Lower extremity peripheral artery disease (PAD) is estimated to affect 200 million people globally, including 8-12 million people in the United States [1,2]. Atherosclerosis in the leg arteries obstructs blood flow, causing claudication pain and early fatigue, and this severely reduces walking ability in the affected patients. Our previous work showed that forward push-off is deficient in patients with PAD [3]. Hence, assistive devices such as ankle-foot orthoses and exoskeleton footwear are being developed to help patients with PAD walk further and with less pain. Roll-over shape (ROS) is considered an important design goal for such assistive devices to mimic the equivalent rocker shape generated by healthy lower limbs during the forward progression. ROS remains invariant to walking speed, carrying additional weight and walking with different types of footwear [4]. Our goal is to compare ROS characteristics between patients with PAD during pain-free and pain-induced overground walking and healthy older individuals.

## Methods

Gait data of twenty patients with PAD (Age:  $64.1 \pm 6.6$  years) and fifteen healthy older controls (Age:  $72.9 \pm 5.5$  years) were analyzed for ROS parameters from a previously approved study. Gait kinematics and kinetics were recorded using an eight-camera 3D motion capture system and a force plate embedded in the walkway. Three gait trials at self-selected walking speed for the most affected leg during a pain-free and pain-induced overground walking were used. Patients rested between trials to ensure pain-free walking and then claudication pain was induced using a clinical protocol [5] for the pain-induced trials. The leg with lower ankle-brachial index and most symptoms was considered as the most affected.

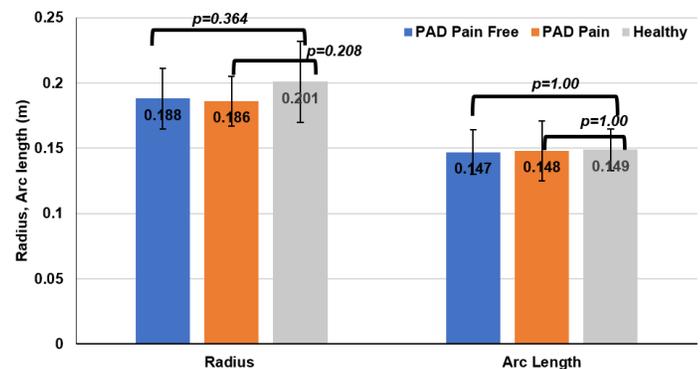

**Figure 1:** Roll-over shape in a representative patient with peripheral artery disease during overground walking.

The ankle-foot ROS was generated by transforming Center of Pressure (CoP) in the direction of forward progression from the lab-based coordinate system to the shank-based coordinate system. These transformed CoP data points were fit with a circular arc to characterize the ROS using parameters such as radius and arc length as shown in Figure 1. The MATLAB<sup>TM</sup>

based optimization algorithm was used to find the best fitting circular arc. Height normalized ROS radii and arc length were calculated for each subject. Independent t-tests with Bonferroni correction were used to independently compare roll-over characteristics ( $p < 0.05$ ) between controls vs. patients with PAD in each walking condition.

## Results and Discussion

The mean roll-over radius and arc length were not significantly different when compared between Controls and PAD both in the pain-free (Figure 2;  $p = 0.364$  and  $p = 1.00$ ) and in the PAD pain-induced ( $p = 0.208$  and  $p = 1.00$ ) walking conditions.

**Figure 2:** Mean roll-over radius and arc length during pain-free and pain-induced walking in patients with PAD and healthy older individuals. ( $p$  values are adjusted for Bonferroni correction)

Our results show that the ROS is preserved in PAD even while patients walk with claudication pain. This finding is in agreement with the general invariance model of ROS during different walking conditions in healthy young individuals [4]. Furthermore, our data support the proposition that preserving ROS is important for forward progression during walking. Literature shows that patients with PAD have modified ankle kinematics while walking with claudication pain compared to healthy older people [5]. Future studies will investigate whether altered ankle kinematics are driven by patients' inherent desire to preserve ROS during walking.

## Significance

Invariance of the ROS in patients with PAD makes it a potential design objective for assistive devices that are being developed for them.

# Infant Transportation: Ground Reaction Forces During Gait

Kathryn L Havens<sup>1</sup>, Ryan Zerega<sup>1</sup>

<sup>1</sup>Division of Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, CA

Email: khavens@usc.edu

## Introduction

The physical demands of new motherhood are extensive yet have not been systematically explored. Infant homo sapiens are born helpless, and caregivers must transport them during early infancy. They may choose to do so in a number of different ways: carrying in their arms, carrying in an infant car seat, wearing on their body in a structured baby carrier, or pushing in a stroller.

Researchers have begun to explore the effects of carrying an infant on biomechanics during walking. Compared to unloaded walking, holding an infant in a baby carrier on the body alters trunk mechanics as well as lower extremity joint loading [1-3]. Interestingly, compared to an unloaded condition, Brown et al. [4] showed that walking using baby carriers yielded an increase in impact peak vertical ground reaction force (GRF), braking and propulsive peak GRF and ground reaction force impulse (GRI).

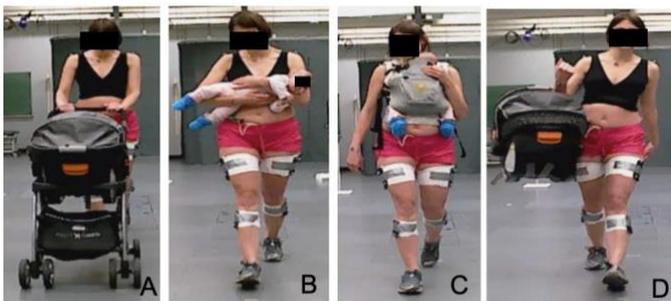

These studies demonstrate that carrying infants affects gait biomechanics. But it is unclear how this relates to the health of mothers, as only healthy nulliparous young adults have been analyzed. The unique experience of pregnancy and childbirth make the application of these results to mothers unclear.

Therefore, the purpose of this study was to characterize the ground reaction forces of healthy mothers while carrying their own infants in various ways.

## Methods

Six healthy mothers (age =  $34.3 \pm 2.6$  yr, height =  $1.7 \pm 0.1$  m, weight =  $62.5 \pm 7.1$  kg) participated. They brought their infants (age =  $14 \pm 2.4$  wk, weight =  $6.2 \pm 0.8$  kg) to the Jacqueline Perry Musculoskeletal Biomechanics Research Laboratory at USC.

Each participant completed 3 trials of overground walking at self-selected speeds under multiple conditions (**Figure 1**): without infant (unload), pushing infant in their own stroller (Stroller - A), holding infant in arms (Arms - B), babywearing by holding infant anteriorly on their body in their own structured baby carrier (Wear - C), and holding infant in an infant car seat (Carseat - D).

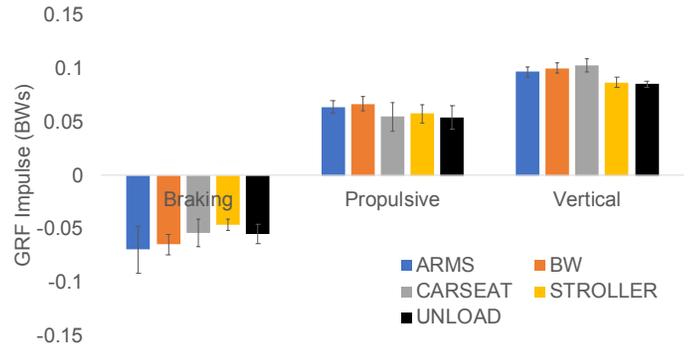

**Figure 1:** Gait conditions: A) Stroller, B) Arms C) Wear, D) Carseat.

GRFs were collected using AMTI force plates embedded into the lab floor (900Hz). Stance time and peak GRFs were identified. GRI was calculated as the area under the GRF-time curve. GRF variables were normalized to body weight. Custom code (MathWorks, Natick, MA) was written to identify peak GRF, impulse, and timing.

Nonparametric Friedman tests were used to compare variables between gait conditions ( $\alpha < 0.05$ ), and Wilcoxon

signed-rank tests were used as a post-hoc analysis ( $\alpha < 0.05/10 = 0.005$ ).

## Results and Discussion

**Figure 2:** GRF Impulse: Braking, propulsive, and vertical. For visual purposes, vertical impulse was divided by 10.

Vertical GRI ( $\chi^2(5) = 17.44$ ,  $p=0.002$ , **Figure 2**) and vertical peak GRF ( $\chi^2(5) = 16.48$ ,  $p=0.002$ ) differed between conditions. This pilot study was underpowered to identify any post-hoc differences. As carrying an infant is ultimately a load carriage task, the increased vertical forces is not surprising. The weight of the infants represented  $\sim 10\%$  of the body weight of participants. Increases in peak vertical force were approximately proportional, with Arms and Wear increasing peak forces by  $\sim 15\%$ , and Carseat  $\sim 20\%$ . This is consistent with other studies on infant carriage [4, 5] and also backpack loading.

Braking GRI ( $\chi^2(5) = 11.36$ ,  $p=0.023$ ), peak braking GRF ( $\chi^2(5) = 13.6$ ,  $p=0.009$ ), and propulsive GRI ( $\chi^2(5) = 11.52$ ,  $p=0.021$ ) differed between conditions. The time spent braking did not differ. This suggests that braking GRI differences were driven by differences in force magnitude rather than time of force application [4, 5].

Stance time differed between individuals ( $\chi^2(5) = 14.56$ ,  $p=0.006$ ), indicating that individuals self-selected to perform the tasks at slightly different speeds. This is consistent with previous research [1], but may affect GRF magnitudes.

The results of this pilot study suggest that mothers modulate their forces when carrying their infant. Increased forces indicate that mothers are exposed to additional stresses, which may be deleterious. Additional data is needed to clarify these relationships.

## Significance

Approximately 4 million women give birth in the United States each year, and many suffer from persistent low back and pelvic pain even following birth. Increased loads experienced while carrying their infant may place them at greater risk. A better understanding of these loads is the first step to mitigating pain.

# Stride Time and Variability in Older Adults Walking on an Uneven Terrain Treadmill

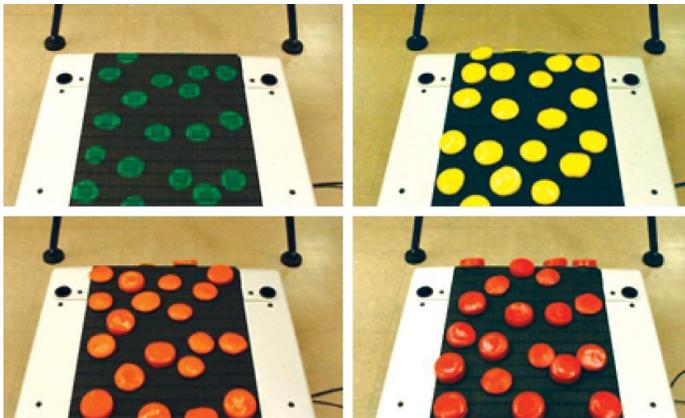

Rohan Gupta<sup>1</sup>, Ryan J. Downey<sup>1</sup>, Natalie Richer<sup>1</sup>, and Daniel P. Ferris<sup>1</sup>  
<sup>1</sup>Department of Biomedical Engineering, University of Florida  
Email: rohan.gupta@ufl.edu

## Introduction

The purpose of this study was to examine the stride time and stride time variability in older adults as they walked over varying levels of uneven terrain on a treadmill. In the real world, humans encounter a range of terrain, some of it having uneven surfaces. We hypothesized that increasing the unevenness of the treadmill surface would result in subjects walking with shorter stride times and greater stride time variability. If the level of terrain unevenness led to greater stride time variability, it would be one indication that the unevenness of the treadmill could be used to increase the difficulty level of walking and decrease gait stability.

## Methods

A group of 14 adults (7 females, mean age = 77.2, SD = 3.75 years) walked on a treadmill with four different surfaces to simulate varying levels of terrain unevenness (Fig. 1) [1]. The treadmill speed was adjusted for each individual but remained constant across all four surfaces. Prior to the treadmill trials, subjects walked on an 8-meter overground version of the surfaces to find their self selected walking speeds. The treadmill speed was set to 75% of each person's slowest self-selected walking speed (slowest across all conditions). The average speed for testing across all subjects was 0.58±0.20 m/s (mean±SD). Subjects completed two walking trials per surface lasting three minutes per trial. The order of the surfaces was randomized.

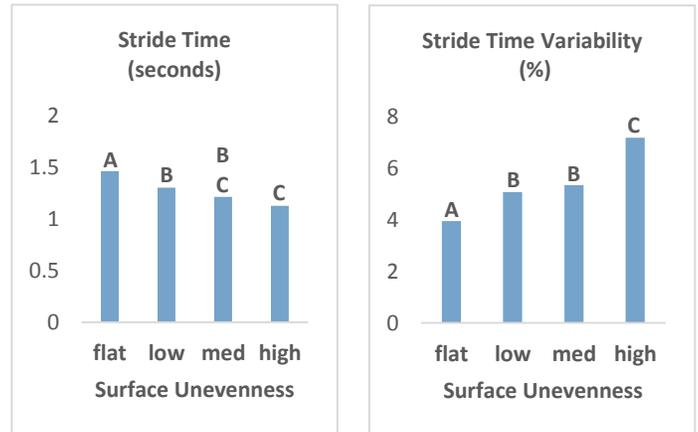

**Figure 1:** We secured different sized cylindrical hard foam pucks to the surface of a Woodway treadmill using hook-and-loop fasteners. The puck height varied from ~1.3, 2.5, and 3.8 cm, with a diameter of ~10-12 cm. The flat surface (green) had no pucks but flat circles. The surface unevenness level increased from yellow (low) to orange (med) to red (high) pucks.

Subjects wore capacitive insoles to measure foot pressure (loadsol, Novel GmbH, 200 Hz). We used Matlab to identify heel strike events and calculate stride duration kinematics. For each trial, we calculated two outcome variables: the average stride time (in seconds) and the stride time variability (% stride duration). We tested the hypotheses with a repeated measures ANOVA with pairwise comparisons using Tukey's method.

## Results and Discussion

As the difficulty of the uneven surface increased, the average stride time decreased ( $F_{3,39}=20.1$ ,  $p<0.001$ ) and stride time variability increased ( $F_{3,39}=26.7$ ,  $p<0.001$ ) (Fig. 2).

**Figure 2:** Mean stride time and stride time variability across all subjects. Conditions that do not share a letter are statistically different. An increase in surface unevenness led to shorter stride times and greater stride time variability.

Compared to flat treadmill walking, the most difficult surface unevenness used in this study increased stride variability by 82%. This increase is similar in magnitude to the effect of dual-task walking in elderly participants. Walking while performing a verbal fluency task or a difficult backward counting task led to an increase in stride time variability of 77% and 54%, respectively, compared to single-task walking [2].

## Significance

Having a repeatable and robust method for increasing walking difficulty facilitates studying gait biomechanics and control in younger and older subjects. We used treadmill surface unevenness as a means to increase walking difficulty and gait instability. The stride time and stride time variability results suggest the uneven terrain treadmill is effective as an experimental tool for these purposes.

# Ankle Power and Stiffness During Gait in Children with Hypermobile Ehlers-Danlos Syndrome

Anahita A. Qashqai<sup>1</sup>, Nicole Vigon<sup>1</sup>, Alyssa J. Schnorenberg<sup>1</sup>, Michael Muriello<sup>2</sup>, Donald Basel<sup>2</sup>, and Brooke Slavens<sup>1</sup>

<sup>1</sup> University of Wisconsin-Milwaukee, Milwaukee, WI, USA

<sup>2</sup> Medical College of Wisconsin, Wauwatosa, WI, USA

Email: \*[Anahita@uwm.edu](mailto:Anahita@uwm.edu)

## Introduction

Hypermobile Ehlers-Danlos syndrome (hEDS) is the most frequent subtype of the heritable connective tissue disorder Ehlers-Danlos syndrome [1]. Often, individuals with hEDS report musculoskeletal pain, fatigue, instability, and recurrent dislocations in ankle. These conditions lead to early onset osteoarthritis and osteoporosis [1]. Laxity of tendons and ligaments is considered a major determinant for musculoskeletal complaints in the hEDS population and can be evaluated by measuring joint stiffness [2]. An important question is whether these complications in the ankle joint affect joint dynamics in children during musculoskeletal development. Thus, the aim of this study is to quantify ankle joint dynamics during gait in children with hEDS and compare them to typically developing children.

## Methods

Eight children (4 males, 4 females, age:  $14.5 \pm 2.8$  years) with hEDS participated in this study. A modified Newington-Helen Hayes marker set was utilized. A 15-camera Vicon T-Series motion capture system and four AMTI force plates [3] acquired lower extremity (LE) motion and ground reaction forces, respectively. Each subject completed multiple walking trials at a self-selected speed. The Vicon Plug-in Gait LE inverse dynamics model computed 3D joint dynamics. For comparison to typically developing children similar data was obtained from 83 children (age:  $10.5 \pm 3.5$  years) from Schwartz et al. [5].

Ankle dorsiflexion/plantarflexion (degrees), peak ankle moment (Nm), stiffness (Nm/degree), sum of generated power (W), and sum of absorbed power (W) were computed. Ankle joint stiffness was calculated as the derivative of the ankle moment in the sagittal plane versus the ankle joint angle during the second rocker (from the first relative maximum plantar flexion angle to maximum dorsiflexion angle in stance phase) and a linear regression was fitted [4]. The positive and negative areas under the power curve were measured to determine power generation and power absorption, respectively. The Mann-Whitney U-

test was applied to compare the hEDS and typically developing groups (significance level  $< 0.05$ ).

## Results and Discussion

While the dorsiflexion/plantarflexion range of motion of the hEDS group was similar to the typically developing group, the corresponding ankle moment and power were significantly different (Fig. 1. a-c). Compared to typically developing children, those with hEDS generated significantly more power ( $30.1 \pm 15.4$  W vs.  $11.6 \pm 5.2$  W) and absorbed significantly more power ( $16.9 \pm 3.9$  W vs.  $4.7 \pm 0.2$  W).

Significantly higher ankle moments (Fig. 1b) and powers (Fig. 1c) were observed in the hEDS group, though there was no significant difference in joint stiffness between the two groups. This may be an indication of increased effort and energy demands in children with hEDS as compared to typically developing children. The ankle joint in children with hEDS generated and absorbed more power during the stance phase compared to healthy children. Additional data collection is underway to enhance our understanding of gait dynamics metrics such as ankle power and stiffness in children with hEDS.

## Significance

This novel research is one of few quantitative studies of patients with hEDS. We found that children with hEDS appeared to have differences in moments and powers during gait while joint ranges of motion were not significantly different. The long-term goal of this research is to improve hEDS diagnosis and to develop effective therapeutic interventions based on these dynamic joint differences to maximize quality of life for children with hEDS.

## Introduction

Despite the infinite number of potential strategies for walking, humans tend to walk with a stereotypical pattern. This behaviour is believed to arise, in part, from the optimization of one or more performance criteria related to, for example, energetic cost, stability, or smoothness [1]. However, optimization of motor patterns is a computationally challenging problem if one considers, for example, muscle activations at each time point to be separate decision variables. Solving the control problem in this manner requires high-dimensional trajectory optimization. Also, it is believed that when humans encounter a change or disturbance imposed by the environment the corresponding reactive responses have a synergistic structure [2].

Dynamical movement primitives (DMPs) have been proposed as low-dimensional control policies to account for the synergistic structure of motor commands [3]. In the present paper, we used positive mechanical cost of transport as the cost function of interest for our optimizations. We hypothesized that we can learn the DMPs for nominal walking kinematic data and, using an energy optimization framework, generalize these motor patterns to different walking speeds and explain metabolic cost measures observed experimentally.

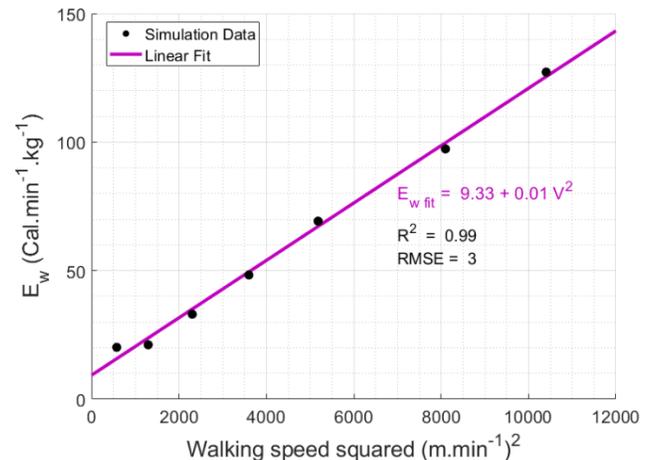

## Methods

We constructed an anthropometric biped that walks on a treadmill in the sagittal plane in Matlab SimScape. The biped consisted in three degrees of freedom (DOFs), including hip, knee and ankle flexion/extension on each limb and two translational plus one rotational DOF in the torso. The lower-extremity joints were actuated by motors designed in Matlab Simulink. Also, the biped-treadmill interaction was modelled via viscoelastic elements. We represented each joint angle trajectory as a DMP where we fit the joint angle timeseries from a single participant walking at 1 m/s using locally weighted regression with Gaussian kernels.

The task was for the biped to complete a full stride starting from right push-off. We used positive mechanical cost of transport as the cost function and also added penalties to this cost term to satisfy equality constraints on the initial and final states to ensure a cyclic gait behavior. We used a genetic algorithm to find the energetically optimal walking patterns where the decision variables of interest were the gait period and joint angle amplitudes. These were the two free parameters used to manipulate the DMPs.

## Results and Discussion

We found a linear relationship between the positive mechanical energy expenditure and the walking speed squared (Figure 1). These results are similar to those from Ralston [4], which showed that there is a linear relationship between metabolic rate and the walking speed squared.

**Figure 1:** We found a linear relationship between the simulated optimal energy expenditure and the square of walking speed.

After normalizing this relation by the speed, we found the optimal speed of walking to lie around 0.7 m/s. This differed from the corresponding energy optimal speed value in experiments, shown to be ~1.3 m/s [4]. This likely occurred simply because in the literature, the energy expenditure is based on respiratory data, while in our model, there was no energy cost associated with standing still since we did not simulate muscle-like resting energy cost. This could result in having resting state or isometric energy terms ruled out from the modeling. Hence, a next step could be to use a more physiologically plausible model of energetics as the cost function in our optimizations.

## Significance

Understanding whether there are quantifiable performance criteria that can explain a wide range of observed human behaviors is a fundamental question of human motor control. A benefit of using a low-dimensional optimization framework is that it will need less number of variables in optimization, thus it will take far less time to find the optimal patterns, compared to full trajectory methods. In addition, it is more consistent with the concept of synergistic control of movement, which may better mimic the physiological constraints on learning and control.

### Introduction

Up to 35% of sedentary women get injured, when they start participating in physical activity [1]. Sedentary adults are often encouraged to walk for physical activity, which leads to 25% of all adults getting overuse injuries [1]. Patellofemoral pain (PFP) occurs in 10% to 23% of young adults [2,3]. Thus, sedentary young adult women may be at risk for PFP during walking. The pathomechanical model hypothesizes that small peak knee flexion angle and peak knee extensor moment during walking would likely increase stress on the patellofemoral joint leading to PFP [4]. Additionally, large knee abduction and external rotation angles and hip adduction and internal rotation angles at peak knee extensor moment have also been associated with PFP [4]. The purpose of the study was to determine differences in walking biomechanics associated with PFP following 30 minutes of walking in sedentary and active young adult women.

### Methods

Thirty (15 sedentary, 15 active) young adult women (age: 23 (3) years; height: 1.64 (0.08) m; mass: 61.6 (9.6) kg) were recruited and provided written informed consent. Retroreflective markers were placed on the lower extremities and trunk of participants to define joint centers and track body segments [5]. Participants walked across the gait laboratory for five good trials at  $1.4 \pm 5\%$  m/s. Three-dimensional gait analysis was performed using motion capture sampling at 200 Hz and force plates sampling at 1000 Hz. Next, participants walked for 30 minutes on a treadmill at a self-selected pace where they could “talk but not sing” per Centers for Disease Control and Prevention (CDC) physical activity recommendations [6]. Participants then walked for five additional good trials across the gait laboratory.

Joint angles were determined using joint coordinate systems [5] and joint moment was determined using inverse dynamics. Peak knee flexion angle and peak knee extensor moment were determined during the first 60% of stance. Data were filtered using a low pass fourth-order Butterworth filter at 6 Hz. Means, standard deviations, and effect sizes were determined for all variables of interest. Dependent t-tests were used to compare peak knee flexion angle and extensor moment before and after 30 minutes of walking. A p-value of  $< 0.05$  was considered significant. Findings were also compared to minimum detectable differences (MDDs) determined from laboratory data (Table 1).

Table 1: Walking biomechanics before and after 30 minutes of walking in young adult women

	Sedentary (n=15)			Active (n=15)			MDD
	Before walk Mean (SD)	After walk Mean (SD)	Effect size (d)	Before walk Mean (SD)	After walk Mean (SD)	Effect size (d)	
<b>Peak knee flexion angle (°) *</b>	13.7 (5.2)	15.9 (5.5)	0.4	16.8 (4.8)	18.2 (5.6)	0.3	3.6
<b>Peak knee extensor moment (Nm/kg)</b>	0.44 (0.22)	0.53 (0.20)	0.5	0.61 (0.21)	0.64 (0.22)	0.1	0.15
<i>Knee abduction angle (°)</i>	-0.1 (2.1)	-0.1 (2.8)	0.0	0.2 (3.3)	1.0 (3.8)	0.2	1.3
<i>Knee external rotation angle (°)</i>	8.0 (4.0)	6.0 (4.5)	0.5	3.5 (4.4)	0.9 (4.4)	0.6	2.6
<i>Hip adduction angle (°)</i>	9.3 (2.3)	9.2 (2.7)	0.0	8.6 (2.6)	8.6 (2.7)	0.0	1.2
<i>Hip internal rotation angle (°)</i>	6.0 (4.7)	2.8 (5.7)	0.6	5.4 (4.7)	1.6 (4.7)	0.8	1.6

\*:  $p < 0.05$ ; Nm/kg: Newton-meters per kilogram; primary variables: bold; secondary variables at peak knee extensor moment: italics

### Results and Discussion

Sedentary and active young adult women had similar responses to 30 minutes of walking (Table 1). Peak knee flexion angle significantly increased following 30 minutes of walking in the sedentary ( $p=0.026$ ) and active ( $p=0.045$ ) groups. However, these increases had small effect sizes and did not increase more than the MDD in either group. Peak knee extensor moment did not change following 30 minutes of walking in the sedentary ( $p=0.061$ ) and active ( $p=0.210$ ) groups. These results suggest that the stress on the patellofemoral joint likely did not increase following 30 minutes of walking. These findings are similar to those previously determined for peak knee flexion angle and extensor moment in active young and mid-life adults following 30 minutes of walking [7,8]. The results for knee abduction and external rotation angles and hip adduction and internal rotation angles at peak knee extensor moment further support this finding.

Overall, there were only a few biomechanical changes following 30 minutes of walking in sedentary and active young adult women, none of which were associated with PFP. Therefore, walking for 30 minutes did not increase stress on the patellofemoral joint, indicating no increased risk of PFP in either sedentary or active young adult women.

### Significance

Our findings suggest that both sedentary and active young adult women can walk for 30 minutes without detrimental changes to walking biomechanics that may increase their risk of PFP. Thus, sedentary young adult women can safely follow CDC guidelines to walk for physical activity at a pace where they can ‘talk but not sing’.

# Biomechanical Analysis of Hippotherapy Using 3-D Motion Capture and Surface Electromyography

Anne Marie Holter<sup>1</sup>, Nathan Luzum<sup>1</sup>, Grace Cassidy<sup>1</sup>, Chandler Sizer<sup>1</sup>, Jack Lipold<sup>1</sup>, John DesJardins, PhD<sup>1</sup>

<sup>1</sup>Clemson University Department of Bioengineering

Email: jdesjar@clemson.edu

## Introduction

Hippotherapy is the use of horseback riding as an alternative intervention within physical rehabilitation. This is useful because patients are stimulated to produce 3D movements and muscle excitation patterns that they may not be able to produce on their own<sup>1</sup>. Specifically, it is believed the pelvic motion of the horse is transferred to the rider and generates human kinematics similar to walking, which could be beneficial in the area of gait rehabilitation<sup>2</sup>. The scope of this research is to track horse and rider biomechanics with surface electromyography (EMG) and 3-D video motion capture to monitor horse kinematics and rider biomechanic responses. To further test musculature activation similarities, EMG was paired with motion capture data. It was hypothesized that horseback riding would stimulate similar biomechanic response in the rider compared to healthy gait.

## Methods

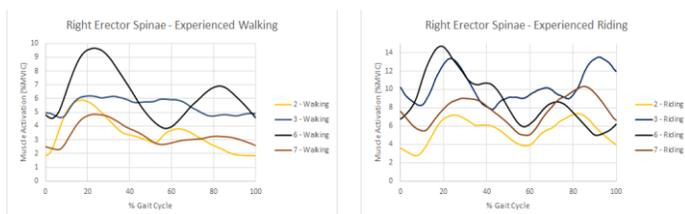

Ten college aged females (18–22 yr) with no known gait impairments and normal BMI (19–24) were enrolled in this study and divided into two control groups, novice and experienced horseback riders. Reflective biomarkers were placed on anatomical landmarks of the subjects and horse for the 3-D video motion capture (Qualisys, Sweden) tracking. Each subject was also equipped with eight EMG sensors (Biometrics, LTD, United Kingdom). These sensors were placed on four key muscle groups (rectus femoris, biceps femoris, rectus abdominis, erector spinae) on each side of the body. Each subject was analysed while horseback riding and while walking on a treadmill at fixed speeds. Three passes were recorded for riding and walking, and a single stride was chosen for each pass and were averaged for single stride comparison.

## Results and Discussion

A summary of EMG data is shown in **Table 1**. EMG waveform data for the right erector spinae can be seen in **Figure 1**. These waveforms were recorded for each of the four muscles of interest.

Comparison	( $\alpha = 0.05$ )
Novice Average - Walking vs. Riding	N/A
Experienced Average - Walking vs. Riding	R. E.S
Novice Maximum - Walking vs. Riding	N/A
Experienced Maximum - Walking vs Riding	R. E.S

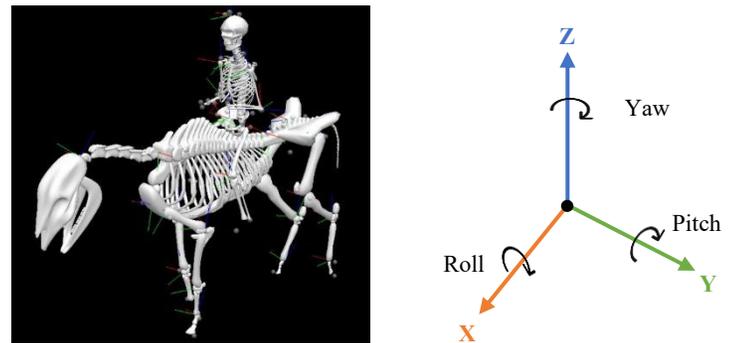

**Table 1:** EMG Data Statistical Summary - 8 muscle data sets within each comparison group. Only right erector spinae in experienced average signals and maximum signals were considered significantly different.

**Figure 1:** Right Erector Spinae EMG Waveform Data

Overall, very little significant differences existed between the peak and average muscle activity of walking and riding in both control groups (**Table 1**). The right erector spinae (R. E.S.) had significantly greater average and peak contractions in the experienced control group while riding. However, all other muscular activity within groups exhibited no significant differences between walking and riding. The significant activity in the right erector spinae may be due to Rider 6's large peak activity, however, they have not been ruled as an outlier because their kinematic riding patterns may provide further insight. The lack of significant differences between walking and riding suggests that horseback riding may stimulate rider musculature similarly to normal, healthy gait.

Sample EMG waveforms exhibited two-peak activity within walking and riding, again referencing their kinematic similarities (**Figure 1**). 3D video motion capture data is still being processed. Rider pelvis and torso Roll, Pitch, and Yaw kinematic patterns will be of interest and angular range of motion will be compared between walking and riding, and further cross correlated to corresponding muscle excitation.

**Figure 2:** Human and rider skeletal model with reference axis

## Significance

Hippotherapy is largely under researched and this data will help lay groundwork for further quantification of horse-rider biomechanical relationships. Specifically, our research group intends to use equine assisted activities as a physical therapy intervention for post-stroke patients, with a focus on gait rehabilitation. This form of physical intervention has the potential to fulfill the need for pelvic movement exercises that stimulate cyclic gait patterns and muscular trunk control.

## Acknowledgments

Our research group would like to acknowledge the Clemson University Equine center for their continued assistance and use of facilities.

# Developing a Synergistic Control Strategy for Knee and Ankle Exoskeleton Assistance

Safoura Sadeqh Pour Aji Bishe<sup>1</sup>, and Zachary F. Lerner<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Northern Arizona University, Flagstaff, AZ, USA

## Introduction

Many studies have been conducted to design exoskeletons in order to assist impaired walking [1], [2]. However, no viable options are available for individuals with moderate-to-severe neuromuscular impairment, like from cerebral palsy (CP), but who are able to walk in some capacity [3]. Commercial full-body exoskeletons, like the EksoGT from Ekso Bionics, are likely too big, bulky and slow to help a child with some walking ability. At the same time, light-duty, single joint exoskeletons may not provide enough assistance for patients with severe CP to walk independently. Therefore, our goal is to design a device that fits in the middle: a lightweight multi-joint exoskeleton where each joint works in coordination with one other.

Our first objective was to develop a simple real-time knee as well as ankle joint moment prediction model and verify our model by comparing the predicted joints moment with the that of estimated by Opensim<sup>®</sup>. Our second objective was to use the model to create an adaptive control strategy capable of providing synergistic ankle and knee assistance based on real-time joint moment estimation. We validated our synergistic controller through comparing the metabolic cost of transportation and ankle as well as knee joints angles with a reference controller by testing on an unimpaired individual.

## Methods

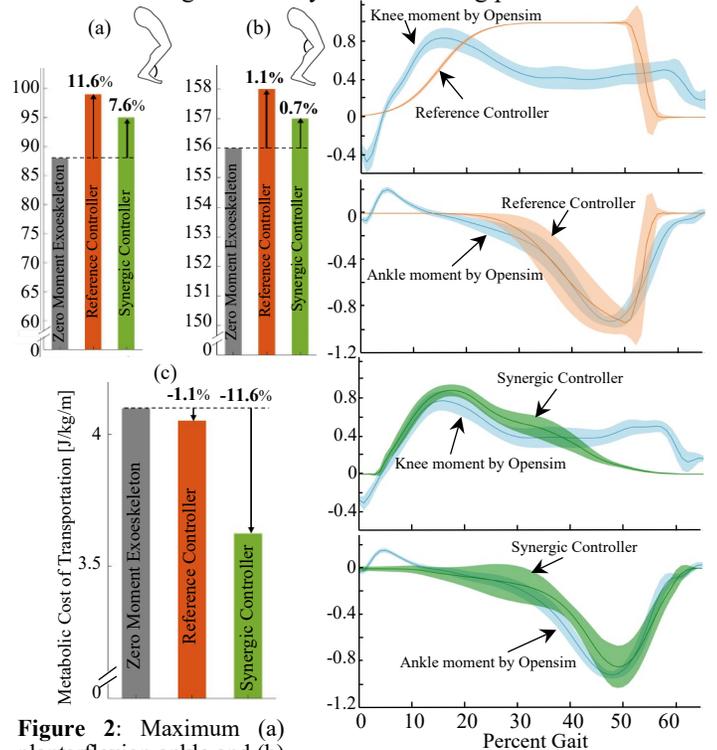

We developed a strategy to control a light ankle-knee exoskeleton based on the calculated biomechanical moment of the respective joints. We used Force Sensitive Resistors (FSRs) to estimate ground reaction forces. The ankle and knee joint moments were calculated using inverse dynamics equations. Then, the joint moments were normalized by dividing by the maximum joint moment during baseline walking. The magnitude of the desired moment was set based on the user's preference. The reference controller was a function of time, providing knee assistance during the stance phase and ankle assistance during the mid-late stance phase. An unimpaired subject was asked to walk over a treadmill while wearing our ankle-knee exoskeleton with (1) zero assistance, (2) the reference controller, and (3) the synergistic controller.

**Figure 1:** The schematic of our biomechanical model of foot-shank, the control strategy based on this model, and the ankle-knee exoskeleton designed in NAU Biomechatronic Lab.

## Results and Discussion

Statistical indices ( $R^2$  of 0.91 and 0.45 as well as root mean square of 0.10 and 0.24 for ankle and knee respectively) shows that our model could predict the ankle plantar flexion moment and stance phase knee moment with reasonable accuracy. The assistance provided by our synergistic control strategy reduced the metabolic cost of walking 11.6%, while the reference controller only reduced it by 1.1% relative to zero moment assistance. Our novel control strategy increased the ankle plantar flexion and knee extension angle of the unimpaired subject during the stance about 7.6% and 0.7% respectively, which is less than the increased angles in the case of walking with the reference controller (11.6% and 1.1%). It means that our synergistic controller decreased the unimpaired individual's cost of walking without effecting remarkably on her walking pattern.

**Figure 2:** Maximum (a) plantarflexion ankle and (b) knee extension angle during stance phase in degree. (c) Metabolic cost of walking.

**Figure 3:** Normalized ankle and knee joint moment estimated by Opensim in compare to the synergistic controller and a reference controller during stance phase.

## Significance

There have been many studies on control strategies for exoskeletons for patients with CP to overcome their walking restriction, but there is a dearth of research on an exoskeletons adaptive-synergistic control strategy for individuals with severe CP, and therefore much research is needed in this area. The ultimate goal of this research is to design a synergistic control strategy suitable for assisting individuals with severe CP.

# Kinematic Response to Adaptive Speed Treadmill versus Fixed Speed Treadmill Walking in Older Adults

Parker, Sheridan M<sup>1</sup>, Hedrick, Erica A.<sup>1</sup>, Knarr, Brian A<sup>1</sup>

<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha NE, USA

## Introduction

Previous literature has reported that treadmill walking at a fixed speed can lower the joint angle kinematic variability of individuals compared to overground walking, as typically seen in a community dwelling environment [1,2]. It is thought that these changes might be due to differences in neuromuscular control on a fixed speed treadmill as a result of constraining the individual's walking speed [2,3]. This study used a novel Adaptive Speed Treadmill (AST) controller to attempt to emulate overground walking based on kinetic and spatio-temporal walking parameters by including unconstrained walking speed as a factor during treadmill walking [4]. However, the kinematic response between Fixed Speed Treadmill (FST) walking and AST walking is not well understood.

The aim of this study is to determine the kinematic response exhibited between AST and FST walking in older adults. Our first hypothesis is that older adults will walk faster on the AST as the AST more closely emulates overground walking. Our second hypothesis is that older adults will exhibit increased hip, knee, and ankle flexion while walking on the AST as the AST allows for unconstrained walking speeds close to overground walking.

## Methods

Sixteen older adult subjects participated in the study (14F, 69.6±4.9 years, 1.6±0.1m, 73.1±12.7kg). The FST condition consisted of three minutes of walking at the participants' self-selected walking speed. The AST condition consisted of three minutes of walking using an adaptive speed treadmill controller. Based on Ray et al. (2018) which found that young healthy adults walk faster on the AST, we have grouped our participants as Responders (RESP), participants who walked faster on the AST, and Nonresponders (NRESP), participants who walked faster on the FST [4]. A 14 camera motion capture system was used to collect hip, knee, and ankle joint kinematics.

Sagittal plane hip, knee, and ankle joint angles were filtered using a 6Hz cut off Butterworth filter. Stride normalized left and right sagittal plane hip, knee, and ankle joint angles were calculated for both FST and AST conditions. Data analysis was performed in Visual 3D and Matlab R2018a.

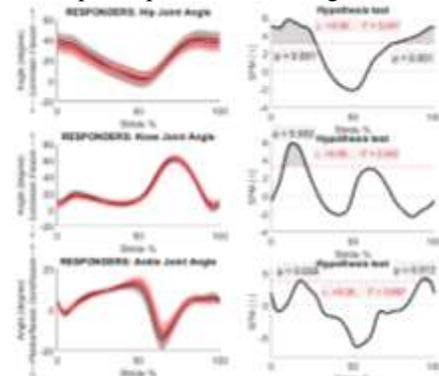

Our previous analysis reported no statistical differences in peak sagittal joint angles for FST and AST conditions for this population. Statistical Parametric Mapping (SPM) analysis was performed for sagittal plane hip, knee, and ankle joint angles comparing AST and FST conditions for both the RESP and NRESP groups to determine kinematic differences throughout the gait cycle. Statistical analysis was performed in Matlab R2018a with significance set to  $\alpha \leq 0.05$ .

## Results and Discussion

Twelve participants walked 0.3±0.2 m/s faster on the AST and were included in the RESP group while four participants walked 0.1±0.1 m/s faster on the FST and included in the NRESP. For the RESP group during the AST condition a 3.1° increase in knee flexion, a 3.8° increase in hip flexion and, a 0.8° increase in ankle dorsiflexion during the loading phase (0-20% stance) was

exhibited (Figure 1). Additionally, during terminal swing (90-100% stance) a 3.3° and 1.4° increase in hip flexion and ankle dorsiflexion, respectively, was exhibited during the AST condition. These values are comparable to previously reported minimal detectable changes for overground walking in older adults [5]. Differences in the loading phase indicates that the RESP group might be changing their kinematic strategy in favor of a more pronounced heel strike and a shorter loading phase due to an increase in walking speed compared to the FST. The 3.3° hip flexion and 1.4° ankle dorsiflexion increases observed during terminal swing may be due to either increases in trunk flexion or earlier activation of the quadriceps and ankle dorsiflexors to increase step length as a result of a 0.3±0.2 m/s increase in walking speed and in anticipation of a shorter loading phase.

There are no significant differences between treadmill conditions for all three sagittal plane joints for the NRESP group, indicating that the NRESP group is not changing their kinematic strategy in response to the different treadmill types. This is potentially due to participants constraining their walking speed.

**Figure 1:** SPM analysis for the RESP participant group. Left graphs depicts stride normalized joint angles for AST (black) and FST (red) conditions. Right graphs show the statistical t-test results for each point during stride.

## Significance

These results indicate that including unconstrained walking speed during treadmill walking via an adaptive speed controller may change the kinematic strategy used by individuals that walk faster compared to a fixed-speed treadmill. Future research is needed to compare AST kinematics to overground community dwelling walking kinematics to determine if the AST is a suitable device for research and/or therapy in clinical populations.

## Introduction

An active gait exoskeleton has the potential to improve a wearer's mobility by providing lower limb torque assistance. To do this, the exoskeleton must have an accurate estimate of the intended gait pattern of its wearer. However, intent recognition with accurate gait estimates is difficult to achieve. As each device creates unique laden mass to the wearer, the wearer will respond with unknown changes to their baseline kinematics. Prior studies have shown that these changes are small but observable [e.g. 1]. Prior results are limited as the subjects were mostly young, healthy males walking on a treadmill, which alters joint kinematics [2]. In this work, we aim to increase understanding of the influence of added mass by presenting the kinematic and kinetic changes of 10 young, healthy participants (6 females and 4 males) who performed overground walking with 6 different conditions of laden mass on their lower body. Our long-term goal is to provide guidance for exoskeleton design which minimizes the estimated changes to the wearer's baseline, or unladen, gait.

## Methods

Ten participants (20-25 years of age) who gave written informed consent completed the IRB approved study. Each participant performed overground walking at a self-selected speed with added masses: 2 or 4 pounds on each shank, 2 or 4 pounds on each thigh, and 8 or 16 pounds on the waist. The 6 added mass conditions were randomized, with 5 trials per condition. An 8-camera Vicon motion capture system tracked reflective markers (n=43) placed on the torso, pelvis, and lower limbs and data were post-processed using Nexus 2.9. Ground reaction forces were recorded on 2 Bertec force plates. Kinematics and kinetics were estimated in OpenSim using subject-specific models. Sagittal plane hip, knee, and ankle kinematics and kinetics were averaged across each subject for each condition. Mean differences in kinematics and kinetics relative to baseline were analyzed [3].

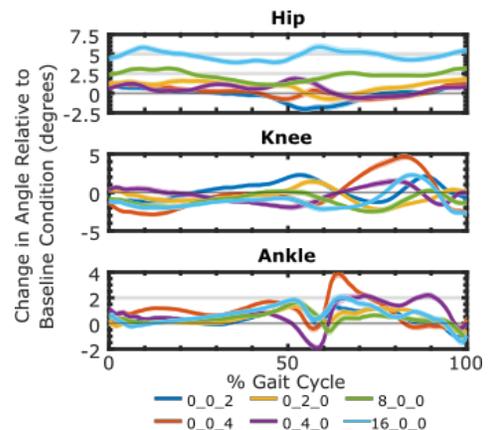

## Results and Discussion

Added mass at the waist, thigh, and shank caused observable changes (<6°) in kinematics relative to baseline (Fig. 1). Changes in joint kinetics were also observable (<0.2 N-m/kg).

Both levels of added waist mass increased hip flexion during the gait cycle, with the 16 pound mass causing the largest changes of 4-6° (Fig. 1: 8\_0\_0, 16\_0\_0). The peak hip flexion moment in late stance was also decreased by up to 0.1 N-m/kg with the 16 pound mass. Despite the larger influence on the hip, changes in both the knee and ankle joints were small for added waist mass. Thus, an exoskeleton design with added waist mass below 8 pounds may reduce changes in walking considerably.

Added thigh mass (Fig. 1: 0\_2\_0 and 0\_4\_0) had the smallest overall impact on the joint kinematics. Both levels of added thigh mass caused joint angle changes under 2° relative to baseline. Added thigh mass also influenced the kinetics, with the 4 pound mass decreasing the peak hip flexion moment and the plantarflexion moment in late stance by ~0.1 N-m/kg. This suggests that exoskeleton designs with up to 4 pounds of thigh mass will be well tolerated by young adults in walking.

Added shank mass, particularly the larger 4 pound mass, caused the largest changes in both knee and ankle kinematics relative to baseline (Fig. 1: 0\_0\_2 and 0\_0\_4). The 4 pound mass led to the largest changes observed at both the knee and ankle joint. The 4 pound mass increased knee flexion throughout stance and reduced knee flexion during the majority of swing reaching a peak of ~5° at 85% of the gait cycle. The larger shank mass caused relatively small changes in ankle angle during stance, but caused larger changes to the ankle kinematics during swing phase. Both levels of added shank mass increased the hip flexion moment in late stance and caused the largest changes in the ankle moments. Therefore, our younger adults had less ability to adapt to added shank mass that is typical of ankle exoskeletons.

**Figure 1.** Mean kinematic changes relative to the baseline condition. Shaded bands are the 95% confidence intervals (CI). Regions where the CI bands do not cross zero were considered statistically significant [3]. Legend indicates added waist, thigh, and shank mass in pounds.

## Significance

As added thigh mass up to 4 pounds was well tolerated by the younger adults, an exoskeleton design that adds thigh mass will likely induce the smallest changes during walking. Although added mass at the waist caused larger changes at the hip, the smaller 8 pound mass caused minimal alterations at the knee and ankle. Therefore, exoskeletons may be better designed if they limit added mass to below 4 pounds and distribute mass across the thigh and waist. Our results suggest that younger adults have the capacity to adapt to added masses representative of an exoskeleton. However, our results are limited since other potential populations for exoskeleton use, i.e. older adults, likely do not have the same capacity to adapt. Future work will extend this study to observe how older adults (65-85 years of age) respond to added mass during walking.

# Treadmill Belt Acceleration Timing Affects Stability During Walking

Esmeralda Vazquez<sup>1,2</sup>, Pawel R. Golyski<sup>2</sup>, Jennifer K. Leestma<sup>2</sup>, and Gregory S. Sawicki<sup>2</sup>

<sup>1</sup>South Atlanta High School, <sup>2</sup>Georgia Institute of Technology

## Introduction

Balance is a major health problem in the United States, with around 30% of adults over 65 years old falling each year – often caused by trips or slips [1]. In a laboratory setting, treadmill belt accelerations are a reproducible way of emulating slips [2]. Previous research using treadmill belt accelerations looked at the effect of acceleration magnitude on walking stability but overlooked the effect of *when* in the gait cycle the perturbation is delivered [3].

During 15-20% of the gait cycle is when a single foot is flat on the ground during initial support and the body's center of mass is posterior to the foot. This leads us to hypothesize that between 15 and 20% of the gait cycle is when individuals are most vulnerable to losing balance during walking due to a rapid treadmill belt acceleration.

## Methods

We had 10 subjects walk on a split-belt treadmill at 1.25 m/s while rapid (15 m/s<sup>2</sup>), brief (0.2 sec) accelerations were applied to a single treadmill belt in a randomized order. While the subjects walked, we “slipped” each leg 10 times at 10, 15, 20, 30, 40, and 50% of the gait cycle. We used three metrics to quantify stability of the step before, during, and for four steps after the perturbation. The three metrics we used to quantify balance were mediolateral dynamic stability margin [4], step width, and step length. Increased dynamic stability and step width, as well as decreased step lengths indicated a participant was destabilized. A linear mixed model was used to evaluate the influence of slip timing for each step. Bonferroni-corrected pairwise comparisons were used for post-hoc tests. An  $\alpha \leq 0.05$  indicated significance. All slips that resulted in balance metrics  $>3x$  the interquartile range were excluded from analysis (12.7% of the data were excluded).

## Results and Discussion

Dynamic stability margins were largest (i.e. subjects were most destabilized) for slips that occurred at 20 and 30% of the gait cycle during the step after the perturbation (Figure 1a). Step widths were larger for 20% slips during the second and third steps after the perturbation (Figure 1b). Step lengths were smaller after

slips delivered at 20 and 30% during the second step after the perturbation (Figure 1c). Our results partially support our hypothesis of 15-20% of the gait cycle being sensitive to slips, but slips delivered at 30% of the gait cycle were also destabilizing as measured by dynamic stability margin, step width, and step length. The reason for this discrepancy could be that our hypothesis was based off of static postures throughout the gait cycle, but velocity is also a major contributor to dynamic stability. Additionally, there was a strong mediolateral response to a posterior belt slip. For example, during slips delivered at 20% of the gait cycle, we found a 43% increase in step width, which is substantially larger than responses due to sinusoidal mediolateral translations of the floor (5% increase) or visual field motion (22%) with 5 cm amplitudes [5].

## Significance

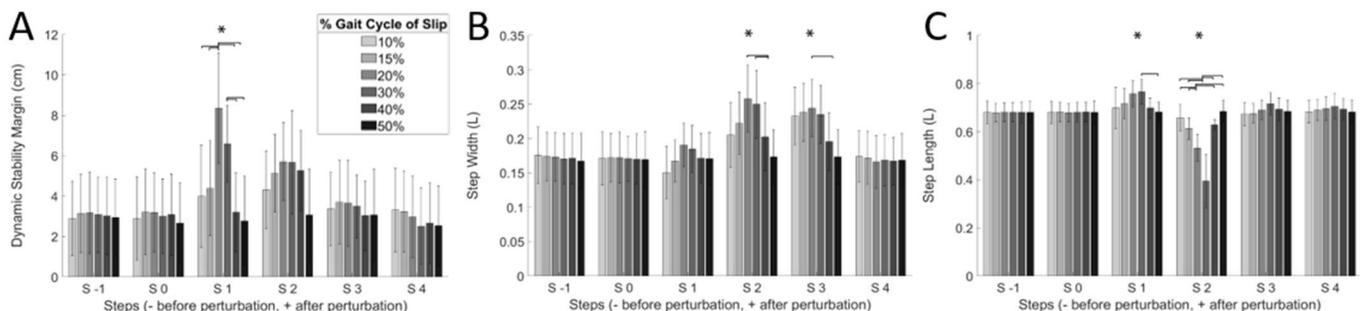

Despite the wide variety of perturbations used to study stability during walking, the extent to which stability varies as a function of the gait cycle is not understood. We found differences in subject stability responses across 6 treadmill belt acceleration timings, with the largest responses occurring during perturbations applied closer to midstance. This finding suggests that to most effectively quantify a person's limit of stability with a belt acceleration, slips should not be applied during heel strike, as is common in literature, but closer to midstance. Furthermore, wearable robots and training regimens designed to prevent slips/trips during walking may also need to prioritize assisting muscles active during midstance.

<sup>3</sup>Department of Kinesiology, East Carolina University, Greenville, NC, USA

email: willsonj@ecu.edu

## Introduction

Plantar fasciitis (PF) is one of the most common musculoskeletal pathologies of the foot, affecting 10% of the American population at least once in their lifetime (1). Mechanical factors are believed to contribute to the etiology and exacerbation of PF. The plantar fascia is the principle supporting structure of the medial longitudinal arch, providing storage and release of elastic strain energy during walking due to the windlass mechanism and arch-spring mechanics (2). Despite the relevance of foot mechanics for this common condition, foot and ankle kinetics in people with PF are largely unknown. The purpose of this study was to compare metatarsophalangeal and ankle joint kinetics during walking between people at different stages of PF.

## Methods

11 people (51 yr, 8 female) with symptomatic plantar fasciitis (SYMP), 6 people (43 yr, 5 female) with a history of plantar fasciitis but no longer symptomatic (ASYMP), and 10 individuals (31 yr, 5 female) with no history of plantar fasciitis (control) provided informed consent and participated in this study. Bilateral 3D lower extremity kinematics (200 Hz) and ground reaction forces (1000 Hz) were recorded during walking on an instrumented treadmill at 1.3 m/s in standardized footwear. Rigid body inverse dynamics and a multi-segment foot model were used to calculate metatarsophalangeal (MTP) and talocrural (TC) joint peak concentric and eccentric power and work. For the SYMP and ASYMP groups, only the symptomatic (n=17) or formerly symptomatic leg (n=9) were included. Both limbs of the control group were used for analysis (n=20). To account for bilateral observations, a mixed effects model with group as a fixed factor and participant as a random factor was used to test for differences in MTP and TC joint power and work between groups. Cohen effect sizes (d) were calculated to describe the magnitude of the difference between groups.

## Results and Discussion

Concentric MTP joint contributions to propulsion occurred following eccentric contractions during the terminal stance phase of walking. Lower mean concentric MTP joint power and work were observed among participants in the SYMP group. Specifically, peak concentric MTP joint power was 37% lower ( $p = .02$ ,  $d = 1.26$ ) than the ASYMP group and 14% lower than the CON group ( $p = .16$ ,  $d = .49$ ). Similarly, concentric MTP joint work in the SYMP group was 46% lower than the ASYMP group ( $p = .01$ ,  $d = 1.14$ ) and 16% lower than controls ( $p = .16$ ,  $d = .57$ ). Eccentric MTP joint power and work were similar between groups. Concentric and eccentric talocrural joint power and work were also similar and within 10% between groups.

The decreased MTP concentric joint power and work during walking reported here for the SYMP group may represent gait adaptations to avoid symptoms, increased energy loss following plantar fascia stretch due to increased hysteresis during the stretch-shortening cycle, or both. Our lab previously identified

decreased plantar fascia longitudinal stiffness among people with symptomatic plantar fasciitis (3), which may contribute to this observed reduction in MTP joint function during gait.

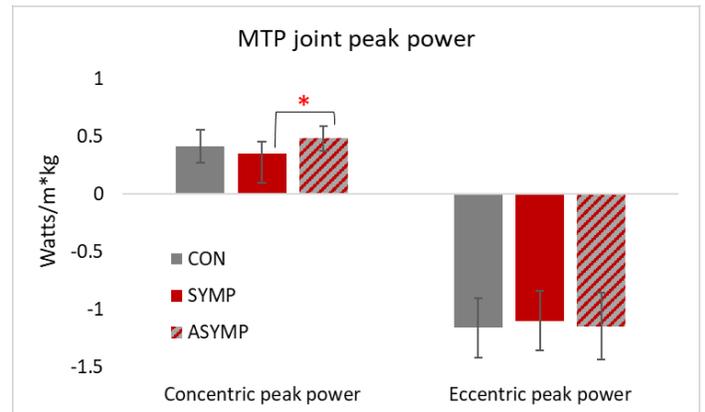

Figure 1. Peak concentric and eccentric MTP joint power during walking in people with symptomatic plantar fasciitis (SYMP), a history of plantar fasciitis but who are no longer symptomatic (ASYMP), no history of plantar fasciitis (CON). Error bars represent  $\pm 1$  SD.

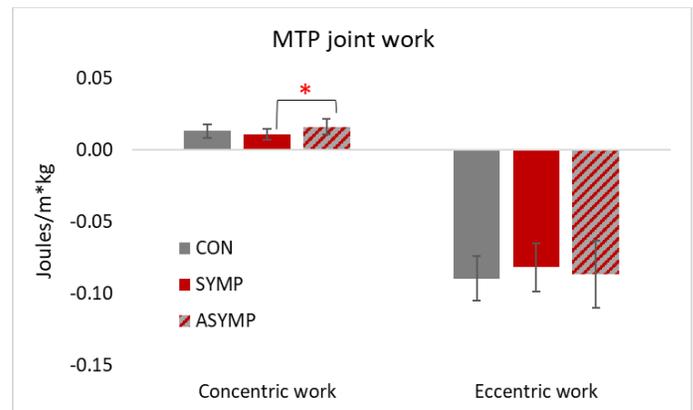

Figure 2. Concentric and eccentric MTP joint work during walking in people with symptomatic plantar fasciitis (SYMP), a history of plantar fasciitis but who are no longer symptomatic (ASYMP), and no history of plantar fasciitis (CON). Error bars represent  $\pm 1$  SD.

## Significance

People with symptomatic PF experience lower MTP joint contributions to propulsion during walking than people without PF with no evident redistribution of load to the ankle. These findings may contribute to gait-related disability and low health-related quality of life in persons with symptomatic PF.

## Introduction

As we age, cognition declines. Continuous declines in cognition may lead to cognitive impairments, and older persons with cognitive impairments demonstrate variable and unstable gait patterns while walking overground (1,5). Variable and unstable walking in older adults with cognitive decline could potentially lead to falls (3). Walking on a treadmill at a fixed-speed constrains walking patterns and reduces gait variability during treadmill walking (4). However, it is unknown if cognitive faculties influence the variability of walking patterns during treadmill walking at fixed speeds. The purpose of this study was to investigate if gait variability during treadmill walking is similar for healthy older adults with lower cognitive function compared to healthy older adults with higher cognitive function. We hypothesized older adults with poor cognitive function would exhibit more variable gait patterns while walking on a treadmill compared to older adults with high cognitive function.

## Methods

30 age-matched ( $\pm 2$  years) healthy older adults ( $73 \pm 3.5$  years; 10 men) were divided into two groups based on their Montreal Cognitive Assessment (MoCA) score, a paper-based test of global cognitive function. 15 participants with a MoCA score  $\leq 23$  were placed in the “Low Cognition” group (average score:  $21 \pm 2$ ), while 15 participants with a score  $\geq 27$  were placed in the “High Cognition” group (average score:  $28 \pm 1$ ). MoCA scores  $\leq 23$  are indicative of clinically relevant cognitive impairment (2). Participants with a MoCA score between 24–26 were not included in the analysis. Three-dimensional motion capture technology recorded kinematic data as participants walked on a treadmill for seven minutes at their preferred walking speed. Standard deviation (SD) and coefficient of variation (CV) of gait speed, stride length, cadence, and double support percent during the last 25 cycles of walking were analyzed to quantify gait variability. Stride length, cadence, and double support for each measure of variability were evaluated separately in two, one-way multivariate analysis of variance with average gait speed included as a covariate. SD and CV of gait speed for each group were analyzed in two separate independent t-tests.

## Results and Discussion

Independent t-tests revealed both SD ( $p = 0.304$ ) and CV ( $p = 0.227$ ) of gait speed were not different between groups. For SD of stride length, cadence and double support percent, multivariate tests revealed no significant differences ( $F(3, 25) = 1.228, \lambda = 0.872, p = 0.320$ ) between groups when controlling for gait speed (Table 1). For CV of stride length, cadence, and double support percent, multivariate tests revealed no significant differences ( $F(3, 25) = 0.618, \lambda = 0.931, p = 0.610$ ) between groups when controlling for gait speed (Table 2). The findings suggest gait variability is not affected by cognitive status when walking on a treadmill. Unlike overground walking where gait variability increases

when cognitive ability is impaired (4), the Low Cognition group demonstrated similar variability while walking on the treadmill to age-matched older adults in the High Cognition group. This suggests the constraints of walking at a fixed speed on the treadmill reduces the impact cognitive faculties have on gait variability. Previous studies (6) have shown that while walking overground, executive function is associated with controlling pace (i.e. gait speed, step length). Walking on a treadmill, however, controls these aspects of gait, and is perhaps why no differences in variability were observed between our groups. It is important to note, however, these data were taken from the last 25 cycles of walking at the end of seven-minutes of treadmill walking. It is possible we did not find any significant differences in gait variability between the groups because the participants had acclimated to walking on the treadmill at the time points analyzed. This suggests older adults with low cognitive scores can learn to walk more consistently on a treadmill like older adults with high cognitive scores during short bouts of walking. Future studies should examine gait performance earlier in treadmill walking exposure, or examine changes to gait variability when walking on a treadmill at a fixed speed versus a self-propelled treadmill. This could help us better understand gait variability adaptation in older adults with different levels of cognitive acumen.

## Significance

Older adults with lower cognitive function exhibit similar variability in gait patterns as age-matched older adults with higher cognitive function when walking on a treadmill. It is possible that having healthy older adults with lower cognitive function practice a less variable walking pattern through treadmill training could lead to reduced variability during overground walking. Reduced gait variability could potentially reduce the incidence of falls in this population.

## Introduction

Insufficient knee extension at initial contact (IC) has been identified as clinically frequent and significant among gait deviations in pediatric cerebral palsy (CP). This gait deviation can persist even after a combination of physical therapy, pharmacological, or surgical interventions to improve contracture and spasticity. Biofeedback training that provides participants meaningful cues to augment their inadequate native physiological feedback has shown its potential in gait retraining. However, very few studies have explored biofeedback gait retraining in pediatric CP. In order to help pediatric patients achieve more symmetric and efficient gait, our research team developed a two phase visual kinematic feedback system, and reported a positive effect with one gait retraining session [1]. The current paper reports adaptation to the feedback across multiple training sessions by a pediatric participant with hemiplegic CP.

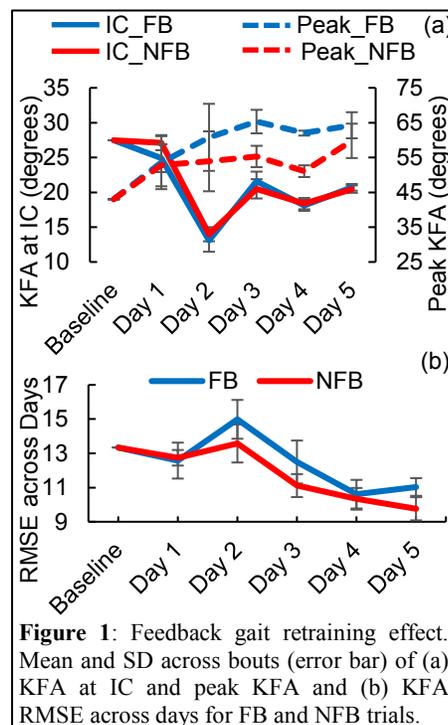

## Methods

Three inertial sensors (MTW Devkit, Xsens, NL) were placed on the participant's thigh, shank and heel. The knee flexion angle (KFA) was defined as the difference between the thigh and shank sensors' rotational orientation about their longitudinal axis. The target knee flexion pattern was selected from typically developing children's patterns. Error metrics were used to drive the feedback display on a computer monitor for the extension and flexion periods via two corresponding needles. A scoring system based on the feedback is incorporated for participant motivation. An adolescent with right hemiplegic CP (male, age 14.7 yrs) who presented with insufficient knee extension at IC and decreased swing phase knee flexion, participated in this study. The participant underwent 5 training sessions over 3 weeks. A baseline trial was recorded during each training day while the participant walked on the treadmill at a comfortable speed. The speed was controlled in four 6-minute training bouts with 3-minutes of rest between bouts. Each training bout included a 3-minute trial with Feedback (FB) and a 3-minute trial with No Feedback (NFB), with the sequence of trials randomized for each bout. For each FB trial, the participant was asked to follow the cues on the monitor and try to modify his knee flexion pattern to rotate the needles towards the target range, whereas for each NFB trial, he was asked to recall and maintain this pattern. The root-mean-square error (RMSE) was calculated from the difference in KFA between the target and the performed patterns. Descriptive statistics were used to describe the changes in KFA at IC, peak KFA, and RMSE across days between FB/NFB conditions.

## Results and Discussion

In comparison with the baseline trial on Day 1, the KFA at IC in the FB and NFB trials both decreased markedly on Day 1 and

Day 2, increased on Day 3, and remained at around 20° on Day 4 and Day 5, while the peak KFA showed an overall increasing tendency from Day 1 to Day 5 (Fig. 1a). The RMSE in the FB and NFB trials both decreased markedly on Day 1, Day 3, and Day 4 (Fig. 1b). A decreasing trend in RMSE was also observed from Day 2 to Day 5. The decreasing standard deviation (SD) of KFA at IC across days indicated that the participant had started to learn the pattern. The increase of RMSE on Day 2 was caused by overcorrected extension during mid and late stance, which was observed in recorded video and also supported by lower extension scores on Day 2 (FB: 22, NFB: 53) compared with Day 1 (FB: 218, NFB: 145). Starting from Day 2, the RMSE in the FB trials was higher than that in the NFB trials (Fig. 1b),

**Figure 1:** Feedback gait retraining effect. Mean and SD across bouts (error bar) of (a) KFA at IC and peak KFA and (b) KFA RMSE across days for FB and NFB trials.

which was attributed to higher peak KFA in FB (Fig. 1a). We expect that increasing the training dosage or number of sessions would help to consolidate adaptation and further reduce error.

## Significance

The multi-session real-time visual feedback training shifted participant's knee flexion trajectory towards the target, with error reduced across training sessions. This paper highlights the presented feedback training paradigm and its potential applications to clinical practice. Testing of a larger sample with a longitudinal examination of functional measures is ongoing.

## Introduction

Measuring metabolic cost is time consuming and cumbersome for both experimenter and participant alike. Despite this drawback, metabolic cost is an important measure for biomechanical studies of locomotion and will continue to be used. Some have estimated metabolic cost using a wide array of measurements such as breathing rate, perspiration, and muscle activity<sup>1</sup>. Others used estimation techniques to approximate steady-state metabolic cost, shortening the duration of collection<sup>2</sup>. As muscles are the primary energy consumers during locomotion and EMG sensors are readily available, it follows that measuring muscle activity could be used to accurately estimate metabolic cost in real-time. One important aspect to metabolic estimation is whether the estimated values follow the same trends as originals (e.g. when walking at a constant speed there is a parabolic trend that determines the metabolically optimal and preferred step frequency (SF)). We hypothesize the metabolically optimal SF will be the same SF to minimize overall EMG activity.

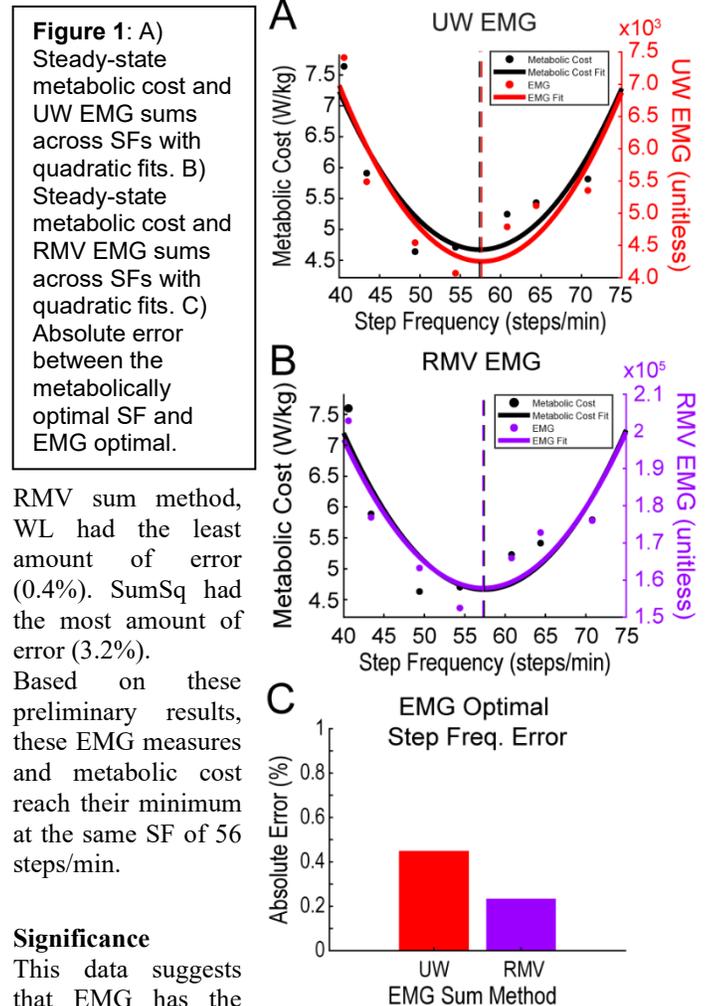

## Methods

We measured EMG and metabolic cost of a healthy adult male while walking on a treadmill at 1.3 m/s. The participant walked for 15 minutes to habituate (preferred SF and  $\pm 20\%$ ), followed by a 35-minute randomized SF sweep between  $\pm 30\%$  of preferred SF (7 trials total at 5 minutes each). SF was commanded using an audible metronome. Ground reaction forces (GRFs) were measured to quantify step durations and segment EMG data per gait cycle. The subject had 8 EMG sensors placed on the following leg muscles: Tibialis Anterior, Medial Gastrocnemius, Soleus, Vastus Medialis, Rectus Femoris, Bicep Femoris, Gluteus Medialis, Gluteus Maximus.

Muscle-specific EMG activity of each trial was quantified using 3 mathematical measures: integral (INT), sum square (SS), and waveform length (WL, i.e. geometric length) between 2.5 and 4.5 minutes. For each measurement, the muscle-specific EMG were summed using weights based on relative muscle volume (RMV) or without weights (unweighted; UW). A quadratic fit was made across trials for each EMG measure and the minimum was calculated. The SF where the minimum value occurred was compared to the metabolically optimal SF. EMG adaptation time (time it takes to reach steady-state, i.e. average of last minute of trial) was the first time when three consecutive steps of the EMG measure were within  $\pm 2$  std of the steady-state value.

## Results and Conclusion

Using the UW sum method, SumSq had the least amount of error (0.5%). WL had the highest absolute error (3.4%). Using the

RMV sum method, WL had the least amount of error (0.4%). SumSq had the most amount of error (3.2%). Based on these preliminary results, these EMG measures and metabolic cost reach their minimum at the same SF of 56 steps/min.

## Significance

This data suggests that EMG has the potential to estimate metabolic cost in real-time while preserving key trends. EMG could be used as a substitute for metabolic measurement, decreasing experimental time and effort. Further, EMG can assist with the optimization of parameters for controls of exoskeletons, as metabolic cost is normally a performance/cost metric. In the future, we plan to investigate how quickly EMG reaches steady-state compared to metabolic cost, directly predict metabolic cost using EMG, and implement this method to optimize exoskeleton control.

# Musculoskeletal Model of Muscle Characteristics with Varied Bodyweight Support

Angel Bu<sup>1</sup>, Mhairi K. MacLean<sup>1</sup>, Han Nguyen<sup>1</sup>, and Daniel P. Ferris<sup>1</sup>

<sup>1</sup>University of Florida, Gainesville, Florida, USA

## Introduction

Bodyweight support can aid gait rehabilitation and provide an experimental perturbation to study human locomotion biomechanics. Increasing bodyweight support causes a decrease in ground reaction forces during walking [1] but it is unclear how bodyweight support affects muscle fiber operating lengths. OpenSim is a predictive musculoskeletal modeling program that can be used for gait analysis in rehabilitation facilities and in research to provide insight into biomechanics [2]. The relationship between muscle activation, velocity, length, and force during movement can be estimated using OpenSim. Our objective was to determine how bodyweight support level during human walking affected muscle activation and muscle fiber length. We hypothesized that muscle activation would decrease with increased bodyweight support and that limb extensor muscle fiber excursion would decrease with increased bodyweight support.

## Methods

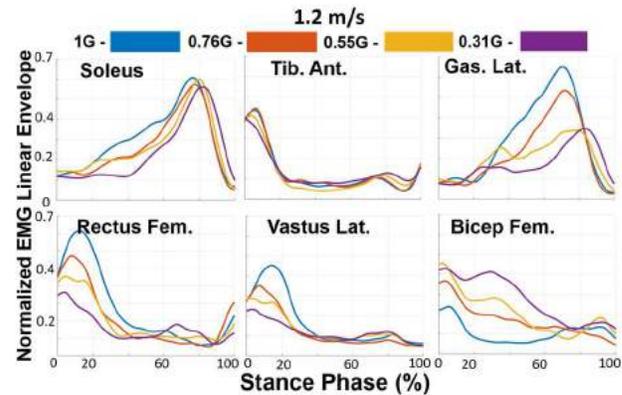

Eight healthy participants [5 female, 3 male; 24±1 years of age, body mass 69±6 kg, mean±s.d.] walked overground at 1, 0.76, 0.55 and 0.31 gravity (G) at approximately 1.2 m/s. We used a custom bodyweight support system mounted to a rolling trolley on the ceiling. The system was attached to a harness which was pulled up by constant force springs. We used overground force plates, a motion capture system, and unilateral electromyography on the right leg to measure ground reaction forces, kinematics, and muscle activity, respectively.

We used OpenSim 4.0 to compute inverse kinematics and inverse dynamics during right leg stance phase, which we used as inputs for muscle analysis to calculate muscle lengths. For each bodyweight support level, we calculated the average normalized fiber length, defined by OpenSim as fiber length/optimal length, across participants. We normalized the electromyography (EMG) linear envelopes to the maximum EMG value for the subject then averaged across bodyweight condition. The data were processed using the MOTO-NMS pipelines [3] and MATLAB.

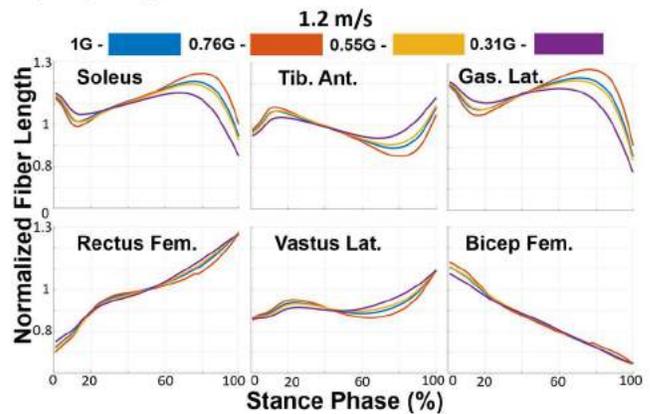

## Results and Discussion

As bodyweight support increased, muscle activation noticeably decreased for all muscles except the biceps femoris which saw an increase in activation (Fig. 1). With increased bodyweight support, every muscle except the biceps femoris long head saw a decrease in normalized fiber length excursion (Fig. 2). Both results were in agreement with our hypotheses.

The bicep femoris showed increased muscle activity with increased support, despite the fiber length excursion showing minimal change. We had expected to find that the increase in muscle activation of the biceps femoris was related to the muscle operating at a different point on the muscle force-length relationship. However, muscle length remained relatively the same.

**Figure 1:** Normalized EMG linear envelopes for 6 muscles at different bodyweight support levels.

**Figure 2:** Normalized fiber length, described as fiber length over the optimal fiber length, calculated during stance phase for 6 muscles at different bodyweight support levels.

## Significance

Bodyweight support affects not only ground reaction forces and muscle-tendon forces, but also can affect muscle fiber excursions during walking as well. As expected, we found a decrease in muscle activation and a decrease in the range of muscle fiber excursion with greater bodyweight support levels. These findings provide insight into the muscle mechanical changes that accompany the use of bodyweight support for rehabilitation and scientific study of walking biomechanics.

## Introduction

Stroke is a leading cause of disability that results in neuromotor impairments that contribute to slower and more inefficient walking. As a consequence, walking rehabilitation is a major focus after stroke. The 6-Minute Walk Test (6MWT) is a popular outcome measure used to assess functional walking capacity after stroke; however, the performance-based metrics often evaluated (e.g., the total distance walked) do not identify the underlying neuromotor impairment. Elucidation of the biomechanical contributors to reduced 6MWT performance is necessary for the advance of individualized rehabilitation interventions that target the specific deficits limiting function. Biomechanical variables such as the peak propulsion force (i.e., the peak of the anterior ground reaction force) and the propulsion impulse (i.e., the integral of the anterior ground reaction force) have been shown to contribute to walking function after stroke<sup>1</sup>; however, these magnitude-based metrics do not account for key temporal aspects of propulsion function that may affect walking after stroke—such as the timing of the propulsion peak<sup>2</sup>. The objective of this study was thus to determine how the timing of the propulsion peak relates to 6MWT performance. We hypothesized that propulsion peak timing would contribute to 6MWT performance above and beyond the propulsion magnitude metrics of peak and impulse.

## Methods

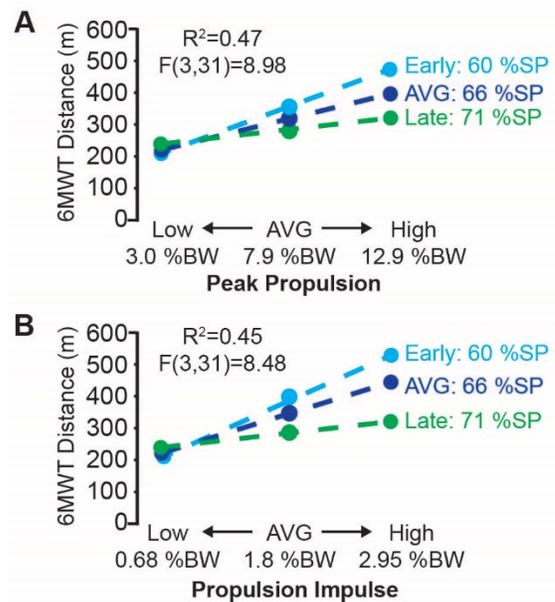

Data for thirty-four individuals with chronic post-stroke hemiparesis were available for this study. The total distance walked during the 6MWT served as the primary clinical outcome of interest. Metrics related to propulsion magnitude (i.e., peak propulsion and propulsion impulse) and timing (i.e., the timing of the propulsion peak) were extracted from the paretic anterior-posterior ground reaction forces generated during 30 seconds of treadmill walking and then averaged. The propulsion magnitude metrics were expressed as %bodyweight (%bw). Peak propulsion timing was expressed as %stance phase (%sp).

All statistical tests were performed in MATLAB 2019a. Two moderated regression models were examined to evaluate the influence on 6MWT distance of the propulsion magnitude metrics and the timing of the propulsion peak. The first model included peak propulsion, peak propulsion timing, and their interaction. The second model included the propulsion impulse, peak propulsion timing, and their interaction. Significant interactions were evaluated at  $\pm 1$  standard deviation of the moderators. Alpha was set to 0.05.

## Results and Discussion

Peak propulsion force ( $R^2 = 0.37$ ,  $p < 0.01$ ) and propulsion impulse ( $R^2 = 0.32$ ,  $p < 0.01$ ) individually contributed to 6MWT distance. Adding peak propulsion timing and its interaction to these models increased the variance explained for both peak propulsion force ( $R^2 = 0.47$ ,  $adjR^2 = 0.41$ ,  $F(3,31) = 8.98$ ,  $p < 0.01$ ) and propulsion impulse ( $R^2 = 0.45$ ,  $adjR^2 = 0.40$ ,  $F(3,31) = 8.48$ ,  $p < 0.01$ ). Significant interactions with peak propulsion timing in each model ( $ps < 0.05$ ) indicate that the timing of peak propulsion during the stance phase of walking moderates the relationship

between the magnitude of propulsion (i.e., both the impulse and the peak) and the distance walked during the 6MWT. More specifically, individuals with lower propulsion magnitudes walked less distances than those with higher propulsion magnitudes; however, among those with higher propulsion magnitudes, individuals with earlier peak propulsion timings walked farther distances (see Figure 1).

**Figure 1:** The relationship between propulsion magnitude—both (a) peak propulsion and (b) propulsion impulse—and 6MWT distance is moderated by the timing of the propulsion peak.

## Significance

Deficits in the timing of the propulsion peak may contribute to impaired long distance walking function after stroke. While previous research has highlighted the importance of the magnitude of paretic propulsion to poststroke walking, the present study demonstrates that the timing of the propulsion peak affects the total distance walked during the 6-minute walk test above and beyond the magnitude of paretic propulsion. Post-stroke gait rehabilitation may need to target both the magnitude and timing of paretic propulsion to maximize outcomes.

## Plantar Shear Stress Increases with Added Body Mass

Hwigeum Jeong, Spencer R. Petersen, Jared M. Staten, Jordan K. Grover, and Dustin A. Bruening  
Brigham Young University, Provo, UT, USA  
email: [hwiguem@gmail.com](mailto:hwiguem@gmail.com)

### Introduction

Elevated body mass has been shown to increase vertical plantar pressure [1] that presumably contributes to: collapsed arch height, reduced plantar mechanoreceptor sensitivity, postural instability, and altered gait mechanics [2,3,4,5,6]. However, increased body mass may also affect plantar shear that may be further associated with these alterations [6]. For example, in obese subjects, plantar shear likely contribute to tissue spreading, leading to the noted increase in foot contact area [1]. In addition, while plantar pressures are increased with acutely added body mass, foot arch height does not appear to change [7], indicating that kinematic changes likely occur over time secondary to altered pressure and shear. The measurement of these shear may help better understand the effects of body mass on foot mechanics. The aim of this study is to determine the effects of added body mass on plantar shear and arch height during gait.

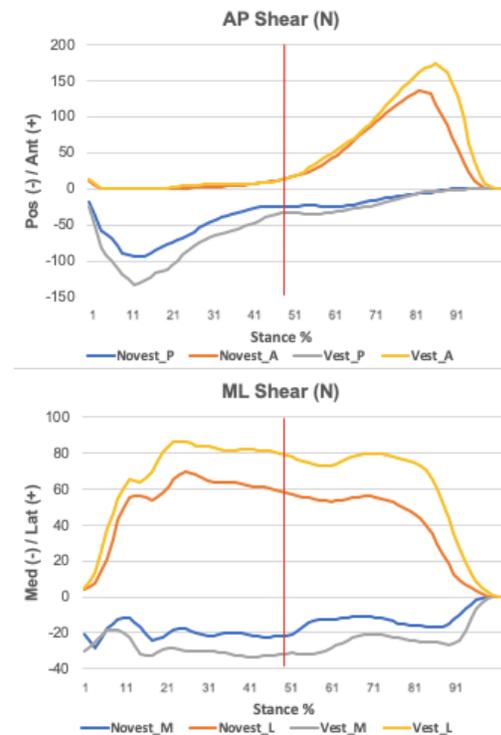

### Methods

Eight healthy male adults ( $22 \pm 3$  years,  $24 \pm 1$  BMI) walked across a 5.5 m long elevated walk-way with a pressure and shear sensing system (FootSTEPS, ISSI, 50 Hz, 25 Hz filter) mounted in the center and level with the walkway. A motion capture system (Qualisys, Inc.) was used to capture foot motion (100 Hz, 6 Hz filter) according to a multi-segment foot model using 23 reflective markers with shank and heel clusters [8]. Walking trials were performed with and without a weighted vest (20% of the participants own body weight, evenly distributed front to back) in random order. Three successful walking trials were recorded for each condition while the participants walked at their own set preferred speed with clean foot placement on the FootSTEPS sensing area. Plantar shear forces were analyzed using custom LabView software. Plantar tissue spreading was represented by the difference between total anterior and total posterior forces (AP spreading) and between total medial and total lateral forces (ML spreading) at the mid-stance transition point between braking and propulsion (i.e. when net AP forces are zero). Foot arch height was calculated in Visual 3D software as the sagittal plane angle between the hindfoot and midfoot segments at mid-stance. Metrics were compared between conditions with paired t-tests ( $\alpha = 0.05$ ).

### Results and Discussion

The mean walking speed was  $1.22 \pm 0.28$  m/s. ML shear forces showed consistent spreading effects across stance, while AP shear showed primarily unidirectional (i.e. dragging) effects in early and late stance, with spreading effects in mid-stance (Figure 1). The vest condition resulted in higher AP ( $P=0.008$ ) and ML ( $P=0.001$ ) spreading effects compared to the non-vest condition at the mid-stance. For foot arch height, however, there was no statistical difference ( $P=0.87$ ) in the midfoot joint angle ( $^{\circ}$ ) between conditions. These results suggest that the effects of body mass that eventually cause foot deformation may be insidious. In other words, although foot arch height seems intact after acutely increased body mass, soft tissues around the feet are under greater stresses that may cause

collapse of both the medial longitudinal and transverse foot arches and/or cause foot injuries as time elapses. In this respect, kinematic data only provide information about the end-result of foot deformation, but not the cause of the consequences. Therefore, kinetic data sensitive to altered mechanical stimuli may be useful to understand and prevent foot deformities.

**Figure 1.** The vertical red line represents the transition point.

### Significance

These results suggest that elevated body weight increases plantar tissue shear stress, causing both spreading and dragging effects. While this study only evaluated acute effects, the results, combined with previous studies, suggest that these stresses may be implicated in foot morphology breakdown and decreased mechanoreceptor sensitivity, both of which may contribute to deteriorated postural control and gait mechanics. This is particularly relevant to those who are obese or consistently carry a heavy mass, such as military soldiers, and may be exposed to the potential risks of postural instability and lower limb injuries.

## Introduction

Walking post-stroke is frequently characterized by slower speeds, due in large part to a precipitous decrease in paretic limb push-off [1]. This decrease in push-off, frequently quantified as the peak of the anterior component of the ground-reaction force vector (FP), often requires persons post-stroke frequently rely on compensatory gait strategies such as vaulting and increased push-off from their healthy leg [2]. A critical target for rehabilitation, therapy frequently aims to elicit volitional improvements in paretic limb push-off with unfortunately lackluster results. Therefore, rehabilitation approaches that do not require volitional changes in gait are needed. To address this need, we aim to develop a novel dynamic treadmill training approach. Our dynamic treadmill controller uses changes in tied-belt treadmill speed to modulate the magnitude of paretic and non-paretic push-off. For example, accelerating the treadmill during paretic push-off should increase the magnitude, as push-off magnitude scales linearly with walking speed [3]. Similarly, decreasing the speed during non-paretic push-off should decrease compensatory push-off from that limb. Importantly, we can customize the treadmill speeds and timing of the speed changes to shape each individual's push-off. As such, we hypothesized that walking in our dynamic treadmill would result in greater push-off from the leg moving quickly during push-off than that moving slowing during push-off in young healthy participants. The results will be used to refine treadmill control for persons post-stroke.

**Figure 1:** Peak propulsive force and trailing limb angle for left and right legs. During the Dynamic Treadmill condition, treadmill speed was 0.75 and 1.5 m/s at push-off for left (green) and right (blue) legs, respectively.

## Methods

10 healthy young adults (mean±SD; age: 22.3±3.6 years, 4M/6F) participated. Subjects first walked normally for 2 minutes each at 0.75 – 1.5 m/s on a dual-belt instrumented treadmill (Motek Medical, Amsterdam, NL) while we collected motion capture and

ground reaction force data. Subjects then walked for 10 minutes using our closed-loop dynamic treadmill controller. For all trials, a motion capture system (Vicon Nexus, Denver, CO) recorded the trajectories of markers placed on subjects' pelvis and lower extremities for estimating joint kinetics. Briefly, the dynamic treadmill controller alternated the tied-belt speeds within a gait cycle between 0.75 m/s and 1.5 m/s based on participants' anterior-posterior ground reaction forces. More specifically, the controller set the belt speeds to 0.75 m/s during the braking phase of the right leg then to 1.5 m/s during the propulsive phase of the right leg. Given the tied-belt nature, this resulted in speeds of 1.5 m/s through braking and 0.75 m/s through propulsion for the left leg.

## Results and Discussion

Speed linearly modulated bilateral FP and trailing limb angle. The dynamic treadmill condition resulted in 22% greater FP ( $p<0.01$ ) but 8% smaller trailing limb angle ( $p=0.02$ ) in the left leg (when treadmill moved at 0.75 m/s) than the right leg (when treadmill moved at 1.5 m/s).

Our dynamic treadmill controller elicited differential effects in push-off between the left and right legs using only changes in tied-belt treadmill speed. Nevertheless, we completely reject our hypotheses such that a fast treadmill speed actually resulted in significantly lesser push-off than the slow speed. These confounding but exciting results are seemingly due to disruptions to the pendular center of mass mechanics. We look forward to presenting this and follow up experiments specifically exploring joint-level and center of mass mechanics of walking with speed-modulated push-off demands.

## Significance

Split-belt treadmill training and robotic and/or exoskeleton-based rehabilitation show great promise for improving walking post-stroke with a big limitation: accessibility. Here, we demonstrate that a single treadmill belt can provide asymmetric gait training solely with appropriately timed within-stride changes in belt speed. This new line of research aims to characterize appropriate speed changes to elicit improved push-off intensity in groups with a unilateral deficit such as that observed in persons post-stroke. These data will support plans to develop standard treadmill controllers for asymmetric gait training.

## Introduction

Understanding how people control and maintain stability during perturbed walking could be beneficial for preventing falls [1]. We have previously shown that brief decelerations of belt speeds applied during right leg midstance of every stride can perturb walking and balance [2]. We found that subjects initially decreased anterior-posterior margin of stability when first experiencing the perturbations but adapted back towards baseline [2]. Visual cueing of the perturbations may increase adaptation because the visual cues may facilitate an anticipatory strategy. A previous study showed that providing visual feedback prior to an upcoming locomotor maneuver enhanced preparatory locomotor adjustments such as decrease margin of stability in the direction of the anticipated maneuver [3]. The aim of this study is to determine whether visual cueing of the magnitudes of impending belt decelerations applied during midstance of every stride facilitates adaptation to the perturbations. We hypothesized that adaptation of anterior-posterior margin of stability will be greater with visual cueing of the impending perturbations compared to no cueing.

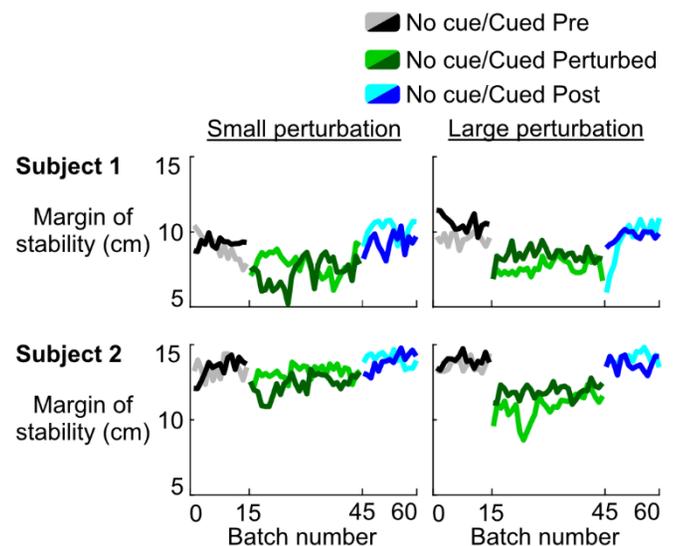

## Methods

Two healthy young subjects walked on a dual belt treadmill (M-Gait) for 4 trials at a speed of 1.0 m/s while lower body movements were recorded using a motion capture system (OptiTrack). There were 2 cueing conditions (cued or no cue) and 2 perturbation magnitudes (small and large). Each trial started with 2 minutes of unperturbed walking (pre), followed by 4 minutes of perturbed walking (perturbed), and concluded with another 2 minutes of unperturbed walking (post). During perturbed walking, the right belt speed quickly decelerated by either 0.2 m/s or 0.5 m/s for 200 ms during right midstance and then returned to 1.0 m/s. For the cued conditions, a small or large rectangle representing the small (0.2 m/s) and large (0.5 m/s) decelerations were displayed on a monitor placed in front of the subject at left heel strike, ~600 ms before the perturbation at right midstance. No rectangle was shown if there was no perturbation. A no-perturbation catch stride occurred randomly 1 out of every 5 strides during perturbed walking. We calculated margin of stability at every left heel strike as the anterior-posterior distance between the extrapolated center of mass and the toe marker of the leading foot. We calculated the average of the margin of stability for every 5 strides to examine adaptation. Pre was the last 5 strides. Early and late perturbed were the first 3 and last 3 strides during the adaptation period.

