking on different irregular surfaces using data collected from wearable sensors with satisfactory performance.

The results indicate the strong potential of using LSTM and wearable sensors to track human gait and prevent falling injuries in real-world settings. Furthermore, this method can also be used in numerous biomechanics related settings, such as tele-rehabilitation and physical motion analysis.

## Acknowledgments

This investigation was made possible by Grant No. T42 OH008416 from NIOSH.

# Do Switched Linear Dynamical Systems Provide Robust Kinematic Predictions of Healthy Treadmill Gait at Different Speeds?

Taniel Winner<sup>1</sup>, Trisha Kesar<sup>2</sup>, Lena Ting<sup>1,2</sup>

<sup>1</sup>W.H. Coulter Dept. Biomedical Engineering, Emory University and Georgia Institute of Technology, Atlanta, GA, USA

<sup>2</sup>Department of Rehabilitation Medicine, Division of Physical Therapy, Emory University, Atlanta, GA, USA

Email: [twinner3@gatech.edu](mailto:twinner3@gatech.edu)

## Introduction

Generalizable models that can characterize each patient's kinematics can provide a more objective gait measure than current subjective clinical ratings used to diagnose and treat gait dysfunction. Machine learning methods can classify different gait patterns, demonstrating that these algorithms can distinguish between different dynamics. Recently, data-driven SLDS models have been used to predict transitions between single and double support gait phases [1]. SLDS models can also predict joint kinematics over relatively long time horizons. However, we do not know whether these models generalize across different walking speeds. Here we tested the ability of SLDS models trained on an individual's kinematic data at a single speed to effectively reconstruct kinematic data of a different gait speed. We show that SLDS representations trained at one speed can identify gait phase from data obtained at a different gait speed. However, prediction of future kinematics over timescales of up to 1 second, require individual- and speed- specific models.

## Methods

Two healthy individuals (1 male -28 years, 1 female -28 years) were enrolled in this pilot study. Participants walked on a treadmill at a comfortable self-selected speed and at a fast speed. Kinematic data was collected at 100 Hz using a 7-camera Vicon system and force data was collected at 2000 Hz using an instrumented dual-belt treadmill. We used SLDS to model the bilateral lower limb joint angle trajectories during gait. An SLDS is a set of linear dynamical systems with discrete modes that govern when to switch between the individual linear models using Hidden Markovian model approach. Specifically, we used an autoregressive SLDS, which can be written as in (1).

$$\mathbf{x}_{k+1} = \mathbf{A}_{z_k} \mathbf{x}_k + \mathbf{w}_k(z_k) \quad (1)$$

Where  $z_k \in \{1, \dots, N\}$  is the discrete mode,  $\mathbf{x}_k$  is the state vector at time step  $k$ ,  $\mathbf{A}_{z_k}$  is the linear system parameters and  $\mathbf{w}_z(z_k)$  is a zero-mean, Gaussian noise term [2]. We trained an SLDS with four discrete modes on 9 trials of each participant's gait data at one speed and tested the model's ability to predict gait phases and kinematics at different speeds.

## Results and Discussion

Despite the ability of SLDS to predict gait phase with high accuracy (>92%) at different speeds, kinematic predictions do not appear to generalize for a different gait speed of the same individual. Fig. 1 shows that it does not have accurate kinematic prediction of a gait speed different to the one it was

trained on. Training and testing SLDS models (n=6) on different trials (on subject A) of the same gait speed of 0.9 m/s resulted in an average phase prediction accuracy (aPPA) of  $92.8\% \pm 0.7\%$  and average root mean square error (aRMSE) over all joint angle reconstructions of  $3.3^\circ \pm 0.6^\circ$  (range:  $1.2^\circ - 8.0^\circ$ ). When testing these models on 1.3 m/s speed data trials (n = 9) of subject A, the aPPA decreased by 0.17% and aRMSE increased by 166.9% (range:  $4.4^\circ - 17.8^\circ$ ). Training and testing SLDS models (n=6) on different trials (of subject A) of the same gait speed of 1.3 m/s resulted in aPPA of  $96.9\% \pm 0.8\%$  and aRMSE  $2.9^\circ \pm 0.4^\circ$  (range:  $1.2^\circ - 6.6^\circ$ ). When testing these models on 0.9 m/s speed data trials (n = 9) of subject A, the aPPA decreased by 4.7% and the aRMSE increased by 161.0% (range:  $3.8^\circ - 16.5^\circ$ ).

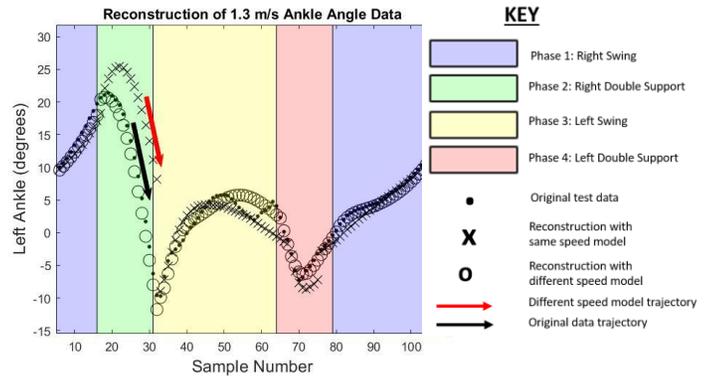

Figure 1: Left ankle reconstructions using different SLDS models tested on 1.3 mps data.

## Significance

SLDS models do not appear to generalize across individuals or gait speeds. Perhaps this suggests that SLDS is unable to handle non-linearities within different gaits. SLDS can infer gait phase predictions but not kinematic predictions, and as such, may be used in applications where the determination of changes in the gait phase is necessary (perhaps exoskeleton development). Future studies will evaluate machine learning algorithms to improve the generalizability of these models.

# Effect of Unilateral Ankle Loading on Spatiotemporal Gait Parameters during Treadmill Walking

Haneol Kim<sup>1</sup>, Matthew Beerse<sup>2</sup>, and Jianhua Wu<sup>1</sup>

<sup>1</sup>Georgia State University, <sup>2</sup>University of Dayton. Email: [hkim162@student.gsu.edu](mailto:hkim162@student.gsu.edu)

## Introduction

One has to continuously adapt to changing conditions during walking, including both external and internal disturbances [1]. Unilateral loading has been used to investigate the effects of inertial manipulations on kinematic gait patterns in healthy adults [2]. Step-to-step gait pattern seems to be stable under unilateral loading. However, the effect of unilateral loading on the long-range correlation of spatiotemporal parameters is largely unknown. Long-range correlation may reveal the nondynamic structure of variability of a time-series data.

The purpose of this study was to investigate the effects of unilateral ankle load on spatiotemporal parameters between loaded and unloaded sides in young adults. We hypothesized that with increasing unilateral load, differences between the loaded and unloaded sides may become larger in spatiotemporal parameters and their long-range correlations.

## Methods

Twenty healthy young adults (aged 18-35 years, ten males and ten females) participated in this study. Male subjects had higher body mass, height, and leg length than the female subjects. Kinematic data was captured using a Vicon motion capture system. Participants completed treadmill walking at four load conditions in a random order: A0, A25, A50, and A75, representing no load, 0.8%, 1.6%, and 2.4% of body weight, respectively. The load was placed above the ankle of the non-dominant leg, which was not used to kick a ball.

Each participant's preferred overground walking speed was used to set their treadmill speed. Subjects walked on a treadmill for five minutes under each load condition and then rested for five minutes between conditions. Step length was normalized by leg length to minimize the height effect. Step time and foot clearance were also calculated for both loaded and unloaded sides. Detrended fluctuation analysis (DFA) was applied to these gait parameters to investigate long-range correlation embedded in the time-series data.

**Table 1:** Mean of normalized step length (NSL), step time (ST), foot clearance (FC), DFA alpha of NSL (DFA\_NSL), DFA alpha of ST (DFA\_ST), and DFA alpha of FC (DFA\_FC) at each load condition.

	Side	A0	A25	A50	A75
NSL	Loaded	0.638	0.639	0.646	0.654
	Unloaded	0.647	0.644	0.651	0.653
ST	Loaded	0.525	0.537	0.546	0.555
	Unloaded	0.526	0.525	0.519	0.517
FC	Loaded	2.408	2.347	2.459	2.561
	Unloaded	2.414	2.438	2.476	2.492
DFA_NSL	Loaded	0.770	0.705	0.731	0.732
	Unloaded	0.741	0.734	0.775	0.731
DFA_ST	Loaded	0.798	0.731	0.763	0.736
	Unloaded	0.724	0.724	0.757	0.822
DFA_FC	Loaded	0.724	0.741	0.764	0.808
	Unloaded	0.752	0.682	0.775	0.718

Our preliminary analysis did not demonstrate a gender difference in normalized step length, step time, and foot clearance and their DFA alpha values. Therefore, we collapsed the data from the male and female subjects for further analysis. Two-way (4 condition  $\times$  2 side) repeated ANOVA was conducted on these variables at a significant level of  $\alpha=0.05$ .

## Results and Discussion

Normalized step length increased with unilateral ankle load and the loaded side had a smaller value than the unloaded side. There was a condition effect ( $p=0.003$ ) and a side effect ( $p=0.014$ ). Post-hoc analysis revealed that A0 was different from A50 and A75, and A25 was different from A75.

While step time at the loaded side increased with the load, it decreased at the unloaded side. Statistical analysis demonstrated that there was a condition by side interaction ( $p<0.001$ ). Post-hoc analysis revealed that there was a difference between the loaded and unloaded sides for all the load conditions except A0.

Foot clearance generally maintained similar values between the loaded and unloaded sides regardless of load. Statistical analysis revealed no main effect, nor an interaction. This suggests that unilateral load may affect spatiotemporal parameters more in horizontal than in vertical.

DFA alpha was around 0.75 for all the parameters regardless of load, suggesting these parameters were correlated within the time-series of data. Statistical analysis revealed no main effect, nor an interaction for all the parameters. This indicates that long-range correlation of spatiotemporal parameters was not affected by unilateral ankle load. Therefore, young adults can consistently modulate nondynamic structure of variability of spatiotemporal parameters while changing these parameters to accommodate an external disturbance such as a unilateral ankle load.

## Significance

This study indicates that normalized step length and step time are affected by external ankle loading as expected. However, foot clearance mostly maintained similar values, suggesting the priority of safely clearing the ground while adapting to different ankle loads. In addition, the similar DFA alpha values across load conditions suggest that our neuromuscular system may be robust in maintaining a similar structure of variability (i.e., long-range correlation) while accommodating to an external load. An analysis of long-range correlation can be used for studying movement patterns in clinical populations to understand their movement deficits, or for assessing the effect of physical rehabilitation to improve the rehabilitation design and its outcomes.

## Acknowledgments

I would like to sincerely thank all the participants.

### Introduction

Backward walking (BW) overground has been characterized as being a simple time-reversal of forward walking (FW). High correlations in joint kinematics between FW and time-reversed BW overground are seen in adults and school-aged children [1]. However, little research has been conducted in children comparing BW and FW patterns on a treadmill even though significant differences in gait patterns have been established between overground and treadmill walking in both adults and children [2]. Thus, we aimed to investigate the correlation between FW and BW kinematics in school-aged children during treadmill walking at different speeds. We hypothesized that kinematic variables would be highly correlated between FW and time-reversed BW on a treadmill at all speeds.

### Methods

We recruited 19 typically developing children (10M/9F) aged 6-12 years. Subjects completed bouts of treadmill walking for 2 minutes each; each bout represented a different walking condition. These conditions included FW and BW at 3 speeds: normal (equal to self-selected overground speed), slow (75% of normal), and fast (125% of normal). Kinematic data were collected using an 8-camera Vicon motion capture system. Electromyography (EMG) data were collected from the leg muscles using a Delsys EMG system. Correlations between FW and time-reversed BW [3,4] were calculated at the hip, knee, and ankle for each speed condition (Fig. 1).

**Fig. 1:** Representative graphs of the hip, knee, and ankle kinematics during forward (solid line) and time-reversed backward (dotted line) walking on a treadmill at the normal condition.

### Results and Discussion

School-aged children demonstrated high coefficients of correlation between FW and BW kinematics at the hip ( $r=0.83-0.99$ ) and knee ( $r=0.76-0.99$ ) that were largely unaffected by speed (Fig. 1). At the ankle, however, correlations were much lower at all speeds ( $r=0.31-0.44$ ). Inter-subject variability was high across all three joints, and the hip and knee joints showed much higher coefficients of determination than the ankle joint across three speed conditions (Table 1).