## Results and Discussion

Both subjects reduced margin of stability from pre to early perturbed for all perturbations except the no cue small perturbation, indicating that the belt decelerations perturbed baseline walking and balance (Fig. 1). The two subjects gradually increased margin of stability from early to late perturbed back towards baseline (pre), indicating that subjects were able to adapt to all perturbations (Fig. 1). Visual cueing increased margin of

stability compared to no cueing for the large perturbation, which supports our hypothesis but not for the small perturbation, which opposes our hypothesis. Further, the magnitude of the decrement in margin of stability was greater with cueing compared to no cueing for the small perturbation, which also does not support our hypothesis. For both subjects, the reduction in margin of stability from pre to early perturbed for the large perturbation was larger compared to the small perturbation, regardless of visual cueing, which indicates that larger perturbations were more challenging (Fig. 1). These results partially support our hypothesis and suggest that visual cueing is more beneficial when the mechanical perturbation is more challenging.

**Figure 1.** Margin of stability time course for the different visual cueing conditions for both subjects. 1 batch = 5 strides.

## Significance

We found that visual cueing does not necessarily improve adaptation to perturbations during gait. These preliminary findings provide additional insight on how visual feedback could be used during gait rehabilitation and fall prevention. We plan to collect more subjects to determine whether this behavior occurs in more subjects and in older adults.

<sup>3</sup>College of Health Solutions, Arizona State University, Tempe, AZ, USA; <sup>4</sup> Department of Mechanical Engineering, Northern Arizona University, Flagstaff, AZ, USA; \*Corresponding author email: zachary.lerner@nau.edu

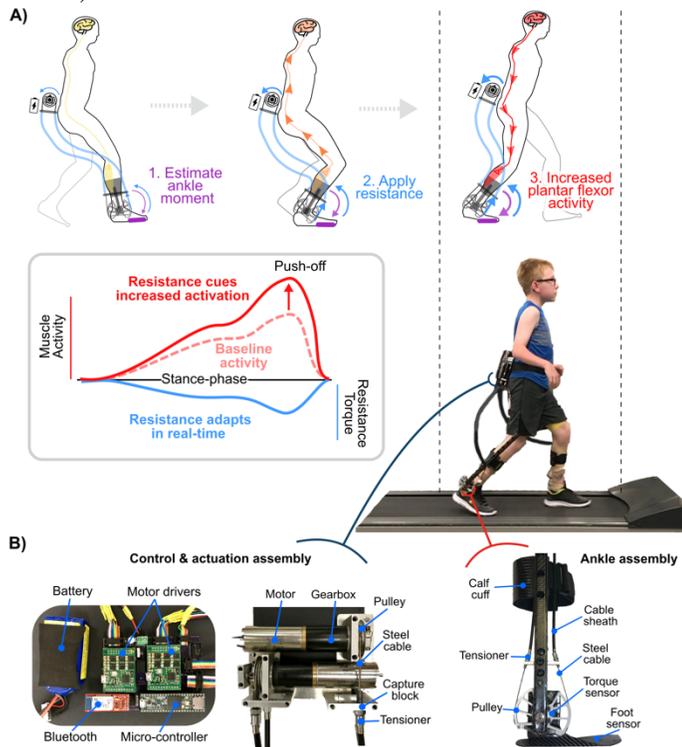

## Introduction

Children with cerebral palsy (CP) have weaker and poorly coordinated ankle plantar flexors, which likely contributes to their higher metabolic cost of transport and limitations in activity [1]. Despite the significant contribution of this deficit, the current standard of care for improving motor function in CP is not addressing functional ankle performance. We recently developed a novel intervention, wearable adaptive resistance (Fig. 1), with the primary objective of improving ankle plantar flexor function while walking [2].

The purpose this pilot clinical trial was to determine the efficacy of wearable adaptive resistance training for rapidly improving walking ability in children with CP. We hypothesized that a short, four-week training with wearable adaptive resistance would improve neuromuscular function of the ankle plantar flexors for a more efficient gait pattern that would enhance performance on clinical tests of mobility and endurance.

## Methods

Six children with CP (hemi- and diplegia, Gross Motor Function Classification System I-II, ages 12 – 17 years, five males and one female) were recruited.

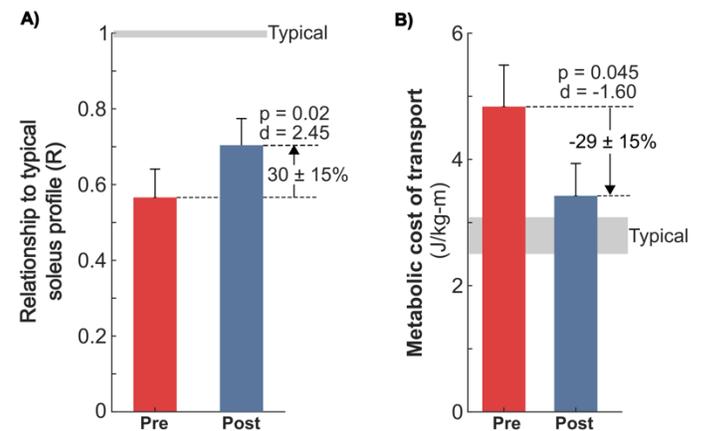

**Figure 1:** Wearable adaptive resistance A) control mechanism and B) device components.

Pre- and post-assessments included: 1) History and physical by a physical therapist; 2) Gait analysis at a preferred walking speed on a treadmill while measuring full-body 3D kinematics and muscle activity of the soleus; 3) Metabolic cost of transport; 4) Timed up & go (TUG) and six-minute walk test (6MWT).

Participants completed ten, 20-minute training sessions with wearable adaptive resistance over four weeks. Resistance level started at 0.025-0.075 Nm/kg and was increased progressively based on performance and perceived level of exertion.

Paired t-tests with correction for multiple comparisons were run to determine the effect of training on the following primary outcome variables: shape of soleus activation profile, metabolic cost of transport, TUG time, and 6MWT distance.

## Results and Discussion

**Figure 2:** Pre- and post-training A) soleus activation profile shape compared to a typical profile and B) metabolic cost of transport at a preferred walking speed.

Following training, participants displayed a more typical muscle activation profile of their ankle plantar flexors ( $30 \pm 15\%$ ,  $p = 0.02$ , Fig. 2A), leading to improved metabolic cost of transport ( $29 \pm 15\%$ ,  $p < 0.05$ , Fig. 2B), and enhanced performance on tests of functional mobility (TUG,  $11 \pm 9\%$ ,  $p = 0.04$ ) and walking endurance (6MWT,  $13 \pm 9\%$ ,  $p = 0.05$ ). The rate at which wearable adaptive resistance training elicited improved function was 3 – 6 times greater than what has been reported previously for gait training interventions [3,4].

## Significance

This relatively low-cost and wearable intervention was designed for translation to both clinical practice and personal use at home. The inherent accessibility of wearable interventions provides individuals with the opportunity to significantly increase the frequency of targeted neuromuscular rehabilitation.

## Compensations during Step Ascent Contribute to Stair Climbing Ability in Multiple Sclerosis

Paul W. Kline<sup>1,2</sup>, Cory L. Christiansen<sup>1,2</sup>, Emily R. Hager<sup>1,2</sup>, and Mark M. Mañago<sup>1</sup>

<sup>1</sup>University of Colorado Anschutz Medical Campus, Aurora, CO, USA;

### Introduction

Multiple sclerosis (MS) is a chronic autoimmune-mediated disorder of the central nervous system affecting up to 1 million people in the United States [1]. Numerous studies have demonstrated movement compensations during overground walking involving proximal (trunk and pelvis) and lower extremity kinetics and kinematics [2,3]. However, there is a paucity of evidence on other aspects of physical mobility that relate to functional independence and community participation, including stair climbing. The purpose of this study was to: 1) compare trunk and pelvis motion and lower extremity joint moments during a step ascent task in patients with MS and a matched control group and 2) identify key biomechanical contributors to stair climbing ability in patients with MS.

### Methods

Twenty patients with MS (16 F, 49±12 y, BMI: 24.8±5.4 kg/m<sup>2</sup>, Expanded Disability Status Scale – EDSS: 1.5-5.5) and 10 matched control participants (7 F, 48±12 y, 23.7±4.2 kg/m<sup>2</sup>) were enrolled. All participants underwent 3D motion analysis while ascending a 15.2 cm step in which marker trajectories were recorded using a motion analysis system (Vicon Motion Systems, Oxford, UK) at 100 Hz. Force platform data under and adjacent to the step were simultaneously recorded at 1200 Hz. Three step ascent trials were recorded with each limb as the leading limb. Stair climbing ability was assessed using ascent time during the Functional Stair Test [4]. Participants were instructed to ascend one flight of 4 steps as quickly and safely as possible. Two trials were performed and the mean used for data analysis.

Joint moments were calculated with an inverse dynamics approach and normalized to body mass. Peak joint moments were extracted from the three step ascent trials and averaged to result in a single result for hip, knee, and ankle for each limb in the MS group. A mean of left and right limb values for the control group was used for data analysis. Total sagittal and frontal plane trunk and pelvis angular excursions were determined by subtracting the minimum segment angles from the maximum segment angles during step ascent.

Comparisons between the stronger and weaker limb for the MS group were performed using paired sample t-tests. Comparisons of both limbs (MS group) to the control group were done using independent two-sample t-tests. Pearson correlations were used to assess relationships between step ascent biomechanical variables and stair ascent time. Variables with significant correlations were considered for a multiple linear regression model and a backward stepwise method was used to identify the key biomechanical contributors to stair ascent time.

### Results and Discussion

When leading with the stronger limb during step ascent, increased sagittal plane trunk excursion (9.3±3.1 vs 7.6±2.6°,  $p=.041$ ), greater peak knee extensor moment (1.19±0.29 vs 0.88±0.23 Nm/kg,  $p=.002$ ), and reduced trail limb peak ankle

plantar flexor moment (-1.11±0.17 vs -0.92±0.24 Nm/kg,  $p=.001$ ) were observed compared to leading with the weaker limb in the MS group. Sagittal plane pelvis (*stronger*: 10.4±4.0 ( $p=.001$ ), *weaker*: 10.1±5.2 ( $p=.009$ ), *control*: 5.4±1.8°) and frontal plane trunk excursions (*stronger*: 5.1±2.2 ( $p=.016$ ), *weaker*: 5.2±2.6 ( $p=.025$ ), *control*: 3.1±1.4°) were greater when leading with either limb in the MS group compared to the control group, while trail leg peak ankle plantar flexor moments (*stronger*: 1.11±0.17 ( $p=.032$ ), *weaker*: 0.92±0.24 ( $p<.001$ ), *control*: 1.26±0.16 Nm/kg) were reduced when leading with either limb compared to the control group. Functional Stair Test time correlated with sagittal ( $r=.607$ ,  $p<.001$ ) and frontal plane pelvis excursions ( $r=.411$ ,  $p=.008$ ) and trail limb peak ankle plantar flexion moments ( $r=.418$ ,  $p=.007$ ). The regression model identified sagittal and frontal plane pelvis excursion to be the primary contributors to Functional Stair Test time (Adj R<sup>2</sup>=.458).

The ability to target movement-based interventions for people with MS requires an understanding of movement mechanics during step ascent. The results of this study provide understanding of lower extremity joint moments during a step ascent task in people with MS. Consistent with prior studies demonstrating quadriceps and ankle plantar flexor muscle weakness [5], this study found reduced peak joint moments at the knee and ankle. In addition, larger trunk and pelvis excursions when leading with both the stronger and weaker limbs indicate a potential compensatory movement strategy for reduced peak ankle plantar flexor and knee extensor moments during step ascent tasks in people with MS. Finally, the results of the regression model suggest larger sagittal and frontal plane pelvis excursions may be the primary biomechanical contributors to slower stair ascent time.

### Significance

People with MS ascend a step with larger trunk and pelvis excursions, reduced knee extensor moments, and reduced trail limb ankle pushoff compared to matched controls. Increased pelvis motion and reduced ankle pushoff are associated with poorer stair climbing ability and may serve as targets for future interventions designed to optimize functional movement.

## Introduction

Spinal cord injury (SCI) disrupts the connection between the brain and spinal cord, impacting motor and sensory function. Current rehabilitation treatments cannot recover pre-injury functionality, leaving lasting effects on individuals' mobility and quality of life. Both invasive and non-invasive spinal stimulation have demonstrated the ability to restore voluntary motor control of stepping-like patterns in individuals with complete paralysis after SCI [1]. Non-invasive spinal stimulation research has focused on walking recovery in a gravity neutral condition or with a gait assisting exoskeleton [2, 3]. We investigated the ability of non-invasive transcutaneous spinal stimulation (tSCS), combined with locomotion training to promote recovery of over ground walking in individuals with incomplete SCI. We hypothesized that improvements in functional gait after tSCS would correspond with improvements in subject intra- and interlimb coordination.

## Methods

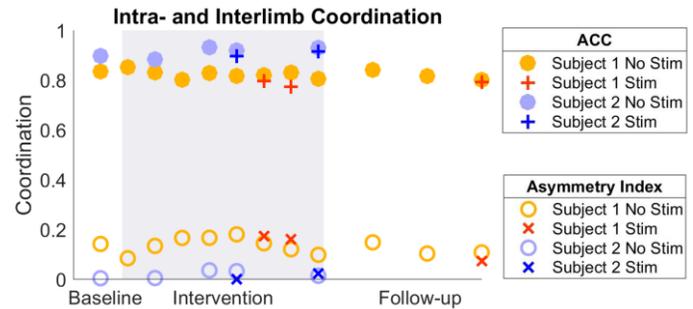

We enrolled 2 males with incomplete cervical SCI. Subject 1 was 64 years old, 3.5 years post injury, and classified as C4 American Spinal Injury Association Impairment Scale (AIS) D at baseline. Subject 2 was 64 years old, 4 years post injury, and classified as C6 AIS D at baseline. Both participants underwent a total of 8-weeks of locomotor training only and 8 weeks of locomotor training combined with tSCS.

Three-dimensional gait analysis and the 6-minute walk test (6MWT) were performed during baseline, throughout the intervention, and up to three months post-intervention. Intralimb coordination was evaluated as the angular component of correlation of correspondence (ACC) of the right leg, which measures the consistency of the knee-hip relationship for all gait cycles [4]. We calculated spatial interlimb coordination as the magnitude of the average difference between the left and right step length divided by the sum of step length for both legs, known as the spatial asymmetry index [5]. Kinematic interlimb coordination was also evaluated using the correlation coefficient and slope comparing joint angles from each side of the body.

## Results and Discussion

Both participants increased the distance they could walk during the 6MWT, a change that was sustained at follow-up visits. Subject 1 walked 34 meters (m) at baseline, 88 m after the intervention, and 76 m at 3-months follow-up. Subject 2 walked 199 m at baseline, 377 m after the intervention, and 361 m at 2-months follow-up. We sought to explain the improved functional gait by examining kinematics. Neither intra- nor interlimb coordination, however, changed significantly throughout the study (Figure 1). There were also no significant changes in gait coordination when spinal stimulation was turned on and off on the same day. Previous studies reported that tSCS was able to recover coordinated stepping-like patterns during walking in a gravity neutral device or while wearing an exoskeleton [1, 3]. The lack of change we observed in gait coordination during tSCS

may suggest that our participants' improvement in gait was from other factors [4]. At baseline, our participants had high ACC close to one, the ideal intralimb coordination, and relatively low spatial asymmetries close to zero (Figure 1). Since our subjects had high initial coordination, walked overground, and actively loaded their limbs, we may not be able to use gait coordination as a sensitive measure of their functional changes after tSCS.

**Figure 1.** Evaluation of intra- and interlimb coordination was done at baseline, during the intervention (grey box), and up to 3 months follow-up. Gait analysis was always performed with spinal stimulation turned off, but some days it was also performed with the device turned on, marked by x's and +'s.

Further research is needed to expand the study's sample size to evaluate the biomechanical and neuromuscular changes induced by tSCS. Additional work also needs to be done examining the physiological mechanisms of spinal stimulation.

## Significance

Stepping and coordination have previously been used to quantitatively describe changes in function as a result of therapy after SCI. However, these results indicate that traditional quantitative measures of gait coordination do not identify changes in coordination with spinal stimulation. Other measures of gait may be needed to systematically evaluate the impact of tSCS on walking function, a critical first step to implementing tSCS in clinical SCI rehabilitation.

# Acute effects of whole-body vibration on stair ascent in children with Down syndrome

Diego M. Ferreira<sup>1</sup> and Jianhua Wu<sup>1</sup>

<sup>1</sup>Department of Kinesiology and Health, Georgia State University, Atlanta, GA, USA. Email: jwu11@gsu.edu

## Introduction

Ascending stairs is a common daily activity that is necessary to navigate households and many other buildings. Children with Down syndrome (DS) have lower muscle strength and poorer balance control, resulting in an underdeveloped ability to navigate staircases [1]. Children with DS demonstrate shorter step lengths and slower step velocities when approaching a staircase compared to typically developing (TD) children [1]. Additionally, children with DS demonstrate underdeveloped locomotor adjustments while ascending a staircase [2].

Whole-body vibration (WBV) is a new intervention and has been shown to improve muscle strength and walking endurance in individuals with DS [3]. However, it is not known if WBV can help improve functional tasks in children with DS. Therefore, this study aimed to investigate the acute effects of a single session of WBV on stair ascent in children with DS. We hypothesized that step length would increase and step time would decrease, resulting in a faster step velocity during the approach and ascent phases after WBV.

## Methods

We have recruited five subjects (2M/3F, 11.3±2.36 years) for this study. Subjects completed 5 trials of stair ascent during 3 time points (baseline, pre-WBV, and post-WBV). The lack of a significant difference between the baseline and pre-WBV conditions suggests there might not be a learning or warm-up effect on stair ascent. Each subject walked along a walkway with 2 imbedded force plates to a 3-step staircase with a riser height of 24 cm, and then ascended the staircase [1]. Rest was given between trials, including a 10-minute break between the baseline and Pre-WBV conditions. The post-WBV condition occurred immediately after the session of WBV.

Subjects completed 10 bouts of 30 seconds on a Galileo side-alternating WBV platform (25 Hz, 2 mm) with 1 minute rest between bouts. An 8-camera Vicon motion capture system was used to collect the spatial-temporal gait parameters for the 2 steps before the stairs (-2 & -1) and 2 steps during stair ascent (step 1 & 2). Gait variables included step length, step time, and step velocity for these four steps. Step length was normalized by each subject's leg length. Step time and velocity were normalized using the equations below [4]:

$$\text{Normalized step time} = \text{step time} / \sqrt{\text{leg length} / g}$$

$$\text{Normalized step velocity} = \text{step velocity} / \sqrt{\text{leg length} * g}$$

where  $g$  is the gravitational acceleration (9.81 m/s<sup>2</sup>). Two-way (2 step x 3 time) repeated ANOVAs were conducted for the approaching and ascent phases, separately. Post-hoc pairwise comparisons with Bonferroni adjustments were conducted when necessary at a significance level of  $\alpha=0.05$ .

## Results and Discussion

During the approaching phase, step length was shorter but step time was longer and step velocity was slower at step -1 compared to at step -2 (Table 1). There was a step effect on step

length, step time, and step velocity (all  $p<0.05$ ). However, there were no differences between before and after WBV (Table 1).

During the ascent phase, step length was longer and step velocity was faster but step time was shorter at step 1 compared to step 2 (Table 2). There was a step effect on all three variables (all  $p<0.05$ ). Also, step velocity increased after WBV, particularly at step 2. There was a time effect on step velocity ( $p<0.05$ ). Post-hoc analysis revealed that step velocity at step 2 increased from baseline to post-WBV.

**Table 1.** Means (SD) of variables during approaching phase

Variable	Step	Baseline	Pre-WBV	Post-WBV
Step length *	-2	0.51 (0.12)	0.57 (0.08)	0.61 (0.16)
	-1	0.38 (0.17)	0.38 (0.19)	0.43 (0.23)
Step Time *	-2	1.84 (0.09)	1.78 (0.23)	1.77 (0.28)
	-1	1.96 (0.28)	2.12 (0.53)	1.68 (0.18)
Step Velocity *	-2	0.28 (0.07)	0.33 (0.09)	0.36 (0.13)
	-1	0.20 (0.11)	0.20 (0.12)	0.26 (0.13)

Note that \* represents a difference between steps

**Table 2.** Means (SD) of variables during ascent phase

Variable	Step	Baseline	Pre-WBV	Post-WBV
Step length *	1	0.70 (0.09)	0.67 (0.09)	0.68 (0.11)
	2	0.36 (0.05)	0.35 (0.04)	0.36 (0.05)
Step time *	1	2.92 (0.37)	3.59 (1.75)	3.20 (1.01)
	2	6.25 (4.27)	4.30 (1.09)	3.44 (0.70)
Step velocity *‡	1	0.24 (0.05)	0.23 (0.11)	0.23 (0.09)
	2	0.08 (0.04)	0.09 (0.02)	0.11 (0.02)

Note that \* represents a difference between steps; ‡ represents a difference between baseline and post-WBV

## Significance

These preliminary results suggest that a single session of WBV can modulate neuromuscular function by increasing step velocity while ascending a staircase. Further analysis of joint kinematics and kinetic is needed to determine if WBV provides benefits to other biomechanical aspects of this activity. Since WBV is an easy modality to administer, this would make a modality for children with DS more convenient and less strenuous than typical therapy. The use of WBV training could be implemented in this population's therapy to address motor deficits and potentially improve their daily motor activities and the quality of life.

## Movement coordination during humeral elevation in individuals with newly acquired spinal cord injury

Margaret Finley, PT, PhD<sup>1</sup>, Elizabeth Euler, MS<sup>1</sup>, Shivayogi V. Hiremath, PhD<sup>2</sup>, Joseph Sarver, PhD<sup>3</sup>

<sup>1</sup>Department of Physical Therapy and Rehabilitation Science, Drexel University

Email: maf378@drexel.edu

### Introduction

Evidence regarding physical impairments during the initial, recovery phase in individuals with spinal cord injury (SCI) is limited to studies on range of motion and gross muscle strength<sup>1</sup>, without investigations of shoulder girdle kinematics during overhead reaching. Analysis of this task is critical as alterations have been shown to be sensitive to various chronic musculoskeletal impairments<sup>2</sup> and neurological conditions such as stroke.<sup>3</sup> Kinematic analyses in individuals with long duration SCI is limited to transfers, weight relief maneuvers, wheelchair propulsion and weight bearing tasks rather than overhead reaching. While conducting a larger longitudinal study, we became aware there is a gap in knowledge regarding movement patterns in individuals with newly acquired SCI. Therefore, the goal of this abstract is to present an important novel clinical observation of shoulder girdle kinematics during overhead reaching in individuals with newly acquired SCI. In addition, this exploratory pilot study will describe a novel approach for quantifying scapulohumeral coordination as a potential method for motion classification.

### Methods

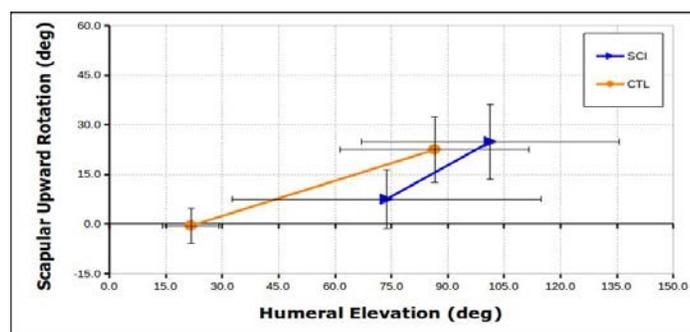

Adults with newly acquired SCI (n=8) and age and gender matched uninjured controls (n=8) completed the Musculoskeletal Pain survey<sup>4</sup>, a clinical shoulder evaluation and a kinematic assessment of an overhead reaching task. Three-dimensional kinematics of the trunk, scapula, and humerus of the dominant limb were collected (100 Hz) with The MotionMonitor™ (Ascension TrakStar, Innovative Sports Training, Inc., Chicago, IL).<sup>5</sup> Coordination analysis of scapular upward rotation with humeral elevation (scapulohumeral rhythm) was performed by identifying the linear range of scapular upward rotation during elevation. The humeral elevation angles for initiation and end of the linear range was calculated and expressed as a percentage of maximal humeral elevation.

Differences between groups ( $p \leq 0.05$ ) were assessed for musculoskeletal shoulder pain score, velocity of elevation, plane of humeral elevation, scapular rotations (external, upward, posterior) and thoracic kyphosis at each humeral elevation angle (initiation, 30°, 60°, 90°, 120°, maximum elevation). Effect sizes were calculated for between group measures. Scapulohumeral movement coordination was quantified as the initial and final humeral elevation angle at which scapular upward rotation and humeral elevation were linearly correlated. The initial and final 'linear' elevation angles were averaged for each subject and are reported in both absolute (degrees) and relative (percentage of motion) terms. Group comparisons were analyzed ( $p \leq 0.05$ ). Post hoc correlation analysis revealed a significant inverse association of shoulder pain with maximum elevation ( $r = -0.72$ ,  $p = 0.04$ ) in those with SCI.

### Results and Discussion

Individuals with SCI had a higher level of shoulder pain per the Musculoskeletal Pain Survey ( $p = 0.01$ ,  $\delta = 1.7$ ). No difference in

velocity or plane of elevation existed, however, the group with SCI had less maximal humeral elevation compared to the control group ( $p = 0.04$ ,  $SCI = 117.4^\circ \pm 5.8^\circ$ ;  $control = 132.1^\circ \pm 3.4^\circ$ ). Individuals with SCI had significantly reduced scapular upward rotation at 120° elevation. Movement coordination was altered in those with SCI as the linear relationship started later ( $p < 0.001$ ) in the motion (52% compared to 5% for controls) and ended significantly later ( $p = 0.004$ , 93% compared to 68% for controls). Furthermore, the linear relationship spanned a significantly ( $p = 0.02$ ) smaller range of humeral elevation for SCI group (16.2° vs 23.2° for controls) (Figure 1).

**Figure 1:** Scapulohumeral movement coupling demonstrated as linear range of scapulothoracic upward rotation during humeral elevation by groups

### Significance

This is one of the first studies to demonstrate that individuals with acute SCI have reduced maximal humeral elevation, with only 50% of the sample able to achieve 120° elevation. In a typical day, wheelchair users reach overhead (above 90°) five times more often than able-bodied controls. Coordination/coupling analysis revealed different patterns of motion in this early phase following SCI. Linear relationship of scapular upward rotation to humeral elevation occurred later and had a smaller total range of motion. This delayed upward rotation may predispose individuals to aberrant movement patterns that could lead to development of impairments, such as impingement and/or increased pain.

# Changes to Walk Speed: Programming Deep Brain Stimulators for Parkinson's Patients

Christopher P Hurt<sup>1</sup>, Daniel J Kuhman<sup>1</sup>, Carla Rigo Lima<sup>1</sup>, Melissa Wade<sup>1</sup>, Harrison J Walker<sup>1</sup>

<sup>1</sup> University of Alabama at Birmingham, Birmingham, AL, U.S.A

Email: cphurt@uab.edu

## Introduction

Deep brain stimulation (DBS) is an effective therapy for individuals with Parkinson's disease (PD) after pharmacologic interventions no longer optimally control motor symptoms<sup>1</sup>. A recent meta-analysis showed that walk speed improves with DBS, however outcomes varied substantially from large to negligible improvements<sup>2</sup>. However, these measures of gait function were recorded after initial clinical programming sessions. It is possible that gait speed was not measured across all available contacts on the DBS lead suggesting outcomes may not be optimized for gait. Given the clinical and diagnostic utility of walk speed, this measure could provide a simple, objective and integrated clinical tool to assess DBS efficacy for gait, balance, and other motor symptoms if it was assessed during initial programming sessions. The purpose of this study was to investigate clinically meaningful changes in gait function and the reliability of walking speed in participants with PD during a programming session of individuals who have surgically implanted DBS devices.

## Methods

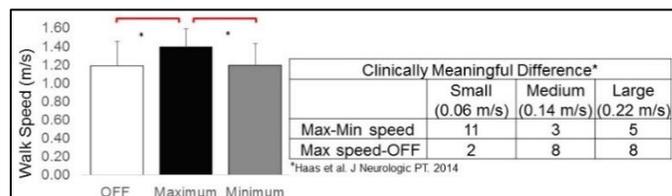

Nineteen participants with PD (age 59.1±7.1 years) underwent surgery to implant a multi-contact, directional DBS lead in the subthalamic nucleus. Participants visited the lab one-month after implantation for device activation. Each DBS electrode was tested for clinical benefit with a standardized pulse width of 60 μs and a frequency of 130 Hz by a trained nurse practitioner. The novel DBS device contains six individual contacts and two virtual rings formed by 3 directional contacts each, and individual dorsal and ventral rings. Contacts were tested in random order to avoid an ordering effect. The individuals were tested in the practically defined "OFF" state (>12 hours without PD medicine). Individuals completed four 10m walking trials at a comfortable speed (CWS) with the device OFF and ON for each of the 10 DBS settings (6 directional contacts, 2 virtual rings, 2 individual rings). To determine whether CWS was reliable across trials within each contact, intraclass correlation coefficients (ICC) were quantified for each contact or ring. To determine the efficacy of DBS, maximum and minimum walking speeds captured with the CWS captured prior to device activation using a repeated measures ANOVA. We also categorized changes in walk speed relative to clinical meaningful differences for persons with PD<sup>3</sup>

## Results and Discussion

Walking speed differed substantially across directional DBS contact segments, within and across participants (p<0.001).

Table 1. ICC values for all contacts tested and OFF condition with 95% confidence intervals.

Contact	1	2	3	4	5	6	7	8	9	10	OFF

95% C.I.	0.936	0.883	0.916	0.926	0.897	0.919	0.911	0.914	0.91	0.937	0.938
	0.99	0.979	0.985	0.985	0.982	0.982	0.984	0.983	0.982	0.988	0.988

Post hoc analyses revealed that the average maximum recorded

Figure 1. A) Comparison of walk speed between OFF medicine/DBS and the Maximum and Minimum walk speed per participant across contacts. \*denotes significance p<0.05 B) Number of participants experiencing a clinically meaningful difference in walk speed with DBS stimulation.

walking speed with DBS (1.36 ± 20.1 m/s) was significantly faster than both the minimum speed with DBS (1.17± 24.1 m/s) and DBS off (1.18 ± 25.7 m/s, p<0.000 for both comparisons, Figure 1A), while no significant difference was detected between DBS off and minimum speed DBS on (p=1.000). Across all DBS testing conditions, 18% of the tested rings or contacts actually yielded slower walking speeds however the best contacts tested resulted in at least medium clinically meaningful differences in 89% of participants (Figure 1B). ICC values for walking speed data were all above 0.949, which suggests excellent reliability (Table 1). When looking at the 95% confidence intervals, the lower limit of the interval was above 0.900 in 8 of the 10 DBS trials, suggesting excellent reliability while 2 of the 10 were greater than 0.883 suggesting good reliability. To the best of our knowledge this is the first study to show that walk speed can be used as a reliable measure to assess gait function while programming DBS and moreover we observed a clinically meaningful speed increase.

## Significance

Walking speed is a clinically meaningful, reliable measure that may be used to assess the effect of programming individual DBS contacts to maximize improved gait function in PD. Next-generation directional and closed loop DBS devices have the potential to provide greater improvements in gait and balance by tailoring stimulation parameters to optimize efficacy.

# Gait and Balance Characteristics for Adults with Degenerative Cervical Myelopathy

Daniel Richie, Arghavan Farzadi, Andrea Hesse, Shelby Miracle, Amy Minnema, Ajit M.W. Chaudhari, Francis H. Farhadi  
The Ohio State University, Columbus, OH, USA  
Email: [daniel.richie@osumc.edu](mailto:daniel.richie@osumc.edu)

## Introduction

Patients with degenerative cervical myelopathy (DCM) present with a range of motor and sensory symptoms, including poor coordination and loss of balance. When symptoms worsen despite non-surgical treatment, decompression surgery may be recommended. Currently there are no objective criteria to help guide surgical recommendations; therefore, individual patient outcomes have wide variability [1]. Gait parameters, specifically gait speed, stride length and step width, have been postulated to track disease progression as well as response to surgical intervention [2]. However, step width can be difficult to measure in the clinic compared to stride length or speed. Therefore, this study aims to characterize the gait and balance of a pre-operative DCM population and then determine a predictive model for step width from gait speed and stride length that will allow objective assessment of a patient's functional ability during clinical care.

## Methods

12 DCM patients (age:  $63 \pm 13$ y; 8 female; height  $166 \pm 9$ cm) gave informed consent in accordance with procedures of the Institutional Review Board of The Ohio State University. These patients have mild to moderate physical function impairment from DCM (PROMIS Physical Function Score of  $40.5 \pm 2.2$ ). Patients were tasked with three 30-second, eyes closed standing-balance trials to measure postural sway. Then participants completed four 10-meter walking trials at self-selected pace. Spatiotemporal parameters were extracted from a ten camera Vicon motion capture system with markers placed on both feet. Marker trajectories were low-pass filtered using a 4<sup>th</sup> order zero-pass Butterworth filter at 6Hz. Spatiotemporal parameters were normalized to height for the predictive model. Standing balance data was collected at 1000Hz using a Bertec balance plate and low-pass filtered using a 4<sup>th</sup> order zero-pass Butterworth at 20Hz.

## Results and Discussion

The balance data was analysed for the root-mean square of the medial-lateral (RMS-ML) sway of the center of pressure. The DCM patient balance data was compared to healthy older adults (N = 38; age:  $83 \pm 8$ y; 30 female) [3] and the spatiotemporal gait data was compared to healthy older adults (N = 294; age:  $79 \pm 5$ y; 186 female; height  $167 \pm 6$ cm) from a separate study [4], shown in Figure 1.

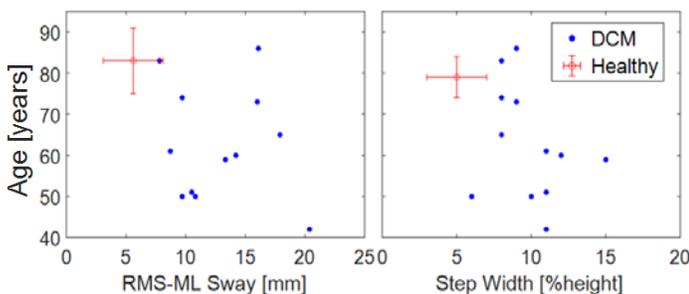

Figure 1: Comparing DCM to Healthy Older Adults

Figure 1 shows the younger DCM group has significantly more medial-lateral sway during standing balance than the healthy, older group. Also shown is the significant increase in step width for the DCM group. Not shown in Figure 1, the younger DCM group had similar gait speed and stride length to the older, healthy adults. To describe a relationship of step width by gait speed and stride length, refer to Figure 2. This relationship shows no significant correlation for step width. This was confirmed with a multivariate least square linear regression for step width predicted by gait speed and stride length (all normalized by height). The regression results in an  $R^2 = 0.1$ .

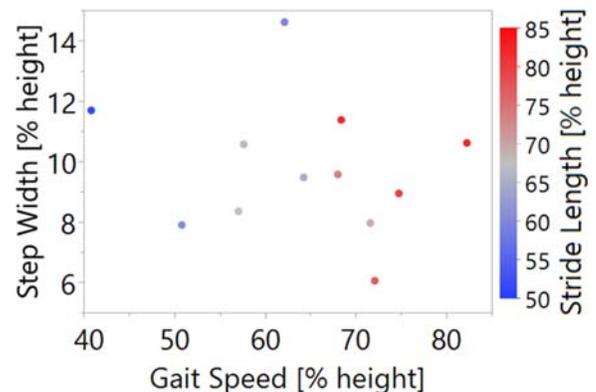

Figure 2: Relationship Between Gait Parameters for DCM

The data presented is significant as it helps to quantify the balance deficits observed in DCM patient groups. The younger DCM group had greater medial lateral sway and step width while walking with the same speed and stride length of older, healthy adults. This leads to the conclusion that the DCM group would show significant balance deficits compared to an age-matched healthy group. By characterizing the balance and gait of the pre-operative DCM population, these parameters can now be tracked post-operatively over time and used to assess the patient's response to surgical intervention.

## Significance

This research enforces the importance of a multi-disciplinary approach to improving patient clinic care and leveraging biomechanics to improve surgical outcomes. With this research, the loss of balance observed in DCM patients is quantified and can now be tracked during recovery to inform clinical and surgical decision-making for future patients. The methods used here could be applied to other pathologies where patients experience loss of balance and an intervention is performed. Examples of pathologies include, traumatic brain injuries, cancer, Parkinson's, stroke and other spinal cord injuries.

# Gait Variability in Persons with Parkinson's disease after Individualized Physical Therapy

Srikant Vallabhajosula\*, Morgan Reich, Krista Nunn, Crystal Ramsey  
Department of Physical Therapy Education, Elon University  
Email: [\\*svallabhajosula@elon.edu](mailto:*svallabhajosula@elon.edu)

## Introduction

Persons with Parkinson's disease often exhibit deficits with balance and gait. These deficits often put them at a high risk of falling and decreased quality of life. One of the measures of fall risk level is gait variability. Previous research reported increased stride-to-stride variability among individuals with Parkinson's disease.<sup>1</sup> Moreover, recent research has been focused on using backward walking as a challenging assessment of dynamic balance.<sup>2-4</sup> While exercise interventions like Tai Chi have been shown to have mixed results on improving gait<sup>5</sup>, literature on the effectiveness of using individualized physical therapy in a group setting to improve gait variability is sparse.

The purpose of this study was to evaluate changes in gait variability of individuals with Parkinson's disease during forward and backward walking after 3 months of individualized physical therapy. We hypothesized that gait variability would decrease.

## Methods

Ten individuals with Parkinson's disease (5 females, H&Y score between I and III) aged 60 years and above were recruited.

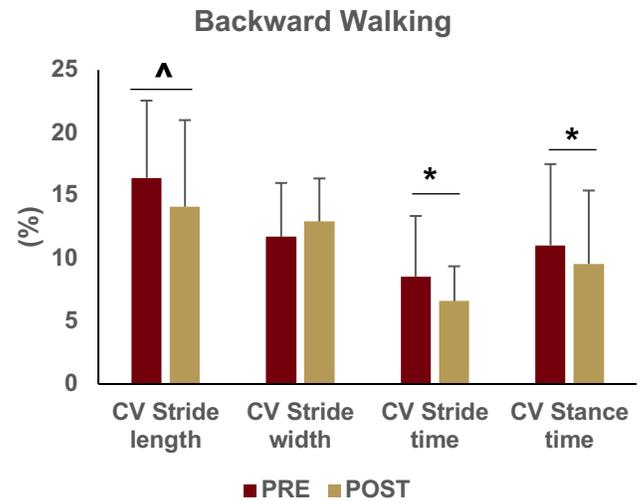

Participants completed one-hour intervention sessions conducted twice a week for three months. The intervention consisted of a 5-minute warm up, followed by 20 minutes of aerobic activity. Participants self-selected the aerobic activity but were asked to exercise at a rate of perceived exertion level of at least 7/10. Aerobic exercise activity was followed by activities focused on body structures and functions such as dual-tasking, dynamic balancing, obstacle crossing, and walking in different directions which affected the participant's participation goals.

Gait assessment was done before (PRE) and after (POST) the intervention using a 16' pressure-sensor based walkway. Participants walked 5 times at a comfortable pace in forward and backward directions. Within-subject coefficient of variation (CV) was computed for stride length, width, time and stance time. A paired samples t-test was done.

## Results and Discussion

For forward walking (Figure below), only stance time variability increased significantly (by 18%;  $P=0.012$ ).

For backward walking (Figure below), there was a significant decrease in variability of stride time (by 23%;  $P=0.016$ ) and stance time (by 13%;  $P=0.023$ ). Stride length variability decreased by 14% albeit with a trend towards significance ( $P=0.063$ ).

Data from the current study was similar to those reported previously.<sup>3</sup> The results support the hypothesis in the backward walking but not in the forward walking. While it is not entirely clear why variability increased in the forward direction but decreased in the backward direction, specificity of training could have contributed to these findings. Specifically, participants worked on activities like obstacle crossing in forward direction and walking backwards which may have resulted in the results observed.

## Significance

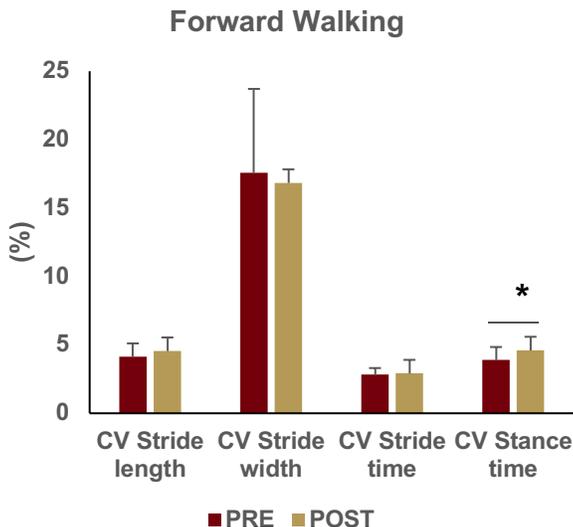

Decrease in gait variability during a more challenging task like backward walking could highlight the importance of using individualized physical therapy interventions for individuals with Parkinson's disease. Whether such improvements are related to decrease in fall risk needs to be further evaluated.

## Acknowledgments

This study was supported by the Parkinson's Foundation.

# Differences in Knee Joint Angle between Parkinson's Disease "on" and "off" Medication across Varying Levels of Visual Flow

Zachary Ripic<sup>1</sup>, Jeonghoon Oh Ph.D.<sup>2</sup>, Dayun Jeon<sup>1</sup>, Joseph Signorile Ph.D.<sup>1</sup>, and Moataz Eltoukhy Ph.D.<sup>1</sup>

<sup>1</sup>University of Miami, Department of Kinesiology and Sport Sciences

<sup>2</sup>University of Georgia, Department of Kinesiology

Email: zar17@miami.edu

## Introduction

Parkinson's Disease (PD) manifests through motor symptoms such as akinesia, bradykinesia, tremor, and rigidity.<sup>1</sup> Additionally, gait disturbances arise with disease progression and as patients transition between medication states. Current efforts seek to reduce this through various cueing interventions that target gait disturbances by extracting discrete spatiotemporal, kinematic, or kinetic variables.

The purpose of this study was to identify differences that occur over the gait cycle between PD patients "on" and "off" medication with and without varying levels of visual flow which may simulate cueing interventions. We hypothesized that differences would be observed in knee joint angle between PD medication groups. Additionally, these differences would be dependent on varying levels of visual flow implemented through carpet patterns displayed on the walking surface.

## Methods

Analyses presented in the current study were conducted on de-identified gait data from PD patients "on" medication (PD ON), and PD patients "off" medication (PD OFF). Initially, PD subjects performed gait trials in each medication condition on a control (blank) carpet. The following four visits were randomized for medication condition and four different carpet conditions with varying patterns.

Gait trials were captured with an optoelectronic motion capture system (BTS Bioengineering, Milano, Italy) using the Vicon Plug-in-Gait Model (Vicon Motion Systems Ltd., Oxford, UK). Kinematic trajectories and gait events were processed using Matlab r2019b (MathWorks, Natick, MA). Gait cycles were extracted using subsequent heel strikes. Kinematic trajectories were time normalized to 100 percent of gait cycle and coded for subject and carpet types. Outliers at each time point were removed and normality was checked using Kolmogorov-Smirnov test. Data from each subject and carpet type were averaged across time points and resampled to contain eight observations in each condition (8 x 5 conditions x 2 groups = 80 total observations).

Data were analysed using a statistical parametric mapping (SPM) approach implemented via publicly available spm1d package for Matlab (spm1d.org). Data were analysed using a 2-by-5 factorial ANOVA where significant effects are indicated as exceeding a critical threshold ( $\alpha = .05$ ) above which only 5% of equally smooth random data would be expected to cross<sup>2,3</sup>.

## Results and Discussion

Results show a significant effect of medication on knee joint angle during late swing phase. PD ON exhibited significantly less knee flexion from 89-100% gait cycle ( $p < .05$ ) (Figure 1). No significant results were observed for carpet condition or medication-by-carpet condition effects for this sample. Varying levels of visual flow had no effect in or between medication states for these patients. Observed differences in knee joint angle between medication conditions may provide benefit to further cueing interventions. Importantly, research shows PD patients

"off" medication walk slower with increased cadence and reduced range of motion in lower limb joints when compared to healthy age-matched controls<sup>4</sup>. Further, others have shown PD fallers also exhibit increased flexion in the swing limb during minimum toe clearance which was thought to be an adaptation to increased knee flexion in the stance limb<sup>5</sup>. Results of the present study indicate, at least during late swing, knee joint angles differ depending on medication state which may be an important target for further developments in cueing interventions that seek to mitigate abnormalities observed during gait in PD populations.

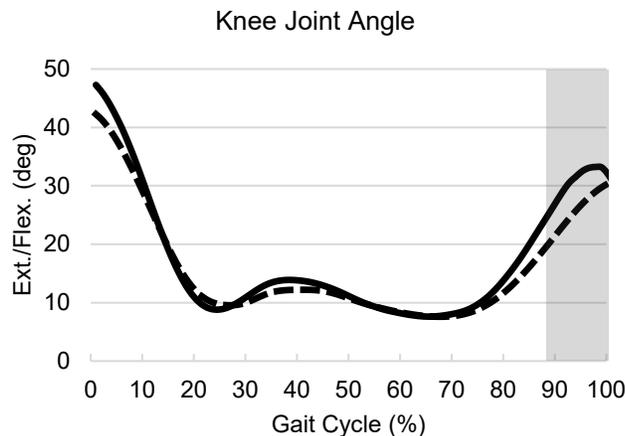

Figure 1: Sagittal plane knee joint angle. Knee joint angle differed between PD ON (- -) and PD OFF (-) from 89-100% of gait cycle indicated by shaded region ( $p < .05$ )

## Significance

The present study offers an alternative method, not strictly as a replacement but an expansion from discrete spatiotemporal, kinematic, or kinetic variables commonly used to quantify gait characteristics in PD populations. Future developments in cueing interventions may benefit by identifying and targeting specific deficiencies that occur during the gait cycle in these patients.

## Introduction

People with Parkinson's disease (PD) often exhibit an atypical gait which is characterized by a decreased step length, increased cadence, and increased gait variability<sup>1</sup>. These gait characteristics can be mitigated by using simple visual (e.g. lines on the floor) and auditory (e.g. beeps from a metronome) cues<sup>1</sup>. Cues such as these are enhanced when they are action-relevant (i.e. related to the task), for instance using footprints instead of lines and recorded footstep sounds instead of beeps<sup>2,3</sup>. However, these cueing strategies are currently limited to the confines of a clinic or laboratory. Recent advances in augmented reality (AR) may allow for these cues to be delivered in a mobile and on-demand fashion. However, literature on AR cueing and Parkinsonian gait remains inconclusive<sup>4</sup>. Studies have also yet to compare the different action-relevant sensory cues to identify which modality is most effective in addressing Parkinsonian gait. As such, the purpose of this study was to compare the effects of AR-based action-relevant sensory cues and to investigate the usability of a novel AR device in providing sensory cues to people with PD. We generally hypothesize that the novel AR platform will acutely improve the gait characteristics of people with PD.

## Methods

Ten people with PD are being recruited for this ongoing study. Participants are instructed to complete three walking trials across a 10-meter pathway for each of the following conditions: no cues (NC), action-relevant visual cues (VC), action-relevant auditory cues (AC), and combined action-relevant audio-visual cues (AVC) (Figure 1A). Step length, step length variability, cadence, and cadence variability are acquired at 200Hz from all trials using seven inertial measurement units placed on the legs and pelvis. Step length and cadence are normalized to their mean values from the NC condition while gait variability measures are reported as coefficients of variation (CoV). A Magic Leap One AR headset was used to provide action-relevant sensory cues to the participants (Figure 1B). The System Usability Survey (SUS) is used to assess the feasibility of implementing cues using the platform for this population, where a score greater than or equal to the 68<sup>th</sup> percentile demonstrates above average usability<sup>6</sup>.

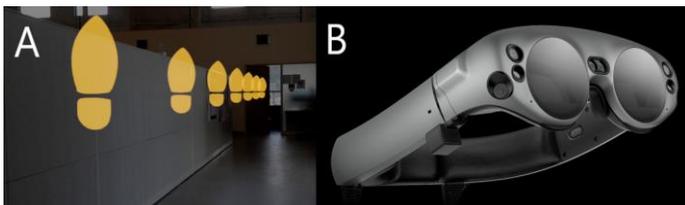

Figure 1: (A) VC condition; (B) Magic Leap One AR Headset.

## Results and Discussion

Preliminary data from one person with PD demonstrates that the AVC condition produced the greatest increase in step length and decrease in cadence (Table 1). This is in contrast to a previous study that discussed no additional improvements from combining

visual and auditory cues<sup>1</sup>. It is possible that, since the cues combined in the previous study were not relevant to walking, their combination led to a split in attention which has been known to negatively affect people with PD<sup>7</sup>. However, by using action-relevant cues in the current study, competition for attention may have been reduced—leading to the observed improvements. Moreover, none of the cue types used in the current study improved gait variability (Table 1), contrasting with previous action-relevant cueing studies which have demonstrated positive effects on step length and cadence variability<sup>2,3</sup>. This may be attributable to a switch to a more conscious control of walking as the participant attempted to sync each step with the action-relevant sensory cues<sup>6</sup>. The participant also gave the AR platform an above average percentile score in the SUS. The device we are using rated higher than a proprietary one used in a previous study<sup>4</sup>, possibly because it weighs less (316g from 530g), has a wider field of view (50° from 45°), and uses action-relevant cues (footprints vs staircase). It seems then that delivering combined action-relevant sensory cues through the Magic Leap One is effective in improving some elements of Parkinsonian gait. More data is currently being collected to confirm these results.

Table 1: Gait measures normalized to mean values from NC condition and SUS score of person with PD.

Condition	Step Length	Cadence	Step Length CoV	Cadence CoV	SUS Score
NC	0.00%	0.00%	8.11%	5.30%	72.50
VC	8.11%	-3.64%	12.50%	9.28%	
AC	8.11%	-1.99%	9.00%	5.74%	
AVC	11.35%	-8.28%	9.22%	6.50%	

## Significance

The noted improvements in gait from this study indicate the potential to use AR as a non-pharmacological method for treating the effects of Parkinson's disease on gait. With this device, users can receive visual and auditory cues on-demand during performance of daily living activities. This can lead to positive implications beyond walking ability by increasing opportunities to engage in a more active and social lifestyle.

## Acknowledgments

The authors gratefully acknowledge the PAR-D Lab in helping with the development of the software used with the AR headset.

## Intermuscular Coherence within the Upper Limb in Persons with Essential Tremor

DB Free<sup>1</sup>, I Syndergaard<sup>1</sup>, AC Pigg<sup>1</sup>, S Muceli<sup>2</sup>, J Thompson-Westra<sup>3</sup>, K Mente<sup>4</sup>, CW Maurer<sup>5</sup>, D Haubenberger<sup>3</sup>, M Hallett<sup>3</sup>, D Farina<sup>6</sup>, SK Charles<sup>1</sup>

Email: daniel.free816@gmail.com

### Introduction

Essential Tremor (ET) affects millions of people, but traditional treatment options leave many patients unsatisfied [1]. Peripheral suppression techniques could prove beneficial to these patients. However, there is uncertainty on the way to apply these techniques because we do not currently know which muscles or joints are most responsible for a given person's tremor.

One difficulty in identifying which muscles are most responsible for tremor is that tremorogenic activations in different muscles are not independent of each other. Previous studies have focused on the relationships between isolated muscle pairs, typically around a single joint [2-3]. To date, no study has characterized the relationship between tremorogenic activity in muscles throughout the arm, from shoulder to wrist. The purpose of this research was to quantify these intermuscular relationships within the upper limb in tremor patients.

### Methods

24 ET subjects participated in this study. They performed both postural and kinetic tasks using seven targets in a workspace representative of activities of daily living. Each task was repeated 3 times. Muscle activity was recorded in the 15 major superficial muscles of the arm during these tasks.

The resulting raw EMG signal was processed using the common approach of high-pass filtering (20 Hz), rectification, and low-pass filtering (20 Hz). Next, the coherence between each muscle pair for every subject-task-repetition combination was computed. The maximum of the coherence in the tremor band (4-12 Hz) was then extracted, resulting in a 15-by-15 symmetric coherence matrix for each subject-task-repetition combination.

Our statistical analysis consisted of characterizing the overall pattern of coherence and its variability between subjects and over time, and then calculating the effects of control variables, which included task type (postural, kinetic), arm configuration (target 1-7), and subject characteristics (sex, tremor severity, duration, and onset). To determine the similarity in the coherence patterns between control variables, we calculated the two-dimensional correlation between pairs of coherence matrices corresponding to different control-variable combinations, and then averaged the correlations.

### Results and Discussion

Overall, the average maximum coherence in the tremor band was greatest among synergistic muscle pairs (**Figure 1**).

We found that the coherence patterns between subjects and over time were somewhat correlated ( $r = 0.50$  and  $0.46$ , respectively). In addition, we found that while the magnitude of coherence changed significantly between some levels of each grouping (task type, target, and subject characteristics), the patterns of coherence remained largely unchanged (mean  $r \geq 0.85$  in all cases). In other words, the distribution of coherence is not

significantly influenced by task type, target, or subject characteristics (sex, tremor severity, duration, and onset).

Phase calculations were only reliable for muscle pairs with significant coherence, which were synergists. These muscles pairs were consistently in phase, with a phase difference of  $3.5^\circ \pm 26.4^\circ$  (mean  $\pm$  SD), suggesting a common descending tremor signal for muscle pairs with high coherence.

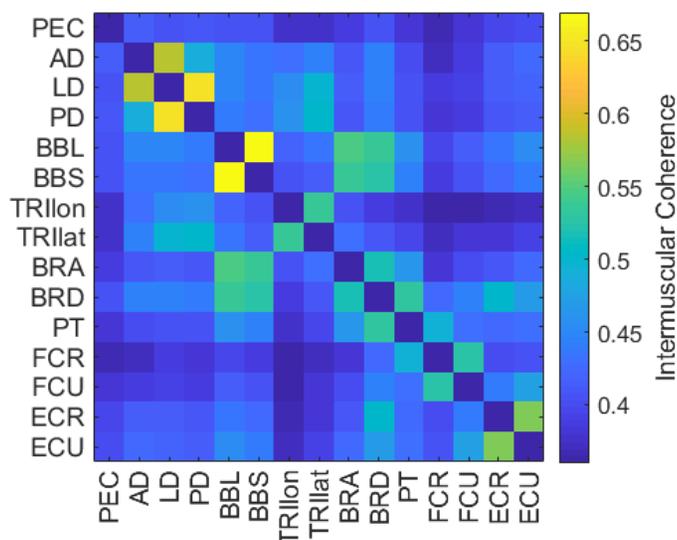

Figure 1: Intermuscular coherence in the tremor band between upper limb muscles, ordered proximally to distally: pectoralis major (PEC), anterior deltoid (AD), lateral deltoid (LD), posterior deltoid (PD), long and short heads of biceps brachii (BBL, BBS), long and lateral heads of triceps (TRIIlon, TRIIlat), brachialis (BRA), brachioradialis (BRD), pronator teres (PT), flexor carpi radialis (FCR), flexor carpi ulnaris (FCU), extensor carpi radialis (ECR), and extensor carpi ulnaris (ECU). Diagonal values were zeroed to emphasize other elements of the matrix.

### Significance

This study is the first to characterize the coherence in tremor-band activity between muscles from the shoulder to the wrist. This characterization is one step in the process of determining which muscles are most responsible for tremor; quantifying the relationships in tremorogenic activity between muscles will allow us to interpret future investigations of the relationships between tremorogenic muscle activity in various muscles and the resulting tremor in the various degrees of freedom of the upper limb.

# ECG Artifact Subtraction from Intramuscular Diaphragm EMGs in Humans with Acute Spinal Cord Injuries

Clayton N. Wauneka<sup>1</sup>, Paul Freeborn<sup>1</sup>, Emily J. Fox<sup>1,2</sup>

<sup>1</sup>Brooks Rehabilitation Motion Analysis Center, Jacksonville, FL, USA

## Introduction

Intramuscular diaphragm stimulation, also known as diaphragm pacing (DP), is an emerging strategy to promote respiratory function and weaning from mechanical ventilation after severe cervical spinal cord injury (c-SCI). DP involves surgical insertion of wires into the diaphragm that connect to an external pulse generator. Most individuals receiving DP have residual capacity to sustain ventilation without the pacer for short periods, allowing for recording of diaphragm electromyograms (EMGdi). Quantification and analysis of these EMGdi may be valuable for assessment of respiratory function after c-SCI. However, these signals are typically contaminated by electrocardiogram (ECG) artifact which must be removed for subsequent analysis.

The subtraction method is a common approach that subtracts an artifact template from an original, contaminated signal. [1-2]. This approach is most successful if a separate (often unattainable) ECG recording is utilized *and* if the artifact is consistent and has a large amplitude relative to the EMG signal. If these conditions are not met, then the template may be a poor representation. This is particularly evident in recordings in c-SCI patients with severely impaired breathing and cardiac function. To address these challenges, we developed an automated modified subtraction method (MSM) to improve template accuracy for artifacts of varying characteristics, without use of a separate ECG recording.

## Methods

**Step 1 (locate ECG artifacts):** Prior methods have required a separate recording of the ECG signal [1] and prior template information [2], and then application of a cross-correlation method to locate ECGs. The MSM approach utilized the Pan-Tompkin method [3] to automatically find *approximate* locations of the ECG artifacts from a single recording that contained EMGdi contaminated with ECG.

**Step 2 (create ECG template):** To increase efficiency and minimize need for manual selection of isolated ECG artifacts [1-2], an algorithm was developed to identify the location of each isolated ECG. ECG was considered isolated if it occurred while the diaphragm was not active (i.e., between breaths). In addition, this method used the maximum number of isolated ECG samples within a recording to create the template.

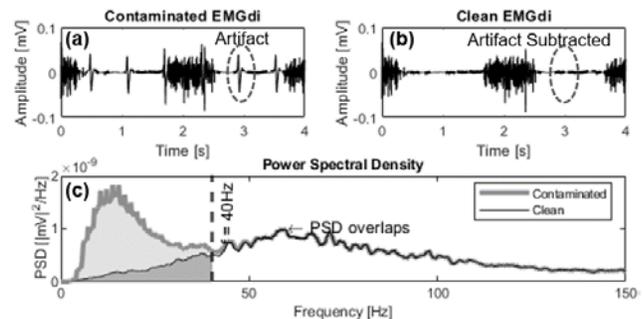

**Step 3 (align and scale ECG template):** To improve alignment of the ECG template, the template was cross-correlated with a region of the original contaminated signal (~700 ms) where ECG artifacts were approximately located. The template was then shifted based on the location of the max cross-correlation value. The ECG template was scaled to match varying ECG sizes by multiplying the template by a scale factor (SF):

$$SF = \frac{\text{Artifact Max Value} - \text{Artifact Min Value}}{\text{Template Max Value} - \text{Template Min Value}}$$

A 30 ms region around the ECG peaks (max and min.) was used to determine the SF components. A max SF value was set for each scaling value. The SF values, which were used to scale the template for isolated ECGs, were averaged together to create the max SF.

**Step 4 (subtraction):** The MSM removed ECG artifacts from the contaminated signal by subtracting the aligned and scaled ECG template from the original signal.

To demonstrate the effectiveness of the MSM, it was applied to the recorded EMGdi from a patient hospitalized for acute traumatic c-SCI (male, age: 59, C3 injury level motor complete; Fig. 1). The patient was receiving mechanical ventilator support and used a diaphragm pacer, which was disconnected during EMGdi recordings (2 kHz sampling rate). The EMGdi power spectral density (PSD) was calculated before and after the MSM (Fig. 1c) to quantify which frequency bins contributed most to the signal variance.

**Figure 1:** Plot of contaminated EMGdi (a) and clean EMGdi signal (b). Plot of the PSD of both the contaminated and clean EMGdi signal (c).

## Results and Discussion

The contaminated and clean EMGdi, Fig. 1a and b, illustrate the reduction of ECG artifact while maintaining EMGdi activity after application of the MSM. Figure 1c demonstrates that nearly 33% of the signal power in the original signal was within the 0–40 Hz spectrum. This was expected since the largest portion of the ECG power lies between 0-25 Hz [2]. Conversely, after applying the MSM, about 12% of the power was within the 0-40 Hz spectrum. This suggests the MSM removed most of the artifact composed of low frequencies while retaining relevant EMGdi signal in the same spectrum. The plots demonstrate (Fig. 1) the effectiveness of MSM to remove ECG from EMGdi signals.

## Significance

Applying the MSM may efficiently produce a higher quality EMGdi signal from complex patients such as those with acute c-SCI, where ECG artifacts are particularly challenging to remove. The MSM may be a valuable process in preparing recordings for analysis of diaphragm function and respiratory control in c-SCI patients.

**Introduction**

Deep brain stimulation (DBS) is a therapy for individuals with Parkinson's disease (PD) after pharmacologic interventions no longer optimally control motor symptoms<sup>1</sup>. Traditional DBS devices deliver electrical stimulation "omnidirectionally" from circular contact segments (i.e., "ring-mode"). Newer DBS devices include radially oriented contact segments, providing clinicians the ability to steer electrical current and shape the electrical field around the stimulator to maximize therapeutic benefit and minimize side-effects<sup>2</sup>. While these tools promise to maximize efficacy to better treat resistant symptoms of PD it is unclear how these newer devices affect overall movement function. For this initial investigation we sought to quantify the dynamic range in physical performance of DBS to affect physical function by individuals with PD. We further sought to quantify the extent to which individual contacts or circular rings affected quantitative aspects of gait, balance, and upper extremity dexterity during an initial DBS programming session.

**Methods**

Nineteen participants with PD (age 59.1±7.1 years) underwent surgery to implant a multi-contact, directional DBS lead in the subthalamic nucleus. Participants visited the lab one-month after implantation for device activation. Each DBS electrode was tested for clinical benefit with a standardized pulse width of 60 μs and a frequency of 130 Hz by a trained nurse practitioner. The novel DBS device contains six individual contacts and two virtual rings formed by 3 directional contacts each, and individual dorsal and ventral rings. Contacts were tested in random order to avoid an ordering effect. The individuals were in the practically defined "OFF" state (>12 hours without PD medicine). Individuals completed the following tasks: a 10m walking test, a timed up and go (TUG), the 9-hole pegboard test and quiet stance while standing barefoot on force plate for one minute. These tasks represented gait function, mobility, upper extremity dexterity and static balance. All tasks were performed with the device OFF and ON for each of the 10 DBS settings (6 directional contacts, 2 virtual rings, 2 individual rings). Data was ordered from best to worst relative to performance and averaged across participants. To determine whether ring-mode or an individual contact was more effective we performed a repeated measures ANOVA to compare the best contact, the best ring or OFF DBS. Post hoc comparisons were made using a Bonferroni correction.

**Results and Discussion**

A dynamic range of performance was observed for all measures from improvements that represented clinically significant changes to values that represented worsening of function (Figure 1). This dynamic range suggests that optimizing improvements in movement are possible but may require quantifying task performance during these programming sessions. When comparing the extent to which individual contacts differed compared to ring-mode, a significant

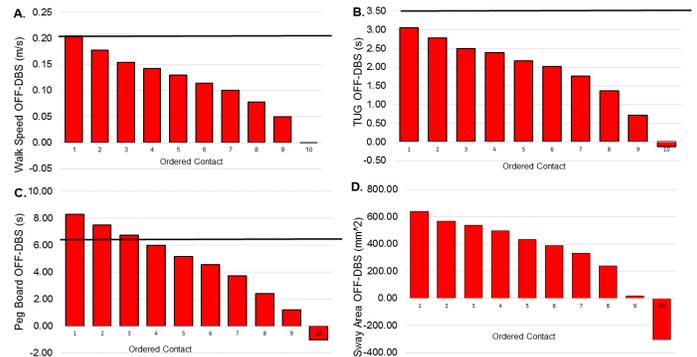

Figure 1. Dynamic Range of tasks when averaged from best to worst performance for A-Walks Speed B-Timed up and go (TUG) C-9-hole pegboard D-Sway area of quiet stance. The solid black line in A) B) and C) represent the minimal clinical difference.

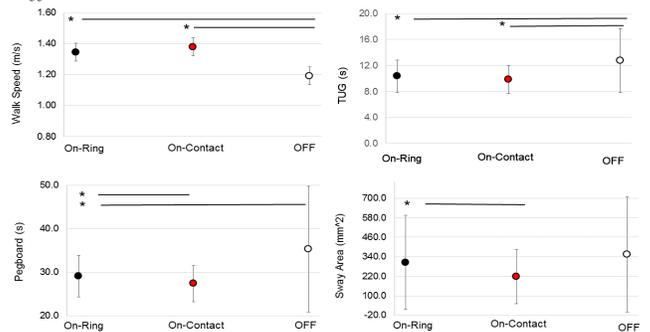

Figure 2 Comparison of best performance from ring vs. contact vs. OFF deep brain stimulation for walk speed, TUG, Pegboard, and Quiet stance. \*Represents significant post hoc difference between conditions highlighted with the line.

difference was observed. A single contact was as good as a continuous ring (Figure 2) for walk speed (p=0.17) and for Timed up and go (p=0.07) or better for pegboard (p=0.02) and sway area, measured for quiet stance (p=0.02). This suggests a single contact may be effective for improving specific functions and multiple independent contacts may optimize different functional aspects of movement.

**Significance**

Next-generation directional DBS devices have the potential to provide greater improvements in gait and balance and upper extremity movement by tailoring stimulation parameters to optimize efficacy. This study represents the first step of using quantitative data to optimize and standardize programming for greater clinical efficacy for individual patients with PD who require DBS.

## Introduction

Around half of anterior cruciate ligament (ACL) injuries are treated through reconstruction (ACLR), [1] but literature lacks mechanical investigation of these reconstructions in a dynamic athletic task and rupture environment. The objective of this study was to ascertain the feasibility of investigating ACLR mechanics in a rupture environment during simulated landing tasks in a validated mechanical impact simulator. It was hypothesized that the mechanical impact simulator model would generate non-fixation failures in the ACLR grafts and that ACLR grafts would achieve higher peak strain prior to failure than the native ACL, but that the failures would occur with reduced external loading compared to the native ACL.

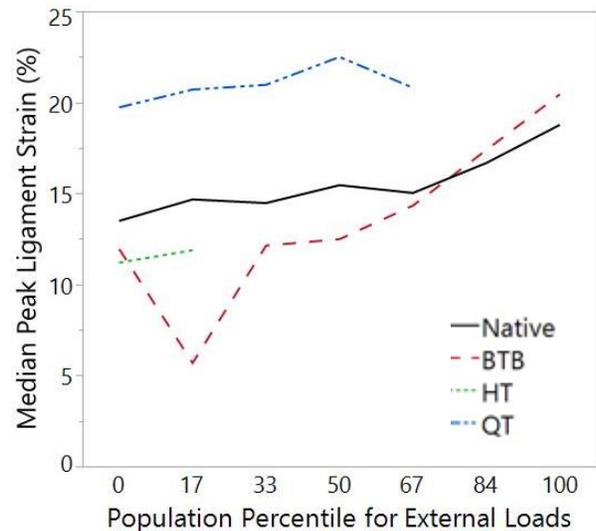

## Methods

This was a descriptive laboratory study. Four cadaveric lower extremities (Age: 41(34.5, 46.8); Mass: 79.6(75.8, 90.8)) were subjected to simulated landing in a previously described mechanical impact simulator model. [2] External joint kinetics recorded from an *in vivo* population of 44 healthy athletes were applied to each joint in an increasing stepwise manner. Simulations were repeated until ACL failure was achieved. Strain gauges that continuously recorded ligament strain were implanted on the native ACL and ACLR grafts prior to simulation. Repeated measures design was used to test each specimen in the native ACL and three separate reconstruction states (bone tendon bone (BTB), hamstrings (HT), and quadriceps (QT)). Due to limited sample size, results are presented as medians and interquartile ranges.

## Results and Discussion

ACL injuries were generated in 100% of specimens. All native ACLs experienced damage to the ligamentous structure, while graft substance damage occurred in 58% of all ACLRs, and in 75% of BTB grafts (Table 1). In the remaining trials, damage occurred to the graft fixation sites. BTB and QT grafts survived greater magnitudes of simulated loading than HT grafts, but smaller magnitudes than the native ACL. 11 of the 12 ACLR grafts tested survived at least one impact trial. BTB grafts most closely represented the native ACL strain response (Figure 1).

The mechanical impact simulator provided a viable construct for mechanical examination of ACLR grafts in a simulated rupture environment. At the time of surgery, ACL

**Figure 1:** Median peak ligament strain for each ACL state at each magnitude of external loading (0th to 100th percentile of the *in vivo* cohort) applied to the specimen's knee.

reconstruction complexes are weaker than the native ACL when subjected to equivalent loading. BTB grafts most closely resembled the native ligament and provided the most consistent graft substance damage.

## Significance

Mechanical outcomes supported BTB as the clinical standard for mimicking the native ACL. As 92% of ACLRs survived baseline impact, and jump landing generates ~4x the ground contact force of gait, this model advocated ACLR graft ability to sustain force magnitudes generated from immediate weight-bearing during ACLR rehabilitation. Future integration of an animal surrogates to the model would be desirable to quantify ACLR graft performance throughout the healing process.

Email: [camila.grant@nih.gov](mailto:camila.grant@nih.gov)

## Introduction

Patellofemoral pain (PFP) is prevalent in both the athletic and general populations, reducing quality of life and potentially leading to osteoarthritis<sup>1</sup>. It is a complex multifactorial condition, making it difficult to ascertain the patient-specific etiology of pain. Clinical decision-making is hampered by this lack of granularity into the causes of PFP. Demographics (e.g., sex, height, weight) may play a role in mediating the susceptibility of developing PFP. For example, PFP is more prevalent in females, but the reasons for this have not been well explored. Thus, the aim of this study is to address the potential influence of demographic characteristics on patellofemoral (PF) maltracking, with the specific hypothesis that sex, height, weight, and BMI influence kinematics, whereas age does not.

## Methods

As part of an ongoing IRB-approved protocol, this retrospective study included 42 skeletally mature patients with idiopathic PFP and 80 healthy controls, recruited from 2009-2019. The demographic covariates assessed were age, sex, height, weight, and body mass index (BMI). 3D PF kinematics were quantified from dynamic cine-phase contrast MR images. Multiple regression analyses were run to determine the influence of covariates on PF kinematics (R, ver. 3.6.0). To avoid redundancy, for each outcome of interest (PF medial-lateral and superior-inferior shift, tilt, and flexion) was evaluated using two separate models: model\_B (covariates: group, age, BMI, sex) and model\_HW (covariates: group, age, height, weight, sex). To evaluate the effect of covariates on between-groups differences in PF kinematics, the group variable (PFP vs. controls) was always kept in the model, regardless of its significance. Upon violation of model assumptions, statistical outliers were removed. Significance was set at  $p < 0.05$ .

## Results and Discussion

Patellar medial-lateral shift was influenced by weight and by BMI in model\_HW and model\_B (Table 1). Flexion was influenced by height and weight in model\_HW, but not influenced by any covariate in model\_B. Superior-inferior shift and tilt were not influenced by any covariates in either model. Age and sex were not significant covariates in either model. Group had a significant effect for flexion and tilt. The lack of group significance in medial-lateral shift was likely due to the fact that the nine outliers (3 controls, 6 PFP) removed from model\_HW and 12 outliers (5 controls, 7 PFP) removed from model\_B had the most extreme medial/lateral shift, which drastically reduced the difference in shift between groups.

The relationship between weight and patellar kinematics has not been previously explored. However, based on studies<sup>2,3</sup> assessing the quadriceps influence on patellar maltracking, we postulate that with a greater quadriceps force demand, needed to accommodate a heavier leg, the patella flexes and shifts more laterally. Differences in the distal femoral geometry may explain the increased patellar flexion seen in taller individuals. It was surprising that sex did not influence PF kinematics;

however, this should be taken with caution, as the higher prevalence of PFP among females led to a smaller cohort of males included in this study. Stratifying age (e.g., pre- and post-bone fusion or time since symptom onset) may help reveal a more nuanced relationship between age and PF kinematics.

## Significance

There is a clear influence of key demographic parameters on PF kinematics in patients with PFP and controls. The fact that weight, a modifiable measure, influences both patellar shift and flexion has strong implications for future research and clinical intervention. In our recent review on PF kinematics<sup>4</sup>, the majority of included papers did not report cohort weight and/or BMI and, even fewer matched cohorts based on height, weight, or BMI. Clinically, for patients who are overweight and experiencing PFP, weight loss may have a dual benefit of reducing joint stress and maltracking. Lastly, until definitive evidence demonstrates a lack of influence of sex and age on PFP, these characteristics should be taken into account when investigating the etiology of PFP. Controlling for population characteristics is a crucial in research, well beyond our focus on investigating the mechanisms of PFP. Methodology addressing these variables must be adopted moving forward.

## Introduction

Dynamic tasks can magnify kinematic and kinetic differences between healthy knees and those with an anterior cruciate ligament reconstruction (ACLR) [1], likely due to increasing the mechanical loading of the knee during biomechanically challenging tasks. We previously found that individuals with an ACLR exhibited significantly lower peak knee flexion moments than controls when descending stairs, a difference we did not detect during overground walking [2]. Further, we observed that these differences were more pronounced when descending to another step as opposed to descending to the floor, suggesting that the primary driver of differences in joint mechanics between ACLR subjects and controls was an increased locomotor task demand. However, it is yet unknown if this increased task demand could further detect differences in the generated knee muscle forces between ACLR subjects and controls.

The purpose of this study was to examine how increasing locomotor task demand might differentiate estimates of knee muscle forces between healthy control subjects and ACLR subjects with a hamstring tendon (HT) or patellar tendon (PT) autograft. We hypothesized that more demanding locomotor tasks would better discriminate changes in knee muscle forces after an ACL reconstruction. Given that the intrinsic mechanics of the supporting musculature would be affected by the graft type used in the reconstruction [3], we further hypothesized that changes to knee muscle forces after an ACLR would manifest differently based on the graft type.

## Methods

We used musculoskeletal modelling and simulation to identify individual knee muscle forces in ACL-reconstructed ( $n = 9$ , age =  $30 \pm 8$  yrs, 5 with HT graft, ) and control subjects ( $n = 6$ , age =  $28 \pm 4$  yrs) when walking overground and descending stairs, derived from motion capture data and ground reaction forces in OpenSim. We restricted our analysis to the stance phase (foot contact through toe-off), yielding 162 separate simulations for overground walking, step-to-floor stair descent, and step-to-step stair descent. Muscle forces were time normalized as a percentage of the stance phase, and amplitude normalized to the maximum isometric force of the generic model scaled by each subject's mass.

We evaluated between-group differences in muscle force using statistical parametric mapping. A one-way ANOVA

tested for a main effect ( $\alpha = 0.05$ ) between subject groups (controls, ACLR HT, ACLR PT). Posthoc pairwise comparisons with a Bonferroni correction focused on differences between ACLR subjects vs the controls.

## Results and Discussion

Our results support our hypothesis that increased locomotor task demand can differentiate estimates of knee muscle forces in ACLR subjects by graft type, presenting predominantly as changes in quadriceps muscle forces. The quadriceps had long instances during loading and midstance where subjects with an ACLR exhibited significantly reduced muscle forces compared to controls, primarily in the vasti (Fig. 1). These instances within the vasti appeared consistently across all tasks, and grew longer with increased task demand. ACLR HT subjects demonstrated significantly reduced muscle forces during all tasks, but only during the more demanding stair descent task did ACLR PT subjects present significantly reduced muscles forces.

The gastrocnemii exhibited significantly increased gastrocnemii muscle forces for ACLR PT subjects at moments leading up to push-off over level ground (i.e., during walking and stair decent to floor), but we saw no significant differences within peak force production. It was only during the more demanding stair descent to step task did ACLR HT subjects exhibit significant differences in gastrocnemii muscle force from controls, occurring during peak force production within the loading phase.

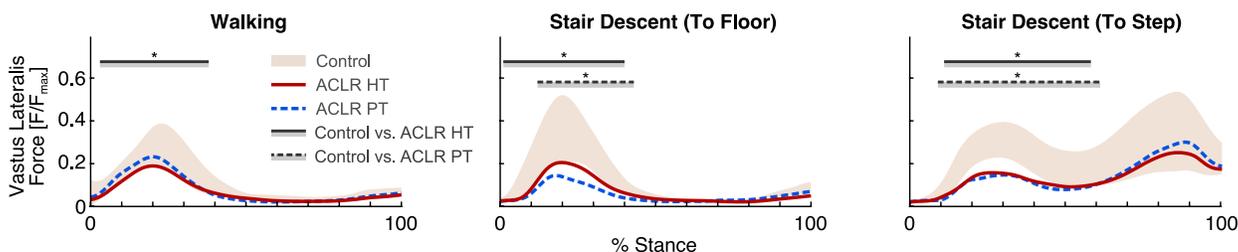

The few differences in hamstrings muscle force were limited to short instances within the initial loading response or push-off phases, but these differences were not consistent across the tasks.

## Significance

Post-surgical rehabilitation strategies employ a variety of dynamic tasks aimed to restore the knee joint [4], and might benefit from therapy targeted at restoring hamstring muscle force. This research also emphasizes the utility of increasing task demand to further detect residual deficits after ACLR, which may provide important clinical metrics of recovery.

# Optimal Placement of Suspension Fixation Tunnel to Restore Proximal Tibiofibular Joint Stability: A Finite Element Study

<sup>1</sup>Musculoskeletal Institute, Atrium Health, Charlotte, NC, USA

Email: \*[Shangcheng.Wang@atriumhealth.org](mailto:Shangcheng.Wang@atriumhealth.org)

## Introduction

The Proximal tibiofibular joint (PTFJ) connects the fibular head to the posterolateral side of the proximal tibia. The anterior and posterior ligament bundles and interosseous membrane are the primary passive structures to stabilize this joint. The injury or rupture of these passive structures, although not common, can lead to PTFJ dislocation or chronic instability and lateral knee pain. When non-operative interventions fail, surgical intervention is needed to restore PTFJ stability. Bicortical suspension fixation (BCSF) is a promising technique and has been very successful in treating distal tibiofibular instability. Unlike screw fixation, it does not require hardware removal after healing and allows physiological motion of the PTFJ which may be important for ligament healing. Unlike anatomic ligament reconstruction, bicortical suspension fixation does not require a harvested tendon graft.

However, the ideal placement of the suture tunnel is still subjective. It is not clear how the variations in tunnel placement can affect the restoration of PTFJ stability. Currently, the joint stability can only be confirmed by pushing the fibular head (anterior shuck test) after the rope is placed and tension is applied. If the PTFJ is still unstable, a second BCSF device is needed [1]. Thus, this study first created a finite element model of an intact PTFJ; virtual ligament resection and tight rope repair were consequently performed. Forty-eight models of BCSF repair were created by varying the location of the entry point of the guide tunnel on the fibular head and the exit point on anteriomedial tibia. We hypothesized that the location and orientation of the bicortical suspension fixation significantly affects the restored joint stiffness.

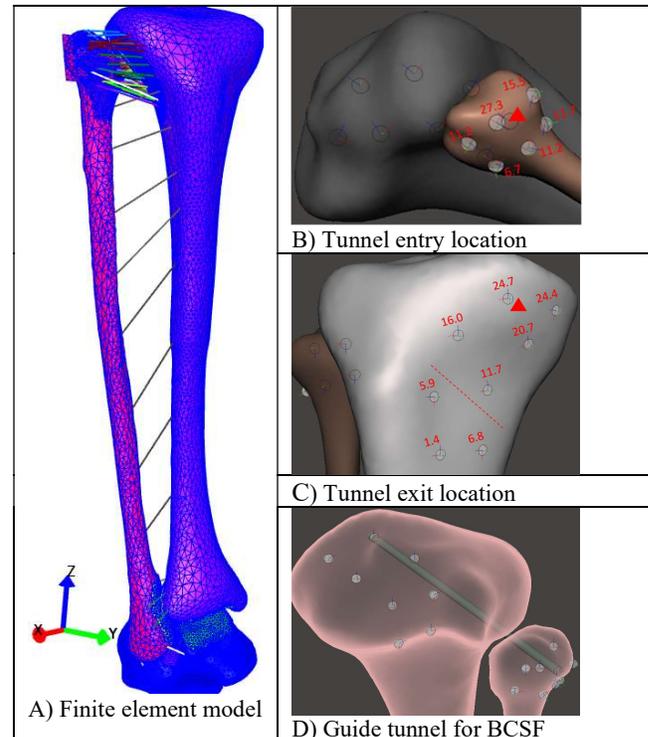

## Methods

A finite element model of the lower leg including proximal and distal tibiofibular joints was created from MRI data of a female subject in the Visible Human Project (Fig. 1). The anatomic structures of the tibia, fibula, talus, and calcaneus bones were segmented using 3D Slicer software; bones were modeled as rigid bodies. Ligaments and membranes were modelled as tension-only linear springs. The origin and insertion of these ligaments were determined from anatomy atlas and papers. The stiffness and failure strain of each ligament were obtained from several biomechanical papers [2].

The bicortical suspensory fixation was also simulated by a tension-only linear spring. The BCSF was placed through a guide tunnel drilled from the posterolateral fibular head toward anteriomedial tibia, just medial to the tibial tubercle [1]. Considering the small sizes of the button and suture, six detailed designs of entry point and 8 designs of exit point were created (Fig. 1). The combinations of these designs resulted in 48 BCSF repair models. The stiffness and failure strain of the BCSF were based on mechanical testing of Fiberwire®.

Intact, posterior ligament-resected, and BCSF-repaired models were created by changing the corresponding spring stiffnesses. Anterior shuck test of the PTFJ was simulated for each created model by applying a 100 Newton compression force on the posterior palpable surface of the fibula head. The anterolateral

displacement of the fibular head was recorded before any ligament failed. PTFJ stiffness was calculated based on a displacement-force curve.

**Figure 1:** the created finite element model A) and design of tight rope placements, including 6 designs of tunnel entry location on fibular head B) and 8 designs of tunnel exit location on tibia C). One design of BCSF placement is shown in D). The result of average PTFJ stiffness was shown beside each entry/exit point, and the optimal location was marked with a triangle on B) and C).

## Results and Discussion

The injury of the posterior ligament decreased PTFJ stiffness from 10 N/mm to 1.6 N/mm, which would make the PTFJ unstable. Paired t-tests revealed that the placement of BCSF affects the restoration of PTFJ stiffness; this confirms our hypothesis. Some placements of BCSF resulted in a PTFJ stiffness less than 10 N/mm. The highest restored stiffness was 53.8 N/mm, with its entry at proximal and posterolateral fibular head (Fig.1 B), and its optimal exit at proximal and medial tibia which is close to the medial collateral ligament attachment area (Fig.1 C).

## Significance

PTFJ instability is a very disruptive condition, its relatively uncommon occurrence has prevented a standardized method of repair. This study provides insight on the placement of bicortical suspension fixation devices for the repair of the PTFJ as a standardized method.

## Introduction

Reduced knee extension moment symmetry and increased surgical limb frontal plane projection angle (FPPA) range of motion (ROM) during bilateral landing are associated with an increased risk for sustaining a second anterior cruciate ligament (ACL) injury in patients following ACL reconstruction (1). Additionally, low knee flexion ROM symmetry during a unilateral drop landing is prospectively associated with worse self-reported pain and quality of life (2). Recent work has identified clinically feasible methods to quantify these outcomes (3-5). Load sensing insoles have excellent validity (ICC = 0.97) for assessing impulse symmetry (3), and can explain 61% of the variance in knee extension moment symmetry (4). Additionally, automated 2D video analysis has excellent validity (ICC > 0.91) for assessing FPPA ROM and knee flexion ROM (unpublished data). The purpose of the present study was to explore the ability of using load sensing insoles and two videocameras to identify landing mechanics deficits in patients who are 6-12 months following ACL reconstruction. We hypothesize that relative to healthy controls, patients following ACL reconstruction would have reduced impulse symmetry and increased surgical limb FPPA ROM during a bilateral landing and reduced knee flexion ROM symmetry in a unilateral landing.

## Methods

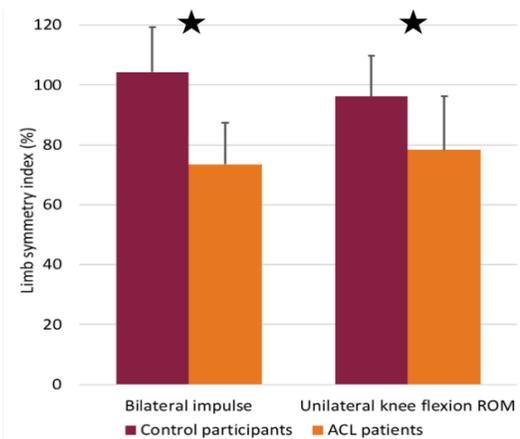

16 patients recovering from a primary unilateral ACL reconstruction (7 male/9 female) who were between 14 and 30 years old, 6 and 12 months post-operative ( $9.7 \pm 2.0$  months), and preparing to return to sports which involved jumping, and 16 healthy control participants (7 male/9 female) who were between 18 and 30 years old and participated in jumping sports signed IRB approved informed consent and participated in the present study.

All participants completed 7 bilateral forward drop vertical jumps to a distance of half their bodyheight and 7 unilateral drop landings on each limb, all from a 31 cm high box. Plantar impact forces were measured bilaterally using loadsol<sup>®</sup> sensors (100 Hz, Novel Electronics, St. Paul, MN). Reflective markers were placed bilateral on the lateral thigh, femoral epicondyle, and shank. Frontal and sagittal plane videos were collected using an iPad Pro and an iPhone 6S (240 Hz, Apple, Cupertino, CA). Each marker was automatically digitized throughout each trial using Automated Video Analysis for Dynamic Systems (5). All participants wore standardized neutral cushioned running shoes, but were allowed to wear their own athletic clothing. ACL patients were tested at one of two local rehabilitation centers, and control participants were tested at a university athletic center. Outcomes were chosen based on previous literature that identified risk factors for a second ACL injury (1, 2). Surgical limb or non-dominant limb FPPA ROM and impulse limb symmetry index (LSI) were computed during bilateral landing, and knee flexion ROM LSI was computed during unilateral landing. LSIs were computed as the ratio between surgical (non-dominant) and non-surgical (dominant) limbs. Outcomes and

demographics were compared between groups using independent samples t-tests with an alpha level of 0.05.

## Results and Discussion

The ACL reconstruction patients were younger than control participants (ACL:  $17.1 \pm 1.4$  years; control:  $23.7 \pm 2.7$  years;  $p < 0.001$ ). However, height and weight were similar between groups (both  $p > 0.135$ ). Compared to healthy control participants, ACL reconstruction patients had reduced impulse LSI during bilateral landing ( $p < 0.001$ ,  $d = 2.14$ ) and knee flexion ROM LSI during unilateral landing ( $p = 0.004$ ,  $d = 1.12$ ). However, surgical and non-dominant limb FPPA ROM during bilateral landing was similar between groups ( $p = 0.498$ ,  $d = 0.23$ ).

**Figure 1:** Comparison of LSI outcomes between groups.

Note: \* indicates significant ( $p < 0.05$ ) differences.

The differences observed between groups for impulse LSI and knee flexion ROM LSI are consistent with previous literature. While FPPA has not been previously compared between ACL reconstruction patients and healthy controls, increased FPPA has been prospectively linked to ACL injuries in uninjured athletes (6) and patients following ACL reconstruction (1). Therefore, FPPA is likely an important outcome to assess, despite non-significant differences observed in the present study.

## Significance

The present study objectively assessed continuous kinetics and kinematics in a clinical setting, and found landing deficits which have been linked to risk for second ACL injury and greater self-reported pain. These assessment methods could be useful for return to sport testing in patients following ACL reconstruction.

### Introduction

Individuals with history of anterior cruciate ligament reconstruction (ACLR) often exhibit aberrant movement patterns compared to their uninjured peers. Asymmetries between limbs during drop vertical jump landing tasks are often utilized as a component of return to sport criteria and patient-reported function.

The purpose of this study was to evaluate limb symmetry indices during a drop vertical jump landing task following ACLR. Secondly, the purpose of this study was to assess the ability of limb symmetry indices to predict patient-reported activity level and knee function.

### Methods

14 recreationally active individuals with history of primary unilateral anterior cruciate ligament reconstruction (ACLR) participated in this study. Participant demographics are included in Table 1.

Participants completed testing 6-months following ACLR. Participants were asked to self-report activity level prior to and following ACL injury and surgery utilizing the Tegner Activity Scale (TAS) and knee function during activities of daily living utilizing the International Knee Documentation Committee Subjective Knee Evaluation Form (IKDC).

Biomechanical assessment of peak vertical ground reaction force (vGRF) and peak knee flexion angle were conducted utilizing three-dimensional motion capture (Vicon Motion Systems, Ltd., Oxford, UK) and two integrated force platforms (Advanced Medical Technology Inc., Watertown, USA).

Clusters with retro-reflective markers were placed bilaterally on participants using tape at the lateral thighs and shanks, navicular of the feet, and the upper thoracic and lumbar spine. A stylus with four retro-reflective markers was utilized to identify major anatomical landmarks in order to estimate joint centers.

Participants were instructed to drop off a 30-cm box, positioned at a distance ½ participant height away from the force platform. Participants were shown the jump-landing task and were instructed to drop from the box and immediately jump upward in order to attain maximal height.

Knee joint biomechanics were processed utilizing a standard inverse dynamics approach. Data were analysed during the descent, landing phase. Limb symmetry index (LSI) was determined by between limb differences of peak knee flexion angle and peak vGRF utilizing the following equation:

$$LSI = (involved\ limb\ value / uninvolved\ limb\ value) \times 100\%$$

Pearson product moment correlation coefficients (*r*) were utilized to evaluate the relationships between self-reported activity level (TAS), self-reported knee function (IKDC), vGRF limb symmetry (LSI), and knee flexion limb symmetry (LSI).

Sex (M/F)	6/8
BMI (kg/m <sup>2</sup> )	28.27 ± 6.07
Time Since Surgery (months)	6.47 ± 0.98
Graft Type	11 Hamstring/ 2 Patellar/ 1 Hamstring-Allograft
IKDC	82.10 ± 8.48
Tegner Before*	8 [5, 10]
Tegner Current*	5 [1, 8]

**Table 1:** Participant demographic information is reported as mean ± standard deviation unless otherwise indicated. \*median [range].

### Results and Discussion

All participants (14) demonstrated limb symmetry surpassing the widely utilized 90% clinical cut-off for knee flexion angle during drop landing (98.99 ± 16.13). However, only 29% of participants (4) met clinical cutoffs for vGRF limb symmetry (71.31 ± 19.24).

Knee flexion LSI and vGRF LSI were moderately correlated (*r* = 0.597). Knee flexion LSI was not correlated with current self-reported activity (*r* = 0.190) nor knee function (*r* = 0.057). vGRF LSI was not correlated with self-reported activity (TAS), *r* = 0.108, nor knee function (IKDC), *r* = 0.124.

Self-reported activity level (TAS) and knee function (IKDC) were not related to drop vertical jump performance in young individuals 6-months following ACLR. Limb symmetry outcomes, including knee flexion LSI and vGRF LSI were moderately correlated, *r* = 0.597.

Patient-reported knee function and activity level surveys should be utilized in conjunction with objective outcome measures in order to evaluate function in young individuals 6-months following ACLR. Utilizing subjective measures alone may not provide enough information about knee function following ACLR in order to determine young patients' readiness for return to sport. In addition, the combination of objective and subjective measurements may provide better insight into patient function and prevention of secondary ACL injury.

### Significance

The relationship between functional performance and patient-reported survey outcomes has been investigated previously, but the relationship between limb asymmetries during a drop landing vertical jump task and patient-reported knee function and activity level had not been previously investigated. Asymmetries during landing tasks are often associated with increased risk of secondary ACL injury. Importantly, this provides further evidence that there is a need to utilize objective and subjective measures together in order to determine return to play readiness for young individuals with a history of ACLR.

## Introduction

Arthrogenic muscle inhibition (AMI) after anterior cruciate ligament (ACL) injury and reconstruction prevents complete activation of thigh musculature and results in impaired strength recovery [1]. However, it is currently unknown if quadriceps motor unit (MU) characteristics differ between the injured and noninjured limb after ACL injury. It was hypothesized that the injured limb would demonstrate inhibition compared to the noninjured limb. Specifically, inhibition would be demonstrated by smaller MU action potential (MUAP) peak amplitude, lower neural drive, higher recruitment thresholds, and higher average rate coding than the noninjured limb.

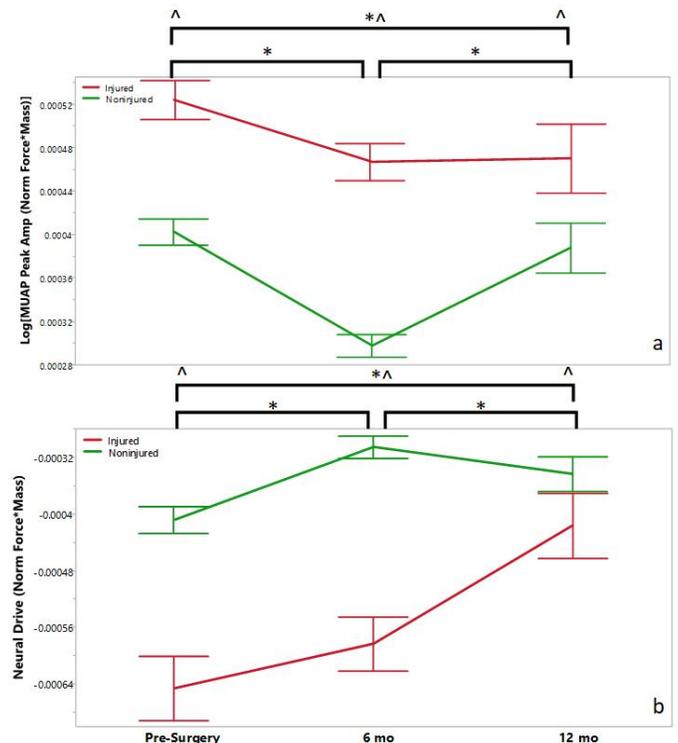

## Methods

Thirty subjects participated in the study (13 male, 17 female; age:  $19.1 \pm 3.1$  years; height:  $172.8 \pm 8.8$  cm; weight:  $77.2 \pm 15.1$  kg). Subjects were recruited at Pre-Surgery and 6 months post-surgery. Data were acquired at 6 month intervals ( $\pm 1$  month), resulting in 3 groups (Pre-Surgery, 6 mo, and 12 mo).

Subjects were seated on a HumacNORM dynamometer chair for testing (CSMi; Stoughton, MA). Surface EMG (sEMG) was recorded at 20 kHz (Delsys; Natick, MA). Standard sEMG preparation was performed and electrodes were placed on the vastus medialis (VM) and vastus lateralis (VL) for quadriceps testing according to SENIAM standards. sEMG signals were recorded by a 5-pin array sensor. The signals from the sensor electrodes were differentially amplified and bandpass filtered (20–450 Hz). Three maximal voluntary isometric contraction (MVIC) trials were conducted, and the peak force was determined to establish target forces of 10-50% MVIC. With a randomized protocol, subjects followed a trapezoidal shape, with a 10-second isometric contraction at the target force. EMG decomposition was completed with *Delsys dEMG Analysis* software. MU data was extracted and analyzed with *JMP 14 Pro* (SAS; Cary, NC) statistical software via linear regression ( $p < 0.05$ ) and Tukey's *post-hoc* analyses when appropriate. MU data were normalized to force and mass before analysis. Neural drive is defined as the change in initial rate coding and average rate coding.

## Results and Discussion

Injured limb MUAP peak amplitude was higher than the noninjured limb for all three groups (Fig. 1a;  $p < 0.001$ ). MUAP peak amplitude was significantly different between all groups and lowest 6 months post-surgery ( $p < 0.001$ ). Injured limb neural drive was lower than the noninjured limb for all three groups and increased from pre-surgery to 12 months post-surgery (Fig. 1b;  $p \leq 0.02$ ). Injured limb recruitment threshold and average rate coding was higher than the noninjured limb for all three groups ( $p < 0.001$ ). There were significant differences between groups for average rate coding and recruitment threshold, except between pre-surgery and 12 months post-surgery recruitment threshold ( $p = 0.07$ ) and average rate coding for 6 and 12 months post-surgery ( $p = 0.28$ ).

**Figure 1:** a) MUAP peak amplitude and b) neural drive between groups and limbs. ^ indicates significant difference between limbs; \* indicates significant difference between groups

The results partially support the hypothesis. Neural drive was lower and average rate coding and recruitment thresholds were higher in the injured limb, but MUAP peak amplitude was higher in the injured limb. This may suggest that larger MUs are recruited, increased recruitment threshold and average rate coding are a compensatory mechanism following ACL injury to efficiently recruit smaller MUs. Voluntary muscle force production can be controlled by modification of neural and motor control variables, which include MU recruitment, neural drive, recruitment threshold, and average rate coding.

## Significance

Current rehabilitation protocols fail to fully restore quadriceps strength and function, as demonstrated by poor return-to-sport testing rates [2]. It may be possible that current rehabilitation methods fail to adequately address the underlying alterations in neural control of muscle function. Thus additional neuromotor strategies should be implemented to address MU inhibition.

# Modeling the Effect of Femoral Anteversion on Knee Extensor Muscle Force and Anterior Knee Mechanics

Benjamin B. Wheatley<sup>1</sup>, Mark A. Seeley<sup>2</sup>

<sup>1</sup>Department of Mechanical Engineering, Bucknell University, Lewisburg PA, USA

<sup>2</sup>Department of Orthopaedic Surgery, Geisinger Medical Center, Danville PA, USA

Email: [b.wheatley@bucknell.edu](mailto:b.wheatley@bucknell.edu)

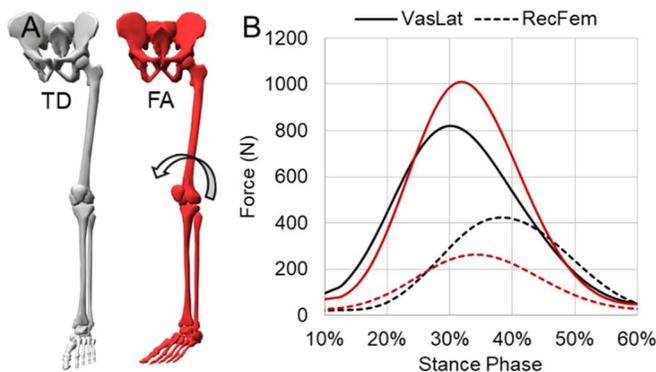

## Introduction

Severe anterior knee pain limits mobility and is associated with osteoarthritis. High femoral anteversion or excessive torsion of the femur can contribute to joint pain, and in extreme cases is treated surgically with femoral derotational osteotomy. There currently exists no standard to determine the location and extent of de-rotation to optimize patient outcomes. The goal of this work is to develop and employ a computational framework to study the effect of femoral anteversion on patellofemoral joint mechanics.

## Methods

A coupled musculoskeletal-finite element modelling approach was developed for this work. In short, an open-source tool designed to simulate surgical intervention for cerebral palsy patients (SimCP) [1] was used to alter femoral anteversion and associated muscle attachment points on the OpenSim FullBodyModel [2]. With freely available motion capture and ground reaction force data [2], inverse kinematics and static optimization methods were used in OpenSim to estimate knee extensor muscle forces during gait for two cases: typically developing lower limb torsion (TD) and increased femoral anteversion by 40° (FA) (Figure 1A).

Scaled knee extensor muscle force vectors (Figure 1B) were then input into four subject-specific finite element models of the patellofemoral joint (Figure 2A). Three models were built from subjects with typically developing patellofemoral joint morphology (S1-S3), while one was built from a subject with a hypoplastic patella (S4). The resulting finite element simulations of peak force during stance across both femoral anteversion conditions provided comparisons of cartilage mechanics.

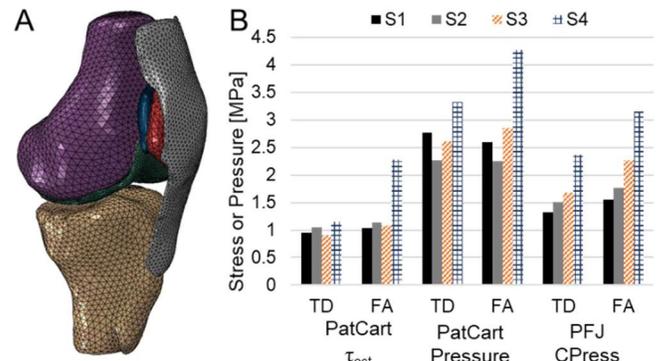

**Figure 1:** A) Morphological differences between typically developing (TD) and +40° femoral anteversion (FA) models. B) Vastus lateralis (solid) and rectus femoris (dashed) muscle forces for TD (black) and FA (red) models as a function of stance phase.

## Results and Discussion

Increases in femoral anteversion of the musculoskeletal model yielded ~200N changes in muscle force for the vastus lateralis (increase) and rectus femoris (decrease) (Figure 1B). Of the four finite element geometries, the hypoplastic subject model (S4) increased maximum cartilage octahedral shear stress and

hydrostatic pressure by ~1 MPa with increasing femoral anteversion, while the other models saw negligible changes (Figure 2A). However, increases in mean joint contact pressure were observed across all models (Figure 2B).

Our results suggest that in addition to altered hip kinematics [3], femoral anteversion may alter knee extensor activation patterns and could negatively impact anterior knee cartilage mechanics. Our finite element results generally agree with the observation that patellofemoral cartilage mechanics are sensitive to increases in vastii forces [4]. However, we have suggested that shifting load between knee extensor muscles can also affect cartilage stress, particularly in patients with malformed patellofemoral geometry. However, future pre- and post-surgery clinical data are needed to better understand the interactions between muscle activity, gait dynamics, and patellofemoral mechanics.

**Figure 2:** A) Representative finite element model of the patellofemoral joint. B) Finite element modeling results, comparing maximum patellar cartilage octahedral shear stress, maximum patellar cartilage pressure, and mean patellofemoral joint contact pressure for typically developing (TD) and femoral anteversion (FA) muscle forces. Comparisons are made between four subject patellofemoral joint geometries (S1-S4).

## Significance

We present a musculoskeletal-finite element modelling workflow that suggests increases in femoral anteversion could alter knee extensor muscle activity and patellofemoral joint mechanics, particularly in patients with malformed patellae. Future clinical data are needed to validate this workflow such that it can be used to aid in patient-specific surgical planning.

## Lower Extremity Muscle Force Adaptation to Increased Q-Factor in Stationary Cycling

Tanner Thorsen.<sup>1</sup>, Erik Hummer<sup>1</sup>, Joshua Weinhandl<sup>1</sup>, and Songning Zhang<sup>1</sup>

<sup>1</sup>The University of Tennessee, Knoxville

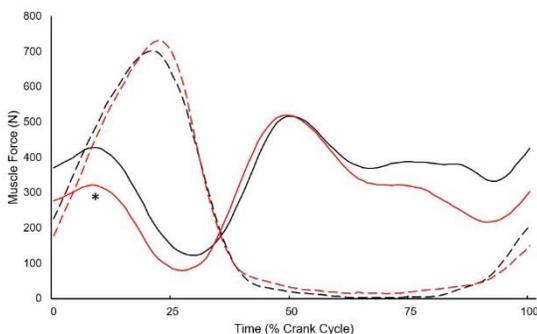

Email: [tthorsen@vols.utk.edu](mailto:tthorsen@vols.utk.edu)

### Introduction

We have previously shown that as the Q-Factor (QF), inter-pedal width, of a bicycle is increased, the internal knee abduction moment (KABM) increased and the knee extension moment (KEM) remained unchanged [4]. Peak medial pedal reaction force (PRF) also increased while peak vertical PRF did not change. Our recent musculoskeletal simulation results suggest that, with increased QF, the contact force at the medial compartment of knee joint (MCF) increases, yet the total knee contact force (TCF) remains unchanged [3]. It is well known that muscle forces are the key contributor to joint contact forces [2], however, it is unknown if differences in forces produced by knee-joint spanning muscles explain the increased MCF and unchanged TCF. Therefore, the purpose of this research was to identify changes of knee-joint spanning muscle forces as a result of increasing QF during stationary cycling.

### Methods

Sixteen recreationally active people (8 male 8 female) cycled on a stationary ergometer at a workrate of 80 Watts and a cadence of 80 rotations per minute at two QF: Normal QF (150mm), and Wide QF (276mm). Wide QF was increased using two pedal extenders. Three-dimensional kinematic data (240 Hz, Vicon) and pedal reaction forces using two custom instrumented bike pedals (1200 Hz, Kistler) were collected. A modified gait2392 model with a knee that includes hinge joints for the medial and lateral compartments [1] was used to estimate muscle forces with static optimization and TCF and MCF with joint reaction analysis (3.3 OpenSim, SimTK, Stanford University).

**Figure 1:** Knee flexor and extensor muscle group forces during cycling with increased QF. Knee Flexors —, Knee Extensors ---, Wide QF = red. \* denotes significance between peaks of same muscle group.

Individual muscle forces as well as two muscle groups (the summed muscle forces of the knee flexors (i.e. the hamstring muscles, sartorius, and the gastrocnemius muscle), and knee extensors (i.e. the quadriceps muscles)) were analyzed. Paired samples t-test and Cohen's d were used to detect differences between conditions.

### Results and Discussion

As a group, the knee extensors did not produce different peak forces at Wide QF (Table 1). Individually the rectus femoris produced 60% greater peak force with increased QF. The knee flexor muscles produced 20% less peak force, with the sartorius, and semitendinosus producing lower peak forces. The biceps femoris short head produced 24% greater peak force at Wide QF. Time of peak force production for all muscles and muscle groups remained unchanged.

The trends in peak knee-spanning muscle force production partially suggest that a combined effect of no change in force of the knee extensors (lest a small increase from the rectus femoris muscle) and diminished peak force production of the knee flexors may have contributed to increased MCF. Accounting for the relatively small absolute increase in muscle force for the rectus femoris and sartorius muscles (58.0 N and 6.9 N respectively), solitary analysis of knee-joint-spanning muscles may be insufficient to explain the increase of MCF without increased TCF. Qualitative analysis of hip extensors and hip abductor muscle groups suggest that non-knee-joint-spanning muscle groups may affect MCF.

**Table 2:** Selected knee joint spanning muscle forces (N) at Normal and Wide QF during cycling. d = Cohen's d.

	Q-Factor		p-value	d
	Normal QF	Wide QF		
Knee Flexors	471.66	378.43	<b>0.046</b>	0.45
Knee Extensors	742.81	754.28	0.757	0.06
Rectus Femoris	101.31	159.29	<b>0.008</b>	0.80
Semitendinosus	23.56	15.93	<b>0.012</b>	0.59
Biceps Femoris	149.65	185.39	<b>0.002</b>	0.70
Sartorius	21.23	28.11	<b>0.001</b>	0.47

### Significance

This study is the first study to identify differences in knee-spanning muscle force production as it pertains to increased QF during cycling. Increasing QF appears to elicit no real change in knee extensor muscles, and, suggests that the knee flexors respond with decreased force. These results do not fully explain the increase in MCF and future work may seek to further identify the effect of non-knee-joint-spanning muscle groups on MCF.

# Serum Cartilage Oligomeric Matrix Protein Response to Braced and Non-braced Walking in Individuals with Anterior Cruciate Ligament Reconstruction

Alyssa Evans-Pickett<sup>1</sup>, Hope C. Davis-Wilson<sup>1</sup>, Christopher D Johnston<sup>1</sup>, J. Troy Blackburn<sup>1</sup>, Brian Pietrosimone<sup>1</sup>

<sup>1</sup>MOTION Science Institute, Department of Exercise and Sport Science, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States

Email: [alyssa7evans@unc.edu](mailto:alyssa7evans@unc.edu)

## Introduction

Individuals with anterior cruciate ligament reconstruction (ACLR) are at high risk for developing post-traumatic osteoarthritis (PTOA). It is hypothesized that aberrant knee joint loading leads to increased deterioration of tibiofemoral articular cartilage following ACLR.<sup>1</sup> Knee braces are commonly marketed to reduce loading of the tibiofemoral articular cartilage in patients with cartilage injury at risk of PTOA onset. Currently, it remains unknown if knee braces used to reduce cartilage loading benefit articular cartilage health. Cartilage oligomeric matrix protein (COMP) is a biomarker of cartilage breakdown that is associated with osteoarthritis progression and is responsive to mechanical loading during walking. A greater increase of serum COMP following a single walking session may be representative of a worse knee cartilage response to loading in individuals post-ACLR.

The purpose of our study was to determine if acute serum COMP response differs between a braced and unbraced condition following a standardized 3,000 step walking protocol in individuals with ACLR.

## Methods

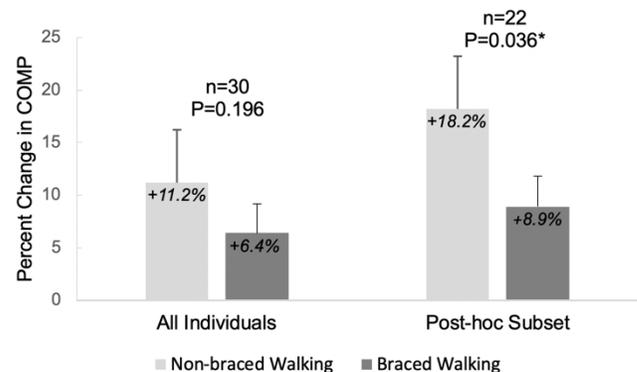

30 individuals with ACLR (15 females, 22±4 yrs, 173±8 cm, 72.4±12.8 kg, 52±38 months post-ACLR) participated in a cross-over study. All individuals participated in both loading conditions (Braced Walking and Non-braced Walking) on separate days in a randomized order. For both sessions, participants sat for 45 min prior to the standardized 3,000 step walking protocol. Individuals walked on a treadmill (Bertec, Columbus, OH, USA; Model S020008) at the same self-selected speed in both conditions. During the braced condition, individuals were fitted with the same off-the-shelf brace using the manufacturer's guidelines (Rebound Cartilage; Ossur, Reykavik, Iceland). The brace used in this study is marketed to reduce tibiofemoral loading. Blood was collected from the antecubital region of the arm before and immediately after the standardized walking protocol. Serum was isolated and quantitatively assessed for COMP using a commercially available ELISA kit (R&D systems, Minneapolis, MN, USA). COMP response due to each loading-condition was calculated as the percent change score from pre- to post-walking (%ΔCOMP).

Paired t-tests were used to compare %ΔCOMP between the Braced and Non-braced Walking sessions. A separate *post-hoc* analysis was conducted in a subset of individuals, who demonstrated increased COMP from pre- to post-walking (>0μg/ml increase in COMP during non-braced walking), to determine if differences in %ΔCOMP existed between condition (n=22, 9 females, 23±5 yrs, 175±8 cm, 75.5±12.8 kg, 58±41 months post-ACLR).

## Results and Discussion

There was no significant difference (P=0.196) in %ΔCOMP between the Braced and Non-braced Walking sessions for all 30

individuals. However, there was a significant difference (P=0.036) between Braced and Non-braced %ΔCOMP in individuals who demonstrated an increase in COMP from pre- to post-walking (Figure 1).

**Figure 1: Percent Change in Cartilage Oligomeric Matrix Protein (COMP) Due to Non-Braced and Braced Walking.** Figure 1 depicts the mean percent change in serum COMP due to walking a standardized 3,000 step walking protocol both with (Braced Walking) and without (Non-braced Walking) a knee brace designed to offload articular tissues both for all individuals (n=30) and in a subset of individuals who demonstrated increased COMP (>0μg/ml increase in COMP during non-braced walking; n=22).

## Significance

Overall, our results demonstrate that using a brace to reduce tibiofemoral loading during 3,000 steps of walking may not influence acute serum COMP concentrations compared to walking the same number of steps without a brace. Yet, our *post hoc* analysis demonstrates that the braced condition results in decreased serum COMP concentrations in a subset of individuals who demonstrate an increase in serum COMP concentrations following unbraced walking. This suggests that bracing to reduce tibiofemoral loading may produce a beneficial knee cartilage response following ACLR in individuals who display an increase in serum COMP following walking. Future research is needed to elucidate the effect of bracing on the multifaceted outcomes associated with PTOA development following an ACLR.

# Biomechanical Evaluation of a Novel, All-Inside Posterior Medial Meniscal Root Repair via Fixation to the Posterior Cruciate Ligament

Nahir A. Habet<sup>1</sup>, Bryan M. Saltzman, Marc T. Duemmler<sup>1</sup>, David Trofa, Keith T. Corpus, Susan Odum, Juan Carlos Carrillo Garcia<sup>1</sup>, Durham Weeks, Patrick Connor, Dana P. Piasecki, James E. Fleishli, Dax Varkey  
<sup>1</sup>Atrium Health, Charlotte, North Carolina  
Email: Nahir.habet@atriumhealth.org

## Introduction

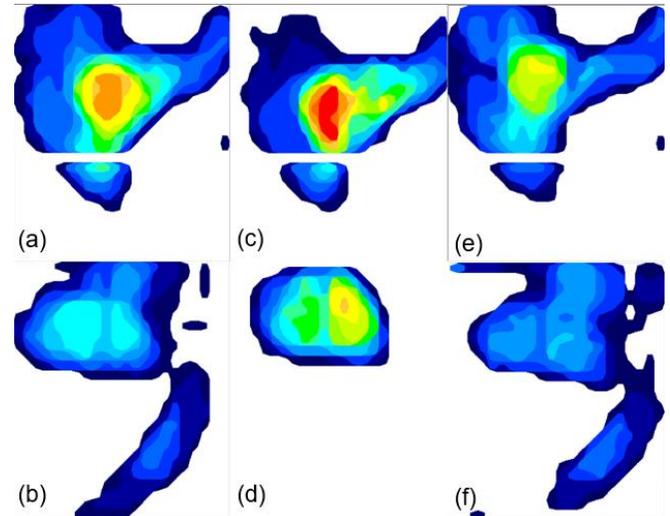

The menisci are integral to normal knee mechanics by dispersing contact forces over a broad area of the tibia through increased congruity of the tibiofemoral articulation.<sup>1</sup> The meniscal root has significant effect on peak loads transferred through the knee.<sup>2</sup> Repair of the meniscal root has been demonstrated to reproduce the ability of the meniscus to effectively recreate the functionality of an intact meniscus suggesting that repairing the root could minimize the progression of joint degeneration seen with meniscectomy or non-operative management of a meniscal root tear.<sup>3,4,5</sup> The purpose of this study was to evaluate the tibiofemoral contact mechanics of a novel, all-inside posterior medial meniscal root repair technique via suture fixation to the PCL, and to compare with that of the intact knee and the knee with a root tear.

## Methods

Tibiofemoral contact mechanics were recorded in 8 (4 male, 4 female) fresh-frozen cadaveric knee specimens using pressure sensors that were placed onto the medial and lateral tibial plateaus. Each knee underwent 3 testing conditions related to the posterior medial meniscal root: (1) intact knee; (2) root tear; and (3) all-inside repair via suture fixation to the PCL. Knees were loaded with a 1000-N axial compressive force at 4 knee flexion angles (0°, 30°, 60°, 90°). Calculations were performed for contact area, mean contact pressure, and peak contact pressure in each testing condition.

## Results and Discussion

Across all knee flexion angles, there was an overall mean 26.3% reduction in contact area with root tear (vs. intact,  $p=0.0002$ ), but only a 3.2% reduction with repair (vs. intact,  $p=0.443$ ). The 31.6% increase in overall mean contact area from root tear to repair was significant ( $p=0.0297$ ). Across all knee flexion angles, there was an overall mean 24.3% increase in contact pressure with root tear (vs. intact,  $p<0.0001$ ), and a 5.2% decrease with repair (vs. intact,  $p=0.696$ ). The 31.1% decrease in overall mean contact pressure from root tear to repair was significant ( $p=0.0037$ ). Across all knee flexion angles, there was an overall mean 10.6% increase in peak contact pressure with root tear (vs. intact,  $p<0.0001$ ), and a 1.7% decrease with repair (vs. intact,  $p=0.9833$ ). The 12.4% decrease in overall mean peak contact pressure from root tear to repair was not statistically significant ( $p=0.531$ ). The novel repair increased contact area above intact values at all knee flexion angles apart from 0° flexion, decreased mean contact pressure below intact for angles except for 0° flexion, and decreased peak contact pressure below intact at 60° and 90° flexion. In most testing conditions and with overall averaging across knee flexion angles, the novel, all-inside posterior medial meniscal root repair with suture fixation to the adjacent PCL fibers restored contact area, contact pressures, and peak contact pressures to that of the intact knee or better (Fig. 1).

**Figure 1:** Pressure maps of medial and lateral menisci at 30° knee flexion: (a) lateral meniscus of intact knee, (b) medial meniscus of intact knee, (c) lateral meniscus of torn meniscus root, (d) medial meniscus of torn meniscus root, (e) lateral meniscus of repaired root, (f) medial meniscus of repaired root.

## Significance

This new technique provides a posterior medial meniscal root repair construct that restores most tibiofemoral contact mechanics, and offers theoretical benefits of technical ease and reduced demand for an exact ‘anatomic’ repair location when compared with the current gold-standard transtibial pullout technique for repair.

## Seasonal Variations in Vertical Stiffness and Jump Height in Ncaa Division-I Soccer Athletes

Michelle E. Ramsey<sup>1\*</sup>, Brett S. Pexa<sup>2</sup>, Kevin R. Ford<sup>3</sup>, and Justin P. Waxman<sup>1</sup>

<sup>1</sup>Department of Exercise Science, High Point University, High Point, NC

<sup>2</sup>Department of Athletic Training, High Point University, High Point, NC

<sup>3</sup>Department of Physical Therapy, High Point University, High Point, NC

Email:\* [mramsey1@highpoint.edu](mailto:mramsey1@highpoint.edu)

### Introduction

Measures of lower-extremity stiffness are shown to be associated with measures of athletic performance, such as vertical jump height, among others.<sup>1,2</sup> Although some have assessed changes in jump height over the course of an athletic season<sup>3</sup>, less is known about seasonal variations in stiffness and the extent to which such variations are associated with changes in athletic performance. Therefore, the purpose of this study was to examine seasonal variations in vertical stiffness and maximum vertical jump performance, and to assess whether seasonal variations in stiffness are associated with changes in vertical jump height.

### Methods

Fifty-eight NCAA Division-I men's ( $n = 27$ ,  $19.6 \pm 1.3$  yr,  $1.8 \pm 0.1$  m,  $75.9 \pm 6.9$  kg) and women's ( $n = 31$ ,  $19.1 \pm 1.1$  yr,  $1.7 \pm 0.1$  m,  $65.1 \pm 6.6$  kg) soccer athletes completed vertical stiffness ( $K_{\text{Vert}}$ ) and maximal countermovement jump height ( $\text{CMJ}_{\text{Height}}$ ) assessments at two separate time points: pre-season and mid-season.  $K_{\text{Vert}}$  was assessed via two trials of stationary, double-leg, barefoot hopping on a force platform to the beat of a metronome set at 2.2 Hz.  $\text{CMJ}_{\text{Height}}$  was assessed via three maximal effort CMJ trials on a force platform. Athletes were allowed to swing their arms during CMJ trials.  $K_{\text{Vert}}$  was later calculated as the ratio of peak vertical ground reaction force to maximal center of mass displacement<sup>4</sup>, whereas  $\text{CMJ}_{\text{Height}}$  was calculated via vertical velocity at the instant of takeoff (via numerical integration of the reaction force).<sup>5</sup> Trials were then averaged for use in statistical analyses. Differences in  $K_{\text{Vert}}$  and  $\text{CMJ}_{\text{Height}}$  were assessed via separate mixed-model ANOVAs, with an a-priori alpha level of  $\leq 0.05$  used to denote statistical significance. Sex (male or female) was used as the between-subjects factor, whereas time (pre-season or mid-season) was used as the within-subjects factor. Simple linear regression was then used to assess the extent to which pre- to mid-season changes (mid-season – pre-season) in  $K_{\text{Vert}}$  were associated with changes in  $\text{CMJ}_{\text{Height}}$ .

### Results and Discussion

The time-by-sex interaction for  $\text{CMJ}_{\text{Height}}$  was statistically significant,  $F(1, 51) = 10.04$ ,  $\eta^2_{\text{Partial}} = .17$ ,  $p = .003$ . Irrespective of time,  $\text{CMJ}_{\text{Height}}$  for male athletes (mean  $\pm$  standard error:  $39.15 \pm 1.00$  cm) was significantly greater than that of female athletes ( $30.03 \pm 0.91$  cm,  $p < .001$ ); however, the interaction was such that males displayed a reduction in  $\text{CMJ}_{\text{Height}}$  from pre-season to mid-season ( $40.65 \pm 0.98$  vs.  $37.65 \pm 1.68$  cm) whereas females displayed an increase in  $\text{CMJ}_{\text{Height}}$  from pre- to mid-season ( $27.48 \pm 0.89$  vs.  $32.59 \pm 1.52$  cm). The time-by-sex interaction was not statistically significant for  $K_{\text{Vert}}$  ( $p = .093$ ); however, there were significant main effects of both time,  $F(1, 51) = 10.00$ ,  $\eta^2_{\text{Partial}} = .16$ ,  $p = .003$ , and sex,  $F(1, 51) = 5.99$ ,  $\eta^2_{\text{Partial}} = .11$ ,  $p = .018$ . The time main effect was such that, irrespective of sex,  $K_{\text{Vert}}$  significantly decreased from pre- to mid-season ( $0.44 \pm 0.07$  vs.  $0.42 \pm 0.08$  kN/m/kg). The sex main effect was such that,

irrespective of time, male athletes displayed significantly greater  $K_{\text{Vert}}$  values compared to female athletes ( $0.46 \pm 0.01$  vs.  $0.41 \pm 0.01$  kN/m/kg). Pre-season to mid-season change in  $K_{\text{Vert}}$  were not associated with changes in  $\text{CMJ}_{\text{Height}}$  ( $R = 0.061$ ,  $R^2 = 0.004$ ,  $p = .666$ ).

Collectively, the main findings of this study show that: (1) male athletes displayed higher  $K_{\text{Vert}}$  and  $\text{CMJ}_{\text{Height}}$  compared to female athletes, (2)  $K_{\text{Vert}}$  decreased from pre- to mid-season, (3) although  $\text{CMJ}_{\text{Height}}$  decreased in male athletes from pre- to mid-season, female athletes displayed an increase in  $\text{CMJ}_{\text{Height}}$  over the same period, and (4) although both  $K_{\text{Vert}}$  and  $\text{CMJ}_{\text{Height}}$  changed from pre- to mid-season, the change in  $K_{\text{Vert}}$  was not associated with changes in  $\text{CMJ}_{\text{Height}}$ . Future studies examining the effect of workload on such measures, and studies assessing seasonal variations over more frequent time points, appear warranted.

### Significance

The findings of this study add to the current body of knowledge regarding changes in vertical stiffness and jump performance that occur during a competitive soccer season. Although both vertical stiffness and jump height changed over time, the noted change in jump was not related to changes in vertical stiffness. Additionally, the findings of this study demonstrate that changes in vertical jump performance during a competitive season are not the same for men and women, suggesting that researchers and clinicians should be encouraged to collect additional data related to workload and fatigue in future studies to better understand potential underlying factors driving such changes. Additional work related to what information the vertical stiffness assessment can provide is needed before having true clinical utility.

## Introduction

Athletes commonly perform dynamic movements under simultaneous cognitive load (e.g., surveying the field, reacting to an opponent). These scenarios are also associated with increased risk of anterior cruciate ligament (ACL) tears [1]. Cognitive function has been associated with ACL injury risk [2] and has recently been implicated in explaining changes in injury-relevant knee mechanics during a sidestep cut with a sport-specific dual task (i.e., dribbling a soccer ball) in male soccer players [3]. Understanding the spectrum of cognitive-motor relationships regarding altered knee mechanics when adding cognitive tasks during athletic movements may provide novel opportunities for developing injury prevention programs.

The purpose of this study was to determine associations between baseline cognitive function and knee mechanics during sidestep cutting with simultaneous cognitive and/or sport-specific tasks. Our hypothesis was that lower cognitive function would be associated with larger changes in peak knee flexion angle, abduction angle, and abduction moment during dual-task sidestep cutting.

## Methods

Thirty female soccer athletes participated in this two-visit study (20.5±3yrs, 62.7±9.1kg, 1.7±0.1m). The first visit consisted of a cognitive test battery to characterize baseline working memory, processing speed (PS), attentional control, and multitasking abilities [4,5]. Composite z-scores represented baseline cognitive ability in these domains, where AC was broken into accuracy (AC\_acc) and response time (AC\_rt) components, and the multitasking composite score combined performance on concurrent primary and distractor tasks. On a separate day, participants performed a sidestep cut under randomly ordered cutting conditions that included: 1. baseline: anticipated direction with no additional task, 2. ball handling (BH): while also dribbling a soccer ball, 3. unanticipated: reacting to a directional cue (straight or 45° cut) that was provided ~400ms prior to initial contact of the cutting step, 4. memorization (M): a visual array of letters was presented for 1s prior to starting the trial that participants memorized and then recalled a randomly chosen letter after performing the sidestep cut, 5. memorization + ball handling: combined M and BH conditions, and 6. memorization plus visual attention (M+VA): the same protocol as M, but the letter to be recalled was displayed during the sidestep cut. Kinematic and kinetic data were analyzed for the non-dominant limb during the cutting step.

Changes, relative to baseline, in early stance peak knee abduction angle and moment along with peak knee flexion were the three dependent variables ( $\Delta pKAbA$ ,  $\Delta pKAbM$ ,  $\Delta pKFA$ ). Positive values indicate more abduction and flexion.

All cognitive composite z-scores were entered as candidate predictors for stepwise linear regression ( $\alpha_{\text{enter}} = \alpha_{\text{remove}} = 0.15$ ) to identify cognitive domains that were associated with  $\Delta pKAbA$ ,  $\Delta pKAbM$ , or  $\Delta pKFA$  during the six dual-/multitask conditions.

## Results and Discussion

Significant relationships between the cognitive composite z-scores and knee mechanics change scores were observed for the ball handling (BH) condition (**Table 1**). The results suggest that slower processing speed was associated with greater increases in pKAbA while ball handling. Additionally, higher attentional control accuracy (and a trend for faster response times) was associated with less pKFA when ball handling. Other associations (multitasking during the M condition and working memory during the M+VA condition) were observed, but statistical significance depended on a few influential observations.

**Table 1:** Stepwise regression results for the BH condition indicating the models' R<sup>2</sup> and p-values along with the cognitive composite scores included in the model and the factor p-values.

	<b>Ball Handling (BH) Condition</b>
$\Delta pKAbA$	R <sup>2</sup> = 17.1%; p=0.026 [PS p=0.026]
$\Delta pKFA$	R <sup>2</sup> = 36.0%; p=0.003 [AC_acc (p=0.012), AC_rt (p=0.106)]

The most robust associations between cognitive function and knee mechanics were revealed during a sport-specific dual task of dribbling a soccer ball. Even during this anticipated change of direction task, processing speed was associated with pKAbA. Implicating processing speed as a predictor of cognitive-motor function is consistent with findings from Herman et al. for an unanticipated jump landing task [6]. However, our current findings are somewhat inconsistent with our previous work that found visual-spatial memory being more relevant during the same task, albeit in an experienced male soccer cohort and using different cognitive assessments [3]. Collectively, results from these studies may indicate the dependence of cognitive-motor relationships on population and cognitive assessments.

## Significance

Sport injuries are multifactorial in nature and warrant multifactorial preventative strategies. Our results further support cognitive function as a covariate for neuromuscular control during dual-/multitasking movements, which are reflective of common sport scenarios.

## Introduction

Abnormal gait biomechanics contribute to post-traumatic osteoarthritis development after anterior cruciate ligament reconstruction (ACLR) [1]. It is suggested that individuals with ACLR exhibit large asymmetries in gait kinetics between limbs and compared to controls [2]. Thus, characterizing gait kinetic asymmetries is vital when monitoring ACLR patients [2]. There is also evidence to suggest task complexity (*i.e.* walking vs. stair descent) magnifies biomechanical deficits in ACLR patients between limbs and compared to controls [3]. During gait, altering speed is a means of increasing or decreasing task complexity [4]. Evidence suggests healthy individuals are able to maintain ground reaction force (GRF) symmetry when task complexity is altered (*i.e.* increased or decreased gait speed) [4]. Yet, it is unclear if ACLR patients are similarly able to maintain GRF symmetries across gait speeds. It is possible ACLR patients may have a differential response to altered task complexity compared to controls; information that can be useful for future studies aiming to evaluate gait deficits in those with ACLR.

The purpose of this study was to examine the effects of walking speed demands (100%, 120%, and 80% self-selected walking speed) on resultant GRF limb symmetry indices (LSI) between ACLR patients and healthy individuals. Outcome variables included the 1<sup>st</sup> and 2<sup>nd</sup> peak and unloading resultant GRF (*i.e.* GRF between the 1<sup>st</sup> and 2<sup>nd</sup> peak).

## Methods

Thirty patients 9-weeks post ACLR (Age = 20.6 ± 5.4 yr, BMI = 23.9 ± 3.3 kg/m<sup>2</sup>, graft = 25 patellar, 4 hamstring, 1 quadriceps tendon) and 15 healthy control participants (Age = 23.1 ± 4.5 yr, BMI = 23.6 ± 2.7 kg/m<sup>2</sup>) were recruited and underwent treadmill walking at three speeds (100%, 120%, and 80% of self-selected walking speed). Self-selected gait speed was determined using a stopwatch while participants walked over-ground across a 20 m walkway. Participants were given one practice trial, then, the average of three trials was used to determine self-selected speed. GRFs were collected at 1000 Hz while participants walked on an fully instrumented Bertec split-belt treadmill. One 65 s trial was collected at each speed (order: 100%, 120%, and 80%). Participants were allowed to familiarize to each speed prior to initiation of the 65 s data recording. Analog force data were analyzed offline using LabVIEW and lowpass filtered using a zerolag 4<sup>th</sup> order Butterworth filter (100 Hz). Ensemble averages of the resultant GRF were calculated and normalized to body weight (N). Outcome variables from both limbs were used to compute LSI as the ratio of the reconstructed relative to contralateral limb in ACL patients. In controls, the limb with the

lowest 1<sup>st</sup> peak resultant GRF was used as the matched “reconstructed limb” for all speeds. Two (Group) by three (Speed) repeated measures ANOVAs were used to compare LSI between speeds and groups ( $\alpha < 0.05$ ).

## Results and Discussion

The Group by Speed interaction was significant for the 1<sup>st</sup> peak ( $F_{2,86} = 12.38, P < 0.01$ ), 2<sup>nd</sup> peak ( $F_{2,86} = 12.55, P < 0.01$ ) and unloading resultant LSI ( $F_{2,86} = 9.36, P < 0.01$ ). Post-hoc comparisons (Bonferonni adjusted) indicated all resultant LSI’s (1<sup>st</sup>, 2<sup>nd</sup>, unloading) differed across speeds in patients with ACLR-reconstruction but not controls ( $P > 0.05$ ). At fast speeds, all resultant peaks were different between groups ( $P < 0.01$ ). Only the 1<sup>st</sup> peak differed between groups at slow speeds. ( $P > 0.05$ )

Results suggest increasing gait speed magnifies resultant GRF asymmetries while decreasing speed diminishes GRF asymmetries in patients with ACLR. In healthy controls, gait symmetries were maintained regardless of gait speed, supporting previous research [4]. The inability to maintain similar GRF symmetries in patients with ACLR may be partially attributed to underlying neuromuscular dysfunction, like quadriceps weakness, amongst other factors such as pain or kinesiophobia [5]. Nonetheless, our results suggest resultant GRF asymmetries during gait may be partly mediated by gait speed as LSIs were less than 5% asymmetrical at speeds below self-selected. Thus, it may be beneficial to evaluate gait kinetics at speeds above self-selected in order to characterize the extent of gait biomechanical asymmetries in patients with ACLR.

## Significance

Walking at fast speeds exacerbated gait asymmetries which may be beneficial when evaluating ACLR individuals in more chronic time periods, when gait deficits may be less pronounced than in early time periods post-surgery. Further research is needed to understand if evaluating gait at faster speeds is beneficial to better detect subtle gait deficits in those several years from ACLR.

# Asymmetry and Sex Differences in Ankle and Hindfoot Kinematics During Gait

Shumeng Yang<sup>1</sup>, Tom Gale<sup>1</sup>, MaCalus Hogan<sup>1</sup>, William Anderst<sup>1</sup>

<sup>1</sup>University of Pittsburgh, Department of Orthopaedic Surgery

Email: [shy41@pitt.edu](mailto:shy41@pitt.edu)

## Introduction

Recovery progress of patients with lower limb injuries is commonly monitored by measuring differences between the injured and uninjured side. Ankle sprains are the most common injury in sports and recreation and can lead to chronic ankle instability (CAI), which may affect lower limb biomechanics<sup>1</sup>. To properly evaluate the effects of surgery and rehabilitation in CAI and other ankle pathologies, it is first necessary to establish a normative database to characterize typical side-to-side differences in ankle and hindfoot kinematics in healthy adults.

In addition, previous work has identified differences in bony morphology<sup>2</sup> and injury rates<sup>3</sup> between males and females in the ankle and hindfoot. However, only one study, using single-plane fluoroscopy, has investigated ankle and hindfoot kinematics differences between males and females<sup>4</sup>.

The aims of this study were: (1) to determine within-subject ankle and hindfoot kinematics differences between the dominant and nondominant sides and (2) identify sex-dependent differences in ankle and hindfoot kinematics over the support phase of gait. We hypothesized that females would have greater tibiotalar and subtalar ROM and that sex-dependent differences would exist in ankle and hindfoot continuous kinematics curves.

## Methods

Following Institutional Review Board approval and informed consent, data was collected from 20 participants (10M, 10F; average age: 30.8 ± 6.3 years). All participants were healthy adults with no history of major knee or ankle injuries.

Subjects walked at a self-selected speed on a laboratory walkway. Biplane radiographs of the ankle and hindfoot were collected for 1 second at 100 frames/s. Two walking trials were collected for each side. CT scans were used to create subject-specific 3D models of the distal tibia, talus, and calcaneus. A validated volumetric model-based tracking technique<sup>5</sup> was used to match the subject-specific bone models to the biplane radiographs with a precision of 1.2° and 0.5 mm. Anatomic coordinate systems were created for each bone using an automated algorithm<sup>6</sup> and tibiotalar and subtalar 6 DOF kinematics were calculated for each side using ordered rotations<sup>7</sup>.

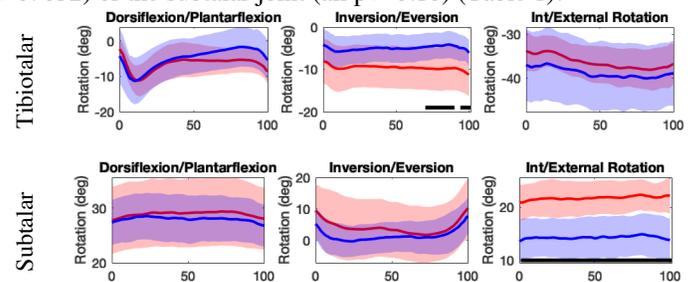

Joint kinematics were filtered with a 4<sup>th</sup> order butterworth filter using residual analysis<sup>8</sup> and then interpolated to percent stance phase. The two trials for each side were averaged prior to analysis. Differences in ROM were identified using t-tests, and differences in the continuous kinematics curves were identified using one dimensional statistical parametric mapping (SPM)<sup>9</sup> with significance set at  $p < 0.05$  for all tests.

## Results and Discussion

The average difference between dominant and nondominant sides in the continuous kinematics curves was 3.9 deg and 1.4 mm or less for all rotations and translations, respectively, at the tibiotalar and subtalar joints. These differences exceeded our measurement accuracy by a factor of 3, suggesting kinematics asymmetry can be commonly detected using this measurement system. No differences between dominant and nondominant side

ROM were observed at the tibiotalar (all  $p > 0.15$ ) or subtalar joint (all  $p > 0.08$ ). These results provide a benchmark for comparison when evaluating side-to-side differences in patients after surgery or rehabilitation.

Significant differences in the continuous kinematics curves were found between males and females in tibiotalar inversion from 70-90% stance ( $p = 0.037$ ) and from 94-100% stance ( $p = 0.049$ ) (Figure 1, top), and subtalar PD translation ( $p=0.003$ ) and internal rotation ( $p<0.01$ ) (Figure 1, bottom) over the entire stance phase. In contrast to the previous study<sup>4</sup>, we did not find greater stance phase ROM in females at the tibiotalar joint (all  $p > 0.052$ ) or the subtalar joint (all  $p > 0.10$ ) (Table 1).

**Figure 1:** Average (solid line) and standard deviation (shaded regions) of rotational kinematics for the tibiotalar (top) and subtalar (bottom) joints for males (blue) and females (red) during the stance phase of gait. The black line on the bottom of each chart represents periods of significant differences identified by SPM.

**Table 1.** Average (± SD) ROM during the stance phase of gait for the tibiotalar and subtalar joints. No significant differences were observed.

## Introduction

Anterior cruciate ligament reconstruction (ACLR) alters strength and neuromuscular control of the quadriceps. Despite meeting current return-to-sport benchmarks after rehabilitation, high re-injury rates still persist[1]. In an effort to better identify patient readiness to return-to-sport and decrease risk of re-injury, novel measures of patient function are being developed[2,3]. An example of one of these novel measures comes from recent work that used Lyapunov exponent (LyE), a nonlinear metric, to describe control of shear ground reaction forces in ACLR patients[3]. Their study found that ACLR patients had diminished control (higher LyE values) compared to healthy subjects, indicating altered function despite meeting majority of criteria for return-to-sport. The ability to measure force control of the quadriceps during a clinically reproducible task, such as the leg press, may be important for further describing patient function and guiding return-to-sport testing. This work aimed to describe a method for measuring force control of the quadriceps during the leg press as well as develop baseline comparative values of force control in healthy individuals. We hypothesized there would be no differences in force control between the dominant limb, non-dominant limb, and both limbs working together in a young, healthy population.

## Methods

14 healthy subjects performed continuous repetitions of the bilateral leg press, while the feet remained stationary, for two minutes at 20% of their estimated one repetition maximum (1RM) at 60bpm. Force profiles of dominant and nondominant limb were measured individually using a set of custom, validated force platforms that interfaced with the leg press machine. To describe the total force throughout the task, force profiles of the dominant and non-dominant limb were summed together. Peak force values were extracted from each force profile and normalized to each subject's 1RM. Force control was measured using LyE, which was calculated using Wolf's algorithm [4]. Descriptive statistics were calculated for normalized peak forces and LyE values. A one-way repeated measures ANOVA with a Bonferroni corrected post hoc analysis was performed to compare LyE values from the total, dominant limb, and non-dominant limb force profiles ( $\alpha=0.05$ ).

## Results and Discussion

Our hypothesis that force control (measured as the LyE value calculated from force profiles) would not differ between the dominant limb, non-dominant limb, and total was partially supported with a significant main effect being found ( $\eta_p^2 = 0.395$ ). Force control was not significantly different between

dominant and non-dominant limbs. This was expected due to subjects not having a significant history of lower extremity injury and is in agreement with previous work that demonstrated similar force control between limbs during a simulated cutting task [3]. However, contrary to our hypothesis, force control of the dominant limb was diminished compared to the total and may be due the separate roles of the dominant limb as a "driver" and the non-dominant limb as a "stabilizer" during bilateral mobilizing tasks [5].

In summary, this work describes how force control of the quadriceps can be measured in a clinically implementable manner by using low-cost force platforms with nonlinear analysis during the leg press. The baseline values developed through this work may be used as a point of comparison for determining abnormal force control in individuals with ACLR.

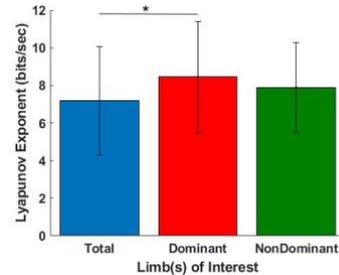

Figure 1: Bar chart of Lyapunov Exponent during the leg press task. \* $p=0.001$ .

## Significance

This work describes a method for measuring force control of the quadriceps in a manner that may be performed in a clinical setting. Future work will focus on the relationship between force control and return-to-sport outcomes with the intent of developing measures that, when used in conjunction with current return-to-sport benchmarks, further describe patient readiness to return-to-sport and reduce re-injury rates.

## Introduction

Individuals who sustain an anterior cruciate ligament (ACL) injury and undergo ACL reconstruction (ACLR) are at high risk of developing posttraumatic osteoarthritis (PTOA).<sup>1</sup> There is evidence that the biological processes involved in the progression to PTOA, including breakdown of critical components of tibiofemoral articular cartilage (e.g., type-II collagen) begin early after ACL injury. It has been proposed that the persistent aberrant gait biomechanics that are common following ACLR hasten the progression of PTOA by perpetuating abnormal biological tissue changes.<sup>2</sup> A stiffened-knee strategy (i.e. lesser knee flexion angle [KFA] and lesser internal knee extension moment [IKEM],) has been linked to PTOA development. There is a dearth of longitudinal studies to evaluate if early changes in joint tissue metabolism associate with later changes in gait biomechanics. The purpose of this study was to determine if KFA and IKEM differed at 6 months post-ACLR in individuals with the highest synovial fluid (SF) concentrations of type-II collagen turnover (C2C:CPII) compared to those with lowest SF C2C:CPII measured in the first 15 days prior to ACLR.

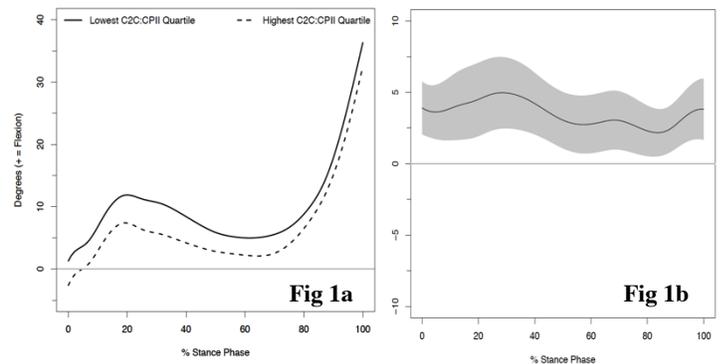

## Methods

Thirty-eight individuals with an ACL injury were initially included in the study (55% females, 20.9±3.5 yrs, 25.2±5.3 BMI) and SF was aspirated 6.9±4.2 days following ACL injury. All individuals underwent ACLR using the same bone-patellar-tendon-bone allograft procedure. Six months following the ACLR, over-ground gait biomechanics were collected at a self-selected comfortable walking speed. A 3-dimensional motion capture system (Vicon, Nexus, Denver, Colorado, United States) was used to collect and integrate marker trajectories with force data collected using 2 force plates (40 × 60 cm, FP406010, Bertec Corporation, Columbus, Ohio, United States) embedded in a 6m walkway. IKEM were normalized to the product of bodyweight (N) and height (m) and KFA was described as the angle of the tibia relative to the femur. Commercial enzyme-linked immunosorbent assays were used to evaluate type-II collagen breakdown (C2C) and type-II collagen synthesis (CPII) concentrations in SF. Greater C2C:CPII ratios were interpreted as greater collagen breakdown compared to synthesis (i.e. greater type-II collagen turnover).<sup>2</sup> Next, we stratified the cohort into quartiles in order to determine the individuals with the highest (1<sup>st</sup> quartile) and lowest (4<sup>th</sup> quartile) SF C2C:CPII at the time of injury. Finally, we conducted a functional analysis of variance to determine the mean differences and corresponding 95% confidence intervals in KFA and IKEM throughout stance at 6 months post-ACLR between the highest and lowest SF C2C:CPII groups. The highest and lowest groups were considered to be different at points of stance where mean differences and corresponding 95% confidence intervals (CI) did not cross zero.

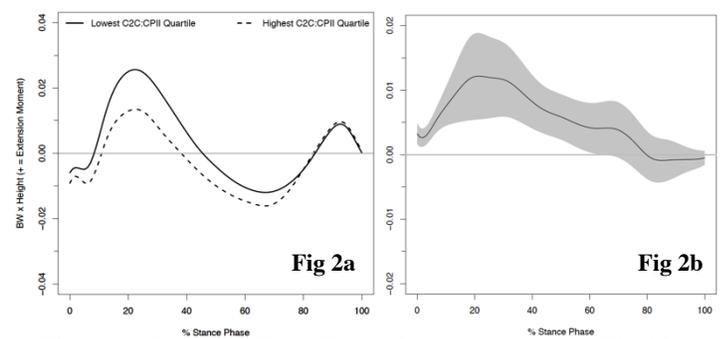

## Results and Discussion

10 individuals were included in the highest SF C2C:CPII group (5 females, 20.9±3.1 yrs, 25.2±4.4BMI) and 10 individuals were included in the lowest SF C2C:CPII group (6 females, 20.3±4.5

yrs, 26.9±8.4BMI). Individuals in the highest SF C2C:CPII group demonstrated lesser KFA throughout the entirety of stance phase compared to individuals in the lowest SF C2C:CPII group (Figure 1). Similarly, the highest SF C2C:CPII group demonstrated lesser IKEM between 1 and 89% of stance (Figure 2).

**Figure 1: Knee Flexion Angle:** (A) The highest SF C2C:CPII group (dotted line) demonstrated lesser KFA throughout the entirety of stance phase compared to the lowest SF C2C:CPII group (solid line), (B) as determined by the mean difference and 95% CI not crossing 0 throughout stance.

**Figure 2: Internal Knee Extension Moment:** (A) The highest SF C2C:CPII group (dotted line) demonstrated lesser IKEM between 1 and 89% of stance, (B) as determined by the mean difference and 95% CI not crossing 0 for that portion of stance.

## Significance

Our study demonstrates that greater SF concentrations of type-II collagen turnover in the first several days following ACL injury are associated with a more stiffened-knee gait strategy 6 months following ACLR (i.e. lesser KFA and IKEM throughout the majority of stance). Future studies may seek to modify early biochemical changes immediately following ACL injury to determine the effect on later changes in gait biomechanics that may perpetuate poor longer-term joint health.

## Does the Pavlik harness treatment cause lower extremity biomechanical changes in infants?

Safeer F. Siddicky<sup>1</sup>, Junsig Wang<sup>1</sup>, William Hefley III<sup>1</sup>, Brien Rabenhorst<sup>1</sup>, Elizabeth Aronson<sup>1</sup>, Erin M. Mannen<sup>1</sup>

### Introduction

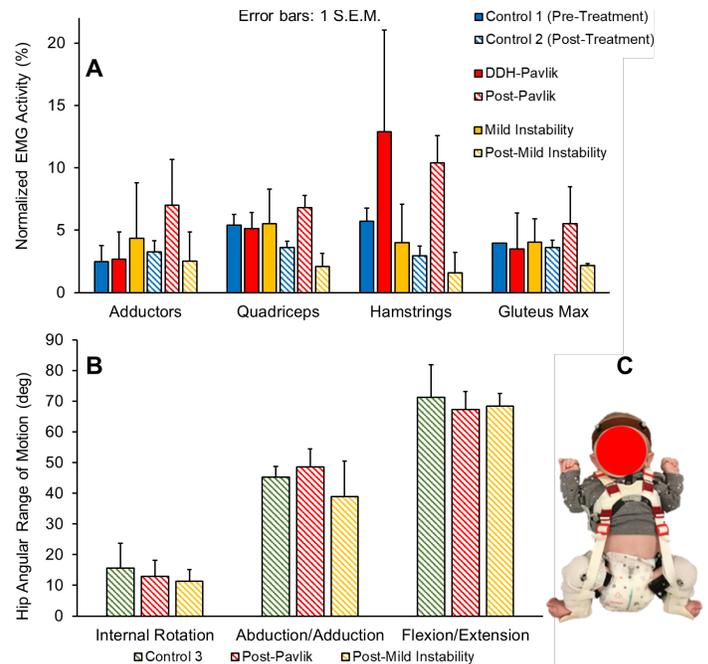

Developmental dysplasia of the hip (DDH) occurs in 5.5/1000 full-term babies<sup>1</sup>. The Pavlik harness (PH) non-surgically treats DDH grades 1-3 with 80-92% success<sup>2</sup>. While it is theorized that the mechanism of spontaneous femoral head reduction using a PH is a result of passive abduction of the hip by the weight of the lower limbs during deep sleep<sup>3</sup>, the role of active hip movements within the PH in aiding spontaneous reduction has not been explored. Although PH is the best option to achieve closed reduction for babies <6 months, it is restrictive/uncomfortable, requiring 24/7 usage for many weeks; a duration which varies widely based on the severity and among clinicians<sup>4</sup>. Additionally, prolonged harness wear may have negative indications like avascular necrosis or femoral nerve palsy<sup>5</sup>. Therefore, it is critical to better understand the biomechanical impact of closed reduction treatment to improve upon the decades-old PH. The purpose of this study was to measure lower-extremity muscle activity and hip ranges of motion of (1) DDH infants at Pavlik Harness treatment onset and after successful treatment, and (2) infants with mild hip instability who did not require Pavlik harness treatment at the onset of an observation period for dysplasia and after a normal ultrasound. The recorded values were compared to healthy age-matched controls.

### Methods

Infants lay supine on a mat for 60 seconds. Surface electromyography (Delsys, 1000 Hz) and motion capture (Vicon, 100 Hz) measured the lower-extremity muscle activity (adductors, quadriceps, biceps femoris, gluteus maximus) and hip range-of-motion of 26 infants. These included DDH infants at PH treatment onset and after successful treatment (n=3), infants with mild hip instability (no PH) at the beginning and end of clinical observation (n=3), and healthy age-matched controls (n=20).

### Results and Discussion

The treatment or observation durations were  $11 \pm 6.3$  weeks for infants with DDH and  $7 \pm 5.4$  weeks for infants with mild instability. DDH infants (in the harness at first visit and out of it at follow-up) showed similar muscle activity to controls at both visits, while the mild instability cohort's muscle activity was similar at the first visit but lower at follow-up. At follow-up, DDH infants, as well as the mild instability cohort, showed similar hip range-of-motion to controls, but the mild instability cohort showed lower abduction/adduction ROM. Treatment durations for Pavlik harness treatment fell within the range of values reported in literature, but varied widely (4 to 17 weeks). The lower muscle activity of the mild instability cohort at follow-up may indicate that while the instability is resolved based on ultrasound findings, it is likely that the lower muscle activity may still pose a risk of future instability for these infants. This is also indicated in the lower hip abduction/adduction range of motion at follow up for these infants. Additionally, the mild instability cohort may have lower muscle activity compared to the DDH cohort due to lower opportunity to actively use muscles against resistance (i.e. the Pavlik harness foot strap).

**Figure 1.** (A) Normalized EMG activity, (B) hip range of motion, and (C) Motion capture markers and EMG sensors on participant.

Limitations of the study include a small sample size in the hip dysplasia population, and a data collection length of only 60 seconds. Future directions include continued enrollment for this study, and utilizing hip ultrasound to examine infants with hip instability in different positions and infant gear. As physicians continue to prescribe the use of the Pavlik harness, further research needs to be conducted on the biomechanical impact of positioning for infants with hip instability, both for treatment and long-term hip health.

### Significance

While the Pavlik harness is the gold-standard for closed reduction of DDH in children younger than 6 months, understanding the biomechanical changes infants undergo in such orthopedic devices may educate clinicians' decisions on treatment course and duration.

## Introduction

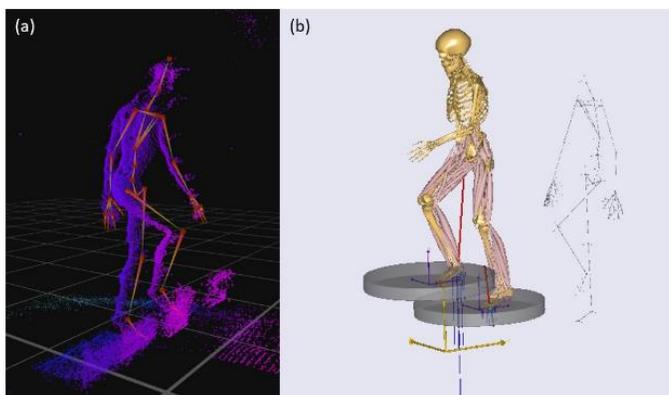

Although stair ambulation and other common activities should be included in the rehabilitation of the long-term effects of ACL injury on knee function, most studies have focused on examining ACL deficient during level walking [1]. When compared to level walking, stair climbing produces increasing 12-25 % loading in the knee joint and, consequently, a larger range of external moments. Based on our literature reviews, developing practical laboratory setup as a tool during stair climbing to assist in evaluating the abnormalities in lower extremity that arise from an ACL deficiency.

Therefore, the aim of this study is to develop and validate a full-body musculoskeletal gait model driven by a single depth sensor to estimate the ground reaction forces (GRFs) produced during stairs climbing in patients with ACL reconstruction.

## Methods

Fifteen individuals with ACL injury who had undergone reconstructive surgery with Bone-Patellar Tendon-Bone Autograft (BTB) at least one year prior to recruitment were enrolled in this study. GRFs data during stair climbing were collected using a custom-built 3-step wooden staircase without handrails.

The Kinect v.2 depth sensor (Microsoft Corp. Redmond, WA) was located at 2.5 m from the staircase, at a height of 0.75 m from the ground. The subjects performed three trials at their normal walking speeds with barefoot. The depth data was analyzed by subtracting the background depth information and tracking the subjects' movement using anthropometric models in order to extract 26 joint trajectories using a customized Matlab code.

**Figure 1:** (a) the depth sensor image data with one sample stair climbing task, (b) AnyBody™ musculoskeletal model (KinectAB) including the stick-figure and inverse dynamic analysis with the estimated ground reaction force (red arrows).

The musculoskeletal GaitFullBody model (AnyBody Technology, Aalborg, Denmark), generated the stair climbing GRFs using a modified version of the method proposed by Fluit et al. and Skals et al. [2-3]. This is attained by 25 artificial muscle-

like actuators that are placed under each foot. To determine the activation level of each actuator, activation threshold distance was set to -0.01 m, and the activation threshold velocity was set to 1.3 m/sec (Figure 1).

Mean differences between the measured and estimated GRFs were compared using paired samples t-tests in order to establish any significant difference between the measured and predicted values. The ensemble curves and associated 95% confidence intervals (CI95) of the GRFs were compared between both approach.

## Results and Discussion

The comparisons between the measured GRFs (force platforms) and the estimated GRFs (AnyBody™ model) at discrete time points during the stair ascent is described in this section. For the ACLR limb, good agreement and consistency were observed for  $A_P$ GRF during the braking (Range ICC: 0.45 ~ -0.86) and propulsive (Range ICC: 0.64 ~ 0.84) phases. Good consistency was also observed for  $v$ GRF during the propulsive (Range ICC: 0.43 ~ 0.85), while poor agreement and consistency were observed during the braking (Range ICC: 0.41 ~ 0.27) phase. However, there were significant mean differences between the estimated and the measured values during the gait cycle for the vertical braking force (MD: 0.25 ± 0.05) and vertical propulsive force (MD: 0.17 ± 0.01). Fair agreement and consistency were observed for  $M_L$ GRF during the propulsive (Range ICC: 0.43 ~ 0.85) phase.

Generally, investigators have estimated the joint forces and torques from inverse dynamics analysis using kinematic data and GRF measurement from force platforms [4]. However, in the present study, we examined the external validity of this approach to estimate the GRFs during stair climbing that are widely used in the assessment and evaluation of patients with ACL reconstruction. The analysis of the GRFs can give valuable information about basic locomotor mechanisms during gait in patients undergoing orthopedic surgery and provide data which can be used to evaluate the progression of the recovery process in terms of their observed gait patterns.

## Significance

This study provided an external validation of a newly developed method to estimate the GRFs during stair ascent that are used in assessment and evaluation of patients who have undergone ACL reconstruction. The ability of the developed model to effectively estimate gait kinetics (e.g. GRFs) was apparent in its ability to effectively assess gait abnormalities due to the ACL injury.

# EFFECT OF SIDE PLANK EXERCISE USING A SLING WITH DIFFERENT HIP ROTATIONS ON TRUNK AND HIP MUSCLES ACTIVATION IN SUBJECTS WITH GLUTEUS MEDIUS WEAKNESS

Seung-Min Baik<sup>1,2</sup>, Kyung-Eun Lee<sup>3</sup>, Jung-Hoon Choi<sup>1,4</sup>, Ji-Hyun Lee<sup>2</sup>, Chung-Hwi Yi<sup>3</sup>, and Heon-Seock Cynn<sup>1,3</sup>

## Introduction

Among several exercises for activating gluteus medius (Gmed), side plank exercise showed highest-level activation of Gmed in healthy subjects [1]. Also, side plank exercise is one of the weight-bearing exercises that better replicate the functional activities of daily living than the nonweight-bearing exercises [2].

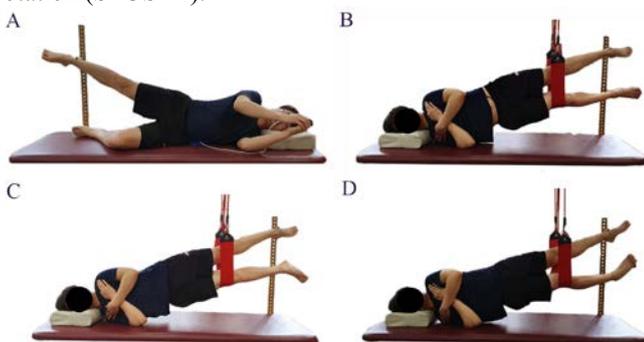

Body weights of individuals can be a resistance for exercise when performing sling-based exercises [3]. Huang et al. (2011) also reported that exercises similar with sling-based exercise are effective in activating the stabilizer muscles such as core muscles [3].

However, it is unclear the effectiveness of side plank exercise using a sling (SPUS) on trunk and hip muscles activation in subjects with Gmed weakness. Therefore, the purpose of this study was to quantify muscle activation of the rectus abdominis (RA), external oblique (EO), lumbar multifidus (LM), Gmed, gluteus maximus (Gmax) and tensor fasciae latae (TFL) during SPUS with three different hip rotations compared to side-lying hip abduction (SHA) exercise.

## Methods

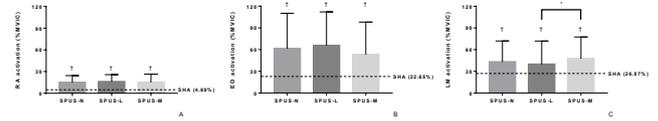

Twenty-two subjects with Gmed weakness were recruited. SHA exercise was performed in the same procedure presented in the previous study [4].

For SPUS with three different hip rotations, subjects were positioned side-lying on the treatment table with test leg contact the treatment table first, and then the both legs were suspended on the sling by a principal investigator (SMB). The narrow sling was positioned at the knee joint of test leg and the height of narrow sling was placed at the perpendicular line drawn across the upper shoulder and the foot of the test leg. Thus, the subjects lifted their hip off the table by abducting the test leg until the spine is in neutral position while abducting the top leg about 20% of hip abduction's maximal range of motion. Three different SPUS are SPUS with neutral hip (SPUS-N), SPUS with hip lateral rotation (SPUS-L), and SPUS with hip medial rotation (SPUS-M).

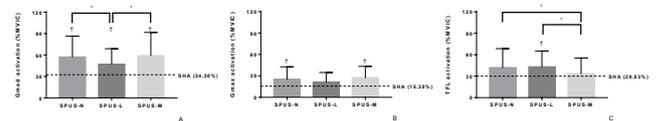

**Figure 1:** A; Side-lying hip abduction, B: Side plank exercise using a sling with neutral hip, C: Side plank exercise using a sling with hip lateral rotation, D: Side plank exercise using a sling with hip medial rotation

## Results and Discussion

**Figure 2:** Comparison of trunk muscle activation among four exercises (A: RA; B: EO; C: LM). %MVIC = percentage of maximal voluntary isometric contraction; RA = rectus abdominis; EO = external oblique; LM = lumbar multifidus; SHA = side-lying hip abduction; SPUS-N = side plank using a sling with neutral hip; SPUS-L = side plank using a sling with hip medial rotation; SPUS-M = side plank using a sling with hip lateral rotation. †Significant difference with SHA ( $p < .01$ ). \*Significant difference between SPUS subgroups ( $p < .01$ ).

**Figure 3:** Comparison of trunk muscle activation among four exercises (A: Gmed; B: Gmax; C: TFL). %MVIC = percentage of maximal voluntary isometric contraction; Gmed = gluteus medius; Gmax = gluteus maximus; TFL = tensor fasciae latae; SHA = side-lying hip abduction; SPUS-N = side plank using a sling with neutral hip; SPUS-L = side plank using a sling with hip medial rotation; SPUS-M = side plank using a sling with hip lateral rotation. †Significant difference with SHA ( $p < .01$ ). \*Significant difference between SPUS subgroups ( $p < .01$ ).

Three SPUS exercises generally showed significantly higher trunk and hip muscles activation than SHA. SPUS-M showed significantly higher Gmed activation than SPUS-L and significantly lower TFL activation than SPUS-N and SPUS-L. The EO, LM, Gmed activation during three SPUS reached the threshold of 40% to 60% MVIC that can effectively stimulate muscle strength gains.

## Significance

Especially, SPUS-N and SPUS-M rather than SPUS-L may be prescribed for patients who have reduced Gmed strength after injuries because they showed significantly higher Gmed activation than SPUS-L. Patients who have Gmed weakness with dominant TFL but have enough trunk stability to prescribe SPUS-M position also may perform SPUS-M because SPUS-M showed significantly lower TFL activation than SPUS-N and SPUS-L.

# EVALUATION OF RUNNING AS A MEANS TO IDENTIFY LIMB SYMMETRY AFTER ACL RECONSTRUCTION

Jacqueline N. Foody<sup>1</sup>, Sarah A. Wilson<sup>1</sup>, Kimi D. Dahl<sup>1</sup>, Matthew T. Provencher<sup>1</sup>, and Scott Tashman<sup>1</sup>

<sup>1</sup>Steadman Philippon Research Institute, Vail, CO, USA

Email: stashman@sprivail.org

## Introduction

Anterior Cruciate Ligament (ACL) tears are a highly prevalent injury and 30% of patients incur a secondary tear<sup>1</sup>. One proposed method of reducing the risk of secondary injury after reconstruction is through return to play (RTP) testing that measures limb-to-limb symmetry. These differences, however, can be difficult to measure with traditional statistical methods. Statistical Parametric Mapping (SPM) allows for the comparison of entire kinematic curves and can identify key parts of a movement cycle where kinematic dissimilarities exist. The long-term goal of this research is to combine Inertial Measurement Units (IMUs) and SPM to develop more discriminatory tests for determining readiness for RTP. The purpose of the present study was to use IMUs and SPM to determine if limb-to-limb kinematic asymmetries occur in uninjured subjects during various running conditions.

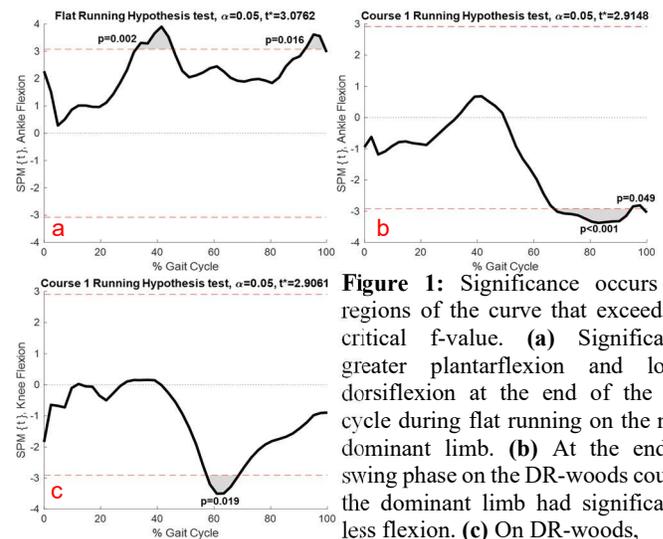

## Methods

Thirty-five healthy adults (28±5 years, 72.4±11.4 kg, 1.75±0.08 m, 14 female) were recruited for this study. Participants had no prior injury or surgery to their lower extremities. This study was approved by an IRB, and all participants provided informed consent. Trunk and lower extremity kinematics were captured using eight IMUs (128Hz, APDM). Participants completed an outdoor obstacle course which included flat and downhill running. For the flat running task (FR, 19 participants), participants were instructed to run between 75-100% of their maximum velocity along a roughly 18m flat, concrete path. For the downhill running task, two courses were used: one (DR-woods, 25 participants) was a roughly 25-deg incline with exposed tree roots and compacted soil and the other (DR-gravel, 10 participants) was an approximately 11-deg incline with a mixed grass and gravel running surface. For both downhill courses, participants were instructed to select a speed where they felt comfortable and in control. Four trials of each task were collected for each participant, and gait cycles were determined by assuming heel strikes coincided with the local maxima in the IMU accelerometers on the feet. Sagittal plane kinematics were extracted from one gait cycle per trial, when the participant was not accelerating, using a custom MATLAB script. SPM (spm1d v0.4.3) was used to conduct paired t-tests to evaluate asymmetry during gait cycles.

## Results and Discussion

During flat running, no significant kinematic asymmetries were found in the knee, hip, or trunk for healthy volunteers. In the ankle, kinematic asymmetries were seen during maximum plantarflexion ( $p=0.002$ ) and at the end of the swing phase ( $p=0.016$ ) (Figure 1a). In an in-lab study using marker-based motion capture, Hughes-Oliver et al found a similar lack of kinematic differences in the sagittal plane in healthy participants during a running task on a 20m walkway using motion capture. This supports the use of IMUs as a fast, reliable way to capture kinematic data.

Similar to flat running, DR-woods showed a significantly greater ( $p<0.001$ ) amount of plantarflexion (Figure 1b) and an increased amount of peak knee flexion ( $p=0.019$ ) on the non-

**Figure 1:** Significance occurs for regions of the curve that exceed the critical f-value. **(a)** Significantly greater plantarflexion and lower dorsiflexion at the end of the gait cycle during flat running on the non-dominant limb. **(b)** At the end of swing phase on the DR-woods course, the dominant limb had significantly less flexion. **(c)** On DR-woods, participants also had significantly greater peak knee flexion on the non-dominant limb.

dominant limb (Figure 1c). DR-gravel only showed a significant difference between limbs in trunk flexion at roughly 60% of the gait cycle ( $p=0.041$ ).

On all three courses, a large standard deviation in trunk flexion indicated wide variability in movement strategy between participants and trials, so trunk motion may not be an appropriate performance measure in the ACLR group. The increased difficulty of the terrain on the DR-woods course likely resulted in more varied running strategies which increased the standard deviation in the kinematic measures. However, healthy participants showed no limb-to-limb asymmetry in their knee or hip during stance when running downhill, regardless of course.

## Significance

Running is an effective task at discerning kinematic similarities in a healthy population, particularly at the knee and hip; however, the terrain should be considered when determining what is normal as symmetry varied between courses. By utilizing SPM, running tasks may have the potential to identify limb-to-limb asymmetries in the ACLR population as part of RTP protocols. Though this has been previously observed in laboratory experiments, this study highlights that an IMU system can be used to identify asymmetries in kinematics in the sagittal plane in more challenging, real-world environments outside of the lab. These devices could potentially assist clinicians in discerning variations in neuromuscular control strategies. Future research will evaluate patient performance in these and other tasks in order to determine their validity as part of an RTP protocol.

# Latency Between Peak Vastus Medialis Activation and Peak Knee Flexion Moment During Gait is Longer in Knees After Anterior Cruciate Ligament Reconstruction With a Bone-Patellar Tendon-Bone Graft

Naoaki Ito<sup>1,2</sup>, Jacob J. Capin, Thomas S. Buchanan<sup>1,3</sup>, and Lynn Snyder-Mackler<sup>1,2</sup>

Email: nito@udel.edu

## Introduction

Sagittal plane gait alterations after anterior cruciate ligament reconstruction (ACLR) are associated with early osteoarthritis (OA) development.<sup>1</sup> Quadriceps weakness is associated with aberrant gait mechanics<sup>2</sup>, and patients with bone-patellar tendon-bone grafts (BPTB) are slower at recovering quadriceps strength compared to those with alternative grafts.<sup>3</sup> Few research studies have evaluated electromechanical delay (i.e., latency) following ACLR.<sup>4</sup> Additionally, the impact of patellar tendon harvest on electromechanical delay is unknown. The purpose of this study was to investigate latency between peak quadriceps muscle activation and external knee flexion moment (pKFM), among patients who received BPTB grafts and those with alternative graft types.

## Methods

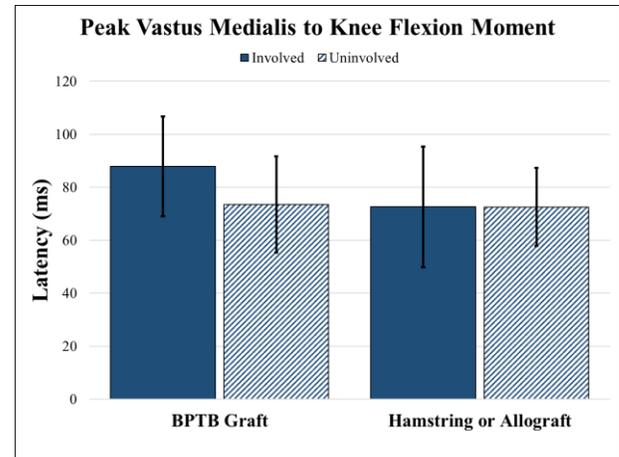

Sixty-seven participants (19 BPTB / 48 hamstring autograft or soft-tissue allograft) were recruited 6±2 months after primary ACLR. Gait kinetics, kinematics, and electromyography (EMG) data (rectus femoris [RF], medial [VM] / lateral [VL] vasti) were collected during overground walking at self-selected speeds. EMG data were high-pass filtered (2<sup>nd</sup> order Butterworth at 30Hz), rectified, and low-pass filtered (6Hz) to create a linear envelope. Signal events for peak quadriceps activations and pKFM during the first 50% of stance were created using Visual 3D (C-motion, Germantown, MD), and latency was determined as the time between the events in milliseconds. 2×2 ANOVA (limb by graft type) ( $\alpha=0.05$ ), adjusted for gait speed as a covariate, was run for our 3 variables of interest (latency between peak RF/VL/VM to pKFM). Demographic variables were evaluated using Pearson Chi-squared tests and T-tests.

## Results and Discussion

Our BPTB group was younger ( $p<0.01$ ), had lower quadriceps strength index ( $p<0.01$ ), and had more non-contact ACL injuries compared to contact injuries ( $p=0.02$ ). No differences were observed for time from surgery to testing, height, weight, BMI, sex distribution, and meniscal status.

Variables	Graft type	Latency (ms)		Limb × Graft interaction (p=)
		Involved	Uninvolved	
RF to pKFM	BPTB	69.6 (11.2)	67.5 (15.1)	0.270
	Other	72.3 (18.1)	64.0 (15.3)	
VL to pKFM	BPTB	78.8 (18.2)	70.4 (17.5)	0.434
	Other	73.9 (19.3)	70.1 (17.6)	
VM to pKFM	BPTB	<b>87.9 (18.9)</b>	<b>73.5 (18.1)</b>	<b>0.031*</b>
	Other	72.6 (22.7)	72.5 (14.7)	

**Table 1:** Mean (SD) latency and significance (Limb×Graft type interaction effect) for variables of interest.

**Figure 2:** Limb-by-Graft type interaction effect ( $p=0.03$ ) was observed; the involved limb in the BPTB group displayed longer latency.

A limb-by-graft type interaction effect was observed for peak VM to pKFM latency ( $p=0.03$ ), with the BPTB group demonstrating longer latency in their involved versus uninvolved limb. There were no interlimb differences in the alternative graft type group (Figure 1). No significant findings were observed for latency between peak RF or VM to pKFM (Table 1).

The patellar tendon's ability to transfer force following ACLR using a BPTB autograft may be compromised. We found longer latency from peak VM to pKFM in the involved limb of the BPTB group relative to the uninvolved limb of the BPTB group, and both limbs of the hamstring autograft and soft-tissue allograft group. Further investigation including a larger sample size is warranted, as significant differences were not observed for the VL or RF to pKFM latencies. Our preliminary findings, however, suggest BPTB graft harvest may accentuate poor neuromuscular control during activities such as gait (due to the longer time between muscle activation and torque production).

## Significance

A graft type specific rehabilitation approach may be necessary to address impairments including altered gait mechanics following ACLR with a BPTB graft. Further research should investigate the role of EMG latency during gait longitudinally after ACLR using larger sample sizes, and the role of patellar tendon morphology<sup>5</sup> on torque production during gait.

## Introduction

Post-traumatic knee osteoarthritis (OA) following anterior cruciate ligament reconstruction (ACLR) is a well documented phenomenon<sup>1</sup>. Several studies have investigated the development of OA within the tibiofemoral compartment following ACLR. We have associated asymmetries in gait mechanics, including underloading of the involved limb's medial compartment (vs. uninvolved), to the eventual development of knee OA 5 years after surgery<sup>2</sup>. Recent reports, however, suggest that patellofemoral OA after ACLR may be as prevalent as, if not more prevalent than, tibiofemoral OA<sup>3</sup>. Despite this high prevalence of patellofemoral OA, little has been done to investigate the potential mechanisms leading to the disease's development within this compartment. Thus, the purpose of this study is to examine the biomechanical state of the patellofemoral compartment in the early months after ACLR. We hypothesize that asymmetries in patellofemoral mechanics (i.e. peak knee flexion angle [pKFA], peak knee flexion moment [pKFM], and peak patellofemoral contact force [pPCF]) will exist 3 months after reconstruction with lesser values within the involved limb.

## Methods

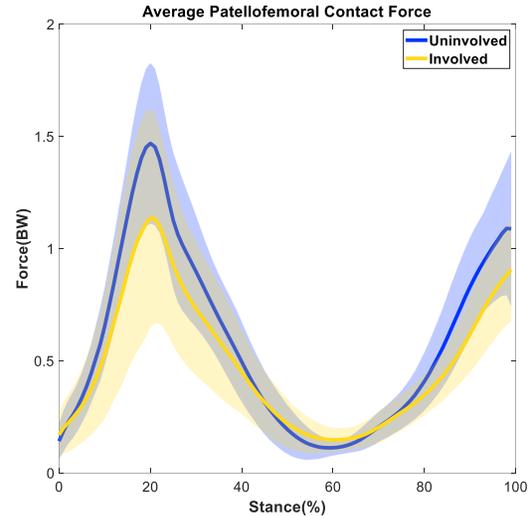

10 participants (7 male, age:  $24 \pm 6$  years, BMI:  $25.4 \pm 2.3$  kg/m<sup>2</sup>) completed overground walking trials at their self-selected walking speed 3 months after ACLR. Kinematics, kinetics, and surface electromyography (EMG) were collected bilaterally and used as inputs into a validated, EMG-informed musculoskeletal model<sup>4</sup>. Patellofemoral contact forces, normalized to the subject's bodyweight (BW), were determined using similar methodologies established by Shelburne *et al.* and Yamaguchi *et al.*<sup>5,6</sup>. Three gait trials for each limb were averaged for every subject. pKFA, pKFM, and pPCF were determined for each limb and then averaged across all subjects to get the average pKFA, pKFM, and pPCF in each limb. A one-tailed student's t-test ( $\alpha = 0.05$ ) was used to compare the peak values for each biomechanical variable across limbs.

## Results and Discussion

As hypothesized, asymmetries in pKFA, pKFM, and pPCF were present 3 months after ACLR with the involved limb displaying lesser values compared to the uninvolved limb (Table 1). Of note, significant underloading of the involved limb's patellofemoral compartment (vs. uninvolved) is occurring at this early time point (Figure 1).

**Table 1:** Involved and Uninvolved Limb Patellofemoral Knee Gait Variables 3 months after ACLR

Variable	Involved	Uninvolved	Significance (p-value)
pKFA (°)	20.11 ± 3.93	21.16 ± 2.36	0.131
pKFM (%BW*HT)	3.72 ± 1.41	5.43 ± 0.81	0.006
pPCF (BW)	1.16 ± 0.51	1.50 ± 0.35	0.023

**Figure 1:** Patellofemoral contact force throughout stance (n=10). Note the involved limb displays a reduced peak compared to the uninvolved limb. [Shaded area =  $\pm 1$  standard deviation]

Reduced involved limb loading (vs. uninvolved limb) early after reconstruction has been linked to eventual OA development within the tibiofemoral joint. A similar mechanism could be occurring within the patellofemoral joint. It should be noted that, as this was only three months after surgery, muscle weakness (i.e. reduced quadriceps strength) may be an essential factor driving these asymmetries in mechanics. Future work needs to assess patellofemoral mechanics at later timepoints to see if these asymmetries persist or resolve with time and needs to examine whether or not there is an association between these altered mechanics and early signs of OA development.

## Significance

Asymmetries in tibiofemoral gait mechanics early after ACLR have previously been associated with the eventual development of tibiofemoral OA. To our knowledge, this is one of the first studies to examine patellofemoral gait mechanics in the early months following ACLR, particularly with regards to patellofemoral contact force. Asymmetries reported here may be associated with the eventual development of patellofemoral OA. This information could be useful in understanding the biomechanical basis for patellofemoral OA development and may be useful in informing the design of preventative rehabilitation techniques to delay the disease's progression later into life.

## Introduction

Anterior cruciate ligament (ACL) injuries are the most common knee injury in sports. The injury usually occurs during landing or cutting tasks, and it can result in immediate knee instability, loss of season and posttraumatic knee osteoarthritis. The biomechanical deficits, such as small knee flexion, excessive knee abduction, are considered to be the risk factors for ACL injury [1]. However, identifying athletes with these biomechanical deficits and training them to move differently is currently done in the biomechanics laboratory which limits the widespread implementation of screening and training. Inertial measurement units (IMUs) are suitable for knee kinematics measurement for their advantages of small size, low cost and portability. Previous approaches using IMUs to assess ACL injury risk during jump landings typically only estimate knee flexion angle [2]. However, the knee abduction angle is also a critical measurement for injury risk assessment [1], though it is challenging to estimate due to its relatively small range of motion. Therefore, the purpose of this study was to develop and validate an algorithm for accurately measuring the 3D knee angle during a landing task.

## Methods

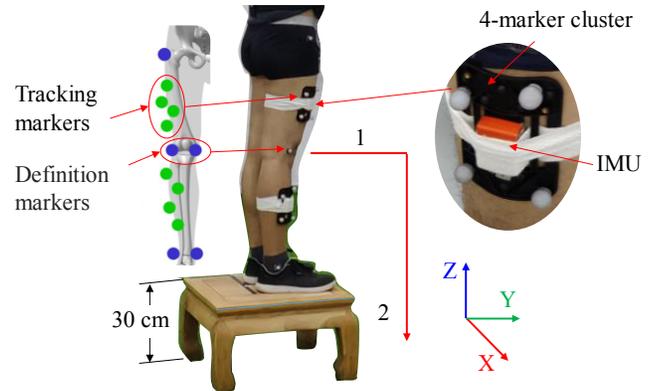

Two IMUs were used for 3D knee angle estimation. To estimate the 3D knee angle, we first estimated the sensor orientation  ${}^{GS}q$  through a two-step complementary filter. The filter updated the orientation using accelerometer and gyroscope data in the first step and corrected the orientation using magnetometer data in the second step. Finite state machines were used to regulate the filter gain in each step according to the acceleration and magnetic disturbances [3]. Then, we calculated the sensor to body segment rotation  ${}^{BS}q$  through Eq. (1), where  ${}^{GB}q$  is a known orientation measured in the calibration stage. Finally, we calculated the orientation  ${}^Bq_{TS}$  through the thigh orientation  ${}^{GB}q_T$  and shank orientation  ${}^{GB}q_S$ , as in Eq. (2). The estimated 3D knee angle was the Euler representation of  ${}^Bq_{TS}$ .

$${}^{GB}q = {}^{GS}q \otimes {}^{BS}q^* \quad (1)$$

$${}^Bq_{TS} = {}^{GB}q_T^* \otimes {}^{GB}q_S \quad (2)$$

Five healthy subjects (age  $32.8 \pm 2.8$  years, height  $174 \pm 5.7$  cm, mass  $63.2 \pm 4.8$  kg, all male) performed validation drop landing testing while wearing 13 markers on their dominant leg. Two 4-marker clusters were used for motion tracking, and the other five markers were used for segment definition (Fig. 1). An IMU (MTw, Xsens, Netherlands) was aligned and fixed on each cluster. Each subject performed drop landing trials from a 30 cm platform. A sixteen camera motion capture system (Vicon, Oxford, UK) and Visual3D (C Motion, MD, USA) were used for computing reference knee joint angles. The IMUs and Vicon system were electronically synchronized, and the sampling rates were both 100 Hz. Subjects first stood on the platform in a neutral pose for 10 s with the foot aligned with the platform as calibration. We assumed the 3D knee angles were all zero in this state.

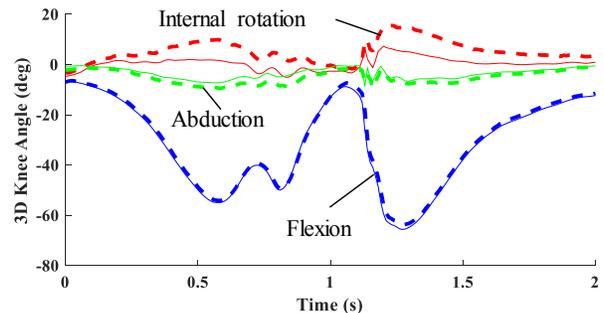

Subjects then performed 10 consecutive drop landings. Mean and standard deviation of the estimated 3D knee angle of all collected trials were calculated for analysis.

**Figure 1:** Experimental setup for the drop landing testing.

## Results and Discussion

The accuracy of the estimated knee flexion angle, abduction angle and internal rotation angle was  $0.17 \pm 1.27^\circ$ ,  $-1.17 \pm 1.71^\circ$  and  $3.18 \pm 2.76^\circ$ , respectively (Fig. 2). Knee flexion angle estimation was substantially more accurate than previously reported approaches [2]. Though previous studies haven't reported IMU knee abduction angle accuracy during drop landings, our findings are notably more accurate than previous estimations during walking [4].

**Figure 2:** Estimated 3D knee angle for a typical trial. Solid lines indicate IMU estimation, and dotted lines represent motion capture reference values.

## Significance

The presented IMU-based 3D knee angle estimation algorithm was relatively accurate in both the sagittal and frontal planes, and could serve as a foundational element to help facilitate in-field biomechanical ACL injury risk assessment.

### Introduction

Walking biomechanics are associated with patient-reported outcomes (PRO) after anterior cruciate ligament reconstruction (ACLR); e.g., vertical ground reaction force (vGRF), knee flexion angle (KFA), and external peak knee adduction moment (KAM). Although associations between walking biomechanics and PRO have been identified, additional complex and still unknown relationships between gait biomechanics and PRO likely exist. Researchers have utilized traditional regression models to investigate associations between discrete biomechanical variables (e.g., peak vGRF) and PRO; yet this approach likely limits the ability to make additional discoveries regarding biomechanical characteristics throughout the entire stance phase of gait for individuals with desirable PRO. The purpose of this study was to test a novel exploratory statistical approach that is capable of clustering ACLR patients based upon functional and discrete walking biomechanics, and then examine potential differences in PRO between the resulting patient clusters. We hypothesized that resulting patient clusters based upon functional and discrete biomechanical measures would differ in PRO and provide direction for future research concerning what biomechanical characteristics are most important in the pursuit of improved PRO for ACLR patients.

### Methods

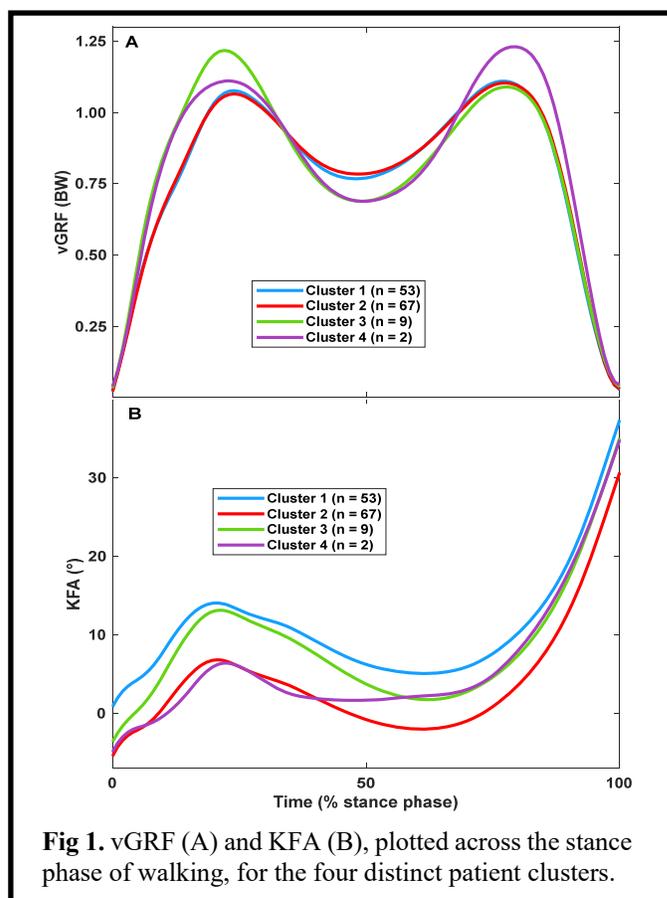

We measured walking biomechanics and Knee Injury and Osteoarthritis Outcome Scores (KOOS) for 131 ACLR patients (Time post-ACLR =  $100 \pm 10$  months; Age =  $21 \pm 3$  yrs; BMI =  $24.4 \pm 3.7$ ). Subjects were categorized as symptomatic or asymptomatic using KOOS scores [1]. vGRF and KFA curves, across the stance phase of gait, and peak KAM values were clustered using a random partition model as prior distribution for B-spline coefficients in a Bayesian hierarchical model embedded with a predictor dependent partition model [2]. Then, clusters were created using a least squares approach [3]. A chi-squared test was used to test for associations between the resulting patient clusters and frequency of symptomatic and asymptomatic patients.