**Table 2:** Mean (SD) of correlation of determination ( $R^2$ ) between forward and time-reversed backward walking.

Speed	Hip	Knee	Ankle
Slow	0.91 (0.07)	0.89 (0.10)	0.25 (0.15)
Normal	0.92 (0.05)	0.87 (0.07)	0.16 (0.18)
Fast	0.92 (0.06)	0.84 (0.09)	0.21 (0.22)

School-aged children adapted their ankle motion differently than adults during BW treadmill walking, limiting their ankle range of motion and utilizing their plantarflexors to a lesser extent. This suggests that although a similar neural control mechanism between FW and BW walking may be present in school-aged children during overground walking, they are not yet able to fully adapt to BW on a treadmill. This is in line with previous findings that treadmill walking patterns continue to mature into adolescence. We suggest that proximal control at the hip and knee may be more advanced by this age, but distal control at the ankle is still under development.

### Significance

The decreased motion at the ankle joint during BW walking may result from children minimizing movement at this joint and compensating using adaptations from the hip and knee in order to improve stability on the moving belt. Repetitive treadmill walking is a common intervention technique in pediatric rehabilitation, with clinicians often modulating direction and speed to facilitate desired adaptations in children's gait patterns [5]. Our finding that distal control at the ankle during backward treadmill walking is not yet mature in school-aged children highlights the need to specifically quantify how young children adapt to these conditions on a treadmill so that clinicians can make informed decisions about rehabilitative protocols.

### Acknowledgments

The authors wish to thank our subjects and their families for their participation in this study.

# Physical Activity Affects Rate of Gait Adaptation and Spatiotemporal Adaptation Strategy

Sarah A. Brinkerhoff<sup>1</sup>, Patrick G. Monaghan<sup>1</sup>, Jaimie A. Roper<sup>1</sup>

<sup>1</sup>Auburn University, Auburn, Alabama

Email: sbrinkerhoff@auburn.edu

## Introduction

The nervous system responds to gait perturbations by adapting mechanics of an existing walking pattern (1). Gait adaptation can be altered by individual factors such as injuries to the nervous and the musculoskeletal systems (2,3). Currently, it is unknown how current and past physical activity influences healthy adaptation. The purpose of this study was to examine the influence of physical activity history, weekly amount of activity, and type of activity on gait adaptation in sedentary and recreationally active healthy adults. We hypothesized that activity history and type of activity (non-cyclic, such as team ball sports, and cyclic, such as running) would predict rate of adaptation. Due to the spatial aspects of non-cyclic sports and the temporal aspects of cyclic sports, we also hypothesized that individuals participating in non-cyclic sports would initially adapt their walking pattern using mostly a spatial strategy, while sedentary individuals and individuals participating in cyclic sports would adapt using mostly a temporal strategy.

## Methods

Three groups of healthy young adults participated in this study: 14 sedentary, 12 currently participating in cyclic sports, and 11 currently participating in non-cyclic sports. We collected information on activity history via a self-report. Participants walked on a split-belt treadmill (SBT) for ten minutes with their non-dominant leg moving twice as fast as the dominant leg (Adaptation). Gait adaptation was measured by the asymmetry in step lengths taken by the fast and the slow legs. Step length asymmetry (SLA) in the first five strides was measured as initial asymmetry (early SLA). Rate of adaptation was determined from the number of steps each participant took before reaching a plateau in SLA. Additionally, we measured the asymmetry in step position (position of ankle relative to pelvis at foot strike) and step timing (time from one foot strike to the subsequent foot strike, multiplied by the average belt velocity) during early SLA (3). To determine predictors of rate of adaptation, the number of steps to adapt SLA was stepwise linearly regressed on early SLA, group, and activity history. Then, to determine the spatiotemporal strategy used by the sedentary, cyclic, and non-cyclic groups, three (one for each group) stepwise linear regressions regressed early SLA on early step position asymmetry and early step timing asymmetry.

## Results and Discussion

Early SLA and activity history, but not activity type, predicted number of steps to adapt SLA. The model explained 22.4% of the variance in rate of adaptation ( $p=0.013$ ,  $r=0.473$ ), where early SLA explained 11.9% and step position asymmetry explained an additional 10.5%. As the magnitude of early SLA decreased, fewer steps were needed to adapt. As the number of consecutive weeks spent active increased, more steps were needed to reach a plateau. Against our hypothesis, the type of physical activity did not predict rate of adaptation. However, only 22.4% of the

variance in rate of adaptation was explained; additional factors likely influence rate of adaptation in healthy young adults and future research should seek to uncover such factors.

Both step position asymmetry and step timing asymmetry predicted early SLA in the sedentary group and in the cyclic group. In the sedentary group, the model explained 59.2% of the variation in early SLA ( $p=0.007$ ,  $r=0.770$ ) where step position asymmetry explained 38.6% and step timing asymmetry explained an additional 20.6%. In the cyclic group, the model explained 87.7% of the variation in early SLA ( $p<0.001$ ,  $r=0.937$ ) where step position asymmetry explained 66.0% and step timing asymmetry explained an additional 21.7%. For both groups, as asymmetry in both step position and step timing increased, early SLA decreased. Conversely, in the non-cyclic group, only step position asymmetry predicted early SLA. The model, and therefore step position asymmetry, explained 57.8% of the variation in early SLA ( $p=0.004$ ,  $r=0.760$ ); as asymmetry in step position increased, early SLA decreased. Healthy young adults participating in non-cyclic activities use a spatial strategy to combat an asymmetric walking pattern, while those that are sedentary or that participate in cyclic activities use a combination of spatial and temporal strategies.

When assessing spatiotemporal strategies and rate of gait adaptation, it is important to account for physical activity history, current activity level, and current type as confounding factors. The populations studied on a SBT commonly have a mobility disability, such as people with Parkinson's disease, and these populations may be less physically active than healthy populations (4). Resulting differences in gait adaptation may be in part due to differences in current or past physical activity.

## Significance

Physical activity history and current type of physical activity influence the rate and the strategy used during early adaptation, respectively. The results of this study will help researchers better understand the individual factors influencing gait adaptation, which is a crucial mechanism in daily life, such as when navigating uneven or changing terrain. It is crucial to understand if physical activity influences gait adaptation in older populations, and if specific physical activity interventions can alter gait adaptation strategies.

# CORRELATIONS BETWEEN CLINICAL PAIN MEASURES AND LOWER EXTREMITY KINEMATICS AMONG INDIVIDUALS WITH LOW BACK PAIN

Janki H. Patel<sup>1</sup>, Katie Butera<sup>2</sup>, Arian Vistamehr<sup>1</sup>, Paul Freeborn<sup>1</sup>, and Emily J. Fox<sup>1,2</sup>

## Introduction

Chronic pain is a complex, multifactorial nervous system disease [1], often associated with secondary complications, such as movement impairments and disability. Specifically, low back pain (LBP) is a prevalent condition and a leading cause of disability, affecting more than 31 million Americans [1]. Individuals with LBP often demonstrate altered movement or adaptations during walking, such as slower gait speed, or increased trunk and pelvis rigidity [2]. These adaptations may represent compensatory strategies to reduce LBP.

LBP severity and disability are often assessed using self-reported clinical measures. Prior LBP studies have largely focused on trunk and pelvis kinematics during walking with limited emphasis on lower extremity (LE) function. However, there is limited knowledge about the associations between self-reported clinical measures and LE kinematics during walking among individuals with LBP. This is a critical step in understanding the impact of LBP severity and disability on fundamental characteristics of walking function. Therefore, the study purpose was to quantify the associations between peak LE joint kinematics during walking and clinical measures of disability and pain intensity in individuals with LBP.

## Methods

Participants were adults with LBP (n=75; 39 females; age: 45 ± 29 years; self-selected walking speed: 1.18±0.19 m/s; fastest comfortable walking speed: 1.88±0.36m/s). Participants self-reported disability (via the Oswestry Disability Index) and pain intensity (via Numeric Pain Rating Scale 0-10). Three-dimensional kinematics were recorded using a 12-camera motion analysis system while participants performed 3 walking trials at a self-selected (SS) pace and 3 trials at a fastest comfortable (FC) pace over ground. LE kinematics were quantified and averaged by the peak sagittal plane hip, knee, and ankle joint angles for the left and right limbs. Associations between peak joint angles, gait speed, and self-reported disability and pain intensity measures were identified using Pearson's correlation (r) and the Benjamini-Hochberg correction was applied for multiple comparisons ( $\alpha = 0.05$ , q-value = 5%).

## Results and Discussion

Higher disability ( $r=-0.49$ ,  $p<0.01$ ;  $r=-0.41$ ,  $p<0.01$ ) and pain intensity ( $r=-0.36$ ,  $p<0.01$ ;  $r=0.33$ ,  $p<0.01$ ) were negatively associated with slower gait speed during both SS and FC walking, respectively. Higher disability was negatively associated with reduced hip extension ( $r=0.38$ ,  $p<0.01$ ;  $r=0.37$ ,  $p<0.01$ ), knee extension ( $r=0.30$ ,  $p=0.03$ ;  $r=0.32$ ,  $p=0.01$ ), ankle plantarflexion ( $r=0.30$ ,  $p=0.03$ ;  $r=0.32$ ,  $p=0.01$ ), and positively associated with greater ankle dorsiflexion during the stance phase ( $r=0.37$ ,  $p=0.01$ ;  $r=0.26$ ,  $p=0.02$ ) during both SS and FC walking, respectively. Higher

pain intensity was negatively associated with reduced hip extension ( $r=0.45$ ,  $p<0.01$ ;  $r=0.45$ ,  $p<0.01$ ) during both SS and FC walking, respectively. Higher pain intensity ( $r=0.30$ ,  $p=0.01$ ) was positively associated with greater hip flexion during SS walking. All other correlations between peak joint angles and clinical measures were not significant.

Due to the proximity of the hip joint to the lumbar region, LBP can lead to compensations, such as increased hip stiffness and anterior pelvic tilt, which could result in restricted range of motion [3]. Restricted proximal joint movement is likely related to restricted movement at the distal joints within the kinematic chain. For instance, a reduction in hip joint extension may contribute to reductions in knee extension and ankle plantarflexion during late stance. Restrictions in LE joint motion may also be a movement strategy to compensate for impaired balance or the difficulty maintaining balance during walking due to LBP or anticipated LBP. Additionally, the associations between gait speed and the pain intensity measures align with results from prior studies that indicate individuals with LBP walk slower. Overall, individuals with reduced peak LE kinematics may be adopting this movement pattern as a compensatory strategy to reduce LBP during walking; this compensatory strategy could potentially contribute to greater disability for these individuals.

## Significance

Overall, the study results provide evidence of associations between LE kinematics during walking and clinical self-report measures of LBP intensity and disability in individuals with LBP. A common goal of clinical interventions is to restore function, restore normal movement, and reduce pain. These study findings therefore suggest that assessment of LE kinematics may be a valuable component of the clinical examination. Measurement of LE kinematics during walking also may be useful in determining appropriate movement-based interventions for individuals experiencing greater LBP severity and/or pain-related disability. The current results provide support for treating pain as a complex nervous system disease that requires the comprehensive assessment of clinical presentation (pain and disability) alongside performance-based measures of walking function.

## Normalizing Kinetic Data Alters Conclusions Based on Obesity

### Introduction

Normalizing mechanical measures based on anthropometric measures is common in biomechanical gait investigations. Hof suggested that normalization creates unitless measures [1], where linear associations between the normalization metric and the dependent variable are commonly assumed [2]. Ground reaction forces and lower extremity joint moments for obese and non-obese individuals have been reported in absolute terms [3], normalized by body mass [3], or normalized by the product of mass and height [4]. These “normalizations” transform the moment into a new variable, but fail to produce a unitless term and lead to equivocal interpretations of outcomes in the literature [3,4]. Thus, our purpose was to better understand the influence of normalization on data interpretation when participants of various body size (e.g., BMI) were investigated within a single study.

### Methods

Ten obese (BMI = 33.8 ± 2.9 kg·m<sup>-2</sup>; 6 Males; age = 26 ± 3 years) and twelve non-obese (BMI = 23.6 ± 2.2 kg·m<sup>-2</sup>; 7 Males; age = 23 ± 3 years) adults walked overground at 1.5 m·s<sup>-1</sup> while motion (100 Hz) and force (2000 Hz) data were collected. These data were low pass filtered at 6 and 50 Hz, respectively, and combined to estimate joint reaction forces and moments. Absolute and unitless measures were then developed by dividing forces by bodyweight and moments by the product of weight and height. Linear correlations between the normalization metric and the absolute and normalized measures were investigated based on

group: obese only (O), non-obese only (NO), and combined group (N+O). Group outcomes were then compared using independent t-tests for both absolute and unitless measures.