### Results and Discussion

The cluster analysis revealed four distinct clusters of ACLR patients. Clusters 1-4 contained 53, 67, 9, and 2 patients respectively. We chose to omit Cluster 4 from additional analyses due to its small size. As expected, significant ( $p < 0.05$ ) differences existed between clusters for the vGRF and KFA curves (Figure 1), and KAM values ( $0.022 \pm 0.006$ ,  $0.022 \pm 0.006$ , and  $0.040 \pm 0.007$  BW·H for Clusters 1-3 respectively). Percentages of symptomatic patients for each cluster were 55, 55, and 33% for Clusters 1-3 respectively; these percentages did not statistically differ, however, this was likely due to the small size of Cluster 3. Although differences in KAM were expected,

the direction of these differences is informative: Cluster 3 patients exhibited much greater peak KAM values than the patients in Clusters 1-2.

These results provide a novel view of relationships between functional and discrete walking biomechanics and PRO after ACLR. The patients with similar vGRF and peak KAM values, yet different KFA curves, achieved similar PRO (Clusters 1 and 2). The Cluster 3 patients exhibited greater vGRF during the first 25% of stance, peak KAM values, and KFA excursion during the first 25% of stance; although not statistically significant, these patients trended toward improved PRO. This suggests, perhaps, that increased peak KAM values, or increased vGRF and KFA excursion during the first quarter of stance might lead to improve PRO for ACLR patients. All of these findings can inform future research studies.

**Fig 1.** vGRF (A) and KFA (B), plotted across the stance phase of walking, for the four distinct patient clusters.

# The Effect of Antegrade vs. Retrograde Femoral Nailing after Traumatic Femur Fracture on the Kinematics and Kinetics of the Lower Body Through Six-Months of Recovery

John Mead<sup>1</sup>, Emily Dooley<sup>2</sup>, Michael Hadeed M.D.<sup>3</sup>, Seth Yarboro M.D.<sup>3</sup>, and Shawn Russell Ph.D.<sup>1,2,3</sup>

University of Virginia, Depts. of <sup>1</sup>Biomedical Eng., <sup>2</sup>Mechanical Eng., and <sup>3</sup>Orthopaedic Surgery, Charlottesville, VA, USA

Email: sdr2n@virginia.edu

## Introduction

Femoral nailing is a procedure conducted to repair a fractured femur. There are two main approaches within femoral nailing: the antegrade procedure enters the femur through the hip, while the retrograde procedure through the knee. Antegrade femoral nailing is used for proximal femur fractures. Retrograde femoral nailing optimal for patients suffering from multiple injuries, ipsilateral femoral neck and shaft fractures, and obese patients<sup>1</sup>.

The purpose of this study was to quantify the differences in how well patients recover following surgery. The method used to quantify differences was to evaluate gait by analyzing the moments and angles about the hip and knee of femoral nailing patients, comparing the results of the retrograde versus antegrade procedures. Previous clinical studies comparing the two operations report quadriceps atrophy, knee stiffness and knee pain in retrograde patients and, atrophy of the hip abductor muscles and hip pain in antegrade patients<sup>2</sup>. These findings support our hypothesis of decreased range of motion of the knee in retrograde femoral nailing and of the hip in antegrade.

## Methods

Experimental data was collected six months after surgery for 6 subjects: 3 antegrade patients (3M; 32±19.08 y.o.) and 3 retrograde patients (2F,1M; 53.67±12.58 y.o.). Subjects were recorded using 3D motion capture and five force plates. Walking trials were collected on a 15m walkway at a self-selected walking speed. A minimum of six trials were analyzed for each subject. The Plug-in-Gait model was used to calculate joint kinematics and kinetics, then exported to Matlab for analysis.

## Results and Discussion

Motion analysis revealed key differences between the retrograde and antegrade procedures, mainly at the hip and knee. Retrograde

patients had reduced knee flexion during early stance, an increased knee abduction moment, and a decreased knee extension moment. The hip extension moment of retrograde patients also decreased. Antegrade patients displayed a decrease in hip abduction moment and hip adduction angle.

Antegrade patients showed significantly less deviation from the control group than retrograde patients. Minor decreases in hip abduction moment and hip adduction angle were observed. This can be attributed to weakened hip abductor muscles and hip pain<sup>2</sup>.

Two of the three retrograde patients had decreased knee flexion during the early stance and a decreased knee extension moment (Fig. 1). All of the retrograde patients were observed to have a significantly higher knee abduction moment during the stance phase of their gait (Fig. 1). The decreased flexion and extension of the injured knee combined with the decreased hip extension moment indicate that the patient is walking with a straighter injured leg, leading to the increased knee abduction moment. The straight leg gait also puts these patients in a more injury prone position.

Increased knee extension moment observed in the retrograde patients puts these patients at a greater risk of suffering a posterior cruciate ligament (PCL) tear, of which hyperextension is a mechanism of injury. Coupled with the fact that PCL injuries are found to be concomitant with femoral fractures<sup>3</sup>, the retrograde procedure likely puts patients at an increased risk of PCL tear.

## Significance

The antegrade femoral nailing procedure is the better procedure of the two, from a kinematic and kinetic standpoint. Following the antegrade procedure, patients had a gait that more closely resembled the gait of the control group. Our findings indicate that

surgeons should opt to perform the antegrade femoral nailing procedure if the opportunity presents itself. Ultimately, the antegrade procedure will better restore the motion of patients to what it was prior to the injury.

## Knee Biomechanical Asymmetries Improve 3 to 6 months After ACLR, but Continue to Persist at 6 Months

Kelsey Neal<sup>1</sup>, Jack R. Williams<sup>1</sup>, Abdulmajeed Alfayyadh<sup>1</sup>, Naoaki Ito<sup>1</sup>, Ashutosh Khandha<sup>1</sup>

### Introduction

Anterior cruciate ligament reconstruction (ACLR) restores stability to the knee but does not prevent the development of post-traumatic osteoarthritis (PTOA). Gait aberrations in the involved limb, such as reduced peak knee flexion angles, flexion moments, and adduction moments (pKFA, pKFM, pKAM respectively), are commonly reported 6 months after surgery and are associated with PTOA<sup>1,2,3</sup>. Our lab has found that individuals who develop radiographic PTOA 5 years after ACLR display significantly lower peak medial compartment contact forces (pMCF) in their involved knee 6 months after surgery, compared to those who do not develop PTOA<sup>2</sup>. While these asymmetries are present up to 1 year after ACLR, they tend to level out by 2 years<sup>4</sup>. However, regaining symmetry this far after surgery may be too late to help slow the onset of PTOA. It is currently unknown how asymmetries in gait mechanics progress in the early months after reconstruction when modifications may be more beneficial to an individual's long-term health. The purpose of this study was to examine how biomechanical asymmetries progress from 3 to 6 months after ACLR. We hypothesized that individuals will be more asymmetric 3 months after ACLR (vs. 6 months).

### Methods

Twenty-two participants (13 males, age:  $22 \pm 6$  years, BMI:  $24.5 \pm 3.6$  kg/m<sup>2</sup>) underwent gait analysis 3 and 6 months after ACLR. Individuals walked overground at self-selected speeds while kinematic (120 Hz), kinetic (1080 Hz), and surface electromyography (1080 Hz) data were collected. Walking speed was maintained at both time points. Joint contact forces and muscle forces were calculated using a validated, EMG-informed, subject specific musculoskeletal model<sup>5</sup>. Quadriceps force was calculated by summing the forces of the rectus femoris, vastus medialis, vastus lateralis, and the vastus intermedius during the first 50% of stance. Peak quadriceps force (pEXT), pKAM, pKFM, and pMCF were variables of interest. Interlimb difference (ILD = involved - uninjured) was calculated for each variable at each time point. A one-tailed Student's t-test ( $\alpha = 0.05$ ) was used to assess significance between knees at each time point.

### Results and Discussion

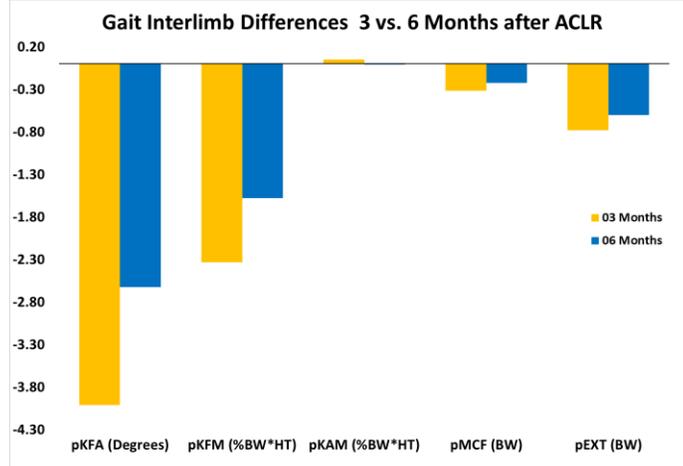

As hypothesized, we found smaller ILDs in all variables of interest at 6 months when compared to the 3-month time point (Figure 1). These trends toward symmetry may be driven by the improved symmetry in peak quadriceps force that is occurring between time points. Of interest, the difference between limbs of many of the biomechanical variables were significantly different regardless of time point (Table 1).

While asymmetries at 6 months after ACLR are linked to the eventual development of OA, this data shows greater asymmetries 3 months after surgery. Asymmetries at 3 months are more pronounced in our cohort, however, it is unknown whether early asymmetries at 3 months initiates long term damage to cartilage and if improving asymmetry between 3 and 6 months after surgery protects the long-term health of the cartilage. Future work will investigate how changes in

asymmetries early after surgery affect the long term biochemical health of knee cartilage.

**Table 1:** Mean involved and uninjured limb values of knee gait biomechanical variables at 3 and 6 months .

Variable	3 Months			6 Months		
	Involved	Uninvolved	p-Value	Involved	Uninvolved	p-Value
pKFA (Degrees)	17.81 ± 6.83	21.82 ± 5.23	<0.001	20.25 ± 4.92	22.88 ± 6.65	0.006
pKFM (%BW*HT)	3.36 ± 1.68	5.70 ± 1.61	<0.001	4.29 ± 1.71	5.87 ± 2.14	<0.001
pKAM (%BW*HT)	2.89 ± 1.18	2.84 ± 0.85	0.42	3.03 ± 1.25	3.04 ± 0.99	0.48
pMCF (BW)	2.69 ± 0.75	3.01 ± 0.43	0.037	2.91 ± 0.60	3.13 ± 0.45	0.081
pEXT (BW)	2.03 ± 0.86	2.81 ± 0.70	<0.001	2.40 ± 0.70	3.00 ± 0.89	0.001

**Figure 1:** Comparison of 3 month and 6 month interlimb values (ILD = involved – uninjured). All gait variables had higher levels of asymmetry at 3 months than 6 months after ACLR.

### Significance

It is well known that asymmetries after ACLR place an individual at risk for developing PTOA, however it is unclear how early these asymmetries need to be resolved to give someone their best chance at long term joint health. This study found that asymmetries between limbs improves from 3 to 6 months after surgery. While symmetrical gait for many is still not obtained by 6 months, this data shows that individuals can regain symmetry during this time which may be critical in preventing the onset of PTOA. If this is the case further rehab and gait training between 3 and 6 months after ACLR may be needed to help individuals regain symmetry.

## Introduction

Injury to the anterior cruciate ligament (ACL) is one of the most common knee injuries occurring in sports. Patients often elect to undergo surgical intervention in an effort to return to high-level sports (RTS) activities. However, ACL reconstructed (ACLR) individuals have an increased chance of suffering a second ACL injury after RTS [1]. While mechanical stability may be restored after surgery, lingering somatosensory impairments may still exist after RTS. Somatosensory deficits may encourage sensory reweighting, forcing the central nervous system to rely more on visual feedback during sports activities [2].

Static postural stability measures have previously been used to evaluate an ACLR patient's knee function before RTS [3,4]. Single-limb postural stability assessments of ACLR individuals have demonstrated mixed results [3,4]. The conflicting findings may be the result of a wide variety of testing positions (flexed or extended knee position), surfaces (rigid or compliant), vision (eyes open (EO) or eyes closed (EC)) conditions, as well as center of pressure (COP) measures.

Visual perturbations used to assess static postural stability may be of increased importance for individuals returning from ACLR. However, assessing only the extremes of vision (EO vs. EC) may not be appropriate for RTS protocols. Stroboscopic glasses are a clinical tool that offers the assessor increased levels of visual disruption [5]. Therefore, we hypothesized that ACLR individuals will rely on vision more than healthy controls (HC) when testing beyond an EO/EC intervention.

## Methods

Thirteen ACLR (F=6, 20±1 years, 1.71±0.09 m, 76.1±8.1 kg, 28.0±9.7 months since surgery) volunteered for this study and were age and sex-matched with recreationally active HC (F=6, 21±2 years, 1.71±0.10 m, 69.5±11.6 kg). During each trial, participants were asked to stand barefoot, on an AMTI force plate (Watertown, MA, USA), under three visual conditions: 1) EO; 2) low visual disruption (LVD); 3) high visual disruption (HVD) using stroboscopic glasses (Senaptec, Beaverton, OR, USA). Ground reaction forces were captured at 1000 Hz for 30s and filtered using a fourth-order, Butterworth low-pass filter with a cut-off frequency of 10 Hz. COP signal calculations for dependent variables were based on previous work [6]. For group comparisons, the ACLR injured limb was compared to the matched limb of the healthy control group. Four two factor (group x vision) ANOVA's ( $\alpha = 0.05$ ) were performed on COP measures (SPSS 26, IBM, USA). Significant main effects were

evaluated using pairwise comparisons with Bonferroni correction.

## Results and Discussion

The findings of this study were partially in line with our hypothesis. First, we expected to observe an interaction effect between the group and vision conditions; however, our results did not support this hypothesis. Main effects for the group condition were observed only for sway area ( $p = .049$ ). No significant differences were observed for the rest of the group COP variables. However, significant differences were found within visual conditions for each dependent variable, which did support our initial hypothesis (Table 1).

In this study, ACLR individuals demonstrated a ~26% increased sway area (281.26 mm<sup>2</sup>/s) when compared to HC (223.93 mm<sup>2</sup>/s). These results are similar to Bonfim [7], who found increased postural sway in ACLR limbs during single-leg stance testing. In contrast to previous literature, our study did not find a significant group difference in RMS distance, mean velocity, or mean frequency measures. Mohammadi [3] found a difference between ACLR and HC limbs for both COP velocity and amplitude measures. Our results are in alignment with Bodkin [4], who also found no significant group difference when reporting mean velocity. These conflicting findings may partially be explained by methodological differences in stance position (knee flexed vs. extended).

## Significance

ACLR individuals did not perform significantly worse on static postural stability measures than HC, as visual disruption was increased. The findings in this study indicate that individuals with ACLR may not rely on increased visual information during static postural stability assessments as original theorized. However, the knee extended testing position may not be challenging enough to observe changes in static postural stability. Clinicians may consider alternate testing positions before evaluating an ACLR patient's postural stability before RTS.

## Introduction

Over 8.5 million sports- and recreational-related injuries are reported per year with over 40% of these injuries occurring to the lower extremity [1]. Participation in sports and physical activity often require single-leg tasks including running, jumping, and landing. During these tasks, the hip acts to dissipate forces, stabilize the lower extremity, and progress the body forward [2].

During weight acceptance of single-leg tasks, the hip flexes, adducts, and internally rotates to dissipate external moments acting on the hip joint [3,4]. Hip musculature weakness and deleterious hip mechanics have been reported in a variety of injured populations. Due to conflicting results in these studies, the relationship among hip strength and hip mechanics remains unclear. Therefore, the purpose of this systematic review was to gather available research and evaluate the association between hip strength and hip biomechanics during single-leg tasks in healthy populations.

## Methods

The protocol of the systematic review was developed using PRISMA guidelines. In November 2019, electronic databases were systematically searched to identify research studies on the relationship among hip strength and lower extremity kinematics during single-leg tasks. Inclusion criteria required 1) healthy adolescent and adults, 2) isometric or isokinetic hip strength, 3) single-leg task, 4) two- (2D) or three-dimensional (3D) hip range of motion (RoM) measure during a single-leg task, 5) correlational study, and 6) cross-sectional design.

Two reviewers independently screened the articles for inclusion (MCG, MCW) and quality (MCG, JTH) and then data were extracted. Meta-analyses were conducted using Comprehensive Meta-Analysis Software (Biostat, Inc.; Englewood, NJ) analysing the correlation between hip strength (abduction, external rotation, and extension) and hip RoM (frontal, transverse, and sagittal). Hip strength measures were stratified into either abduction (HABDS), external rotation (HERS), or extension (HEXTS) for subgroup analyses. Significance was set at  $p < 0.05$ .

## Results and Discussion

The systematic search returned 14,969 articles. Fifty-seven articles underwent full-text review and 11 were included for analysis. Results from the meta-analysis can be found in Table 1.

No relationship was found among hip strength and frontal plane hip adduction RoM. Stratification of hip strength tests

revealed a significant negative relationship between HABDS and frontal plane hip RoM ( $p=0.037$ ). A significant negative relationship was found among hip strength and transverse plane hip RoM ( $p=0.006$ ). Stratification of hip strength tests revealed a significant negative relationship among HEXTS and transverse plane hip RoM ( $p=0.018$ ). No significant relationships were found among hip strength and sagittal plane hip RoM or when hip strength tests were stratified.

Increased frontal and transverse plane hip motion has been implicated with increased patellofemoral joint stress and patellofemoral pain in athletic activities [5-7]. While the meta-analyses calculated statistically significant correlations, the weakness of the  $r$ -values questions the clinical significance of the results and warrants further investigation. A variety of factors may influence the weakness of the relationships. The total sample size was  $82 \leq n \leq 302$  for each meta-analysis; however, none of the individual studies had sample sizes larger than  $n=40$ . The sample sizes for individual studies may not be large enough for these relationships to be clinically meaningful. A variety of populations (e.g. males, females, combined sexes) and single-leg tasks were included in this systematic review and meta-analyses. Kinematic motion analysis methodologies (2D or 3D) were also not consistent between studies. Though the meta-analyses showed homogeneity, results should be understood in the context of these limitations. The relationship among hip strength and hip kinematics may be sex-, task-, and/or methodology-specific.

## Significance

Results of the systematic review highlight the importance for further investigation among the relationships of hip strength and hip kinematics during single-leg tasks. The current literature is varied regarding task, sex, methodology and lacks adequate sample sizes. Meta-analysis results do suggest lower HABDS and HEXTS are related to greater frontal and transverse plane hip RoM, respectively, while sagittal plane hip RoM is not associated with hip strength.

## Introductions

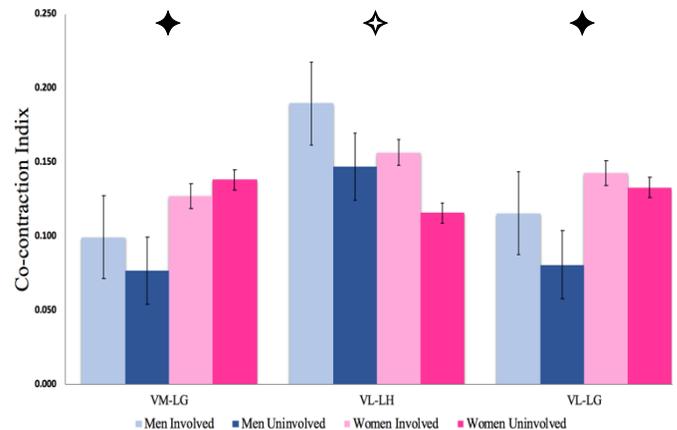

Gait aberrations after ACL reconstruction (ACLR) are a commonly reported phenomenon<sup>1</sup>. One of the most frequently examined gait biomechanical variables after ACLR is external knee adduction moment which many consider to be representative of medial compartment loading<sup>1,2</sup>. However, these studies fail to account for the possibility of co-contraction between knee agonist/antagonist muscle pairs which may also influence tibiofemoral loading. Muscle co-contraction indices (CCIs), a representative measure of co-contraction, can give insight into the relative amount of co-contraction between muscle pairs; with a higher CCI indicative of more co-contraction<sup>3</sup>. High CCIs of knee muscles are associated with quadriceps weakness<sup>4</sup>, and women after ACLR display weaker quadriceps compared to men<sup>5</sup>. Also, sex differences exist in gait mechanics between men and women<sup>6,7</sup>, which might alter CCIs among sexes. Despite extensive investigations into altered gait mechanics after ACLR, little is known about CCIs during the early months after surgery. Thus, the purpose of this study was to examine CCIs in the involved and uninvolved limbs for both sexes in patients 3 months after ACLR. We hypothesized that the involved limb would display higher CCIs compared to the uninvolved limb, and women would display higher CCIs compared to men.

## Methods

45 participants (27 men, 18 women, age:  $22.9 \pm 7.0$  yrs, BMI:  $25.0 \pm 3.5$  kg/m<sup>2</sup>) 3.1  $\pm$  0.6 months after ACLR performed overground walking at self-selected speeds. Electromyography (EMG) data were collected bilaterally for the following muscles: rectus femoris (RF), vastus medialis (VM), vastus lateralis (VL), medial hamstring (MH), lateral hamstring (LH), medial gastrocnemius (MG), and lateral gastrocnemius (MG). EMG data were high-pass filtered at 30Hz, rectified, and low-pass filtered at 6Hz, and normalized to maximum voluntary isometric contractions. CCIs of six muscle pairs: VM-MH, VM-MG, VM-LG, VL-LH, VL-LG, and VL-MG were calculated using Visual 3D (C-motion, Germantown, MD). For each muscle pair, CCIs were defined as the lowest EMG signal divided by the highest EMG signal, multiplied by the sum of these values<sup>3</sup>. The average CCIs between 100ms before heel strike to peak knee flexion angle were reported for each muscle pair<sup>3</sup>. A  $2 \times 2$  (limb  $\times$  sex) repeated measures ANOVA ( $\alpha=0.05$ ) was run to compare CCIs between each limb and sex. Demographic variables were compared using t-tests and chi squared analysis.

## Results and Discussion

No significant differences in age, graft type, and BMI existed between sexes. Our hypothesis was partially supported; participants tended to walk with higher CCIs in the involved limb (vs. uninvolved limb) with a main effect of limb observed for the VL-LH pair ( $p = 0.02$ ). Also, main effects of sex were observed for VM-LG ( $p < 0.01$ ) and VL-LG ( $p = 0.01$ ) muscle pairs (Figure 1). In both groups, women had higher CCIs regardless of limb (Figure 1). No other main or interaction effects were observed for the remaining variables of interest.

**Figure 1:** ♦ Main effects of sex for VM-LG ( $p < 0.01$ ) and VL-LG ( $p = 0.01$ ). For both variables, women had higher CCIs regardless of limb. ◇ Main effect of limb for VL-LH ( $p = 0.02$ ). The involved limb had higher CCIs than the uninvolved limb regardless of sex.

Our findings suggest that CCIs after ACLR differ based on sex. However, given that there were no effects of limb for these variables, it is unknown if the findings in sex differences were a result of the ACLR, or if this is reflecting typical sex differences in gait, as this is the first study to assess CCIs grouped by sex. It should be noted that differences in sex only occurred in the muscle pairs containing the lateral gastrocnemius which may indicate that this muscle is being used differently between sexes following reconstruction. The VL-LH pair is more representative of our expected findings with the involved limb displaying high CCIs. Future studies need to investigate CCIs during gait at later time points after surgery and need to examine if there are associations between high CCIs and measures such as quadriceps strength and kinesiphobia that may potentially influence muscle activation patterns during gait.

## Significance

This study reiterates the importance of early gait interventions and quadriceps strengthening to address altered gait following ACLR. Our findings between sex add to the current knowledge of gait differences among sexes, and why women may be more likely to develop OA following ACLR<sup>8</sup>. Further research should investigate possible contributors to high CCIs such as kinesiphobia or poor quadriceps strength and activation.

# Joint Angular Impulse and Neuromuscular Control in the Y Balance Test™ in ACLR Individuals

Moore, Logan N.<sup>1</sup> Decker, Meredith N.<sup>1</sup> Ricard, Mark D.<sup>1</sup>

<sup>1</sup>The University of Texas at Arlington, College of Nursing and Health Innovation, Department of Kinesiology

## Introduction

The Y Balance Test™ (YBT) is used to measure lower extremity dynamic balance and stability [5]. The YBT is a modified version of The Star Excursion Balance Test (SEBT) looking solely at three reach distances (anterior, posteromedial, and posterolateral) [3, 5]. Dynamic stability tests have been used by clinicians to detect injury risk and as a criterion for return to sport in patients with anterior cruciate ligament (ACL) injuries [2-4]. Patients that have had ACL reconstruction (ACLR) are at a higher risk of reinjury of the ACL and development of osteoarthritis in the knee [1, 2]. Continued dynamic stability tests post rehabilitation could provide insights in the increased risk of reinjury. To our knowledge, there have been no studies focused on neuromuscular control and the joint moments of the lower extremity in patients that are several years out from ACLR. The purpose of this study was to determine if limb to limb differences were present in lower extremity joint moments and neuromuscular control in ACLR patients several years post reconstruction in the anterior direction while performing the YBT.

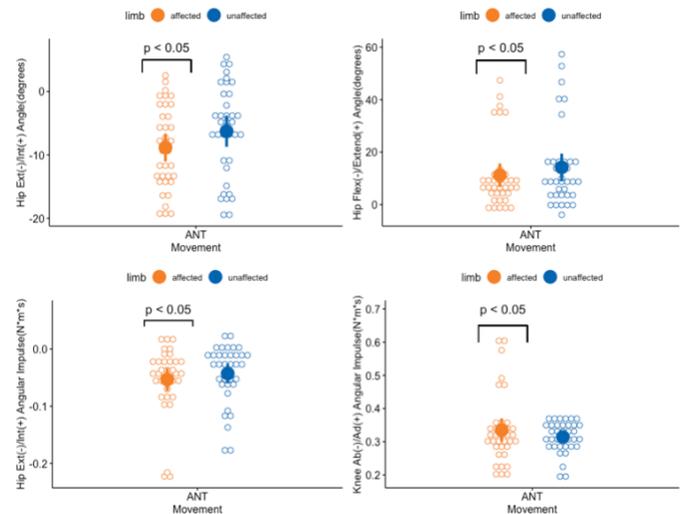

## Methods

Data collection occurred in one session in the University's Biomechanics Laboratory. Twelve recreationally active adults (male=5, female=7, age=24.7±3.6yrs, mass=76.1±12.3kg, height=168.7±10.1cm) volunteered to participate in this study. All participants had a previous history of unilateral ACLR with an average time of 7±3.1 years post reconstruction. EMG data were recorded at 1000 Hz using DE 2.1 electrodes (Delsys Inc.) for gastrocnemius, gluteus maximus, gluteus medius, biceps femoris, semimembranosus, tibialis anterior, vastus medialis, and vastus lateralis. Participants completed 3 trials of the YBT while being recorded at 100 Hz using Vicon Nexus software and an AMTI force plate (1000 Hz). EMG data was processed by using a critically damped low pass filter and normalized to the maximum amplitude attained during all YBT attempts by muscle. 3D internal joint moments about the hip and knee joints were computed using Visual3D and integrated from 100 ms prior to, and 100 ms after max reach in YBT. Linear mixed-effects were used to determine differences between limbs (affected, unaffected) in joint angles and joint angular impulses with EMG linear envelopes as covariates.

## Results and Discussion

There was no significant difference in the anterior reach between the affected 54.92 ± 9.40 cm and unaffected 54.09 ± 9.40 cm,  $p = 0.23$  limbs in the YBT. In the knee joint, the angular impulse for the affected limb was found to have significantly greater abduction impulse, and there was no significant difference found in the knee joint angles (Figure 1). The hip of the affected limb was demonstrated to have significantly greater external rotation and to have greater extension. The angular impulse of the affected limb in the hip was shown to have greater external impulse. While not significant ( $p=0.08$ ), there was a greater hip abduction impulse in the affected limb.

While there were no significant differences in maximal reach distance, how the reach was obtained did change. To compensate for putative deficiencies in the affected limb, subjects exhibited greater knee joint abduction (valgus alignment) and greater hip external rotation and hip extension to attain the same reach distance, when compared to the unaffected limb. These differences in joint angular impulses and joint angles illustrate dynamic balance asymmetries. Dynamic balance asymmetries may be indicative to having a greater risk of injury in the affected limb. There were no significant differences in the maximal amplitude of the EMG between limbs, however strength measurements could further explain the asymmetries in joint angular impulse and neuromuscular control in ACLR patients.

**Figure 1:** Mean ± 95% CI for hip and knee joint angles and joint angular impulse centered at ± 100 ms at maximum reach by limb (affected, unaffected) in the YBT anterior direction.

## Significance

In the anterior direction of the YBT, there were significant differences in the hip and knee joint angular impulses at maximum reach in the affected limb in patients several years post ACLR. There were significant differences in hip joint angles in the affected limb. Continued dynamic stability testing needs to occur post ACLR to identify limb asymmetries and prevent future knee injuries.

# Fiber Splay Obscures Macroscopic Mechanical Measurements of Ligament Stiffness: Implications for ACL Graft Selection

Callan Luetkemeyer<sup>1</sup>, Ryan Rosario<sup>1</sup>, Jonathan Estrada<sup>1</sup>, and Ellen Arruda<sup>1</sup>

## Introduction

Understanding the material properties of ligaments and tendons is important for graft selection, tissue engineered graft design, and computational modeling. However, despite decades of research, even basic material properties like fiber tangent modulus (slope of the uniaxial stress-strain curve) elude scientific consensus. For example, the middle third of a patient's patellar tendon (PT) is a commonly used graft for reconstruction of the anterior cruciate ligament (ACL), but it is debated whether PT material properties are sufficiently similar. Prevailing opinion considers the PT to be a stiffer material than the ACL, since several studies comparing the two have reported a larger tangent modulus for the PT graft [1,2]. Still, others have reported conflicting evidence [3,4].

Collagen fibers tend to spread out, or splay, near the ligament-bone interface. In this study, the influence of fiber splay on the measured (apparent) tangent modulus of the ovine PT and anteromedial (AM) and posterolateral (PL) bundles of the ACL was investigated using experimental, analytical, and computational methods.

## Methods

An idealized analytical model of fiber splay was created using the quantities shown in Fig. 1a to describe the splay geometry. Fibers were assumed to be linear elastic. A mathematical relationship between apparent (grip-to-grip) tangent modulus and true material modulus was derived, which we called the "splay ratio."

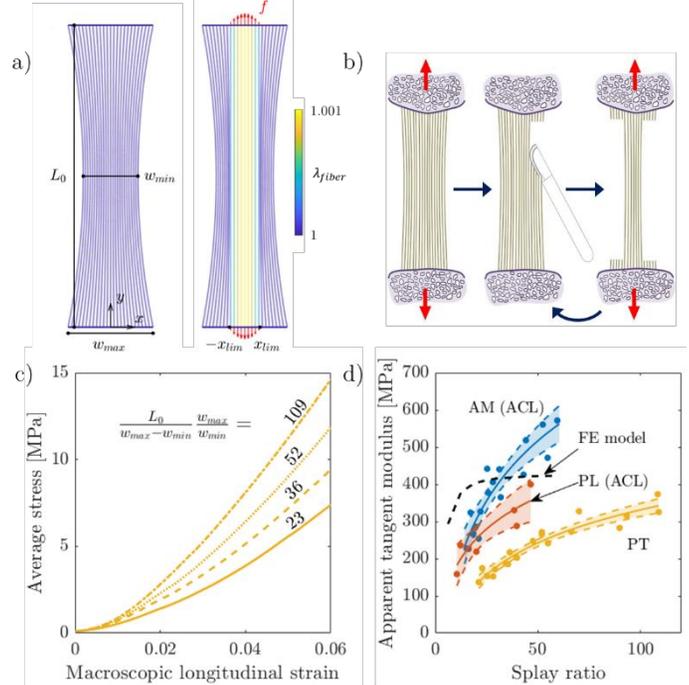

Results were enhanced with a finite element (FE) model (using material properties published by Marchi et al. [5]) and experimental measurements, depicted in Fig. 1b. Briefly, bone-ligament-bone samples were loaded uniaxially at 0.1 mm/s. Fascicles were removed from the outer edges of the specimen to yield a larger splay ratio, and the mechanical test was repeated. This was repeated 2-4 times to determine the effect of splay ratio on apparent tangent modulus.

## Results and Discussion

The analytical model revealed a geometric relationship between the apparent tangent modulus and true material modulus, which we called the splay ratio  $\left(\frac{L_0}{w_{max}-w_{min}} \frac{w_{max}}{w_{min}}\right)$ . The model predicted that differences in fiber splay geometry would yield different fiber recruitment patterns (see Fig. 1a), causing the PT graft to appear stiffer and more linear than the ACL bundles.

Experimental results confirmed that the apparent tangent modulus increased with increasing splay ratio for the ovine PT and both ACL bundles. The effect of splay geometry on the macroscopic stress-strain curve is illustrated by data collected for a single PT sample in Fig. 1c. As the most splayed collagen fascicles were removed, the average stress in the ligament was larger at the same macroscopic displacement (see traction distribution  $f$  in Fig. 1a). Experimentally measured apparent tangent moduli at 5% grip-to-grip strain are plotted against splay ratio for the PT and both ACL bundles in Fig. 1d. Linear and nonlinear regression analysis indicated that the relationship was highly significant, with  $p < 0.01$  for each group. The 3D FE model

produced similar results. Notably, the PT was more compliant than both ACL bundles for similar splay ratios.

**Figure 1:** A simplified analytical model (a) was used to derive a relationship between apparent and true material modulus (splay ratio). Uniaxial mechanical tests were performed at multiple splay ratios (b) to examine the validity of the model. Experimental results show that apparent material stiffness increases with increasing splay ratio for the ovine PT (c), and both bundles of the ACL (d).

## Significance

Material properties, by definition, are independent of specimen geometry. Therefore, the results of this study suggest that material properties of ligaments are likely not identifiable with macroscopic stress-strain measurements.

The current results suggest that the PT is a more compliant material than the ACL bundles. However, the PT graft (middle third of the PT) is probably a stiffer structure than the ACL. This raises an important question: does an ACL graft need to mimic the a) native ACL material properties, b) force-extension relationship, or c) both? If true material properties are of interest (i.e. for computational modeling), strain heterogeneity can be taken into account with full-field mechanics methods [6].

email: [erictor@uw.edu](mailto:erictor@uw.edu)

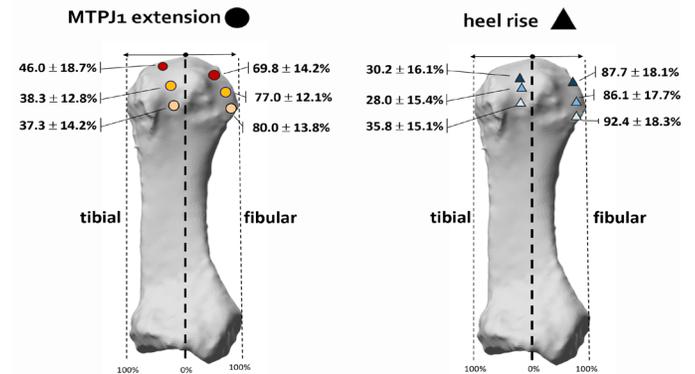

### Introduction

The foot sesamoid bones act as essential shock absorbers, metatarsal head protectors, and tendon moment arm amplifiers during gait. Given these important roles, they are involved directly or indirectly in several toe pathologies, making their study an area of clinical interest [1]. However, due to difficulties in imaging these small bones, 3D kinematic data of normative sesamoid motion is sparse [2]. Additionally, with the recent increased interest in weight-bearing cone-beam computed tomography (CT), we sought to test the feasibility of using a low-dose scanner for reconstructing the sesamoid motion of the great toe. The primary goal of this project was to quantify the normative motion of the tibial and fibular sesamoids in a series of controlled cadaveric experiments.

### Methods

Twelve fresh human foot and ankle specimens were prepared and tested in a custom biomechanical testing apparatus assembled around a pedCAT (Curvebeam, USA) weight-bearing cone-beam CT scanner. The device applied axial half-bodyweight load and six tendon forces to produce a range of first metatarsophalangeal (MTPJ1) extension motion in both 1) a standing position and 2) heel rise (simulating terminal stance of gait). Specimens were mechanically loaded into seven poses between a neutral foot position and maximum toe extension. At each static pose, a low-dose CT scan was acquired and used to derive the bone kinematics and anatomical coordinate systems. Coordinate systems were based on distal metatarsal geometry and used to scale motion between specimens of different sizes.

likely related to the more medially directed passage of load through the plantar aspect of the foot during normal gait.

**Figure 2:** Medial-lateral sesamoid motions for MTPJ1 extension and heel rise positions expressed as a percentage of the metatarsal width for three poses: neutral, intermediate, and maximum MTPJ1 extension.

Along the medial-lateral direction (Figure 2), the sesamoids track together, medially with extension of the MTPJ1. Under the larger axial loading of heel rise, the sesamoids have less medial motion, moving in a plane closer to true sagittal. During heel rise, both sesamoids were shifted more laterally relative to the extension activity; however, the fibular sesamoids shifted to the most lateral margin of its compartment throughout the motion. This apparent shift is likely from the medially-moving metatarsal head with increasing axial load [3]. Contact at the less congruent margins of the joint may put the sesamoid at risk for subluxation.

### Significance

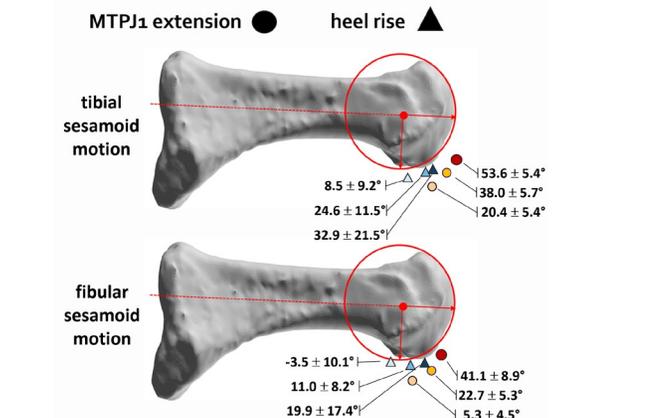

The anatomical location and role of the sesamoids make them interesting, but challenging bones to quantify kinematically with imaging. This study demonstrated that low-dose weight-bearing CT scanning could be used to quantify 3D sesamoid motion. The motion patterns of the sesamoids were distinct for each simulated activity. Proper deployment of the sesamoids is essential to the protection of the articular surfaces and for efficient gait. Further investigations into sesamoid-metatarsal joint congruity, morphology, and the feasibility of tracking in vivo sesamoid motion using biplane fluoroscopy are underway. These kinematic data may provide a basis of comparison for clinical diagnosis of sesamoid dysfunction or elucidate how MTPJ1 replacement designs could be improved by considering the contributions of sesamoids to great toe stability and function.

**Figure 1:** Sagittal plane sesamoid motions for MTPJ1 extension and heel rise positions expressed in a distal metatarsal coordinate system for three poses: neutral, intermediate, and maximum MTPJ1 extension.

### Results and Discussion

Both sesamoids moved anterodorsally with toe extension, as expected (Figure 1). Compared to the fibular sesamoid, the tibial sesamoids rotated about the metatarsal medial-lateral axis roughly 12 degrees more in the sagittal plane during heel rise to cover more of the distal metatarsal head (Figure 1). This is most

# Iliotibial Band Wave Speed Modulates with Hip Abduction Moments

Stephanie G. Cone<sup>1</sup>, Josh D. Roth<sup>1,2</sup>, and Darryl G. Thelen<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, University of Wisconsin – Madison, Madison, WI

<sup>2</sup>Department of Orthopedics and Rehabilitation, University of Wisconsin – Madison, Madison, WI

## Introduction

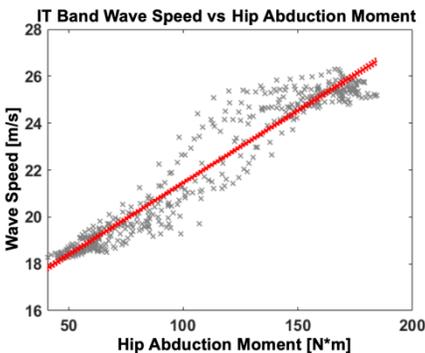

The iliotibial (IT) band is a long, complex structure extending proximally from the tensor fascia latae, the gluteus maximus, and the iliac crest and inserting distally primarily on to Gerdy’s tubercle on the proximal tibia. As such, active modulation of the IT band is believed to generate abduction and flexion torques at the hip. Inherent stiffness of the IT band may play an important role in providing passive anterolateral stability about the knee. While such mechanical roles are presumed based on anatomy and modelling efforts [1], it is challenging to evaluate *in vivo* IT band loading. Shear wave tensiometry provides a potential solution, given the relationship that exists between wave propagation speed and axial tissue loading in tendons [2]. The objective of this exploratory study was to evaluate whether tensiometers could track IT band wave speed during isometric hip abduction. We also measured IT band wave speeds during walking and running, and compared it to nominal hip abduction torque patterns observed in such tasks.

## Methods

Shear wave tensiometers were secured on the IT band approximately 5-10 cm above the femoral condyles unilaterally on 6 healthy adults (3M/3F). Shear wave speeds were measured from the IT band during a standing, isometric hip abduction task. External loads were collected from a uniaxial load cell secured to a cuff about the ankle. Ten second trials of the hip abduction task were performed cyclically in triplicate.

Linear regressions between hip abduction torque and wave speed were performed on individual trials, and goodness of fit was assessed as  $R^2$  values. Multi-way ANOVA tests were performed for the slope of each linear regression with trial, subject, and task as main effects. An overall p-value of 0.05 was considered significant.

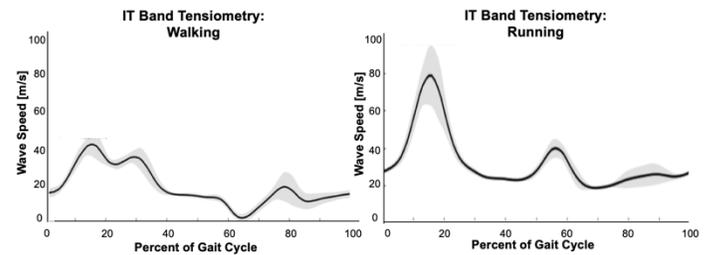

## Results and Discussion

**Figure 1:** IT band wave speed modulated with hip abduction moment. Linear regression was used to assess the slope of the wave speed-moment relationship.

IT band wave speeds consistently increased with hip abduction moment for all subjects. The slope of the wave speed-moment relationship was relatively consistent across repeat tasks, but varied considerably ( $p < 0.05$ ) across subjects (Figure 1).

Linearity of the relationship was also variable, with  $R^2$  ranging from 0.36 to 0.93. Variability was primarily attributable to a subset of individuals exhibiting considerably lower wave speed magnitudes, which could have resulted from differences in ITB band morphology, sensor placement and or wave propagation through subcutaneous tissues. Ascertaining the relative influence of such factors will be important in calibrating the wave speed-tension relationship for individuals.

**Figure 2:** IT band wave speeds measured during walking and running reveal task-specific differences in loading patterns within the tissue both in magnitude and timing. Lines and shaded regions represent mean  $\pm$  standard deviation over 10 second trials.

IT band wavespeeds during walking and running reveal highly repeatable patterns over the gait cycle (Figure 2). Phases of higher wave speeds during stance are similar to hip abduction moment as ascertained from traditional motion analysis. These results suggest that shear wave tensiometry provides a unique opportunity to ascertain functional IT band loading during walking, running and other locomotor tasks.

## Significance

This works shows that shear wave tensiometry may provide a unique opportunity assessing the functional *in vivo* behaviour of the IT band, a complex tissue which is traditionally difficult to study. Tensiometry could provide data for evaluating model predictions of IT band loading, and be used to evaluate IT band function in both healthy and pathologic cases. Potential applications include the evaluation of IT band syndrome in runners, and investigations of orthopaedic procedures that alter IT band geometry (e.g. all-epiphyseal ACL reconstruction) [3].

# Hamstrings Training Program improves Drop Vertical Jump performance and efficacy of movement in female athletes

Luca Rigamonti<sup>1,2</sup>, Nathaniel A Bates<sup>1</sup>, Takashi Nagai<sup>1</sup>, Ryo Ueno<sup>1</sup>, Rena F. Hale<sup>1</sup>, Timothy E. Hewett<sup>3</sup>, Nathan D Schilaty<sup>1</sup>  
<sup>1</sup>Department of Orthopedic Surgery, Mayo Clinic, Rochester, MN, USA; <sup>2</sup>School of Medicine and Surgery, University of Milano-Bicocca, Monza, Italy; <sup>3</sup>Sparta Science, Menlo Park, CA, USA. Email: [rigamonti.luca@mayo.edu](mailto:rigamonti.luca@mayo.edu)

## Introduction

Lower extremity neuromuscular training programs are utilized to decrease injury risk, with particular reference to the anterior cruciate ligament (ACL) [1]. Training is also used to enhance sports performance. Hamstrings:quadriceps strength ratio (H:Q) is an important estimate of optimal knee function as a H:Q ratio below 0.6 is associated with risk of ligament and muscular injury [2,3]. Further, higher risk of ACL injuries in females can be attributed to poor neuromuscular control and muscular balance [4]. Hamstrings-specific training programs are intended to increase muscular strength and flexibility, improve interaction with quadriceps contraction, and enhance joint movement through neuromuscular control [5]. The objective of this study was to evaluate the impact of hamstrings-specific training on jump performance and biomechanics in female basketball athletes. The hypothesis tested was that athletes who completed training would exhibit better jump performance and biomechanics than controls.

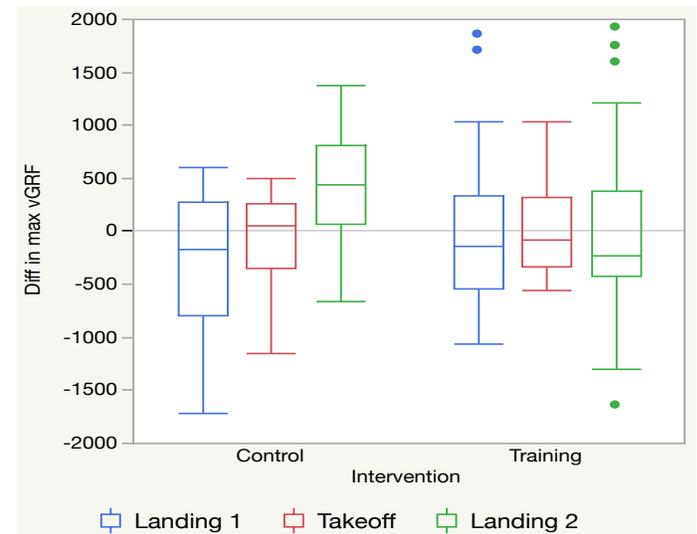

## Methods

A total of 43 female high school basketball athletes underwent biomechanical evaluation both before and after their season. Subjects were divided into Control (n=17) and Trained (n=26) groups. Every athlete in the trained group was educated to carry out a specific dynamic hamstrings exercise sequence during their warm-up two times per week throughout the season. The control group did not receive any supplemental exercise beyond their standard team warm-up. The Pre and Post evaluation included drop vertical jump (DVJ) tasks. DVJs can be divided in three phases: the first landing (Land1), the vertical jump (Takeoff) and the second landing (Land2). [3] Change in bodyweight (BW), jump height, vertical ground reaction force (vGRF) from each jump phase, and braking power during landing were collected from each subject. An average of three DVJ trials was collected for each variable and used for statistical analysis (Table 1). The difference between Post and Pre season for each athlete was calculated (Figure 1), a simple t-test was used to compare Control and Trained group (P<0.05).

## Results and Discussion

Jump height and flight time were both higher in the Trained group (P<0.05). Average vGRF during Land1 was higher in the Trained group, but not statistically significant (P=0.22). This is likely correlated with higher jump performance. During Land2 the vGRF was lower in the Trained group (Figure 1) and approached statistical significance (P=0.07). Difference in Braking Power

during Land2 was significantly lower in the Trained group (P<0.05). Overall hamstrings-specific training upgraded the efficacy of the movement as jump performance improved in the Trained group without subsequent increase to vGRF on landing, which is a variable that associates with injury risk [4].

**Figure 1:** Difference in vGRF between Post and Pre season evaluation in the three different phases of DVJ: Land1, Takeoff and Land2. Lower vGRF in landing phases is related with lower risk of knee injury.

## Significance

The current hamstrings-specific training was effective improving jump performance without increasing biomechanical ACL risk factors. Additionally, we previously demonstrated that the same program was effective improving hamstrings strength and flexibility. Based on these findings, it is highly recommended that female athletes should incorporate hamstrings-specific exercises during their warm-up programs.

## Introduction

Determination of hindfoot, forefoot, and hallux kinetics is important in clinical gait analysis. Several current multi-segmental foot models have the capability to calculate segmental kinetics, however, the complexity of the data collection for these models limits their utility in clinical settings [1-2]. A mathematical algorithm capable of distributing the single composite ground reaction force (GRF) amongst multiple foot segments has been developed. Accurate distribution will allow for segmental kinetics to be determined without the need for additional equipment, additional time spent in the gait lab, or targeted walking by patients.

Understanding the biomechanics of the segmental foot is critical to the proper care of patients with a variety of orthopaedic impairments (e.g., cerebral palsy, Charcot-Marie-Tooth disease) and foot deformities, such as clubfoot, equinovarus, and pes planovalgus. Accurate knowledge of three-dimensional (3D) ankle (hindfoot to tibia) and mid-tarsal (distal-foot to hindfoot) kinetics during walking and other functional activities is essential for identifying the effects of such injury and disease.

## Methods

Bilateral data was collected from 10 typically developing pediatric subjects (n=5 male, age=14.1 ±2.1 yrs). Motion capture data was collected using the previously validated kinematic Milwaukee Foot Model (MFM) [4] for the shank, hindfoot, forefoot, and hallux segments.

The algorithm's distribution of the GRF is based upon the three phases in existing models used in induced acceleration analyses. In these models, kinematic constraints are placed on the foot as a function of the center of pressure (COP) as developed by Lin et al (Fig 1) [5]. Phase one, corresponding to heel strike, occurs when the location of the COP is posterior to the axis created by the medial and lateral calcaneus (Axis 1). At this phase, the GRF is acting only on the hindfoot segment. Phase two, corresponding to foot flat, begins as the COP moves past Axis 1. At this point the GRF begins to distribute between the hindfoot (HF) and distal-foot (DF) (forefoot/hallux) segment based on the equation in Fig 1, where d1 is the shortest distance from Axis 1 to the COP and d2 is the shortest distance from Axis 3 to the COP, F<sub>H</sub> is the hindfoot force, F<sub>D</sub> is the distal-foot force, and F<sub>T</sub> is the total force. Phase 3 occurs when the COP approaches Axis 3, d2 approaches zero, and the hindfoot raises from the ground, allotting the entire GRF to the distal foot. An adjustment was made to allocate 10% of the total force to the hindfoot, while the hindfoot is in contact with the ground; the other 90% is distributed using the above equation.

Evaluation of the GRF modeling technique was completed using an RSscan pedobarographic pressure platform synced with an AMTI (GRF) force plate to allow for simultaneous collection of force plate and plantar pressure plate data [2]. Paired t-tests were used to compare peak force, time to peak, and total force for the HF and DF segments as output by the two algorithms (α=0.05).

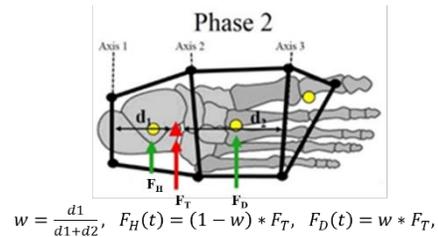

Figure 1: GRF distribution based on COP

## Results and Discussion

Fig 2 shows an example trial comparing the force distribution algorithm to the RSscan force distribution. 102 trials were analyzed. No statistical difference was found between the algorithm and the RSscan: HF peak force (p=0.31), HF time to peak (p=0.93), HF total force (p=0.41), DF peak force (p=0.32), DF time to peak (p=0.32), or DF total force (p=0.26).

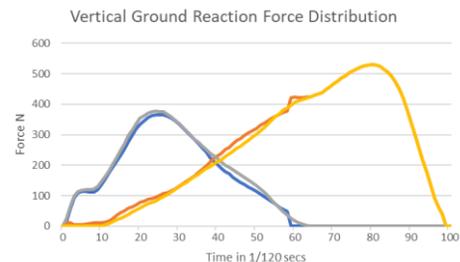

Figure 2: Dark Blue: Algorithm HF, Light Blue: RSscan HF, Dark Orange: Algorithm DF, Light Orange: RSscan DF

The results demonstrate the feasibility of dividing the ground reaction force amongst foot segments with typical motion capture protocols without the need for a plantar pressure plate. An accurate force division allows for calculation of kinetics at the mid-tarsal joint.

## Significance

Understanding normal mid-tarsal function is imperative in pathologies such as plantar fasciitis [6]. Our algorithm can be used to understand the moments and power at the mid-tarsal joint. Identifying kinetic corridors for the moments at the ankle and mid-tarsal joints will allow for better comparison and discovery of differences in pathological feet, leading to better management of gait challenges. Future work will be performed to divide the distal foot into forefoot and hallux segments allowing for kinetics at the MTP joint and to validate the algorithm using a population with foot impairments.

## Introduction

Post-traumatic osteoarthritis (PTOA) affects over 50% of patients with tibial pilon fractures [1]. PTOA status is most often assessed using KL grade based on arthritic changes seen on plain radiographs including osteophyte formation, sclerosis, and joint space narrowing. KL grading is subjective and lacks sensitivity needed for early PTOA monitoring [2]. The lack of reliable early indicators of PTOA impedes the study of preventive measures. In-clinic weight bearing CT (WBCT) now allows 3D assessment of the ankle in a functional pose, enabling a fuller analysis of degenerative joint changes. This study investigated longitudinal changes in the tibiotalar 3D joint space width (JSW) over the course of 18 months after operative treatment of pilon fractures.

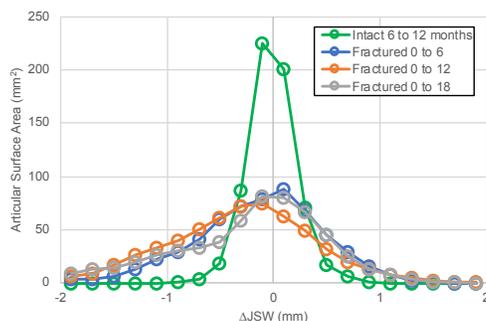

## Methods

Sixteen patients with unilateral tibial pilon fractures were enrolled at three institutions under IRB approval. WBCT scans were obtained at 6, 12, and 18 months after operative fixation. 3D triangulated models of tibial and talar subchondral bone surfaces were segmented from WBCT scans using a semi-automated method and then smoothed in Geomagic Design X. The scan data and models from different follow-up times were aligned in 3D Slicer based on image intensities in the talus. Contralateral intact ankle models from 6 month scans were mirrored across a mid-sagittal plane and registered to fractured ankles as a pre-fracture (0 month) stand-in. 3D JSW was computed as the normal distance from the center of each talar mesh face to the nearest point on the tibial surface. The 6-month fractured talus was used as a common datum for all JSW measurements interpolated onto this surface mesh. The JSW distributions were analyzed by measuring the percent joint area under three distance thresholds (T1 = 2.23 mm, the mean intact JSW, T2 = 1.89 mm, 1 standard deviation below the mean, and T3 = 1.55 mm, 2 standard deviations below the mean). The change in 3D JSW ( $\Delta$ JSW) was also computed for all points with JSW < 4 mm. The  $\Delta$ JSW from 6 to 12 months on the intact ankles was used to assess measurement reliability.

## Results and Discussion

The  $\Delta$ JSW varied among fractured ankles in magnitude and timing (Figure 1). The intact ankles, used to assess reliability, had  $\Delta$ JSW equal to  $-0.01 \pm 0.11$ mm. The fractured ankles saw the most joint space narrowing from 6 to 12 months ( $\Delta$ JSW =  $-0.16$

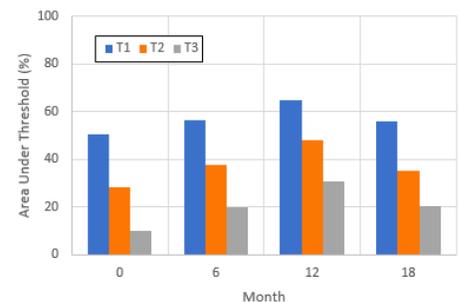

**Figure 1:** Areas of the articular surface on the fractured ankles have  $\Delta$ JSW that show substantial narrowing of the joint space.

$\pm 0.23$  mm), with 14/16 experiencing narrowing. There was also a trend towards narrowing from 0 to 6 months ( $\Delta$ JSW =  $-0.12 \pm 0.30$  mm), with 9/16 decreasing in JSW. From 12 to 18 months, the joints averaged widening ( $\Delta$ JSW =  $0.10 \pm 0.19$  mm) with only 4 ankles continuing to narrow.

The intact ankles averaged the least area under all JSW thresholds (T1 = 50%, T2 = 28%, T3 = 10%) (Figure 2). The

**Figure 2:** Fracture timepoints show larger regions of narrow joint space as compared to the intact (0 month).

fractured ankles had similar JSW distributions at 6 months (T1 = 57%, T2 = 38%, T3 = 20%) and 18 months (T1 = 56%, T2 = 35%, T3 = 20%). The joints averaged larger areas of narrow JSW at 12 months (T1 = 65%, T2 = 48%, T3 = 31%). The larger narrowing and higher percentages of narrow regions present in the fractured ankles compared to the intact suggest progressive cartilage degeneration. Variability in the timing and magnitude of these joint changes are consistent with clinical experience that the speed and quantity of cartilage loss varies between fractures, as does PTOA incidence. Future work will examine the extent to which early 3D JSW changes correlate with PTOA development and the onset of clinical symptoms.

## Significance

WBCT scans enable longitudinal analysis of 3D JSW degeneration consistent with PTOA development. From 0 through 12 months post pilon fracture, decreases in average 3D JSW and increases in percent area with low JSW were measured.

# Custom Orthosis Prescription is Needed to Reliably Reduce Harmful Contact Stress after Intra-Articular Fracture

Bryan Tanner, Kirsten Anderson, Jason Wilken, Molly Corlett, Donald D. Anderson  
 University of Iowa, Iowa City, IA  
 Email: don-anderson@uiowa.edu

## Introduction

Despite operative treatment, the joints of patients with intra-articular fractures (IAFs) of the distal tibia are often subject to elevated contact stresses from residual incongruity that increase the risk for post-traumatic osteoarthritis (PTOA) [1]. Custom dynamic orthoses (CDOs) have been shown to improve function while relieving joint pain in patients after severe lower extremity trauma [2] and may be a suitable adjunct for IAF treatment. CDOs can decrease load transfer across the tibiotalar joint [3], but residual incongruities vary widely, so custom patient-specific prescription may be required. The goal of this study was to investigate whether a custom CDO design prescription would be needed to effectively reduce contact stress exposure in patients.

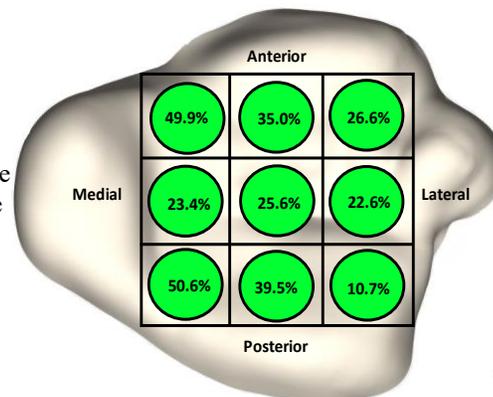

## Methods

A generic musculoskeletal OpenSim model with 92 musculo-tendon actuators (gait2392 model) was scaled to model 7 patients with surgically treated ankle IAFs [4]. Generic motion data were applied to body-weight scaled models, generating ankle joint reaction forces and muscle control matching the kinematic profiles. A coordinate limit force resisting ankle flex/extension and an in-line spring for brace offloading were added to each case. For the generic brace, a rotational stiffness of 4 Nm/rad\*kg, 0° neutral angle, and 6000 N/m offloading spring were used. Contact stress exposures were calculated across the segmented post-op tibial articular surfaces using discrete element analysis (DEA) [5]. Then 3 different brace design parameter combinations were tested for each case to determine the one most effective at reducing contact stress exposure compared to the generic design (Table 1). Contact stress exposure distributions were divided into 9 clinically relevant regions on the articular surface of the distal tibia to study the influence of the different CDO designs.

## Results and Discussion

The generic brace design substantially reduced the max contact stress exposure in nearly all cases, with the average reduction being 31.5% (Figure 1). The use of a case-specific custom brace design reduced the contact stress exposure an additional 3%, on average, but in some cases the benefit was more substantial, approaching a 20% further reduction in some regions.

**Figure 1:** Reduction in contact stress exposure for the generic CDO, averaged over the 7 cases that were studied.

## Significance

The data suggest that different brace designs can more or less effectively reduce contact stress exposure at the tibio-talar joint. A single generic brace can predictably reduce contact stress exposure, but differing parameters are necessary to directly address the elevated joint contact stresses of individual patients. Elevated joint contact stress has been linked with an increased risk of PTOA, which if allowed to progress, has damaging effects further down the road. This study provides evidence that custom CDOs would be more effective than generic CDOs in relieving joint contact stress and mitigating PTOA, when regarding the population of IAF patients.

# Medio-Lateral Ankle Fluency In People With Chronic Ankle Instability During Dynamic Movement Trials

Nolan King, SPT<sup>1</sup>, Tarang Jain, PT, DPT, PhD<sup>2</sup>

Physical Therapy and Athletic Training, Northern Arizona University, Flagstaff, AZ

Email: [Tarang.Jain@nau.edu](mailto:Tarang.Jain@nau.edu)

## Introduction

Ankle sprains are a common injury that occurs in the athletic as well as general population. While ankle sprains tend to be discounted in the general public, they have been shown to significantly alter mobility and lifestyle, which increases the risk of developing osteoarthritis after an initial ankle injury.<sup>1</sup> Chronic ankle instability (CAI) is defined as a presence of ankle “giving way” and a feeling of instability that is present for a minimum of one year.<sup>2</sup> CAI has been shown to disrupt postural stability and neuromuscular control, and may affect ankle dorsiflexion and fluency during running and jumping activities.<sup>1,3</sup>

Deficits in neuromuscular control in individuals with CAI due to damage to the mechanoreceptors in the ligaments and possibly the muscle spindles have been well documented in the literature.<sup>1,3,4</sup> Specifically, the poor neuromuscular control of the peroneus longus and peroneus brevis is prevalent in those that develop CAI.<sup>4</sup> Our study aims to determine the difference in medio-lateral displacement at the ankle joint during dynamic movement tests in subjects with chronic ankle instability compared to healthy individuals. We hypothesized that people with CAI would demonstrate reduced medio-lateral ankle control compared to healthy controls.

## Methods

18 subjects participated in a set of three dynamic movement tests (Table-1). The Cumberland Ankle Instability Tool was used to determine CAI in participants with a cutoff score of less than 25 indicting participants with CAI.<sup>5</sup> For the drop vertical jump (DVJ) test, the subject dropped from a stationary box and immediately upon landing jumped as high as possible vertically and recover on both feet. In the single leg drop (SLD) test the individual hopped off on one foot and landed on the opposite foot. For the crossover drop (COD) test the individual hopped laterally, landing on the opposite leg. All testing was performed in the Human Performance Lab, Northern Arizona University and was approved through the Institutional Review Board.

Kinematic data were collected at 300 Hz using an eight camera VICON motion analysis system (Oxford Metrics Group Ltd., UK). Reflective markers were placed using the ‘Plug-in-Gait’ full body marker set. In some trials the the missing data were filled using a custom written program in Vicon BodyBuilder for Biomechanics. Inverse dynamics calculations were performed within VICON Nexus software and data were further processed and analyzed in Matlab R2019a (The Mathworks Inc., USA). Fluency of the ankle movement on the involved/dominant side in the coronal plane was calculated by a method adapted from Smeulders et al. (2001).<sup>6</sup> Two-way Analysis of Variance (ANOVA) with a polynomial first order (linear) contrast post hoc test was used to compare the effects of SLD, COD, and DVJ trials on mean fluency values between the CAI and healthy group. An a priori  $\alpha$ -value of 0.05 was used to determine statistical significance for all tests.

	CAI group (n=10)	Healthy group (n=9)
Age, y	25.4 (2.3)	25.8 (7.4)
Gender, M/F	5/5	4/5
Height, cm	167.4 (8.2)	169.1 (11.9)
Mass, kg	66. (7.8)	62.8 (11.6)
CAIT Questionnaire score	18.1 (3.0)	29.3 (0.7)
Ankle ‘giving-way’ in past 6 months	8.1 (6.1)	0.2 (0.4)

CAIT – Cumberland Ankle Instability Questionnaire

Values are mean (std dev) unless otherwise indicated

**Table 1:** Demographics of the study participants

## Results and Discussion

The subject groups were reasonably matched for age, gender, height, mass and ranges of motion (Table 1). CAI group scored on average lower in the CAIT questionnaire, indicating that they had lower ankle function. Fluency of the ankle movement in the coronal plane was significantly different between groups ( $p=0.023$ ) and demonstrated a significant linear contrast (COD: CAI -  $0.10\pm0.32s$  vs healthy -  $0.19\pm0.23s$  ( $p=.002$ ); SLD: CAI -  $0.19\pm0.49s$  vs healthy -  $0.24\pm0.28s$  ( $p=.06$ ); DVJ: CAI -  $0.23\pm0.29s$  vs healthy -  $0.22\pm0.23$  ( $p=.41$ ). These preliminary findings suggest that ankle movement in patients with CAI was least fluent in COD and most fluent in DVJ. Patients with CAI also showed larger medio-lateral ankle joint center excursions, which indicates lack of ankle control.

These findings can be interpreted as insufficient motor control during the COD task, or it could be interpreted as a protective strategy, utilized by patients with CAI to avoid further injury. Ankle fluency asymmetry or maladaptive landing technique may explain elevated re-injury rates and the presence of chronic morbidities observed in patients with ankle sprain. The lack of control could arguably result in loading of the articular cartilage on locations that are normally not loaded, which may implicate early development of osteoarthritis.

## Significance

To our knowledge, there is no previous literature evaluating ankle coronal plane control during dynamic movement trials in patients with CAI. Ankle rehabilitation strategies should target medio-lateral ankle control to develop optimal neuromuscular control and perturbation exercises for patients with CAI.

# Higher Volar Tilt and Volar Offset of a Total Wrist Arthroplasty are Associated with Larger Wrist Range-Of-Motion

Bardiya Akhbari<sup>1</sup>, Amy Morton<sup>2</sup>, Kalpit Shah<sup>1</sup>, Janine Molino<sup>2</sup>, Douglas Moore<sup>2</sup>, Arnold-Peter Weiss<sup>2</sup>, Scott Wolfe<sup>3</sup>, Joseph Crisco<sup>1,2</sup>  
<sup>1</sup>Brown University, Providence, RI, <sup>2</sup>Rhode Island Hospital, Providence, RI, <sup>3</sup>Hospital for Special Surgery, New York, NY  
Email: [bardiya\\_akhbari@brown.edu](mailto:bardiya_akhbari@brown.edu)

## Introduction

Total Wrist Arthroplasty (TWA) has been used in fewer patients compared to knee and hip arthroplasty mostly due to its high complication rates.<sup>[1]</sup> Alignment of the knee and hip prostheses strongly correlate with implant performance, and malalignment is a known contributor to implant failure. For TWA, optimal implant alignment has not been defined. More importantly, the effect of implant malalignment on range-of-motion (ROM) has not been studied. Therefore, the aims of this study were to define the alignment of TWA components using three-dimensional (3D) analysis and to determine the influence of alignment on ROM *in-vivo*.

## Methods

Six osteoarthritic patients (74.7 ± 5.6 yrs, 2F, 2R) with wrist replacements (Freedom<sup>®</sup> size 2, Integra LifeSciences) were recruited after IRB approval. None of the patients had a prior radius fracture that would cause the change in radii alignment.

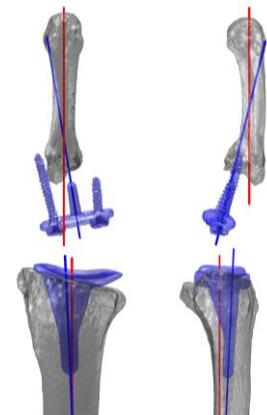

A single CT scan (Lightspeed<sup>®</sup> 16) was acquired of each wrist (80 kVp/80 mA; 0.39 × 0.39 × 0.625mm<sup>3</sup>), and surface models of the carpal component, third metacarpal, and resected radius were generated using Mimics (Materialise).<sup>[2,3]</sup> A digital model of the radial component was generated using a 3D surface scanner (Artec Space Spider<sup>™</sup>). Orthogonal coordinate systems were defined for the radial and carpal components based upon geometrical features. Rotational alignments were defined as the orientation between bone's coordinate system and the component's coordinate system as volar-dorsal tilt (VDT) and radial-ular tilt (Figure 1). Translational alignments were defined in the same views (e.g. volar-dorsal offset [VDO])

Biplanar videoradiography (75 kV/80 mA, 200Hz) was used to capture dynamic implant motion while each study participant performed active tasks of wrist motion: flexion-extension, radial-ular deviation, and circumduction. ROM in each direction of flexion, extension, radial, and ulnar deviation were calculated by tracking the implants using a 2D to 3D registration software (Autoscooper).<sup>[2]</sup> Motions were described relative to the neutral pose.

Linear regression was used ( $\alpha$ -level of 0.10 due to small sample size) to determine the relationship between ROM and alignment parameters.

## Results and Discussion

In our cohort, wrist ROM was 49 ± 8° in extension, 27 ± 13° in flexion, 17 ± 5° in radial deviation, and 18 ± 10° in ulnar deviation. Linear regression demonstrated that flexion, radial deviation, and ulnar deviation were significantly ( $p = 0.057, 0.002, \text{ and } 0.019$ ) higher for patients with larger volar tilt of the radial component.

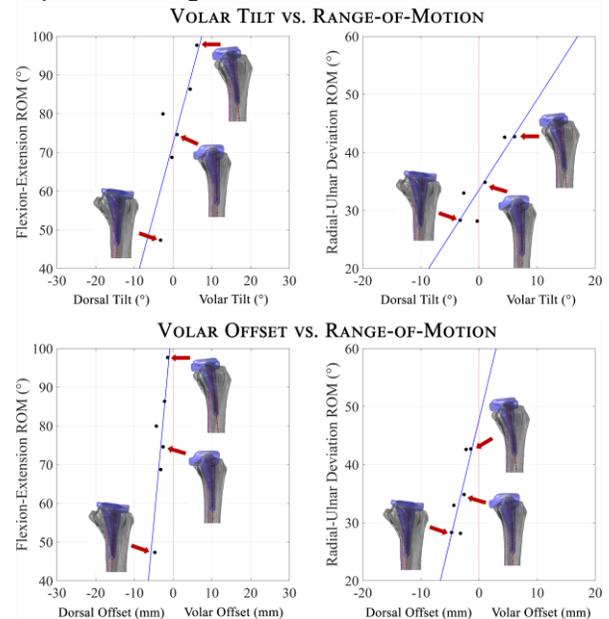

**Figure 1.** The alignment was defined by radial/ulnar tilt or offset (left) and volar/dorsal tilt or offset (right).

Overall flexion-extension and radial-ular deviation were also correlated with the radial component's VDT ( $p = 0.047$  and  $0.015$ ) and VDO ( $p = 0.055$  and  $0.050$ ) indicating an increase of 3.7° and 1.6° per degree increase in volar tilt, and 10.8° and 4.2° increase in ROM for every millimeter of volar offset (Figure 2). Previously, the importance of maintaining alignment to obtain good ROM outcome after distal fracture has been reported,<sup>[4]</sup> and this study reflects similar findings for TWA.

We observed correlations between volar tilt and volar offset of the radial component and ROM in flexion, radial deviation, and ulnar deviation, possibly due to reduced constraint of the polyethylene cap by the radial component when tilted volarly. Interestingly, extension was not correlated with the alignment in our cohort ( $p = 0.34$ ), which suggests that extension is likely constrained by soft tissue envelope of the hand or post-surgical scar, and not the geometry of the implant.

This study was limited by the small cohort of 6 subjects and the single implant's design. Future studies should investigate the impact of malalignment on the functional outcomes.

**Figure 2.** Overall range-of-motion increased as the radial component's volar tilt and volar offset increased.

## Significance

We demonstrated that the patients who have a radial component that is more volarly tilted have a higher range of flexion-extension and radial-ular deviation motions.

## Introduction

Reverse total shoulder arthroplasty (rTSA) has become an increasingly popular procedure for treating patients with rotator cuff arthropathy and glenohumeral joint disease. Past rTSA studies assessing functional changes using motion capture have used pre- and post-op comparisons, the patient’s opposite shoulder, or control groups significantly below the age of the rTSA population<sup>[1-3]</sup>. A pre- and post-op comparison does not allow for a normative comparison and shoulder studies that have included a representative control population were limited to assessing controlled, in-plane motion<sup>[4]</sup>. Also, the use of the opposite shoulder may not be representative of an unaffected control<sup>[5]</sup>. Normative performance during an activity of daily living (ADL) may change with age<sup>[6]</sup> and average age of an rTSA recipient is approximately 70 years<sup>[7]</sup>. Therefore, to more accurately characterize the differences between the rTSA and the anatomic joint, a representative healthy subject population is needed. The overall goal of this study is to establish a database comprised of joint kinematics and motion path for 40 healthy, age-matched controls. Preliminary data from n = 6 age-matched, healthy controls are presented.

## Methods

All aspects of this study were approved by FDA IRB and all participants gave informed consent. Twelve tasks representative of ADLs were developed from 3 validated patient reported outcome surveys (PROs). Preliminary data from six healthy participants (69.2 ± 4.9 age, 2F/4M) performing three trials of each task were collected. Thirty-three retro-reflective markers were placed on bony landmarks of each participant and tracked in 3D space using a ten-camera Vicon motion capture system. Shoulder joint kinematics were calculated using the Vicon Plug-In-Gait upper body model. Average range of motion and peak angle were calculated for each degree of freedom in the shoulder (flexion/extension, abduction/adduction, and internal/external rotation).

## Results and Discussion

Here, we focus on three tasks: reaching overhead, washing opposite shoulder, and putting on a t-shirt. Figure 1 shows the average trajectory across all three trials for all participants (Blue) and individual trajectories (Black) for each task and shoulder degree of freedom. Table 1 shows the average and standard deviation of RoM and peak angle values.

## Significance

This study will produce the first database inclusive of a wide variety of ADLs for a representative population of TSA patients using a large number of subjects to characterize shoulder motion. With characterization of the healthy control motion path during ADLs, improved understanding of the effect that rTSA implants have on user motion path and function during ADLs may inform rehabilitative outcomes for these patients as well as regulatory evaluation of these types of devices.

## Effects of sex and vision on shoulder position sense

### Introduction

Proprioception is a key component of injury prevention and recovery. Factors with potential influence should be examined in any instance where risk or rate of injury is high. Upper extremity pathologies comprise a high percentage of work-related musculoskeletal disease and women are at significantly higher risk than men when comparing within the same occupation [1]. While it is well known that sex differences exist in skeletal and muscular architecture and factors of motor control [2], differences in proprioception have not been fully elucidated. Further, exploration of this topic is justified by the current conflicting evidence in the field. Some assessments of sex differences in upper limb proprioception have found women to be more accurate at position matching tasks [3], whereas others have found no differences in accuracy [4]. Vision of the proprioceptive target has also varied between studies and therefore the effect has not been fully clarified. The aim of this study was to utilize a joint position sense (JPS) test to assess proprioceptive differences between females and males with and without the aid of vision. It was hypothesized that a) under both visual conditions, females would be less accurate and precise in position matching than males and b) both sexes would be less accurate and less precise without the aid of vision.

### Methods

Forty (20F, 20M) healthy, right limb dominant participants completed 4 JPS trials with the right shoulder under both vision (V) and no vision (NV) conditions to a target angle of 90°. Distractor angles were added to mitigate effects of training. A fully immersive virtual reality system was used to provide visual and auditory information to participants and to collect kinematic data. Participant setup is displayed in Figure 1. During trials under the V condition, participants were able to see the position of their upper limb throughout the task, during trials under the NV condition, participants were able to see the position of their upper limb during the presentation phase but not during the replication phase. Angle of the right shoulder was recorded throughout. Independent two-sample t-tests ( $\alpha=0.05$ ) were used to determine differences between males and females in the V and NV conditions. Dependent two-sample t-tests ( $\alpha=0.05$ ) were used to determine differences between V and NV in females and males.

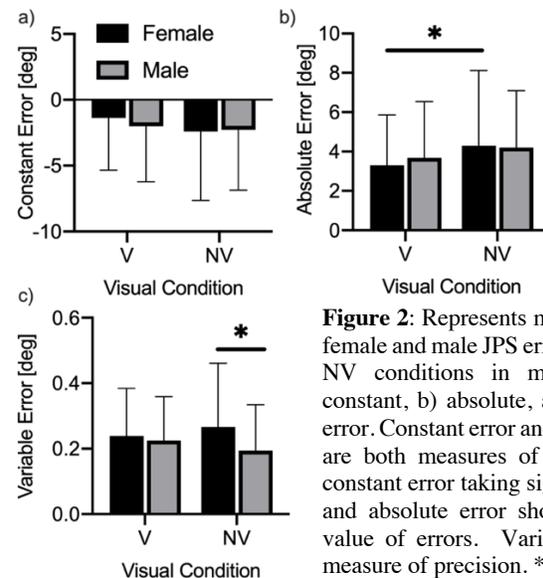

**Figure 1:** Participant seated in kneeling chair, VR headset with over-ear headphones fitted to their head, tracker affixed to the wrist. Faded arm outline shows starting position of JPS trial, solid arm outline shows target angle of 90°.

### Results and Discussion

Under neither visual condition was a difference between sexes found in constant or absolute error, measures of accuracy (Figure 2 a,b). Under the V condition, no difference between sexes was found in variable error, measure of precision, but under NV

condition females were less precise than males ( $p<0.05$ , Figure 2 c). These results refute hypothesis a, indicating that there is no difference in JPS accuracy between sexes and no difference in precision when vision is available. The difference seen in the NV condition indicates that vision contributes more to JPS precision in females than in males.

**Figure 2:** Represents mean and SD of female and male JPS error under V and NV conditions in measures of a) constant, b) absolute, and c) variable error. Constant error and absolute error are both measures of accuracy with constant error taking sign into account and absolute error showing absolute value of errors. Variable error is a measure of precision. \* $p<0.05$

Within the sexes, no differences in constant and variable error were seen (Figure 2 a, c). In males, no difference in absolute error was seen, females displayed higher absolute errors in NV as compared to V conditions ( $p<0.05$ , Figure 2 b). These results partially refute hypothesis b, as males showed no differences regardless of visual condition whereas females were less accurate without vision than with vision when both undershoots and overshoots of the target were considered equally.

In total, these results indicate a) no sex differences in measures of proprioceptive accuracy, b) lower proprioceptive precision in females without the aid of vision, and c) lower proprioceptive accuracy in females without the aid of vision.

### Significance

These findings contribute to the overall picture of sensorimotor distinctions between the sexes. While differences clearly exist in other musculoskeletal and motor control factors, proprioceptive differences are not strongly indicated by these results. However, the apparent reliance on vision in females may contribute to the design of workplace layouts and trainings.

## Body Position Effect on Scapulohumeral Rhythm

Matthew J. Petersen<sup>1</sup>, Traci Bush<sup>2</sup>, David Stapleton<sup>3</sup>, Vassilios Vardaxis<sup>2,3</sup>

<sup>1</sup>College of Osteopathic Medicine, <sup>2</sup>Department of Physical Therapy, & <sup>3</sup>Human Performance Lab, Des Moines University, Des Moines, IA, United States

### Introduction

Dynamic motion of the shoulder complex predominately occurs at the glenohumeral (GH) and scapulothoracic (ST) joints with concurrent motion at the acromioclavicular and sternoclavicular joints [1]. Scapulohumeral rhythm (SHR) is the coordinated motion occurring at these joints during arm elevation, a clinical parameter affected in most shoulder disorders [1,2]. SHR has been described by Inman [3] as a 2:1 ratio between motion at the GH and ST joints, respectively, and since has been expanded to the illustration of the 3-D motion via three angle-angle plots for arm elevation tasks in the sagittal, scapular, and frontal plane [1] with the trunk in the upright posture (seated or standing). However, functional motion during daily living and occupational tasks, is not performed upright and requires modified/awkward postures with increased risk of shoulder pathology [4]. Body position specific patterns of muscle activation and coordination were elicited for the same task, during rehabilitation protocols on healthy volunteers [5], which may affect the SHR. Thus, this study aims to investigate the effect of seated upright, sidelying, prone, and supine body positioning on the SHR during arm (thoracohumeral) elevations in the frontal and sagittal planes.

### Methods

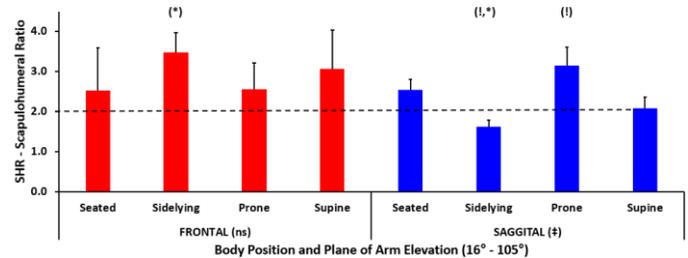

Twenty (20) healthy male participants without any musculoskeletal problems volunteered for the study. Participants completed 5 trials of arm elevation (dominant side) in the sagittal and frontal planes at 4 different body positions (Seated, Sidelying, Prone, and Supine) to ~120 degrees while maintaining a straight arm, with palm on the plane of elevation, and thumb extended. A motion analysis system with 10-cameras (Motion Analysis Corp.) at 120 Hz was used to capture 3D data of reflective markers attached to upper-limb and torso. Reference frames were defined for the thorax, scapula, and humerus and Euler angles were used to compute positioning and 3D rotations of the scapula relative to the thorax, humerus relative to the scapula, and humerus relative to the thorax according to ISB [6].

The SHR was calculated between 16 and 105 degrees of thoracohumeral elevation as the slope between the GH and ST motion. Statistical analysis of the SHR was performed using one-way repeated measures ANOVA on body position, separate for each plane. Paired t-tests were used to assess differences across planes for each body position ( $\alpha < 0.05$ ).

### Results and Discussion

The average age and BMI of the participants were:  $24.4 \pm 1.3$  years, and  $25.6 \text{ kg/m}^2$  (range 20.4 to  $33.4 \text{ kg/m}^2$ ) respectively. The SHR (average  $\pm$  standard error) values across the 4 different body positions, for each plane separate, are shown in Figure 1. There were significant differences between body positions in the SHR for the sagittal plane arm elevations ( $p < 0.001$ ). In the prone body position the flexion task was performed with limited ST upward rotation and the opposite was true in sidelying compared to other body positions (Figure 1, “!”). In sidelying,

while performing the abduction task, the ST upward rotation was the least (reflected as SHR greater than 3:1) and was significantly lower than the flexion task (Figure 1, “\*”).

**Figure 1:** Mean ( $\pm$ SE) of the scapulohumeral ratio (SHR) calculated in 2 different planes (Frontal and Sagittal) at 4 different body positions (Seated, Sidelying, Prone, and Supine). (ns, ‡) One-way ANOVA Repeated Measures  $p < 0.05$ ; (!) Bonferroni adjusted contrast difference from all others (within the plane)  $p < 0.008$ ; (\*) Paired t-test difference between planes  $p < 0.0125$ .

Interestingly, for the frontal plane elevation task the SHR was greater than 2:1 for all body positions, showing greater (non-significant) ratios for the sidelying and supine body positions. The scapula 3D rest/initial orientation also varied, with body position and task, specifically showing significant upward rotation of  $11.8 \pm 7.2^\circ$  and  $14.7 \pm 7.8^\circ$  in the supine position for the abduction and flexion tasks, respectively. Despite the considerable limitations of the SHR calculation, ignoring the ST motions in the int/external rotation and the ant/posterior tilt, it reflects differences in task and body position on the GH and ST contribution to thoracohumeral arm elevation [7]. The overall 3D GH and ST motion contribution to arm elevation has been shown to vary with task dynamics [1]. The present study underscores the gravitational vector direction effects relative to the plane of motion and the resting/initial scapular position/orientation.

### Significance

Differences in the SHR were observed in non-symptomatic adults between body positions, often used for clinical tests/measures and exercises aiming to assess function and alter the rehabilitation exercise intensity. When restoration of altered kinematics is the therapeutic goal, body position and plane of elevation effects should be considered.

# Glenoid Lateralization Increases Abduction ROM and Strength After Reverse Shoulder Arthroplasty

Clarissa LeVasseur<sup>1</sup>, Gillian Kane<sup>1</sup>, Alexandra S. Gabrielli<sup>1</sup>, Albert Lin<sup>1</sup>, and William Anderst<sup>1</sup>

<sup>1</sup>Department of Orthopaedic Surgery, University of Pittsburgh

Email: [cll100@pitt.edu](mailto:cll100@pitt.edu)

## Introduction

Reverse shoulder arthroplasty (RSA) is a common procedure to reduce pain and restore function in patients with rotator cuff arthropathy [1]. Clinical outcomes after RSA are favorable; however, functional outcomes still remain suboptimal. *In vitro* studies suggest that modifications in prosthesis design and surgical technique can improve range of motion and functional outcomes after RSA [1], however controversy still exists as to the best implantation technique and prosthesis geometry for maximizing shoulder function after RSA. This controversy persists due to the lack of quantitative *in vivo* kinematics to guide this debate. In order to achieve the long-term goal of improving functional outcomes after RSA, shoulder kinematics following RSA must be accurately characterized.

The aim of this study is to investigate relationships among surgical technique, prosthesis geometry and functional outcomes (kinematics and strength) after RSA. We hypothesized that lateralization would increase the total work done in the abduction plane and that humeral retroversion would alter the contact center on the glenosphere during abduction.

## Methods

12 RSA patients consented to participate in this ongoing IRB approved study (7M, 5F, average age: 66.8±6.3 yrs., time since surgery: 2.5±1.2 yrs.). Lateralization and humeral retroversion were recorded from surgical notes. Isokinetic strength was recorded across each participant's full range of motion for flexion/extension, ab/adduction, and internal/external rotation at 30°/second on a Biodex machine. Additionally, participants performed 3 trials of abduction in the scapular plane while synchronized biplane radiographs of the shoulder were collected at 50 image/s for 2s. Subject-specific models of the humerus and scapula with their respective implants were created from CT scans and matched to the biplane radiographs to measure scapular and humerus motion with sub-millimeter accuracy [2] for 7 of the 12 participants thus far. A 3D CAD model of the polyethylene insert, provided by the manufacturer, was fit into the CT-based humeral tray. The motion of the center of contact between the polyethylene and the glenosphere was calculated. A Spearman's correlation was used to evaluate the relationship between lateralization and peak torque, ROM, and total work done. Significance was set at  $p < 0.05$ .

## Results and Discussion

Six participants had no lateralization and 6 had lateralization between 2mm and 7mm. Retroversion ranged from 20° to 40°.

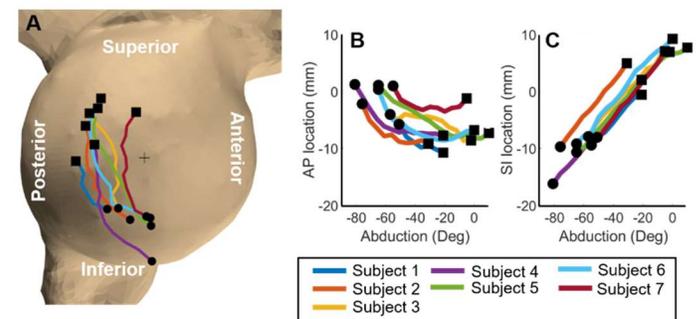

There was a moderate correlation between the total work done during abduction and lateralization (Table 1,  $p = 0.04$ ), as well as between abduction/adduction ROM and lateralization (Table 1,  $p = 0.02$ ). Total work done and ROM for flexion/extension and internal/external rotation were weakly to moderately correlated with lateralization, however, neither were significant (Table 1, all  $p > 0.055$ ). Our result of a positive correlation between

lateralization and abduction ROM confirms previous studies that have found that lateralization increases abduction ROM [3].

**Table 1.** Correlations between lateralization and strength or kinematics. Bold values indicate significance.

	Peak Torque (Nm)	Total Work (J)	ROM (°)
Abduction	$\rho = 0.45$	$\rho = \mathbf{0.62}$	$\rho = \mathbf{0.67}$
Adduction	$\rho = 0.32$	$\rho = \mathbf{0.57}$	
Flexion	$\rho = 0.36$	$\rho = 0.42$	$\rho = 0.49$
Extension	$\rho = 0.19$	$\rho = 0.54$	
External Rot	$\rho = 0.54$	$\rho = 0.42$	$\rho = 0.51$
Internal Rot	$\rho = 0.25$	$\rho = 0.39$	

The center of contact between the polyethylene insert and the glenosphere varied more in the AP direction than the SI direction between subjects (Figure 1). Subject 2, who had a retroversion angle of 40°, demonstrated a more superior center of contact at similar abduction angles compared to the other six subjects who all had retroversion angles of 20° (Figure 1C). Additional subjects with a retroversion of 40° are needed to confirm that retroversion affects implant contact patterns.

**Figure 1.** (A) Center of polyethylene contact on the glenosphere during abduction. Circles indicate the start of data collection in lower abduction angles while squares represent maximum abduction. (B) AP location of the center of contact with respect to abduction angle. (C) SI location of the center of contact with respect to abduction angle.

## Significance

This novel dataset improves our understanding of how prosthesis design and surgical technique affect *in vivo* functional outcome after reverse shoulder arthroplasty. This information help surgeons optimize patient functional outcomes.

## Introduction

Overhead athletes are a specific subset of athletes whose sport requires a majority of the movement to occur with the upper arm above the head. Due to the nature of these sports and the repetitive motions and stresses associated with them, overhead athletes are prone to upper extremity injuries<sup>1</sup>. The instability of the shoulder complex coupled with the fact some of these motions, such as the baseball pitch, produce the highest measured velocities recorded in humans place the shoulder at particular risk of injury in overhead athletes. In an effort to mitigate the risk of injury and improve performance in the given sport, an overhead athlete's shoulder undergoes well-documented orthopedic and physiological adaptations<sup>2</sup>.

Specifically, baseball pitchers commonly present altered passive range of motion (ROM) and rotator cuff strength in the dominant arm when compared to the non-dominant side<sup>2</sup>. Recent studies have suggested clinical measures of ROM and strength may be related to the amount of stress a pitcher shoulder is subject to during a pitch<sup>3</sup>. The purpose of this study was to describe the relationship shoulder ROM and rotator cuff strength have with shoulder kinetics in the baseball pitch.

## Methods

This study was approved by the Sanford Health Institutional Review Board. Twenty-one (n=21) collegiate baseball pitchers participated in the study. Data was collected on two separate occasions prior to the start of the collegiate season. The first session was a clinical evaluation where subject height, weight, arm length, shoulder passive ROM, and rotator cuff strength were collected. After establishing anthropometrics and a brief warmup, glenohumeral internal rotation (IR) and external rotation (ER) was measured passively for each arm using established methods<sup>2</sup>. Isokinetic external and internal rotator cuff strength was measured both eccentrically and concentrically for each arm using a Biodex at three separate speeds (90, 180, and 270 degrees/sec). Peak torque was collected from the Biodex for eccentric and concentric actions of both the external and internal rotator cuff muscles for each arm at all three speeds. Subjects then returned approximately two weeks later for a bullpen session where motion capture data was collected in a biomechanics lab. Fifty markers were applied to each pitcher and tracked with a twelve camera Qualisys motion capture system operating at 300 Hz. Pitchers threw ten fastballs from an artificial mound at a target approximately the size of a strike zone 45 feet from the rubber. The five fastest pitches for strikes were selected and used for analysis.

Biomechanics data was computed in Visual 3D. Pitching shoulder joint moments and forces were estimated in the shoulder joint coordinate system in accordance with ISB recommendations. Kinetics and isokinetic data were normalized to anthropometrics prior to analysis. Peak IR torque and peak shoulder distraction force were the dependent variables chosen as estimates of the amount of stress the shoulder experiences throughout the pitch. Linear regression models were used to

assess the relationship between the clinical data and shoulder kinetics ( $\alpha=0.05$ ).

## Results and Discussion

None of the ROM data collected was significantly related to shoulder stress in the pitch. However, a trend was exhibited when comparing peak shoulder IR torque and the amount of increased ER the shoulder undergoes during the cocking phase (active ER) relative to the passive ER measured. A greater difference between active and passive ER approached a significant relationship with increased peak shoulder IR torque ( $p=0.07$ ,  $R^2=0.18$ ).

Bilateral imbalance of the eccentric external rotator musculature was significantly related to peak shoulder distraction force ( $p=0.02$ ,  $R^2=0.33$ ). A greater ratio in dominant/non-dominant arm strength was associated with higher peak distraction force in pitchers when measuring eccentric external rotator strength at 270 degrees/sec. Unilateral imbalance of the eccentric external and internal rotator musculature was significantly related to increased shoulder IR torque ( $p<0.05$ ,  $R^2=0.21$ ). A greater ratio of ER/IR strength was associated with higher shoulder IR torque when measuring eccentric ER and IR strength at 90 degrees/sec.

Clinical measures of ROM were not significantly related to shoulder stress in the baseball pitch even when comparing bilateral differences. Similarly, no single measure of isokinetic rotator cuff strength was significantly related to shoulder stress. Only after assessing strength ratios bilaterally or between muscle groups were significant relationships discovered. These results suggest that evaluating isokinetic strength ratios between arms or agonist and antagonist muscle groups may be more indicative of injury risk than any stand-alone isokinetic strength measure. Further, the results may give clinicians or trainers a better understanding of what to evaluate during a pre-season screen of an overhead athlete's glenohumeral ROM or strength.

## Significance

Recent upper extremity literature has struggled to identify specific characteristics of an overhead athlete's shoulder complex that are related to increased biomechanical loads during activity. The current study provides insight for clinical measures that can be evaluated without expensive motion capture technology that may be related to increased injury risk in overhead athletes. It is likely that ROM, strength, and mechanics are all interconnected regarding injury risk in these athletes and it is paramount that researchers and clinicians attempt to understand these relationships to ensure the safety of any ballistic athlete.

# Rotator Cuff Tears and Humeral Elevation in Manual Wheelchair Users with Spinal Cord Injury and Able-bodied Controls

Omid Jahanian<sup>1</sup>, Brianna M. Goodwin<sup>1</sup>, Meegan G. Van Straaten<sup>1</sup>, Stephen M. Cain<sup>2</sup>, Ryan J. Lennon<sup>1</sup>, Jonathan D. Barlow<sup>1</sup>, Naveen S. Murthy<sup>1</sup>, Melissa M. B. Morrow<sup>1</sup>  
<sup>1</sup>Mayo Clinic, Rochester, MN, <sup>2</sup>University of Michigan, Ann Arbor, MI, USA  
Email: Jahanian.Omid@mayo.edu

## Introduction

The shoulder is the most common site of musculoskeletal pain and pathology in manual wheelchair (MWC) users with spinal cord injury (SCI) [1]. The prevalence and progression rate of shoulder pathology in this population is notably higher than able-bodied individuals [2]. The primary purpose of this study was to compare the progression of rotator cuff (RC) pathology over one year in MWC users with able-bodied individuals. We also aimed to investigate the effects of MWC use on humeral elevation and its contribution to the high prevalence of RC tears in individuals with SCI.

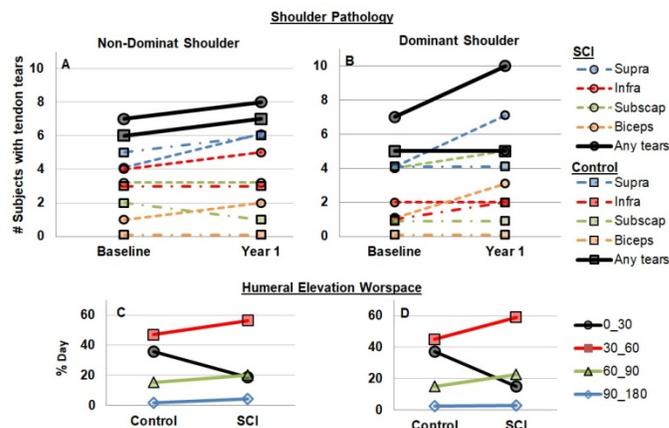

## Methods

Under Mayo Clinic IRB approval, 16 MWC users (15 males, age (SD): 37(13) yrs, injury level: C6–L1, median years of MWC use (interquartile range): 5(4) yrs) and 16 age and sex-matched able-bodied controls were recruited. Bilateral shoulder magnetic resonance images (MRIs) were completed and assessed on two occasions, at baseline visit and approximately one year later using an established rubric [3]. Bilateral humeral elevation angles for a subset of 11 MWC users and controls were calculated throughout one or two typical day(s) (after baseline MRI) from body segment orientations using accelerometry and gyroscope data from three wireless inertial measurement units (Opal, APDM Inc., USA) worn on the bilateral upper arms and anterior torso [4]. McNemar's test was used to compare the prevalence of RC tears between baseline and year 1. Wilcoxon Signed-Rank test was used to compare humeral elevation levels between two cohorts. Differences between participants with and without any tear were compared using Student's two-sample t-test for age and humeral elevation levels. All tests were two-sided with a 0.05 significance level.

## Results and Discussion

The bilateral shoulder (14 non-dominant and 15 dominant shoulders) MRI findings indicated that progression of any tears across the RC and the long head of biceps tendons increased for the dominant shoulder of SCI cohort in comparison to the controls; however, the difference was not statistically significant ( $p = 0.063$ ; Fig. 1A-1B). The progression of the RC pathology was not different between the two cohorts for the non-dominant side. MWC users without tendon tears were significantly younger than those with tendon tears on the non-dominant side at baseline ( $p = 0.018$ ) and year 1 ( $p = 0.042$ ), and on the dominant side at year 1 ( $p = 0.021$ ). The effect of age was stronger for able-bodied participants on both sides and time points ( $p < 0.001$ ).

MWC users spent significantly less time in 0-30° of humeral elevation than the controls ( $p = 0.050$  (dominant);  $p = 0.011$  (non-dominant)). This could be mainly due to resting seated postures in SCI group rather than active movements. MWC users spent more time in other humeral elevations than controls, but the differences were not statistically significant (Fig. 1C-1D). Able-bodied participants without tendon tears on their non-

**Figure 1.** Rotator cuff and biceps tendon tears and humeral elevation angles in MWC users with SCI and able-bodied controls. A and B demonstrate the number of participants with any tendon tears (Any tears) or individual muscle tendon tears across the supraspinatus (Supra), infraspinatus (Infra), subscapularis (Subscap), and biceps at baseline and year 1 for MWC users with SCI (circles) and able-bodied controls (squares). C and D demonstrate the percentage of time controls and MWC users with SCI spent in humeral elevation levels for their non-dominant (C) and dominant (D) arms throughout a typical day.

dominant side spent significantly less time in 90-180° of humeral elevation ( $p = 0.044$ ) than those with tendon tears. There were no significant associations between other humeral elevations and presence of tendon tears for both cohorts.

## Significance

The higher progression rate of RC pathology in MWC users with SCI than in able-bodied controls indicates that MWC use may predispose individuals with SCI to RC disease beyond intrinsic factors, such as age. The different functional humeral workspace for MWC users compared with able-bodied controls may be a contributor to the observed differences in incidence and progression of RC pathology between these two cohorts. Lack of significant associations between humeral elevations and presence of tendon tears in the SCI cohort might be due to the small sample size. Further investigation with a larger population of MWC users and controls is underway to elucidate the evolution of shoulder pathology and arm use following SCI.

## A Comparison of Methods to Estimate Scapular Kinematics for Brachial Plexus Birth Injuries

R. Tyler Richardson<sup>1</sup>, Stephanie Russo<sup>2</sup>, Matthew Topley<sup>3,4</sup>, Ross Chafetz<sup>4</sup>, Scott Kozin<sup>4</sup>, Dan Zlotolow<sup>4</sup>, and James Richards<sup>3</sup>

Email: [rtr12@psu.edu](mailto:rtr12@psu.edu)

### Introduction

Glenohumeral (GH) motion deficits and scapulothoracic (ST) compensations are commonly observed in patients with brachial plexus birth injury (BPBI)<sup>1,2</sup>. Various interventions are employed to improve GH function, however, assessment of GH function in dynamic conditions is lacking due to challenges in measuring dynamic scapular orientation and the inability to distinguish between GH and ST contributions to shoulder motion. The acromion marker cluster with single calibration (S-AMC) has been used to estimate ST kinematics in healthy populations<sup>3</sup> but is unsuitable for BPBI<sup>4</sup>. An updated AMC double calibration method (D-AMC) that interpolates estimated ST orientations based on humerothoracic (HT) elevation<sup>5</sup> is currently recommended<sup>6</sup>, but has yet to be assessed in BPBI. A new linear model (LM) approach utilizing measurable HT orientation and acromion process position to estimate ST orientation has been validated in healthy adults<sup>7</sup>, but has not been tested in BPBI. This study evaluates the ability of the S-AMC, D-AMC, and LM to estimate ST orientation in static positions across a full shoulder range of motion by comparing against palpation in BPBI. We hypothesized that ST errors between LM and palpation would be less than those of D-AMC and much less than those of S-AMC.

### Methods

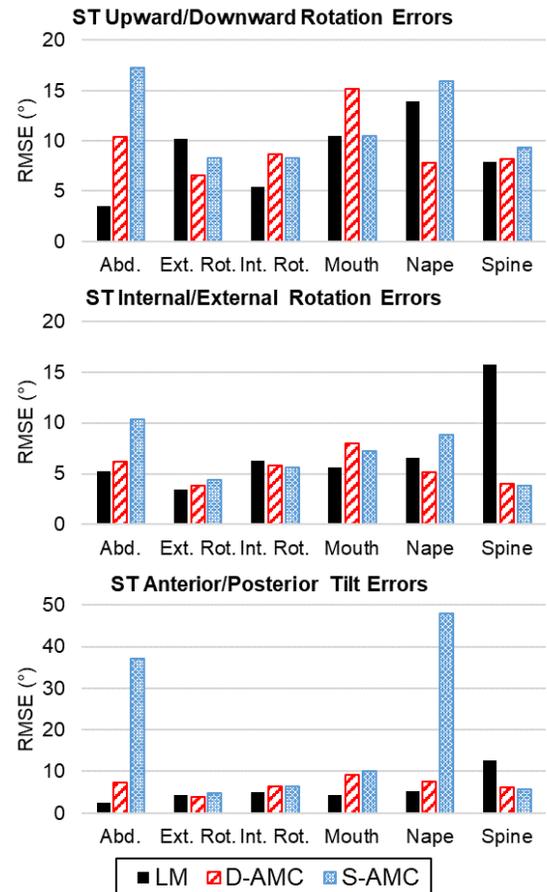

Trunk and arm orientations of 19 BPBI participants were measured with motion capture. Subjects completed 14 static positions encompassing a full spectrum of shoulder motion. In each position, scapular markers were placed to determine ST orientation. HT and ST angles were calculated. All 14 positions served as test positions for evaluation. For each position, a "leave-one-out" approach was used to create a LM using multiple linear regression on data from the 13 other positions to generate equations that estimated ST angles based on HT orientation and acromion process position. ST angles estimated by each method were compared to palpation and average root mean square errors (RMSE) for each approach were calculated across all participants on each ST axis of motion for each test position.

### Results and Discussion

LM and D-AMC produced comparable RMSE values that were generally within established acceptable limits ( $<10^\circ$ )<sup>3</sup> for most positions/axes; S-AMC values were occasionally much larger (Fig. 1). The percentage of errors  $>10^\circ$  for all subjects and positions in this study varied across the three ST axes: LM (9.9-16.0%), D-AMC (1.8-7.3%), S-AMC (2.9-9.2%). Overall, these results do not support our hypotheses.

Estimating ST orientation in BPBI is more challenging than in a healthy population as RMSE values for all methods were close to or beyond the upper ranges reported in all previous healthy analyses<sup>3</sup>. Similar to past findings<sup>5</sup>, D-AMC was superior to S-AMC especially on internal/external rotation and anterior/posterior tilt. LM had exceptionally large errors for certain positions that involved HT or ST angle values beyond those of the other 13 positions used to develop the LM; this highlights a LM limitation that should be considered when using

this approach. The D-AMC produced acceptable RMSE values for most positions/axes and was the least likely of all methods to produce  $>10^\circ$  errors for an individual subject.

**Figure 1:** RMSE values for ST orientation at select and representative test positions exemplifying a variety of functional arm postures.

### Significance

Current methods for estimating dynamic scapular orientation are less than ideal for BPBI. Use of the D-AMC, however, may be appropriate for certain motions/scenarios and would provide new insights into dynamic ST and GH joint function to ultimately facilitate surgical planning and outcomes assessment in BPBI.

## Introduction

Brachial plexus birth injury (BPBI) occurs during a difficult childbirth when damage ensues along the brachial plexus nerve bundle [1]. Lifelong arm impairment persists in 30-40% of cases [2], with muscle weakness, limb disuse, and musculoskeletal deformities [3]. Loading at the glenohumeral joint is altered, but the main causes of that alteration are unclear. In addition, nerve injury location can alter outcome severity [4]. In both nerve rupture (*postganglionic*) and nerve avulsion (*preganglionic*), loading alterations could be, in part, due to limb disuse, decreased optimal muscle length, or decreased muscle mass. To determine whether limb disuse may be a major contributor, we compared both postganglionic and preganglionic injuries to a disarticulation model observed to have similar disuse of the affected limb.

## Methods

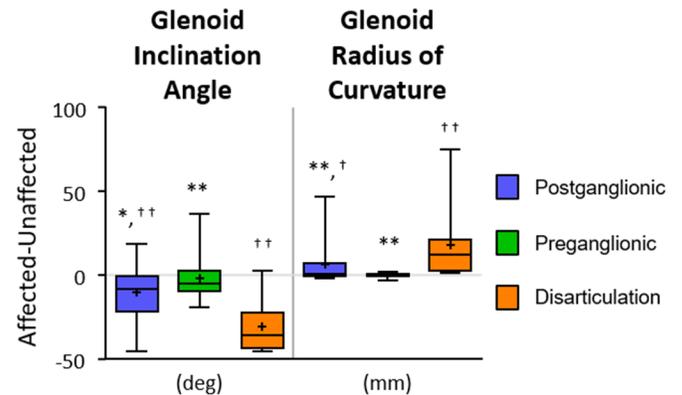

Sprague Dawley rat pups were assigned to three groups (n=16 each): postganglionic neurectomy, preganglionic neurectomy, and elbow disarticulation. Interventions were performed 3-5 days postnatally on one side with the contralateral limb serving as a control. Neurectomies included C5-C6 nerve root excision either distal (postganglionic) [5] or proximal (preganglionic) [6] to the dorsal root ganglion. The disarticulation group underwent amputation of the forearm at the elbow.

Scapulae and humeri were scanned using micro-computed tomography (36  $\mu$ m, SCANCO  $\mu$ CT 80) and analyzed in Mimics (Materialise). Measurements included glenoid version angle (GVA), inclination angle (GIA), and radius of curvature (GRC), and humeral head thickness (HHT), width (HHW), and radius of curvature (HRC). Affected vs. unaffected limbs were compared within groups with paired t-tests. Group comparisons were made on affected-unaffected differences via one-way ANOVA with Tukey's posthoc tests (normally distributed) or Kruskal-Wallis with Dunn posthoc tests (non-normally distributed). Analyses were performed in GraphPad Prism ( $\alpha=0.05$ ).

## Results and Discussion

**Scapula Results:** Postganglionic and disarticulation groups both showed changes in affected vs. unaffected limbs, with smaller affected limb GIA (postganglionic: -31%, disarticulation: -83%) and larger (more flattened) affected limb GRC (postganglionic: +119% trend,  $p=0.064$ , disarticulation: +374%) (Fig. 1). Compared to disarticulation, postganglionic BPBI tended to have smaller reductions in affected GIA (-96%,  $p=0.052$ ) and had significantly smaller changes in GRC (-71%), and preganglionic also had smaller changes in GIA (-98%) and GRC (-102%) (Fig. 1). **Humerus Results:** Preganglionic and disarticulation groups showed deficits in affected vs. unaffected limbs. Preganglionic affected limb tended to have reduced HHT (-11%,  $p=0.065$ ) and had reduced HHW (-9%) and HRC (-13%), and disarticulation affected limb had reduced HHT (-8%). No group differences were found. **Discussion:** Similar to our previous study [7], we found primarily humeral head detriments (not scapular) with preganglionic injury but scapular detriments (not humeral head)

with postganglionic injury. This study includes disarticulation, which allows assessment of disuse contributions to glenohumeral deformity with BPBI. In the scapula, morphological changes with postganglionic injury were similar, though less severe, than with disarticulation, suggesting limb disuse contributes substantially but is not the only factor. Humeral head morphology, particularly width and curvature, was altered more in affected limbs for preganglionic injury than disarticulation, suggesting limb disuse has little effect and other factors (e.g., other forms of altered loading or the nerve injury itself) drive changes at this site.

**Figure 1.** Compared to disarticulation, post- and preganglionic injury had smaller reductions in GIA and less flattening in curvature (\* $p<0.1$ , \*\* $p<0.05$ ). † $p<0.1$ , †† $p<0.05$  affected vs. unaffected limbs.

## Significance

Our work suggests macrostructural deformities seen in post- and preganglionic BPBI are not due solely to limb disuse. While postganglionic deformity may result partly from limb disuse, it does not display the same severity of deformity as disarticulation. Preganglionic injury has worse humeral deformity in the affected limb than disarticulation and very little alteration of the glenoid, suggesting limb disuse is not a driving factor for preganglionic BPBI. This work allows further exploration of mechanisms of deformity and confirms that limb disuse substantially drives glenoid deformity but not humeral head deformity.

# Adaptations in trabecular bone microstructure following brachial plexus birth injury are not due solely to limb disuse

## Introduction

Brachial plexus birth injury (BPBI) results in lifelong arm impairment in 30-40% of cases [1], producing muscle weakness, arm disuse, joint morphological changes [2], and underlying microstructural bone changes in the shoulder [3]. The severity of these consequences differs based on injury location, with nerve rupture (*postganglionic*) producing more severe outcomes than nerve avulsion (*preganglionic*) [4]. Primary underlying drivers have yet to be investigated, specifically, the direct effects of nerve injury versus limb disuse, which occurs following both post- and preganglionic injury. The objective of this study was to compare trabecular bone microstructure for post- and preganglionic BPBI to that for a disarticulation model with similar limb disuse.

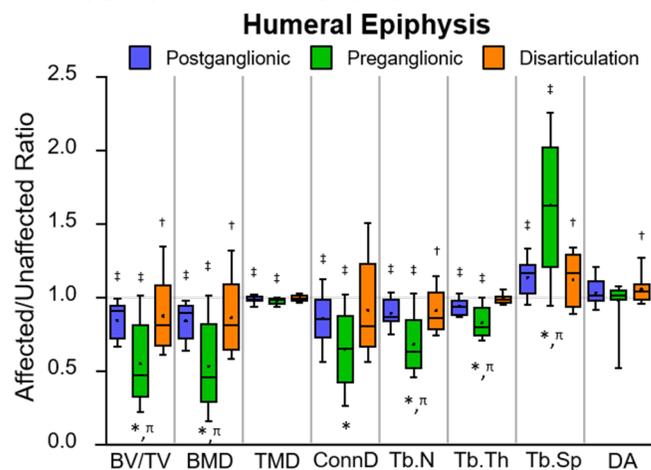

## Methods

Sprague Dawley rat pups were separated into postganglionic neurectomy, preganglionic neurectomy, and elbow disarticulation groups (n=16 each). Rats received interventions 3-5 days after birth on one arm with the contralateral serving as a control and were sacrificed at 8 weeks. The interventions were C5-C6 nerve root excision distal (postganglionic) [5] or proximal (preganglionic) [6] to the dorsal root ganglion or forearm amputation (elbow disarticulation). Scapulae and humeri were harvested and scanned using micro-computed tomography (10  $\mu$ m, SCANCO  $\mu$ CT 80). Distal scapula (glenoid) and proximal humerus (epiphysis, metaphysis) regions were analyzed for standard trabecular metrics [7]: bone volume fraction (BV/TV), bone mineral density (BMD), tissue mineral density (TMD), connectivity density (ConnD), trabecular number (Tb.N), thickness (Tb.Th), and separation (Tb.Sp), and degree of anisotropy (DA). Affected and unaffected limbs were compared via paired t-tests; groups were compared for affected/unaffected limb ratios using one-way ANOVA with Tukey's posthoc tests (normal distribution) or Kruskal-Wallis with Dunn posthoc tests (non-normal) in GraphPad Prism ( $\alpha=0.05$ ).

## Results and Discussion

**Limb comparisons:** Postganglionic and preganglionic groups had significantly less robust trabecular bone in the affected vs. unaffected arm throughout all scapula and humerus regions, with reduced BV/TV, BMD, TMD, ConnD, Tb.N, and Tb.Th, and increased Tb.Sp in the humeral epiphysis of the affected arm (Fig. 1). The disarticulation group also had trabecular deficits in the affected arm throughout the scapula and trends for trabecular deficits (reduced BV/TV, BMD, and Tb.N, and increased Tb.Sp and DA) in the humeral epiphysis but no limb differences in the metaphysis. **Group comparisons:** Few differences were observed between the neurectomy groups and the disarticulation group in the scapula and humeral metaphysis regions. In the humeral epiphysis, affected/unaffected ratios showed trabecular bone for postganglionic was similar to that of disarticulation, while preganglionic bone had more deficits (Fig. 1). Specifically, preganglionic showed larger reductions than disarticulation in affected BV/TV (ratio 0.64 vs. 0.87), BMD (0.62 vs. 0.86),

ConnD (0.71 vs. 0.91), Tb.N (0.74 vs. 0.91), and Tb.Th (0.86 vs. 0.89), and larger increases in Tb.Sp (1.50 vs. 1.12), along with a trend for greater decreased TMD (0.98 vs. 0.99,  $p=0.098$ ). **Discussion:** Post- and preganglionic injury both resulted in detriments to affected arm trabecular bone throughout the glenohumeral region, while disarticulation effects were less consistent and more apparent in the scapula than the humerus. Group differences were most prominent in the humeral epiphysis; compared to disarticulation, postganglionic injury had similar effects, while preganglionic injury produced a substantially less robust trabecular microstructure. These results suggest that disuse has a more profound effect on glenoid than humeral trabecular bone and is a stronger driver for trabecular adaptation following postganglionic than preganglionic injury.

**Figure 1.** Preganglionic injury resulted in less robust trabecular bone than postganglionic injury ( $^{\dagger}p<0.05$ ) and disarticulation ( $^*p<0.05$ ).  $^{\dagger}p<0.1$ ,  $^{\ddagger}p<0.05$  affected vs. unaffected limbs.

## Significance

Disuse has a larger role in trabecular bone adaptations following post- than preganglionic BPBI and is especially detrimental in the glenoid. Severe preganglionic trabecular deficits in the humeral epiphysis are driven by mechanisms beyond limb disuse. Understanding how different factors contribute to microstructural adaptations will inform more effective BPBI treatments.

### Introduction

Approximately 300,000 rotator cuff repair surgeries are performed annually in the United States [1]. The goal of post-op rehabilitation is to allow healing of the repaired cuff while restoring function and range of motion [2-4]. It is a prolonged and demanding process [5,6] which can require a full year for the shoulder to feel normal again [5]. Using a patient's asymptomatic contralateral shoulder, normalization of the affected shoulder motion is defined as "changed kinematics toward symmetrical bilateral motion" [7]. While studies have demonstrated the potential for normalization of shoulder kinematics between 1 and 2 years after surgery [7,8], the timing and process for how the normalization occurs is unknown. Thus, the purpose of this study was to perform a biomechanical evaluation of patients with rotator cuff tears pre-op and post-op to elucidate the changes occurring across the rehabilitation process as compared to the non-injured arm.

### Methods

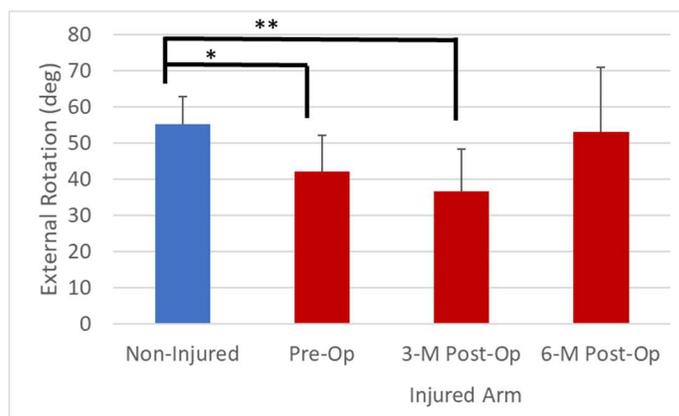

Seven adults (mean age 62.0 +/- 5.3 years) with a rotator cuff tear participated in three test sessions: 0-12 weeks prior to surgery, and an average of 3 months and 6 months after surgery. A 15-camera Vicon T-series motion capture system tracked 27 reflective markers on the upper extremity (UE) while the subject performed five trials of maximal thoracohumeral external rotation, from an adducted state with the non-injured arm, followed by the injured arm. A biomechanical model [9] was applied to calculate the UE kinematics of the thoracohumeral joint over the duration of the task. Group averages and standard deviations were computed for the peak thoracohumeral external rotation angle for both arms at each visit. The Wilcoxon signed rank test was used to compare the non-injured arm to the injured arm at each time ( $p < 0.05$ ).

### Results and Discussion

Results indicate the peak external rotation of the non-injured arm was significantly greater than the injured arm both pre-op ( $p = 0.0391$ ) and at 3 months post-op ( $p = 0.0156$ ) (Fig. 1). There was no difference in the peak external rotation achieved by the non-injured and injured arm 6 months post-op ( $p = 0.5781$ ). The deficit in motion observed pre-op does not return to a typical amount until 6 months post-op. When examining the pre-op data individually, 4 of the 7 subjects performed the task at a deficit greater than 10 degrees compared with the non-injured arm, with an average of 22.4° (4.9°) less external rotation. At 3 months post-op, 3 of the 7 subjects increased their peak external rotation, but only by an average of 6.0° (5.7°). At 6 months post-op 4 of the 7 subjects still performed the task at a deficit compared to their non-injured arm, with an average difference of 14.2° (3.9°).

Many believe that appropriate rehabilitation, particularly within 3 months postoperatively, is the key to good functional outcomes [4,5]; however the optimal rehabilitation protocol is still being deliberated [3]. Although the goal of most

rehabilitation protocols after a rotator cuff repair is to restore active range of motion by 3 to 4 months [6,10], this exploratory study showed that not only was this not achieved by most of the patients by 3 months post-op, but it was not achieved by half of them at 6 months post-op. Further work is underway examining additional joints of the shoulder complex, muscle activation patterns, and functional tasks.

**Figure 1:** Group average (1 standard deviation error bar) peak external rotation for the injured-arm (red) pre-op and at 3 months and 6 months post-op, and the non-injured arm (blue). Asterisks indicate statistical difference between injured and non-injured arms ( $p < 0.05$ ).

### Significance

Knowledge of the pre-op alterations and post-op normalization of the movements of the shoulder joint complex compared to the non-injured arm is critical to improve and shorten the post-op recovery process, including more targeted exercises. This work sets the premise for developing targeted rehabilitation interventions by helping to identify critical times during the post-op rehabilitation phases when interventions should be administered.

# CHARACTERIZING STIFFNESS AND COUPLING AMONG FIVE DIGITS OF THE HUMAN HAND

Oppizzi Giovanni<sup>1,2</sup>, Sanjana Rao<sup>1</sup>, Dongwon Kim<sup>1</sup>, and Li-Qun Zhang<sup>1,2</sup>

<sup>1</sup>University Maryland, Baltimore

<sup>2</sup>University Maryland, College Park,

Email: goppizzi@umd.edu

## Introduction

Our hand is one of the most complex organs. It is an essential tool for our daily life, so much that a big portion of our motor cortex is dedicated to its control. This being said, it is apparent that a coupling relation exists between the five digits that does not allow us to move them independently from each other. There has been a lack of quantitative characterizations of couplings across the five digits. The purpose of this study was to characterize the coupling relationships that exist across the 5 digits during passive movement.

## Methods

To accurately measure the forces and positions of individual fingers, we modified a commercial exoskeletal device, the Hand of Hope (Figure 1). Modifications were made to add force and position measurements of each digit. This allowed us to measure the forces and displacement at each of the five digits. Spacer was placed at the proximal phalanges so that each of the fingers can stretched to the extended position. Five subjects (4 female and 1 male, age 20-60) were evaluated. The subject's hand was strapped into the device and all fingers were extended to the extended position where they were subsequently locked in place. At this point, we asked the subject to relax all digits and started moving them one at a time, while keeping the others locked, for around 10 cycles each at 15mm/s. During the movement, forces and displacement were recorded for each of the 5 digits.

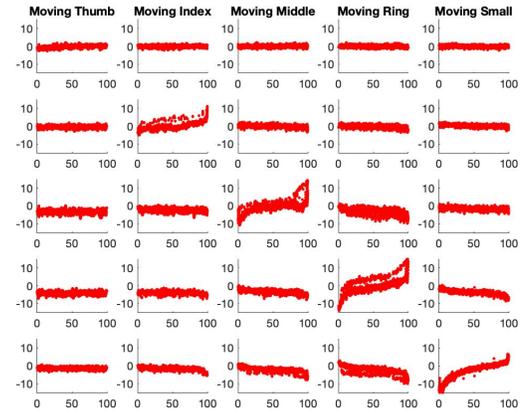

**Figure 1:** The modified exoskeleton hand robot. Each digit was equipped with a dedicated servomotor and loadcell. Spacers were added at the proximal phalanges to reach the extended position.

## Results and Discussion

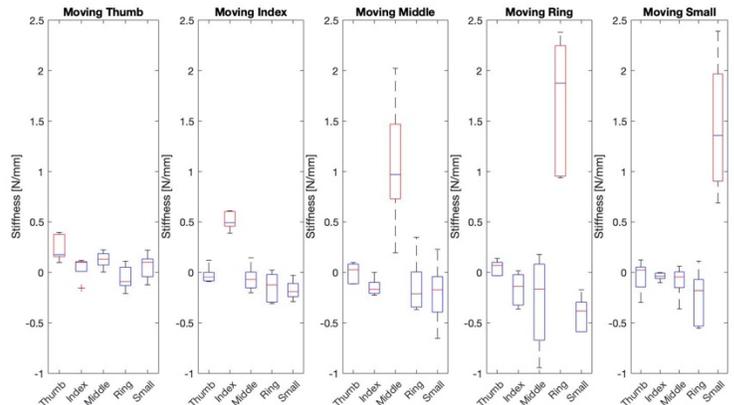

The outcome of these measurements was what was referred to in other publications [1] as the passive stiffness matrix. The diagonal elements of this matrix (local stiffnesses) represent the stiffnesses developed at the finger when moving that specific digit. On the other hand, the off-diagonal elements represent the coupled stiffness recorded at all the other four digits that are kept locked at the extended position. Especially in the case of the local stiffnesses, it was apparent how it is not constant throughout the range of motion, and even at the same position, the value can be different depending on the direction of the passive movement and the position on the force-displacement hysteresis loop. For the purpose of this study, we elected to consider stiffnesses during

extension (Fig. 2), in particular we chose to evaluate it at near full extension.

**Fig. 2:** Stiffness properties across the five digits. On the columns, the results of each trial in which only one finger was moved. On the rows, forces were measured at each digit (thumb, index, middle f, ring f, and small f), respectively. X axis is ROM% (0 max extension, 100 max flexion), Y axis is stiffness (N/mm)

What we found was, to start with, higher values for local stiffnesses, and strong coupling in three most lateral fingers (middle finger, ring finger and little finger) across all subjects (Fig. 3).

**Fig. 3:** Local stiffness is highlighted in red and coupled stiffness in black. Note the right 3 columns showed the strong coupling among the 3 most lateral fingers.

## Significance

The findings emerged in this study, while interesting on their own, also represent an important foundation for future studies. It will be interesting to evaluate how coupling is affected in patients after stroke, for example.

## Introduction

Prosthetic users must contend with and adapt to the additional mechanical and physical constraints of a prosthesis to perform a motor task. Persons with unilateral transtibial amputations (TTAmp) have been shown to use hip-dominant strategies compared to persons with intact limbs (INTACT) during various movement tasks such as gait, vertical jumping, and cycling<sup>1,2,3</sup>. Whether this compensatory behavior is a ubiquitous strategy used by TTAmp across all tasks or whether it is task specific is of considerable interest to define mechanisms of motor control in this population. The back squat is a well-defined task with eccentric, energy absorption and concentric, energy generation phases making it suitable to explore a range of compensations. Therefore, this case study was to determine compensation strategies utilized by a TTAmp compared to an INTACT while performing a back squat. We hypothesize that there will be greater relative contribution of hip joint work done in the amputated limb compared to sound limb.

## Methods

One male TTAmp (119.8kg) with an Össur VSP foot (energy storage and return component mounted in series with a hydraulic damper) and one male INTACT control (81.4 kg) signed informed consent to participate in this IRB approved study. The participants performed 5 sub-maximal back squats at 75% of their one-rep max (102.3 kg) following a warm-up. Lower limb kinematics and kinetics were quantified for each limb with 39 passive reflective markers using a Full Body PlugInGait model (Vicon, Oxford, UK). Net joint power was calculated using an inverse dynamics approach. The work done at each joint attributed to total limb work (J/kg) was calculated by integration of each of the respective power curves<sup>4</sup> and converted to a percent of total limb work. A two-way RM ANOVA was run to find the main and interaction effects of limb (R vs. L) and amputation status (AMP vs. INTACT) on each joints' percent contribution to total limb positive and negative work. Where significant interactions were observed, simple pairwise comparisons were conducted.

## Results and Discussion

The hip contributed significantly more to total limb positive work than the knee and ankle in left ( $p < 0.001$  and  $p = 0.001$ , respectively) and right ( $p < 0.001$  and  $p = 0.001$ , respectively) limbs of TTAmp, and the right ( $p < 0.001$  and  $p = 0.003$ , respectively) limb of INTACT.

While the knee contributed significantly more to total limb negative work than the ankle and hip in the left ( $p < 0.001$  and  $p = 0.005$ , respectively) and right ( $p < 0.001$  and  $p < 0.001$ , respectively) limbs of INTACT, similar patterns were not observed in TTAmp. The hip contributed significantly more to total limb negative work than the ankle in the left and right limb

of TTAmp ( $p < 0.001$ ). The hip contributed significantly more than the knee in the left limb but not the right limb ( $p < 0.001$ ,  $p = 0.349$  respectively) of TTAmp (Figure 1).

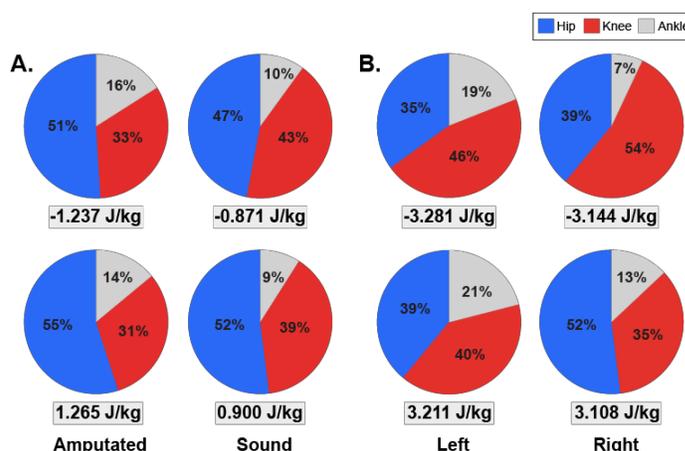

Figure 1: Negative (top row) and positive (bottom row) total limb work per joint in TTAmp (panel A) and INTACT (panel B).

TTAmp utilized a hip dominant strategy to both absorb and generate energy in both limbs whereas INTACT absorbed more energy at the knee. Interestingly, the ankle joint contributed greater negative work than positive work on the amputated and sound limb (15.8% vs 14.2%) suggesting TTAmp loaded the prosthetic foot to get as much energy return as possible allowing the prosthetic side a greater contribution to energy system.

## Significance

This case study provided insight on compensation strategies used by prosthetics users during a back squat. Findings suggest greater relative reliance on both hip joints in the amputated and sound limbs vs. asymmetric hip joint work seen during other tasks. These findings may also inform prosthetic foot design and prescription for similar functional weight training tasks. The TTAmp utilized a strategy to load the prosthetic foot during the eccentric phase and was able to utilize the energy returned for the concentric phase, highlighting the benefits of prosthetic feet with high energy storage and return properties for this task. Further work is warranted to define how consistent these strategies are across a larger sample of TTAmp.

Email: [rriemer@bgu.ac.il](mailto:rriemer@bgu.ac.il); website: <http://www.bgu.ac.il/~rriemer/>

## Introduction

An exoskeleton is a wearable device, designed to enhance physical abilities during human activities. Several exoskeletons have succeeded in assisting walking [1], running [2] and hopping [3]. The goal of these exoskeletons is to reduce the effort expended during aerobic tasks (i.e. the metabolic rate). However, exoskeletons which assist during anaerobic tasks (specifically, vertical jumping) have not yet been thoroughly researched. During countermovement vertical jumping, there is a negative work phase in the knee, followed by positive joint work. Therefore, a passive exoskeleton (based on a spring) can assist knees during a jumping activity.

In this study, we built a passive knee exoskeleton for vertical jumping, and performed an experiment to gain knowledge on exoskeleton-human interaction.

## Methods

Eight healthy males (age:  $25.1 \pm 3.0$  years; mass:  $71.7 \pm 3.6$  kg; and height:  $1.73 \pm 0.02$  m) participated in this study. All subjects provided informed written consent before participating in the study. The study was approved by Ben-Gurion University's Human Research Institutional Review Board.

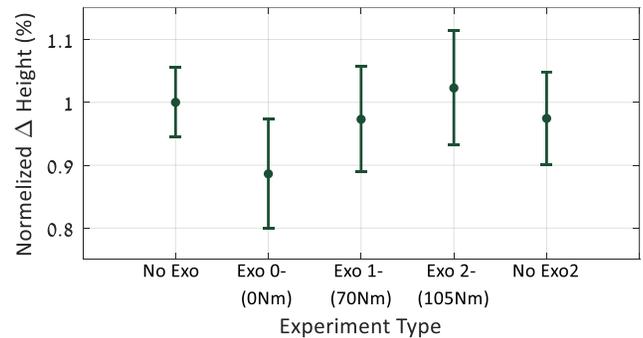

The passive knee exoskeleton consists of aluminium frames, attached to the leg with wide Velcro stripes. Rubber springs provide the assistance torque. The overall device mass is 1.5 kg, for each leg. The subjects performed vertical jumps under five conditions: without the device (No Exo); with the device but with no spring connected (Exo0); with the device and with springs that provide 70 Nm at a 90° knee bend (Exo1); with springs that provide 105 Nm (Exo2); and without the device again (No Exo2). The performance order of the conditions with the device was randomized for each subject. The subjects followed a warm-up routine, and then performed eight vertical jumps under each condition. They were instructed to jump as high as possible, and to keep their hands crossed on their chest. Data was collected from the last five jumps. The subjects rested for 1.5 minutes between jumps, to prevent the effect of fatigue.

Subjects' motion was recorded using 14 cameras (Qualisys), and ground reaction forces were recorded using an instrumented treadmill (Bertec). Inverse dynamics was performed using Visual 3D (C-Motion). Rectus Femoris (RF) and Gastrocnemius medialis (GM) muscle activity was measured using surface electromyography (Trigno, Delsys). Next, MATLAB code (Math Works Inc) was used to calculate the difference in the center of mass height (from detachment to maximum jump height) and work performed at each joint (from full bending to detachment).

## Results and Discussion

The average height difference from detachment to maximum jump height, for each of the conditions, was normalized by the average height difference gained in No Exo condition, and is presented in Fig. 1. Repeated measures analysis of variance (ANOVA) revealed that the average normalized difference in

height for Exo2 was greater by  $13 \pm 5\%$  than for Exo0 ( $P < 0.001$ ), and greater by  $5 \pm 0.1\%$  than for Exo1 ( $P = 0.04$ ). Exo2 was no different from No Exo ( $P = 0.69$ ).

**Figure 1:** The average height difference from detachment to maximum jump height, normalized by the No Exoskeleton (No Exo) condition

There was no difference between the maximum amplitude of EMG in RF and GM, under all conditions ( $P > 0.05$ ). There was no difference in average ankle joint work between all five conditions. The average total work at the knee joints (i.e. the biological knee work and exoskeleton work) with No Exo2 was greater than all the conditions with the exoskeleton ( $P < 0.01$ ). The work at the hip joints without the exoskeleton (No Exo and No Exo2) was lower than with the exoskeleton ( $P < 0.05$ , for all the conditions). This might suggest that the subjects changed the way they jump, but that they still did not fully utilize the exoskeleton. In future research, we will train the subjects to better utilize the exoskeleton, by storing more energy in the springs.

**Table 1:** The average work done by each joint (J)

Condition \ Joint	Ankle	Knee-total	Knee-bio	Exo	Hip	All 3 joints
No Exo	128.6	220.3	220.3	-	195.2	544.1
Exo0	129.6	192.3	192.3	-	242.1	563.9
Exo1	139.7	206.6	104.3	102.2	242.6	588.8
Exo2	141.1	192.1	51.3	140.9	247.8	581.0
No Exo2	123.8	239.5	239.5	-	176.5	539.8

## Significance

The results contribute to a better understanding of the interaction between an exoskeleton and the human body, and could improve the design of exoskeletons in future.

### Introduction

Unilateral amputees often experience decreased muscle efficiency during gait as a result of the anatomic asymmetries induced with most current prostheses designs. Amputees tend to load 58% of body weight on the intact leg 42% of body weight on the prosthesis.<sup>1</sup> During the prosthesis swing phase, there is higher and prolonged muscle activity seen in the plantar flexion of the intact leg for push-off to ease foot clearance of the prosthesis.<sup>2</sup> During the prosthesis pre-swing phase, transfemoral amputees have a plantar flexion deficiency on the prosthesis, which reduces forward propulsion during pre-swing.<sup>3</sup> This leads to an energy expenditure increase of 60% in transfemoral amputees' gait compared to normal gait, with prosthesis weight and moment of inertia being prime contributors to this issue.<sup>3</sup> The prevalence of falls among lower-limb amputees is estimated to be as high as 52% within a year.<sup>3</sup> Stability issues may be caused by toe clearance, knee-buckling, proprioception, and balance. There is a need to develop a novel lower-limb prosthesis that will focus on foot clearance, forward propulsion, and proprioception.

The proposed lower-limb prosthesis will dynamically lengthen and shorten during gait to improve muscle efficiency and increase the load symmetry between the intact leg and prosthesis. During the prosthesis swing phase, the prosthesis will shorten for easier foot clearance. During the prosthesis pre-swing phase, the prosthesis will extend for increased forward propulsion. The dynamic lengthening and shortening of the prosthesis will result in a reduction of the lateral center of mass and swing inertia to improve proprioception and stability.

### Methods

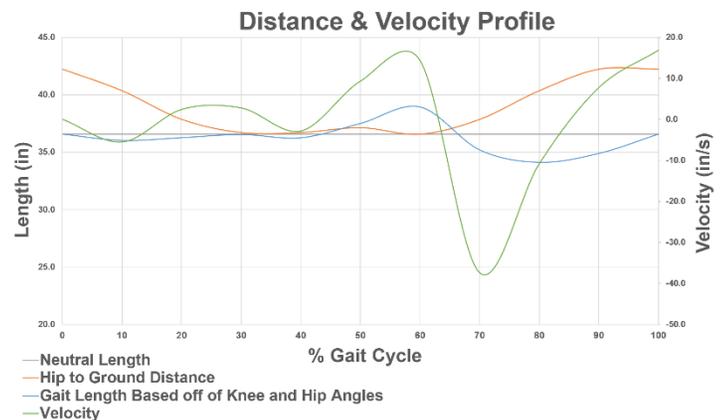

An initial prototype has been developed using an external motor and cam system that uses a cable to affect length adjustment of the prosthesis. (Figure 1) The system was designed telescopically for the cable to pull the top and bottom components together or separate them. The cable is pulled by an arm that follows the cam; as cam diameter increases the cable pulls the components together to shorten the prosthesis and as the cam diameter decreases the prosthesis lengthens. One revolution around the cam represents one gait cycle. Following institutional IRB approval, two transfemoral amputees were able to ambulate with the prototype on a treadmill at a speed that was timed with the speed of cam rotation and prosthesis' dynamic linear motion.

**Figure 1.** Prototype (left), cam and cable set-up (right)

### Results and Discussion

The prototype can support a patient's weight, adjust to the length needed during the gait cycle and shorten to provide foot clearance for swing through. A more compact electromechanical drive system will be needed for a self-contained prosthesis design.

**Figure 2.** Model of distance and velocity profile during gait

The first prototype proved the concept that a prosthesis with dynamic linear motion can replace the functions of a knee joint. From experimental observation and mathematical modeling of joint angles<sup>4</sup>, we will find the optimal weight, and the length and velocity profile of the telescopic system. (Figure 2) This will determine the required power and help conserve energy in a compact electromechanical drive system. The prototype will be tested kinematically to determine foot clearance distance, forward propulsion, and lateral center of gravity displacement.

### Significance

There are currently no lower-limb prosthetics on the market that replace the flexion/extension of a knee joint with dynamic linear motion. The dynamic linear adjustable prosthesis is patent pending. The claims of the patent include a prosthesis with a distal and proximal end, where an actuator modifies the distance between ends to alter the length of the prosthesis. The prosthesis can include rotational joints, multiple actuators, springs, shock absorbers, and a control system.

We hypothesize that a dynamically adjusting prosthesis can improve load symmetry through an optimized clearance distance and propulsion force. We anticipate that such a device would improve prosthesis control and quality of life for amputees.

## Influence of Asymmetry on the Metabolic Costs of Walking

### Introduction

Persons with a unilateral transtibial amputation face a greater metabolic demand during walking than able-bodied individuals [1]. This increase in the metabolic cost of walking may partially explain why the majority of persons with amputations do not engage in a sufficient amount of physical activity to avoid comorbidities of a sedentary lifestyle [2].

Inertial asymmetries in individuals with unilateral lower extremity amputations have been simulated in individuals without amputation by adding mass to one leg [3]. Others replicated asymmetrical gait in able-bodied individuals via an asymmetrical audible metronome [4,5]. In either case of persons with unilateral transtibial amputation or able-bodied individuals asymmetrically manipulated, it is not understood how much the mechanical and spatiotemporal asymmetries contribute to the metabolic cost of asymmetrical walking. Therefore, the purpose of this study was to determine how temporal and inertial asymmetries influence the metabolic costs of walking.

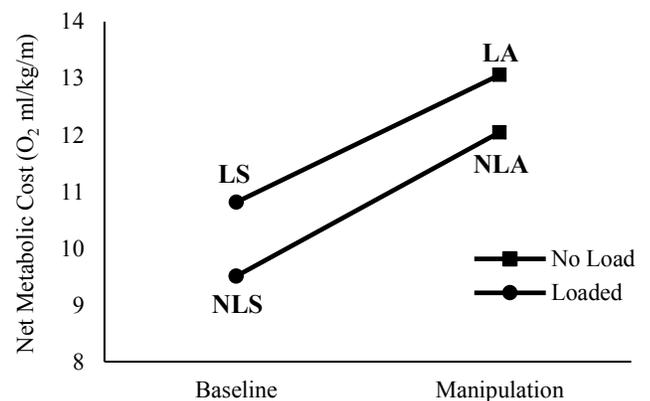

### Methods

Ten persons ( $F = 6$ ,  $1.73 \pm 0.09$  m,  $66.5 \pm 14.3$  kg,  $27 \pm 2$  years,  $275 \pm 143$  min/week of activity) were recruited to participate in two baseline conditions and two subsequent manipulation conditions during a single data collection session. The baseline conditions were designed to represent normal walking in symmetrically unweighted (NLS – No Load Symmetrical) and unilaterally weighted walking (LA – Loaded Asymmetrical). Manipulation conditions were designed to replicate gait manipulations where symmetry (LS – Loaded Symmetrical) or asymmetry (NLA – No Load Asymmetrical) were forced and do not represent the natural gait patterns used in the baseline conditions. Conditions were achieved with the addition of a unilateral 2kg mass attached to the ankle, a symmetrical metronome, or a metronome set to elicit asymmetrical walking at the magnitude caused by the unilateral mass. Spatiotemporal measures were calculated in Visual 3D (C-motion, Germantown, MD) from motion capture data (VICON, Englewood, CO) and ground reaction force data from a tandem-belt instrumented treadmill (AMTI, Watertown, MA), while gas exchange and metabolic cost were measured via indirect calorimetry with a metabolic cart (Parvo Medics, Sandy, UT). A repeated measure ANOVA was performed to determine if the metabolic cost of walking differed between conditions. Two, two factor (load x swing time, load x manipulation) ANOVAs were performed on net metabolic cost of walking data.

### Results and Discussion

In general, the findings reveal a significant increase in the net metabolic cost of walking for all conditions compared with the baseline normal walking (NLS) data. There was an interaction between load and swing time symmetries where metabolic costs

increased when forcing non-normal swing time symmetry, e.g., a greater cost during NLA compared with NLS and a greater cost during LS compared with LA. This is supported by manipulation conditions (i.e., LS and NLA) resulting in a significantly greater metabolic cost than baseline conditions. In turn, one factor of load or swing time symmetry may not have a greater effect on the metabolic cost of walking, but rather a manipulation from the natural gait pattern symmetry increases the metabolic costs of walking (Figure 1).

**Figure 1:** Main Effect of Manipulating Swing Time Symmetry. No interaction was noted between factors of load and manipulation; however, both main effects were found to be significant ( $p < 0.05$ ).

### Significance

Both unilateral mass and asymmetrical metronome resulted in an increase in the net metabolic cost of walking relative to unperturbed walking. Further, the factor of manipulating the natural temporal gait patterns that arise from the presence of a unilaterally added mass significantly increased the net metabolic cost of walking. In turn, the attempt to overcome the resulting temporal asymmetry from an interlimb mass asymmetry resulted in a metabolic penalty. To avoid increasing the metabolic demand that persons with a unilateral transtibial amputation are faced with during walking, clinicians should avoid forcing a symmetrical gait pattern. Forcing individuals to walk symmetrically in the presence of a lower extremity inertial asymmetry results in a higher metabolic cost than simply allowing individuals to choose a preferred gait pattern which results in a temporal asymmetry during walking.

# Ankle Exhibits Consistent External Quasi-Stiffness Behavior Across Level, Sloped, and Uneven Terrain: Implications for Prosthesis Design

Harrison L. Bartlett<sup>1,2</sup> and Michael Goldfarb<sup>1,2</sup>

<sup>1</sup>Vanderbilt University, Nashville, TN, USA

<sup>2</sup>Synchro Motion, LLC, Franklin, TN, USA

## Introduction

Humans regularly encounter sloped and uneven terrain during everyday activities such as walking on a cracked sidewalk or hiking. However, the majority of human walking studies are performed on smooth, level ground. These level-ground studies shed light on the underlying mechanisms of human walking and have also provided insights that guide the design of prosthetic limbs. One such insight commonly utilized in the design of prosthetic feet is the observation that during the mid-stance phase of level-ground walking, the ankle exhibits a spring-like relationship between ankle torque and ankle angle, which will here be called internal quasi-stiffness. Internal quasi-stiffness provides a strong basis for spring-like prosthetic feet that store and release energy during the stance phase of walking. Unfortunately, these level-ground walking behaviors are not consistent on sloped or uneven terrain, and as such, current prosthetic foot designs are suboptimal under those conditions. In order to design prosthetic feet that can accommodate various terrains, the gait of unimpaired individuals should be examined on uneven and sloped terrain to glean design insights.

A previous study on uneven terrain walking observed that during mid-stance, unimpaired individuals maintain a consistent spring-like behaviour between ankle torque and the orientation of the shank in the world coordinate frame (referred to as shank angle)[1], which will here be called external quasi-stiffness. The current study builds upon [1] to determine if this external quasi-stiffness behaviour observed in uneven terrain walking extends to level ground and globally sloped walking.

## Methods

Data from [2] were analyzed to assess the degree to which external quasi-stiffness is maintained while walking across globally sloped terrain. The data analyzed consists of ten unimpaired subjects walking on slopes ranging from -6 to 6 degrees in 3 degree increments at a speed of 0.8 m/s. Reflective markers were used to track the motion of limb segments, and joint torques were calculated using inverse dynamics methods detailed in [2]. Ankle torque, ankle angle, and shank angle were computed during mid-stance phase of gait on each global slope. The consistency of internal quasi-stiffness was assessed by examining the slope (internal quasi-stiffness) and torque zero-crossing (internal quasi-stiffness set point) of the ankle torque vs. ankle angle trajectories (Fig. 1a). The consistency of external quasi-stiffness was assessed similarly by examining the slope and torque zero-crossing of the ankle torque vs. shank angle trajectories (Fig. 1b).

**Figure 1:** Ankle torque vs. ankle angle during middle stance (a) and shank angle (b) for unimpaired subjects walking on sloped ground ranging from -6 degrees (dark green) to +6 degrees (light green) compared with level-ground (black dashed line). The range of ankle torque zero-crossing values in each plot is indicated with a gray shaded band. Fig. 1a shows the ankle joint internal quasi-stiffness while Fig. 1b shows the ankle joint external quasi-stiffness.

## Results and Discussion

The trajectories in Fig. 1 begin at the left-most position and move from left to right, with the magnitude of ankle torque increasing as the individual progresses through stance. Fig. 1a shows that the ankle joint internal quasi-stiffness is relatively inconsistent across various ground slopes. In contrast, the similar trajectories shown in Fig. 1b indicate that the ankle maintains a relatively consistent external quasi-stiffness during sloped walking. This result is consistent with [1], indicating that the external quasi-stiffness behaviour is maintained during mid-stance of walking on level, sloped, and uneven terrain.

## Significance

Just as internal quasi-stiffness models of ankle function during level ground walking have inspired the design of current spring-like prosthetic feet, this external quasi-stiffness model of walking on various terrains may be able to lend insights into the design of prosthetic feet capable of walking on sloped and uneven terrain.

# Repeated Error-Based Gait Training for Non-Traumatic Amputation: Proof of Concept Study

Paul W. Kline<sup>1,2</sup>, Noel So<sup>2</sup>, Thomas T. Fields<sup>2</sup>, and Cory L. Christiansen<sup>1,2</sup>

<sup>1</sup>University of Colorado Anschutz Medical Campus, Aurora, CO, USA

<sup>2</sup>VA Eastern Colorado Healthcare System, Aurora, CO, USA

Email: cory.christiansen@cuanschutz.edu

## Introduction

Chronic gait pattern compensations are common for people with unilateral, non-traumatic transtibial amputation (TTA), and are characterized by asymmetrical step lengths.<sup>1</sup> Such sustained gait compensations likely contribute to secondary musculoskeletal conditions that can affect functional mobility and quality of life.<sup>2</sup>

Error-augmentation gait training (EGT) has demonstrated promise in correcting asymmetrical step lengths after non-traumatic TTA.<sup>3</sup> Using a split-belt treadmill, EGT can be applied by exaggerating step length asymmetry using separate belt speeds under each lower limb. Such an EGT protocol has shown potential for immediate adaptation to greater step length symmetry in patients with non-traumatic TTA.<sup>3</sup> It is unknown if repeated exposure to EGT can lead to persistent adaptation, beyond the immediate response of a single session.

The purpose of this proof-of-concept study was to examine the feasibility and responsiveness of a four-week EGT protocol for people with unilateral, non-traumatic TTA. We hypothesized that repeated EGT sessions over four weeks would be feasible based on protocol fidelity, safety, and participant acceptability. In addition, we hypothesized a small-medium effect of improved step length symmetry 1-week following the intervention.

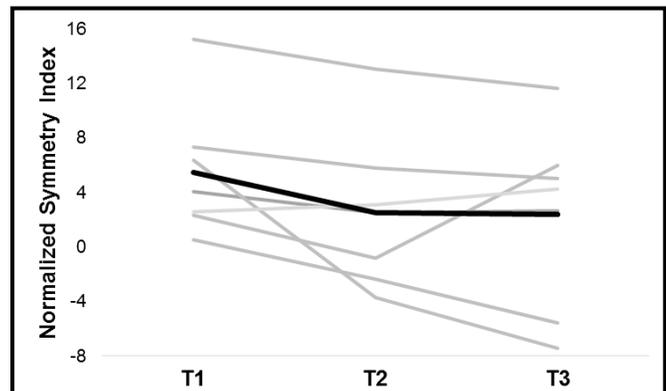

## Methods

Eight participants (8 M, 65±9 years old, 30.8±4.3 kg/m<sup>2</sup>, 41±33 months since TTA, 7±3 comorbidities) with unilateral, non-traumatic TTA were enrolled in an EGT protocol using a split-belt treadmill (Bertec Corporation). The intervention included 8, 30-minute sessions delivered over a 4-week period. Each session included five, three-minute sets of EGT at a 2:1 ratio of asymmetrical belt speeds. The faster belt was set to 75% of the participant's self-selected overground gait speed.

Feasibility outcomes included EGT dose goal attainment compared to protocol (protocol fidelity), number and type of adverse events (safety), and Intrinsic Motivation Inventory – Interest/Enjoyment subscale (acceptability). Step length during overground walking at self-selected speeds were assessed at baseline (prior to EGT), once a week during the EGT protocol, and one-week following the last EGT session. Between-limb step length symmetry was calculated using the Normalized Asymmetry Index (NSI).<sup>4</sup> Responsiveness to EGT was evaluated with Cohen's *d* effect size from baseline to one-week follow-up.

## Results and Discussion

Seven of the eight participants (87.5%) completed the intervention at the prescribed dose (intensity and duration), with an average overground walking speed of 1.0±0.1 m/s. One participant did not complete the protocol due to a skin blister on their residual limb, which was possibly related to the intervention. This participant completed only one session of EGT, which was deemed insufficient exposure to warrant outcome testing. No falls, musculoskeletal injuries, or increases in pain occurred. Participants rated EGT to be acceptable based on

**Figure:** Mean (black line) and individual participant (grey lines) between-limb step length symmetry at baseline (T1), week 4 of EGT (T2), and one-week post-EGT follow-up (T3).

scores above 5 on the Intrinsic Motivation Inventory – Interest/Enjoyment subscale ( $6.6 \pm 0.5$ ; mean  $\pm$  SD).

Average between-limb step length was more symmetrical one-week following EGT ( $2.41 \pm 6.59$ ) compared to baseline ( $5.47 \pm 4.91$ ) indicating a moderate effect size ( $d=0.52$ ). Individual step length symmetry responses varied (Figure).

The results partially support our hypotheses, demonstrating high protocol fidelity, participant acceptability, and a signal of efficacy for the four-week EGT protocol. The single residual limb skin blister was concerning, as it was possibly related to increased walking exposure. This finding support the idea that neurovascular comorbidities associated with non-traumatic TTA require close attention, including thorough skin tolerance assessment and cautious progression of EGT for this population.

## Significance

To date, only single-session EGT studies have been performed for people with TTA, which have demonstrated gait symmetry adaptability.<sup>3,5</sup> Based upon this current study, four weeks of EGT using a split-belt treadmill is feasible for people with unilateral non-traumatic TTA and may modify step length asymmetry up to a week after intervention. The study of EGT efficacy is warranted, in pursuit of intervention to optimize gait patterns and reduce functional limitations with this patient population.

## Effect of Intrepid Dynamic Exoskeletal Orthosis (IDEO) design on knee total joint moment and gait parameters.

Wyatt D. Ihmels<sup>1</sup>, Tatiana Djafar<sup>1</sup>, Julianne Stewart<sup>1</sup>, John Collins<sup>1</sup>, & Trevor Kingsbury<sup>1</sup>  
<sup>1</sup>Clinical Biomechanics Laboratory, Naval Medical Center San Diego, San Diego, CA, USA  
 Email: [wyatt.ihmels@gmail.com](mailto:wyatt.ihmels@gmail.com)

### Introduction

The Intrepid Dynamic Exoskeletal Orthosis (IDEO) provides mechanical compensation for patients with inadequate ankle function [1]. However, this compensation may alter biomechanics up the kinetic chain during gait. In fact, IDEO users exhibit decreased knee sagittal plane range of motion compared to control counterparts [1]. Currently, the impact of the IDEO on knee joint moments during gait compared to an unbraced shod condition is unknown. Additionally, the design of the IDEO has recently been updated from posterior laminated cylindrical rods (Old) to an interchangeable flat strut (New). To our knowledge, comparison of gait parameters between the two brace designs has not yet been performed. Thus, the purpose of this study was to examine temporal-spatial parameters of the two IDEO brace designs and determine the impact of IDEO on the knee total joint moment during gait.

### Methods

Participants for this study were identified through a retrospective search of our clinical registry. Inclusion criteria included a completed gait analysis both shod and wearing an IDEO (Old or New). Each gait analysis included the participant walking at a self-selected speed for a series of passes until three successful force-platform foot strikes and five total strides were collected for each condition (IDEO and SHOD). Forty (20 Old; ht: 1.81 ± 0.06 m, wt: 98.8 ± 11.8 kg, age: 35.6 ± 8.1 and 20 New; ht: 1.80 ± 0.05 m, wt: 96.1 ± 15.8 kg, age: 34.2 ± 7.9 years) participants met this inclusion criteria.

During each pass, temporal-spatial parameters and knee biomechanics were quantified from synchronous marker and GRF data. Standard inverse dynamics were used to calculate knee joint moments which were normalized to participant mass (kg) and height (m). MATLAB (Mathworks, Natick, MA.) code was used to estimate knee joint load by calculating peak knee total reaction moment (TKM) using knee flexion, abduction, and internal rotation, moments, as well as TKM sagittal (TKM<sub>sag</sub>), frontal (TKM<sub>front</sub>) and transverse (TKM<sub>trans</sub>) plane components [2].

For analysis, temporal-spatial parameters (velocity, stride length, and stride width), peak stride (0 – 100%) TKM, and TKM<sub>sag</sub>, TKM<sub>front</sub>, and TKM<sub>trans</sub> components were calculated and sent to a two-way RM ANOVA for main effect and interaction analysis ( $\alpha = 0.05$ ) of group (IDEO and SHOD) and brace (Old and New).

### Results and Discussion

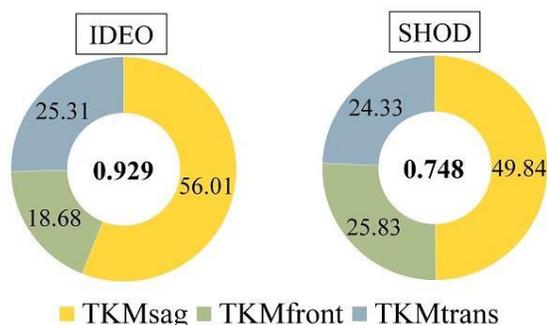

Use of the IDEO increased velocity 0.11 m/s ( $p < 0.001$ ) and stride length 0.14 m ( $p < 0.001$ ) compared to the SHOD condition (Table 1), demonstrating an increase in functional recovery [3]. However, no differences were seen in stride width

**Table 1:** Mean (SD) temporal – spatial parameters during gait at self-selected speed.

	Velocity (m/s)		Stride Length (m)		Stride Width (m)	
	New	Old	New	Old	New	Old
IDEO	1.29 (0.1)	1.31 (0.2)	1.41 (0.2)	1.51 (0.1)	0.36 (0.3)	0.36 (0.3)
SHOD	1.17 (0.2)	1.22 (0.2)	1.31 (0.1)	1.38 (0.1)	0.36 (0.3)	0.35 (0.3)

( $p = 0.156$ ). Further, no significant differences in velocity ( $p = 0.505$ ), stride length ( $p = 0.070$ ), or stride width ( $p = 0.948$ ) were evident between Old and New braces, indicating that gait performance may not differ between IDEO designs.

Participants displayed a 19.5% increase in peak TKM with IDEO compared to an unbraced SHOD condition ( $p < 0.001$ ; Fig. 1). Greater TKM with IDEO use during gait may lead to reduced overall knee joint health, as higher knee joint loads can induce cartilage degeneration and development of knee osteoarthritis [4]. However, IDEO use also increased TKM<sub>sag</sub> 6.2% ( $p = 0.037$ ) and decreased TKM<sub>front</sub> 7.2% ( $p = 0.037$ ) compared to SHOD. Erhart-Hledik et al. [4] previously reported participants with greater TKM<sub>sag</sub>, accompanied by reduced TKM<sub>front</sub>, exhibited a decrease in detrimental cartilage changes compared to participants with greater TKM<sub>front</sub> contribution. Thus, the shift in TKM components displayed in the current study may represent the most ideal compensation for the increased knee joint load with IDEO use.

**Fig 1:** Mean TKM and TKM components (0 – 100%) for IDEO and SHOD conditions

### Significance

Wearing an IDEO improved patients' gait parameters and subsequent functional outcomes. IDEO also increased peak TKM and risk of cartilage deterioration, but shifted TKM components in perhaps the least detrimental way possible to accommodate for the heightened knee joint load.

# Effects of Incremental Mass Changes on Wheelchair Motion Using Robotic Tester

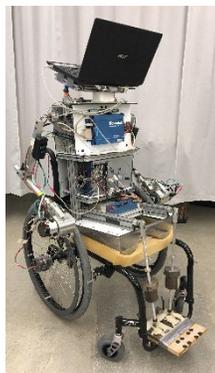

Jacob Misch\*, Stephen Sprigle PT PhD  
Rehabilitation Engineering and Applied Research (REAR) Lab, Georgia Institute of Technology  
Email: \* [mischjp@gatech.edu](mailto:mischjp@gatech.edu)

## Introduction

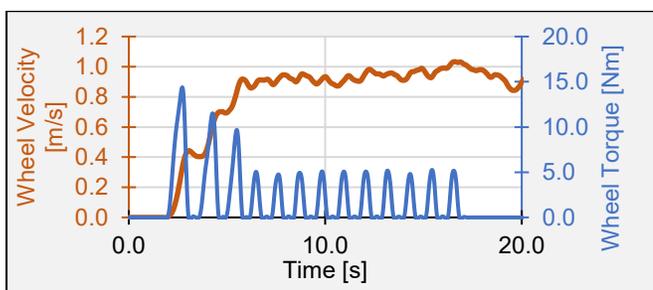

In an effort to reduce shoulder strain and energetic exhaustion during manual wheelchair (MWC) motion, it is imperative to optimize the vehicle via examination of each design choice. Tire selection and proper maintenance often far overshadow the impacts of mass when using human subjects, even with 10 kg added to the system.<sup>[1, 2]</sup> However, differences of less than 3 kg separate “standard” from “ultra-lightweight” MWCs, among other criteria. This work showcases a method of using a robotic mechanism<sup>[3]</sup> to investigate parameters that are hard to precisely control with human subjects.<sup>[4]</sup> In this study, the robot propelled MWCs with cyclic strokes of torque to replicate the acceleration and coasting that occurs during human motion. We measured the differences in wheelchair motion due to incremental changes in both system mass and weight distribution.

## Methods

The Anatomical Model Propulsion System (AMPS) seen in

**Figure 1** was employed as a surrogate for testing the MWCs. Torque was applied from motor ‘hands’ to custom push-rims on the drive wheels. The AMPS applied the standardized torque profile from **Figure 2** to each chair. The trajectory was designed to feature 3 strong “acceleration” pushes followed by 10 identical “steady-state” pushes to maintain velocity. 30 total trials were collected per configuration, with 15 in one heading direction and 15 in the other, to normalize over any inconsistencies in the floor. The analysis period consisted of datapoints between the start of the first push (2.0 s) and the end of the last push (17.0 s).

**Figure 2:** Representative applied torque profile and resulting wheel velocity during a single straight overground trial.

For this experiment, five configurations were used. The AMPS and MWC collectively weighed 93.6 kg with 72% of the weight centered over the drive wheel axle. This was used as the baseline case (+0 kg on the shelf or the footrest, represented as 0S, 0F). A Dibond metal shelf was added under the seat to fasten +2 kg and +4 kg at the center of mass without shifting weight distribution. Moving the weights from the center of mass to the footrest shifted the center of mass forward to 69% over the drive wheels for +2 kg and 66% for +4 kg.

## Results and Discussion

The power input to the system was calculated by multiplying torque applied to the wheels with the angular speed of the wheels. Work input, in Joules, was calculated by integrating the power over the duration of the maneuver. One outcome parameter, propulsion cost, was defined as the cumulative sum of work divided by the total distance traveled during the maneuver. A more tangible and descriptive outcome parameter was the total distance travelled by the center of mass during the maneuver.

**Table 1:** Propulsion costs and distances of each configuration.

Config	Total Propul. Cost (J/m)				Total Dist. Traveled (m)			
	Mean	StDev	Effect Size	% Change	Mean	StDev	Effect Size	% Change
0S, 0F	13.06	0.17	-	-	11.37	0.37	-	-
2S, 0F	13.15	0.14	0.53	+0.65%	10.85	0.45	1.27	-4.61%
4S, 0F	13.21	0.16	0.88	+1.13%	10.58	0.40	2.03	-6.90%
0S, 2F	13.23	0.18	0.93	+1.25%	11.00	0.44	0.91	-3.24%
0S, 4F	13.37	0.17	1.76	+2.34%	10.44	0.45	2.27	-8.21%

The data collected in **Table 1** show only slight differences in propulsion cost across the 5 configurations. The Cohen’s *d* effect sizes of medium (0.5) to large (>0.8) imply that the configurations are distinctly grouped, yet the percent differences are less than 2.5%. In contrast, the average total distance traveled by the configurations show much greater difference between groups. All effect sizes are large, and the distances are noticeably different by the human eye. The standard configuration travels at least 0.3 m farther than any other case. Added mass appears to be the dominant factor over weight distribution for travel distance.

## Significance

This work demonstrates the importance of examining the MWC system, independent of the human occupant. By mimicking the propulsion torque profile of the human user, the AMPS was able to propel the chairs with high repeatability, and measured small discrepancies in the motion between configurations representing frame masses of standard and ultra-lightweight MWCs.

Interestingly, this study highlights the minimal effect of mass on the propulsion cost and its relatively large effect on distance travelled. The +4 kg configuration rolled nearly 1.0 m less than the standard configuration, an effect that is magnified when the weight distribution is shifted forward over the casters. Thus, despite minute differences in the configurations spanning multiple categories of MWCs, both parameters are optimized at lower masses loaded mostly over the rear wheels.

# Finger Gesture Recognition of Forearm Amputee according to the Sampling rate

Taehee Kim, Jongman Kim, Bummo Koo, and Youngho Kim\*

Department of Biomedical Engineering and Institute of Medical Engineering, Yonsei University, Korea

Email: \*younghokim@yonsei.ac.kr

## Introduction

Surface electromyogram (sEMG) is effective to control prostheses for forearm amputees. Pattern recognition techniques with the selection of some feature vectors have been applied to control various finger gestures. However, sEMG features, especially in the time domain, may vary depending on the sampling rates[1]. In addition, the recognition accuracy also depended on the feature selection. The objective of the study was to determine the effect of the sampling rate and the feature selection of sEMG on the finger gesture recognition for forearm amputees.

## Methods

The Non-Invasive Adaptive Prosthetics (NinaPro) datasets<sup>[2]</sup> was used for the study, in which EMG signals were collected from 11 amputees with a sampling rate of 2,000Hz. In NinaPro datasets, 52 different hand gestures were performed using 12 sEMG sensors (Trigno Wireless, Delsys, USA). In this study, only 7 hand gestures were used: fist, pointing index, thumbs up, 2 finger (index and thumbs) grasp, sphere grasp, cylinder grasp and extension of index and middle finger. Data from only 8 sEMG sensors, equally spaced around the forearm at the height of the radio-humeral joint, were selected for the study. The extracted sEMG data were segmented into 250ms windows with 100ms moving. The segmented data were down-sampled from 2,000 to 50 with divisors of 2,000 (50, 80, 100, 125, 200, 250, 400, 500 and 1,000). All data were low-pass filtered at the cut-off frequency based on the Nyquist sampling theory.

Mean average value (MAV), waveform length (WL), zero crossings (ZC), slope sign changes (SSC) were calculated as sEMG features of artificial neural network (ANN) for every window<sup>[3]</sup>. The performance of a trained classifier was determined using the cross-validation. MATLAB (Mathworks, USA) was used to analyse the data and Scheffe's post hoc test was performed to determine the statistical differences using SPSS (IBM, USA). A probability of the null hypothesis was set by 0.05.

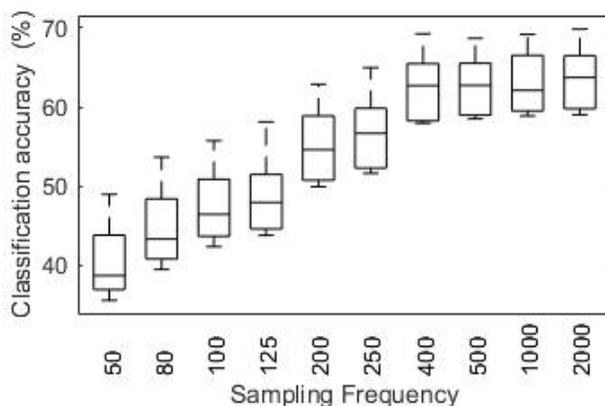

Figure 1: Classification accuracy according to sampling rate.

## Results and Discussion

Figure 1 shows the classification accuracy for different sampling rates. In general, the classification accuracy increased with the sampling rate of EMG signals. 2,000Hz sampling showed the highest accuracy (63.47%), but no statistical significance was found in the classification accuracy for different sampling rates from 400Hz to 2,000Hz ( $p > 0.407$ ). However, significantly low classification accuracy was observed in the sampling rates below 400Hz. 50Hz sampling showed the lowest classification accuracy (40.51%).

Table 1 shows that classification accuracy for feature selections with different sampling rates. For every feature selection, the higher sampling rates, the higher accuracies were achieved. 4 features combination showed the highest accuracy (63.47%) in 2,000Hz and ZC showed the lowest (23.23%) in 50Hz.

Tables 1 : Classification accuracy with different EMG feature selections (%).

EMG features	Sampling rate			
	50 Hz	200 Hz	400 Hz	2,000 Hz
MAV	44.7 ± 6.3	54.3 ± 6.2	56.9 ± 5.62	57.5 ± 5.4
WL	42.9 ± 6.4	54.7 ± 6.6	59.0 ± 5.60	60.5 ± 4.4
ZC	23.2 ± 2.3	37.8 ± 3.5	46.7 ± 4.63	46.4 ± 4.3
SSC	31.1 ± 1.5	41.0 ± 4.8	47.5 ± 5.08	42.7 ± 3.3
4 features combination	40.5 ± 4.0	50.9 ± 6.1	58.2 ± 5.06	63.5 ± 4.9

## Significance

The present study showed that sampling rate of sEMG clearly affected the accuracy in gesture recognition: Too low sampling rate of sEMG would be inappropriate. In addition, the combinations of some important time domain features would be suitable for the good ANN-based classification performance. Further studies with other amputee subjects would be required to confirm the present results.

## Modulating Distal Foot Energetics Using A Customized Deformable Foot Orthosis

Adrienne D Henderson<sup>1</sup>, Thomas A Hulcher<sup>1</sup>, Dustin Bruening<sup>2</sup>, Elisa S Arch<sup>1</sup>  
<sup>1</sup>University of Delaware, Newark, DE; <sup>2</sup>Brigham Young University, Provo, UT  
 Email: ahendo@udel.edu

### Introduction

Efficient gait is fundamental for independent living. By producing large amounts of positive power late in stance, the ankle has long been considered the primary driver for forward propulsion. Certain pathologies decrease the ankle-foot (A/F) system's power production, leading to less efficient gait. To mitigate this power loss, ankle-foot orthoses (AFOs) are commonly prescribed to enhance a patient's ankle energetics. However, with current AFOs, many patients only have limited gains in ankle power and thus forward propulsion.

Recent research shows the foot does not simply act as a rigid lever but actively contributes to gait energetics.<sup>1</sup> As such, we believe an AFO that seeks to improve foot energetics may enhance user outcomes. Specifically, we hypothesize that a deformable foot orthosis (i.e. AFO footplate) that stores and returns energy could help improve A/F energetics and thus, eventually, gait efficiency. This study's purpose was to determine if a deformable foot orthosis can store and return energy to a typical A/F system in a beneficial way.

### Methods

Eight healthy subjects (age:  $27.7 \pm 4.4$  yr, height:  $171.1 \pm 8$ cm, weight:  $74.7 \pm 17.1$ kg) first performed a baseline barefoot (BF) gait analysis with anthropometric measurements (foot length, width, MTP joint axis) in order to personalize bilateral carbon fiber foot orthoses with a deformable forefoot region. Once manufactured, the subject returned to the lab to walk with two footwear conditions: with minimalist shoes (SH) and with the foot orthoses inside the minimalist shoes (ORTH). Subjects walked at 0.8 statures/sec for all three conditions while kinetic and kinematic data were collected. A three-marker cluster on the superior midfoot was used to track the foot (MFT). Three subjects had three extra markers on their heel to allow ankle power to be calculated when the foot was tracked by the hindfoot, thereby allowing ankle energetics to be discriminated from midfoot energetics. Power curves and work done for the ankle-midfoot (tracked by MFT), ankle (tracked by HFT), distal foot, and A/F complex (ankle-midfoot + distal foot) were extracted for all three conditions. A repeated measures ANOVA with a post hoc test using a Bonferroni correction was used to evaluate changes across conditions for all work metrics except net ankle work (i.e.  $n=3$ ).

### Results and Discussion

The positive distal foot work was significantly greater in the ORTH condition compared to both BF and SH ( $p<0.001$ ) showing the deformable orthosis did indeed return energy. The ankle-midfoot seemed to respond to this by decreasing its net work in the ORTH vs. SH ( $p=0.006$ ). These changes resulted in a relatively equal net A/F complex work across conditions ( $p=0.63$ ). The ankle powers calculated with the MFT tracking likely includes ankle + some midfoot energetics whereas HFT tracking more likely isolates the ankle joint. The ankle powers using HFT tracking were consistently lower than the ankle-midfoot power, supporting the notion that some midfoot

energetics were included in the ankle-midfoot parameters. This is further supported by a comparison of ankle-midfoot and ankle peak powers in the BF/ SH with ORTH conditions. The ankle power and work remained relatively consistent across conditions unlike the ankle-midfoot metrics which see decreases in ORTH. This suggests power from the foot orthosis influences energetics elsewhere in the foot and perhaps is not affecting the ankle.

### Significance

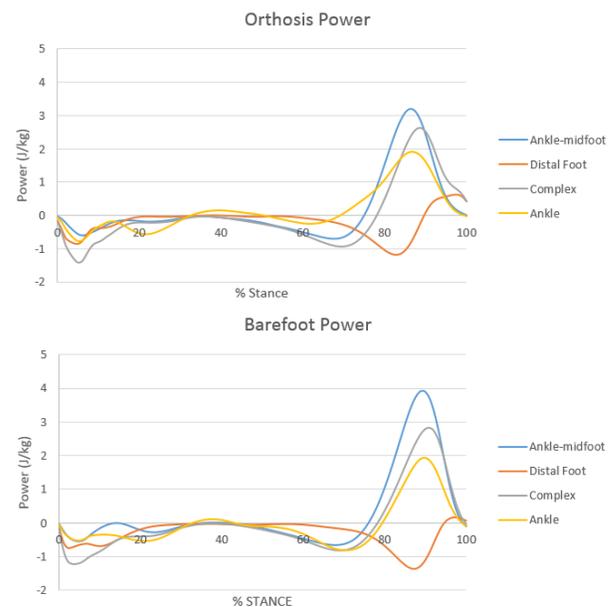

Deformable foot orthoses can store then return energy in a beneficial way to the A/F complex for typical individuals. This new technology could prove effective in patients with A/F impairments (e.g. stroke survivors) to enhance A/F energetics and potentially improve gait efficiency.

## Introduction

Custom carbon ankle-foot orthoses (AFOs) have enabled many individuals with lower limb musculoskeletal injuries to return to high impact activities [1,2]. A rigid footplate acts as a lever to allow the posterior portion of the AFOs to deflect to store and return energy. During activities, such as running, this energy storage and return can be best achieved when using a forefoot strike pattern to utilize the longest lever arm. A forefoot strike pattern has also been reported to reduce impact forces, rate of force development, and impact shock [3] in healthy individuals. Because these impact variables are linked to overuse running injuries [4], it is important to identify how using a custom carbon AFO for running affects these metrics. Few studies have investigated these devices during running and have found interlimb asymmetry with the unaffected limb having higher loading rates than the AFO side and on the upper end of average values reported in the literature in healthy adults [5]

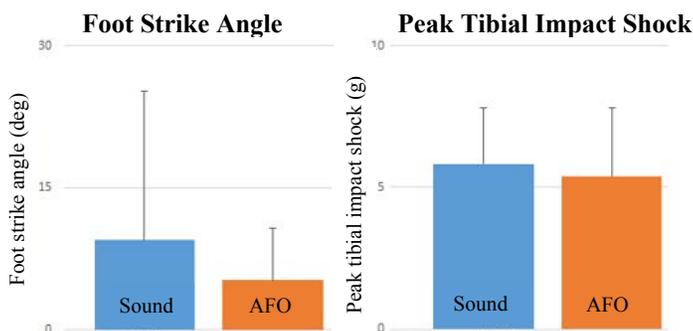

## Methods

Ten individuals (3 female, 37.1±4.4 years, 1.75±0.09 m, 83.0±16.5 kg) with musculoskeletal injuries requiring the use of a passive dynamic AFO (Intrepid Dynamic Exoskeletal Orthosis, IDEO) participated. The IDEO is a custom, carbon fiber AFO with a rigid footplate aligned in plantar flexion, a tibial cuff, and a posterior strut that deforms to store and return mechanical energy. It was required that all participants had worn their AFO for at least 2 months prior to study involvement. Participants ran at a self-selected speed over level ground while kinematic (240 Hz) and kinetic (1200 Hz) data were recorded. Vertical ground reaction forces were recorded from 8 force platforms embedded in the running path and tibial acceleration was recorded from shank-mounted, triaxial accelerometers. Footstrike angle, rate of force development, and peak tibial shock were compared between the sound and AFO limbs using paired t-tests ( $p < 0.05$ ).

## Results and Discussion

There were no significant differences between limbs for foot strike angle at initial contact or tibial impact shock ( $p > 0.05$ ) (Figure 1). These results are contrary to our hypothesis that there would be a decrease in both metrics due to the design of the AFO footplate in plantar flexion, which is intended to encourage a mid-to-fore-foot striking pattern at initial contact. Subjects largely adopted rearfoot strike patterns, which is less advantageous for mechanical energy storage and return. These results suggest that the design of an AFO or alignment of an AFO by itself is not sufficient to lead to the desired outcome of encouraging mid to forefoot striking. These results are in line with a recent case study that showed that a biofeedback training protocol was necessary

for a participant to use a mid to forefoot strike while running in an IDEO [6].

**Figure 1:** (Left) Foot strike angle and (Right) Peak tibial impact shock are not statistically significantly different between the AFO and sound limbs. Dorsiflexion is positive for foot strike angle.

The average running speed of subjects in this study (3.08 m/s) was relatively slow. Footstrike angle is known to change with running speed. Thus, it is possible that these results would change with participants who run faster because our outcomes are speed dependent.

## Significance

The study results indicate that the design of an AFO by itself is insufficient to cause an individual to adopt an atypical footstrike pattern. This outcome suggests that a training program may be necessary to encourage running patterns that take better advantage of the mechanical properties of the device and encourage symmetry between limbs.

## Introduction

Robotic exoskeletons can reduce metabolic cost in healthy individuals restore mobility in patients with peripheral artery disease (PAD) [1]. PAD is a cardiovascular disease produced by atherosclerosis of the leg arteries. The primary symptom of PAD is claudication or pain in the legs during walking, which severely shortens the distance a patient can walk. Up to 40% of the metabolic cost of walking comes from the hip muscles [2]. Different groups have been developing rigid exoskeletons and soft exosuits that assist the hip. Assisting at the hip has the advantage that the exoskeleton mass is positioned close to the center of mass, which minimizes the energy cost of the added mass. Soft exosuits have the advantage that they allow greater freedom of movement. However, soft exosuits often cannot apply the same torque magnitudes as rigid exoskeletons, and they rely on friction with the skin to remain anchored.

The purpose of this work was to develop a semi-rigid hip exoskeleton that can connect to and be powered by an existing actuation unit, to address the limitations of current existing soft exosuits. We evaluated the device performance by analyzing the match between desired and actual torque applied to the hip joint.

## Methods

The two pieces of the exoskeleton, anchor to the wearer via friction and compression, but they also stay locked on the body as a consequence of the actuation moment (Figure 1).

**Figure 1:** A) Hip exoskeleton setup. The waist belt attaches to a person. The two thigh-braces with the loadcells (Futek) measure the flexion and extension moment. B) Semi-rigid anchoring mechanism. The semi-rigid waist belt anchors to the waist by compression and because it gets stuck when the actuation force tries to rotate the belt. C) A soft waist waist-belt would only be able to anchor based on compression and friction.

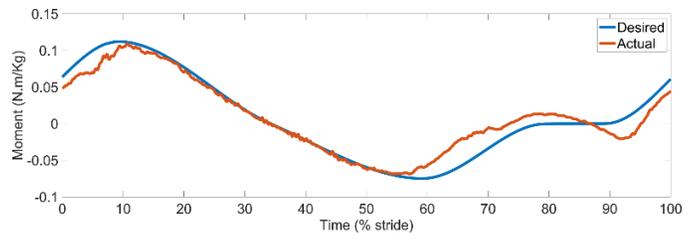

We have also developed a high-level temporal controller. This controller enables sinusoidal extension and flexion moment profiles to be applied independently on each leg as a function of the stride cycle percentage. The timings of heel strikes, and toe offs are based on the vertical ground reaction force using an adjustable detection force threshold [3]. Since it is not possible to

predict precisely when an ongoing walking step will end, the percentage of the step time is estimated based on the most recent heel contact time and a moving average of previous steps. The low-level controller developed by HuMoTech was used to minimize the error between actual and desired forces [4]. The actuation unit delivers the extension moment. We use a set of antagonistic springs, to deliver the flexion moment [5]

This new design will be tested in experiments aimed at developing faster and more clinically feasible human-in-the-loop optimization algorithms for patients. To measure the moment applied to the hip joint, we multiplied the lever arms by the flexion and extension forces, which allowed the desired sinusoidal profile across each percent of the gait cycle.

## Results and Discussion

In preliminary testing, we have found a good match between the desired and actual torque for each leg (Figure 2). To achieve this result, we needed to adjust for proportional, derivative, and damping gains of the controller.

**Figure 2:** Desired versus actual moment profile. Extension moment is shown as positive, and flexion moment is shown as negative

## Significance

The semi-rigid design of our exoskeleton introduces advantages in comfort and efficiency of control in patient populations because it requires less friction and compression than soft exosuits. Our initial work demonstrates a good match between the desired and actual torque the exoskeleton is able to generate for each leg.

## Development of a system for assistance at the center of mass

Arash Mohammadzadeh Gonabadi, Prokopios Antonellis, and Philippe Malcolm  
Department of Biomechanics and Center for Research in Human Movement Variability  
University of Nebraska at Omaha, Omaha, NE USA  
Email: \*[amgonabadi@unomaha.edu](mailto:amgonabadi@unomaha.edu)

### Introduction

Walking can be modeled as an inverted pendulum. However, ankle push-off is needed to redirect the center of mass from the downward phase of one step to the upward phase of the next step which requires metabolic cost. Different groups have been developing devices to reduce metabolic cost. Inverted pendulum models [1] and studies with exoskeletons [2] suggest that timing is important for assisting walking. The purpose of our study was to develop a tether system that could generate horizontal forces with desired force magnitudes and timings.

### Methods

We developed a system based on an existing control platform and cable actuation unit (HuMoTech, Pittsburgh, PA, Figure 1).

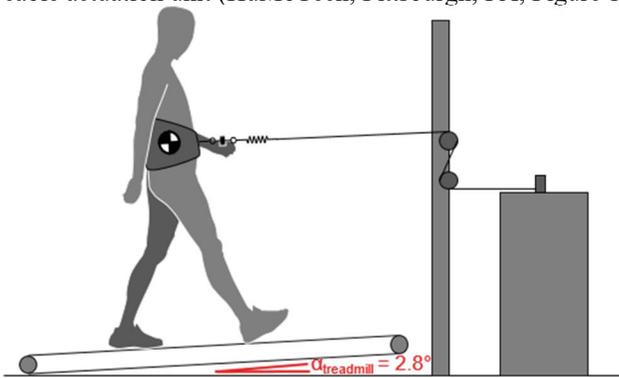

Figure 1: System setup.

The actuation unit produces forces via a direct-drive rotary motor. A force-control algorithm allows to program force profiles that follow a sinusoidal pattern with a desired timing in a repeatable way every step [3]. It is known that adding a series elastic element can improve the tracking of desired forces [4]. High stiffness allows faster response times, however, it might create noise. Intermediate stiffness can enhance force tracking, but it might add delay. A range of stiffnesses was tested by combining multiple loops of Thera-band in parallel. We additionally examined two metal springs.

### Results and Discussion

We found that increasing stiffness reduced the root mean square error (RMSE) but this also led to an increase in oscillations in the actual force, characterized using an oscillation metric from [5]. This resulted in an ideal compromise of approximately  $3000 \text{ Nm}^{-1}$  (Figure 2). The optimal stiffness seems to be of a similar order of magnitude as stiffnesses used in other cable devices ( $2280 \text{ Nm}^{-1}$  [5] and  $2500 \text{ Nm}^{-1}$  [6]). The steel spring with the highest stiffness ( $2577 \text{ Nm}^{-1}$ ) had a within-step RMSE that was about twice as high as the Thera-band spring with similar stiffness. The lowest RMSE value was 1.2% of body weight (BW) which is within the range of a similar tether that has been developed for applying constant forces [7].

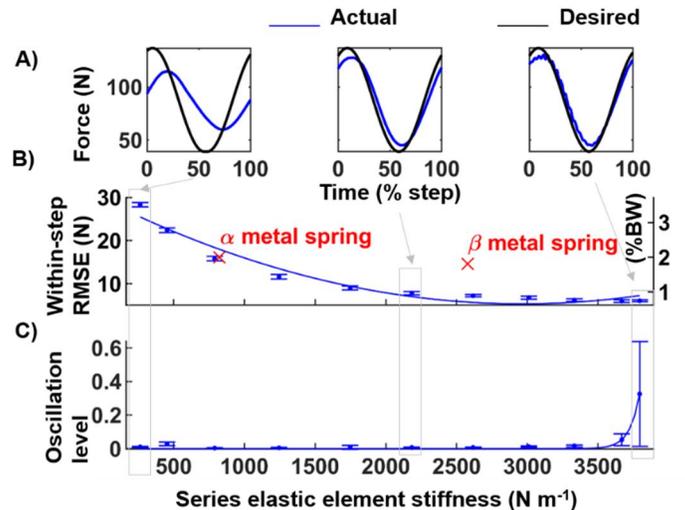

Figure 2: Series elastic stiffness optimization. A) Actual force (blue) and desired force (black) of walking with different series elastic element stiffnesses. B) Within-step RMSE versus stiffness. Dots and error bars show the mean and standard deviations of the steps of all Thera-band conditions. Red crosses show results from two steel springs. The blue lines are curve fits. C) Signal oscillation level.

### Significance

By optimizing the series elastic element stiffness, we achieved accurate force tracking. Assisting with a tether that allows to apply forces with accurate timing could lead to greater assistance levels and metabolic cost reductions than exoskeletons, which could be helpful in clinical settings.

# Biomechanical Evaluation of a Wearable Passive Shoulder Exoskeleton

Morteza Asgari <sup>a\*</sup>, Dustin L. Crouch <sup>a</sup>

<sup>a</sup> Mechanical, Aerospace, and Biomedical Engineering Department, University of Tennessee, Knoxville

\* [sasgari@vols.utk.edu](mailto:sasgari@vols.utk.edu)

## Introduction

Movement disability involving the shoulder is associated with orthopedic (e.g. rotator cuff tears [1]) and neurological (e.g. stroke [2]) health conditions. Shoulder impairment can prevent patients from performing activities of daily living and, thus, substantially affect their quality of life and self-esteem. Wearable exoskeletons could meet the need for movement assistance to assist or rehabilitate upper extremity function in patients with shoulder disability. While many exoskeletons are “active” (e.g. motorized), mechanically passive exoskeletons may be a more practical and affordable solution to provide continuous, home-based movement assistance for patients. However, it is imperative to first understand how wearable passive exoskeletons interact with their users prior to clinical translation. We have developed a wearable, passive, cable-driven shoulder exoskeleton (WPCSE) that incorporates a cam wheel gearing component to compensate for part of the shoulder moment due to gravity. The objective of this pilot study was to evaluate how the WPCSE affects the activity of muscles crossing the shoulder during upper extremity movements.