### Results and Discussion

When considering both groups together and data in absolute terms, forces and moments were related to body size normalization metrics (i.e., body weight and body weight \*height; see Table 1). Once normalized, only one significant correlation remained (i.e., hip extensor moment), but it was opposite in sign from the original correlation. Within the NO group normalization had the desired effect, as no relations were observed between the force or moment measure and the normalization metric. In O, normalized braking force was strongly correlated with bodyweight.

### Significance

Given the relationship between the normalized hip joint moment and its normalization metric when group data were combined, data from groups who vary based on body mass index should not be combined for data interpretation in future studies.

# Effects of Marker Placement and Body Sizes on Frontal Plane Center of Mass Motion During Walking: A Preliminary Study

Hang Qu, Yu-Pin Liang, Li-Shan Chou  
 Department of Kinesiology, Iowa State University, Ames, IA, USA  
 Email: \*[hangqu@iastate.edu](mailto:hangqu@iastate.edu)

## Introduction

Estimation of the whole-body center of mass (COM) depends on body segment anthropometric measurement and kinematic data measured using a motion capture system with reflective markers adhered to bony landmarks [1]. Various marker sets are commonly employed for motion data collection. However, soft tissue composition and body mass distribution could differ among participants with different body sizes. Therefore, the purpose of this study was to compare the whole-body COM medial-lateral (M-L) kinematics derived from data collected with different marker sets during walking.

## Methods

This is an ongoing study. Eleven adult participants were recruited and classified into two groups based on their BMI: the overweight/obese group (4 participants: one female, height: 1.70±0.12 m, weight: 85.66±10.35 kg, BMI: 29.06±3.64 kg/m<sup>2</sup>) and normal weight group (7 participants: four females, height: 1.72±0.12 m, weight: 61.15±14.08 kg, BMI: 20.94±2.15 kg/m<sup>2</sup>).

A twelve-camera motion analysis system (Oqus 6+, Qualisys AB, Sweden) was used to acquire three-dimensional (3D) Kinematics data. Three whole-body reflective marker sets (MS1, MS2, MS3) were employed in the study. For MS1, a multi-segment trunk, a head, arms, forearms, hands, a coda pelvis, thighs, shanks, and feet were modelled [2, 3]. The MS2 was a modified arrangement based on the Helen Hayes marker set, a head, a trunk, arms, forearms, hands, a Visual 3D pelvis, thighs, shanks, and feet were modelled. For MS3, the segment modelling was similar to the MS2. However, four-marker-mounted clusters were used as tracking markers instead of discrete markers during the dynamic trials [3, 4].

Participants were asked to perform 5 trials of barefoot level walking with their self-selected speeds (average speed ± 5%) when fitted with each marker set. Marker trajectories were smoothed using a 4th order zero-lag Butterworth low pass filter at a cutoff frequency of 12 Hz. All marker data were processed and calculated using the Visual 3D software (6.0, C-Motion, Inc., Germantown, MD). Position of the whole-body COM was computed based on the segmental mass and COM location with weighted-sum method. COM velocity and acceleration were obtained from the first and second derivatives of COM positions using the finite-difference method. The range of COM displacement and peak velocities and accelerations in the frontal plane were identified during a gait cycle, which was defined between two consecutive heel strikes of the right foot.

A 2×3 two-way (Group × Marker set) univariate ANOVA was performed separately to detect differences between groups (overweight and healthy weight) and marker sets (MS1, MS2 and MS3). When an interaction and/or main effect was revealed, a post-hoc comparison with Bonferroni adjustments were used to detect differences between groups and step width conditions. An *a priori* alpha level was set to 0.05.

## Results and Discussion

No interactions between body sizes and marker sets were found, thus the selected critical events collapsed by body sizes and by marker sets (Table 1). Although no group differences in gait velocity or M-L COM displacement were detected, overweight/obese group showed a greater lateral velocity right after the initial (~5% % gait cycle) heel strike of the right leg, and greater peak accelerations on both M-L directions (~60% gait cycle), compared to the normal group. These results suggested overweight or obese individuals may control their frontal plane COM motion differently than normal individuals. A faster COM sway velocity or acceleration could impose challenge in momentum control and could lead to a higher risk of sideway imbalance.

All participants demonstrated consistent patterns of M-L COM kinematics among three marker sets. Also, the timing of peak COM velocities and acceleration consistently occurred around the early and end period of the stance phase (~60% of the gait cycle), respectively. Even though the calculation using MS2 may underestimate the peak lateral velocity compared to MS1 (*p*=.023) and MS3 (*p*=.041). All three marker sets resulted in a similar COM trajectory in the frontal plane during walking regardless of body sizes.

## Significance

Differences in body sizes and variations in marker sets could affect the determination of whole-body COM [5]. It is essential to exam whether the whole-body COM kinematics could be consistently estimated with different marker sets among patients with different body sizes.

**Introduction**

During gait initiation, postural control strategies are used to achieve stability and efficiency during transition from a static to dynamic posture (1). Changes in gait initiation strategies have been observed in aging populations and populations with neurological disorders (1). However, dynamic postural control strategies have also been shown to be altered by environmental stimuli (3).

Anticipatory postural adjustments (APAs), help to mitigate the threat of postural instability and have been associated with forward progression velocity (4,5). Such control strategies are crucial for successful gait initiation performance and even more so when faced with unfamiliar settings and surroundings (6). The performance of motor tasks in a research setting with a research team present may constitute such an unfamiliar environment.

Indeed, in-laboratory and real-world gait speed have a weak correlation, which may be influenced by the addition of researcher observation (7). Yet, it remains unclear how manipulating a research setting by varying the number of researchers may impact gait initiation performance. Greater understanding of the influence of deliberate and critical observation of researchers contributing to gait initiation performance may enhance our ability to translate laboratory-based findings to ‘real world’ setting outside of the laboratory.

The aim of this study was to assess the effects of increasing audience size on gait initiation performance and early steady state step parameters. We hypothesized that as audience size increased, the speed of each step would increase along with an increase in APA magnitude.

**Methods**

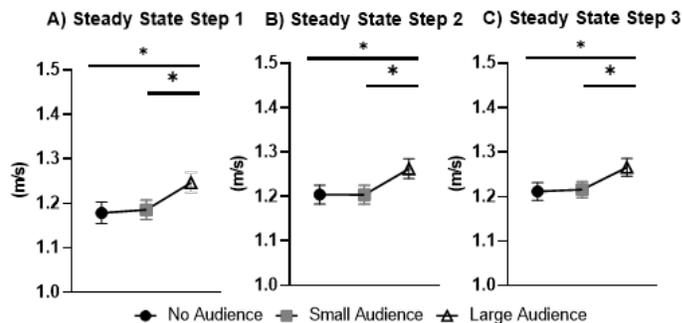

Twenty-one college-aged individuals participated in the gait initiation analysis (14 females, 7 males, 21 ± 1 years old, 167.7 ± 16.1 cm, 72.3 ± 15.4 kg). Participants wore 6 wireless inertial sensors and were asked to walk four lengths of a 9.3m walkway at their typical speed (APDM, Portland, OR). Participants completed this protocol in three different conditions: 1) no research audience present, 2) a small audience with two researchers present and 3) a large research audience with 6-10 researchers present. Gait initiation parameters measured included: 1) Peak APA amplitude in the anteroposterior direction (APA-AP) and mediolateral direction (APA-ML), 2) Duration of APA, 4) APA first step duration, 5) After initial foot contact with the lead swing leg, early steady state step speed was also measured. A one-way repeated measures MANOVA was conducted to test for differences in peak APA-AP, peak APA-ML, the duration of APA, APA first step duration and early steady state step speed across each of the no, small and large audience conditions.

**Results and Discussion**

The multivariate analysis revealed statistical significance between the audience size conditions,  $F(14,68) = 2.901, p =$

0.002. There was a univariate effect for speed of each of the early steady state steps, first step,  $F(2,40) = 17.547, p < 0.001$ , second step,  $F(2,40) = 14.258, p < 0.001$  and third step,  $F(2,40) = 13.390, p < 0.001$ . Post-hoc tests revealed significant increases in the speed of steps between the no audience and large audience condition, and between the small audience and large audience conditions. No significant increases in step speed were observed between the no audience and small audience conditions (**Figure 1**). Our findings suggest that participants walked faster when increased number of observers were present. Therefore, it is plausible that in-laboratory findings may conflict with actual performance in a ‘real world’ setting outside the laboratory environment where such observation and evaluation is atypical.

There was no effect of increasing research audience size on APA-AP, APA-ML, duration of APA or APA first step duration. Gait initiation is a demanding task for the central nervous system compared to straight ahead walking. (6) It is possible that a heightened stimulus may be required to achieve the same magnitude of change as observed in steady-state gait.

**Figure 1:** Mean and standard error steady state step speeds across audience conditions. \*denotes  $p < .001$ .

**Significance**

Differences in stepping speed were most pronounced in the large audience condition, indicating that participants walked faster when a larger number of observers were present. This is also supported by the lack of difference observed between the no and small audience conditions. However, increasing observation did not impact postural control mechanisms during gait initiation. These results highlight the importance of translation and extrapolation of lab-based findings, as differences in movements produced when under observation, such as in a lab setting, may limit the generalizability to real life settings outside the laboratory. We recommend researchers should keep number of researchers consistent, and or report the number of researchers present during a data collection to acknowledge the impact of observation on performance.

# Dorsiflexion Restriction Highlights the Role of Early-Stance Modulation of Tibialis Anterior in Forward Body Propulsion

Shakiba Rafiee\*<sup>1,2</sup>, Joanne Klossner<sup>1</sup>, Tim Kiemel<sup>1,2</sup>, and Ross Miller<sup>1,2</sup>

<sup>1</sup> Department of Kinesiology (<sup>2</sup> Neuroscience and Cognitive Science Program), University of Maryland, College Park, USA

Email: \*[shrafiee@umd.edu](mailto:shrafiee@umd.edu)

## Introduction

Our research goal is to identify how the nervous system stabilizes walking by continually making small modulations (adjustments) in the rhythmic pattern of muscle activations. Our previous studies, using a combination of external perturbations and system identification, have suggested a role for early-stance tibialis anterior (TA) muscle modulation in forward body propulsion and speed control<sup>1,2</sup>. However, TA activation in stance has been mostly thought of as a mechanism to prevent foot-slapping or even as a brake on the speed. To clarify the role of early-stance TA modulation, in the current study we added a restriction that limits the contribution of the dorsiflexor muscles to gait and studied the “restricted” gait response to external lower-body mechanical perturbations. We expect that by increasing resistance to dorsiflexion, in response to external perturbations the nervous system would have to adopt alternative strategies to control propulsion and help the subjects maintain balance on the treadmill. The absence of this response would suggest TA modulation is not important for controlling propulsion.

## Methods

We have collected data from 7 participants in accordance with University of Maryland IRB. The subjects walked on a treadmill at 1.4 m/s for 12 250-s trials split between 2 conditions: 1) normal and 2) restricted, where dorsiflexion in both ankles was restricted using a traditional Achilles tendon taping method. The subjects were perturbed by small continuously-changing forces applied to their legs through a spring-motor mechanism<sup>2</sup>. Lowpass-filtered white noise signals were used to specify the mechanical perturbation (position of the motor). The kinematic data and surface electromyography were recorded from the legs and trunk. Phase-dependent impulse response functions ( $\phi$ IRFs) were calculated that describe the changes in kinematics and muscle activations in response to brief perturbations applied at any phase of the gait<sup>1,2</sup>.

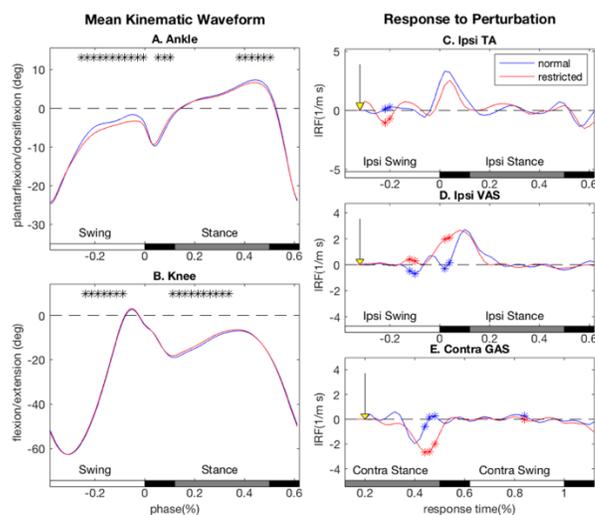

## Results and Discussion

The taping method restricted dorsiflexion during late stance and through swing (Fig. 1A). The restriction also significantly decreased the knee flexion during mid stance (Fig. 1B). These changes in kinematics resulted in a significantly shorter step length (not shown) in the restricted condition, compared to the normal condition, which is consistent with the previous findings<sup>3</sup>.

With restriction, both the TA and vasti (VAS) muscles saw a significant decrease in their peak activation during early stance, which is also consistent with the ankle orthosis literature<sup>4</sup>. The peak activation of the gastrocnemius (GAS) muscle during late stance also significantly increased in the restricted condition.

In response to the mechanical perturbations during swing that caused a forward perturbation of ankle position, the TA activation increased during early stance in both conditions. The difference between responses during early stance was not significant (Fig. 1C). The VAS muscle activation during early stance increased significantly more in the restricted condition (Fig. 1D). This early stance modulation of VAS is suggested to

play a role in forward body propulsion<sup>2</sup>. The mechanical perturbation, applied during swing, increases the length of the same step (not shown). In the absence of the TA contribution to foot-placement correction, the early stance modulation of VAS compensate for the foot being too far in front of the body, by accelerating the center of mass (COM) forward. In response to mechanical perturbations during swing, the contralateral GAS muscle activation during late stance decreased significantly more in the restricted condition (Fig. 1E). This muscle modulation contributes to speed control during push-off. In the restricted condition, in response to the mechanical perturbation, the COM is not propelled forward as much (not shown), the decrease in contralateral GAS muscle activation helps decrease the next step length (not shown) and controls the placement of the contralateral foot relative to the body.

**Fig. 1:** Average waveforms of kinematics (A-B) and the muscular responses to the mechanical perturbations (C-D) in the normal (blue) and restricted (red) conditions. Asterisks indicate significant differences between conditions ( $p < 0.05$ ). The bars on the horizontal axes indicate gait phase: (white = swing, gray = single support, and black = double support). The yellow arrows indicate the perturbation phase.

## Significance

Our study highlights the role of early-stance modulation of TA in forward body propulsion, as when TA’s ability to perform work was reduced, the nervous system compensated for this speed control mechanism by modulating the VAS and GAS muscles during early and late stance respectively.

## Length vs time: Dominant strategies to increase speed in older adults

Sidney T. Baudendistel, Abigail C. Schmitt, Matthew Terza, Amanda Stone, Chris J. Hass  
Department of Applied Physiology and Kinesiology, University of Florida, Gainesville, FL

### Introduction

The ability to modulate walking speed is essential to maintaining independence for older adults. Both fastest walking speed (FS) and usual, comfortable speed (CS) decline with age, resulting in a loss of community ambulation. Yet, FS deteriorates more rapidly<sup>1</sup>. The transition of CS to FS can be achieved by decreasing step time and/or increasing step length. Reduced balance, strength, and neuromuscular changes (e.g. redistribution of joint torque) associated with aging may also contribute to the selection of a strategy to increase speed. The strategy chosen to increase speed impacts the kinematic and kinetic signature of the walking pattern<sup>2</sup>, but it is unknown why participants may select or prefer one strategy over another.

We investigated the correlates associated with the strategies to increase speed and determined if there were differences between older adults who increase step length compared to those who decrease step time when increasing speed.

### Methods

Fifty-seven sedentary older adults at risk for mobility disability completed a biomechanical assessment including walking (5 trials of CS and FS), static balance (eyes open and closed, 3 trials each of 30s), isokinetic dynamometry, and mobility (Short Physical Performance Battery's chair stand time).

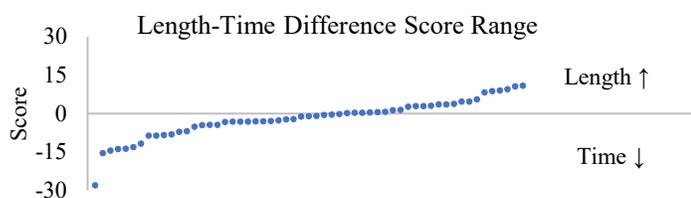

Length-Time Difference (LTD) is a common measure to quantify the strategy used to increase walking speed<sup>2</sup>. A positive LTD represents an increased step length strategy, a negative LTD represents a decreased step time strategy, and an LTD score of 0 represents equal percent change (%Δ) in step time and length.

$$LTD = \left( \frac{\text{length}^{fast} - \text{length}^{usual}}{\text{length}^{usual}} \right) - \left( \frac{\text{time}^{fast} - \text{time}^{usual}}{\text{time}^{usual}} \right)$$

Since CS is considered a vital clinical sign<sup>3</sup>, this analysis includes correlates and comparisons between LTD and both kinetic (peak knee moment, peak hip and ankle power, peak propulsive force and impulse) and kinematic (walk ratio, gait stability ratio, cadence, step length, step time) measures of CS walking. Balance measures included range and velocity in the medial-lateral direction and the 95% confidence ellipse area.

Correlation coefficients were calculated between outcomes and LTD across all participants regardless of positive or negative LTD group ( $p < .05$ ). T-tests confirmed homogeneity between the two strategy groups including: CS and FS and %Δ speed. Five separate multivariate analyses of variance were used to compare those who had a positive LTD and those who had a negative LTD for strength/mobility, eyes open balance, eyes closed balance, CS kinetics, and CS spatiotemporals ( $p < .05$ ).

### Results and Discussion

Significant negative correlations were found between three outcomes and LTD (range:-27.87 to 10.97, Figure 1): peak propulsive force ( $r = -.357$ ,  $p = .007$ ), propulsive impulse ( $r = -.300$ ,  $p = .026$ ), and chair stand time ( $r = -.273$ ,  $p = .043$ ). Participants that relied on increases in step length (+LTD) displayed decreased propulsion during CS and reduced chair stand time. No other variables were significantly correlated to LTD.

After categorizing participants by those who used time ( $n = 33$ ,  $LTD = -6.26 \pm 5.98\%$ ) vs. length ( $n = 24$ ,  $LTD = .25 \pm 3.52\%$ ), no differences were found between CS ( $p = .669$ ), FS ( $p = .727$ ), nor %Δ of speed ( $p = .947$ ). Balance ( $p = .322$ ) and CS kinematics ( $p = .352$ ) were not significant at the multivariate level.

Those who modulated speed with increased step length had significantly better strength ( $\Lambda = .816$ ,  $F = 3.235$ ,  $p = .031$ ), with reduced time to complete chair stands (14.16s vs 17.43s,  $p = .023$ ). Peak isokinetic knee ( $p = .463$ ) and ankle ( $p = .455$ ) moments at 60°/s were not different at the univariate level. Kinetic variables were significantly different between groups at the multivariate level ( $\Lambda = .781$ ,  $F = 2.689$ ,  $p = .032$ ), driven by peak propulsive impulse ( $p = .008$ ) with no other variables reaching significance. Those who used a step length strategy had significantly less propulsive impulse (20.61N\*s vs. 17.35N\*s) when walking at their CS than those who modulated step time.

In the current study, we found those who decreased step time during FS were weaker and required more propulsive impulse to create a similar CS. This was reflected with both a significant, continuous correlation and when grouping participants by LTD. This may represent a ceiling of propulsion that limits the ability to increase speed when needed. Comparatively, those who increased step length may have additional “propulsive reserve” to modulate walking speed. Ankle plantarflexion moment and power are functionally limiting factors for older adults<sup>4</sup>, thus increasing step length to increase speed may not be possible for those who use more propulsive impulse during CS walking.

In those at risk for future mobility disability, propulsion at a comfortable speed and strength were correlated to the strategy used to increase speed, either increased length or decreased step time. Those who decreased step time to improve speed were weaker but used more propulsive force during comfortable walking, perhaps limiting their ability to modulate speed safely.

### Significance

Further investigation of LTD could be helpful in identifying personalized gait interventions and understanding why pathological populations adopt a higher cadence during walking.

## Comparison of Joint Mechanics of the Dominant vs. Non-Dominant Lower Limbs During Locomotion

Stephanie Molitor<sup>1,2\*</sup>, Karl Zelik<sup>1,2,3</sup>, Kirsty McDonald<sup>1,4</sup>

<sup>1</sup>Dept. of Mechanical Engineering, Vanderbilt University

Email: stephanie.molitor@vanderbilt.edu\*

### Introduction

It is common practice for biomechanical analyses of gross, bilateral motor tasks to consider the independent functional role of each lower limb. For example, when kicking a ball, the joints of the dominant limb (hip, knee, and ankle) typically move through a greater range of motion (ROM) and are cumulatively responsible for increased positive power production compared to the non-dominant limb [1]. However, the influence of limb dominance is rarely considered in walking and running research, where biomechanical symmetry between the legs is generally assumed [2]. It remains unclear whether this is a valid assumption, especially at the more distal joints. Recent work from our laboratory found that prosthetic device users who had lost their dominant limb preferred to have a toe joint added to their prosthetic foot, whereas all other participants preferred a prosthesis that lacked toe joint articulation. This suggests a potential link between limb dominance and distal joint kinematics; however, differences in foot kinematics have not been studied in relation to limb dominance in an able-bodied population. The current study therefore aims to compare dominant and non-dominant kinematics and kinetics for the hip, knee, and ankle, as well as foot kinematics (via a multi-segment model), throughout a walking and running stride. We hypothesized that dominant limb joints would move through an increased ROM compared to non-dominant limb joints.

### Methods

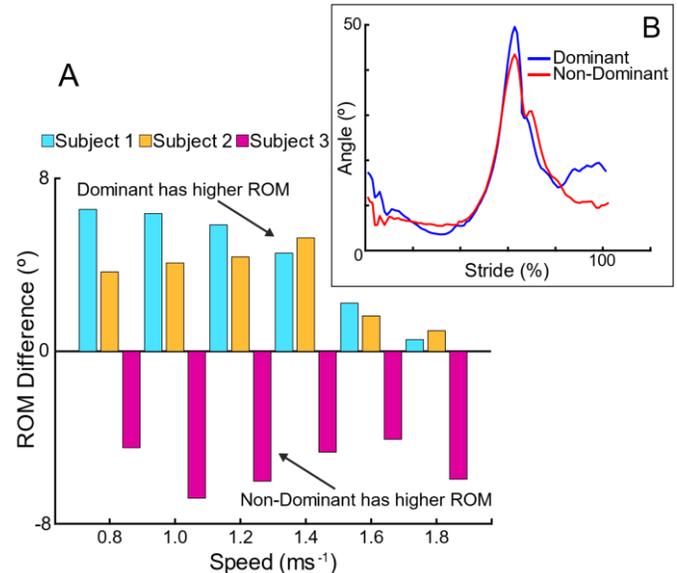

Able-bodied individuals ( $N=3$  to date, but data collection will resume shortly) completed walking and running tasks (speeds of 0.8-4.0  $\text{ms}^{-1}$ ) on a treadmill (Bertec) with motion capture (Vicon) markers placed on their lower limbs and feet in accordance with the multi-segment foot model outlined in [3]. After these trials, participants were asked to complete a revised Waterloo footedness questionnaire in order to determine their lower limb dominance as well as the strength of dominance [4].

Kinematic and kinetic data were calculated for the hip, knee, and ankle, as well as foot kinematics (Visual3D). For brevity, we present only metatarsophalangeal joint (MPJ) kinematics, but plan to share more comprehensive results at the conference. Statistical parametric mapping (SPM) analyses will also be employed on the complete dataset (target:  $N=12$ ).

### Results and Discussion

Based on the questionnaire, all three subjects exhibited weak to moderate right-limb dominance. Average differences in MPJ ROM generally fell between 4-6° (Fig. 1). Two subjects displayed a greater ROM on their dominant limb (positive values in Fig. 1), and one subject showed a greater ROM on their non-dominant limb (negative values in Fig. 1). While more testing is required to draw conclusions, we observed small but consistent differences between the dominant and non-dominant limbs of all participants. The differences between the dominant and non-dominant MPJ ROM for individual strides mirrored the average trend for each subject 90% of the time. Differences in ROM were also found between the dominant and non-dominant

limb for the ankle, knee, and hip; however, similar to the findings in [5], these differences were smaller in magnitude.

**Figure 1:** (A) MPJ ROM differences between dominant and non-dominant limbs. (B) Mean MPJ angle for Subject 1, walking at 1.0  $\text{ms}^{-1}$ .