## Methods

The study was approved by the University of Tennessee, Knoxville IRB. The WPCSE used in this study was designed to compensate for approximately one-fourth of the shoulder moment due to gravity for a 50<sup>th</sup> percentile adult male (the design could be customized for individuals in future studies). Four able-bodied participants (3 males, 1 female, age = 27.25(4.45) years, height = 173.75(6.65) cm, weight = 68.40(5.12) kg) performed three different movements: shoulder elevation (from 0° to 90° to 0°) in the sagittal and frontal planes,

and shoulder flexion (from 0° to 90° to 0°) in the horizontal plane (i.e. at a constant shoulder elevation angle of 90°). Participants repeated each movement 10 times both with and without the WPCSE. Electromyograms (EMG) of shoulder muscles were recorded at a sampling frequency of 3000Hz using surface electrodes (TeleMyo 2400 G2, Noraxon, AZ, USA). The targeted muscles were anterior (AD), middle (MD), and posterior deltoid (PD), pectoralis major (PM), latissimus dorsi (LD), infraspinatus (ISP), trapezius (TRAP), biceps brachii (BB), and triceps brachii (TB). Prior to data collection, we measured EMG during maximum voluntary contractions (MVCs). Three-dimensional positional data of the arm and thorax were also recorded using a 7-camera infrared motion capture system (OptiTrack). The raw EMG data were rectified, low-pass filtered (4<sup>th</sup> order Butterworth, cut-off frequency = 3Hz), and normalized to the MVCs. The linear-enveloped EMG signals were divided into positive elevation/flexion and negative elevation/flexion phases, based on the kinematic data. For each movement phase, normalized root mean square (nRMS) was calculated and averaged across five repetitions. Finally, paired t-tests were performed to compare nRMS between movements with and without the WPCSE. In this preliminary study, to identify trends, differences were considered significant for  $\alpha \leq 0.05$  without correction for multiple tests.

## Results and Discussion

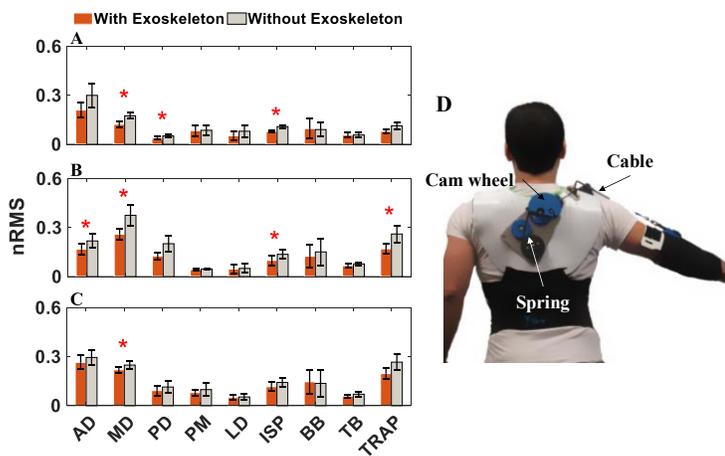

Our preliminary findings showed that, during positive elevation/flexion, nRMS was lower for trials with the WPCSE (Figure 1). The nRMS difference was significant for the MD, PD, and ISP muscles during sagittal-plane elevation; AD, MD, PM, ISP; TRAP muscles during frontal-plane elevation; and MD during horizontal-plane flexion. During negative elevation/flexion, nRMS was similar between trials with and without the WPCSE. The results demonstrated that the WPCSE can successfully reduce neuromuscular activity at the shoulder during positive elevation/flexion movements without resisting negative elevation/flexion movements. Our future work will focus on testing different levels of assistance to find a desirable range for the exoskeleton assistance for which the WPCSE most enhances shoulder motor function and biomechanics.

## Significance

Our promising preliminary results suggest that WPCSEs may be suitable for providing continuous, at-home assistance to patients who suffer from low to moderate shoulder disability.

## Introduction

Powered prosthetic ankles can restore the monoarticular function of the soleus muscle during walking, which provides a burst of Push-Off power in late stance. However, the benefits observed from powered ankles (e.g., magnitude of metabolic cost reduction) have often been less than those theorized/expected [1], [2].

One potential explanation is that powered ankles do not restore the biarticular function of the gastrocnemius muscle, which provides a mechanical coupling across the ankle and knee. The gastrocnemius appears to play an important role in transmitting power between proximal and distal body segments. Indeed, simulation [3] and experimental [4] studies provide preliminary evidence that restoring the gastrocnemius ankle-knee coupling to individuals with lower limb amputation (ILLA) may improve walking performance above and beyond restoring soleus function alone. For instance, ILLA demonstrated reductions in prosthesis-side hip and knee joint torques when gastrocnemius function was restored in combination with a powered ankle [4]. However, it is unclear if restoring the gastrocnemius function is only important for prosthetic ankles that generate sufficiently high magnitudes of Push-off power, or whether the gastrocnemius behavior itself (e.g., gastrocnemius stiffness) should be tuned differently based on the powered ankle behavior. This knowledge gap remains because benefits of an artificial gastrocnemius (AG) have not yet been compared across various levels of powered prosthetic ankle Push-Off.

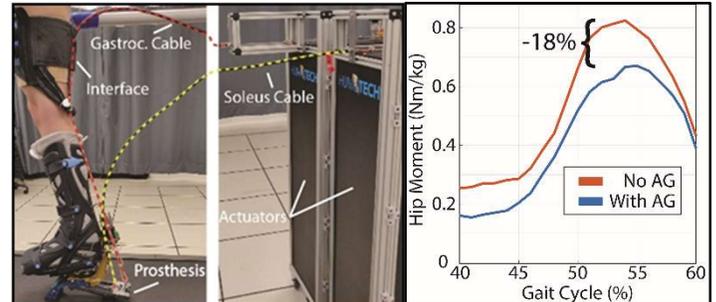

The objective of this study is therefore to emulate gastrocnemius-like ankle-knee coupling in ILLA, and to characterize its effect on whole-body gait biomechanics across various levels of prosthetic ankle Push-Off power and across various levels of gastrocnemius stiffness. We predict that kinematic and kinetic effects of the artificial gastrocnemius will be larger for higher levels of prosthetic ankle Push-Off power.

## Methods

To study the role of the gastrocnemius we are using a robotic emulation system (HuMoTech) that we customized to include: a soleus actuator (to emulate the powered ankle prosthesis), a separate gastrocnemius actuator (to vary behavior of the ankle-knee coupling), a soft conformal leg interface (which attaches to the user's thigh to provide an anchor point for the gastrocnemius), and a foot prosthesis (a modified version of HuMoTech's standard prosthetic hardware, Fig. 1). We have developed a controller that can command the artificial soleus and gastrocnemius in a repeatable, accurate, and precise manner. As subjects walk, we can independently manipulate the dynamics of the soleus and gastrocnemius, in order to systematically analyze how different parameters affect gait.

Otherwise healthy ILLA (N=5) attended an initial familiarization session. Participants then returned for a second session, during which the artificial ankle (soleus) Push-Off power and the artificial gastrocnemius stiffnesses were systematically varied as participants walked at  $1.1 \text{ m}\cdot\text{s}^{-1}$ . Ground reaction forces (Bertec), kinematic marker data (Vicon), and electromyography

signals (Delsys) were recorded. It is expected that a more complete (e.g., N=10) dataset will be presented at ASB.

**Figure 1:** Experimental Set-up (left), Example of Prosthetic Side Hip Torque with vs. without the AG (right).

## Results and Discussion

We have verified the controller's ability to emulate different gastrocnemius spring stiffness profiles during walking as well as its ability to provide various levels of ankle (soleus) Push-Off power while working in tandem with the artificial gastrocnemius. We are partway through our data collection and will continue to test unilateral, transtibial ILLA while we sweep across a range of stiffness values for a passive artificial gastrocnemius, and also sweep across different ankle prosthesis Push-Off powers.

Preliminary results confirm that walking with an artificial gastrocnemius has a considerable effect on gait biomechanics, including reducing prosthesis-side hip moments during Push-Off (Fig. 1). Comparison of how the artificial gastrocnemius affects gait kinematics and kinetics for higher vs. lower magnitudes of prosthetic ankle (soleus) Push-off power is presently underway, and the newest results will be presented at ASB.

## Significance

The results from this study will provide deeper understanding of the role of the gastrocnemius and how it interplays with soleus behavior during walking, as well as inform how to improve the benefits ILLAs received from powered prosthetic ankles.

# Leg Muscle Activation Patterns in Persons with a Unilateral Transtibial Amputation Using a Powered Compared to Passive-Elastic Ankle-Foot Prosthesis during Level and Uphill/Downhill Walking

<sup>1</sup>Zane A Colvin, & <sup>1,2</sup>Alena M. Grabowski

<sup>1</sup>University of Colorado, Boulder, CO; <sup>2</sup>Eastern Colorado Healthcare System, Denver, CO

Email: Zane.Colvin@colorado.edu

## Introduction

During the single support phase of level ground walking, the mechanics of the body can be modelled by an inverted pendulum that conserves kinetic and potential energy of the center of mass. During double support, the leg muscles generate and dissipate work to retain walking speed [1]. When walking uphill and downhill, the muscle activity of the legs changes to accommodate a net increase or decrease in gravitational potential energy.

People with a transtibial amputation typically use an energy storage and return (ESAR) prosthetic foot to walk. This type of prosthesis acts like a spring but cannot produce net positive work or power. Thus, a biomimetic powered ankle-foot prosthesis has been developed that includes an ESAR prosthetic foot and a battery-powered motor to mimic the muscles surrounding the ankle. Though previous studies have noted compensatory leg muscle activity in people with a transtibial amputation using an ESAR prosthesis, it is unclear how leg muscle activity changes with use of a powered prosthesis [2]. Thus, we measured leg muscle activity during walking on level, uphill and downhill slopes when people with a transtibial amputation used an ESAR and powered prosthesis. We hypothesized that use of a powered prosthesis would reduce leg muscle activity for the affected leg (AL) and unaffected leg (UL) compared to use of an ESAR prosthesis.

## Methods

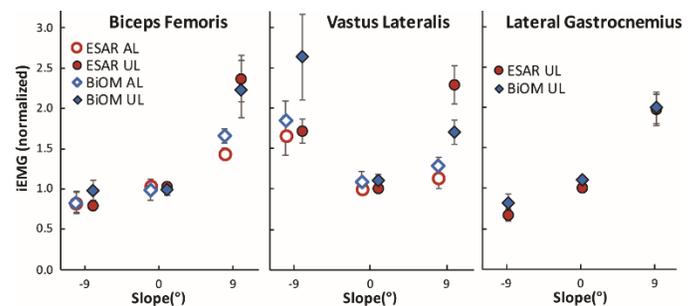

Ten subjects (4 F, 6 M;  $79.7 \pm 14.97$  kg;  $1.7 \pm 0.075$  m) with a transtibial amputation walked on a force measuring treadmill (Bertec, Columbus, OH) at 1.25 m/s using their own ESAR prosthesis and the BiOM powered prosthesis (Ottobock, Duderstadt, Germany). Each subject walked on slopes of  $0^\circ$ ,  $\pm 3^\circ$ ,  $\pm 6^\circ$ , and  $\pm 9^\circ$  while we measured muscle activity (Noraxon, Scottsdale, AZ) from the biceps femoris (BF), gluteus maximus (Gmax), gluteus medius (Gmed), rectus femoris (RF), and vastus lateralis (VL) of both legs and the lateral gastrocnemius (LG), soleus (Sol), and tibialis anterior (TA) of the UL.

We band-pass filtered (10-499 Hz) raw electromyography (EMG) data using a 4<sup>th</sup> order Butterworth filter. Then, we rectified, low-pass filtered using a 4<sup>th</sup> order Butterworth filter with a 10 Hz cutoff, and integrated EMG (iEMG) data over stride time. We determined stride time from subsequent heel strikes within the same leg using a 20 N vertical ground reaction force threshold and analyzed 10 strides for each leg. We normalized iEMG for each muscle and leg to that same muscle's iEMG during level ground walking using the ESAR prosthesis. All analyses were done using custom Matlab scripts (Mathworks, Natick, MA)

We used two-way repeated measures ANOVAs to determine the effect of slope and prosthetic design on iEMG for all muscles and specifically compared iEMG for the BF, VL, and LG because these muscles perform hip extension, knee extension, and ankle plantarflexion, respectively.

## Results and Discussion

The iEMG of every muscle increased with slope when subjects walked using an ESAR and BiOM prosthesis with the exception of VL and RF. VL and RF iEMG increased with the magnitude of the slope (Fig. 1). Throughout all tests, the main effect of prosthetic design on iEMG for both legs and all muscles was not significant ( $p \geq 0.080$ ). Therefore, we reject our hypothesis that use of the BiOM would reduce iEMG compared to use of an ESAR prosthesis during walking on level ground and slopes. The main effect of slope on iEMG was significant for the BF, VL, and LG ( $p \leq 0.0002$ ).

**Figure 1.** Mean normalized iEMG of the Biceps Femoris, Vastus Lateralis, and Lateral Gastrocnemius of the affected leg (AL) and unaffected leg (UL) during walking on slopes of  $-9^\circ$ ,  $0^\circ$ , and  $9^\circ$  while subjects used an energy storage and return prosthesis (ESAR) or a powered prosthesis (BiOM). Error bars are standard error.

## Significance

We found that use of a powered prosthesis by subjects with a transtibial amputation did not significantly change the iEMG during walking on level ground and slopes compared to use of a passive-elastic prosthesis for any muscle measured in this study. Future research is planned to explore how use of a powered prosthesis affects leg muscle activity magnitude and timing.

## Introduction

In the absence of volitional or microprocessor control, the knee of a mechanical transfemoral prosthesis must be configured for two critical behavioral requisites of the limb during the swing phase of gait; shortening via *flexion* to allow the swing limb to pass the stance limb, followed by late phase *extension* to achieve an external moment to passively resist buckling on loading [1]. This behavior may be modified by adjusting the level of swing phase knee flexion damping ( $KFD_{SW}$ ); higher values of which will attenuate the flexion that occurs shortly after foot-off due to a double pendulum effect. Given that the trajectory of the foot depends on the orchestration of rotations at the hip and ankle in addition to those at the knee, it is unclear how changes in  $KFD_{SW}$  in isolation are accommodated holistically during the swing phase. The objective of this study was to systematically explore the effect of adjusting  $KFD_{SW}$  on the swing phase dynamics of individuals with a transfemoral amputation during locomotion. We specifically aimed to provide a fuller understanding of the implications surrounding these two primary, yet competing, functional requirements for knee motion, i.e. (i) foot clearance and (ii) knee extension in preparation for foot contact.

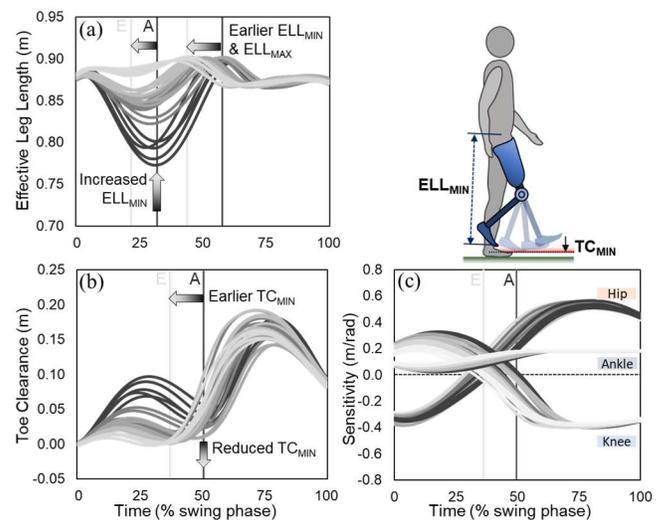

## Methods

Five individuals with a unilateral transfemoral amputation (2M, 3F;  $47.4 \pm 18.2$  yrs,  $1.60 \pm 0.10$ m,  $73.6 \pm 24.8$  kg) were fitted with a passive, single-axis prototype knee [2] that permits adjustment of  $KFD_{SW}$  from 0 Nm/rad/s (mechanical friction only) to  $\sim 1.80$  Nm/rad/s via medial or lateral attachment of a series of lightweight rotary hydraulic dampers. Five damping settings (A-E) were selected for each participant within a range determined based on individual body mass. With each setting, following a brief period of familiarization, participants performed repeat traverses of a motion laboratory at a comfortable self-selected pace. Kinematics of the lower limbs, pelvis and trunk were captured at 120Hz using a motion capture system (Motion Analysis Corp., Santa Rosa, CA). Swing phase toe clearance (TC; vertical distance toe to floor), effective leg length (ELL; distance hip to toe), and knee flexion angle were computed, alongside the sensitivities of vertical toe position to angular displacements at the hip, knee and ankle [3]. Key features of these profiles; selected maxima, minima and their timings, were compared across the 5 damping conditions for each participant. The relationships between  $KFD_{SW}$  and each variable were assessed at an individual level by linear and 2nd order polynomial regressions, with  $R^2$  values extracted to measure the amount of variance accounted for by each model fit.

## Results and Discussion

Clear quadratic trends ( $0.82 \leq R^2 \leq 0.98$ ) were observed in all variables. With increasing damping coefficient, knee extension occurred earlier in swing phase, promoting a greater timing symmetry. However, minimum TC reduced in magnitude with

increased damping, and both minimum TC and maximum ELL occurred earlier (Fig. 1a, b); temporally closer to the instance at which the limb must pass the stance limb, with implications for toe catch. TC became less sensitive to changes in hip flexion (Fig. 1c), suggesting a lesser ability to control toe clearance without employing proximal or contralateral compensations. Further, the pre-swing timing of minimum TC observed with higher damping may limit recovery options should a trip occur at this instance, due to the difficulty of effecting a successful ‘lowering’ strategy with a transfemoral prosthesis [4].

**Figure 1:** Effect of increasing  $KFD_{SW}$  on (a) effective leg length (ELL), (b) toe clearance (TC), and (c) sensitivity of vertical toe position to lower limb joint rotations (positive values: clearance of the toe will be increased by joint flexion). Lines A, E indicate mean  $TC_{MIN}$  for lowest and highest damping respectively. Data from a single participant; 5 strides per condition. Shading dark to light in order of increasing damping.

## Significance

In addition to highlighting broader implications surrounding swing phase damping selection for the optimization of mechanical knees, this work reveals important design considerations that may be of utility in the formulation of appropriate control strategies for computerized devices.

## Introduction

Lower limb prosthesis prescription mainly depends on the experience and knowledge of the prosthetist. While the interaction between the prosthetic knee and foot is critical to the safety of transfemoral prosthesis users (TFUs), there are few recommendations guiding their prescription. This interaction is especially important during stance when knee buckling can result in a fall [1,2,3], with significant implications for health [1] and healthcare cost burden [4]. Hence there is a need for a standardized approach to understand how the combination of different prostheses and their mechanical function affects TFUs biomechanics. This study quantified the interaction effect of prosthetic knee alignment and ankle-foot mechanism mechanical function (roll-over shape (ROS)) on stance-phase prosthetic knee stability (prosthetic knee moment) using a walking simulation.

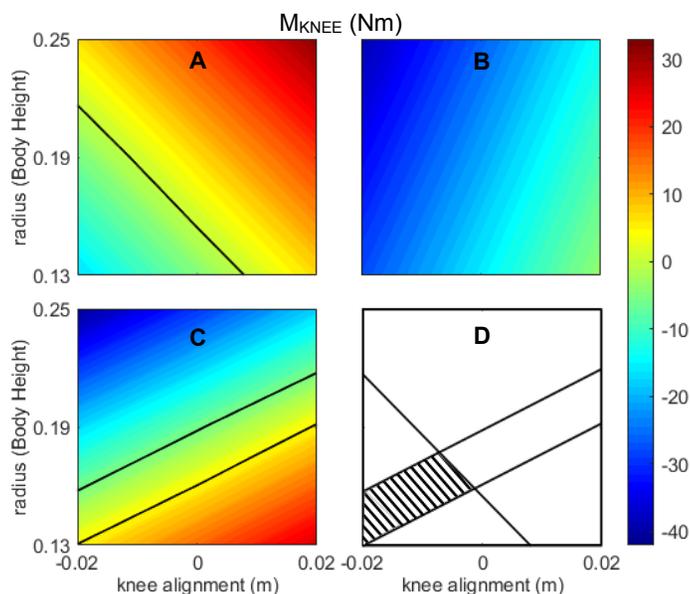

## Methods

A numerical sagittal-plane walking model was designed in MATLAB to simulate prosthetic stance phase of TFU gait on level ground based on a single inverted pendulum (IP). Knee center of rotation position modelled knee alignment and was defined by its distance along the IP long-axis from the hip (coinciding with the body center-of-mass) and perpendicular offset from the long-axis. A curved rocker rigidly attached to the bottom of the IP rod modelled foot stiffness and was defined as the ankle-foot ROS (i.e. center of pressure (COP) progression). The hip horizontal trajectory from experimental data was the model input, and outputs were: hip vertical trajectory, knee and COP trajectory, sagittal-plane GRFs, and knee and hip moments.

The model was validated against laboratory TFU gait data [5] by calculating the root mean squared error (normalized by the st. dev.) between model outputs and experimental data. The model was used to predict the effects of varying prosthetic knee alignment and ankle-foot ROS radius within boundaries according to the literature: posterior/anterior knee axis offset of 0.02 m [3]; ROS radius between 0.13 and 0.25 × body height, ranging from a more compliant to a more rigid prosthetic foot [6].

## Results and Discussion

Validation results suggest the model adequately simulated TFU gait during prosthetic single-limb support (SS) (RMSE normalized by SD: 0.64 – 4.59), when knee stability is most at risk given reliance on the prosthetic limb and proximal anatomy. Agreement with laboratory data was best when knees with limited or no SS flexion were considered. Fig. 1 displays predicted effects of component interactions on knee moment. During SS, an external extensor moment is necessary at the start and middle to avoid knee buckling, limiting selection of knee alignment and ankle-foot ROS to the solution area beneath the constraint (solid black line) for the SS start (Fig. 1A), while no constraints exist during middle SS (Fig. 1B). At the end of SS (Fig. 1C), transition from a knee extensor to small flexor moment is desirable to facilitate knee break to prepare for swing, denoted by a narrow band (e.g. 10 Nm) around a zero moment (between

**Figure 1:** Contour plots displaying predicted prosthetic knee moment (positive values for external flexor moments (Nm)) at the (A) start (solid line corresponding to 0 Nm), (B) middle and (C) end (solid lines defining a hypothetical band of  $\pm 5$  Nm around a zero moment) of prosthetic limb SS. (D) Cross-hatched solution area.

two solid black lines). These constraints combine to create the cross-hatched solution area (Fig. 1D) that limits the selection to posterior to in-line knee alignment combined with low to medium ankle-foot stiffness to maximize SS knee stability. The selection may be further constrained by clinical considerations such as the prescription of a certain prosthetic foot or prosthetic knee alignment. This means operating respectively along a fixed horizontal line or a fixed vertical line in the plots of Fig. 1.

In summary, despite the limitation of this IP-based simulation in that it predicts the external knee moment without addressing how this moment is managed by TFUs or their prosthetic knee, the results can inform the selection of the optimal knee alignment and ankle-foot mechanism to maximize TFU stability and safety during SS. Clinicians can work within a band of tolerance derived from the simulation results to optimize the prosthetic system.

## Significance

Predictions based on this simple walking model can further inform in-vivo systematic investigations on commercial devices interactions, thereby providing evidence for future Clinical Practice Guidelines on transfemoral prostheses design.

# Characterization of human arm stability in relation to unstable viscous environments

Fatemeh Zahedi, and Hyunglae Lee\*

School for Engineering of Matter, Transport, and Energy, Arizona State University

Email: \*[hyunglae.lee@asu.edu](mailto:hyunglae.lee@asu.edu)

## Introduction

In our daily activities, we sometimes have interaction with unstable environments that challenge the stability of the arm [1]. Many studies have demonstrated how the central nervous system is capable of controlling arm mechanical impedance, in particular arm stiffness, to compensate for the environmental instability [2].

Viscosity or damping is another important component of the mechanical impedance, which is a major energy dissipator that helps achieve limb/joint stability. However, due to technical challenges in reliably estimating arm viscosity, this component has been relatively understudied compared to arm stiffness [3]. Given this challenge, rather than directly measuring arm viscosity, this study investigates how stably the human arm can interact with unstable viscous (damping-defined) environments. In particular, we characterized the lower-bound of viscosity of unstable environments that the arm can stably interact with.

## Methods

A 7 degrees-of-freedom robotic arm (LBR iiwa R820, KUKA, Germany) with a 6-axis load cell (Delta IP60, ATI, NC) was used in this study. Two distinct controllers were implemented: a position controller to provide rapid perturbations to disturb the arm posture in either anterior-posterior (AP) or medial-lateral (ML) direction, and an admittance controller to simulate unstable viscous environments. The study was limited to a horizontal plane. Subjects were seated with their trunk securely strapped to a rigid chair, and held the handle connected to the robot end-effector. A visual feedback display (at a distance of ~1 m) helped subjects to complete posture maintenance task by showing current and target hand positions.

Arm stability was evaluated around the neutral posture, defined as follows: shoulder in ~70° of abduction, ~45° of horizontal flexion, and the elbow in ~90° of flexion. Nine evenly distributed points around the neutral posture ( $\pm 6$  cm in AP and ML directions) were tested. Zero stiffness and constant inertia were simulated in the horizontal plane and only viscosity was varied to change level of unstable viscous environments.

In each of the 9 postures, arm stability in both AP and ML directions was tested. For trials in the AP (or ML) direction, the environment viscosity in the ML (or AP) direction was constant at 30 Ns/m. The viscosity in the AP direction was varied from the initial value of -30 Ns/m, and subtracted by 10 Ns/m until the human arm could not stably interact with the simulated viscous environment anymore. If the arm failed to stabilize at the initial value, viscosity was added by 10 Ns/m until stable interaction was achieved. From this point, the viscosity was changed based on the bisection method until the difference of the viscosity values for stable interaction and unstable interaction was less than 5 Ns/m. The viscosity for the final successful trial was regarded as the lower-bound of environment viscosity that the human arm could stably interact with. The same algorithm was implemented for the ML direction, except that the initial viscosity was -10 Ns/m and the changing interval was 5 Ns/m. These values were

chosen based on preliminary experiments and previous findings on higher arm impedance in the AP direction than the ML [4].

Ten young, healthy subjects participated in this study, which was approved by the Institutional Review Board of Arizona State University (STUDY 00010123).

## Results and Discussion

Group analysis on 10 subjects demonstrated that, in average across all 9 testing postures, the lower-bound of environment viscosity that the human arm can stably interact with was -50.3 (2.9) Ns/m for the AP direction and -21.6 (4.0) Ns/m and for the ML direction. Results for each of the 9 testing posture are shown in Fig. 1. Higher arm stability in the AP than ML direction is consistent with previous findings that human arm stiffness is significantly higher in the AP than ML direction. It is also worth to note that the arm has less capability of adjusting to unstable viscous environments when it is closer to the body and when it is laterally displaced for the AP and ML directions, respectively.

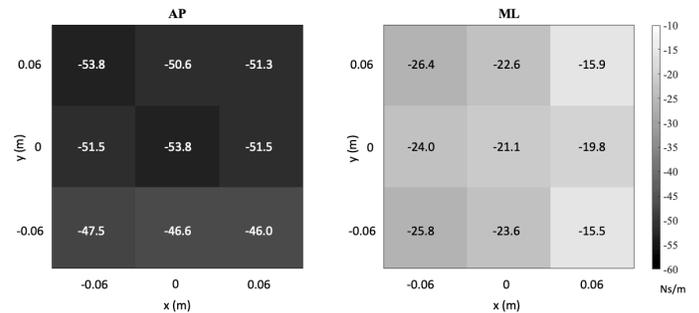

Fig. 1: Lower-bound of environment viscosity that the arm can stably interact with for each of the 9 testing postures for AP and ML directions. The mean of 10 subjects is presented.

## Significance

Compared to arm stiffness, arm viscosity has been relatively understudied and this limits the performance of devices (e.g., wearable robots and rehabilitation robots) involving physical interaction between the neuromuscular system and surrounding environments. Knowledge on the level of unstable viscous environments that human can stably interact with can be utilized to improve the overall performance of these devices, specifically, transparency and agility, without compromising stability.

### Introduction

As the climate of prosthetic devices has evolved, the number of available prosthetic feet has greatly risen. Clinicians have limited guidelines to aid in prosthetic prescription for individuals with lower extremity amputation. Furthermore, most comparative research has been contradictory or non-committal, which makes it difficult for clinicians to understand which devices will maximally benefit a given user. The objective of this study was to examine the dynamic function (radius of curvature (ROC), effective foot length ratio (EFLR), and instantaneous radius of curvature (IROC)) of 3 different types of prosthetic feet: Energy Storing and Returning (ESR), Articulating (ART), and Powered (PWR). This information may be critical in advancing our understanding of the most effective prosthetic designs, which can aid in evidence-based clinical practice and prosthetic prescription guidelines. We hypothesized that the ART and PWR feet would generate similar roll-over shape characteristics that would suggest improved dynamic functionality compared to ESR feet.

### Methods

Motion capture and kinetic data were captured for 12 people with unilateral transtibial amputation during overground walking at the Veterans Affairs New York Harbor Healthcare System (VA NYHHS) and Walter Reed National Military Medical Center (WRNMMC). Each patient completed data collection for each of the 3 feet after acclimating to each foot for one week. Center of pressure (COP) data were transformed into the shank coordinate system during single limb stance. EFLR, a measure of the percentage of the foot that is effectively used during a step, was calculated as the distance from the prosthetic heel to the most anterior point of the COP progression divided by the overall length of the foot. Circular arcs of best fit were also applied to the COP data to determine roll-over shape characteristics, such as height-normalized ROC (Hansen, 2003). The IROC was calculated by evaluating the first derivative of COP forward travel with respect to shank angle. The peak IROC is representative of the fastest COP forward travel.

**Figure 1:** EFLR bar plot (left), height-normalized ROC (center), and peak IROC (cm) (right). \* Statistically significant change at  $p < 0.05$ .

### Results and Discussion

Figure 1 shows that EFLR of the PWR foot ( $0.68 \pm 0.04$ ) was significantly lower compared to ESR ( $0.75 \pm 0.07$ ) and ART feet ( $0.76 \pm 0.09$ ) ( $p < 0.05$ ). Reduced EFLR of the PWR device indicates that the COP did not progress as far anteriorly during single leg stance, which can correlate to a reduced ankle lever arm in late stance, decreasing walking efficiency. Furthermore, the PWR group also had a significantly smaller ROC ( $0.14 \pm 0.02$ ) than the ART group ( $0.16 \pm 0.03$ ) ( $p < 0.05$ ), but not compared to the ESR group ( $0.15 \pm 0.03$ ) ( $p = 0.24$ ). Reduced ROC suggests less stability during single leg stance because the foot is rotating about a smaller rocker. However, it is unclear if the small differences found are clinically significant. Lastly, the PWR group had the lowest peak IROC ( $25.5 \pm 5.9$  cm) and was trending towards significance compared to the ART group ( $32.8 \pm 12.4$  cm) ( $p = 0.066$ ), but not significantly different than the ESR group ( $30.6 \pm 9.4$  cm) ( $p = 0.11$ ). Decreased forward travel, as indicated by lower peak IROC, suggests reduced standing stability (Curtze, 2009). Of note, the PWR foot is specifically designed to provide powered plantarflexion at terminal stance and is therefore not active during the single limb stance phase in which this analysis was conducted. We believe the motor could be causing an angular load at the ankle which may play a role in limiting the effectiveness of the passive mechanical components of the foot.

### Significance

Prosthetic prescription practices continue to be rooted in anecdotal evidence and manufacturer claims. Clinicians can use the information presented in this study to help prescribe devices that mimic effective rocker shapes to assist in dynamic activities. Manufacturers can design new componentry and prosthetic devices that better approximate the rocker shapes of the physiological ankle-foot complex to reduce interlimb asymmetries (Ferris, 2012). In this investigation, we showed that the PWR foot, while designed to provide biologically normative push-off power, provided less biomimetic function during single-leg stance and utilized less of the effective foot length. As the evolution of prosthetic feet continues, synergy between passive elements and advanced features must be maintained to effectively mimic the physiological ankle-foot complex.

## Introduction

Regulation of dynamic balance and generation of forward propulsion are key requirements for community ambulation, which typically involves adaptability tasks (e.g., obstacles, long steps). Previous studies in healthy adults have shown that the ankle plantarflexors are primary contributors to both of these important biomechanical functions [1-2]. However, individuals post-stroke often have plantarflexor weakness, poor balance control in the mediolateral direction [3-4], and reduced forward propulsion generation by the paretic leg [5]. Further, these individuals commonly use ankle foot orthoses (AFOs) to assist with foot clearance during swing, which may adversely affect their ankle mobility and plantarflexor output during stance. Previous research analyzing healthy adults showed walking with a solid AFO negatively influences forward propulsion generation and balance control [6]. However, it is not clear if AFOs similarly affect individuals post-stroke. Thus, the purpose of this study was to assess the influence of a commonly prescribed articulated AFO on mediolateral balance control and generation of forward propulsion during walking adaptability tasks in individuals post-stroke. We hypothesized that a) walking with an AFO would negatively influence mediolateral balance control and generation of forward propulsion by the paretic leg and b) poor mediolateral balance control would be associated with reduced generation of forward propulsion since the ankle plantarflexors are key contributors to both biomechanical functions.

## Methods

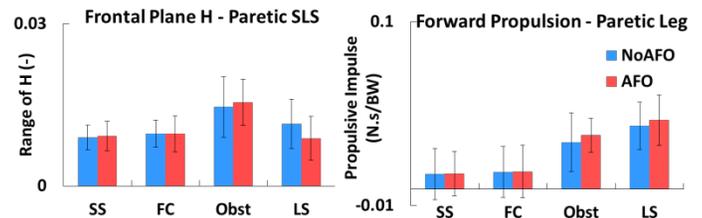

Nine individuals with post-stroke hemiparesis (4 left hemiparesis; age:  $53.7 \pm 11.3$  years; 3 female; walking speed:  $0.71 \pm 0.44$  m/s) were assessed while walking with and without their prescribed articulated AFO. Three-dimensional ground reaction forces (GRFs) and kinematics were collected at 2000 Hz and 100 Hz, respectively, during self-selected (SS), fastest-comfortable (FC), obstacle negotiation (Obst) and long step (LS) walking tasks. Mediolateral balance was assessed as the range of frontal-plane whole-body angular momentum ( $H$ ) during paretic single leg stance [4].  $H$  was normalized by body mass, height and a term similar to Froude number [4]. Forward propulsion was calculated as the time integral of the anterior GRF (normalized by body weight) during late stance of the paretic leg. Differences between the AFO and NoAFO conditions were assessed using a paired t-test within each walking condition. Relationships between mediolateral balance and forward propulsion were assessed using Pearson's correlation.

## Results and Discussion

For all walking tasks, there were no significant differences in mediolateral balance control or forward propulsion generation when walking with and without an AFO ( $p > 0.05$ ; Fig. 1). Thus, our first hypothesis was not supported. These findings

contradict our previous observation in healthy adults walking with a solid AFO [6], which is likely due to the articulated AFOs allowing greater ankle mobility and plantarflexor output.

Mediolateral balance control was correlated with forward propulsion during the SS AFO ( $r = -0.80$ ,  $p = 0.007$ ), FC AFO ( $r = -0.65$ ,  $p = 0.049$ ), and FC NoAFO ( $r = -0.74$ ,  $p = 0.017$ ) walking conditions. That is, more impaired forward propulsion generation (i.e., smaller value) was associated with poorer mediolateral balance control (i.e., larger  $H$  value), supporting our second hypothesis. This finding was particularly interesting as it highlights the association between forward propulsion in the anterior direction and dynamic balance in the mediolateral direction, which is likely due to the ankle plantarflexors being a primary contributor to both quantities. These findings also highlight that the articulated AFO design does not hinder these key biomechanical functions during stance in both frontal and sagittal planes.

**Figure 1:** Range of frontal-plane  $H$  (during paretic single leg stance) and forward propulsion (generated by the paretic leg) during AFO and NoAFO walking conditions.

## Significance

Here, we found that wearing an articulated AFO during a variety of walking (SS and FC) and adaptability tasks (Obst and LS) did not adversely influence mediolateral balance control and forward propulsion in individuals post-stroke. Since these walking tasks require varying amounts of ankle mobility and plantarflexor output, this finding suggests that the articulated AFO allowed for sufficient ankle output across all tasks. Given the widespread use of AFOs post-stroke, it is important to understand the potential influence of AFO use on walking mechanics and motor output as they could encourage adverse gait compensations and accelerate muscle atrophy. Further research is needed to assess the influence of other AFO designs (with more rigid ankle support) on walking mechanics and motor output during walking adaptability tasks.

# Asymmetry, Instability and Functional Deficits in Transtibial Prosthesis Users During Squatting, Lifting and Sit-to-Stand

Rachel H. Teater, Kirsty A. McDonald, Gerasimos Bastas, and Karl E. Zelik  
Department of Mechanical Engineering, Vanderbilt University, Nashville, TN, USA

## Introduction

Lower limb prosthesis users (LLPUs) experience mobility challenges that can impair their ability to carry out activities of daily living, affecting quality-of-life and independence [1]. The vast majority of LLPUs use a passive ankle-foot prosthesis where the ankle joint or foot keel is locked at a fixed angle relative to the shank. Extensive research has characterized the ability of these devices to replicate biological movement and function during walking [2]. However, it is less well understood how conventional prosthetic feet perform during functional transitions and other movements, such as standing up from a chair, picking up an item off the ground, or squatting down. These tasks involve ankle and/or toe flexion in healthy individuals—degrees of freedom that are not included in most passive prosthetic feet. We expect that the lack of ankle and toe joint mobility may contribute to the task performance deficits LLPUs experience. For instance, prosthetic device limitations may lead unilateral LLPUs to perform tasks in a highly asymmetric manner; overloading their intact lower limb and thus contributing to overuse injury or degenerative joint disorder risks. Prosthetic design modifications could potentially improve their comfort, safety, and ability to complete these tasks without overloading their intact lower limb. To investigate this, we aim to (1) characterize lower limb loading asymmetry, stability, and functional deficits of LLPUs during essential everyday movements while wearing their prescribed passive ankle-foot device and (2) investigate if prosthetic design modifications improve symmetry and perceived stability, or overcome functional deficits. We predict that restoring ankle flexion will improve functional movements such as squatting and lifting and toe flexion will assist in lunging and reaching tasks.

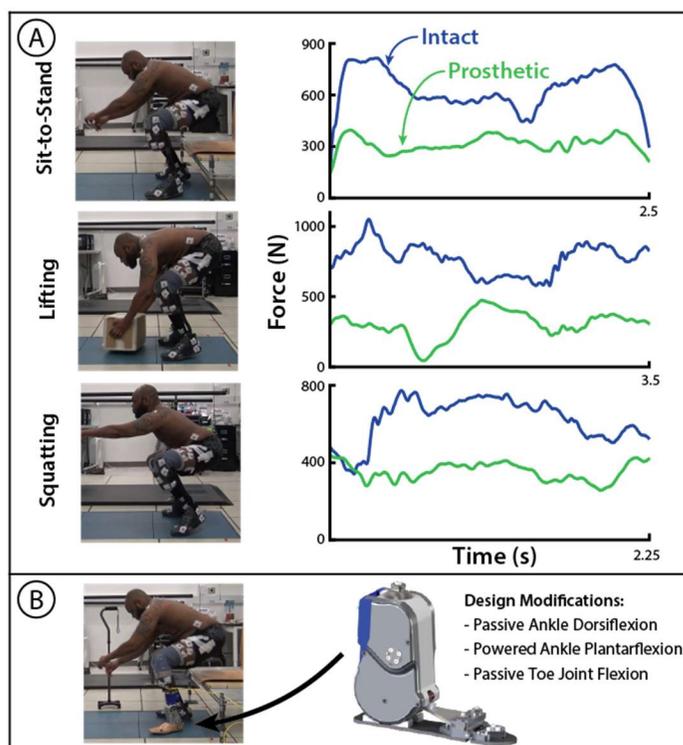

## Methods

Through reviewing the scientific literature and interviewing local LLPUs, physicians, and prosthetists, we identified several tasks that LLPUs completely avoid or find challenging, and have the potential to be improved by modifying prosthetic ankle-foot design. We are now conducting a comprehensive human movement study evaluating transtibial LLPUs during these identified tasks: sit-to-stand (and stand-to-sit), lifting, squatting, lunging, and reaching. To address the first objective, we are collecting data with users performing variations of all tasks in their prescribed passive prosthesis. We then use the Vanderbilt Powered Ankle [3] to emulate specific device design modifications that are expected to improve the ability of LLPUs to complete these tasks, i.e., adding ankle and/or toe articulation. For each task, we are collecting participant feedback on perceived effort, stability, and comfort in addition to collecting full motion capture (Vicon) and ground reaction force (GRF; AMTI) data.

## Results and Discussion

Preliminary vertical GRF data from one participant performing representative sit-to-stand, lifting, and squatting tasks wearing his prescribed prosthesis (Fillauer AllPro) is presented in Figure 1. During each of these tasks, the participant's intact lower limb experienced forces more than twice the magnitude of force on

their prosthetic limb. This was consistently seen across multiple trials and variations of these tasks. In pilot testing using the powered prosthesis, there were noteworthy improvements in subjective feedback related to effort, stability and comfort when utilizing increased ankle dorsiflexion during the sit-to-stand task (Fig. 1B). Data collection is ongoing with expanded analyses (e.g., stability, lower limb joint kinematics/kinetics) expected to be completed for multiple subjects prior to the conference.

**Figure 1:** (A) Transtibial LLPU performing sit-to-stand, lifting (10 kg), and squatting wearing his prescribed prosthesis with corresponding vertical GRF. (B) The Vanderbilt Powered Ankle allows us to investigate device modifications by modulating ankle and toe mobility.

## Significance

Biomechanical assessments of functional movement deficits in LLPUs are lacking. Understanding how users complete these tasks in their current passive devices and identifying prosthetic design modifications that increase functional ability is an essential step towards improving the standard of care for LLPUs. New devices that increase stability, symmetrical loading, and/or comfort could lead to reduced falls and overuse injuries.

# Myoelectric Control Of An Ankle Exoskeleton In Continuous And Discrete Movements

Rachel L. Hybart<sup>1\*</sup> and Daniel Ferris<sup>1</sup>

<sup>1</sup>Human Neuromechanics Laboratory, J. Craton Pruitt Department of Biomedical Engineering, University of Florida, Gainesville, FL  
Email: rhybart@ufl.edu \*

## Introduction

Real world use of lower extremity exoskeletons will require not only assistance for walking but also for discrete motor tasks. Traditional control strategies for exoskeletons usually focus on timing of gait events (heel strike and toe off) [1]. Real world movements include very short bouts of walking with non-steady state transition periods (turning, stopping, starting) [2], and noncyclical motions for discrete tasks.

One control strategy that should work for both continuous and discrete tasks is proportional myoelectric control. Myoelectric control uses electromyography (EMG) from the user to control the exoskeleton motor, allowing smooth transitions between continuous and discrete motions. Past research has shown humans are adept at learning to use proportional myoelectric control of lower extremity exoskeletons during walking [3], but it is not clear how training from walking carries over to noncyclical motor tasks.

The purpose of our study was to determine if subjects practicing walking with robotic ankle exoskeletons would improve their performance on a subsequent noncyclical, discrete motor task compared to subjects that did not practice walking with the exoskeletons. We hypothesized that individuals that practiced walking with the exoskeletons powered would perform better on the subsequent motor task than the subjects without walking practice.

**Figure 1:** A subject wearing the Dephy Exoboot ankle exoskeleton.

## Methods

We adapted a myoelectric controller to control commercially available robotic ankle exoskeletons (ExoBoot, Dephy, Inc.) (Figure 1). The controller used filtered and scaled soleus EMG to enable plantarflexion assistance. 5 participants (3M, 2F) walked on a treadmill at 1.2 m/s while wearing ExoBoots on each leg for 30 minutes, after which they completed a series of discrete force tracking tasks. One group wore the ExoBoots unpowered during walking and powered during the discrete task. The second group wore the ExoBoots powered during both walking and the discrete task. During the discrete task the participants tried to match a

target force displayed to them on a screen, with their right leg onto a force plate. The participants applied the force to a force plate for 2-7s, returned to rest, and repeated with a different target force. Participants completed 20 repetitions of force application and returning to rest. The magnitude and duration of each force target varied across the 20 trials.

## Results and Discussion

The participants in the powered walking group showed better initial force tracking and faster learning in the discrete task than the unpowered walking group. The group that had powered walking practice had a lower initial root mean square error (RMSE) for the discrete task than the control group. Both groups showed a negative slope of the RMSE between the 1<sup>st</sup> and 20<sup>th</sup> repetitions, but the powered walking group had a steeper slope. The steeper slope was indicative of faster learning during discrete force tracking task.

The powered walking group decreased their mean EMG amplitude by 17.54% during the 30 minutes of practice walking with the exoskeletons. That indicated that the subjects showed substantive adaptation to controlling the exoskeletons.

These results suggest that training with robotic ankle exoskeletons during walking carries over to noncyclical, discrete motor tasks. The performance in the subsequent force tracking task was greater for the group that had 30 minutes of walking practice.

## Significance

One disadvantage of current lower limb exoskeleton controllers is their inability to easily transition from continuous to discrete tasks. Control strategies focused on steady state, constant speed walking on flat surfaces are limited in their applicability to real world implementation. Discrete movements are important during walking gait transitions such as turning or stopping, and to uneven terrain or obstacles. We found that adaptation to a myoelectric-controlled ankle exoskeleton during walking leads to better performance when using the same device in a discrete motor task.

This research also gives insight into the neural substrates for controlling continuous and discrete tasks. Motor adaptation carryover from walking to noncyclical discrete motor tasks suggests that the neural substrate responsible for the adaptation is used in controlling both tasks. This is particularly important to training and use of robotic exoskeletons intended for real world use for either rehabilitation or occupational reasons.

## Introduction

The most common spinal cord injury (SCI) classification is incomplete quadriplegia (45%-60%); the majority occur in the C5-C7 spinal segments. Studies show the highest priority among individuals with a quadriplegic SCI is restoring grasping ability [1,2]. Patients with an incomplete C5-C7 SCI lose grasping abilities but wrist function is retained [3]. Rehabilitation techniques apply the tenodesis effect, an orthopedic phenomenon that uses wrist extension for grasping and wrist flexion for releasing. Current tenodesis wrist-hand orthoses (WHOs) engage only the thumb and index finger, meaning only 20% of activities of daily living (ADLs) can be completed [3].

## Methods

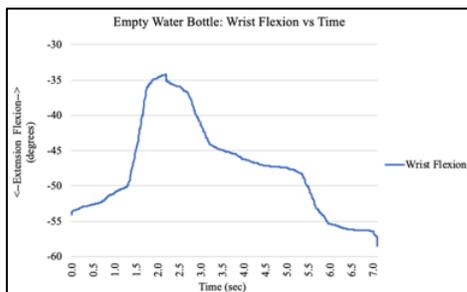

This feasibility study tested a student designed powered WHO on ten able-bodied individuals (avg. age: 42.7 years old). The prototyped WHO utilizes a modified version of the tenodesis effect (wrist flexion for grasping, wrist extension for releasing) to help individuals with an incomplete C6-C7 SCI independently complete ADLs. Subjects used the WHO to complete feeding and grooming tasks in front of a motion capture system. Results were analyzed through OpenSim to get wrist joint angles, which would help determine if someone with a C6-C7 SCI, who likely has limited wrist range of motion (ROM), could use this device [4].

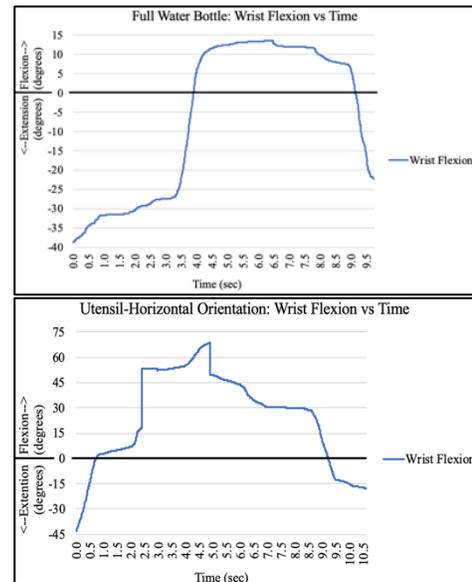

**Figure 1:** Left: Prototyped WHO. Middle: 3-D printed index finger and thumb linkages. Right: Removable flex sensor housed in pocket.

## Results and Discussion

Graphical data shows a greater degree of wrist extension was used versus wrist flexion in the majority of tasks. An exception was the *Full Water Bottle*, which can be considered an outlier due to difficulty picking up this object. Subjects failed to lift this object, and in an attempt to get a more secure grasp they over compensated with more wrist flexion. Figures 2 and 3 show graphs for a single subject.

**Figure 2:** Empty water bottle required more wrist extension

**Figure 3:** Top: Full water bottle- more wrist flexion than other tasks. Bottom: Utensil-horizontal orientation- maximum wrist flexion.

A greater degree of wrist flexion is required for grasping thin, small diameter (<0.5in) objects. These objects (utensil, brush, toothbrush, razor) in a horizontal orientation require more wrist flexion than in a vertical orientation. The utensil, the thinnest object, in a horizontal orientation requires the most wrist flexion.

Individuals with a C6-C7 SCI (future study), with limited wrist ROM, should still be able to use this device because it can be individually customized such that wrist motion input is disproportionate to finger motion output. For example, the WHO can be programmed to output 4° of finger motion for every 1° of wrist motion input. If a user is limited to 10° of wrist extension, the device can be programmed to open the finger linkages 40°.

## Significance

This WHO is customizable, lighter, and easier to use than currently available orthoses. Since the operational code can be customized, individuals with limited wrist ROM (e.g. C6-C7 SCI), can still use this device to independently complete ADLs.

## Introduction

When people lose a limb due to amputation, they lose not only motor function, but also sensory information about the state of that limb. A variety of approaches have attempted to reintegrate this sensory information, many of which are invasive [1]. We developed a system that substitutes this missing information from an ankle-foot prosthesis in a noninvasive manner. In our approach, a wrist exoskeleton allows users with amputation to both control and receive feedback from their prosthetic ankle in real time via teleoperation (Fig. 1A).

## Methods

**System Design:** We built a wrist exoskeleton that senses wrist angle with an accuracy of  $0.18^\circ$  and provides up to 1 Nm of wrist flexion or extension torque using a capstan drive mechanism. This exoskeleton interfaces with an existing ankle-foot prosthesis emulator that previously operated only under torque control [2].

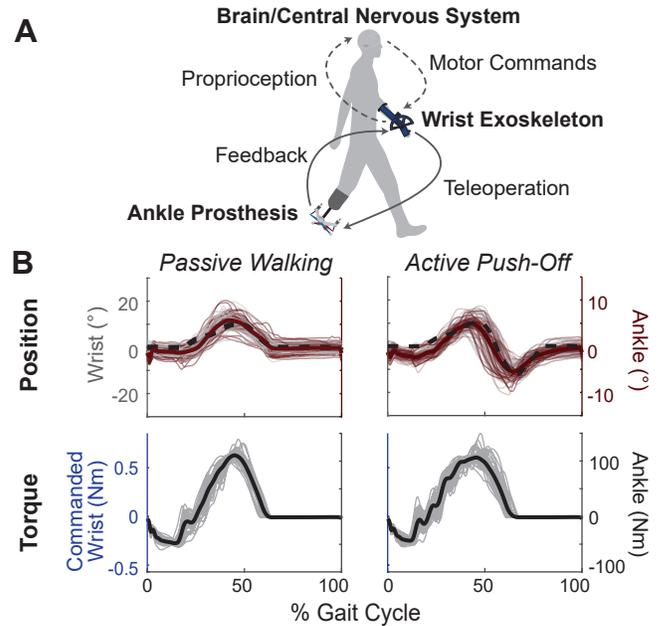

**Control Schemes:** We developed a position control scheme in which the prosthesis angle is commanded to a scaled position of the wrist angle. We tested position control with and without haptic feedback, where a user was able to feel torque at the wrist proportional to the ankle prosthesis torque.

**Pilot test:** We verified the feasibility and performance of the system with one participant with a transtibial amputation. Eventually we expect that participants will discover their own desired trajectories as they walk, but in this study we dictated desired trajectories to the participant in order to evaluate user ability to control the wrist exoskeleton. Both desired and measured trajectories were displayed on a monitor in front of the participant as they walked on a treadmill. We assessed the ability of the participant to control the prosthesis by measuring error between desired and measured wrist angle. We assessed mechatronic performance of the system by measuring error between desired and measured prosthesis angle.

The participant completed training trials that consisted of following two different desired sine wave trajectories while seated and standing, followed by walking with desired trajectories emulating passive walking or active push-off. Tests were completed over the span of two days, and each training and testing trial lasted five minutes. Data were analyzed for the last 60 seconds of each trial.

## Results and Discussion

We achieved good control fidelity of the ankle prosthesis, with error lower than human proprioception (RMSE =  $0.8^\circ$ , compared to ankle proprioception error of  $2.3^\circ$  [3]). Although the subject initially had high errors in wrist trajectory (RMSE =  $5.8^\circ$ ), by the end of the second day they were able to control the wrist exoskeleton with accuracy greater than human proprioception for both desired trajectories (RMSE =  $1.6^\circ$ , compared to wrist proprioceptive error =  $2.2^\circ$  [4]). Results from the second day are shown in Fig. 1B. Qualitatively, the participant preferred the haptic feedback conditions, which they said made position control more intuitive. However, we noticed that providing haptic feedback caused small oscillations in the torque profiles. Future

**Figure 1:** **A.** We use a wrist exoskeleton to both control and receive haptic feedback from an ankle-foot prosthesis to restore the motor control loop. **B.** The two desired trajectories with haptic feedback are shown, in addition to how well the wrist and ankle matched these trajectories and the resulting torque profiles. The dashed line indicates the desired trajectory, and bold lines indicate averages.

work will investigate the cause of these oscillations and mitigate them.

We developed the hardware and control schemes necessary to provide a person with amputation both real-time feedback and control of their prosthesis. We demonstrated the feasibility of this system by validating both our system performance and the ability of a user to voluntarily modulate wrist position in real time with only limited training.

## Significance

This teleoperation system will allow testing of novel prosthesis control and feedback strategies that could be used to provide more accurate sensory feedback and facilitate motor learning. Long-term, we aim to discover which parameters amputees intend to optimize during gait, and compare these strategies to those of automated prosthesis control systems.

# Stumble recovery strategies for healthy individuals and transfemoral prosthesis users

Maura E. Eveld<sup>1</sup>, Shane T. King<sup>1</sup>, Karl E. Zelik<sup>1</sup>, and Michael Goldfarb<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Vanderbilt University, Nashville, TN, USA

Email: maura.eveld@vanderbilt.edu

## Introduction

Transfemoral prosthesis users (TFPUs) fall 200x more often than healthy individuals [1]. In order to develop interventions (e.g., prostheses) to decrease their fall likelihood, it is important to understand (1) reflexive mechanisms that help prevent falls in healthy populations, and (2) deficiencies in recoveries of the TFPUs.

Concerning (1), it has been established that healthy individuals employ one of three *primary strategies* to recover from a stumble: elevating, lowering, or delayed lowering. However, we have observed that participants used one of two *sub-strategies*: with or without an aerial phase (i.e., jump). Only two prior studies have mentioned an aerial phase [2]; thus the frequency, causes, effects, and implications of these sub-strategies are unknown. This knowledge gap limits how prosthetic interventions are designed/controlled.

Concerning (2), TFPU stumble recovery has been rarely studied. In one study all TFPU participants recovered from perturbations [3], but the perturbation was simulated without a physical obstacle to clear. In the second all TFPUs fell, but stumbles were only elicited at 50% swing. Recovery strategies used/attempted were not consistent between studies, leaving a gap in understanding. A comprehensive characterization of TFPU stumble recovery strategies is needed to identify functional deficiencies of current prostheses, and inform design of next-generation prostheses to help prevent falls.

The overarching goal is to provide a better understanding of both healthy and TFPU stumble recovery by addressing the aforementioned knowledge gaps. Specifically, we aimed to: (1) Characterize the incidence of the aerial phase for each primary recovery strategy in healthy participants, across swing phase, and across speeds, and (2) characterize the recovery strategies of TFPUs for each limb across swing phase.

## Methods

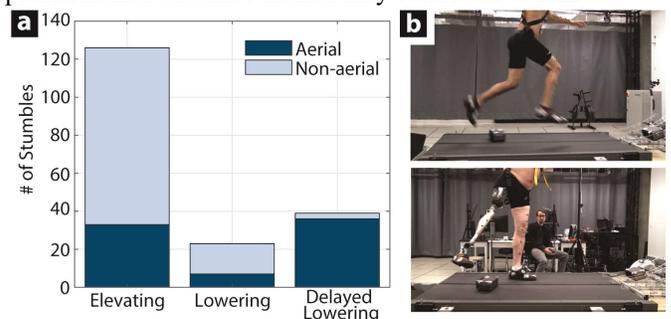

For (1), seven healthy participants were stumbled 28 times each at 1.1 m/s using our custom obstacle perturbation system [4]. One participant was tested at two additional speeds, 0.8 and 1.4 m/s. For (2), one TFPU participant was stumbled six times, three times per limb. Testing on additional TFPUs is ongoing and will be presented at the conference. The perturbations were targeted to occur at a range of points in swing phase. Ground-reaction forces and kinematics were collected and joint-level kinematics/kinetics were estimated. For each stumble, the swing percentage of perturbation was calculated and the strategy used/attempted was recorded.

## Results and Discussion

Regarding (1), the aerial phase occurred in 40% of recoveries for 1.1 m/s trials. It was used in 92% of delayed lowering strategies, 30% of lowering strategies, and 26% of elevating strategies (Figure 1). For perturbations during 40-70% swing phase, 90% of these resulted in aerial phases. For the single participant tested at multiple speeds, the aerial phase was employed in 92% of 1.4 m/s trials, 32% of 1.1 m/s trials,

and 7% of 0.8 m/s trials. Thus the aerial phase was more likely to be used to recover from mid to late swing-phase perturbations and at higher walking speeds. In order to accomplish this aerial recovery with a prosthetic device, an active ankle joint may be required, and device loading capabilities may need to be considered in order to land safely.

Regarding (2), the TFPU participant recovered from all stumbles on his prosthetic side. For the early/mid-swing perturbations, the participant lowered behind the obstacle with the prosthetic limb, followed by a short contralateral step and a hop to clear the obstacle. For the late-swing perturbation, the participant used ipsilateral circumduction to clear the obstacle instead of a hop. On the sound side, the participant attempted an elevating strategy for the early-swing perturbation, and attempted a lowering strategy for mid/late-swing perturbations, but ultimately fell. Thus, sound side stumbles were more dangerous for this TFPU. We are evaluating if this observation holds true in other TFPUs. For stumbling on the prosthesis side, a lack of active knee flexion may contribute to the prolonged recovery (i.e., more recovery steps compared to healthy controls). For stumbling on the sound side, a lack of active plantarflexion and knee flexion may contribute to falls.

**Figure 1:** (a) Breakdown of strategies used in healthy stumble study. (b) Aerial phase during recovery for healthy participant (top), and circumduction during recovery for TFPU participant (bottom).

## Significance

This is the first study to quantify the prevalence of the aerial phase during healthy stumble recovery, and also the first study to analyze the recovery/falls of a TFPU across a range of swing phase perturbations with a physical obstacle to clear. The insights gained from both healthy and TFPU stumble recovery provide a roadmap for how to successfully design reflexes into a robotic lower-limb prosthesis in order to reduce fall incidence and subsequent injury for this TFPU population (300,000 in U.S. alone).

<sup>2</sup>School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, USA

Email: bmcclain3@gatech.edu

## Introduction

Of the lower limb joints, the knee joint creates the smallest amount of total positive mechanical work when walking on level ground; however, its role is greater during inclined walking. The knee extension moment increases during uphill walking, which has been correlated to increased knee extensor muscle activation. This can lead to elevated knee joint loads. Therefore, providing assistance at the knee joint during early stance, when the knee exhibits a larger knee moment, has the potential of reducing the knee extensor activation and the knee joint load [1]. Individuals with walking difficulties often exhibit higher tibiofemoral forces compared to able bodied individuals, which can impede mobility and the patient's independence. A previous study has investigated the knee joint load in children with crouch gait, however the methodology exhibited some limitations, involving not considering co-contraction or variations in user's muscle activity [2]. To address this, we utilized an electromyography (EMG) -informed neuromusculoskeletal model to estimate the knee joint reaction load during walking. The following details preliminary results to investigate the capability of a robotic bilateral knee exoskeleton for reducing the knee joint load in able-bodied adults walking uphill. The primary hypothesis is that the assistance provided at the knee joint during early stance will reduce the quadriceps force required for walking and thus decrease the peak knee joint load during early stance compared to the unpowered condition.

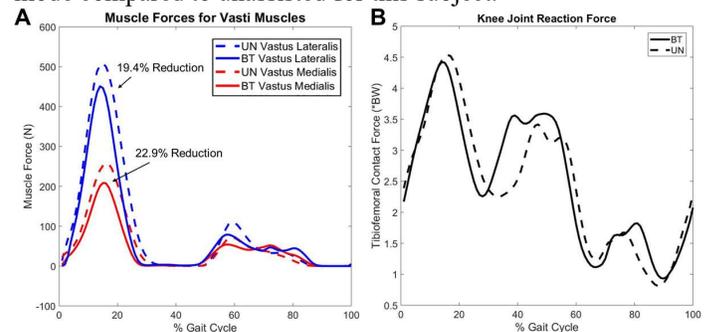

## Methods

This study was approved by the Georgia Institute of Technology Institutional Review Board. The following displays initial results for one able bodied adult subject. The experiment involved two sessions, training and data collection. The subject walked at 1.1 m/s on a 15% gradient treadmill while wearing the bilateral powered knee exoskeleton. Knee extension assistance was provided by a biological torque controller during early stance, 0-30% of gait cycle. EMG data were collected on six muscles associated with knee extension and flexion (vastus lateralis, vastus medialis, rectus femoris, biceps femoris, semitendinosus, and lateral gastrocnemius) on the right leg. Motion capture, force plate, and device data were also collected. Utilizing MATLAB, Vicon, and OpenSim the collected data were analyzed to calculate the muscle forces and joint reaction load at the knee joint [3][4].

## Results and Discussion

During walking with powered assistance, there was a decrease in the peak knee extensor muscle force RMS compared to the unpowered condition. Additionally, it is shown that the muscle force duration is decreased in the powered condition compared to unpowered (Figure 1A). This is due to a decreased duration of muscle activation when the assistance is active. There is also a reduction in the peak knee joint force during early stance, where the knee extensor muscles are the largest contribution to the joint

load (Figure 1B). These results support the primary hypothesis that the assistance is able to reduce the quadriceps forces and the knee joint load during early stance, when the assistance is active. However, there is an increase in the knee joint reaction force later in the gait cycle when the assistance is not active. This increased joint load has been correlated to increased activation of the hamstring muscles as well as the gastrocnemius in assistance mode compared to unassisted for this subject.

**Figure 1:** A. Muscle Forces for Vasti Muscles between unpowered (UN) condition and Biological Torque (BT) assistance with the percent RMS reduction labeled. B. Knee Joint Reaction Load between unpowered condition (dashed) and Biological Torque assistance (solid). Peak reaction force exhibited a 2.5% \*BW reduction when assistance was provided compared to the unpowered condition.

## Significance

This study investigated the effect exoskeleton assistance has on the knee joint load of able bodied adults. Our preliminary results show that the exoskeleton assistance is able to reduce the muscle force of the primary knee extensor muscles and reduce the knee joint load when the assistance is active. This analysis method exhibits some limitations, including the optimization weighting may introduce some error in tracking the moment and muscle activation, the muscle force is determined from activation normalized to the maximum voluntary muscle activation of a specific user, which can be difficult to capture even with a detailed protocol, and the results are still an estimate of the actual joint load. In future works, we aim to study the effect exoskeleton assistance has on pediatric patients with walking difficulties due to abnormalities at the knee joint, such as crouch gait or genu recurvatum. The EMG informed method is critical to better estimate the joint loads in these patients, as there is frequently high coactivation while walking.

# An automatic human-in-the-loop tuning algorithm for a robotic ankle prosthesis depends on an understanding of gait quality

Kinsey Herrin, Sam Kwak, Audra Davidson, Navya Katragadda, Margaret Berry, Young-Hui Chang

Georgia Institute of Technology  
Email : kinsey.herrin@gatech.edu

## Introduction

There are more than 1.6 million people living with limb loss, which is expected to more than double by 2050.<sup>1</sup> Powered robotic prostheses may improve metabolic cost, joint loading, and overall mobility<sup>2</sup>, but the tuning process associated with a powered prosthesis for an individual user is problematic in that it is: 1. time consuming for busy clinicians and 2. currently completed in clinical settings based on subjective, observational metrics. These problems represent a barrier for access to technology, so efforts to streamline timing towards receipt of a natural physiologically functioning prosthesis would be beneficial both for patients and providers. However, this challenge assumes that there is an ideal, natural physiological gait pattern already defined for humans wearing a powered prosthesis. There are many ways to measure gait, making it challenging to determine a “gold standard” ideal gait for an individual. Studies have attempted to combine biomechanical measures (joint angles, kinetics, etc.) to create indices of gait quality, but it is unclear what measure is most sensitive to changes in gait and which is an optimal “gold standard” for which a device should be tuned against. Therefore, in this preliminary study we test four metrics of gait quality on two human subject groups: healthy controls for whom we have applied systematic joint restraints and an individual with a transtibial amputation using a prosthesis emulator.

## Methods

IRB approval for this study was obtained prior to enrollment of subjects. Following informed consent, five healthy control subjects walked in three joint-immobilization conditions including an ankle immobilizer orthosis, a knee orthosis locked in 180° extension, and the combined ankle orthosis and knee orthosis together. Subjects also walked without wearing any restraints as a control condition. One subject with a transtibial amputation walked with his everyday passive prosthesis and a prosthesis emulator<sup>3</sup> while the tuning parameter space was explored for “optimal” gait quality according to current clinical procedures. Gait quality was assessed using the Prosthetic Observational Gait Score (POGS)<sup>4</sup>, the Gait Deviation Index (GDI)<sup>5</sup>, the Gait Quality Index (GQI)<sup>6</sup>, and kinetic data (impulse asymmetry). Data were compared to control values using a repeated measures ANOVA with a significance level set to  $\alpha=0.05$ .

## Results and Discussion

Data for control subjects showed that impulse asymmetry could discriminate between the ankle immobilized condition and the combined knee and ankle conditions. This trend was followed by the POGS as well. Neither metric could discriminate differences between the knee immobilized condition and the other conditions. The Gait Deviation Index and Gait Quality Index were unable to discriminate between any of the three immobilized conditions. (See Fig 1) This data may indicate that while time consuming, POGS represents an accurate means for determining natural gait. Additionally, load sensors incorporated into a prosthesis to measure impulse could provide valuable information as to proper tuning of a powered device. GDI and

### Healthy controls with joints immobilized

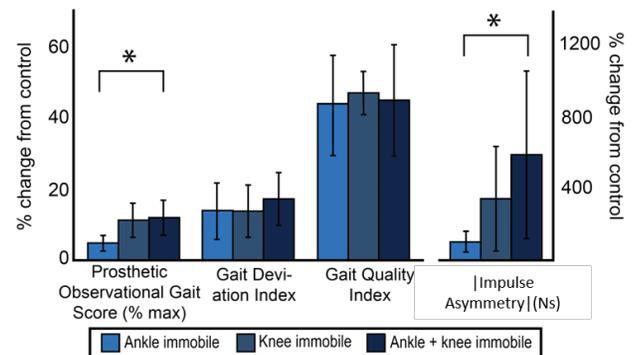

Fig 1. POGS, GDI, GQI and Impulse Asymmetry for healthy controls with systematic joint restraints

### Patient with below-knee amputation matched to control

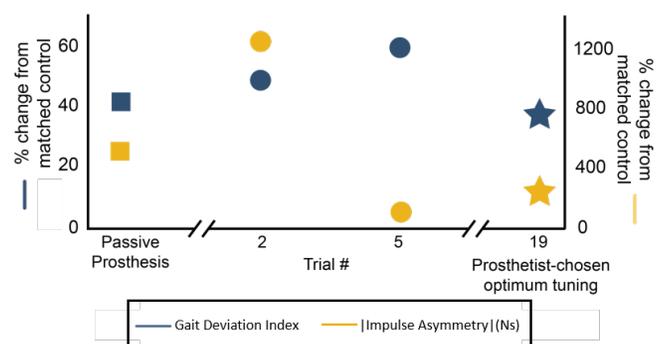

Fig 2. GDI and Impulse Asymmetry for individual with transtibial amputation using everyday, passive prosthesis and powered prosthesis emulator

Impulse Asymmetry were calculated for the passive prosthesis and 19 tuning trials for the powered prosthesis emulator. (See Fig 2) As the device was tuned according to standard clinical procedures, both GDI and Impulse Asymmetry improved with use of the powered prosthesis compared to baseline measures with the subject’s everyday prosthesis. Sensors that would allow for this information to be available in vivo could reduce time spent during the initial and follow up tuning processes.

## Significance

Broader understanding of what constitutes normal, physiological gait and how to quantify it is imperative for the advancement of prosthetic devices if they are going to be applied clinically.

# Use of Nearly-Invisible, Non-restrictive Sensory Insoles as Treatment for Idiopathic Toe Walking: A Case Series

Mark Geil<sup>1</sup>, Kinsey Herrin<sup>2</sup>, Leila Rahnama<sup>1</sup>, Cylie Williams<sup>3</sup>, Justin Jarrells<sup>1</sup>, Micah Poisal<sup>1</sup>, Erica Sergeant<sup>1</sup>, Kimberly Soulis<sup>1</sup>

<sup>1</sup>Kennesaw State University, <sup>2</sup>Georgia Institute of Technology, <sup>3</sup>Monash University, Melbourne, Australia  
Email: \*[mgeil@kennesaw.edu](mailto:mgeil@kennesaw.edu)

## Introduction

Idiopathic Toe Walking (ITW) is diagnosed in children three and older who walk on their toes despite no apparent contributing disorders and can result in severe and debilitating loss of ankle range of motion when it persists into childhood<sup>1</sup>. ITW gait is characterized by initial contact with the toe instead of the heel and early heel rise in stance phase. ITW is a diagnosis of exclusion that is only given when all other orthopedic, developmental, and neurological causes have been ruled out<sup>2</sup>. A critical barrier to effective treatment of ITW in children is that current approaches are limited to controlling symptoms by restricting motion of the foot and ankle or manually or surgically altering tendon length. These approaches are variably effective and are focused on orthopedic presentation and not underlying etiologies<sup>3</sup>. Based upon previous studies, we believe that some children with ITW are sensory-seeking<sup>2</sup>, and may respond well to in-shoe interventions. In this study, we investigated a novel treatment intended to address tactile stimulation of the plantar surface of the foot, without constraining joint movements.

## Methods

Children recruited for the study were between ages 4 and 12, had a clinical diagnosis of ITW, and were at least six months post any treatment (e.g. orthoses, Botox, serial casting, etc.). To be eligible, they also had to display at least 5° dorsiflexion range of motion and screen as possibly or definitely sensory-seeking on the Short Sensory Profile. Following informed consent, subjects were fit with flexible, textured sensory insoles (Fig. 1) and instructed to wear for a four-month period in this IRB approved study. At both initial fitting and final four-month assessment, instrumented 3D gait analysis was conducted in three conditions: shoes and insoles, shoes only, and barefoot. Additionally, the weight bearing lunge test was conducted at each assessment to assess range of motion, and parental feedback was assessed using the Orthotic and Prosthetic User Survey (OPUS).

Figure 1: Flexible, textured insoles (Naboso Technology, Brooklyn, NY)

## Results and Discussion

Two subjects have completed the trial to date, a five year old male (A) and a seven year old female (B). Parents of both subjects reported 100% favorable results on the OPUS regarding factors related to device fit, appearance, and durability. These results are somewhat expected given the non-invasive and nearly invisible nature of the insoles hidden inside the child's shoes. Temporospatial parameters with respect to footwear condition (barefoot versus shod with insoles) and time condition (baseline versus follow-up) were inconsistent, but indicate the possibility

of improvement. For example, Subject B showed little change in average speed at baseline when the insoles were introduced (1.44 vs 1.40 m/s), but faster walking at follow-up only in the insole condition (1.57 with shoes and insoles, 1.36 barefoot). Gait Variability Index also decreased at follow-up for this subject. Ankle range of motion increased at follow-up in both children, by 5.2 and 5.1 degrees. In both subjects, percent of steps with initial heel contact (not toe contact) improved with insoles at baseline, and improved at follow-up in both the barefoot and insole conditions (Fig. 2). Interestingly, Subject B showed 100% heel contact with the insoles at both baseline and follow up time points, with reduced knee flexion angle at initial contact. In this limited sample, sensory insoles were effective at controlling ITW upon initial donning and after 4 months of wear.

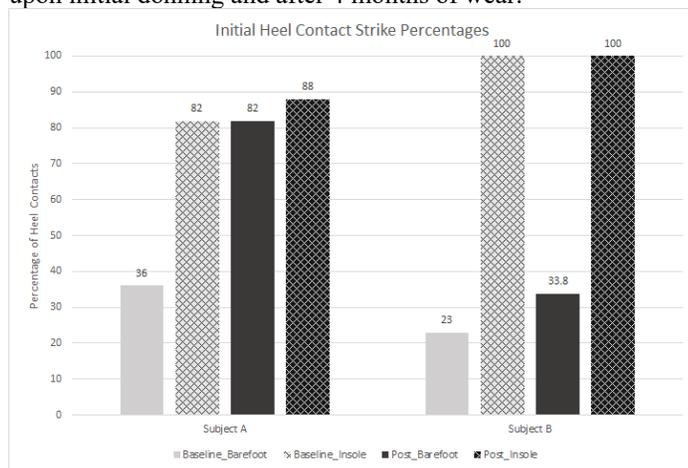

Fig 2: Normal Heel Strike percentage at baseline and follow-up

## Significance

While limited in sample size, the results of this study are promising, because current clinical treatments are aimed at mechanically limiting joint motion or even surgically altering tendon length. This treatment addresses a possible etiology for ITW (at least in some children) with the potential to improve our understanding of this unique clinical presentation and remove the term “idiopathic” from the diagnosis.

## Introduction

As of 2005, approximately 35% of the 1.6 million people living with limb loss in the US were women [1]. Compared to men, women with leg amputations experience greater: pain, dissatisfaction with prosthetic fit and appearance, number of prostheses received but also greater rejection rates, and limitations in footwear [2, 3]. Ability to wear appropriate shoes is important for social integration, and while prostheses exist to accommodate different heel heights their effect on walking biomechanics has not been fully studied. The aim of this study was to assess the effects of walking with different heel heights and heel height adjustable prosthetic feet on gait biomechanics of women with transtibial amputation (TTA), as well as the effects of walking with a misaligned prosthetic foot.

## Methods

Participants performed over-ground walking trials at self-selected normal speeds wearing footwear with three different heel heights: flat (0 rise), athletic shoe (1.25" rise) and heel (2" rise); and two types of adjustable prosthetic feet: Runway (Freedom Innovations, Irvine, CA), and Accent (College Park, Warren, MI). Prosthetic configurations (prosthesis+shoe) were randomized and participants were blinded to the prosthetic foot.

The prosthesis was first aligned by a prosthetist to the athletic shoe, followed by data collection. The athletic shoe was then switched to a flat shoe, without prosthesis adjustment, followed by data collection. Participants were then allowed to self-align the prosthesis to the flat and heel shoe, followed by data collection for both shoes. An unloaded self-aligned dorsiflexion angle was measured with a goniometer after each realignment. This protocol was repeated with the second prosthesis.

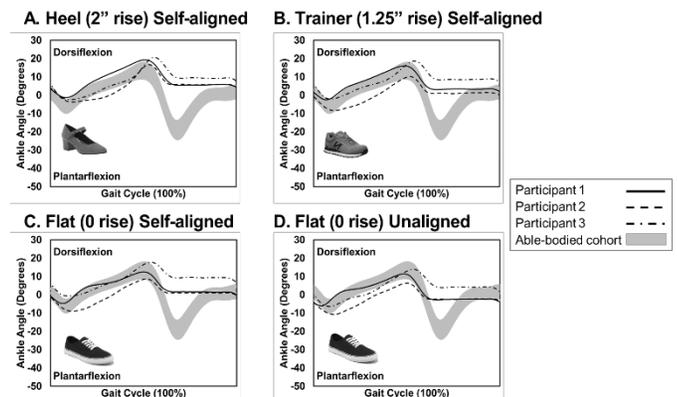

Kinematic data of the lower limbs, trunk and pelvis were collected with a digital motion capture system (Motion Analysis Corporation, Santa Rosa, CA) at 120 Hz. Kinetic data were collected at 960 Hz with six walkway-embedded force plates (AMTI, Watertown, MA). Data were analyzed with Visual 3D (C-Motion, Inc. Germantown, MD).

## Results and Discussion

Three female participants (36±9 yrs, 1.62±0.07 m, 64.2±11 kg) with unilateral TTA participated. Time since limb loss was on average 14 (±6) years. All participants accommodated quickly to each condition, despite differences in footwear (heel height and compliance) and limited time to adjust. All participants were able to self-align the foot without difficulty. Findings from only one prosthesis are reported, as both feet had similar results.

Participants maintained consistent prosthetic side kinematics (knee, hip, pelvis obliquity and tilt motion) through ankle joint (set alignment) accommodation. Adaptation of the prosthetic ankle joint allowed for similar ankle motion across heel heights with a shift towards increased dorsiflexion when wearing higher heel heights (Fig 1 A-C). Consistent vertical ground reaction force (GRF) peaks were present across heel heights, however

slight delays in second GRF peak occurred with 2" heels, accompanied by longer stance times. Wearing flat shoes with misaligned prosthesis required kinematic adjustments and resulted in an expected shift towards plantarflexion (Fig. 1 C-D). Misalignment led to changes in knee and pelvis motion, and were accompanied by altered first and second GRF peak magnitudes.

**Figure 1:** Effects of different heel heights (A-C) and ankle alignment (C-D) on ankle flexion of the prosthetic foot-shoe complex.

Overall, the three prosthesis users adapted to each footwear and alignment condition with minimal changes in kinematics and kinetics. This suggests that using heel height adjustable prostheses can generate consistent gait dynamics without new compensatory mechanisms when walking with different heel height shoes. The participants also expressed the importance of having the option to wear different shoes for daily activity and the need for an adjustable prosthesis. Future work includes expanding cohort size beyond this pilot study, and bench testing of these prostheses with footwear to characterize their mechanical function for aiding interpretation of these results.

## Significance

These results may inform on the influence of different shoes on prosthetic gait, and the utility of heel height adjustable prosthetic feet in promoting consistent biomechanics. This study helps address the unique considerations for women with amputation during rehabilitation, and may aid development of more evidence-based, sex-inclusive practice guidelines.

## Introduction

Toe joint can impact a gait economy and performance while undergoing substantial flexion/extension during normal walking. To provide the benefits of a toe joint to the amputees, researchers have attempted to mimic human toe joint in their prostheses. [1] proposed a powered toe joint, and [2] applied interchangeable springs to mimic a human toe joint during prosthetic walking, which inevitably require additional parts, and thus more weight.

We previously proposed the structural pattern and material of the 3D printed prosthetic foot in [3]. However, it is not known yet how the joint kinematics/kinetics and toe joint bending are affected by the new design. Thus, in this study, we investigate how the ankle/toe joint kinematics/kinetics vary in accordance with the 3D printed prosthetic foot characteristics while walking.

## Methods

**Figure 1:** 3D printed prosthetic foot; (A) re-entrant structure using ABS, (B) re-entrant honeycomb with bending zone (BZ) using onyx [3]

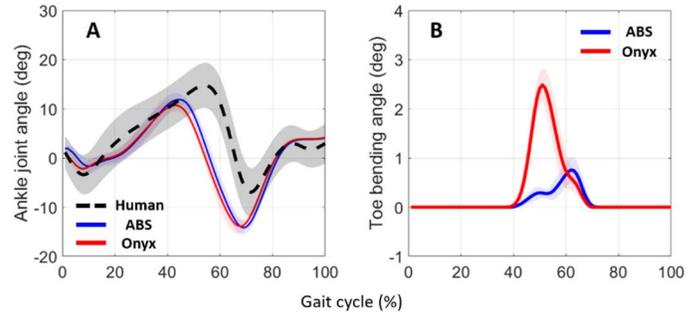

Note that there was no stiffness difference between two proposed foot structures (Figure 1) under the small bending conditions according to the simulation result in [3]. Therefore, we focus only on the foot material in this paper.

A treadmill walking experiment was conducted using a powered transfemoral prosthesis (AMPRO II, [4]) with two different feet (ABS and onyx foot), depicted in Figure 1. A healthy subject (male, 31 yrs., 1.70 m, 70 kg) participated using an L-shape simulator and walked at his preferred speed (0.60 m/s). Joint kinematics were recorded by the optical encoders on the prosthesis. Joint kinetics were estimated based on the current from the actuators of the prosthesis. The toe bending was measured using IMUs, defined as the relative angle between the forefoot and midfoot. The control framework adopted was impedance control at the ankle and a hybrid of impedance and tracking control at the knee [4].

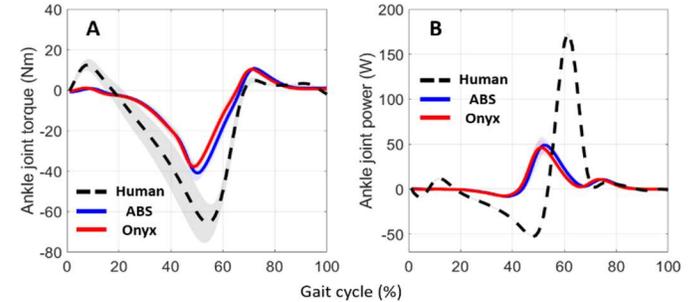

## Results and Discussion

The onyx foot had lesser ankle dorsi-flexion than the ABS foot (Figure 2A), resulting in lesser ankle joint torque (Figure 3A). However, the difference is minimal. In Figure 2B, the greater toe flexion (2.46 °) was clearly shown when the onyx foot is used, while that of the ABS foot is smaller (0.74 °). Yet, differing from the simulation result (15 °) in [3], this flexion is still small, even in the case of onyx. This may indicate that the toe stiffness of both feet is still too stiff. Also, an insufficient loading condition due to the simulator and less body weight (compared to the simulation) can be another possible reason of a small toe flexion. Further studies should be conducted with a diverse compliant toe.

In Figure 3, the ABS foot shows a slightly larger joint torque and power than the onyx foot, even though not significant.

**Figure 2:** Kinematic comparison between ABS, onyx foot, and human data; (A) ankle joint angle (B) toe joint angle. Bold lines and shaded regions refer to the average and  $\pm 1$  s.d. of 20 consecutive steps.

**Figure 3:** Kinetic comparison between ABS, onyx foot, and human data; (A) ankle joint torque (B) ankle joint power. Bold lines and shaded regions refer to the average and  $\pm 1$  s.d. of 20 consecutive steps.

Compared to the human data at a faster walking speed of 0.80 m/s [5], both feet show smaller dorsiflexion and earlier push-off, possibly due to a slight mismatch in the timing at the controller. Also, note that the ankle torque and power are smaller due to the restricted torque limit of the actuator on the prosthesis.

In this study, both feet are similar in most measures. However, since onyx foot shows more toe bending, which is more similar to human data, the onyx foot would be a preferred option.

## Significance

This study shows the ankle/toe joint kinematics/kinetics using two different 3D printed feet with new structure to replicate the toe joint. Even though there was no significant difference between two proposed feet in most of the measures, still one foot showed relatively significant toe bending. This can be a good starting point for the new consideration of prosthetic foot design. Also, the proposed foot shows almost half weight (540 g) compared to the previous studies [1], [2]. Further designs for toe joint and more realistic loading conditions will be considered to maximize the biomechanical benefits of 3D printable prosthetic feet during walking.

# Adjustable prosthetic socket improves symmetry of transfemoral amputees during walking

Joshua R. Tacca<sup>1,2</sup> and Alena M. Grabowski<sup>2</sup>

<sup>1</sup>Dept. of Mechanical Engineering & <sup>2</sup>Dept. of Integrative Physiology, University of Colorado, Boulder, CO, USA  
joshua.tacca@colorado.edu

## Introduction

Adults with unilateral transfemoral amputation walk using prostheses attached to rigid prosthetic sockets that surround the residual limb. A standard socket used by people with transfemoral amputation is a suction socket that is molded to fit the users residual limb and uses a valve to release air and create a sealed connection between the socket and leg.

During walking, many people with unilateral amputation use a passive prosthesis, which typically results in asymmetric biomechanics such as greater loading of the unaffected (UL) compared to affected leg (AL) [1]. Asymmetry may increase osteoarthritis risk [2] and low-back pain [3] compared to non-amputees. Socket design can influence AL comfort and may change the biomechanics of both legs. Board et al. [4] found that users of a vacuum-assisted suction socket had more symmetric step lengths and ground contact times compared to users of a standard suction socket. An adjustable socket may further improve comfort and biomechanical symmetry during walking. Quorum Prosthetics (Windsor, CO) has developed a socket that uses adjustable panels to provide a custom fit to people with lower limb amputation (Quatro). Due to a better fit, we hypothesize that use of the Quatro socket will decrease contact time and peak ground reaction force asymmetry of people with transfemoral amputation compared to using a suction socket.

## Methods

Three subjects (2M, 1F;  $46.0 \pm 18$  yrs;  $70.7 \pm 5$  kg;  $1.74 \pm 0.01$  m) with unilateral transfemoral amputation walked on a force measuring treadmill (Bertec, Columbus, OH) at 0.75 – 1.50 m/s at 0° and at 1.25 m/s at  $\pm 3^\circ$  and  $\pm 6^\circ$ . Subjects walked with a standard suction and an adjustable Quatro prosthetic socket.

We measured perpendicular ground reaction forces (GRFs) at 1000 Hz, filtered them using a 4<sup>th</sup>-order low-pass Butterworth filter with a 30 Hz cut-off and used a 20 N GRF threshold to calculate contact time ( $t_c$ ). We also detected 1<sup>st</sup> and 2<sup>nd</sup> peak GRFs ( $f_{z1}$  and  $f_{z2}$ , respectively) of the AL and UL from 10 strides (Matlab, Mathworks, Natick, MA). In addition, we calculated the symmetry index (SI) of each of these parameters using the equation (Eqn. 1) defined by Robinson et al. [5], where X refers to a calculated variable and 0% is perfect symmetry.

$$SI = \left| \frac{X_{unaffected} - X_{affected}}{0.5(X_{unaffected} + X_{affected})} \right| \times 100\% \quad (1)$$

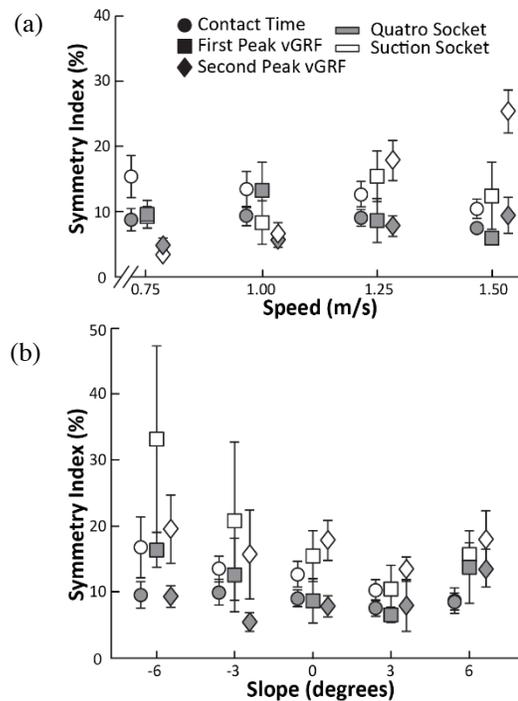

We constructed a linear mixed effects model ( $\alpha = 0.05$ ) to determine the effect of socket type and speed on each SI when walking on a level treadmill. Then, we constructed a linear mixed effects model ( $\alpha = 0.05$ ) to determine the effect of socket type and treadmill slope on each SI when walking at 1.25 m/s (R-Studio, Boston, MA).

## Results and Discussion

For level walking, when using the Quatro compared to suction socket the magnitude of  $t_c$  SI decreased by 4.4% ( $p = 0.0013$ ) but for both sockets there was no effect of speed on  $t_c$  SI ( $p = 0.1037$ ; Fig. 1a). When walking on slopes using the Quatro compared to suction socket the magnitude of  $t_c$  SI decreased by

3.5% ( $p = 0.0118$ ) and for both sockets the magnitude of  $t_c$  SI decreased by 0.4% per 1° increase in slope ( $p = 0.0133$ ; Fig. 1b).

During level walking, there was no effect of socket or speed on  $f_{z1}$  SI ( $p = 0.4175$ ,  $p = 0.9727$ ; Fig. 1a). Across slopes, there was no effect of socket or slope on  $f_{z1}$  SI ( $p = 0.0757$ ,  $p = 0.0587$ ; Fig. 1b). During level walking with the Quatro compared to the suction socket, the magnitude of  $f_{z2}$  SI decreased by 5.9% ( $p = 0.0083$ ) and for both sockets  $f_{z2}$  SI increased by 17.4% per 1 m/s increase in speed ( $p = 0.0001$ ; Fig. 1a). When walking across slopes using the Quatro compared to the suction socket, the magnitude of  $f_{z2}$  SI decreased by 8.1% ( $p = 0.0008$ ) but for both sockets there was no effect of slope on  $f_{z2}$  SI ( $p = 0.7059$ ; Fig. 1b).

**Figure 1.**  $t_c$ ,  $f_{z1}$ , and  $f_{z2}$  symmetry indices across (a) speeds and (b) slopes. Error bars are SEM. 2 of 3 subjects walked at 1.50 m/s in (a).

## Significance

Decreased asymmetry using the Quatro compared to suction socket may be due to improved socket fit and comfort. Future studies will examine prosthetic socket fit by measuring socket pistoning during walking. The results from this study can be used to inform prosthetic socket designs.

## Acknowledgments

We thank Joe Johnson and Quorum Prosthetics.

## Introduction

As of 2005, 1.6 million people were living with a loss of limb, with this number being projected to more than double by the year 2050 [1]. Poor prosthetic fit increases the likelihood of those who have had an amputation having a secondary complication [2].

Depending upon the setting, a prosthetist could evaluate the fit of their patient's device during treadmill or overground walking. Previous studies have found that peak vertical ground reaction force (GRF) is greater during overground walking compared to treadmill in healthy subjects [3]. Additionally, previous studies have found that those with transfemoral amputations have greater vertical and anterior/posterior (A/P) GRF in their sound limb compared to their prosthetic limb [4].

The aim of this study is to compare GRF of subjects with transfemoral amputations during overground and treadmill walking. We hypothesize that there will be greater GRF on the sound side compared to the prosthetic side and greater GRF during overground compared to treadmill walking.

## Methods

Eleven individuals with transfemoral amputations were recruited via clinician referrals and local support groups (age: 24 to 63 years, weight: 59.0 to 130 kg, and height 1.6 to 1.9 m). All participants provided written informed consent prior to participating in this IRB-approved study.

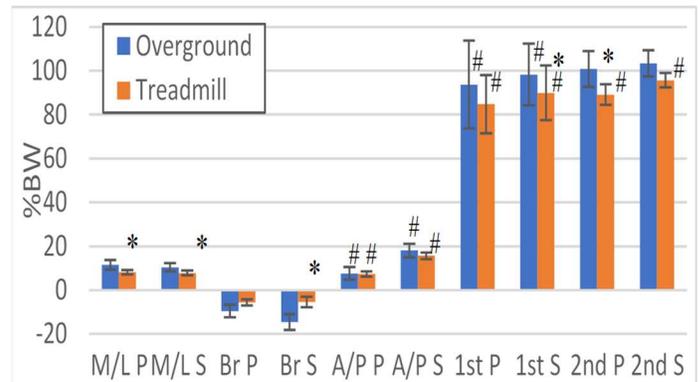

Subjects were fitted with a full body marker set and recorded using a 12-camera Vicon Vantage system to measure gait kinematics. During 10 overground trials, subjects walked across the lab space taking 1-3 steps on the Bertec instrumented treadmill per trial at the midpoint of the walking bout. During the 2 to 10 treadmill trials, 9 to 12 steps were recorded per trial, with the speed set to match their self-selected overground speed. GRF data was collected at 1000 Hz for all trials.

GRF data was filtered using a fourth-order Butterworth filter with a 20 Hz cutoff frequency and then normalized to body weight (%BW). Heelstrike and toeoff were determined as the moment when the vertical GRF exceeded and went below 50 N. Output from the Vicon system was reviewed to determine which trials needed to be omitted from the analysis due to the subject crossing over onto the wrong force plate.