Upon completion of data collection and analysis, we will have a more holistic view on how limb dominance may affect hip, knee, ankle, and foot biomechanics. Moreover, SPM will allow us to determine where in the gait cycle these differences are most pronounced for both walking and running.

### Significance

This study will be the first to statistically analyze continuous time-series data across the gait cycle when characterizing biomechanical differences between the dominant and non-dominant limbs during locomotion. It is expected that results will determine whether limb dominance should be considered in future gait analyses, and could inform the design or prescription of prosthetic feet.

## Decreased Balance Confidence Related with Limits Maximum Speed among Older Adults

Jutaluk Kongsuk<sup>1</sup>, and Christopher P. Hurt<sup>1</sup>

<sup>1</sup>University of Alabama at Birmingham, Birmingham, AL, U.S.A.

Email: [jutalukk@uab.edu](mailto:jutalukk@uab.edu)

### Introduction

Our previous study suggested that older adults become unstable on a step by step basis at slower walking speeds than younger adults<sup>1</sup>. Aspects of the walking performance of older adults related to their balance confidence suggesting an observable link between more cautious behavior and dynamic stability while walking. However, the static measure of balance confidence did not reflect how the individuals' perception was modified by an increasingly challenging task. The purpose of this study was to explore a dynamic range of balance confidence, measured using a novel approach while performing a dynamic walking task and investigate whether decreased balance confidence or decreased dynamic stability while performance of a challenging walking task may be a possible cause of decreased willingness to experience activities.

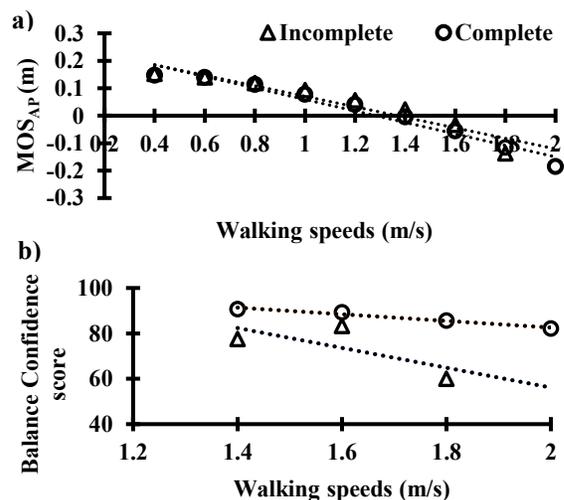

### Methods

Fourteen older participants (68±2.62 years) were asked to complete the Activities Specific Balance Confidence (ABC) Scale, which measures their confidence in performing activities of daily living without losing their balance<sup>2</sup>. Participants were asked to walk on a treadmill at a range of speeds from 0.4 m/s, increasing 0.2 m/s, up to either 2.0 m/s OR a speed they chose to stop. Kinematic data was collected and a measure of gait stability, the margin of stability in the anterior direction at heel strike (MOSAP) was quantified, step-by-step<sup>3</sup>. Prior to increasing each treadmill speed, participants were asked if they wanted to attempt a faster speed and to rate their balance confidence in walking at a faster speed without losing their balance. This measure provided a more dynamic measure of balance confidence compared to the traditional measure. The primary variables assessed were differences of the last two sampled values of balance confidence as well as MOSAP at the last speed attempted, and the quantified slope of the line of the last 3 values between balance confidence and MOSAP. Participants were grouped based on whether they could or could not complete all walking trials. Comparisons between groups were made with Independent T-test and Mann-Whitney U test.

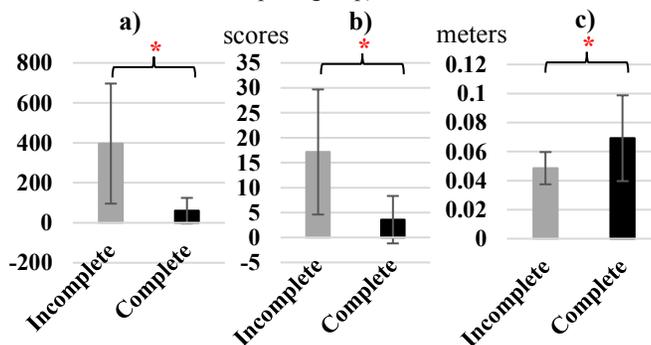

### Results and Discussion

Ranges of MOSAP and balance confidence while performing the scaled treadmill speeds between groups are presented in Figure 1. Participants were grouped (n=7 in each group) that they could (70±2.44 years) or could not (67±2.43 years) complete all walking trials. No significant difference was detected in the standard ABC scale and difference for the last 2 values of MOSAP between groups. Significant differences were detected in the maximum speeds achieved between groups, the range of gait stability, as well as the differences on the last 2 values of sampled balance confidence (p=0.005, p=0.001, and p=0.026, respectively). Further, those that could not complete all speeds had a greater slope in the dynamic

measure of balance confidence and gait stability compared to those who completed all speeds (p=0.025, Figure 2).

**Figure 1:** Walking speeds vs a) MOSAP and b) Balance confidence vs for Older adults who could complete and could not complete the entire walking speeds (Note: 0.4-1.2 m/s, n=7; 1.4 m/s, n=4; 1.6 m/s, n=3; 1.8 m/s, n=1 for an incomplete group).

**Figure 2:** Differences between Older adults who could complete and could not complete the entire walking speeds a) sensitivity of MOSAP and Balance confidence b) the last 2 values of Balance confidence, and c) the last 2 values of MOSAP.

### Significance

Some older adults who were less willing to experience instability at faster walking speeds on the treadmill might relate with their reduced balance confidence. Sensitivity of dynamic measure of balance confidence may reflect to a perception of loss of stability, this may be an interesting factor in decreased willingness to experience activities for some older adults.

# Effects of Smartphone Operation on Pedestrians' Gait Performance: An Outdoor Study

Yue Luo<sup>1</sup>, Haolan Zheng<sup>1</sup>, Yuhao Chen<sup>1</sup>, Wayne C.W. Giang<sup>1</sup>, and Boyi Hu<sup>1</sup>

<sup>1</sup>Department of Industrial and Systems Engineering, University of Florida, Gainesville, FL, USA

Email: \*boyihu@ise.ufl.edu

## Introduction

Smartphone dependency has become a serious concern for pedestrian safety. In 2010, an estimation of two million smartphone-engaged pedestrian injuries were reported<sup>1</sup>. However, the risk of smartphone use during walking was still underestimated by pedestrians, indicated by the high frequency (84%) of smartphone use been observed on the street<sup>2</sup>. One reason for the risk underestimation maybe that people have no clear understanding of how gait is changed under smartphone usage during public walking. Therefore, the purpose of the study was to investigate the effect of different smartphone operations on gait performance during outdoor walking.

## Methods

Eight healthy college students (six females & two males) were recruited from the University of Florida. Participants, with seventeen wearable inertial sensors attached (MVN Awinda) to record gait performance<sup>3,4</sup>, were instructed to complete four walking conditions (Walking Only, Walking-Reading, Walking-Tapping, and Walking-Gaming), each with six repetitions. For each trial, participants performed one smartphone operation throughout the 15-meter outdoor walking. Reading referred to a paragraph reading (100-150 words). Tapping referred to number tapping task (ascending order, 1-20). And gaming referred to a number matching game to find number equals to two switches before in a sequence of rapid changing numbers. The order of walking conditions were counter-balanced. All participants used the same smartphone (Moto g6, Motorola) throughout the experiment. Nine kinematics parameters in anterior-posterior plane, including the maximum flexion angle of: 1) C7-T1, 2) T12-L1, 3) L5-S1, 4-5) bilateral hip, 6-7) knee, and 8-9) ankle were extracted for each stride after a 2<sup>nd</sup> order low-pass Butterworth filter, with beginning and lasting two strides removed<sup>5</sup> (MATLAB R2019b). Univariate repeated-measures ANOVAs and post-hoc pairwise comparison (Fisher's LSD) were then performed (SPSS 26).

## Results and Discussion

Table 1 summarizes the effects of walking conditions on kinematic parameters. The independent variable was revealed to have significant impact on spinal kinematic parameters, including C7-T1, T12-L1, and L5-S1 flexion angles ( $p < 0.001$ ). Among lower limb kinematic, hip flexion angles were significantly effected by walk-

ing conditions ( $p < 0.001$ ). Similar effect was found in knee flexion angles (left knee:  $p < 0.001$ , right knee:  $p = 0.001$ ). However, a non-significant difference was observed in ankle flexion angles ( $p = 0.057$  and  $0.113$  for left and right ankles, respectively).

Participants demonstrated larger neck flexion in higher cognitive load tasks (i.e. tapping & gaming) than lower cognitive load task (i.e. reading). It might be the case that, to process information with higher cognitive load, participants tried to have a closer look at the target on the phone to better perceive the details of the target. However, it might increase the risk of falling or collision injuries because visual detection via peripheral vision was attenuated. Compared with the walking only condition, the restricted lumbar (L5-S1, T12-L1) and hip movement during smartphone-engaged walking indicated body posture adaptations to hand-smartphone interaction, probably with the intention to better maintain the core balance of the locomotion system<sup>6</sup>. Tapping, which is a similar task of texting, had most obvious lumbar restriction. The effect of smartphone use on the gait performance, however, was less obvious on knees and ankles, possibly because of the stabilization from the inverted pendulum model of lower limbs during walking. In general, instead of proximal joint movement, smartphone-engaged walking relied more on distal joint movement.

## Significance

In order to decrease the smartphone-engaged pedestrian injuries, results from this study could be used as evidence of the recommended levels of phone engagement in public environments. Smartphone application developers could also refer to this study for usage intervention design among pedestrian users.

# Ankle dynamics during overground walking with bodyweight support

Mhairi K. MacLean<sup>1</sup>, Daniel P. Ferris<sup>1</sup>

<sup>1</sup>University of Florida, Gainesville, Florida, USA

Email: \*[mmaclean@ufl.edu](mailto:mmaclean@ufl.edu)

## Introduction

Bodyweight support is a tool used for gait rehabilitation and can also be used experimentally to better understand human locomotion biomechanics. Providing more bodyweight support decreases vertical ground reaction forces during walking but it is not clear how bodyweight support alters joint dynamics during walking. The ankle displays piece-wise linear relationships between joint moment and ankle angle over the stance phase, sometimes referred to as quasi-stiffnesses [1,2]. The quasi-stiffnesses may be related to inherent musculotendon mechanical properties, allowing individuals to take advantage of stretch and recoil of tendinous structures. Our aim was to test whether the piece-wise linear quasi-stiffnesses of the ankle were similar across a range of bodyweight support levels (simulated gravity levels). The bodyweight support should alter peak joint moments during gait, testing whether there is a relationship between joint moment and quasi-stiffness. We hypothesized that the characteristic linear moment-angle relationships would be similar across bodyweight support levels [3]. Subjects walked at multiple speeds in addition to multiple simulated gravity levels.

## Methods

Twelve participants [7 female, 5 male; 26±4 years of age, body mass 70±8 kg, mean±s.d.] walked overground at 1, 0.76, 0.55 and 0.31 gravity (G) at 0.4, 0.8, 1.2, and 1.6 m/s. Bodyweight support was provided by a harness attached to constant force springs mounted to a rolling trolley on the ceiling. We used overground force plates and a motion capture system to measure kinetics and kinematics. We filtered and normalized data to the gait cycle.

We identified 4 key events during stance phase: A – Minimum ankle angle, B – 50% of stance phase, C – maximum ankle moment, and D – toe off. For each participant, we fit a linear model between A-B, B-C, C-D, and A-C. We then calculated  $R^2$  for each fit and averaged across participants.

## Results and Discussion

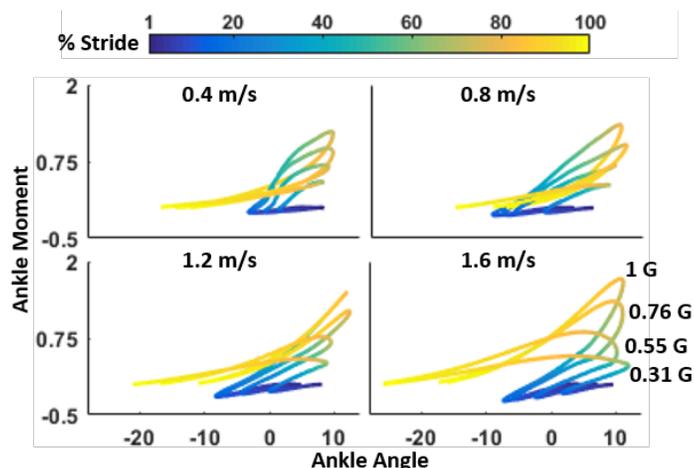

The ankle moment-angle loops changed shape with bodyweight support and speed (Fig 1). The quasi-stiffness of the ankle was also influenced by both simulated gravity level and speed (Fig 2).

The quasi-stiffness of the ankle tended to decrease with reduced gravity across all speeds and linear models (Fig 2). The change was more pronounced between events B-C and C-D. Reduced moments at the ankle could result in less force through the Achilles tendon, moving the tendon mechanics further into the “toe region” and decreasing the stiffness of the musculotendon unit. At lower simulated gravity, relative strength and power increases, allowing subjects to adopt a wider range of gait strategies with fewer constraints.

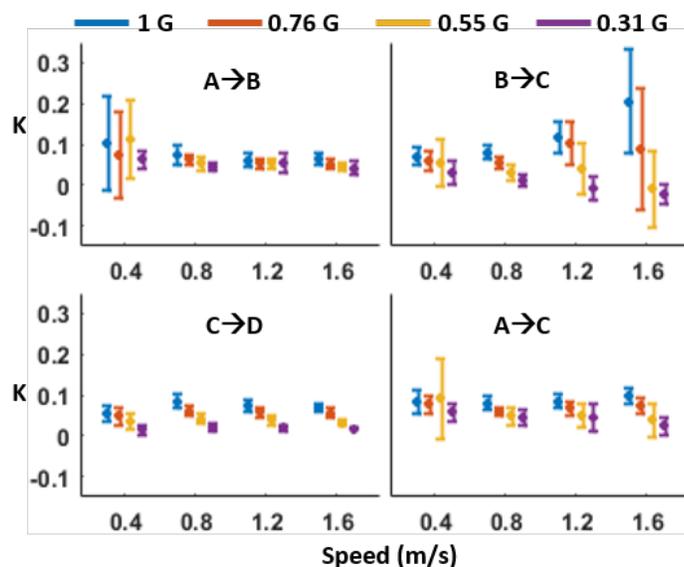

## Significance

These results provide a better understanding of motor adaptation to bodyweight support and reduced gravity locomotion. At lower relative mechanical demand (reduced gravity), humans can alter ankle dynamics as there are fewer biomechanical constraints. This knowledge has application in clinical gait rehabilitation as

overground bodyweight support is increasingly be used as a therapeutic intervention. It also provides insight into the physiological determinants of joint quasi-stiffness during walking.

**Figure 1:** Ankle moment-angle loops during stance phase across speeds and at different levels of bodyweight support. Ankle angle is positive in dorsiflexion and the internal plantarflexion moment is positive.

**Figure 2:** Quasi-stiffness of the ankle as determined by the slope of the best linear fit of ankle moment-angle relationship.

## Acknowledgments

We thank Angel Bu, Han Nguyen, Skyler Levine, and Patrick Costello for their assistance collecting and processing the data.

# Real-time Adaptive Treadmill Controller Optimization: A Parameter Sensitivity Study

Kayla M. Pariser, Jill S. Higginson

Department of Mechanical Engineering, University of Delaware, Newark, DE, USA

Email: [pariserk@udel.edu](mailto:pariserk@udel.edu)

## Introduction

Treadmill gait training is a commonly used rehabilitation technique to increase walking speed via increasing paretic limb push-off forces and trailing limb angles.<sup>1</sup> However, fixed-speed treadmills limit natural stride-to-stride variability that is essential for motor learning.<sup>2,3</sup> To address this, researchers have begun to use adaptive treadmills that alter belt speed in real time based on a cost function considering the user's gait mechanics, such as push-off force impulse, step length, step duration, and position relative to the treadmill center, as cost terms.<sup>4</sup>

The *objective* of this study is to conduct a parameter sensitivity analysis to understand how walking speed, cadence, peak push-off forces, and step-length change as the weight on the push-off force impulse in the adaptive treadmill cost function is altered. We *hypothesize* that as the weight on the push-off force impulse term is increased, the users' peak push-off forces will increase without substantial changes in speed.

## Methods

Six healthy adults (4 females,  $20 \pm 2$  years,  $1.70 \pm 0.11$  m,  $67.17 \pm 10.63$  kg) walked on a split-belt instrumented treadmill (Bertec Corp., OH, USA) at their self-selected (SS) comfortable walking speed on five modifications of the adaptive treadmill controller for two minutes each. The adaptive treadmill controller is defined by the following cost function:

$$v_{i+1} = v_i + \alpha * \left( \frac{v_{new,L} + v_{new,R}}{2} - v_i \right) \pm \beta * p^2_{com}$$

where  $\alpha$  and  $\beta$  are the sensitivity of the treadmill speed to the user's push-off force impulse and their center of mass position relative to the treadmill center respectively.<sup>4</sup> The five conditions were: Half force ( $\alpha \approx \frac{1}{2}\beta$ ), Baseline ( $\alpha \approx \beta$ ), Double force ( $\alpha \approx 2\beta$ ), 2 OM Force ( $\alpha \approx 10^2*\beta$ ), 4 OM Force ( $\alpha \approx 10^4*\beta$ ), presented in random order. Walking speed, cadence, and average peak push-off force were calculated using the analog data (2000 Hz) and average step-length from heel marker locations at right heel strike (100 Hz).

## Results and Discussion

For all treadmill conditions except the 4 OM Force, average SS walking speed varied  $\pm 0.01$  m/s from the Baseline condition. In the 4 OM Force condition, speed decreased by 0.07 m/s (Fig 1a). Similarly, cadence decreased by about 2 steps/min with the 4 OM Force condition and between 0-1 steps/min in other conditions. Average change in stride length from Baseline were mostly small ( $<5\%$  height) and variable. Overall there is quite a bit of variability between participants and seemingly small average changes from the Baseline condition in the aforementioned parameters.

While the treadmill modifications from the Baseline condition do not appear to directly alter the user's speed, cadence, and step length, there were clearer differences observed between average peak push-off forces. Although the sensitivity of the treadmill speed to push-off force impulse was highest in the 4 OM condition, 5/6 participants decreased their push-off

force from the Baseline condition by an average of  $2.4 \pm 3.84\%$  BW. The largest increase in average peak push-off force was achieved with the Half Force condition,  $2.22 \pm 3.05\%$  BW (Fig 1b). These results suggest that there may be a threshold of force sensitivity where individuals will no longer continue to increase their push-off forces and will select slightly slower walking speeds and cadences. Prior to this threshold, however, modifications in push-off force impulse sensitivity in the treadmill controller can result in increases in average peak push-off forces and maintained walking speed from the Baseline condition. However, the large amount of variation in the gait mechanics strategies of the six participants with each treadmill condition suggests that interventions may need to be designed to be user-specific.

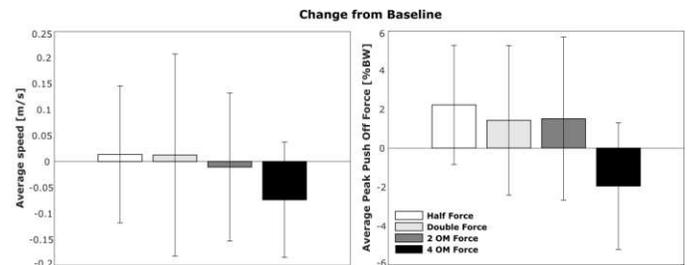

Figure 1. Average  $\pm$  standard deviation of walking speed (a) peak push-off force (b) changes from the Baseline Condition.

## Significance

This preliminary study demonstrates that an adaptive treadmill controller can be optimized to target increased push-off forces, but this must be done on an individual basis to achieve maximum effectiveness. Future work will seek to develop an optimal control simulation framework to understand and predict how a user's gait mechanics will change with modifications to the controller cost function.

## Introduction

Community ambulation requires navigation of various hazards such as curbs, uneven terrains, and obstacles. Foot placement around a hazard is controlled to satisfy two constraints: allow swing foot trajectories that avoid tripping/stepping on the hazard, and maintenance of stability by providing an appropriate base of support relative to the center of mass movement. Tight control of foot placement prior to obstacle crossing [1], and the relevance of step length stabilization for inferring gait stability for unobstructed walking [2] have been established. However, it is not known whether step length is similarly stabilized while negotiating hazards, specifically with the two legs on either side of a hazard. Therefore, the purpose of this study was to determine whether step length is stabilized during adaptive gait tasks.

## Methods

The gait tasks included here were part of separate experiments: experiment 1 (15 young adults, 22.1±5.6 years) performed 15 trials of stepping up and down a curb and experiment 2 (17 young adults, 20.9±1.9 years) performed 15 trials of crossing an obstacle. The curb and the obstacle were placed mid-way on an 8 m walkway. The curb was 4×1×0.15 m (length×width×height). The obstacle was 1×0.008 m (width×depth) and height was 25% of leg length (mean height 0.22 m).

We used the uncontrolled manifold (UCM) approach [3] to quantify the strength of step length synergy. The strength of synergy reflects the negative covariation between the lead and trail foot distances from the curb/obstacle edge that stabilizes their sum, i.e., the step length. A motion capture system was used to identify the distance of the feet on either side of the curb/obstacle edge for each trial. The UCM analysis yields two variance components: one within the UCM ( $V_{UCM}$ , or good variance that does not change the step length), and one orthogonal to UCM ( $V_{ORT}$  or bad variance that changes the step length). We quantified the synergy index ( $\Delta V$ ) as  $(V_{UCM}-V_{ORT})/(V_{UCM}+V_{ORT})$ , which was z-transformed ( $\Delta Vz$ ) for statistical analysis.  $\Delta Vz > 0$  indicates the presence of synergistic covariation in the foot placements on either side of the curb/obstacle that stabilizes step length, with higher positive values indicating stronger synergies. To determine if synergies were present during adaptive gait tasks, one-sample t-tests were performed on  $\Delta Vz$ . One-way ANOVA was performed on (1)  $\Delta Vz$  to determine if the synergy strength was influenced by task, and (2)  $V_{UCM}$  and  $V_{ORT}$  to determine the changes in the variance components that lead to changes in  $\Delta Vz$ .

## Results and Discussion

Synergies were observed for both curb and obstacle crossing ( $t \geq 5.97$ ,  $p < .05$ ; Figure 1A) indicating that step length is stabilized, which likely assists in maintaining gait stability. Step length synergy during curb crossing was lower than obstacle crossing ( $F_{2,44}=24.61$ ,  $p < .05$ ; Figure 1A). The lower synergy resulted from lower good variance ( $V_{UCM}$ ) ( $F_{2,44}=11.24$ ,  $p < .05$ ; Figure 1B). Lower  $V_{UCM}$  indicates that foot placements were more stereotypical for curb crossing, which may result from three possibilities. First, the curb was shorter than the obstacle (15 vs 22 cm), requiring lower muscle activity to cross the hazard, which in turn reduces motor noise and variability. Second, curbs are prevalent in the community, and greater experience with curb crossing may have resulted in lower  $V_{UCM}$ . Third, the demand to move the body center of mass to a new height during curb crossing may impose additional foot placement requirements to facilitate the change in potential energy, thereby reducing  $V_{UCM}$ . Greater experience with curbs may have resulted in lower bad variance ( $V_{ORT}$ ;  $F_{2,42}=6.04$ ,  $p < .05$ ; Figure 1C) as well. However, the reduction in  $V_{ORT}$  was not commensurate with the reduction in  $V_{UCM}$ , resulting in lower synergies for curb crossing.

## Significance

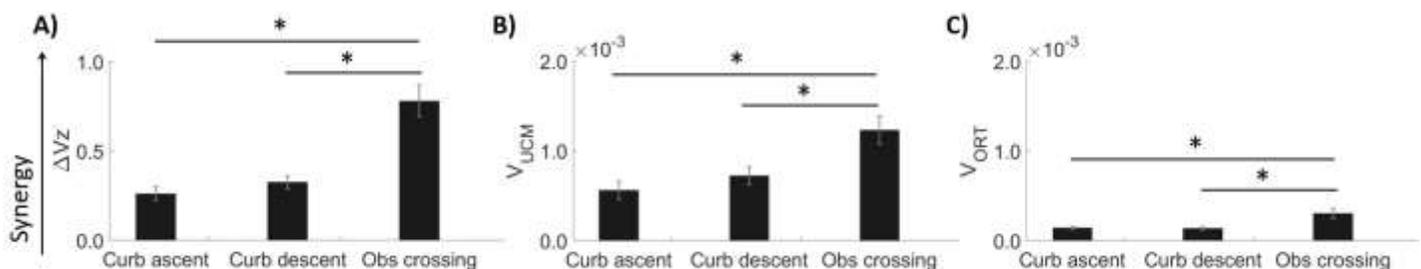

While tight control of foot placement prior to an obstacle has been established, we have demonstrated that the step length, with the two legs planted on either side of a hazard is also a control priority while navigating hazards. Furthermore, task-specific differences in the structure of variance (i.e., the variance components) indicate additional constraints that humans impose on their behaviors. Such insights may not be apparent from conventional or clinical gait analyses and measures. Extending this study to include older and pathological populations will potentially help in understanding the etiology of falls during community ambulation.