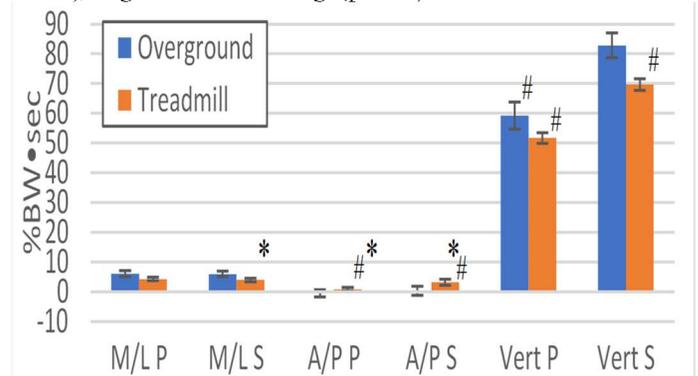

GRF variables including A/P (break and peak), medial/lateral (M/L), and vertical (1<sup>st</sup> and 2<sup>nd</sup> peak) peaks and impulses were averaged over all trials for each subject and analysed. A paired t-test was performed to compare prosthetic and sound limb outcomes as well as walking surfaces (overground or treadmill) for each GRF parameter [5].

## Results and Discussion

Sound side loading was greater than prosthetic side loading during overground and treadmill walking (Figures 1, 2). This supports previous studies which found that those who have an amputation favour putting weight through their sound limb.

**Figure 1:** Average peak GRF output in prosthetic (P) and sound (S) limbs across subjects \*significant for overground and treadmill trials ( $p < 0.05$ ), #significant between legs ( $p < 0.05$ )

**Figure 2:** Average impulse in P and S across subjects \*significant for overground and treadmill trials ( $p < 0.05$ ), #significant between legs ( $p < 0.05$ ).

GRF outputs were greater on average in overground trials compared to treadmill (Figure 1, 2). If the goal is to assess the prosthetic side, M/L peak, 2<sup>nd</sup> vertical peak and AP impulse will likely be less on a treadmill compared to overground. However, they are correlated ( $r = 0.63$  to  $0.69$ ) indicating the treadmill may provide some valuable information that reflects overground walking.

## Significance

Given the difference in GRF between overground and treadmill walking, clinicians should be wary of evaluating fit and alignment of prosthetic devices by having their patient walk on the treadmill. Additionally, researchers should be wary of the limitations associated with testing persons with an amputation during treadmill walking.

## Introduction

When walking, individuals with transfemoral amputation (TFA) use compensatory strategies which often lead to asymmetric joint biomechanics, chronic leg and back pain, joint degradation, increased energetic demands, and increased chance of osteoarthritis.<sup>1,2</sup> Specifically, the hip has to compensate for power lost from missing joints.<sup>3</sup> Powered prostheses are one option of improving gait as they are able to provide similar biological assistance profiles across different walking modes.<sup>4</sup> Our hypothesis is that a powered prosthesis will generate improved bilateral biomechanics than current clinically available passive prostheses, which was initially evaluated based on joint kinematic comparisons.

## Methods

Three subjects with a unilateral transfemoral amputation (male,  $51 \pm 21.1$  years old,  $1.78 \pm 0.07$  m,  $82 \pm 15.5$  kg, K3/K4) consented to participate in this IRB approved study. Subjects performed level and sloped walking on an instrumented treadmill (Bertec, Columbus, OH) using their everyday prosthesis and our powered knee and ankle prosthesis at 0 deg, +7.5 deg, and -7.5 deg. Data was collected using a motion capture system (Vicon, Centennial, CO). Analysis was performed using custom built prosthetic models in OpenSim, an open-source musculoskeletal modeling and simulation platform.

## Results and Discussion

The results show that the inverse kinematics (IK) were symmetrical to biological signals when using the powered device versus their passive device. Specifically, the ankle kinematics on the prosthetic side show increased plantarflexion for both the level and incline walking trials. Furthermore, the intact side shows a reduction in the amount of plantarflexion explained by the ability of the prosthesis to contribute power to push the user forward. No

significant changes were seen in the knee kinematics. It also can be seen that there no major changes in the hip kinematics which may be explained by the additional mass of our prosthetic device as the user may still have to compensate with their hip joint to a certain extent. With the powered prosthesis, the assistance shown during these walking tasks could potentially help reduce the risk of future hip and back related musculoskeletal pathologies. The key result is that powered prosthetic technology may be helpful in restoring functional gait across multiple ambulation modes.

## Significance

Creating smarter powered prostheses for assisting TFA is an important area of research as these devices can restore lost biomechanical function and potentially improve quality of life. For this type of technology to be translated to modern clinical practice, these devices must show improved efficacy over current clinical standards. This is one step in allowing powered prostheses to restore seamless and natural movement to the user.

## Introduction

Wearable robotic devices have the potential to reduce individuals' metabolic costs during walking. However, the success of these devices depends on the ability to appropriately tune the devices' control parameters on a subject-specific basis. As the optimal parameters will likely vary as the person performs different tasks, this must be performed continuously throughout use. One way to obtain these control parameters is through "body-in-the-loop" optimization or real-time optimization based on human physiological data. This approach has been used successfully to tune assistive devices using a participants' metabolic cost data while they walked on a treadmill at a fixed speed [1-3]. Ingraham et al. expanded on this idea by using data from various sensors and linear regression to predict metabolic costs for a variety of activities [4]. While successful, the predictions had error rates three times that of the minimal detectable change (MDC) of metabolic cost for steady-state walking of 17 W [5]. Here, we expand upon existing work by developing a generalizable model using machine learning to predict metabolic costs for multiple activities and individuals.

## Methods

We analyzed data from an open-source dataset [4], which included 8 people performing 22 activities while wearing 15 sensors. We divided our sensor sets into local and global signals. Local signals included data from 6 triaxial accelerometers and 8 surface electromyography electrodes. Global signals included data from an electrodermal sensor and skin temperature monitors, a heart rate monitor and a portable respirometer that collected oxygen consumption, carbon dioxide production, breath frequency, and minute ventilation. The data were filtered and reduced so all resulting features corresponded to one vector per second. This technique assigns a single feature vector to each predicted metabolic cost value on a uniform timescale.

We applied machine learning models including Linear Regression, K Nearest Neighbors (KNN), Bayesian Ridge, a Decision Tree, a Neural Network, and a Random Forest. Each model was built using features from the local signals only, global signals only, and all signals. Additionally, we built a model using only data from a Hexoskin (Hexo) suit, which included global signals and waist accelerometry, to demonstrate performance for a commercially available wearable device. We compared prediction error between each model for each set of data. Model performances were cross-validated using an 80/20 shuffle split, leave one activity out, and leave one subject out.

## Results and Discussion

For the shuffle split approach KNN, Decision Tree, and Random Forest models had the lowest error rate regardless of the dataset (Fig. 1). For leave one subject out, Bayesian Ridge and Linear Regression with Global and Hexo signals generated the best

performance. For leave one activity out, Neural Network had the best performance with Hexo and Global signals.

Though our results show promise in making predictions, our study was limited by the relatively small number of individuals and activities. Thus, the models made predictions consistent with observed data, as demonstrated in shuffle split, and performed worse in leave-one-out analyses for unseen individuals and data. The appropriate algorithm should be selected based on performance across all three cross-validation techniques as a result. Accordingly, we recommend the use of KNN and Random Forest as they have low errors with shuffle split and their performance is more robust to leave-one-participant and leave-one-subject-out analyses.

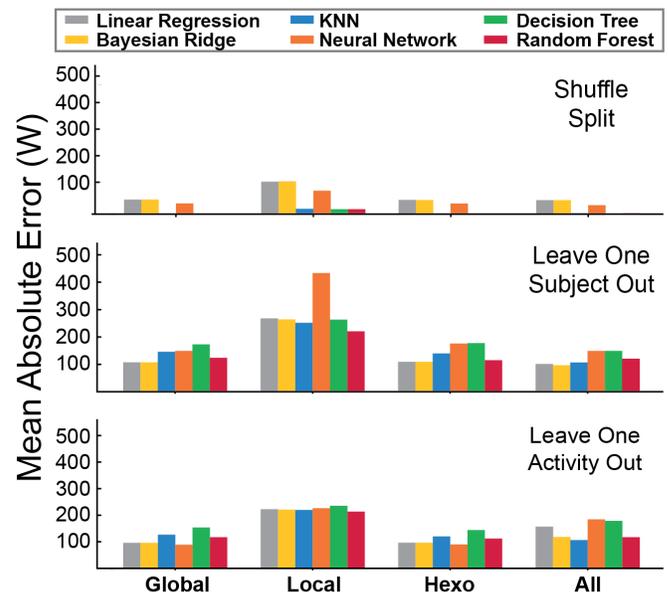

Figure 1: Performance of machine learning models with different sets of sensors and types of validation.

## Significance

Machine learning models predicted real-time metabolic cost with low errors ( $< 2W$ ). These models had moderate errors for unobserved activities ( $< 89 W$ ) and unobserved participants ( $< 110 W$ ). Future work will explore feature engineering to determine if these models can be further improved to reduce the prediction error rate.

## Introduction

Powered prosthetics have been shown to increase a user's walking efficiency and enable higher walking speeds in comparison to the non-powered counterparts. Yet, powered prosthetics suffer from lack of use owing to poor kinematic compatibility, bulkiness, and low adaptability to changes in the terrain. Additionally, current powered prosthetics mandate tedious calibration and tuning procedures, which prohibit their general usage. A possible approach to some of these problems is to focus on improving user-comfort by replicating able-bodied walking with such prosthetics. Many researchers have done this by adopting impedance control strategies. Under this control scheme, the gait is generally divided into 4-6 phases with a unique set of constant impedance control parameters—stiffness, damping, and equilibrium angles—assigned to each phase [1]. But studies such as [2] have revealed that a healthy human's joint impedance varies continuously throughout the stance phase of the gait cycle. Since the objective of a prosthetic's controller is to mimic able-bodied walking, it stands to reason that control parameters must also be human-inspired. Studies such as [3] have implemented algebraic curves within some phases of the control scheme. While the parameters vary continuously and smoothly within the phases, there are likely non-smooth variations during transitions between phases. Further, the controller proposed in [3] relies on a load cell that measures vertical ground reaction force. Such load cells can be expensive and increase the prosthetic's weight. A prior study by the authors proposes an impedance control scheme that varies the impedance parameters continuously and smoothly throughout the stance phase of the gait cycle [4]. Unlike [3], this scheme does not rely on a load cell. The impedance parameters are estimated using a least squares approach like that used in [1]. In the study, [4], the proposed controller was only implemented on a transfemoral prosthetic's ankle joint. This paper documents preliminary attempts at extending the control scheme to the prosthetic's knee joint.

## Methods

The proposed control scheme sections the gait cycle into 4 phases: heel strike (0%) to flat foot (13%), flat foot to heel off (42%), heel off to toe off (62%), and toe off to the end of the gait cycle (100%). The torque generated by the impedance controller is represented as follows.

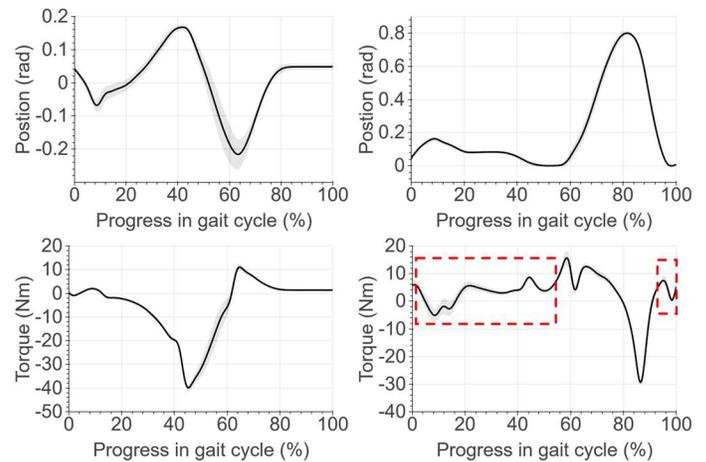

$$\tau(t) = K(t) (\theta(t) - \theta_{eq}(t)) + D(t)\dot{\theta}(t)$$

where  $K(t)$  and  $D(t)$  are the stiffness and damping parameter at the instant  $t$  ( $0\% \leq t \leq 100\%$ ). The term  $\theta_{eq}$  is the equilibrium angle, while  $\theta(t)$  and  $\dot{\theta}(t)$  represent the joint's position and velocity. Both  $K(t)$  and  $D(t)$  are represented by 4<sup>th</sup> order polynomials during the stance phase and a constant value during the swing phase. The polynomials were estimated using a least squares method detailed in [4] and were tuned by scaling and adding an offset. This controller was tested on a transfemoral prosthesis (AMPRO II [4]) with a healthy participant (male, 31 yrs., 1.70 m, 70 kg) using a L-shaped simulator. While the ankle was controlled using impedance control, the knee was controlled

using impedance control during the stance phase, followed by trajectory tracking during until 90% of the gait cycle, and low gain PD control during 90%-100% of the gait.

## Results and Discussion

The generated kinematics and kinetics have been presented in Figure 1. Both ankle and knee kinematics resemble able-bodied walking. The slightly lessened ankle dorsiflexion during mid-stance can be countered with further tuning. While the ankle torque also followed a humanlike trend, the peak torque is significantly lesser than that of healthy human's. This is due to the torque limitations of the prosthetic's actuators.

**Figure 1:** Top left: Ankle position, Top right: Knee position, Bottom left: Ankle torque, Bottom right: Knee torque.

Unlike the ankle, the knee torque deviated from that of a healthy human's. These deviations have been highlighted with red boxes in Figure 1. The first discrepancy is attributed to the controller's high damping parameters. It is believed that the results will improve by constraining the magnitude of damping. The second discrepancy is due to the low gain PD controller.

## Significance

In addition to generating near human-like gait, this controller requires lesser tuning. Additionally, the involved tuning process is easy to carry out [4]. With improvements, the proposed control scheme can undoubtedly make prosthetics easier to use for both amputees and therapists/practitioners. Future efforts are directed at eliminating the entire tuning process via auto-tuning methods such as fuzzy-logic.

## INTRODUCTION

Prosthesis users face unique barriers to physical activity (PA), e.g., socket discomfort, components that poorly accommodate to inclines or uneven surfaces. However, interventions to address these barriers do not always promote PA. For example, changing socket suspension from pin to vacuum, which should increase comfort and mobility<sup>1</sup>, reduces steps per day<sup>2</sup>. In addition, while evidence supports the use of microprocessor-controlled knees to increase self-reported mobility, step counts and duration of activity may be unaffected by the type of knee<sup>3</sup>. To some extent these findings may reflect the fact that traditional measures of PA such as step count do not closely relate to changes in community participation or well-being, which may be expected with increase mobility<sup>4</sup>, and therefore may not well capture the impact of these interventions. Moreover, traditional measure of PA may not well capture the complexity of PA patterns that may also be impacted. Recent studies using detrend fluctuation analysis (DFA) suggest that daily fluctuations in PA are not random, but rather demonstrate scale invariance (appear similar at short and long time scales). This property is thought to reflect overall motor health, is insensitive to total level of activity and is impacted by disease states such as chronic fatigue that alter the temporal nature of the PA<sup>5</sup>. The purpose of this study was to evaluate the relationship between a number of PA measures derived from activity monitors and self-reported outcome measures associated with well-being, community participation and PA patterns in order to provide insight to guide assessments in future intervention studies.

## METHODS

We present data from the first 17 persons with unilateral transtibial amputation recruited into a larger randomized control trial to reduce fear of falling and increase community participation in prosthesis users. To participate, individuals: reported an Activity-specific Balance Confidence (ABC) score <80 and had at least 6 months experience with a definitive prosthesis; they were excluded for: active wounds on weight-bearing surfaces. All participants meeting inclusion were screened by a prosthetist to ensure a well-fitting prosthesis and by a physiatrist to ensure they were safe to engage in low-to-moderate levels of exercise. Participants then completed 6 self-reported measures: ABC; the Fear of Falling Avoidance Behavior Questionnaire (FFABQ) which asks individuals to rate how much fear of falling leads to avoidance of 14 different activities; modified Gait self-efficacy scale (mGES) which asks level of confidence in completing 10 different gait-related tasks; the well-being scale of the Prosthesis Evaluation Questionnaire (PEQ); the Short-form 36 Healthy Survey (SF-36) - we present data from the physical functioning scale only; and the Frenchay Activity Index (FAI) to quantify social participation. Participants wore a Step Watch 3 activity monitor (Modus Health) on their pylon for 1 week, which recorded steps taken in 10 s epochs. From the raw data we calculated 6 PA measures: steps/day (average across all days); median and maximum walking-bout length and number of walking bouts/day, where a bout was defined as  $\geq 5$  consecutive steps; the DFA scaling exponent;

and the “decay” exponent. For DFA, we followed standard procedures<sup>6</sup>: integrate the time series; plot the average size of the fluctuations (variations about the local trend) of data within windows of increasing size  $n$  as a function of  $n$ ; calculate the slope of the best fit line ( $\alpha$ ) on a log-log scale. To calculate the “decay exponent” we fit a histogram of the bout data with an exponential decay function and report the exponent; larger values indicate data is skewed toward more short walking bouts. Independent correlations were run to determine the strength of association between the 6 PA measures and 6 self-reported measures. Due to missing data, the number of points differs across correlations.

		SELF-REPORTED MEASURES						
		Self-efficacy and participation			Quality of life			
		ABC	FFABQ	mGES	FAI	PEQ	SF-36	
ACTIVITY PARAMETERS	Amount	Steps/day	0.18	0.22	0.22	<b>0.68</b> (p=0.004)	0.50 (p=0.085)	0.28
		Bouts/day	0.01	-0.07	0.06	0.58 (p=0.061)	0.23	0.18
		Median bout length	0.02	-0.08	0.18	0.47 (p=0.064)	0.54 (p=0.058)	0.20
		Maximum bout length	0.22	-0.45 (p=0.096)	0.24	0.45 (p=0.082)	<b>0.64</b> (p=0.019)	<b>0.55</b> (p=0.040)
ACTIVITY PARAMETERS	Pattern	DFA exponent	0.31	-0.43	0.22	<b>0.58</b> (p=0.018)	<b>0.66</b> (p=0.014)	0.51 (p=0.061)
		Decay exponent	0.40	-0.14	0.10	0.23	0.52 (p=0.068)	0.47 (p=0.089)

**Table 1:** Correlations between self-reported and PA measures. Grey values correspond to  $p > 0.10$ ; bold values correspond to  $p < 0.05$

## RESULTS

In general, measures of self-efficacy (ABC and mGES) and related activity avoidance (FFABQ), which, theoretically, should directly relate to PA show nearly no associations with PA measures (Table 1). On the other hand, FAI, a direct measure of participation, as well as quality of life (PEQ) are significantly associated with many PA measure of activity including the DFA scaling exponent. The strongest correlation among all measures was between FAI and the traditional PA measure of steps/day.

## CONCLUSION

If activity is an outcome of interest within a prosthetic intervention it may be important to include self-report measures related to activity and quality of life as well as objective measures to assess both amount of activity and pattern of activity to fully understand the impact of the intervention. Additional work is needed to determine the extent to which changes in self-reported measures correspond to changes in PA measures, and vice versa.

## SIGNIFICANCE

Prosthetic interventions should include a wide variety of measures to fully understand their impact on the patient.

# Proportional Myoelectric Control of a Bionic Lower Limb Prosthesis with Series Elastic Actuator

Nicole E. Stafford<sup>1</sup>, Lars Wouterse<sup>2</sup>, Simon van der Helm<sup>2</sup>, and Daniel P. Ferris<sup>2</sup>

<sup>1</sup>University of Florida Department of Mechanical and Aerospace Engineering

<sup>2</sup>University of Florida J. Crayton Pruitt Family Department of Biomedical Engineering

Email: nicolestafford@ufl.edu

## Introduction

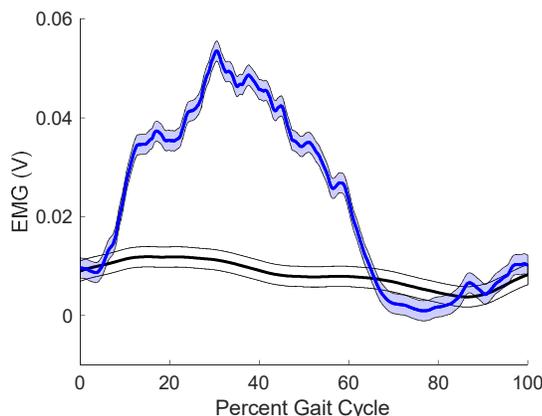

Robotic lower limb prostheses enable mechanical emulation of human gait biomechanics, but more biomimetic controllers are needed to achieve dynamic and agile locomotion. Traditional state-based controllers offer a finite number of movement options which make it difficult to adapt to different daily activities, postural challenges, and terrain [1, 2]. In contrast, proportional myoelectric control uses signals directly from a prosthesis user to modulate ankle position and mechanical power output [3]. Our purpose was to develop a proportional myoelectric lower limb prosthesis with a series elastic actuator that allows testing of different prosthetic controllers in real-world environments.

## Methods

We developed a bionic transtibial prosthesis using a series elastic actuator (Apptroik P170 Orion) controlled by surface EMG mounted on the gastrocnemius within the socket. The controller produced a motor current proportional to rectified, low-pass filtered EMG of the subjects' gastrocnemius. A male subject age 66 with transtibial amputation practiced treadmill walking with the prosthesis under proportional myoelectric control and visual feedback over multiple testing sessions. We collected kinematic, kinetic, and electromyography data across 7 training sessions.

## Results and Discussion

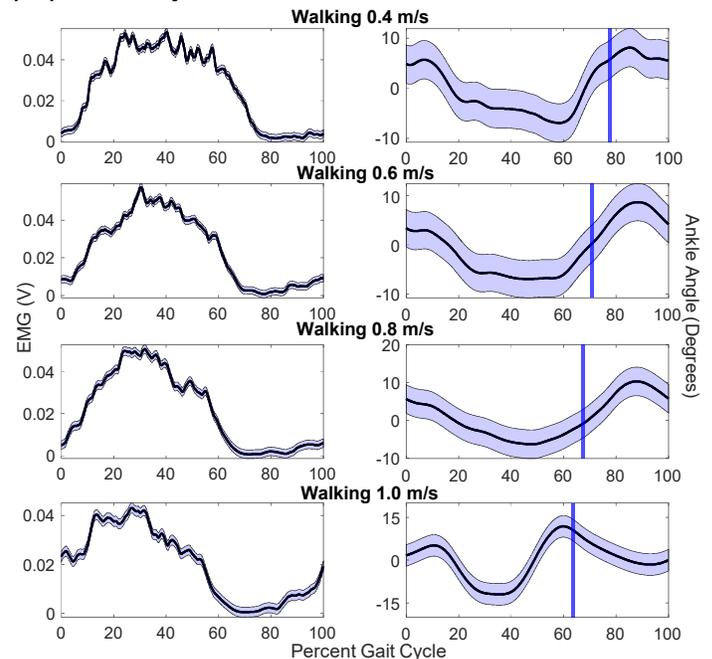

With our proportional myoelectric controller, the subject modified their gastrocnemius activity over the course of training to modify the mechanical output of the bionic prosthesis. **Figure 1** depicts the subjects' initial muscle activity walking with the device compared to after seven sessions with visual feedback. The subject learned to produce a large burst of muscle activity during stance to produce ankle plantar flexion.

**Figure 1:** Low-pass filtered gastrocnemius EMG averaged over 10 steps at 0.6 m/s. Black line shows data after 15 minutes practice. Blue line shows data after multiple training sessions with visual feedback. Shaded regions represent 1 SD.

The subject was able to produce plantarflexion pushoff across multiple walking speeds with the prosthesis (**Figure 2**). At 1.0 m/s, the peak plantarflexion at the end of stance occurred earlier than the slower speeds. Walking at faster speeds required

training, likely due to the motor adaption in timing of muscle activity. These results suggest that the method of gait training likely plays an important role in learning how to emulate intact lower limb biomechanics with a bionic prosthesis under proportional myoelectric control.

**Figure 2:** Low-pass filtered gastrocnemius EMG (above left) and prosthesis ankle angle (above right) averaged over five steps across multiple walking speeds (0.4, 0.6, 0.8 and 1 m/s). For ankle angle, 0 degrees is standing angle and negative is plantarflexion. The vertical blue lines indicate toe off timing for the prosthesis side. Shaded blue region represents 1 SD.

## Significance

Three-quarters of daily human walking bouts are less than 40 steps and <1% take more than two minutes [4]. There is a need for bionic prosthesis controllers that can handle non-periodic, volitional movements to enhance maneuverability [1,2]. Adapting feedforward commands from users via proportional myoelectric control allows users to adapt to a wide range of tasks, conditions, and terrain. We are modifying the prosthesis for wireless locomotion outside of lab environments to study how users modify EMG control signals in the real world.

### Introduction

When deciding which stiffness category of a prosthetic foot to prescribe for individuals with lower limb amputation, clinicians often rely on manufacturer recommendations that are focused on patient weight and activity level. However, there is limited evidence and objective data available to guide the selection of the optimal stiffness category that will match each patient's abilities, goals, and the type of environmental terrains that they typically encounter. Knowledge of mechanical properties such as linear stiffness would likely be useful in the prescription process, as it could enable clinicians to select prosthetic feet with the stiffness categories for which their patients are best suited. While prior studies have begun to quantify compressive linear stiffness properties,<sup>1-3</sup> limited data exists measuring linear stiffness across prosthetic foot stiffness categories and foot sizes. Therefore, the purpose of this study was to compare measured forefoot stiffness properties of commonly prescribed prosthetic feet across stiffness categories and to examine whether foot size affected the relationship between stiffness category and measured stiffness.

### Methods

Data were collected on the following prosthetic foot models: Trulife Seattle Lightfoot2, Freedom Innovations Walk-tek, Össur Vari-flex, Ability Dynamics Rush HiPro, and Fillauer All-Pro. For each model, sizes 27 and 28cm feet were tested. A range of foot stiffness categories accommodating patient weighing between 100 and 250 lbs were tested for each model and size.

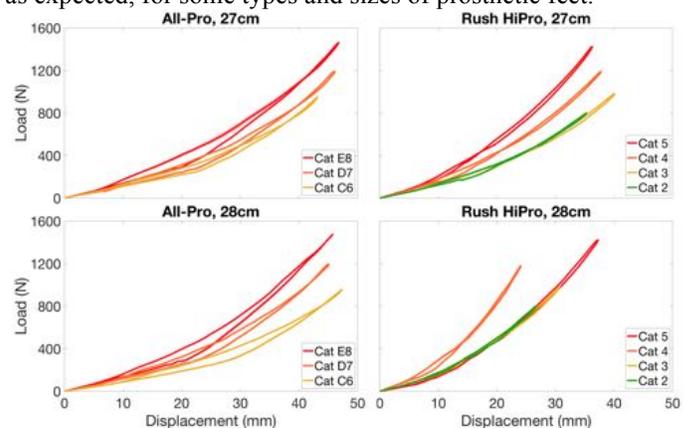

**Apparatus:** A Mikrolar R2000 robot and an 8-camera Vicon motion capture system were used to collect displacement data. A 6-axis AMTI MC3A load cell was used to collect force data.

**Procedures:** Each prosthetic foot was shod with a standardized walking shoe and attached to the load cell using a pyramid adapter. The load cell was then fixed to the R2000 robot with neutral alignment in all planes. Procedures included quasi-static testing at a discrete pylon progression angle of +20° to isolate the forefoot component. Using displacement control, the R2000 compressed each foot for six cycles of loading and unloading. A minimum load of 50N of vertical force was maintained prior to the start of loading and between all testing cycles. Because ground reaction force during walking can reach 1.2x body weight in late stance, a maximum force threshold representative of 1.2x the highest body weight recommended by the manufacturer for the tested stiffness category was used. The first three cycles were considered preconditioning and excluded; data from the final three cycles were averaged for analysis.

### Results and Discussion

Force vs. displacement curves of prosthetic forefeet were compared across stiffness categories and across sizes 27 and 28cm for each of the foot models. The order of prosthetic foot stiffness categories was at times inconsistent with the order of measured forefoot stiffness for multiple foot models and sizes; there were 8 instances out of 28 total (29%) in which the stiffness

categories did not correspond to increasing measured stiffness as expected. For example, in the case of the Rush HiPro, the category 4 had a higher measured stiffness than the category 5 in the size 28cm, though not in the size 27cm feet (Figure 1). Additionally, in both sizes, the lower categories (2 and 3) had nearly the same stiffness. In contrast, the All-Pro models showed consistently increasing measured stiffness across categories, regardless of size. The data suggests that measured prosthetic forefoot stiffness may not increase consistently across categories, as expected, for some types and sizes of prosthetic feet.

**Figure 1:** Example force vs displacement data for prosthetic feet in two sizes. While the All-Pro data conform to the expected order of increasing stiffness with increasing category, there are inconsistencies in the Rush HiPro data across categories and across foot sizes.

### Significance

Prosthetic foot stiffness can play an important role in functional mobility of people with lower limb amputation. The process by which manufacturers classify the categories of feet is unclear. Some may use mechanical testing to assign the category based on measured properties, while others may designate a category by using the same material layout, without testing after production. These findings suggest variation in measured forefoot stiffness across categories (e.g., a higher category may not actually be stiffer). Furthermore, stiffness across categories varied depending on the size of the foot. These findings suggest the importance of publishing standardized mechanical testing results for commercial prosthetic feet to provide objective data that clinicians could utilize when selecting the ideal prosthetic feet and stiffness categories for patients.

Email: [shane.t.king@vanderbilt.edu](mailto:shane.t.king@vanderbilt.edu)

## Introduction

Individuals with transfemoral amputation are 200 times more likely to fall from a stumble [1, 2], which leads to an increase in fall-related injuries and lower community engagement.

The current standard of care is a microprocessor knee prosthesis, which relies upon the user's hip to drive the motion; however, these low-impedance knee joints are easily displaced from their trajectory by an obstacle. A powered device is able to overcome this issue. Inclusion of a motor to drive the knee joint allows the device to actively recover from perturbations.

To test if implementing healthy recovery strategies on a powered prosthesis will reduce users' fall incidence and improve stumble recovery, we have replicated the two primary healthy recovery strategies (i.e., elevating and lowering) [3] on the Vanderbilt Knee (Fig 1, B). However, the most critical component is choosing which strategy to use, which has not been done before. This decision is important because an incorrect selection would lead to a mismatch between the device and the user, making recovery more difficult. We propose that the key to successfully improving stumble recovery for transfemoral prosthesis users is allowing them to drive the actions of the device such that they are able to move together in a coordinated fashion. Thus, the objective of this work is to present the formulation and validation of this controller design.

## Methods

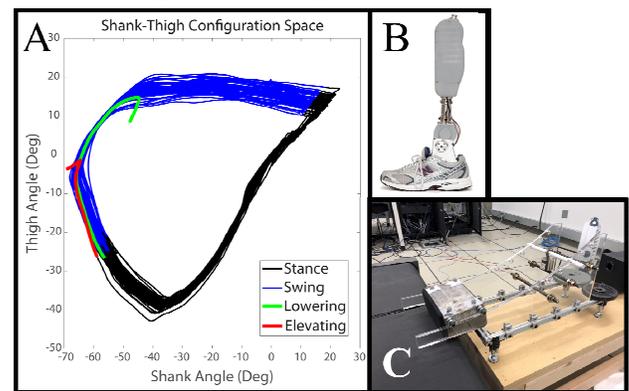

The goal of the controller is to follow the initial dynamics of the user's residual limb several milliseconds after the perturbation. This allows the device to ensure its response is in coordination with the user's movement, while still responding quickly enough to recover. For example, if a user continues to flex their hip shortly after the perturbation, then the powered device has time to use an elevating strategy and bring the leg up and over the obstacle as the user continues to swing their leg. However, if the user stops flexing their hip or begins extending, the device must use the lowering strategy to extend the knee, support the user, and assist as they clear the obstacle in the next step.

To determine the initial response of the user's residual limb, an inertial measurement unit (IMU) on the prosthesis shank and an encoder on the prosthesis knee joint are used to observe the user's thigh and shank angle configuration space which forms a portion of an ellipse during swing phase (Fig. 1, A).

The use of this configuration space was piloted with healthy stumble recovery motion capture data that was collected using an in-house treadmill stumble apparatus [3] (Fig. 1, C). The data showed a distinct bifurcation in the response of the configuration space during a perturbation. Perturbations that resulted in an elevating strategy showed the configuration space trajectory exiting from its typical ellipsoid path towards the exterior of the ellipse, while perturbations that result in a lowering strategy showed the configuration space trajectory exiting towards the interior of the ellipse. The controller uses this bifurcation by analyzing the error of the current

configuration space trajectory compared to the typical configuration space ellipse trajectory. This allows the device to determine which strategy to use to recover from a perturbation.

Testing with the powered prosthesis was performed on one healthy subject using an able-body adaptor (Fig. 1, A) to determine if the trends were the same when using the powered prosthesis with IMU/encoder signals compared to the healthy motion capture data. Additionally, the controller was tested to see if using the bifurcation to choose the recovery strategy allowed for an improved recovery.

**Figure 1:** A) Thigh-shank angle configuration space data. B) Vanderbilt Powered Prosthesis. C) Treadmill stumble apparatus.

## Results and Discussion

Preliminary results collected from the healthy subject using an adaptor have matched the initial configuration space trajectory bifurcations of the original healthy stumble recovery data set. An example of this bifurcation is shown in Fig. 1, A. The controller allowed for the subject to successfully recover from stumble perturbations across a range of timings from early to late swing phase using an appropriate stumble recovery strategy. The next step will be testing the controller on transfemoral prosthesis users to ensure the control system is able to coordinate with their current stumble recovery reflex; data from which will be presented at the conference. Metrics will include ability to recover from the perturbation, time to return to steady state walking, and knee angle trajectory comparisons to healthy recovery data to show the benefits of the control system.

## Significance

Overall, the control system described herein has the potential to substantially reduce the risk of falling and improve stumble recovery for people with transfemoral amputation. By following the dynamics of the user's body, the controller works in concert with the user's recovery instead of impeding it.

# Does the use of a Powered Assistive Ankle Exo Device Augment Cost of Transport?

Leif Hasselquist<sup>1</sup>, Meghan O'Donovan<sup>1</sup>, Kari Loverro<sup>1</sup>, Jonathan Kaplan<sup>1</sup>, and Clifford Hancock<sup>1</sup>

<sup>1</sup>Combat Capabilities Development Command Soldier Center, Natick, MA 01760

Email: \*[leif.hasselquist.civ@mail.mil](mailto:leif.hasselquist.civ@mail.mil)

## Introduction

Our product test identifies a key question when designing an ankle worn augmentation device for healthy populations, how do you provide enough assistance during gait to decrease cost of transport (COT) without disrupting natural gait mechanics enough to incur a significant penalty or increase to COT? The cost of transport (COT) for human (or animal) locomotion is defined as (energy cost)/(body weight × distance traveled). It is a dimensionless quantity to express the energy efficiency of transporting the person (via gait) from point A to point B. [1] Deviations from preferred gait mechanics appear to always incur a metabolic cost (i.e., increased COT). This suggests that preferential gait characteristics are selected in large part to minimize metabolic cost. [2] The goal of this product test was to determine whether a powered, untethered, ankle-worn exoskeleton can produce a measurable metabolic cost reduction that may be linked to a change in gait dynamics during Soldier-relevant locomotor tasks with body-borne loads.

## Methods

A total of 12 (11 M, 1 F, age:  $26 \pm 5$  yrs; height:  $176 \pm 8$  cm; weight:  $80 \pm 8$  kg.) active duty infantry Soldiers volunteered as participants. They represented a healthy Soldier population and met all physical and injury screening criteria. Each participant conducted one familiarization session prior to testing. Each test session consisted of four, 7 minute instrumented treadmill (AMTI, USA) trials at a prescribed speed of 1.25 m/s and under two device conditions (Exo, No-Exo). Two load conditions were tested at a 0% grade and at a 4% grade. A No load (NL, 1.5 kg), and approach march load (AML, 42 kg) condition were tested at 0% grade. The AML and a fighting load (FL 27.7 kg), were tested at a 4% grade. To calculate COT we measured the participants' energy cost via an open circuit respirometry system (Cosmed, USA). To determine gait kinetic changes we collected traditional measures of vertical ground reaction force (vGRF) and antero-posterior ground reaction force (A/P GRF). For each condition, the dependent variables of metabolic COT and kinetic measures of peak vGRFs immediately after heel strike and immediately before toe-off, vertical GRF at mid-stance and peak A/P GRF during the braking and propulsive phases of gait were measured. We ran a repeated measures two-way ANOVA to examine the main effects and possible interactions between device (Exo, No-Exo) and load (NL vs, AML at 0% and FL vs AML at 4%),  $\alpha = 0.05$ . If significant interaction effects were observed between device and load, ( $p < 0.05$ ), tests of simple effects were utilized and a Bonferroni correction was applied.

## Results and Discussion

There was a significant main effect of device on mean COT across load at 0% grade ( $p = 0.024$ ) and at the 4% grade ( $p = 0.016$ ). The mean COT at the 0% grade was 11% lower for the Exo condition and 8% lower at the 4% grade for the Exo condition compared to the No-Exo condition (Figure 1). There

were no significant interactions between device and load at either grade tested.

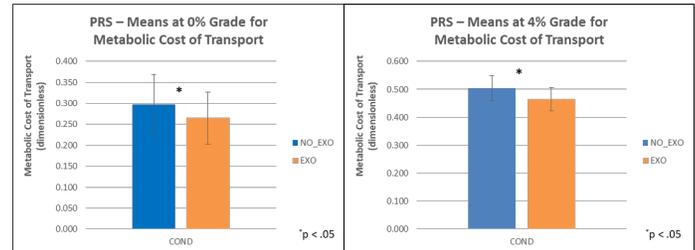

Figure 1: Mean COT for Exo and No-Exo at 0% and 4% grades.

For the kinetic results, the mean vGRF showed no statistically significant differences between Exo and No-Exo conditions at any of the points of interest. There was a significant main effect of device across load on mean peak braking forces at the 0% grade ( $p = 0.001$ ) and at 4% the grade ( $p < 0.001$ ) and propulsive GRFs across load at 0% grade ( $p < 0.001$ ) and at 4% grade ( $p = 0.001$ ). At all points, A/P GRF were higher in the Exo condition compared to the No-Exo condition, indicating an increase in both propulsive and braking forces while wearing the Exo device. The A/P GRF peak braking force at the 0% grade was 8% higher in the Exo condition and 6% higher at the 4% grade for the Exo condition compared to the No-Exo condition. The peak A/P GRF propulsive force at the 0% grade was 6% higher in the Exo condition and 5% higher at the 4% grade in the Exo condition compared to the No-Exo condition.

## Significance

For this product test the Exo ankle system tested appears to significantly reduce the metabolic cost of walking regardless of loads of varying magnitude at multiple grades. Our GRF results demonstrate that this Exo ankle system has little influence on peak vertical forces across the stance phase of gait, but does increase peak A/P forces during braking and propulsive phases. This finding may be attributable to the device's power activation parameters that aim to augment ankle joint moments during walking. There have been few untethered Exo devices that have been able to demonstrate a significant reduction in metabolic cost. Our results indicate that the changes in A/P GRF may be linked to the reduction in metabolic cost for the device tested. It should be noted that our participants demonstrated wide variability in responses to augmentation. Future research in this area, beyond a specific product test, will concentrate on individual variability, adaptation, and acceptance by Soldiers while wearing Exo devices.

## Acknowledgments

We recognize the Soldiers from the US Ranger Training Battalion and Natick Soldier Center detachment for their participation.

# Reduction of Trunk Extensor Muscle Activation using a Cable-Driven Asymmetric Back Exosuit

Jared M. Li<sup>1</sup>, Dean D. Molinaro<sup>1,2</sup>, Andrew S. King<sup>1</sup>, Anirban Mazumdar<sup>1,2</sup>, Aaron J. Young<sup>1,2</sup>  
<sup>1</sup>Woodruff School of Mechanical Engineering at Georgia Institute of Technology, Atlanta, GA, USA  
<sup>2</sup>Institute of Robotics and Intelligent Machines, Georgia Institute of Technology, Atlanta, GA, USA  
Email: jli649@gatech.edu

## Introduction

Musculoskeletal disorders of the back are extremely prevalent in the workforce and are often cited as the top workplace health concern in the United States. These injuries are caused by compression of the lumbosacral joint (L5/S1) due to repetitive lifting, especially asymmetric movements<sup>1</sup>. In response to this, wearable exoskeleton devices have been developed to reduce the risk of back injury, often reporting decreased muscle activation as indication of reduced lumbar loading<sup>2,3</sup>. While effective in mainly symmetric lifting, most of these systems lack controllability or are restrictive of asymmetric motions. We designed the Asymmetric Back Exosuit (ABX) to fill this gap with novel active cable-driven actuation. We hypothesized that this would allow ABX to reduce trunk extensor muscle activation during asymmetry.

## Methods

ABX was designed in order to achieve the functionality of active muscle activation reduction while allowing the user full freedom of movement. Assistive force is applied to the user through the nylon cables that run from actuators on the thighs up to opposite shoulders on a support vest, creating a crossing pattern along the wearer's back. Active assistance is achieved through pulley-gearbox actuators which are regulated by a microcontroller. An inertial measurement unit (IMU) is used to sense trunk orientation and angular velocity relative to the ground. This allows the exosuit to autonomously apply assistance to the user at lift onset and otherwise slack the cables to allow unimpeded motion.

To examine the exosuit's assistance method, a single-subject experiment was conducted to measure the change in activation of trunk muscle groups when lifting a 23 kg weight from the ground onto a table at waist level with a right-to-left 180° twist for five repetitions. Trials consisted of a sweep of assistive force from 5% to 20% of the subject's bodyweight in 2.5% increments as well as a NO EXO condition in which the subject completed the tasks without wearing the exosuit. Delsys Trigno EMG sensors were used to measure the left and right erector spinae, latissimus dorsi, external obliques, and rectus abdominis muscle groups. RMS of each EMG channel was averaged across repetitions and normalized to max activation per muscle group.

## Results and Discussion

As seen in Figure 1, muscle activation reductions of up to 30% and 28% were observed in the left and right erector spinae respectively, as well as 53% for both left and right latissimus dorsi muscles. The trunk flexor muscles (left and right external obliques and rectus abdominis) experienced either a decrease or no increase in activation for most assistance magnitudes. Reduction in activation of erector spinae muscles likely indicates reduced muscular force applied to the L5/S1 joint. This is likely related to decreased joint reaction loads in the lumbar spine.

Because of the cross pattern formed by the actuator cables, assistance that is symmetric in magnitude was supplied to the user

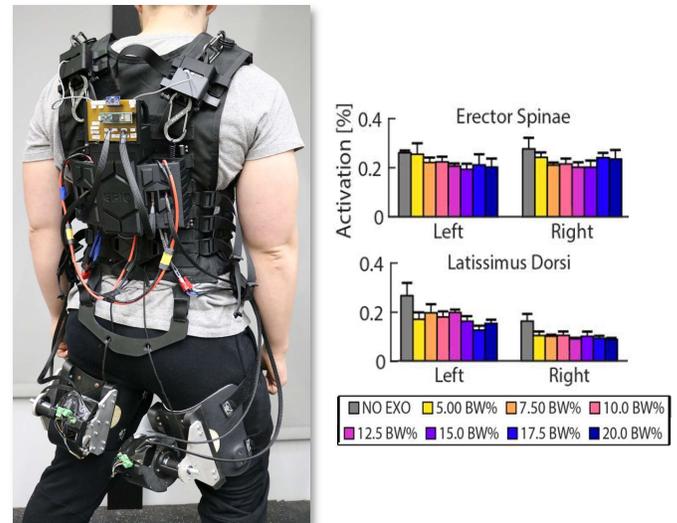

Figure 1: The Asymmetric Back Exoskeleton (left) uses thigh mounted actuators to drive cables attached to opposite shoulders to assist during lifting tasks. RMS electromyography measurements of the erector spinae and latissimus dorsi muscle groups during the asymmetric lift are shown on the right. The results are presented as a function of exosuit assistance by body weight percentage (BW%). The NO EXO condition represents muscle activations without wearing the exosuit. In general, exosuit assistance reduced muscle activation for observed muscle groups.

asymmetrically, demonstrated by the agonistic muscles (left side) experiencing generally greater activation reduction than the antagonistic (right side). Further studies will examine the biomechanical effects (joint reaction loads, lumbar moments) and investigate the results' sensitivity to changing assistance profiles.

## Significance

Our study presents a novel method of providing active assistance during asymmetric lifting. Asymmetric application of assistance characteristic to this exosuit design allows the cables to naturally follow the twist of the lumbar spine. This method has shown to reduce EMG of the measured trunk extensor muscles, with a larger reduction on the leading side. Because of the prevalence of asymmetric lifting in manual materials handling occupations, this assistance method has the potential to greatly reduce risk factors for back injury during natural lifting movements.

## Introduction

Over 600,000 people suffer lower-limb amputations in the US every year which significantly affects their quality of life<sup>1</sup>. This has spurred a race in the research & development of lower-limb prosthetic devices, especially powered ankle prostheses<sup>2</sup>. However, it is a real challenge to have a design, which relies on an active actuator and meets the two key requirements: 1) generates large active power needed for locomotion and 2) a small profile, which fits the size of human ankle joint<sup>3</sup>. A common compromise is to involve a passive actuator i.e a passive spring, which is set in parallel with the active actuator and tuned to release power when the power is needed most. Although passive actuators have the capability to generate large torque, its dynamical properties are fixed and often optimized for walking in most of the existing designs. Besides walking, ankle joints play important roles for other tasks beyond level ground walking, such as sit-to-stand (STS) and stairs ambulation, which expect different dynamical properties from the ankle joints. A key question for prosthesis design is whether it is needed to adjust the dynamical properties of the passive actuator for different tasks. Hence, this study presents a powered ankle prosthesis, which includes a passive spring with adjustable stiffness & equilibrium position. This device permits us to study how the properties of passive actuators, such as stiffness (K) and equilibrium angle ( $\theta^e$ ), affect the capability of the amputee-prosthesis-system to conduct various tasks.

## Methods

For the purpose of testing, a novel powered ankle prosthesis was developed which employs a motor embedded ball screw design in a four bar linkage mechanism for achieving space reduction<sup>4</sup>. A frameless motor kit (UTH-63-B-18- C-x-000, Rated Torque & Speed:0.268 Nm, 7000 rpm, Celera Motion, USA) and ball screw (SD 12x2R 82/100 G7L-Z-WPR, SKF, Japan) were used. The prosthesis has a peak ankle torque of 138 Nm & range of motion of 30° dorsiflexion & 25° plantarflexion. The mechanical spring design was devised using a slider crank mechanism in conjunction with a stack of Belleville springs as shown in Figure 1 below. The equilibrium angle (the angle when the spring engages & disengages from the prosthetic foot) and mechanical stiffness can be modulated by changing the stack arrangement (different belleville springs can be used and can be arranged in parallel or series & hardened washers can be added for achieving a desired stiffness & spacing characteristics). The spring thus designed gives a angular stiffness range of 0-506 Nm/rad and an allowable equilibrium angle range of 10° plantarflexion to 15° dorsiflexion.

In order to study the effect of the passive springs, we shall conduct a STS scheme for two different passive spring configurations. The first spring configuration will be optimized for walking ( $K=361$  Nm.s/rad,  $\theta^e = 0^\circ$ ) and the second one will be optimized for the STS transition ( $K=0$  Nm.s/rad or  $\theta^e = 11^\circ$  for peak angle = 10.7° i.e no spring connected). Both optimizations are based on the Ankle Angle-Torque curves

available in literature<sup>5</sup>. The number of sit-to-stand transitions per minute shall be recorded to quantify the performance of the two setups.

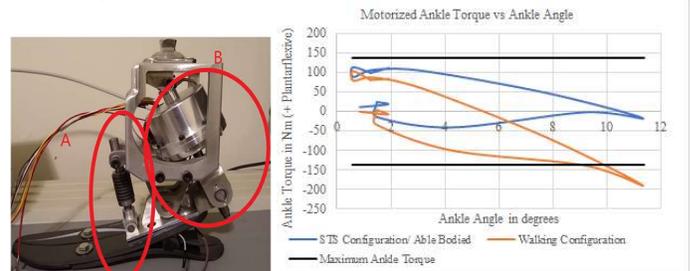

Figure 1. Left (a) The Ankle Prosthesis A-Modular Spring configuration, B- Embedded Ball screw actuator. Right (b) Motorized Ankle Torque vs Angle curves for STS with two configurations & Max Torque.

## Results and Discussion

This study expects a significant 40 % reduction in absolute peak torque from the first spring configuration to the second configuration. This is anticipated since the peak ankle torque & peak ankle dorsiflexion do not occur at the same time during STS unlike in walking. Furthermore, it can be seen from Figure 1(b) that the motor shall need to expend an ankle torque of 200 Nm which is greater than maximum allowable torque of 138 Nm to compress the walking spring configuration while the STS configuration poses no such problem. Hence, given that the above estimates hold true, a conclusion could be drawn that the modular spring configuration shows improved characteristics when compared with a fixed stiffness spring configuration for the ankle prosthesis. We also expect that our human subject tests will demonstrate that the second setup will permit the amputee to do sit to stand more quickly.

## Significance

This is the first effort to explore the impact of the passive actuator's dynamical properties on the performance of powered prosthetic ankle under different tasks. The results of this study provide the evidence that different passive actuators are needed for different locomotion tasks.

# Powered Knee-Ankle Prosthesis Reduces Effort in Intact Limb During Sit-to-Stand Transitions

Grace Hunt<sup>\*1</sup>, Sarah Hood<sup>1</sup>, and Tommaso Lenzi<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering and Utah Robotics Center, University of Utah

\*Corresponding Author Email: grace.hunt@hsc.utah.edu

## Introduction

Standing up is an essential activity of daily life. In non-amputee individuals, standing up involves multiple muscles that span the hip and knee joints. In above-knee amputees, these muscles are severed, and the knee joint is typically replaced with a passive prosthesis, which injects no energy. Thus, above-knee amputees rely on their intact limb and upper body to lift their body during standing<sup>1</sup>. Powered prostheses aim to address this problem by providing positive power at the knee and ankle joints similar to the biological leg. Two previous studies have investigated sit-to stand transitions with a powered prosthesis<sup>2,3</sup>. Both studies found that a powered prosthesis can improve weight bearing symmetry compared to a passive prosthesis, reducing the vertical ground reaction forces (GRF) on the intact side. However, the intact limb's knee power does not seem to be reduced when standing up with the powered prosthesis compared to a passive prosthesis<sup>3</sup>. Thus, it is unclear whether the improvement in weight bearing symmetry observed with a powered prosthesis leads to a reduction of effort.

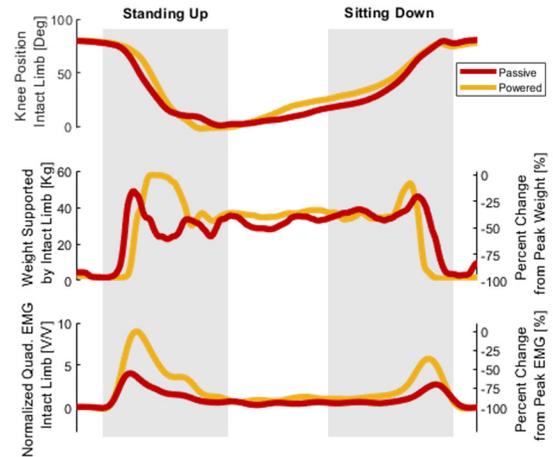

We hypothesize that if using a powered knee-ankle prosthesis results in the intact limb supporting less of the subject's weight during standing up, then the intact limb's muscle effort will also be reduced. To test this hypothesis, we will ask individuals with above-knee amputation to perform sit-to-stand transitions with their passive prostheses and with an experimental powered knee and ankle prosthesis<sup>4,5</sup>, while measuring kinematics, GRF, and intact-leg muscle activations. The goal of this study is to pilot test the experimental protocol with one amputee subject.

## Methods

One individual with an above-knee amputation participated in this study, which was approved by the University of Utah Institutional Review Board. The subject provided written informed consent before the experiment started. The participant performed sit-to-stands under two conditions: (1) using their prescribed passive prosthesis device, and (2) using an experimental powered knee and ankle prosthesis<sup>4,5</sup>. The subject was asked to stand up and sit down at their preferred speed without using their hands for assistance. GRF from each foot was recorded using two force plates (Wii Balance Nintendo)<sup>6</sup>. The subject wore an inertial motion analysis system (MTw Awinda, Xsens, Netherlands) to record kinematic data. A surface electromyography (EMG) sensor (13E202=60, Otto Bock, Germany) was placed on an intact-limb quadriceps muscle (Vastus Lateralis) to measure muscle activations. Data were filtered offline using a zero-lag 4<sup>th</sup> order Butterworth filter. Kinematic and GRF data were filtered at 10Hz, EMG data were filtered at 3Hz. EMG data were normalized to maximum activity during walking with the passive prosthesis.

## Results and Discussion

When subjects stood up using the powered prosthesis, the weight supported by the intact limb was reduced by 9.8 kg compared to standing up with passive prosthesis, a 16% reduction. During sitting down, the weight supported by the intact limb was reduced by 7.2 kg, a 13% reduction. In addition, the subject's

**Figure 1:** Knee position, weight (GRF), and muscle activation (EMG) data from intact limb of subject with above-knee amputation, during standing up and sitting down using subject's prescribed passive prosthesis (yellow) and experimental powered prosthesis (red).

EMG peak activation during standing up decreased 55% with the powered prosthesis, compared to the passive prosthesis. Similarly, during sitting down with the powered prosthesis, EMG peak activation decreased by 54% compared to sitting down with the passive prosthesis. No notable differences were observed in the intact limb's knee kinematics.

These results show that powered knee-ankle prostheses can reduce both the weight that the intact limb must support, and the muscle contraction effort required during standing-up and sitting-down, without impacting the intact limb knee kinematics. Improvements in weight-bearing have been shown by previous studies<sup>2,3</sup>, and our results support these findings. Decreased effort has not been investigated in previous studies. The observed reduction in EMG contraction strongly supports our hypothesis that powered prosthetics can decrease effort during standing up. Future work should include surveys of user-reported effort and fatigue under both conditions, and testing with additional subjects to determine if the observed changes are statistically significant.

## Significance

We provided the first demonstration of muscle effort reduction during sit-to-stand transitions with a powered prosthesis. This pilot test will support a future pilot clinical trial aiming to assess the efficacy of powered knee and ankle prostheses in sit-to-stand transitions for individuals with above-knee amputations.

## Immediate Effects of a Hydraulic Slope Adaptive Prosthetic Foot-Ankle System When Standing on Slopes

Myrriah P. Laine Dyreson<sup>1</sup>, Nicole R. Walker<sup>1</sup>, Gregory Jacobs<sup>2</sup>, Ed Iversen<sup>2</sup>, Andrew H. Hansen<sup>1,3</sup>, and John M. Looft<sup>1</sup>

<sup>1</sup>Minneapolis VA Health Care System; <sup>2</sup>Motion Control, Inc.; <sup>3</sup>University of Minnesota

Email: Myrriah.LaineDyreson@va.gov

### Introduction

In collaboration with the Minneapolis VA Health Care System (MVAHCS), Motion Control, Inc. has developed a hydraulic slope adaptive foot-ankle (SAF) prosthesis. While previous versions of the SAF have been capable of adapting to slopes during walking [Nickel 2014], the SAF's effect on standing posture on varied slopes has not been explored. We hypothesize:

**1)** the SAF will more evenly distribute body weight between the user's sound and affected limbs while standing on varied slopes ( $\pm 5^\circ$ ,  $\pm 10^\circ$ ); **2)** using the SAF will decrease observed torques at the ankle and knee joints while standing on varied slopes ( $\pm 5^\circ$ ,  $\pm 10^\circ$ ); and **3)** using the SAF will result in a decrease in perceived exertion during a five-minute standing task on a  $\pm 10^\circ$  slope.

### Methods

A 55-year-old male (195 pounds, 73 inches tall, K3 ambulator) with rotationplasty amputation was recruited for this preliminary study. The experimental procedures were approved by the MVAHCS IRB. The subject completed testing using their current prescribed energy-storing-and-returning (ESAR) prosthetic ankle-foot and Motion Control's prototype SAF ankle-foot.

Kinetic and kinematic data were collected simultaneously at 120 Hz using 2 AMTI force plates (AMTI, Watertown, MA) surrounded by a stable walkway, and a 16-camera motion capture system (Qualisys, Gotenburg, Sweden). Reflective markers were placed on the affected limb, pelvis, and trunk.

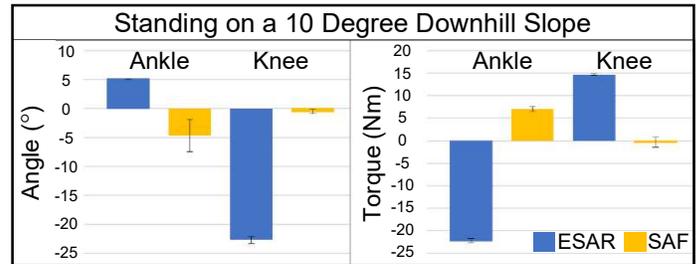

The subject stood quietly on slopes of  $0^\circ$ ,  $\pm 5^\circ$ , and  $\pm 10^\circ$ . Two static trials and three 20-second quiet standing trials for each slope condition were recorded. Single 5-minute trials of quiet standing on  $\pm 10^\circ$  were also recorded. Static trials were recorded with both feet on one force plate while standing trials were recorded with the right and left feet on separate force plates. Following each 5-minute trial, the subject was asked to rate their perceived level of exertion on a 0 (no exertion) to 10 (maximal exertion) scale. These ratings were compared between foot conditions.

All kinematic and kinetic data were processed using Visual3D (C-Motion, Inc., Germantown, MD). Body weight distribution between the affected and sound sides were calculated as a percentage of the total body weight and compared between slope and foot conditions. The angle and torque of the affected side ankle, knee, and hip joints, along with trunk angulation, were also calculated for each standing trial.

### Results and Discussion

Ankle and knee torque magnitudes were decreased when using the SAF while standing on slopes of  $\pm 5^\circ$  and  $\pm 10^\circ$ . The ankle torque direction was favorably reversed while the knee torque was nearly 0 Nm when standing on a  $-10^\circ$  slope using the SAF, as shown in **Figure 1**.

Body weight was more evenly distributed between the sound side and affected side while using the SAF for each slope condition, as shown in **Table 1**. The subject stood with a majority of their body weight on their affected side when standing on a  $-5^\circ$  and  $-10^\circ$  slope with the SAF.

**Figure 1:** Ankle and knee joint angles (left) and torques (right) when standing on a  $-10^\circ$  slope with the ESAR and SAF.

**Table 1.** Percent difference of body weight supported through sound and affected limbs during 20-second quiet standing trials. Negative values indicate body weight distributed more to affected side than sound side.

	-10 deg	-5 deg	+5 deg	+10 deg
ESAR	11.97%	16.03%	16.92%	7.19%
SAF	-8.02%	-4.55%	6.29%	7.91%

The improvements in torques acting on the ankle and knee when using the SAF create a more stable alignment of the affected limb, particularly when standing on a  $-10^\circ$  slope. This improved alignment is believed to be one factor that allowed the subject to stand with more evenly distributed body weight when using the SAF.

The subject's perceived exertion following 5 minutes of quiet standing on a  $-10^\circ$  slope were rated as a 6/10 using the ESAR and a 2/10 using the SAF. Perceived exertion was rated a 2/10 and a 7/10 using the ESAR and SAF, respectively, while quiet standing on a  $+10^\circ$  slope. Percentage of body weight supported by the sound limb increased for all inclination conditions throughout the 5-minute standing trial. However, at both the beginning and end of the trials,  $\sim 10\%$  more body weight was distributed to the affected side when using the SAF compared to the ESAR. Using the SAF allowed the subject to maintain a more even body weight distribution throughout the standing trial.

### Significance

Walking and standing on uneven terrain and slopes are notably difficult tasks for persons with lower limb amputations. To complete these tasks, accommodation to slopes is commonly completed through proximal joint adjustments. With the SAF, slope accommodation occurs through slope adaptation of the prosthetic ankle-foot system. This adaptation may increase user stability on slopes, reduce muscular effort and joint stresses, and decrease the likelihood of overuse injuries on the affected side. Improvements to these detrimental effects may allow persons with amputations to increase their community participation.

## Introduction

Passive-dynamic ankle-foot orthoses (PD-AFOs) are biomechanical assistive devices that help individuals with ankle-foot impairments by providing stability and support to the ankle joint. PD-AFO bending stiffness can be tuned to an individual based on their natural ankle quasi-stiffness (NAS). NAS is typically defined as the linear slope of the ankle joint moment vs. angle curve during the loading phase of stance [1]. However, overall NAS changes across gait speeds [2] and NAS is not constant throughout the loading phase [3]. Thus, AFOs with bending stiffness tuned to a single NAS value may provide inadequate support throughout the entire loading phase, or when walking at different speeds. Novel materials such as shear-thickening fluids may overcome this shortcoming with their rate-dependent properties.

This study's purpose was to investigate the fundamental interactions between a healthy musculoskeletal system and a PD-AFO with a shear thickening fluid (STF) element, known as a rate-activated tether (RAT) [4]. We hypothesized that these novel STF elements used in conjunction with PD-AFOs can provide physiologically appropriate rate-responsive resistance to ankle joint bending.

## Methods

Standard 3D motion-capture kinematic and kinetic data were collected from a young healthy subject (25 yrs, 1.75m, 61kg) walking on an instrumented treadmill while wearing a unilateral STF-AFO. Each of the following conditions was performed at 0.8 statures/s and 1.0 statures/s walking speed: 1) no AFO, 2) AFO w/o STF element, 3) STF-AFO w/ low-viscosity STF, and 4) STF-AFO w/ high-viscosity STF. STFs were polyethyleneglycol with colloidal suspensions containing 48% solids (low visc.) and 50% solids (high visc.). The STF elements were secured to a standard hinged AFO at the heel and posterior shank. Ankle joint angle, ankle joint moment, STF element length, and STF element displacement rate were calculated during stance. STF element length and displacement rate were compared to material property testing data to estimate its resistive force during the loading phase of stance (Figure 1). The loading phase was investigated because during it, the ankle-foot-AFO complex resists excessive dorsiflexion and puts the shank in the optimal position prior to push-off.

## Results and Discussion

Rate-responsive resistance properties are clearly exhibited when using the STF-AFO. The length, deformation rate, and resistance changed throughout the loading phase of stance.

Overall, the RAT displacement rate followed a unique double-hump profile during the loading phase of stance. Compared to the slow walking speed, the fast walking speed had a higher initial peak displacement rate, but a lower second peak. Peak dorsiflexion angle was also lower for the high-viscosity STF condition compared to the lower-viscosity STF condition. This is also exhibited in the lower deformation lengths for the high-viscosity STF condition (dorsiflexion  $\rightarrow$  STF element extension).

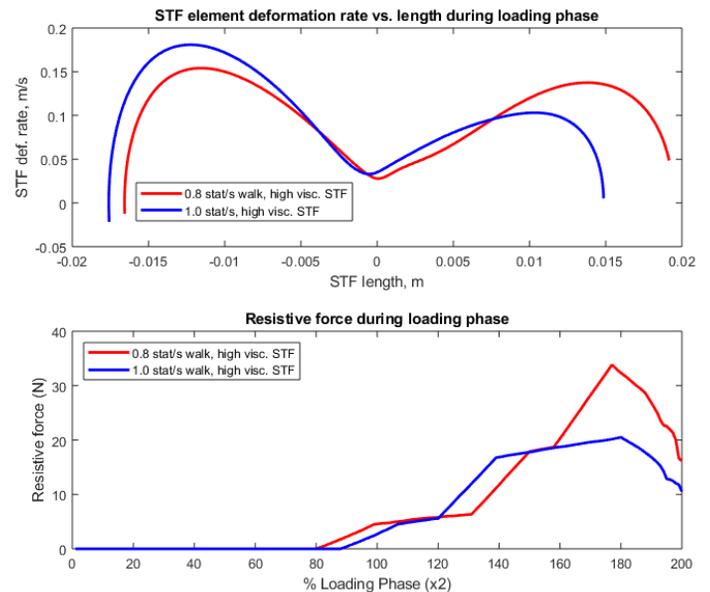

Figure 1: (Top) STF element deformation rate vs. length. Loading phase progresses left-to-right. (Bottom) Resistive force provided by the STF element during the loading phase. Note: STF provides no force during the first ~40% of this phase, since ankle is slightly plantarflexed and the element is slack.

Ankle joint moments and angles during stance did not vary greatly between STFs for either walking speed. However, the STF element is clearly activated and providing resistive force during the loading phase (Figure 1). This indicates that the STF substituted for some ankle joint function during loading.

## Significance

This research pushes the state-of-the-art of PD-AFO design forward by evaluating the feasibility of a rate-responsive PD-AFO. To date, PD-AFOs have only been fabricated with a single, unchanging bending stiffness. This simplicity limits the range of activities for which PD-AFOs are useful as they cannot adapt to changes. The STF-AFO tested can provide supportive force that varies depending on the rate of ankle dorsiflexion. A limitation to this work is that the STF element dissipates energy through its damping properties, in contrast to most PD-AFOs that store and release elastic energy. However, more elastic properties may be attainable through more intricate RAT/spring mechanisms.

## Acknowledgments

The authors acknowledge Dr. Eric Wetzel, and Alexander Lurski from the Army Research Laboratory in Aberdeen, MD for helping with the design and manufacture of the STF elements and for providing the material property testing data used in this study.

# Biomimicry of the Gastrocnemius During Gait for Transtibial Amputees.

Gabriel B Rios Carbonell, Hwan Choi PhD

Department of Mechanical and Aerospace Engineering, University of Central Florida

Email : hwan.choi@ucf.edu

## Introduction

With an increasing population of amputees in the United States, the adverse effects of prostheses that only mimic a portion of the function of the lost limb are becoming more evident. The majority of people with below knee amputation use passive prostheses, which lack the energy recycling system found in an intact leg made by the gastrocnemius, soleus, and Achilles tendon. During walking, these two muscles and the tendon control the storage and release of the energy into the step, adding to its efficiency. With a passive prosthesis, the storage of energy typically occurs in a carbon fiber blade, but the stored energy mostly returns during mid-stance. Only a small amount of energy contributes to propulsion during terminal stance [1]. This lack of propulsion from the passive ankle foot prostheses leads to additional musculature to accommodate proper walking motion. As a result, this can lead to multiple disadvantages such as increased metabolic cost, gait asymmetry, reduced walking stability, and so on. To regulate the energy storage and release of a passive ankle foot prostheses, we proposed a novel timing module that can control energy release timing [2]. However, it is unclear when the passive ankle foot prosthesis releases energy, making it challenging to determine the appropriate timing, which biological elements that can role of plantarflexion during terminal stance. Thus, we investigated how current passive ankle prostheses have different energy release timing compared with an unimpaired gastrocnemius muscle which plays an important role in propulsion [3].

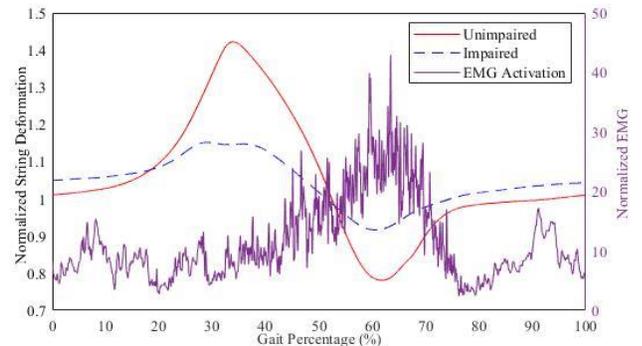

## Methods

In this study, the behaviour of a passive ankle prosthesis was observed and compared to the activation of the unimpaired limb of a K-4 level participant with transtibial amputation. To analyse the deformation of the prosthesis, a set of six motion capture markers were placed on the ankle foot prosthesis and the unimpaired leg. Measurements of the prosthesis deformation and unimpaired ankle joint were taken with motion capture (Vicon, Oxford, UK), focusing mainly on two markers: one placed on the toe and the second on the tibia. The deformation of a passive prosthesis is quite complex. Using the tibia and toe markers as reference, a virtual string can be created between the two markers. The deformation of this string can be used as a representation of the deformation of the prosthesis. A secondary advantage of using this method to measure the deformation of the prosthesis is that use of the same markers on the unimpaired leg the virtual strings have a similar behaviour. This allows both legs to be compared. The observed behaviour also behaves similarly to that of the ankle angle during gait. The activation of the unaffected side of gastrocnemius was measured using a surface electromyography (EMG) sensor (Avanti™ wireless EMG, Delsys Boston, MA). The participant walked on a treadmill set at a self-selected speed. During walking, we measured the time from maximum ankle dorsiflexion to maximum plantar flexion of the intact ankle and the prosthetic foot. The return of the passive prosthesis to its undeformed was considered as plantar flexion. The peak EMG activation timings of the unimpaired

gastrocnemius were identified, and we compared it to the foot deformation of the unimpaired limb.

## Results and Discussion

The release of the energy stored by the gastrocnemius is unlike the abrupt deformation return of the prosthesis (Fig. 1). The dorsiflexion to plantar flexion spanned an average of 17% of the gait cycle for the unimpaired limb while the deformation of the passive prosthesis spanned 19% of the gait cycle on average. The unimpaired leg started the push off about 2.5% of the gait cycle after the prosthesis on average. The activation peak of the unimpaired gastrocnemius and plantarflexion of the unimpaired ankle occurred at a similar time in the gait cycle, (62%). These outcomes suggest that passive prosthesis needs to retain the energy release timing by maintaining deformation after peak deformation.

**Figure 1:** Linear foot deformation compared to the gastrocnemius EMG. All the values were normalized by the values obtained during the anatomic position before the trial

## Significance

These results demonstrate that the passive prosthesis was not able to fully replicate the energy recycling system present in the intact limb. With implementation of a timing module, the control of the release timing can be achieved. The two main parameters that need to be considered when replicating motions of the intact ankle into deformations of a foot prosthesis are the total amount of deformation and the deformation rate. With accurate analysis on how the prosthesis foot deforms in the energy return phase, the proper timing can be achieved. Thus, adjustments can be made to the energy release timing to match the energy return of the unimpaired leg. As the timing of its activity is similar, EMG signal from the gastrocnemii could be used to determine the appropriate energy release timing.

## Introduction

For transtibial amputees, the loss of a lower limb results in compromised standing stability and increased attentional demand when controlling standing posture[1]. Recent study seeking to improve amputee function and standing stability have demonstrated promise for the use of descending neural commands (via direct EMG control) to volitionally and continuously modulate prosthetic ankle joint mechanics [2]. However, the loss of normative feedback mechanisms due to amputation raises the concern of the attentional demand of this control paradigm. Thus, in this pilot study we investigate the effect of training on the automaticity of postural control (via sample entropy analysis of center of pressure excursion (CoP) [3]) using dEMG control of a powered ankle prosthesis.

## Methods

We asked one transtibial amputee to participate in this preliminary study. The participant provided consent in this IRB approved (UNC-CH) study. We asked the amputee participant to stand quietly with his prescribed device and with a powered ankle prosthesis using direct EMG control[2]. We asked the participant to repeat this task after several days of training with the powered device. The participant stood quietly in different visual (eyes open, eyes closed) and attentional conditions (dual-task, single-task). We conducted 30-second trials and randomized the order of conditions and then repeated trials in reverse order.

We recorded CoP excursion via an instrumented split-belt treadmill. We subtracted the mean, filtered (low-pass, 12.5Hz, 4<sup>th</sup> Order Butterworth), and normalized all trials individually by their standard deviation. For sample entropy analysis we downsampled all data to 100 Hz (resulting in data lengths of 3000 points), and selected typical template size and tolerances ( $m = 3$ ,  $r = 0.2$ ) [3]. We conducted a 3-way ANOVA to test for main and interaction effect of Device (Passive, Powered, Trained), Vision (Eyes Open, Eyes Closed), and Task (Dual-Task, Single-Task) on Sample Entropy of CoP Excursion in the Anterior-Posterior (AP) direction.

**Figure 1:** Sample Entropy (Eyes Closed Condition). Grey) Single-Task Yellow) Dual-Task. Standard error bars are shown.

## Results and Discussion

In this pilot study we observed a significant improvement in the automaticity (increased sample entropy) of postural control across various quiet standing tasks as a result of training in the dEMG controlled prosthetic ankle (Fig. 1). Statistical analysis showed device as a main effect ( $p = 0.0282$ ), while all other main and interaction effects did not reach significance. We observed the largest change in sample entropy in the trained condition (Fig.1), however sample entropy seemed unchanged between passive and pre-training conditions.

In the trained condition we observed a trending increase in sample entropy (increased automaticity [3]) during dual task conditions, as attention is diverted away from postural control, similar to previous able-bodied study [3]; however, this trend was not visible in the untrained condition (Fig. 1).

We believe regularity of CoP excursion may have potential as a tool for the investigation of attentional demand in postural control for transtibial amputees. In the passive device conditions we noted a trending increase in entropy (decreased regularity) in the dual-task vs. single-task condition (Fig. 1). This measure (often used in able-bodied population) may provide more meaningful information into the automaticity of postural control under attentional demands for amputees compared with typical measures [1].

This preliminary study has demonstrated the potential for an increase in automaticity of postural control using a dEMG control powered prosthetic ankle. Sample entropy appears to be a promising measure for future study involving attentional demands associated with prosthesis wear. This pilot work motivates us to extend this analysis to more amputees to confirm this finding for the general amputee population.

## Significance

This is the first study to begin to investigate the potential changes in automaticity of postural control using dEMG control of a powered prosthetic ankle. As far as the authors are aware this is the first study employ entropy measures in the evaluation.

## Introduction

Robotic exoskeletons have many potential applications to assist in current rehabilitation procedures [1]. While substantial investigations have shown that lower-limb devices can improve walking economy [2], there is limited information on the effects of assistive devices on static and dynamic postural control. One study performed a sensory organization test (SOT) wearing a lower limb exoskeleton but the device was purely passive [3].

This study aims to determine if a pneumatic, myoelectrically controlled, plantarflexion-assist, ankle exoskeleton affects postural control of the user. We aimed to investigate two hypotheses. First, wearing the exoskeleton may negatively affect balance in the anterior-posterior direction because the device is plantarflexion assist only. Furthermore, because the ankle joint's range of motion and predominant control dof is for plantarflexion the device could increase passive stability in the medial-lateral (ML) direction in each ankle while decreasing the bilateral ML control strategy. Second, how the exoskeleton interacts with postural control processes will depend on internally driven sensorimotor control weighting strategies, which will be tested using a modified SOT (mSOT).

## Methods

We collected motion capture data (Qualisys), force data (Bertec) from two subjects (1 male and 1 female; Ages: 23-25) with no history of neurological or musculoskeletal impairment.

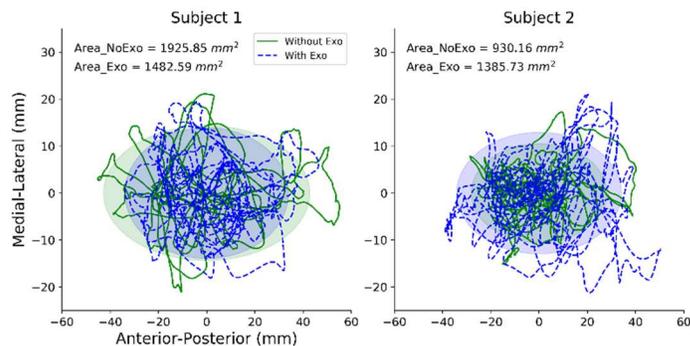

The experimental protocol was a modified version of the SOT, repeated with and without the exoskeleton. The experimental pairings were: eyes open (EO) vs. eyes closed (EC), stable surface (SS) vs. rocker board (RB), and powered exoskeleton (PE) vs. no exoskeleton (NO). The RB rotation axis was parallel to the plantar flexion rotation axis and perpendicular to the treadmill midline. Each trial lasted 20 seconds. Subjects wore an pneumatically-actuated, myoelectrically-controlled, plantarflexion assist, ankle exoskeleton controlled by the soleus muscle [2].

We collected center of pressure (COP) data for the AP and ML directions. We filtered the COP data (2<sup>nd</sup> order, 30 Hz). We calculated a single force vector and COP equivalent to the combination of the force and moment data from the treadmill data for the left and right feet. Then we calculated the AP and ML standard deviations (SD), mean velocity, and used a principal component analysis (PCA) to calculate the ellipsoidal sway area for the COP.

## Results and Discussion

During the EO-SS trial subjects showed no clear differences between exo-on or exo-off conditions. For the EC-SS trial both subjects saw a reduction in the SD of the COP in the AP direction during the exo-on condition. For both RB trials (EO and EC) with the exo-on, both subjects saw an increase in the mean COP velocity in the AP and ML directions (**Fig 1**).

This study served as preliminary data collection which due to limitations of access to resources and people (COVID-19) tested only 2 participants. The pilot data showed that with the exoskeleton on, both subjects saw an increase in mean COP

**Figure 1:** COP displacement (line trace) and sway area (shaded ellipse) in the AP and ML directions for two subjects during the EC-RB trial. When wearing the exoskeleton, Subject 1 showed a reduction, while Subject 2 showed an increase in COP sway area.

velocity during both RB trials in the AP and ML directions. The other measures of postural stability were less consistent. There were no conclusive differences in SD of the COP displacement across conditions. With the exoskeleton on, one subject performed better while the other performed worse in the AP direction. In the ML direction SD of the COP displacement stayed consistent between both conditions. Because the area changes were inconsistent but mean COP velocity increased, it may indicate increased joint stiffness when wearing the exoskeleton.

Future work will include a larger test sample and a condition wearing an unpowered exoskeleton. This new condition will allow us to determine whether changes in mean COP velocity are related to inertial properties of the exoskeleton and not to the assistive properties. We will also further investigate longitudinal training effects and the role of sensory weighting.

## Significance

The effect of exoskeletons on sensory integration in postural control is still largely unknown. This study provides preliminary insights into how assistive devices may modulate the response of postural control and help inform development of novel controllers that enhance both gait and balance.

# Sensitivity of Mechanical Outcomes to Various Stiffnesses of Variable Stiffness Foot (VSF)

Kieran M. Nichols\*<sup>1</sup>, and Peter G. Adamczyk<sup>1</sup>

<sup>1</sup>Mechanical Engineering, University of Wisconsin-Madison, Madison, WI, USA

Email: \*knichols4@wisc.edu

## Introduction

The Variable Stiffness Foot (VSF) is an energy storage and return (ESR) prosthesis that can passively store and return energy to its users through the deflection of a compliant leaf spring keel in the forefoot [1]. It is a semi-active prosthesis, meaning it does not deliver power (from a motor) during stance phase, but it does adjust the stiffness during swing phase. This adjustment allows the user to have a variety of stiffnesses that can be dependent of the type of activity (standing, flat ground walking, ramp and stairs walking).

The VSF (Figure 1) prototype has a rigid ankle and a compliant forefoot keel whose effective stiffness is modulated by a support fulcrum moved by a motor and belt system. A microcontroller controls the movement to modulate the stiffness during swing phase due to user control or foot trajectory reconstructed by an inertial sensor [1].

Previous studies in prosthetics found that increased range of motion for stairs and ramps are associated with improved gait [3]; stiffer ankles (increased moments for small change of angle) are helpful for standing stability [4]; and a compliant forefoot returns more energy to the rest of the body [2].

This study tested these biomechanical effects of the VSF across level walking under three different stiffness settings. We hypothesized that the decreasing forefoot stiffness would lead to increasing ankle plantarflexion, decreasing peak ankle moment, and increasing energy returns in push-off.

## Methods

Seven persons with trans-tibial amputation were included in this experiment, of whom three are analyzed to date. The participants walked across two force plates (one foot on each plate) in a motion capture lab with twelve cameras. The participants walked with three different VSF stiffness settings (compliant, medium and stiff, scaled to each person's body mass) for 3 trials at  $1.1 \pm 0.1$  m/s, with speed tracked using motion capture.

Motion and force data were processed in Visual3D and MATLAB for kinematic and kinetic calculations. We estimated ankle angle and moment according to standard inverse dynamics, and intersegmental power using a deformable body model. Peak values were computed for each stride on the prosthetic side and averaged across the three trials for each stiffness setting.

## Results and Discussion

Each subject had similar trends for the angle, moment, and intersegmental power results and there was support for the three hypotheses. The ankle angles (Figure 2) had the largest plantarflexion excursions for the compliant stiffness setting. The ankle plantarflexion moments were smallest for the compliant settings. The intersegmental ankle power output tended to be largest close to toe-off (around 60% of stride) for the compliant settings.

Figure 1: side view of the VSF [1]

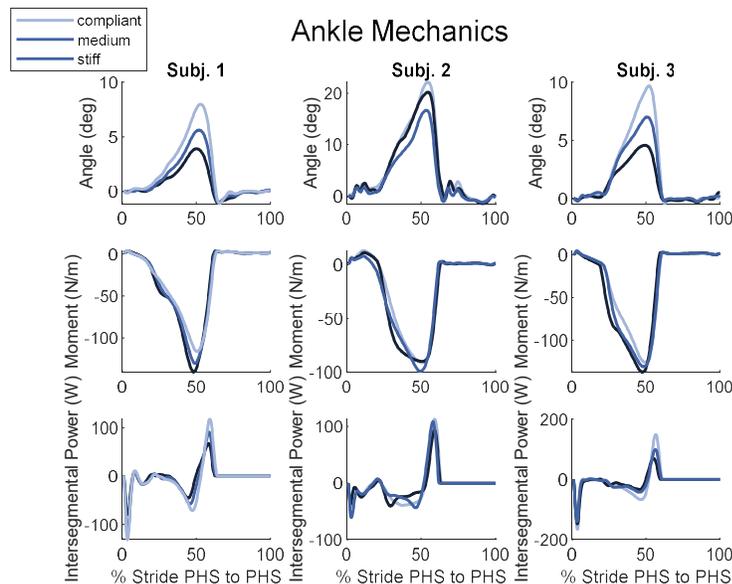

Figure 2: Results showing the angle, moment, and intersegmental power related to the ankle joint for each walking stride on the prosthetic side of the participants. Plantarflexion is in the negative direction. PHS: Prosthetic Heel Strike.

## Significance

Many prosthetic users are limited to using passive feet that have fixed keel stiffness. This limited variability may be optimal for one function, but will not be suited for many different functions like standing, walking on stairs and ramps, and on uneven surfaces. This VSF can give its users the ability to change the foot stiffness that may increase comfort, adaptability, and help users get closer to functional walking. Future analysis will evaluate the ideal stiffness settings for different activities. Semi-active prostheses could also be potentially used in clinics to assess stiffness preferences so prosthetists can better recommend new passive feet.

# Muscle Response During Interaction with a Variable Damping Controlled Robotic Arm

Connor M. Phillips, Fatemeh Zahedi, Hyunglae Lee\*

School for the Engineering of Matter, Transport and Energy, Arizona State University, Tempe, AZ

Email: [\\*hyunglae.lee@asu.edu](mailto:*hyunglae.lee@asu.edu)

## Introduction

Current upper limb exoskeletons rely primarily on positive damping controllers (PDCs). This method, although very safe and stable, requires a large force input from the user and greatly reduces agility. In a previous study, our lab developed a variable damping controller (VDC) that manipulates the robotic damping applied to an environment based on the user's intent of movement ( $\dot{x}\dot{x}$ ). This study showed that subjects using the VDC were more agile in comparison to a PDC and had comparable stability.<sup>1</sup>

Here, we present an electromyography (EMG) study to quantify the difference in muscle activation of our novel VDC compared to fixed positive and negative damping controllers during upper limb physical human-robot interaction (pHRI). There were two hypotheses for this experiment. First, that during the movement phase, the subject would demonstrate less activation in the variable condition compared to the positive, and near equal activation between the variable and negative conditions. Second, that during the stability phase, the subject would demonstrate less activation in the variable condition than the negative, and near equal activation between the variable and positive conditions.

## Methods

Six EMG sensors (Trigno Avanti Sensor, Delsys, MA) were used to measure muscle activation of the brachioradialis (forearm), biceps, anterior and posterior deltoids, and longitudinal and lateral triceps. This data was normalized to the maximum contraction (MVC) of each subject.

A seven degrees-of-freedom (DOF) robotic arm (LBR iiwa R820, KUKA, Germany) with a six-axis load cell (Delta IP60, ATI Industrial Automation, NC) was used for the application of all damping-defined environments. Zero stiffness and 10 kg of mass were simulated in the horizontal plane for all experiments. High stiffness of  $10^6$  N/m was simulated in the vertical plane to constrain vertical movement. Damping of +60 Ns/m was applied for the positive condition and damping of -15 and -20 Ns/m were applied for the negative condition in the mediolateral (ML) and anteroposterior (AP) directions respectively. These quantities were found from a previous human study with the KUKA robot.<sup>1</sup> The range of variable damping was calculated using subject-specific  $k_p$  and  $k_n$  tuning parameters. These quantities scaled the range of the positive ( $k_p$ ) and negative ( $k_n$ ) damping based on the maximum and minimum value of  $\dot{x}\dot{x}$  that the subject could produce.<sup>1</sup> The damping applied during the experiment changed relative to the instantaneous value of  $\dot{x}\dot{x}$ .

Subjects were seated with their torso securely strapped to a rigid seat, facing a feedback visual display at ~1 m. This display provided information on neutral and current hand positions to the subject. Subjects held a handle that was connected to the robot's end-effector, with the shoulder in  $\sim 70^\circ$  of abduction,  $\sim 45^\circ$  of horizontal flexion, and the elbow in  $\sim 90^\circ$  of flexion. This starting posture was considered the neutral position for all trials.

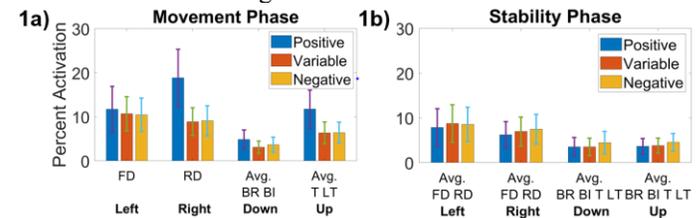

Subjects were tasked with moving as quickly as possible to targets shown on the visual feedback display. The position of the target was  $\pm 0.1$  m away from the neutral position, in both the ML and AP directions.

EMG analysis was divided into two components: the movement phase (MP), and the stability phase (SP). The boundaries between phases were determined by the horizontal position of the robot's end-effector in the horizontal plane. The movement phase began at the onset of movement ( $\pm 0.001$  m) and ended once the subject reached the target ( $\pm 0.1$  m). The stability phase began directly after the movement phase and ended once the subject was able to keep their marker inside of the target for 0.5 seconds. If the subject was unable to do this, all data post-movement phase was included in the stability phase.

Nine young, healthy subjects participated in this study which was approved by the Institutional Review Board of Arizona State University (STUDY 00010123).

## Results and Discussion

Group analysis in the MP revealed that the activation due to the variable condition was less than the positive and near-equal ( $<1\%$ ) to the negative condition in all directions, which directly supports the hypothesis. This was most prominent in the right and upwards directions with differences of 9.94% and 5.11% respectively between the positive and variable conditions. The group results from the SP provide partial support for the hypothesis, as the variable condition is near-equal ( $<1\%$ ) to the positive condition in all directions, while the variable condition is less than the negative in the right (0.52%), down (0.93%), and upwards (0.72%) directions. However, this difference is too small to demonstrate significance.

**Figure 1:** Group averages from the MP (1a) and SP (1b). MP data is the average of agonists in each direction while the SP data is an average of agonists and antagonists. A 95% CI is shown for each condition. Key: FD= Front Deltoid, RD= Rear Deltoid, BR= Brachioradialis, BI=Biceps, T= Lateral Triceps, LT= Longitudinal Triceps.

## Significance

These results provide support for further investigation of the variable damping controller in upper limb pHRI, and the expansion of this study into multidirectional movement. A significant reduction in muscle activation was shown during the MP, which supports consideration for the implementation of this technology into industrial settings. However, this pattern must be replicated in conditions more closely resembling real-world pHRI, where the user may move through a larger range of motion.

# Biomechanical Design and Preliminary Evaluation of an Ankle-Foot Simulator for Ankle Clonus Assessment Training

Yinan Pei<sup>1</sup>, Prateek Garag<sup>1</sup>, Kevin Gim<sup>1</sup>, Christopher M. Zallek<sup>2</sup> and Elizabeth T. Hsiao-Weckslar<sup>1</sup>

<sup>2</sup> Department of Neurology, OSF HealthCare Illinois Neurological Institute, Peoria, IL  
Email: ethw@illinois.edu

## Introduction

Clonus is defined as involuntary and rhythmic (5-8Hz) abnormal muscle contractions observed during passive stretching and caused by lesions in the descending upper motor neuron pathways. It can be present in patients with spinal cord injury, post-stroke, and other conditions of the brain or spinal cord [1]. Clinically, the ankle joint is the most common site to test for clonus. However, successful triggering of ankle clonus requires mastery of the following technique [2]: 1) correctly position the examining hand on the foot, 2) provide a rapid dorsiflexion at sufficient joint velocity, 3) minimize ankle inversion during test, and 4) maintain appropriate load on the plantar surface of the forefoot to continue the clonus. To master this technique, students need to go through repetitive hands-on training. However, in the traditional education scenario, the availability of practice patients is usually very limited; therefore leaving the trainee skill proficiency questionable. To address this problem, we present a new haptic ankle-foot training simulator to provide healthcare learners more accessible practice opportunities.

## Methods

Our goal was to develop a medical training simulator that provides a realistic, safe, and low-noise training environment for the trainees. The series elastic actuation strategy was chosen for its safe human-robot interaction and accurate force control [3]. The specifications of the simulator were derived from the few available quantification studies of ankle clonus [1] and previous devices [4,5]. The simulator, capable of generating a peak ankle torque of 17Nm, was actuated by a 150W Brushless DC motor (M3508, DJI) and a single-stage 3.2:1 timing belt drive (MR5, Misumi). A series spring stiffness (165N/mm) ensured a force control bandwidth of ~14Hz, which was sufficient to replicate oscillatory clonus motion. With known spring stiffness and displacement, interaction force between the examining hand and the simulator were accurately estimated to verify continuous loading needed to maintain clonus.

Fig 1: Ankle-foot simulator prototype

The simulator segment lengths were designed based on a 50<sup>th</sup> percentile Caucasian male. The principal dorsi/plantarflexion (DF/PF) degree of freedom (DOF) was actuated (available ROM: 20° DF to 55° PF), while the auxiliary inversion/eversion (I/E) DOF was passive (ROM: ±10°). Furthermore, the simulator was equipped with 1) a linear encoder to measure spring deflection, 2) two absolute rotary encoders to measure ankle angular position and velocity in DF/PF DOF and joint angle in I/E DOF, and 3) several force-sensitive resistors on the foot shroud to detect whether the trainee's hand was properly positioned on the forefoot and plantar surface.

The simulator was programmed to initiate ankle clonus when the DF stretch speed was faster than 200°/s. To maintain the clonus behavior, a DF torque of 3Nm must be maintained after

the triggering. The frequency of ankle oscillation was set at 5Hz. Sensor signals were sampled at 1000Hz and filtered by a 2<sup>nd</sup>-order Butterworth filter with a cut-off frequency at 20Hz.

## Results and Discussion

The prototype simulator was capable of replicating an experimentally-observed clonus behavior at the ankle with the desired frequency (Fig. 2). Onboard sensors captured the timing of rapid DF stretch and monitored the maintained DF load after clonus was triggered. In the future, these control flow parameters will be iterated based on clinician feedback.

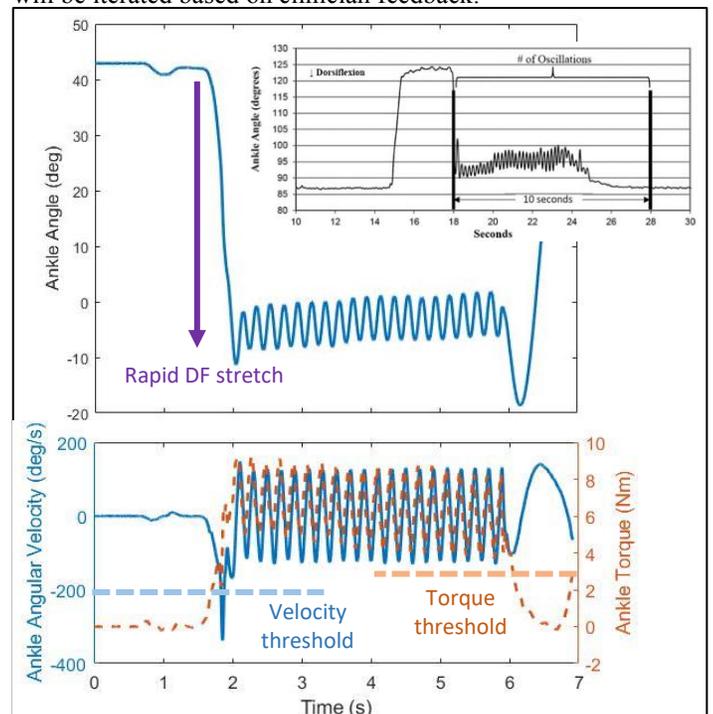

Fig 2: Simulated ankle behavior (blue) compared to experimental clonus behavior from a patient (black) (from [6]). Dorsiflexion is negative.

## Significance

Robotic medical training simulators are becoming more accepted as a supplement to the traditional training process. In the case of ankle clonus, there are very few devices for clinicians to train and no commercial product exists. The preliminary results are promising that our device could fill this gap for medical, physical therapy, and other healthcare students.