# The Effect of Cervical Spondylotic Myelopathy on the Dynamic Stability of Human Gait

Emily Dooley<sup>1</sup>, Hamid Hassanzadeh M.D.<sup>2</sup>, and Shawn Russell Ph.D.<sup>1,2</sup>

University of Virginia, Departments of <sup>1</sup>Mechanical Engineering and <sup>2</sup>Orthopaedic Surgery, Charlottesville, VA, USA

Email: sdr2n@virginia.edu

## Introduction

Cervical spondylotic myelopathy (CSM) is a condition caused by compression of the spinal cord in the neck that results in sensory loss at the extremities due to deterioration of the afferent and efferent nerve pathways. This deterioration results in reduced sensation and motor control of the legs causing difficulty walking due to decreasing dynamic stability.<sup>1</sup> This often presents as a waddling gait with increased step width and time in double support.<sup>2</sup> Angular momentum regulation has been hypothesized as a feedback control mechanism the human body uses to keep itself stable while performing any task. Consequently, angular momentum can be used as a measure of dynamic stability of gait; where greater stability is characterized by minimizing deviation in angular momentum.<sup>3</sup> The aim of this study is to fully characterize the dynamic stability of patients with CSM, resulting in a tool to determine where instability in gait stems from.

## Methods

Experimental data was collected for 56 subjects: 24 controls (9M and 15F,  $56.2 \pm 11.2$  y.o.) and 32 CSM patients (15M and 17F,  $59.9 \pm 10.4$  y.o.). Walking trials were collected on a 15m walkway at a self-selected, comfortable walking speed. A minimum of six trials were used from each subject for analysis. Subjects were recorded using 3D motion capture and five Bertec force plates. The Plug-in-Gait model was used to calculate joint kinematics as well as body segment centers, and exported to Matlab for analysis.

The angular momentum of each body segment was computed as the sum of its local angular momentum and angular momentum of segments about the whole-body center of mass (CoM).<sup>4</sup> Whole-body angular momentum is the sum of all of the segments. Upper-body angular momentum is the sum of the arms, thorax, and head segments, and lower-body angular momentum is the sum of the legs and pelvis. Angular momentum was decomposed into sagittal, frontal, and transverse planes for analysis.

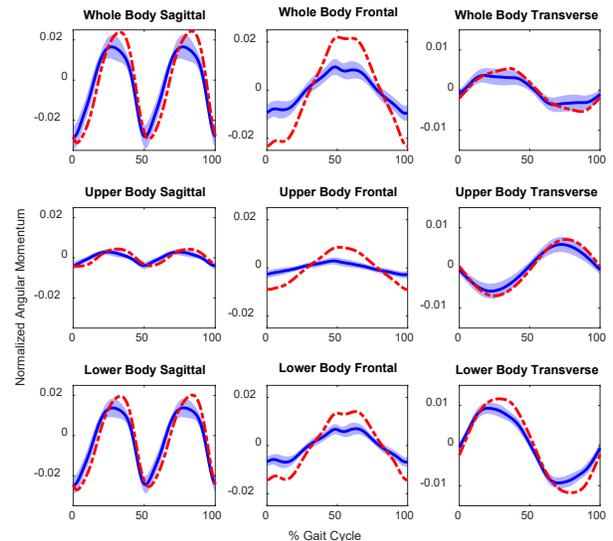

## Results and Discussion

Angular momentum analysis quantifies clear stability differences between the groups, with CSM patients showing greater angular momentum throughout the gait cycle compared to controls, indicating that they are less stable in all planes of motion.

CSM patients had increased angular momentum in the frontal plane (Fig. 1, Col. 2), indicating decreased stability compared to controls in both the upper and lower body. This is reflective of excessive medial-lateral tilting common to the waddling gait pattern seen in this population. Tilting is indicative of rocking from foot to foot over a wider base of support. With this angular momentum analysis it is evident that this decrease of stability is coming from both the upper and lower body rocking in unison, bringing the patient further from stability on each step.

In the sagittal and transverse planes, a phase shift is evident with the patients lagging the control group (Fig 1, Col 1&3). This phase shift reflects CSM patients spending more time in double support, a more stable posture; then abruptly moving a leg through the swing phase, a less stable posture. This instability

compensation manifests as larger, but delayed, peaks in sagittal momentum, suggesting that CSM patients are able to regulate momentum well through extended periods of double support, but poorly regulate momentum through swing phase.

**Figure 1.** Angular momentum over one gait cycle in the anatomical planes. Control population shown as solid blue line with  $\pm 1$  S.D. shaded. Mean of CSM patient population shown in dashed red.

## Significance

Angular momentum analysis on the three anatomical planes is a useful metric for determining stability of human movement, as it can be related to both biological control processes and observed movement patterns. Deeper understanding of the instabilities of various movements can be gained through decomposition of stability to a segment-by-segment level. Understanding which segments of the body have the largest effects on stability in various movements will allow targeted therapies and rehabilitation procedures to be developed to aid populations with instability pathologies.

Specifically, instability of movement decreases functional ability, increasing inactivity. As CSM patients' ability to function independently decreases they become at greater risk of falling, as well as much more dependent on others to care for them. By gaining an understating as to why they are unstable in motion, therapy and rehabilitation strategies can be developed to counteract the deterioration of function. Ultimately, this would return independence to CSM patients, relieving the impact of the condition on the patients, caregivers, and workforce.

# Task Challenge Affects Both Gait and Reaction Time Performance in Young Adults

HyeYoung Cho<sup>1</sup>, and Shirley Rietdyk<sup>1</sup>

<sup>1</sup> Health and Kinesiology, Purdue University, West Lafayette, IN, USA

Email: \* cho273@purdue.edu

## Introduction

In daily life, walking is frequently completed with other tasks, and this multitasking typically results in performance decrements [1]. In general, healthy subjects prioritize gait performance over cognitive task performance when there is no specific prioritization instruction [2]. It is well known that more difficult tasks result in greater gait impairment [3]. However, systematic manipulation of the cognitive task difficulty is relatively understudied. Increasing cognitive task challenge increases the demand on cognitive resources and provides a window into capacity interference during multitasking [4]. Thus, the purpose of this study was to examine how level of both gait and cognitive challenge affects task performance while walking.

## Methods

Fourteen young adults (age: 20.4±1.1 yrs.) completed fifteen conditions: three levels of cognitive task (simple, choice, and Simon reaction time (RT) tasks), three levels of gait task (no obstacle, 15%, and 30% of leg length obstacle heights), baseline for gait task without RT task, and baseline for cognitive tasks while seated. Twelve trials for each condition were block randomized. The RT task appeared once (i.e. discrete RT task) on the monitor at the end of walkway during the approach phase (1-4 steps before the obstacle). In dual task conditions, participants were not given any specific task prioritization instructions. RT, gait speed for one second after presentation of the RT cue, the number of RT errors, and the number of obstacle contacts were measured. RT and gait speed were analyzed with a two-way ANOVA (obstacle height X RT task).

## Results and Discussion

Errors: More obstacle contacts were observed with the highest obstacle (6 vs 17, for 15 vs 30%, respectively), consistent with previous research [5]. The number of obstacle contacts appeared unrelated to the cognitive task. More frequent RT errors were observed with increasing cognitive challenge (1 vs 2 vs 45, for simple vs choice vs Simon, respectively).

A main effect of cognitive task was observed for gait speed ( $p<0.01$ ; Fig. 1A). The slower gait speed for Simon versus baseline indicates that participants only reduced their speed in the most challenging RT task. Gait speed was not affected by the

obstacle task ( $p=0.37$ ), likely due to the fact that speed was calculated one second after the RT cue, which occurred on the unobstructed portion of the walkway for all conditions.

Main effects of cognitive and gait task were observed in RT (Fig. 1B). RT was significantly longer for each level of the RT task ( $p<0.01$ ), the increase in RT with RT task was similar for seated, unobstructed walking, and stepping over obstacles (no interaction was observed). RT while obstacle crossing (both 15 and 30% heights) was significantly longer than seated RT tasks ( $p<0.01$ ; Fig. 1B).

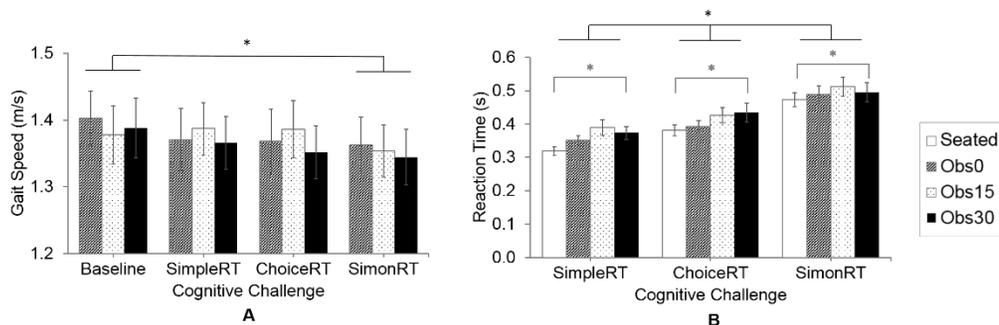

In order to complete the task in the most challenging condition (Simon task and the tallest obstacle), participants had the highest RT and the slowest speed. Although young adults changed both RT and gait performance, they demonstrated greater change in RT (up to 22%) than in gait speed (up to 3%), consistent with the posture first strategy [2]. Similarly, the number of RT errors were affected by the RT task, but not the gait errors. Therefore, capacity interference is evident; young adults did not complete both tasks concurrently without a change in performance in both gait and RT measures. Since older adults are more likely to demonstrate greater performance impairment or different task prioritization strategy, such as posture second strategy, future studies will explore how older adults change performance as a function of the level of both gait and cognitive challenge.

## Significance

Even though the RT task was only completed once while walking, young adults did not have sufficient cognitive resources to complete the task without modifying performance. Increased demands in both the RT and gait tasks further taxed the cognitive resources. In order to accomplish both tasks, young adults adopted a posture first strategy.

# People Can Voluntarily Change Their Lateral Stepping Regulation During Goal-Directed Walking

Anna C. Render<sup>1</sup>, Meghan E. Kazanski<sup>1</sup>, Joseph P. Cusumano<sup>2</sup>, and Jonathan B. Dingwell<sup>1</sup>

<sup>1</sup>Department of Kinesiology, The Pennsylvania State University

<sup>2</sup>Department of Engineering Science & Mechanics, The Pennsylvania State University

Email: \*[acr313@psu.edu](mailto:acr313@psu.edu)

## Introduction

Humans are inherently more unstable in the frontal plane [1]. Thus, appropriate lateral foot placement to stabilize walking from step-to-step is critical to prevent falls. In the frontal plane, humans regulate foot placement over consecutive steps not only to maintain balance, but to achieve other task-relevant goals as well [2]. For normal (unrestrained and unperturbed) walking, healthy humans modulate left and right lateral foot placements ( $z_{Ln}$ ,  $z_{Rn}$ ) to trade off regulating some lateral body position ( $z_{Bn}$ ) and mostly step width ( $w_n$ ) [3]:

$$\begin{bmatrix} z_{Bn} \\ w_n \end{bmatrix} = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ -1 & 1 \end{bmatrix} \begin{bmatrix} z_{Ln} \\ z_{Rn} \end{bmatrix}. \quad (1)$$

But for real-world walking [4], humans have to continually adapt their stepping regulation. Thus, it is important to quantify how healthy humans regulate lateral foot placements across a range of walking conditions. Here, we determined the extent to which humans can voluntarily modify how they regulate  $z_{Bn}$  and  $w_n$  from step-to-step when given explicit goal-directed feedback.

## Methods

Twenty-four healthy adult men and women (12M/12F; age  $23 \pm 3$ ) walked on a treadmill in a virtual environment (Fig. 1A) and completed three, 4-minute trials for 3 conditions: normal walking (NOR), maintaining absolute lateral position (POS) on the treadmill, and maintaining constant step width (WID). During POS and WID, participants were instructed to minimize errors with respect to the goal function:

$$F_q = q_n - q^* = 0, \quad (2)$$

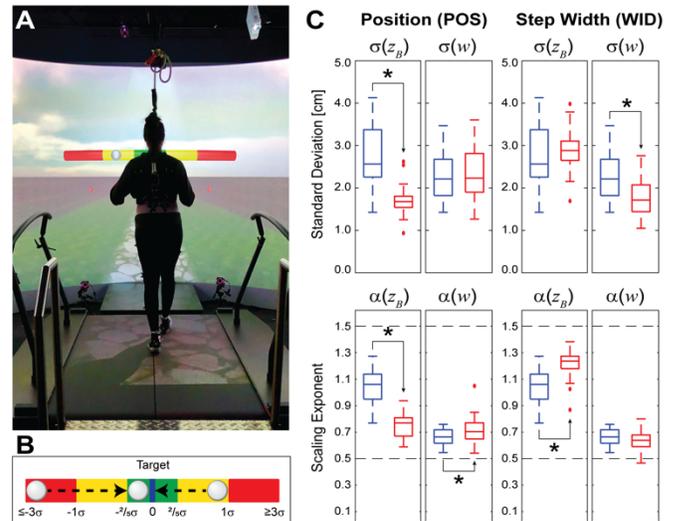

where  $q \in \{z_B, w\}$  and  $q^* \equiv$  the desired goal value. For the POS condition, their goal was to stay at the geometrical center of the treadmill in the lateral direction ( $z_B^* = 0$ ). For the WID condition, their goal was to stay at their own preferred mean  $w$ , as calculated from the NOR condition. Participants were given explicit visual feedback of their performance at each step (Fig. 2B). For each condition, stepping time series of  $z_{Bn}$  and  $w_n$  were extracted. For each time series, variability ( $\sigma$ ) and statistical persistence (DFA  $\alpha$ ; reflecting step-to-step regulation) were calculated.

## Results and Discussion

When given POS feedback (Fig. 1C; left), participants significantly decreased ( $p < 0.001$ ) variability of  $z_B$  compared to NOR. Changes in statistical persistence ( $\alpha$ ) of  $z_B$  also indicated tighter ( $p < 0.001$ ) step-to-step regulation of  $z_B$ . In addition,  $\alpha$  of  $w$  significantly increased ( $p < 0.05$ ) compared to NOR, reflecting weaker step-to-step regulation of step width when more tightly regulating position.

When given WID feedback (Fig. 1C; right), participants significantly decreased ( $p < 0.001$ ) variability of  $w$  compared to NOR. DFA  $\alpha$  of  $w$  remained near  $\alpha = 0.5$ , reflecting continued tight step-to-step regulation of  $w$ . In addition,  $\alpha$  of  $z_B$  significantly increased ( $p < 0.001$ ) compared to NOR, reflecting weaker step-to-step regulation of lateral position when more tightly regulating step width.

In normal walking, humans use multi-objective control of lateral stepping movements to trade-off regulating lateral position vs. step width [3]. Given explicit feedback of task performance relative to the prescribed goal function (2) for each  $q \in \{z_B, w\}$ , humans increased step-to-step regulation of the prescribed  $q$  to decrease variability in that  $q$ . In doing so, humans decreased step-to-step regulation of the complimentary (but non-prescribed) lateral stepping variable.

**Figure 2:** A: Participant walking in the virtual environment. B: Schematic of visual feedback. C: Results for Maintaining Position (left; POS) and Maintaining Step Width (right; WID). Boxplots of variability (top;  $\sigma$ ) and statistical persistence (bottom;  $\alpha$ ) of  $z_B$  and  $w$  between normal walking (blue) and POS/WID conditions (red). Asterisks denote statistically significant differences ( $p < 0.05$ ).

## Significance

To accomplish each prescribed walking task, humans exhibited distinct task-specific tradeoffs between  $w$  and  $z_B$ . These experimental results are in substantial agreement with predictions from our previously published computational model of lateral stepping regulation [3]. Humans adapt lateral foot placement from each step to the next in systematic and predictable ways that depend on the specific task goals to navigate different and complex environments and task requirements.

### Introduction

Flip-flops are a popular warm weather footwear, its style consists of a thong as the upper portion and a thin-flexible sole. Podiatrists often express concerns about flip-flops' impacts on lower extremity health and that the lack of structure may intensify any muscular or skeletal problems pre-existing in the foot<sup>3</sup>. Prior studies have reported differences in peak ankle plantar- and dorsiflexion angles<sup>1</sup>, contact angle and dorsiflexion moments<sup>2</sup>. However, to understand the impact of flip-flops on foot health an analysis of multi-segment foot kinematics is needed. The lack of rigidity of the shoe requires a more detailed analysis to be utilized to fully understand the movements of the foot while walking in flip-flops.

Alterations in foot and ankle kinematics with flip-flops could be attributed to either the lack of an upper or the thin midsole common in a flip-flop<sup>2</sup> but prior work has not considered the effects of these components. For example, the thong of the flip-flop may have an impact on the inter-segmental kinematics of the foot, this may also be attributed to lack of midsole thickness and cushioning in most flip-flops. The purpose of this study was to determine the effect of (H1) the thong of a flip-flop by comparing a closed toe shoe and thick-sole flip-flop with identical soles and (H2) sole thickness and cushioning by comparing a thick-sole flip-flop and a conventional flip-flop on multi-segment foot and ankle kinematics

### Methods

Fourteen healthy participants (ages 21-35 years; BMI < 30 kg/m<sup>2</sup>) were recruited. All participants were free of lower extremity injury and provided informed consent prior to completing study procedures. Overground gait analysis was completed in four shoe conditions (two flip-flops and two closed toe shoes): Twinpin Flip-flop (Reef), Ooriginal sandal (OOFOs), Ultraboost (Adidas) and the OOmng Low Shoe (OOFOs). Participants were fit with a multi-segment foot marker-set and rigid clusters on the lower leg<sup>4</sup> and then walked at a prescribed speed of 1.3 m/s while markers were tracked by 11 infrared cameras (Qualysis Inc. Sweden). Kinematic and kinetic data was processed in Visual 3D (C-Motion Inc., MD). A low pass Butterworth filter with a cutoff frequency of 8Hz was used to filter raw data. Shank-calcaneus (ankle), hallux-metatarsal and calcaneus-metatarsal 3D angles were calculated. Repeated measures ANOVA was used to test for significant differences between shoes. Post-hoc testing with a

least significant difference adjustment was completed where significant main effects of footwear were found.

### Results and Discussion

There was a main effect of shoe for the calcaneus-metatarsal peak flexion (p=0.001) and inversion-eversion (p=0.02) angles, the hallux-metatarsal peak flexion angle (p = 0.017) and ankle plantarflexion (p = 0.032) and inversion angles at toe-off (p = 0.016). There was also a significant shoe effect for peak inversion (p = 0.028), plantarflexion (p < 0.001) and dorsiflexion (p = 0.010) moments. There was a significant effect of the lack of upper (Ooriginal vs low shoe) for the calcaneus-metatarsal and hallux-metatarsal peak flexion angles, ankle plantarflexion and eversion angles at toe-off and peak plantarflexion moment (Table 1). In the flip-flop style shoes (Twinpin vs Ooriginal) there was a significant effect of the midsole structure (H2) on the calcaneus-metatarsal peak flexion and eversion angle, hallux-metatarsal peak flexion angle and ankle plantar-flexion angle at toe-off.

To assess the combined effects of the thong with a structured midsole we also compared the differences between the Ooriginal sandal and low shoe with those of the Twinpin and Ultraboost. For both comparisons there was increased ankle eversion at toe off that is likely related to lack of an upper, this increased joint excursion has previously been associated with overused injuries<sup>1</sup>. However, differences in the peak plantarflexion moment were only found for the OOriginal – low shoe comparison suggesting an interaction of midsole geometry and upper style on gait.

### Significance

Our data shows that the impact of flip-flops on multi-segment foot kinematics and ankle kinetics results from both the lack of the upper but also the midsole structure. These results suggest that flip-flops with a more cushioned midsole may increase within foot sagittal motion and the benefits and consequences of the increased motion should be addressed in future work.

# Self-pace treadmill controllers influence gait variability but not average walking speed

## Introduction

Humans walk daily on a variety of slopes and naturally fluctuate their walking speed. Self-pace controllers incorporated into instrumented treadmills allow subjects to walk at their self-selected walking speed while preserving natural gait fluctuations compared to fixed-speed treadmills [1]. These self-pace controllers are typically designed to match a subject's overground walking speed [2], but there are multiple approaches for implementing self-pace controllers. Thus, quantifying the effects of different controllers on gait is imperative. The purpose of this study was to quantify and compare gait parameters (i.e., speed, step length, and step width) using a range of self-pace controllers during uphill, downhill, and level walking. We hypothesized that different self-pace controllers would result in similar average gait speeds, but more sensitive self-pace controllers that change belt speeds more frequently to match the subject's walking speed will produce greater gait variability.

## Methods

Ten young adults walked on a self-paced instrumented treadmill (M-Gait, Motekforce Link) at three slopes (+10°, incline; 0°, level; -10°, decline) and with three self-pace controller sensitivities (low, medium, and high) for 5 minutes each. We recorded their movement using a motion capture system (Optitrack) to assess gait kinematics. The self-pace controllers adjusted belt speeds by tracking the pelvis location relative to the center position on the treadmill such that greater sensitivity resulted in more frequent belt speed adjustments. Walking speed was defined as the average velocity of the treadmill belts. We used step length variance and step width variance to quantify gait variability. We also detrended speed from step length and decomposed step length variance according to the identified speed-related trends [3]. The last four minutes of each condition was analyzed. We determined statistical differences in gait parameters using a repeated-measures ANOVA at each slope, followed by a Tukey's honest significance different (HSD) test to identify differences between self-pace controllers.

## Results and Discussion

Average walking speeds were similar regardless of self-pace controller sensitivity for each slope (Fig. 1A). The high sensitivity controller, however, had the greatest speed variance, which corresponded with having the most belt speed fluctuations. Not surprisingly, step length variance was also the largest when using the high sensitivity controller, which was observed in all slopes (Fig. 1B). The increased step length variance could simply be the result of increased speed fluctuations. Detrending speed from step length revealed that detrended step length variance was similar for all self-pace controller sensitivities within each slope (Fig. 1B), suggesting that the increase in total step length variance could indeed be largely attributed to the fluctuations in speed. These results supported our hypothesis. Step width variance, however, were not significantly different among the controllers.

Using controllers with different sensitivities resulted in similar average walking speeds. Controllers with greater sensitivity increased speed and step length variability, but not step width variability. These results were consistent across slopes. Previous self-pace studies used self-pace controllers at a level slope and did not detrend speed from gait parameters [1, 2]. Our study indicates that speed fluctuations of self-pace controllers at different slopes need to be accounted for when comparing gait.

## Significance

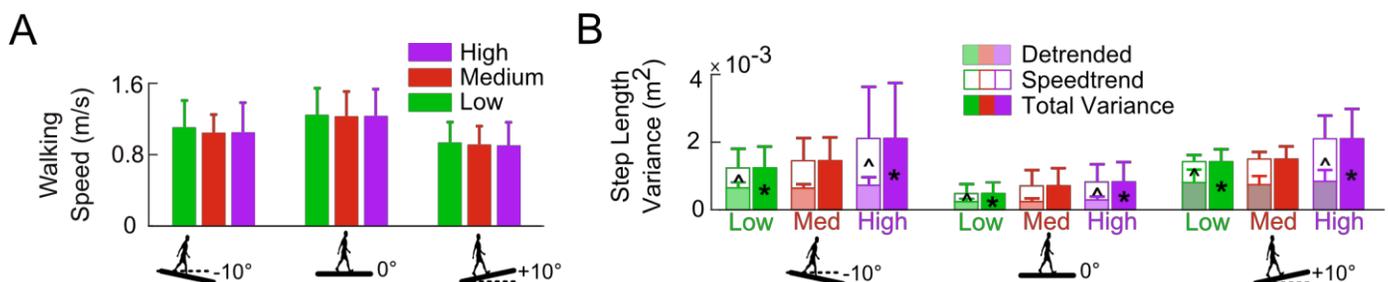

These findings highlight the importance of reporting the speed dynamics of self-pace controlled treadmills at different slopes and the need to use speed detrended gait variabilities to avoid reporting differences in gait that emerge simply as a result of the speed fluctuations of the self-pace controller. These findings also have implications for interpreting energy expenditure and muscle activity for self-pace treadmill walking at different slopes.