## User- and Speed-Independent Slope Estimation for Lower-Extremity Wearable Devices

### Introduction

As more powered prostheses and exoskeletons enter real-world settings, it is important to adapt assistance profiles in dynamic environments using slope level information. Adaptive assistance profiles based on environmental information can help wearable devices keep up with real-time changes in human biomechanics and maximize assistance benefits. Advancements in intention recognition (IR) algorithms have enabled wearable devices to autonomously assist users across different terrains (e.g., ramps and stairs) [1]. IR algorithms are capable of classifying ramps of different slope levels without the need for slope level estimations, but assistance profiles typically remain constant or are scaled based on encoded joint trajectories. The inclusion of slope estimation algorithms and torque scaling equations in the control of wearable devices offer a more natural and effective interface between users and their environment.

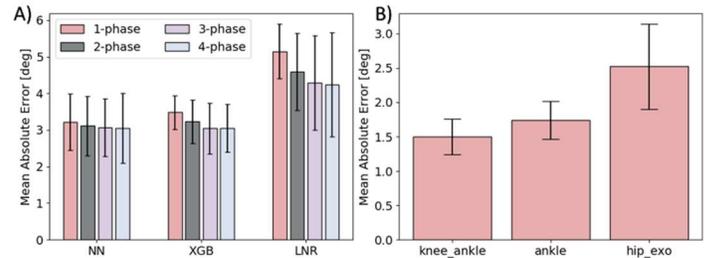

Numerical solutions for slope estimation using inertial measurement units (IMUs) have been shown to be inaccurate due to sensor drift and variations in walking speed [2][3]. Recent work suggests that machine learning (ML) models trained with electromyography (EMG) and mechanical sensor data can accurately estimate slopes at different speeds ( $1.3^\circ$  RMSE) [4]. A limitation of this work is that each slope level was estimated for a short range of speeds.

We hypothesize that training a slope estimator with only mechanical sensor data collected on slope levels across a large range walking speeds can accurately estimate slopes independent of the user and walking speed. Our methodology is expected to generate robust slope estimators that could be readily integrated into the control systems of various wearable devices.

### Methods

This study focuses on evaluating the performance of ML models in estimating a user's slope level while walking on a speed-varying treadmill. Nine able-bodied subjects were fitted with three 6-axis IMUs (foot, shank and thigh) and three goniometers (ankle, knee, and hip). Thirteen static and five dynamic walking trials were collected for each subject. During static trials, slope levels ( $-15^\circ$  to  $+15^\circ$ , incremented by  $2.5^\circ$ ) were held constant while walking speeds changed from 0.6 to 1.4 m/s. During dynamic trials, walking speeds of 1.0 and 1.2 m/s were held constant while slope levels changed from  $0^\circ$  to  $10^\circ$ .

Slope estimation algorithms were evaluated for sensor suites commonly found on ankle prostheses, knee-ankle prostheses, and hip exoskeletons. Signals were filtered and segmented into sliding windows of data, incremented by 50 ms. Mean, standard deviation, min, max, and ending value features were extracted from each window. Analyses across different normalization methods, sliding window sizes, gait phases, and ML models were conducted to minimize slope estimation errors. The performance of neural network (NN), XGBoost (XGB), and linear regression (LNR) models were assessed. The phase dependency of the models was explored across four gait cycle types: 1-phase, 2-phase, 3-phase, and 4-phase. Tested window sizes ranged between 200 ms to 500 ms, incremented by 50 ms.

**Figure 1:** A) Static trial non-optimized model performance across gait cycle types for the knee-ankle case (250 ms window size). B) Optimized XGBoost model performance across all sensor suites using the 1-phase gait cycle analysis method and a 500 ms window size.

### Results and Discussion

For static trials, the NN and XGB model similarly outperformed the LNR model across each phase, for each sensor suite, including the knee-ankle case (Fig. 1A). The XGB model was selected over the NN model for hyperparameter optimization due to its lower average MAE variance. Since there was no significant difference between gait cycle types, the 1-phase gait cycle was selected due to its simplicity. With the optimal window size of 500 ms, static trial average MAE errors of  $1.500 \pm 0.258^\circ$ ,  $1.739 \pm 0.276^\circ$ ,  $2.522 \pm 0.618^\circ$  were achieved for the knee-ankle, ankle, and hip-exoskeleton sensor suites, respectively (Fig. 1B). Future analyses will test the performance of the proposed ML architectures on the dynamic trials, identify a reduced feature space for each sensor suite, and include a Kalman filter to further reduce errors.

### Significance

This user-independent study provides slope estimation solutions that are generalizable to novel users and a variety of wearable devices, including those not explored in this study (e.g., knee exoskeletons). The low errors achieved across dynamic walking speeds and the exclusion of EMG sensors are important steps towards the real-world implementation of slope estimators. Joint torque scaling based on slope level will have a significant impact on the quality of assistance that users receive from lower-extremity wearable devices, which can improve metabolic efficiency, user mobility, and the effectiveness of rehabilitation.

# Performance Evaluation of a Robotic Knee Exoskeleton

Seth Higgins<sup>1</sup>, Nicole Esposito<sup>1</sup>, Hannah Sweatland<sup>1</sup>, Daniel P. Ferris<sup>1</sup>

<sup>1</sup>J. Crayton Pruitt Family Department of Biomedical Engineering, University of Florida, Gainesville, FL, USA

Email: [seth.higgins@ufl.edu](mailto:seth.higgins@ufl.edu)

## Introduction

Robotic exoskeletons could reduce musculoskeletal loading and energy expenditure in military personnel during their everyday activities. Soldiers often carry loads around 50 kg or more, altering gait biomechanics, increasing metabolic cost, and increasing injury risk [1]. A common way to evaluate an exoskeleton's performance is assessing metabolic cost during movement.

The purpose of this study was to determine if a robotic knee exoskeleton (ONYX, Lockheed Martin) could reduce the metabolic cost of locomotion. Previous research showed a similar lower extremity knee exoskeleton reducing metabolic cost while walking up an incline and wearing a loaded backpack [2]. The ONYX is an altered version of that device. We hypothesized that the ONYX would reduce metabolic cost of walking up an incline and walking up stairs while carrying a load.

## Methods

We evaluated the performance of 6 healthy young subjects while walking on a treadmill, and up and down stairs. Subjects walked on a level, inclined (15°), and declined (15°) treadmill at two walking speeds (1.2 m/s and 0.3 m/s for level; 0.6 m/s and 0.3 m/s for incline and decline). Subjects also walked up and down stairs at the University of Florida football stadium at two different cadences set by a metronome (60 steps/min and 40 steps/min). We measured metabolic cost using a wireless device (Cosmed K5) and rate of perceived exertion using a Borg scale (1-10). Subjects completed the tasks with and without the exoskeleton, and with and without a weight vest (18 kg). The exoskeleton used a controller based on a finite state machine tuned to different phases of the movement phase based on kinematic and kinetic sensors. We calculated metabolic cost (W/kg) by using  $\dot{V}_{O_2}$  and  $\dot{V}_{CO_2}$  measurements and the Brockway equation [3].

## Results and Discussion

Metabolic cost increased when wearing the exoskeleton for all conditions (Figure 1 & 2). The knee performs more positive mechanical work during incline walking with a load and stair climbing with a load compared to level and decline walking, and stair descent. As a result, we hypothesized that the exoskeleton would perform the best on inclines and ascents with the load. There was a trend towards a lower percent difference in metabolic cost when walking at an incline and wearing a weight vest, but using the exoskeleton still cost more energy than not using the exoskeleton. Perceived exertion data were in agreement, mostly increasing when using the exoskeleton compared to not using the exoskeleton. The difference was greater at slower speeds and smaller cadences.

These results suggest that the robotic knee exoskeleton did not benefit the user in metabolic cost or perceived exertion for

any of the tasks. Future knee exoskeleton designs should consider how to reduce device mass, increase range of motion and degrees of freedom of motion, and alter the control strategy.

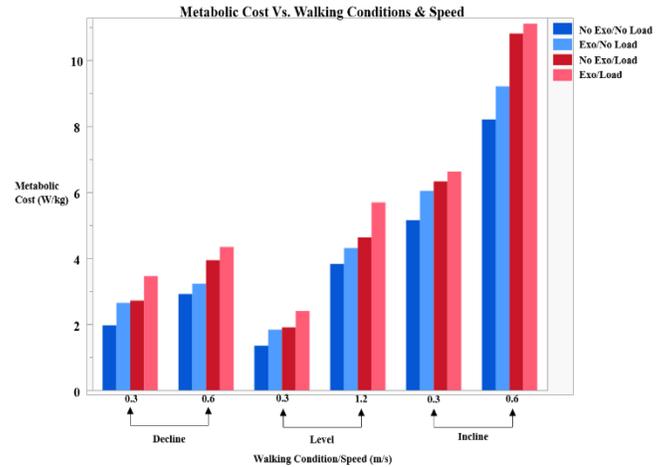

Figure 1: Metabolic cost data for walking conditions.

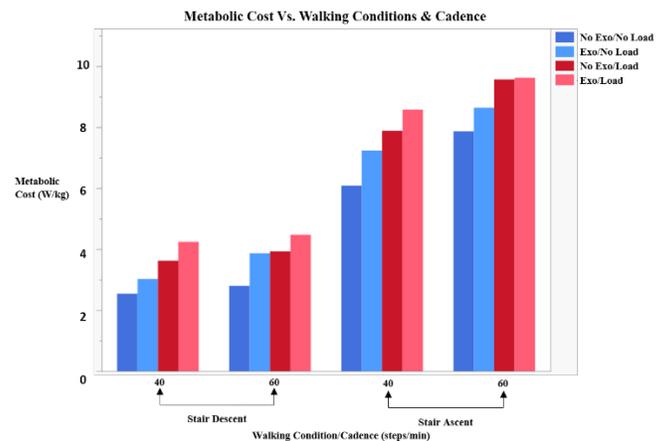

Figure 2: Metabolic cost data for stair conditions.

## Significance

Assessing the benefit of wearing a robotic lower extremity exoskeleton is a multi-factorial problem with metabolic energy expenditure and perceived exertion as two factors. These data suggest that the current design of the ONYX robotic knee exoskeleton does not reduce energy cost or perceived exertion for users. The data can provide insight into the biomechanical and physiological aspects that need to be addressed in future exoskeleton designs.

## Biomechanical Analysis of Device-Assisted Sit-to-Stand Transfers in Young Adults

Shaniel T. Bowen, MS<sup>1</sup>, Krystyna Gielo-Perczak, PhD<sup>2</sup>

<sup>1</sup>Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, USA

<sup>2</sup>Department of Biomedical Engineering, University of Connecticut, Storrs, CT, USA

Email: [stb103@pitt.edu](mailto:stb103@pitt.edu)

### Introduction

Sit-to-stand (STS) transfer is one of the most common activities of independent daily living. The ability to perform this motor task is essential for physical independence and is widely considered as an indicator of postural control and lower-limb strength.<sup>1</sup> This is especially the case for younger adults where injury-related reductions in functional status and capacity have been associated with increased risk of sarcopenia, injury, and obesity.<sup>2</sup> Thus, there is a need for solutions to assist STS transfer. Hence, the aim of this study was to design and evaluate an STS device by assessing postural control during unassisted vs device-assisted STS transfer via force platform analysis.

### Methods

Twenty-five college students (18-25 yrs.) with no mobility impairments were recruited from the University of Connecticut, all of whom provided written informed consent as per the IRB-approved protocol. For the experiment, an adjustable bench was used to adjust the seat height such that participants' hips and knees were bent 90° while sitting on the STS device (Figure 1).

**Figure 1:** STS lifting-seat device on the custom height-adjustable bench.

Participants were instructed to: (1) have their arms crossed against their chest during STS, (2) have their feet shoulder-width apart and flat against the force platform, and (3) to perform STS at a constant, self-selected pace. Three sets of recordings, 5 trials each, were done: (1) unassisted STS (control, C), (2) assisted STS with the device at maximum speed (MS), and (3) assisted STS with the device at an exponentially increasing acceleration (A).

To assess postural control, the (1) average net ground reaction force ( $F_{NETavg}$ ), (2) mean force development rate ( $FDR_{mean}$ ), (3) average net ground reaction moment ( $M_{NETavg}$ ), and (4) mean moment development rate ( $MDR_{mean}$ ) were calculated. In addition, the (1) average medio-lateral displacement ( $ML_{DISPavg}$ ), (2) average anterior-posterior displacement ( $AP_{DISPavg}$ ), (3) 95% ellipse area ( $Ellipse_{95\%}$ ), (4) average velocity ( $V_{avg}$ ), and (5) length (L) were measured. All postural control parameters were normalized to body height and weight. The percent reduction between assisted and unassisted STS was used to quantify the efficacy of the device in improving STS performance.

For this study, differences in outcome measures between unassisted and device-assisted STS were compared using the Friedman test. Post-hoc analysis was performed using the Wilcoxon Signed-Rank test with Bonferroni correction to adjust for multiple comparisons ( $\alpha=.025$ ).

### Results and Discussion

The force platform results are shown in Table 1. The STS device significantly reduced the ground reaction forces and moments, and the force and moment development rates. This effect may indicate decreased lower-limb joint loading due to the increased height and lifting force provided by the STS device prior to seat-off, as reported in previous literature.<sup>3</sup> The average COP velocity and average anterior-posterior COP displacement were reduced with device assistance, implying that the momentum needed for STS was lessened. Thus, the STS device was overall successful in enhancing STS performance by reducing the demand on, and instability in, the postural control system during STS.

Parameter	Without Assistance		With Assistance		Percent Reduction		P-Value
	C	MS	A	C-MS	C-A		
$F_{NETavg}$ <sup>1</sup>	65.4 (4.8)	38.7 (5.3)	38.3 (7.2)	40.6 (8.5)	41.4 (12.0)	<.0001	
$FDR_{mean}$ <sup>2</sup>	258.7 (83.3)	188.2 (59.0)	206.1 (52.6)	20.0 (36.9)	11.4 (35.1)	.002	
$M_{NETavg}$ <sup>3</sup>	2.53 (1.37)	1.32 (0.58)	1.20 (0.61)	38.4 (18.7)	43.7 (19.9)	<.0001	
$MDR_{mean}$ <sup>4</sup>	15.7 (4.8)	12.8 (4.3)	12.9 (3.3)	13.5 (31.3)	15.4 (24.9)	.02	
$ML_{DISPavg}$ <sup>5</sup>	0.64 (0.24)	0.78 (0.28)	0.68 (0.25)	-34.8 (57.0)	-1.1 (25.5)	0.02

L <sup>5</sup>	16.0 (2.5)	29.2 (3.4)	27.6 (4.5)	-83.3 (41.3)	-71.9 (46.1)	<.0001	

**Table 1:** Force platform results. Units: (1) %BW, (2) %BH/s, (3) %BW x BH, (4) %BW x BH/s, (5) %BH, (6) %BH x BH, and (7) %BH/s. P-values: significant overall diff. between assisted and device-assisted STS.

### Significance

These results show that our proposed device was able to lessen the biomechanical effort required for STS transfer. These promising findings reveal the potential benefit the device may give to the mobility impaired.

# Gait Phase Estimation of Powered Transfemoral Prosthesis using RNN

Jinwon Lee, Woolim Hong, and Pilwon Hur

Department of Mechanical Engineering, Texas A&M University, College Station, TX, USA

Email: {jinwon, ulim8819, pilwonhur}@tamu.edu Web: <http://hurgroup.net>

## Introduction

The gait phase informs us of the human's progress in the gait cycle. It is widely used to control powered assistive devices like prosthetics and exoskeletons. The controller's desired trajectories or gains are modified depending on the gait phase. Human walking can be divided into heel-strike, flat-foot, push-off, and toe-off [1]. Human gait is considered to consist of two walking phases: i) stance phase when the foot is in contact with the ground and ii) swing phase when the foot is not in contact with the ground. The first 60% of the gait cycle belongs to the stance phase and the next 40% of the gait cycle belongs to the swing phase.

Recently, there were studies using long short-term memory (LSTM) machine learning to estimate the gait phase. LSTM introduced cell state to solve the long-term dependency problem found in Recurrent Neural Networks (RNN). The concept of the cell state is three gates; forget gate, input gate, output gate. Forget gate is to erase unnecessary past information using the sigmoid function. In the input gate, a sigmoid function decides whether to reflect the new information in the cell state. If new information needs to be reflected, the current cell state is updated through the *tanh* function. The output gate determines which part of the information is sent to the cell's output using a sigmoid function. Finally, the output is fed to the input of the next cell state.

## Methods

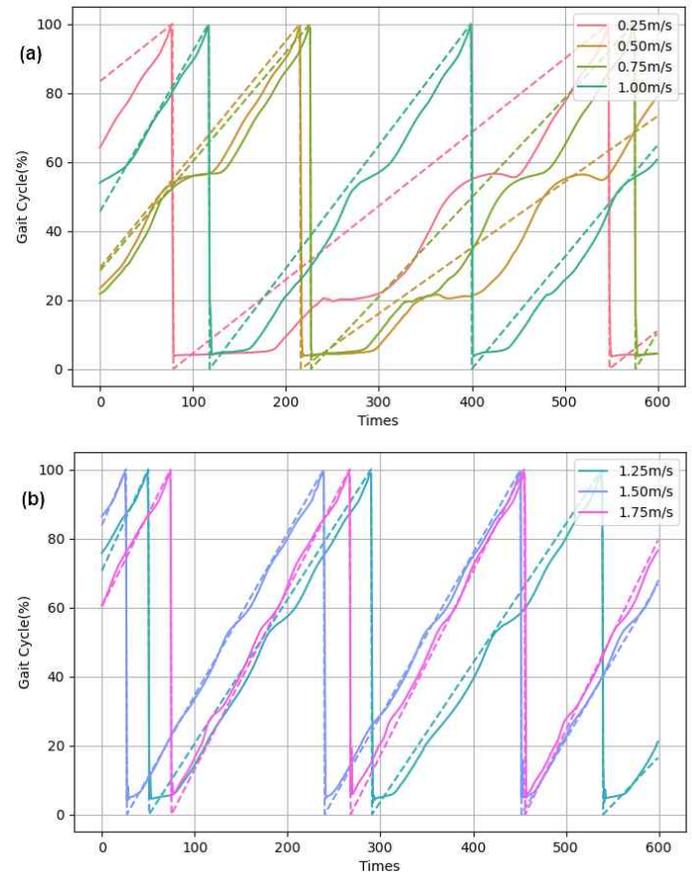

Our network architecture consists of five layers: LSTM (256), bidirectional LSTM (128), LSTM (128), and bidirectional LSTM (64), and fully connected layer. To prevent overfitting, each layer implemented a dropout rate of 0.1 and recurrent dropout rate of 0.4. We used the Adam optimizer with initial learning rate = 0.001, momentum = 0.9, batch size = 128, epochs = 30, and mean squared error (MSE) as the loss function [2, 3].

The data collection experiment had one healthy participant (age:31 years, height:175 cm, weight: 75 kg) who walked on a flat-ground treadmill. The treadmill speed varied from 0.25 m/s to 1.75 m/s. To gather kinematic and force data, we attached two IMU sensor (at the thigh and torso) and one force sensor (at the heel). To train the network's model, we prepared a dataset of 100 steps at three walking speeds (0.75 m/s, 1m/s, and 1.25 m/s). The data was suitably labelled. The refined data consisted of 200 data points per gait cycle. Training on this dataset took 30 minutes to converge with Tensorflow and two RTX 4000 GPU. To verify the model, we collected data for 400 steps at various speeds (0.25 m/s to 1.75 m/s).

## Results and Discussion

Figure 1 shows gait phase estimation. Regardless of the speed, the point where the heel strike occurred was accurately predicted. In particular, the gait cycle was accurately predicted at 1.25 m/s. However, there were a few inaccuracies in predicting the gait phase during the stance phase at lower walking speeds. Since the training data used only data from 0.75 m/s to 1.25 m/s, inaccurate predictions can be expected at slow speeds such as 0.25 m/s. Slow

walking speeds can increase sensor variation, which can cause data noise.

**Figure 1:** Gait cycle according to low walking speed (a) and high walking speed (b). Dotted line is ground truth and solid line is predicted cycle.

## Significance

Powered lower limb assistive devices rely on the gait phase parameter to determine suitable control inputs. Previously, the gait phase was predicted using multiple sensors and complex calculations. To reduce the prosthetic's weight and battery power efficiency, we must reduce the number of required sensors. In this study, we generated a gait phase estimation model using LSTM. The model requires only two IMUs and one force sensor. Future studies will use the trained gait estimation model to control a powered transfemoral prosthesis.

# Lower Limb Response of Transtibial Amputees Stepping on a Coronally Uneven Surface

Krista M. Cyr<sup>1</sup>, Ava D. Segal<sup>2</sup>, Richard R. Neptune<sup>3</sup>, Glenn K. Klute<sup>1,4</sup>

<sup>1</sup>Dept. of Veterans Affairs Center for Limb Loss and MoBility, Seattle, WA; Depts. of Mech. Engr., <sup>2</sup>Colorado School of Mines, Golden, CO; <sup>3</sup>The University of Texas at Austin, Austin, TX, <sup>4</sup>University of Washington, Seattle, WA  
Email: krista.kms@gmail.com

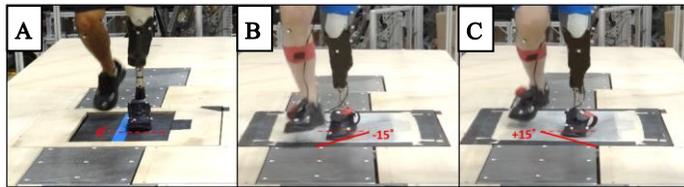

## Introduction

Over half of individuals with lower limb amputation experience falls each year [1, 2], and 73% of outdoor falls are due to environmental factors and uneven surfaces [3]. Such falls are three times more likely to result in injury [4]. Navigating uneven surfaces is important for individuals with transtibial amputation (TTA) to enable their participation in community activities. Currently prescribed multiaxial prosthetic feet for individuals with TTA attempt to store and return energy passively in all axes of deformation, which may not be desirable over unexpected coronally uneven surfaces.

The objective of this research was to quantify the biomechanical response of individuals with unilateral TTA wearing their prescribed prosthesis versus healthy controls while taking a step on a coronally uneven and unexpected surface. These findings may elucidate underlying adaptations that could be addressed through therapeutic and prosthetic interventions.

## Methods

A 12-camera motion capture system recorded marker trajectories of 8 individuals with unilateral TTA and 8 controls without amputations, while walking at their self-selected speed on a novel instrumented walkway with 5 embedded force plates. The middle force plate could be positioned flush to the surface or rotated  $\pm 15^\circ$  in the coronal plane, and could be blinded to participants (Figure 1). Kinematics and kinetics were evaluated during three different surface conditions: unblinded flush,  $15^\circ$  blinded inversion, and  $15^\circ$  blinded eversion. Coronal hip angle (adduction positive, abduction negative), mediolateral foot position of the recovery step relative to the opposite foot, and ankle energy returned [5] were evaluated between groups with a repeated measures analysis of variance ( $p < 0.05$ ).

**Figure 1:** An individual with a TTA stepping on the middle force plate during: (A) the flush condition (unblinded), (B) the blinded eversion condition, and (C) the blinded inversion condition.

## Results and Discussion

The TTA group used a more abducted hip strategy (negative coronal hip angles) compared to controls, especially during

blinded inversion (Table 1). This is similar to previous findings demonstrating premature activation of hip abductors during unexpected inversion of the ankle for subjects with hypermobility [6], therefore this may be a compensatory response for subjects with altered ankle mobility.

The TTA and control groups had a similar mediolateral foot position of the recovery step during the flush condition, but the TTA group took a significantly wider step following blinded eversion and a slightly narrower step following blinded inversion (Table 1). Individuals with TTA may have less control of their center of mass and balance, resulting in recovery step compensations after a step on a coronally uneven surface.

Less ankle energy was returned for the TTA group, significantly during both blinded disturbances (Table 1). This suggests that currently prescribed prosthetic feet are unable to effectively return stored energy to create the same amount of push-off power as healthy controls. Vickers et al. observed a similar lack of ankle power generation for TTA walking on a sagittal plane ramp while wearing their prescribed prosthesis [7]. Individuals with TTA may need to compensate to maintain forward progression, especially on uneven surfaces.

These results give insight into adaptations used by individuals with TTA when taking a step on a coronally uneven surface. These alterations and compensations could lead to increased energy expenditure and risk of falls during activities of daily living or in the community.

## Significance

This study may inform the development of prostheses able to conform to coronally uneven surfaces and rehabilitation therapies for individuals with TTA ambulating on uneven surfaces so they can maintain or increase participation in desired activities.

## Comparison of Trunk Muscle Activity during Modified Side-Bridge Exercises and Traditional Side Bridge Exercise

Chi-Wan Choi<sup>1\*</sup> PT, MPH, Jung-Wan Koo<sup>2</sup>, MD, PhD, Yeon-Gyu Jeong<sup>3</sup>, PT, PhD

<sup>1</sup> Department of Rehabilitation Medicine, Seoul National University Hospital, 101 Daehak-Ro Jongno-Gu, Seoul, 03080, South Korea

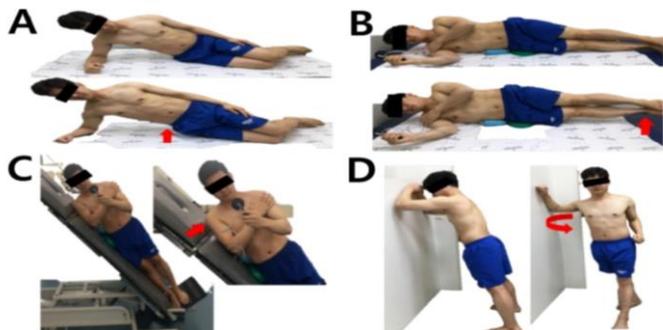

Email: \*[cch4105@gmail.com](mailto:cch4105@gmail.com)

### Introduction

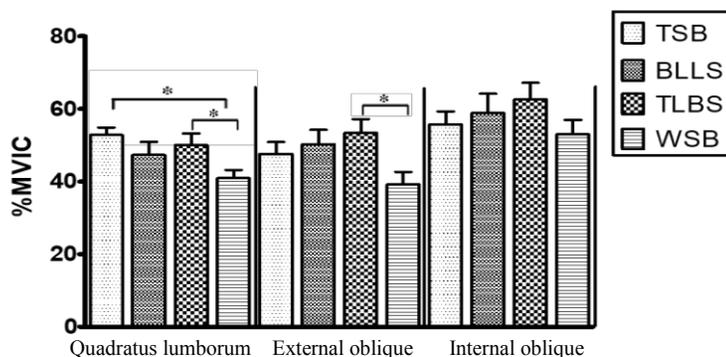

The side-bridge exercise is intended for endurance training and optimal motor control in the early stages of rehabilitation, and many occupational and sporting groups include it as part of injury prevention programs. This exercise helps increase spine stabilization that requires the musculature to be co-contracted for substantial durations. However, there may be some special situations in which it is impossible to tolerate the compressive load on the side supported during the side-bridge, such as in elderly persons with hip or knee replacements and even in athletes with shoulder pain. This leads to three modified side-bridge exercises: both leg lift while side-lying (BLLS), lying on the floor and attempting to raise the legs laterally; torso lift on a 45° bench while side-lying (TLBS), elevating the torso while standing on a 45° bench with the feet anchored; or wall side-bridge (WSB), side-bridge exercises while standing against a wall despite a compromised shoulder, hip, or knee. However, the comparative effects of these traditional side-bridge (TSB) and modified side-bridge exercises on the muscle activities of the lumbar and abdominal wall are not known. The purpose of this study was to examine the effects of three modified side-bridge exercises on the spinal stability muscles such as the external oblique (EO), internal oblique (IO), and quadratus lumborum (QL) compared with TSB for healthy men.

### Methods

A total of 20 healthy men with no known neuromuscular, cardiovascular, or orthopedic conditions, especially low back, shoulder, hip, or knee pain were recruited for this study. The participants performed TSB, BLLS, TLBS, and WSB in a random order. Surface electromyography measured the muscle activity of the EO, IO, and QL. A 1-way repeated-measures analysis of variance assessed the statistical significance of the EO, IO, and QL muscle activity. When there was a significant difference, a Bonferroni adjustment was performed.

**Figure 1:** The side-bridge exercise was used in this study. (A) TSB, traditional side-bridge. (B) BLLS, both leg lift on side-lying. (C) TLBS, torso lift on a 45° bench side-lying. (D) WSB, wall side-bridge.

**Figure 2:** Comparison of the quadratus lumborum, external oblique, and internal oblique muscle activity (%MVIC) for each of the exercises. \* $p < 0.05$  using the post hoc Tukey's test.

### Result and Discussion

There were significant differences in QL ( $p < 0.001$ ) and EO ( $p = 0.007$ ) muscle activity ( $p < 0.001$ ) among the four different exercises. TSB showed significantly greater QL muscle activity ( $p < 0.001$ ) than WSB. TLBS demonstrated significantly greater QL muscle activity ( $p = 0.037$ ) than WSB. TLBS showed significantly greater EO muscle activity ( $p = 0.017$ ) than WSB. There was no significant difference in IO muscle activity ( $p = 0.189$ ) among the exercises. The findings indicate that the effectiveness of BLLS and TLBS was similar to that of TSB in activating the EO, IO, and QL muscles. Given each exercise position of TLBS and BLLS, it is suggested that TLBS may be a practical exercise to activate the EO, IO, and QL in some situations in which it is impossible to tolerate the compressive load on the upper extremity such as for athletes with shoulder pain. BLLS may be effective way for individuals with lower extremities issues including the elderly with hip or knee replacements. In WSB, although it showed significantly less than TSB in activating QL, previous studies recommended WSB for deconditioned patients, implying that in patients unable to perform BLLS or TLBS, EO and IO muscle activity may benefit from WSB. Therefore, three modified side-bridge exercises can be effective therapeutic approaches available for some particular subjects who are unable to perform TSB in clinical practice.

### Significance

This study focused on addressing the validity of the modified side-bridge exercises by identifying the activation of the spine stabilization muscles during the exercises. The data suggest that BLLS and TLBS may be effective rehabilitation techniques to activate EO, IO, and QL in those who are unable to perform TSB as spine stability exercises and WSB may be beneficial for patients unable to perform BLLS or TLBS, activating EO and IO.

# Semi-Unsupervised Machine Learning System for Gait Event Detection, Locomotion Mode Classification and Prediction

Seth Donahue<sup>1\*</sup>, Michael Hahn<sup>1</sup>

<sup>1</sup>University of Oregon, Neuromechanics Laboratory, Human Physiology, Eugene OR

Email: \*[sethd@uoregon.edu](mailto:sethd@uoregon.edu)

## Introduction

Supervised pattern recognition algorithms have become more common recently for identification of gait events, classification and prediction of locomotion mode in control systems for assistive devices. They have been successful in controlled environments with accuracies of  $\sim 95\%$  [1,2]. Despite their success, these algorithms require large sensor arrays, high sampling frequency and expert user defined feature sets from these data [2].

The purpose of this study was to build a novel semi-supervised machine learning system for identification of gait events, classification and prediction of locomotion mode. We present a two component machine learning system to detect gait events, and then classify and predict locomotion mode. The first component is an unsupervised machine learning algorithm, the Beta Process Auto Regressive Hidden Markov Model (BP-AR-HMM). The second component is comprised of supervised learning algorithms; specifically Long Short Term Memory networks (LSTMs) [3]. Data input into this system were from a single mechanical sensor, and the outputs were gait event detection, classification and prediction of locomotion mode.

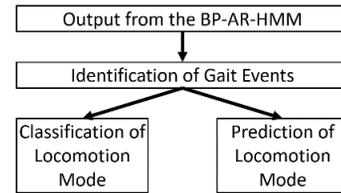

## Methods

Data were collected from sixteen able bodied participants (8 male and 8 female;  $31.1 \pm 14.8$  years,  $173.4 \pm 8.5$  cm,  $66.7 \pm 7.7$  kg). All analyses were performed offline in custom Matlab programs (Mathworks, Natick, MA). Each participant's dominant foot was determined, and this foot was equipped with an IMU (Vicon, Centennial, CO) mounted on the dorsal aspect. Foot ground contact information was recorded with two different systems during the study. The first three participants were equipped with the Noraxon footswitch Telemyo DTS system (Noraxon, Scottsdale, AZ), and the other 13 participants were equipped with Loadsol inserts (Novel Electronics, St. Paul, MN). Ground contact and IMU data were down-sampled to 25 Hz to simulate a minimally sensorized system embedded in an assistive device.

On the first day of the protocol the subjects performed 4 locomotion tasks; stair ascent and descent, level ground walking (including slopes  $<5^\circ$ ) and running. The second day of the study utilized a protocol adapted from Long and Srinivasian [4]. Participants were asked to cross 90 m in a set amount of time. The range of average speeds was 1.3 to 3.0,  $\text{m s}^{-1}$  (1.30, 1.51, 1.73, 1.94, 2.15, 2.36, 2.58, 2.79, 3.00  $\text{m s}^{-1}$ ), encompassing typical human locomotion speeds. Trial order was randomized to minimize learning effect.

Gait events were identified from the output of the BP-AR-HMM. Before each gait event a 75 ms window was used to identify the two most frequently occurring states from the BP-AR-HMM. The state counts from the current foot contact were then used as input into one LSTM for classification of the locomotion mode, and the state counts from the previous three foot contacts were used as input into a second LSTM for prediction of pending locomotion mode (Figure 1). The

hyperparameters of both LSTMs were optimized utilizing a Bayesian optimization function.

**Figure 1:** Flow of the data from the BP-AR-HMM to the LSTMs.

## Results and Discussion

The output of the BP-AR-HMM identified 100% of the measured gait events from the trials on both days. Initial contact was identified with 4 different states, and toe off was identified with 2 states.

Prediction of locomotion mode is critical for functionally adaptable assistive devices. However, to make accurate predictions a number of other systems must work, including the identification of gait events and classification of the current locomotion mode. The classification and prediction accuracies from this study are similar to previous work (Table 1) [1,2], with greatly reduced amounts of data needed as input.

**Table 1:** Classification and prediction accuracies output from two independent LSTMs, combined data from both days.

	Classification (%)	Prediction (%)
Walking	97.8	96.3
Running	92.3	87.8
Stair Ascent	84.2	93.6
Stair Descent	86.1	84.2

A limitation of this study is the system's classifications and predictions do not include ramp output specifically as the ramps the subjects walked on were a maximum of 5% grade, which does not alter limb function enough to elicit a classification difference from level ground walking.

## Significance

We have demonstrated that a machine learning system comprised of the BP-AR-HMM (unsupervised) and two LSTMs (supervised) can accurately label gait events from subject independent data, provide classification of locomotion mode and prediction of locomotion mode. The next steps in this work are to implement this system in an assistive device.

### Introduction

Measuring load and load asymmetry during jump-landing tasks has emerged as a promising tool for anterior cruciate ligament (ACL) injury prevention and rehabilitation following an ACL reconstruction. Larger peak vertical ground reaction forces during landing are associated ( $r = 0.684$ ) with larger peak ACL strains (1) and are prospectively associated with primary ACL injury risk (2). Athletes returning to sport following ACL reconstruction commonly have load asymmetries during landing, which are associated with an increased risk for sustaining a second ACL injury (3). One method to measure load in clinical settings is using force sensing insoles which are wireless, inexpensive, and reliable (4). The loadsol<sup>®</sup>, a load sensing insole, can measure peak normal force and peak normal force symmetry with high accuracy relative to gold-standard embedded force plates and with high between-day repeatability (4). While load sensing insoles could help translate laboratory biomechanics research into clinical settings, laboratory research typically standardizes footwear across participants, as differences in footwear lead to differences in load outcomes (5). Standardized footwear is likely unavailable in most athletic training and rehabilitation centres, which could pose a challenge when assessing landing kinetics.

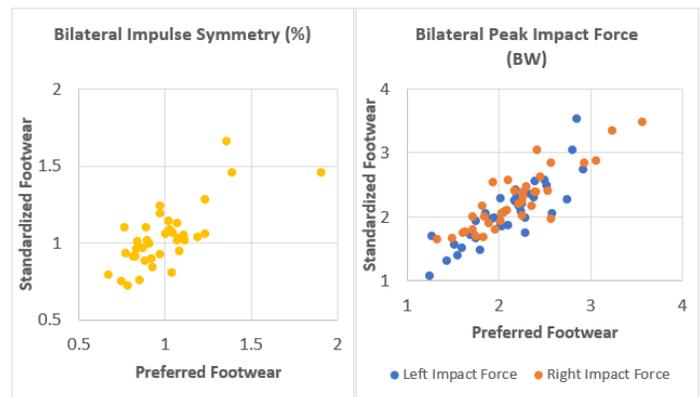

### Methods

Thirty-seven healthy uninjured participants (20 male/17 female; weight:  $68.77 \pm 13.49$  kg; height:  $1.76 \pm 0.08$  m) completed 7 bilateral drop vertical jumps from a 30 cm box, jumping horizontally 50% of their body height and 7 unilateral drop landings on each foot, all completed in a randomized order. Participants were asked to bring the footwear that they would normally wear when participating in an athletic activity on a hardwood surface to the testing session. The protocol was completed under 2 conditions in a randomized order: 1) wearing a standard neutral cushioned running shoe (Nike Zoom Pegasus; Nike Inc., Beaverton, OR) and 2) wearing the participant's preferred athletic footwear. Plantar forces were measured bilaterally during each condition using loadsol<sup>®</sup> sensors sampling at 200 Hz (Novel Electronics, St. Paul, MN). Peak impact force, impulse, peak impact force symmetry (ratio between left and right), and impulse symmetry were computed using a custom-built MATLAB user interface during the first ground impact of both tasks for each condition. All outcomes were normalized to bodyweight and compared between the preferred and standardized footwear conditions using intraclass correlation coefficients (ICC) and paired t-test. Cohen's  $d$  was used to quantify the effect size of all observed significant differences.

### Results and Discussion

The preferred and standardized footwear conditions showed good to excellent agreement for peak impact force and impulse during both tasks, as well as for peak impact force symmetry and impulse symmetry during the bilateral task (ICC = 0.755 – 0.932, Figure 1). However, agreement was moderate for peak impact

force symmetry (ICC = 0.603) and poor for impulse symmetry (ICC = 0.486) during the unilateral landing. Left limb impulse and peak impact force symmetry during the bilateral task and peak impact force during left unilateral landings were significantly different between footwear conditions ( $p < 0.05$ ), however the effect size of each difference was small to medium ( $d = 0.18-0.29$ ). No other significant differences between footwear conditions were observed ( $p > 0.05$ ).

**Figure 1:** Scatter plots comparing the standardized and preferred footwear conditions. Note: Blue data points represent impact forces for the left limb, and orange data points represent impact forces for the right limb.

The present study found that load outcomes have good to excellent agreement when comparing wearing laboratory-standardized footwear and wearing the participant's own athletic footwear while landing. These results suggest that allowing patients to wear their own footwear when examining landing kinetics in athletic and clinical settings will provide laboratory-relevant landing kinetic information. Load symmetry was not consistent between footwear conditions for the unilateral task, which may reflect increased landing variability during unilateral landing independent of the footwear condition. However, as load and load symmetry during bilateral landing are known risk factors for ACL injuries (2, 3), information pertaining to ACL injury risk could be extracted while using non-standardized footwear.

### Significance

The present study demonstrates that quantifying load and load symmetry in settings where standardized footwear is unavailable, will provide relevant information pertaining to the athlete's risk for sustaining an ACL injury.

<sup>3</sup>Department of Psychiatry, Texas Tech Health Sciences Center El Paso, El Paso TX

Email: \*jdeggleston@utep.edu

## Introduction

Recent evidence suggests that nearly 80% of children with Autism Spectrum Disorder (ASD) present with motor impairment [1]. Further evidence suggested children with ASD rely less on visual feedback during movement and rely more on proprioceptive feedback [2]. As such, it has also been observed that children with ASD exhibit greater motor learning when proprioceptive error, not visual error, is present [3]. Given observed motor impairments in this population, motoric output responses to visual live animation biofeedback have largely been understudied.

The purpose of this study was to examine motoric output responses through live animation biofeedback in children with ASD relative to peers with typical development (TD). It was hypothesized that children with ASD will not respond similarly due to deficits in feedback and feedforward processing and sensory stimuli interpretation.

## Methods

30 children (15 with ASD and 15 with TD) between the ages of 8 and 17 participated in the study. Parents of children with ASD provided verbal confirmation of ASD diagnosis. Once participant anthropometrics were obtained, participants were outfitted with seven inertial measurement units (IMUs; Noraxon, Scottsdale, AZ) placed on the sacrum, bilaterally on the distal femurs, proximal tibias, and on the dorsal aspect of the feet. Once secured, participants stood still for a 20-sec calibration.

After calibration, participants completed a pre-test consisting of eight bodyweight squats to their preferred depth. Participants were instructed to start with their feet shoulder width apart; no other instructions were provided. Following the pre-test, participants completed a live animation biofeedback training period consisting of five sets of 10 squats while watching an animated skeleton complete a squat. While watching the animation, participants were instructed to replicate the movements of the model. Two-minute rests were given between sets. Then, the post-test was completed consisting of eight bodyweight squats without the animation but to try to replicate the animation as best as possible.

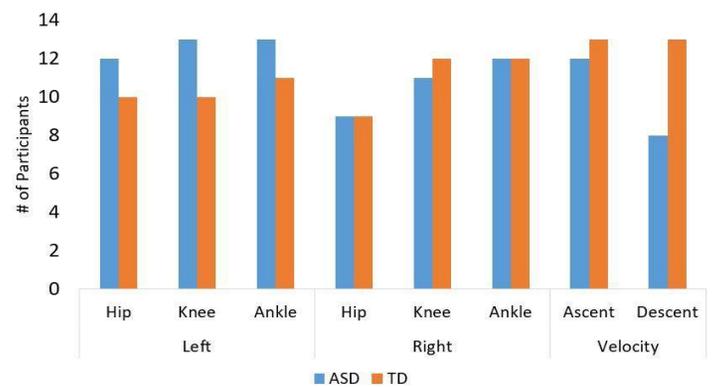

Sagittal plane bilateral hip, knee, and ankle angular joint positions and pelvic position data were exported from Noraxon myoMotion into Visual 3D. Ascent and descent velocity was computed from pelvis data. Mean and standard deviation values for each variable were computed and used for analysis. Dependent t-tests ( $\alpha=0.05$ ) were used to test for statistical differences between pre- and post-tests values for each individual child. Effect sizes (ES) were also computed and assessed with Cohen's *d*.

## Results and Discussion

Statistical significance was observed in nearly every participant when comparing pre- and post-tests angular joint positions (Figure 1). A greater number of ASD participants exhibited statistical significance in lower extremity joint positions, with the exception of the right knee. Examining ES magnitude for lower

extremity kinematics, a similar number of large ES ( $>0.79$ ) were observed in children in both groups.

When comparing ascent velocity pre- and post-test values, a similar number of participants (12 and 13 out of 15, respectively) displayed statistical differences between the groups. Each participant displaying a significant difference also exhibited large ES ( $>0.79$ ). Descent velocity was the only variable where the number of ASD children was far fewer than children with TD. In total, only 8 of 15 children with ASD displayed statistically significant different descent velocity, compared to 13 of 15 children with TD. Furthermore, all 13 children with TD displayed large ES whereas only 6 of 8 children with ASD displayed large ES.

**Figure 1.** Number of participants who displayed statistically significant differences between pre- and post-tests training.

## Significance

Although lower extremity kinematic outcomes were similar between the groups, the differences observed in descent velocity reveal the movement pattern following the live animation biofeedback training, employed by children with ASD was not different than the movement pattern before the training. The limited number of participants with ASD with significant differences in descent velocity are aligned with previously established motor planning impairments [4]. These results support previous findings on learning in the population and expand our understanding on how children with ASD may learn new movements, especially given known motor impairments in the population.

# Automated 2D Video Analysis is Reliable for Assessing Knee Kinematics During Landing

Alexander T. Peebles, Sara L. Arena, and Robin M. Queen

Granata Biomechanics Lab, Department of Biomedical Engineering and Mechanics, Virginia Tech

Email: \*apeebles@vt.edu

## Introduction

Frontal and sagittal plane knee kinematics during landing are prospectively associated with the risk of sustaining an anterior cruciate ligament (ACL) injury in young athletes and in patients following ACL reconstruction (1, 2). 3D motion capture is not feasible to collect in most non-research settings. Therefore, kinematics are often assessed using 2D video analysis in these settings. There are currently many differences in how kinematics are calculated using 2D video analysis when compared with 3D motion capture. Previous studies visually estimated joint center locations for one or two frames during each landing trial, which is subjective and results in reliability issues when comparing 2D video analysis with 3D motion capture during landing (3). Using anatomic markers to estimate joint center locations during a static trial, and automated point tracking software (Automated Video Analysis for Dynamic Systems, AVADS) to digitize markers during movement could improve 2D measurement accuracy (4). This study aimed to explore the validity and repeatability of using automated 2D video analysis to assess frontal and sagittal plane knee kinematics during landing. We hypothesize that 2D video analysis will have good to excellent validity and repeatability.

## Methods

24 healthy recreational athletes between 18-30 years of age (12 male/12 female) signed informed consent and participated in this two sessions study. For each session, participants completed 7 forward bilateral drop vertical jumps to a distance of half their bodyheight and 7 unilateral drop landing on each limb, all off a 31 cm box. The first session was completed in a biomechanics lab, where participants wore form fitting athletic clothing and 43 reflective markers. Kinematics were simultaneously assessed at 240 Hz in 3D using a 10-camera motion capture system (Qualisys, Goteborg, Sweden) and in 2D using an iPhone and iPad (Apple, Cupertino, CA). The second session was completed in a university athletic center, where participants wore their own athletic clothing and 6 reflective markers (bilaterally on the lateral aspect of thigh, femoral epicondyle, and shank aligned in the frontal plane). Kinematics were recorded at 240 Hz in 2D only using an iPhone and iPad.

Knee flexion and frontal plane projection angle (FPPA) were computed using the 3D motion capture data (1, 2). Using the 2D video data, two methods were used to estimate joint center locations on the first frame of the static trial. For the first method, termed *2D Manual*, joint centers were digitized manually using visual landmarks (e.g. the patella) (3). For the second method, termed *2D Computed*, joint centers were determined objectively based on anatomically placed markers. Specifically, in the frontal plane, knee and ankle joint centers were estimated as the midpoint between medial and lateral joint markers and the hip joint center was estimated based on the work by Bell et al. (5). In the sagittal plane, the greater trochanter, femoral epicondyle, and malleoli were used to estimate joint centers (4). *2D Manual* was used to estimate joint center locations for each testing session and *2D Computed* was used for the first session only. For both methods, the lateral thigh, knee, and shank markers were used as

tracking markers during motion, and were also digitized during the static trial. For both methods, and in both planes, an offset angle between a line connecting estimated joint centers and a line connecting tracking markers was created during quiet stance. The lateral thigh, knee, and shank markers were then automatically tracked throughout each video using AVADS (4), and the offset angle determined during stance was used to compute continuous segment orientation during landing. Outcomes included were peak flexion, peak FPPA (valgus), and knee flexion and FPPA range of motion. Outcomes were compared between 3D motion capture and both 2D methods (validity) and between days for *2D Manual* only (repeatability) using intraclass correlation coefficients (ICC) and paired t-tests.

## Results and Discussion

Both methods had good to excellent validity, and *2D Manual* had good to excellent between-day repeatability (Table 1). As the agreement between 3D motion capture and both methods of 2D video analysis were stronger than previously reported (3), we suggest estimating joint centers during quiet stance and using automated software to track segment motion. As validity ICCs were higher for *2D Computed* than *2D Manual*, we suggest using anatomic markers to objectively estimate joint centers. However, as range of motion validity was the same between 2D methods, estimating joint centers is not needed for range of motion. Differences between 3D motion capture and both 2D video analysis methods were observed for each outcome ( $p < 0.05$ ), which is consistent with previous video analysis literature (3, 4).

	<i>2D Comp</i> Validity	<i>2D Manual</i> Validity	2D Manual Repeatability
Bilateral peak flexion	0.973	0.969	0.915
Bilateral flexion ROM	0.978	0.978	0.950
Bilateral peak FPPA	0.877	0.847	0.760
Bilateral FPPA ROM	0.912	0.912	0.907
Unilateral peak flexion	0.968	0.960	0.929
Unilateral flexion ROM	0.979	0.979	0.938
Unilateral peak FPPA	0.907	0.927	0.889
Unilateral FPPA ROM	0.882	0.882	0.887

**Table 1:** Validity and between-day repeatability ICCs.

## Significance

This study developed a method to assess knee kinematics which is valid, repeatable, and feasible for use in non-research settings.

### Introduction

Gait asymmetry has been associated with risk of injury and accelerated disease progression, making it an important area to assess clinically. Data discretization, which is commonly performed when evaluating asymmetry, results in limited interpretation and lost scope of analysis. As opposed to data discretization, analysing continuous data expands the scope of analysis to the entire time series and prevents the loss of potentially important data. Previously developed methods of analyzing continuous data such as the Coefficient of Multiple Correlations<sup>1</sup> and Statistical Parametric Mapping<sup>2</sup> either cannot be used in pathologic populations with abnormal movement patterns or are not defined in concise enough terms to be easily incorporated in clinical care.

The purpose of this study was to develop a method of describing asymmetry in continuous time series data using simple and clinically accessible scores. Total ankle arthroplasty (TAA) patients were used as the clinical test case.

### Methods

Pre-operative vertical ground reaction force (vGRF) data from 120 unilateral post-traumatic TAA patients were obtained from a previously collected data set. Additional vGRF data was collected from 54 healthy older adults within the age range of the TAA patients. For computational purposes, we approximated each continuous time series as 101 equally-spaced points. Two scores were developed and computed to assess asymmetry and movement quality: the symmetry score (SS) and closeness-to-healthy score (CTH).

The symmetry score evaluated the similarity of the vGRF between limbs [Eq 1]. Healthy dissimilarity (N) between limbs was computed from the control data as the average Euclidean length of the difference in the vGRF between limbs. TAA and control curves were normalized to the healthy dissimilarity to maximize interpretability of results. The SS was computed as the Euclidean length of the distance between the normalized curves. Small SS indicates greater side-to-side symmetry.

The closeness-to-healthy score evaluated the similarity of the vGRF to that of a healthy population [Eq 2]. First, an average vGRF curve was computed from the control data. The healthy average and vGRF curves on both limbs in TAA patients and controls were normalized by their Euclidean lengths. The CTH score was computed on each limb separately as the dot product of the normalized average healthy curve and the normalized curve of interest subtracted from one. Small CTH scores indicate vGRF similar to what would be expected in a healthy individual.

SS and CTH scores were compared between TAA patients and controls using unpaired t-tests and Cohen's D effect sizes [JMP Pro 15,  $\alpha=0.05$ ]. Surgical (S) and non-surgical (NS) limbs for TAA patients were compared to non-dominant (ND) and dominant (D) limbs, respectively, for controls.

$$SS = \text{norm} \left( \frac{vGRF_{NS/D}}{N} - \frac{vGRF_{S/ND}}{N} \right) \quad [1]$$

$$CTH = \left( 1 - \frac{\overline{vGRF}}{\text{norm}(vGRF)} \cdot \frac{\overline{vGRF}_{\text{average healthy}}}{\text{norm}(vGRF_{\text{average healthy}})} \right) * 100 \quad [2]$$

### Results and Discussion

TAA patients had higher SS and CTH scores on both limbs compared to controls [SS:  $p<0.001$ ,  $d=0.953$ , | CTH (S/ND):  $p<0.001$ ,  $d=1.179$ , | CTH (NS/D):  $p<0.001$ ,  $d=0.986$ ] (Figure 1). These results align with prior literature demonstrating greater asymmetry and more abnormal gait patterns on the surgical limb pre-surgery in TAA patients<sup>3,4</sup>.

Conceptually, the SS and CTH scores have important clinical implications when evaluating disease progression and surgical recovery. Combined with clinically accessible motion analysis methods such as accelerometers or in-shoe pressure sensors, both scores

could be used to evaluate patients' movement quality prior to disease diagnosis, throughout disease progression, and during rehabilitation to monitor recovery. Results could be utilized in clinical decision making to assess urgency for surgical intervention and whether a rehabilitation protocol can effectively target specific asymmetries.

### Significance

Two scores related to movement asymmetry have been developed and are able to differentiate between healthy controls and TAA patients. These scores could provide clinicians with another tool to objectively assess movement asymmetry and quality from continuous kinetic and kinematic data. These scores could be used to track asymmetry and movement quality throughout disease progression and recovery after surgery.

### Acknowledgments

TAA data was initially collected at Duke University. The Howard Hughes Medical Institute Gilliam Fellowship funded Cherice Hughes-Oliver during this project.

# Comparative Effects of Abdominal Breathing and Dynamic Neuromuscular Stabilization Breathing on Diaphragmatic Movement and Pulmonary Function in Chronic Obstructive Pulmonary Disease

Jongseok Hwang<sup>1</sup>, JungKi Hoon<sup>1</sup>, and Joshua (SungHyun) You<sup>1</sup>

<sup>1</sup> Sports Movement Artificial Robotics Technology(SMART) Institute, Department of Physical Therapy, Yonsei University, Wonju, Republic of Korea

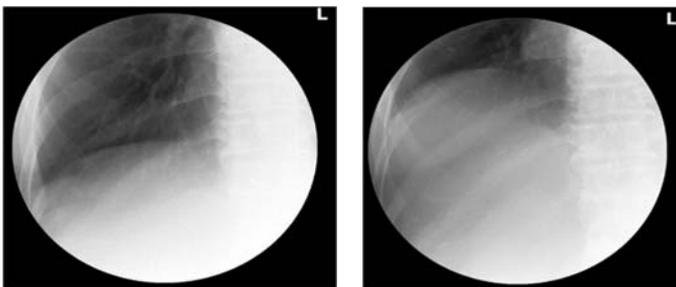

Email: [joshuayou@gmail.com](mailto:joshuayou@gmail.com)

## Introduction

Chronic obstructive pulmonary disease (COPD) is a common chronic pulmonary functional impairment and fourth leading cause of death. It is known that diaphragmatic dysfunction is an important deleterious consequence of the progression of the severity of COPD. The purpose of the present study was to compare a novel Dynamic neuromuscular stabilization (DNS) breathing and abdominal breathing (AB) on diaphragm movements and pulmonary functions in patients with COPD.

## Methods

10 COPD patients randomly assigned to two groups; DNS breathing group and AB group. The present study used a two group pretest-posttest design. In this research, COPD patients underwent fluoroscopy-guided chest X-ray (Figure 1), pulmonary function tests, and modified Medical Research Council (mMRC) questionnaire in before and after training. Each group underwent comprehensive AB or DNS of pulmonary breathing exercise 5 time per week during 7 weeks (30 minutes per session). A paired t-test and independent t-test and Wilcoxon Signed rank were used to analyze data.

**Figure 1:** Radiographic image of the area displaced by diaphragmatic movement during inspiration and expiration for the same chronic obstructive pulmonary disease patient

## Results and Discussion

There were significant improvements in diaphragmatic movements during full inspiration and expiration in the both group fluoroscopy. (48161.80±25137.42mm<sup>2</sup> to 75346.00±24394.66mm<sup>2</sup>; AB Right side P=0.015 and 95027.40±11306.21mm<sup>2</sup> to 155543.40±50163.74mm<sup>2</sup>; DNS Left side P=0.033, 69892.60±14686.71mm<sup>2</sup> to 199941.40±26005.88mm<sup>2</sup>; DNS Right side P=0.001, respectively) Pulmonary function tests indicated that the only DNS presented statistically significant differences in forced vital capacity (FVC) (%) (P=0.024) and the first second of forced expiration (FEV1) (%) (P=0.000) between pre-test and post-test. The DNS group gained enhanced FVC (P=0.028) and FEV1 (%) (P=0.015) than the AB group. The mMRC score showed

significant differences between pre-test and post-test (2.60±0.89 to 1.80±0.44; P=0.016).

This study suggests that the DNS breathing had superior effects compared with the AB in diaphragm movement and pulmonary function in patients with COPD. Our results provide promising evidence that DNS breathing techniques improved diaphragm movement, pulmonary function during pulmonary rehabilitation, and strength while inhale breathing.

## Significance

Our results provide promising evidence that DNS breathing techniques improved diaphragm movement, pulmonary function during pulmonary rehabilitation, and strength while inhale breathing.

## Acknowledgments

## Lower Extremity Biomechanics during Running in Persons Who are Blind: A Preliminary Report

### Introduction

Walking and running are the most common modes of physical activity for individuals who are blind (visual acuity <3/60) [1]. Although biomechanics research has extensively examined gait in sighted healthy (from young to old), clinical, injured, and athletic populations, little research has involved persons with blindness [2-4]. Research has found persons with differing levels of visual impairments walk at reduced speeds, with shorter stride lengths, reduced ranges of motion, and with more mechanical work than sighted controls [2-4]. However, no previous research has examined biomechanics of running in persons who are blind. Therefore, the purpose of this preliminary study was to determine if lower extremity kinematics and kinetics differ in persons who are blind compared to sighted controls. We hypothesized persons who are blind would run with shorter strides and reduced joint kinematics.

### Methods

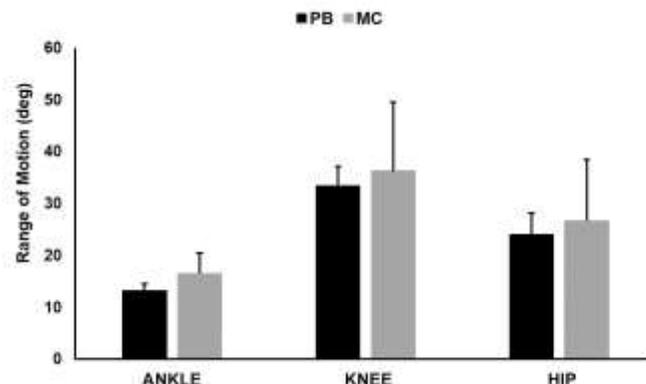

Four persons who are blind (ages 14, 23, 28, and 47 yrs.) and four matched sighted controls (age, sex, and body mass index matched) participated in this study. A ten-camera three-dimensional motion capture system and force platforms recorded lower extremity kinematics and ground reaction forces during level running over an 18 m runway. A warmup of walking and running at self-selected speeds was performed by all participants. For testing, persons who are blind ran independently (with/without cane depending on preference) at their own comfortable, self-selected speeds. All recorded trials were within  $\pm 5\%$  of their average speeds (group average:  $2.7 \pm 0.8$  m/s). Sighted controls performed running at matched speeds. Marker and ground reaction force data were imported into Visual3d and filtered at 10 Hz using a 4<sup>th</sup> order butterworth low-pass filter. Stride length and ankle, knee, and hip ranges of motion (max-min) and peak moments were compared between groups using t-tests.

### Results and Discussion

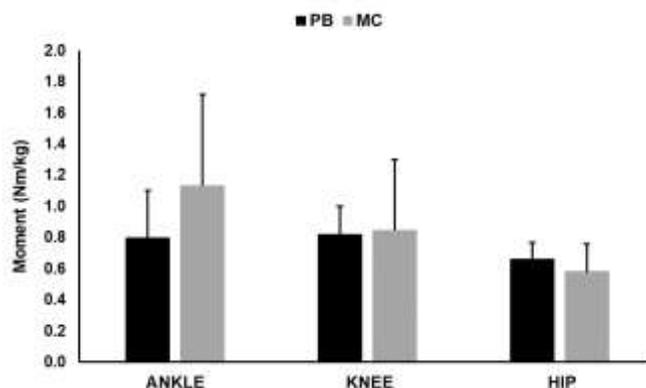

Contrary to the shorter stride lengths during walking found in previous reports [2-4], this preliminary study found no differences between persons who are blind and sighted controls when running at matched speeds ( $1.8 \pm 0.7$  vs.  $2.1 \pm 0.5$  m, respectively,  $p > 0.05$ ). As work within the previous literature did not control for speed or anthropometric differences, it is likely previous results are confounded due to these influential measures.

In addition to stride length, we found no differences in ranges of motion or peak moments for the ankle, knee, or hip joints (Figures 1 & 2; all  $p > 0.05$ ). Given the lack of differences found in this preliminary study, it appears fundamental lower extremity mechanics are robust even without a history of visual learning. In this respect, research regarding running in persons

with congenital blindness could enhance our understanding of the relationships of visual feedback, proprioception, and central pattern generators with human locomotion.

**Figure 1:** Comparisons of ankle, knee, and hip ranges of motion. PB: participants who are blind. MC: matched sighted controls. No differences were found for any range of motion variable.

**Figure 2.** Peak extensor joint moments. For ease of viewing, ankle (plantarflexor) and hip moments were plotted as positive. PB: participants who are blind. MC: matched sighted controls. No differences were found in any joint moment.

### Significance

Although proper running mechanics are not formally taught in structured physical activity contexts (e.g., physical education settings) for persons who are blind [5], these results suggest only minor therapeutic and rehabilitative intervention programming is actually needed. Programming may only truly be needed to increase a person's comfort and familiarity with running in their environment/surroundings.

# Biomechanics In The Real World: Design and Evaluation of a Clinical Balance Tool

Ajit M.W. Chaudhari, Virginia M. Yazzie, Lise C. Worthen-Chaudhari, and Jennifer H. Garvin  
The Ohio State University  
Email: Chaudhari.2@osu.edu

## Introduction

Falls are a significant source of early morbidity and mortality in the aging population, yet the neurological, sensory, and motor changes that lead to increased fall risk often escape early identification and intervention. Vital signs (VS) are commonly used in clinical settings to (1) establish baseline values when initiating care, (2) screen for increased risk of co-morbidities or diseases, and (3) allow for identification and communication of changes from baseline between health care professionals across time and locations.[1] No VS exists for assessing the balance system. Both clinical tests like the Romberg and quantitative measurements of balance like postural sway have been shown to predict increased fall risk,[2, 3] but they are not common practice in primary care settings. Biomechanists and physical therapists have performed these tests for decades, yet unidentified barriers prevent their use in physician clinics, especially in primary care.

This qualitative research study aimed to identify barriers preventing adoption of a biomechanical, quantitative postural control measurement (qPCM) of balance for fall risk prediction and to identify the design requirements that minimize these barriers to facilitate future use of a quantitative balance tool.

## Methods

In this IRB-approved descriptive formative evaluation study, we conducted two rounds of semi-structured interviews in the participants' clinical practice setting. We explored barriers to assessing fall risk and barriers to use of a prototype tool in terms of hardware and software, workflow and communication, and clinical content. We gathered initial information to identify requirements and assess workflow. Participants were able to use an initial and then a modified prototype with clinical scenarios for formative evaluation and usability assessment. Following initial interviews, we modified the prototype and undertook a second set of interviews for further iterative design. We explored the features end users need so that a clinical qPCM tool could be incorporated into a clinical routine for every patient and results used in clinical decision making. We explored alignment of our tool with processes used currently with weight measurement devices. We also assessed the usability of the device in the clinical setting using the System Usability Scale (SUS).[4]

Interview participants were all potential intended users of the device in the medical clinic setting including: (a) medical assistants/physician extenders (n=8), (b) nurse practitioners (n=2), and (c) physicians (n=8) from both academic medical centers and private independent clinics. Five were male and 13 were female. Observations were captured using written notes and audio/video recordings that were later transcribed for analysis.

## Results and Discussion

Several common themes and practices emerged from the first round of interviews with the providers. All 18 providers measure weight as a vital sign in some patients, but only 12 reported taking one or more vital signs on every patient at every visit. Only 4/18 reported always asking patients to remove their shoes when measuring weight. While only providers concerned about falls

were included, only 9/18 providers reported asking patients specific questions regarding fall risk. 9/18 providers reported watching the patient's gait from the waiting room to the examination room as a primary assessment of fall risk. Half of the participants knew or had heard of one or more of the nationally promoted fall risk algorithms from CDC (STEADI), Johns Hopkins University (JHFRAT), or the American Geriatric Society. No providers reported regularly using a standard functional test such as the Timed Up & Go, 30-second Chair Stand, or 4-Stage Balance Test recommended by the CDC, though one physician who typically treats patients with lower-extremity concerns reported having "all of them stand up and try to balance on one leg, or do a one leg squat, and you can tell pretty quickly if they're unsteady, and then watch them walk."

Several barriers for use were identified from the first round of interviews as well. These included time, space, and interpretation of results. Time was unanimously identified as a barrier, because in these care settings the providers are attempting to manage patients who could have many comorbid conditions and the chief complaint (e.g. hypertension, diabetes, prior injurious fall) often guided the encounter. Importantly physicians and nurse practitioners felt it was practicable to add another test to their patient interaction. Space was also identified as a barrier. 16/18 providers reported that weight was measured at a central "vitals station" or "triage room," and these stations generally were only big enough for a weight scale and chair. Another important barrier was interpretation of a complex set of numbers – several providers preferred a device that reports a single number with a scale to interpret it.

In response to the aforementioned, two prototypes of the clinical balance tool were developed and tested. The final balance tool can take the place of a weight scale at a vitals station, and delivers a single balance score along with the patient's weight after 30 seconds. A quick reference card was designed to assist in administering the test and interpretation. The final tool achieved a mean SUS score of 86.8, the 94<sup>th</sup> percentile, indicating a system with excellent usability.[5]

## Significance

This study demonstrated that a quantitative clinical balance tool can meet the needs of users in a primary care clinic setting and has a strong chance of broad adoption. Current work focuses on determining if the tool informs clinical decision-making.

## Lower Limb Kinematic Asymmetries and Correlation to Clinical Measures in Individuals with Parkinson's Disease

Graci Finco<sup>1</sup>, Sarah Moudy<sup>1</sup>, Kendi Hensel<sup>1</sup>, Evan Papa<sup>2</sup>, Nicoleta Bugnariu<sup>1</sup>, Rita M. Patterson<sup>1</sup>

<sup>1</sup>University of North Texas Health Science Center, Fort Worth, TX <sup>2</sup>Idaho State University Health Science Center, Meridian, ID

[Malaka.Finco@my.unthsc.edu](mailto:Malaka.Finco@my.unthsc.edu)

### Introduction

Gait asymmetries have been directly linked to the development of freezing of gait in individuals with Parkinson's Disease (PD),<sup>1</sup> and freezing of gait has been associated with increased falls.<sup>2</sup> Therefore, reducing gait asymmetries can reduce the development of freezing of gait and decrease fall risk.

Greater gait asymmetry has been shown in kinematic rather than kinetic parameters in individuals with PD.<sup>3</sup> However, previous literature in kinematic asymmetry has focused on spatiotemporal parameters, and has not grouped participants by progressive stages of PD. Investigating range of motion (ROM) asymmetries and their correlation to clinical measures may inform rehabilitation techniques to limit the onset and prevalence of freezing of gait and decrease falls.

This study aimed to: 1) compare kinematic asymmetries in three groups: individuals affected with PD unilaterally (UNI), bilaterally (BI), and matched controls, and 2) correlate asymmetries to scores on three clinical measures: the Hoehn and Yahr (H&Y) scale of progression, Unified Parkinson's Disease Rating Scale (UPDRS) of severity, and Timed Up and Go Test (TUG). We expected greatest asymmetry in UNI participants, and strongest correlations to clinical measures in BI participants.

### Methods

Participants with PD and matched controls for age and sex (C) (n=10 each group) ambulated at a self-selected speed for two minutes on a treadmill as part of a larger data set, and kinematics were processed in Visual 3D. PD participants were grouped based on their H&Y score of UNI (1-1.5) or BI (2-3) involvement (n=5 each group). Overall ROM for each joint was averaged from ten steps of each participant's dominant limb (DL) and non-dominant limb (NDL), and waveforms of one gait cycle were averaged for each group (Fig.1). Percent differences assessed interlimb percent asymmetry (IPA), and correlations determined relationships between IPA and clinical measures (Tables 1-2).

### Results and Discussion

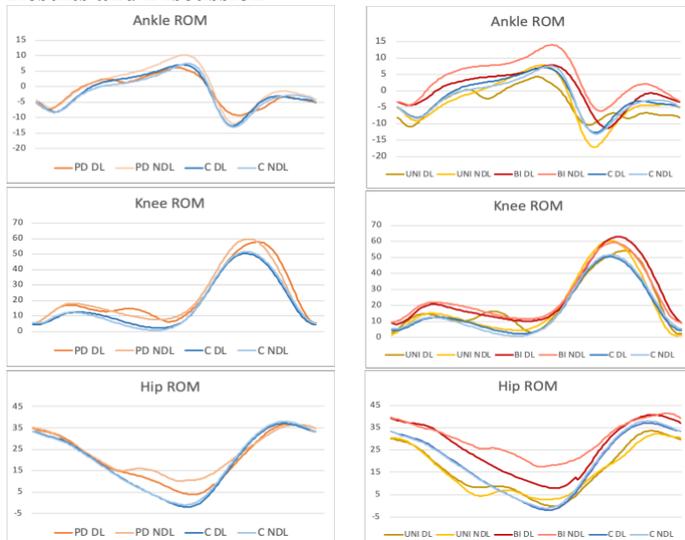

Fig. 1A-F: Left: All ten PD participants compared with C participants. Right: UNI and BI PD participants compared with C participants.

Consistent with previous research, participants with PD had greater interlimb asymmetry than matched controls.<sup>4</sup> BI participants had greatest ankle and hip asymmetry, and showed reduced ankle plantarflexion and hip extension compared to the UNI and C groups. Increased plantarflexion and hip extension in UNI compared to BI participants may be explained by the rigidity in the late stages of PD.

UNI PD	Ankle IPA	Knee IPA	Hip IPA	H&Y Score	UPDRS	TUG
Ankle IPA	1					
Knee IPA	-0.424	1				
Hip IPA	0.881	-0.195	1			
H&Y Score	0.783	-0.462	0.817	1		
UPDRS	0.439	0.489	0.684	0.538	1	
TUG	0.694	-0.771	0.663	0.588	-0.081	1

BI PD	Ankle IPA	Knee IPA	Hip IPA	H&Y Score	UPDRS	TUG
Ankle IPA	1					
Knee IPA	0.172	1				
Hip IPA	-0.362	0.519	1			
H&Y Score	-0.514	0.139	0.918	1		
UPDRS	-0.024	-0.381	-0.871	-0.823	1	
TUG	-0.494	-0.013	0.846	0.985	-0.811	1

Tables 1-2: Weak (0-.3), moderate (.3-.7), and strong (.7-1) correlations of IPA to clinical measures in UNI (top) and BI (bottom) participants.

Lower limb IPAs were not strongly correlated with performance on clinical measures, with the exception of strong correlations between hip IPA to clinical measures in BI participants. In UNI participants, ankle and hip IPA were strongly correlated to H&Y score, while knee IPA was strongly correlated to the TUG. Clinical measures were strongly correlated with each other only in BI participants, indicating these measures better reflect the functional mobility of this group.

### Significance

Future research of gait asymmetry in this population should consider dividing PD participants into groups based on H&Y score of unilateral or bilateral affectedness, since asymmetries between these two groups had marked differences.

Gait deviations and performances on clinical measures are factors in establishing rehabilitation techniques for individuals with PD and monitoring improvement. Performance in these clinical measures did not accurately reflect gait asymmetry, except in hip IPA with BI participants. Other clinical measures that better reflect overall IPA in both UNI and BI groups need to be determined to target rehabilitation techniques to reduce gait asymmetry, freezing of gait, and fall risk.

## Core Stability in Patients Awaiting Hernia Repair

Ajit M.W. Chaudhari, Savannah M. Renshaw, Lindsay M. Breslin, Torri L. Curtis, Melissa D. Himes, Benjamin K. Poulouse  
The Ohio State University  
Email: chaudhari.2@osu.edu

### Introduction

The abdominal core serves several functions for balance, movement, and strength. Disruptions or injury to this area, such as ventral hernia and subsequent repair (VHR), can have life-long consequences for patients' quality of life, return to work, pain, and functional status which makes it essential to understand in the VHR disease process.<sup>1</sup> Core stability is a measure of the body's ability to control the torso following perturbations and how well the muscles of the hips, lumbar spine, and abdominal core work together to perform functions of movement.<sup>2</sup> Currently, few methods exist for measuring core stability in the outpatient clinic setting. We developed the Quiet Sitting Test (QST) to evaluate the activation and performance of the core musculature by providing quantitative measures of core stability, separate from core strength, that allow for assessing and tracking core stability for patients over time.<sup>2</sup>

As the next step in the development of the QST, the purpose of this study was to test whether QST scores of patients awaiting hernia repair differ from healthy individuals without a hernia.

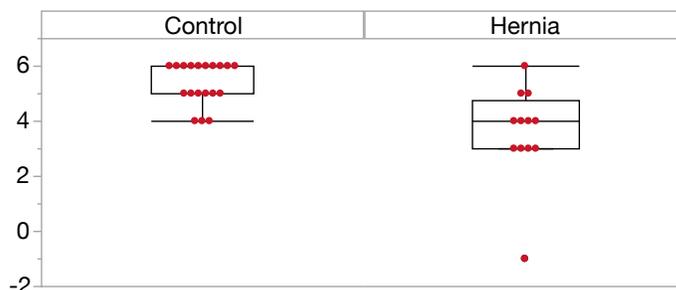

### Methods

Sixty-three participants were prospectively recruited with IRB consent from individuals at our hernia clinic either as a patient, a companion, or a staff member (Table 1). No companions or staff members had a history of hernia. Data from the first 32 hernia-free control participants were used to establish normative values for the QST, while data from the subsequent 31 participants (with hernia and controls) were used to test the hypothesis.

QST was performed by having participants sit on the rounded surface of a BOSU® balance trainer that had been placed on top of a portable force plate (Bertec BP5046) and situated on a flat, elevated surface. Participants sat unmoving for three 60-second trials with their eyes closed while counting backwards, and the force plate measured sway at 1000Hz. The counting task prevented hyper-focus on staying still, thereby resulting in more accurate measures. Specific QST outcome measures included center of pressure path length (COP<sub>exc</sub>). After calculating the mean and trial-to-trial variation (i.e. 95% confidence interval of the standard error of measurement, SEM<sub>95</sub>) of COP<sub>exc</sub> in the first 32 participants, we calculated a composite core stability score based on the absolute difference from the normative population mean in multiples of SEM<sub>95</sub>, where 6 represents normal and <6 indicates worsening core stability, as we have previously reported.<sup>3</sup> This score was then calculated for the 31 participants in the test group and the difference between hernia and control groups tested using a nonparametric two-tailed Wilcoxon exact rank sums test.

	N	Median Age, y (Range)	Mean COP <sub>exc</sub> (mm)	SEM <sub>95</sub> (mm)
Normative	23F, 9M	45.5 (20-62)	411.6	64.4
Control	13F, 6M	33 (23-62)		
Hernia	3F, 9M	54.5 (38-85)		

**Table 1.** Demographics of the group used to define QST normative values including mean, SEM<sub>95</sub>, and composite core stability score; and the two groups tested using the QST.

**Figure 1:** Distribution of QST composite score for control participants and hernia patients awaiting surgical repair. A score of 6 indicates being within normal limits of core stability, while scores <6 indicate poorer core stability.

### Results and Discussion

The hernia group demonstrated significantly worse core stability than the control group (Fig. 1,  $p=0.0004$ ). Ventral hernia disrupts the structure of the anterior abdominal wall in addition to causing pain, so further examination of this group longitudinally is warranted to test the degree to which the poorer core stability is a neuromuscular adaptation to pain or to reduced force-generating capacity of the muscles.

This study also demonstrates the feasibility of quantitatively measuring core stability in the clinic setting. All participants were tested within a fully-operating hernia clinic, and all patients and companions were tested while they awaited their appointment. This confirmation of feasibility in this setting is critical to future exploration of the role of core stability in the natural history of hernia, repair, and rehabilitation, because it would be impracticable to bring large numbers of patients to a research laboratory at multiple timepoints.

We note several limitations to this study. First and most importantly, the normative values we report are not based on function in activities of daily living or quality of life, so validation and minimal clinically important differences must still be established. Second, the gender and age distributions of the groups are a potential source of bias, as the hernia group was more male and older than the other groups (Table 1).

### Significance

The QST will be further evaluated as an adequate surrogate marker for improvement in abdominal core related interventions, including hernia repair, that supplements patient-reported outcomes. QST data may also help inform injury prevention and rehabilitation guidelines that can be tailored to the unique needs of VHR patients.

# Evaluation of Running Biomechanics, CHAMP Performance, and Patient Reported Outcomes of Servicemembers with Lower Extremity Fracture Utilizing an IDEO

Trevor Kingsbury<sup>1</sup>, Shian Liu Peterson<sup>1</sup>, Tatiana Djafar<sup>1</sup>, Julianne Stewart<sup>1</sup>, Kevin Kuhn<sup>1</sup>

<sup>1</sup>Naval Medical Center San Diego, San Diego, CA

Email: [\\*trevor.d.kingsbury.civ@mail.mil](mailto:trevor.d.kingsbury.civ@mail.mil)

## Introduction

Fractures represent a high percentage of reported injuries in the US military and can be a substantial threat to a servicemember's (SM) career. A review of literature indicates that fractures represent between 12-65% of combat injuries with a high percentage of open fractures (50%+) and at the tibia/fibula<sup>1</sup>. From 2000-2006, there were 157,096 ankle and 92,581 foot injuries in just the US Army<sup>2</sup>. Many of these SMs have pain and functional deficits after surgery and physical therapy, and some consider amputation. The Intrepid Dynamic Exoskeletal Orthosis (IDEO) has provided an alternative to amputation for patients who wish to continue high level functional activities. Patients complete a 4 week Return to Run (RTR) training program to learn to properly utilize the device. The device is typically worn during high level functional activities to reduce pain and enhance training capacity. **The purpose of this study is to evaluate running biomechanics, functional performance, and quality of life outcomes for SMs prescribed an IDEO for a lower extremity (LE) fracture and compare them to healthy military runners.**

## Methods

A retrospective data analysis was conducted utilizing a registry protocol (NMCSD.2014.0026). Patients must have been fit with an IDEO at Naval Medical Center San Diego (NMCSD), have completed the RTR program, and have undergone a 3-D running analysis at a self-selected speed at the completion of the program. Ten SMs with lower extremity fracture who utilize an IDEO for running (29±5 years old, 1.79±0.05 m, 91±12kg) were compared to 15 healthy military runners (32±7 years old, 1.78±0.06 m, 82±8kg). Running time distance parameters, frontal and sagittal plane biomechanics of the trunk and pelvis during running, Short Musculoskeletal Function Assessment (SMFA), 4 Square Step Test (4SST), and CHAMP scores were analysed for all groups. A one-way ANOVA was run to determine differences between the two groups ( $p < 0.05$ ).

## Results and Discussion

Descriptive statistics for all running variables are reported in Table 1. Compared to healthy runners, the IDEO patients exhibited significantly less lateral trunk motion during running. IDEO runners also had trends towards shorter step lengths and higher cadence, both of which are taught in the training program. It is noteworthy that IDEO users achieved similar self-selected running speeds and had very low standard deviations in cadence specifically. SMs using an IDEO reported SMFA scores of 23.6±13.9 for Daily Activities, 41.2±19.7 for Emotional, 33.3±18.6 for Mobility, 24.7±12.3 for Function Index, and 25.0±13.6 for Bother Index. These scores are better than the Limb Salvage cohort from the METALs study<sup>3</sup> but significantly worse compared to the controls. This continues to show improved patient reported outcomes for SMs with an IDEO compared to those without. CHAMP performance test consisted of four scores for IDEO SMs: single limb stance (39.2±9.4 s), T-Test (15.4±2.2 s), Illinois Agility test (15.4±1.8 s), and Edgren Side Step test

(20.0±3.2 m). While IDEO users performed poorer than controls, they performed similar to the 75<sup>th</sup> percentile of patients with amputation as reported previously<sup>4</sup>. 4SST (5.3±1.0 IDEO vs 4.5±1.0 control) was not significantly different.

**Table 1:** Descriptive Statistics for Running Biomechanics, significant differences are in bold.

	Control	11.75	3.01		

## Significance

Overall, patients who sustained a LE fracture and use an IDEO for running and other high level activities are running at similar speeds and with similar biomechanics as their healthy counterparts. They have improved patient reported outcomes compared to limb salvage patients who did not have access to an IDEO. Finally, patients perform near the 75<sup>th</sup> percentile of their amputee counterparts on the CHAMP performance test indicating that they have good function and performance in addition to similar running biomechanics to healthy controls. This indicates that the use of IDEO in this population is appropriate and should be continued.

# Effect of body position and external load on knee joint kinematics and muscle activity in healthy young adults during the pendulum test

Diego M. Ferreira<sup>1</sup> and Jianhua Wu<sup>1</sup>

<sup>1</sup>Department of Kinesiology and Health, Georgia State University, Atlanta, GA, USA. Email: jwu11@gsu.edu

## Introduction

The Wartenberg pendulum test has been administered in different populations to assess passive stiffness of the knee. While the test is easy to administer, different body positions have been used for this test. Our previous study showed that an external ankle load equalling to 2% of body weight can increase the number of swing cycles and stiffness of the knee during this test [1]. However, it is not known if a higher amount of ankle load can induce further improvements in the test performance.

Additionally, there is limited quantitative analysis of muscle activity within the quadriceps group during this test. The muscles' contribution during each position and load is critical to understand the contributors to increased passive stiffness in certain populations. Therefore, the purpose of this study was to investigate the effect of body position and ankle loading on the knee kinematic performance and muscle activity in healthy young adults. We hypothesized that an increased ankle load would increase the amount of knee kinematics and muscle activity, and a position of lying down would facilitate the pendulum test compared to other body positions.

## Methods

Twenty adults (10M/10F, 22.44±3.07 years) sat on a table with their legs hanging over the edge of the table. The dominant leg was raised so that the knee was in a full extended position. Subjects were instructed to relax their leg, and then the leg was released allowing it to swing freely until it came to a stop. Three body positions were included: sitting upright, sitting reclined at 45 degrees, and lying supine. Three loading conditions were included: without load (NL), an ankle load equaling to 3% of body mass (AL3), and 6% of body mass (AL6). An 8-camera Vicon motion capture system was used to collect kinematic data of the knee (Fig. 1). Electromyography (EMG) was collected using Delsys wireless surface electrodes on the rectus femoris, vastus lateralis, and vastus medialis. Kinematic variables included: the first flexion excursion (A1), number of swing cycles, relaxation index (RI), stiffness coefficient (K1), and a damping coefficient (B1).

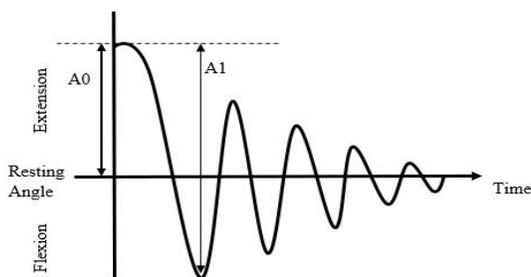

Fig. 1: Knee joint angle during the pendulum test.

RI was calculated as  $A1/A0$ . K1 was calculated using the angular velocity and moment of inertia of the lower leg. B1 was estimated by calculating the damping ratio and natural frequency [1]. The integrated area of EMG during the first flexion excursion was calculated across all the muscles. Two-way (3 position x 3 load)

ANOVAs with repeated measures were conducted for the kinematic variables. Three-way (3 position x 3 load x 3 muscle) ANOVAs with repeated measures were conducted for the EMG variable. Post-hoc pair-wise comparisons with Bonferroni adjustments were conducted when necessary at a significance level of  $\alpha=0.05$ .

## Results and Discussion

Our results indicate that body position affects the number of swing cycles and damping coefficient but did not affect A1, K1, or RI. The significant differences were between the upright & supine and upright & incline position ( $p<0.05$ ). The upright position resulted in greater number of swing cycles, but a smaller damping coefficient compared to the other two positions.

While A1, RI and number of cycles increased from the NL to AL conditions, K1 and B1 decreased (Table 1). The addition of the ankle load increased all of the kinematic variables and muscle activity ( $p<0.001$ ). This indicates that the addition of an ankle load can be used to increase the amount of passive motion about the knee. However, the reduction in K1 and B1 suggests that the knee joint may become less stiff and viscoelastic under the AL conditions. In addition, muscle activity increased between the NL and AL conditions ( $p<0.001$ ). This response indicates that the quadriceps responded to the increased loads by controlling and slowing down the swings. This suggests that as the external load increased, greater muscle activity tends to accommodate the increased moment of inertia of the leg and improve the stability of the joint. This may correspond with the decrease in damping and stiffness coefficients.

Table 1. Means (SD) of kinematics and muscle activity.

Variable	NL	AL3	AL6
A1 (deg)	69.35 (9.58)	74.55 (8.63)*	78.37 (8.79)**
RI	1.84 (0.11)	1.91 (0.12)*	1.92 (0.17)*
Cycles	6.56 (0.86)	10.08 (1.61)*	12.25 (2.09)**
K1 (Nm/rad)	36.17 (7.46)	28.8 (5.47)*	26.35 (5.31)**
B1 (Nm*sec/rad)	0.25 (0.06)	0.18 (0.06)*	0.16 (0.06)**
EMG ( $\mu V \cdot \text{time}$ )	0.06 (0.21)	0.16 (0.50)*	0.26 (0.66)**

Note that \* represents a difference from NL; † represents a difference from AL3.

## Significance

The results indicate that body positions cause small effects on the kinematic pattern of the pendulum test in young adults. Lying down or inclined may provide an alternative position for this test. This may be beneficial to clinical populations who may have difficulty in sitting upright. Additionally, the addition of the ankle load showed increases in passive motion and increased the muscular response. The additional load may be used for developing therapy interventions to address increased passive stiffness of the knee in some clinical populations.

# Kinematics features and experience in differentiating above-knee amputee gait

## Introduction

Observe gait is clinically important to allow physical therapists (PT) and clinicians to assess motor deficits in patients. However, the inconsistent results in the skill of visual assessment lead to a question about whether clinicians are accurate and reliable on gait judgment[1]. Also, little is known about which gait features would base accurate judgments. The purpose of this study is to investigate (1) the differences in observational gait analysis skill between those with different level of clinical experience and (2) the informative kinematics features for differentiating amputee gait.

To answer these questions, we introduced a new method that combines biological motion and principal component analysis (PCA) to gradually mesh amputee and typical walking patterns for raters to rank. The synthesized patterns preserved the kinematics features that allow physical therapists (PT), PT students (PTS), and novice raters to discriminate different levels of gait impairment.

## Methods

Joint motion of three unilateral transfemoral amputee walkers (Walker A, B and C) and health control walkers were utilized to build three biological motion models through PCA. Each model was based on one amputee walker. We then build 6 videos from each model displaying a synthesized point-light walker varying in weighing from 0, 20, 40, 60, 80 to 100% between healthy walking and the given amputee walking features. These videos were used to test the accuracy in differentiating a range of scaled gait abnormalities for 10 PT, PTS and Novice. The goal was to rank the videos from 1 to 6 based on the weighing within 25 secs (Figure 1). Participants performed a total of 30 trials (3 set\*10 repetitions).

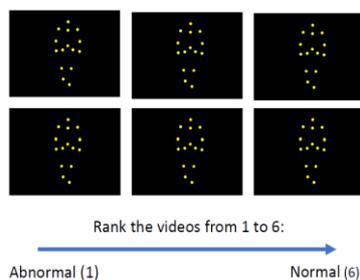

Figure 1. An example of a testing video set for one trial.

Analysis of the first four principle components were used to quantify the amputee gait features that were deviated from normal walking. In addition, the accuracy rate in judging biological videos were used to test the observational gait skill on each rater group.

## Results and Discussion

In sum, we quantified the major dissimilar features between amputee and control walkers that allow individuals to perceive and differentiate walker patterns. The quantified features represent the magnitude of medial-lateral body sway, degree of gait asymmetry, and percentage of gait deviation. We postulate that these gait features are the perceptual variables that allow individuals to differentiate between walkers.

A higher degree of spatial asymmetry in gait was presented especially on Walker A and Walker C. Also, the percentage of gait similarity to health walker (Walker A: 38.3 %; Walker B: 75.47% and Walker C: 89.88%) was associated with accuracy rate (negative relationship). A larger medial-lateral body sway was observed in all amputee walkers (Figure 2).

For the comparison of accuracy rate between rater groups, we found that PT and PTS were the same and the both were more accurate than the Novice group. Because greater learning changes occur at the beginning of practice [3], if the PTS can attend to the information that is beneficial to identify gait impairment, they can perform better than Novice and reach comparable levels of as PT. In addition, the minor differences between PT and PTS was found on PT showing equal ability of accuracy for the whole spectrum from normal to abnormal walking patterns in judging Walker C' videos. Considering, Walker C's gait is 89.88% similar to normal walkers but with a relatively larger gait asymmetry, we postulated that PT likely have learned to promptly attend to and sensitive to gait asymmetry.

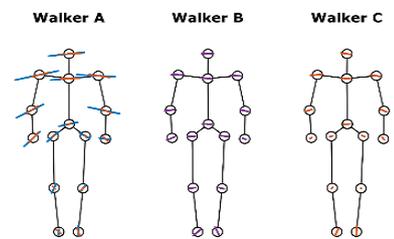

Figure 2. The stick figures of walkers are facing to the viewers. The blue, purple, and red lines indicate the reconstructed joint trajectories of the dissimilar PCs in respected to amputee walker's PC1, PC2, and PC3, respectively.

## Significance

We introduced a new method, combining biological motion and PCA, to synthesize gait dynamics between amputees and a control walker. This new method can be used to improve the current way in training/evaluating the observational gait analysis skill for clinicians since it provides flexibility in presenting different level of gait impairment and excludes redundant sources of information that might not relate to gait. In addition, the identified gait features that PTs attended to might inform the future design of automated, clinically relevant gait evaluation and automatic prosthesis tuning algorithm in the future.

## Introduction

Cerebral Palsy (CP) is defined as a group of non-progressive motor impairments caused by lesions in the developing brain [1]. However, CP is characterized by muscle spasticity and functional loss later in life [2,3,4]. In this research, we monitored muscle oxygenation and hemodynamics using Near Infra-Red spectroscopy (NIRS), trying to capture for the first time the hemodynamic portion of spastic muscle function. NIRS technology allows for continuous and non-invasive monitoring of muscle oxygen saturation, oxy-hemoglobin, and deoxy-hemoglobin concentrations [5].

## Methods

12 participants with CP who were able to walk (4 females, 8 males aged 29.5±7.91 mean±SD) and adults with No Physical Impairment (NPI) (8 females, 6 males aged 26.5±1.51 mean±SD) were evaluated. We measured the change in oxy- and deoxy-hemoglobin concentrations and the muscle saturation (TSI) of Vastus Lateralis (VL) and Rectus Femoris (RF) of the most affected limb using a portable NIRS system (PortaMonand2x Portalite, Artinis, Netherlands). Muscle tissues were continuously recorded at rest and during exercise, while applying venous occlusion (~60 mmHg) to calculate Muscle Blood Flow (MBF) and arterial occlusion (~280 mmHg) to calculate Muscle O<sub>2</sub> consumption (mVo<sub>2</sub>). Participants performed a Maximum Voluntary Contraction (MVC) test, followed by measurements at rest and at one minute of repeated knee extension at 20% and 80% of their MVC. We used a Linear Mixed Model to compare participants with CP and NPI, as well as to compare between the two muscles and between different loads (rest, 20%, 80%). Using the participants' shank length, we calculated the knee extensor torque. Additionally, we calculated muscle efficacy by dividing the mVo<sub>2</sub> by the torque (proxy for metabolic energy divided by mechanical work). In all cases, the significance level was  $p \leq 0.05$ . All statistical analyses were performed using R-Studio.

## Results and Discussion

The maximum knee extensor torque was found to be significantly lower in participants with CP compared to participants with NPI (mean ± SD CP: 19.7± 16.49. NPI 49.61± 16.84N\*m) ( $p=0.00012$ ).

The MBF of participants with CP didn't change in the VL between loads but significantly increased in the RF from rest to 20%MVC and to 80%MVC ( $p<0.001$ ). In the NPI group, MBF was significantly reduced only for the VL muscle, from rest to 80%MVC ( $p=0.008$ ), resulting in a significant interaction between the load and group demonstrating 1.45 and 1.69 times greater increase in MBF for participants with CP compared to those with NPI from rest to 20%MVC ( $p=0.02$ ) and to 80%MVC ( $p=0.001$ ), respectively. mVo<sub>2</sub> of participant with NPI was larger than the mVo<sub>2</sub> of participants with CP at rest ( $p=0.05$ ). In both groups there was a significant increase in mVo<sub>2</sub> from rest to

20%MVC and to 80%MVC ( $p<0.0001$ ). MVo<sub>2</sub> to torque was significantly lower for NPI group ( $P<0.02$ ).

The muscle TSI significantly decreased at 80%MVC compared to 20%MVC, for all participants, with a much greater decrease in NPI than in CP participants [2.3 times vs 1.6 times respectively), resulting in a significant interaction between load (20% to 80%) and TSI ( $p=0.01$ ).

Half recovery time in 80%MVC was twice as high in the NPI group as it was for CP participants ( $p=0.0004$ ). For CP participants, there were no significant differences between loads ( $p>0.3$ ), whereas for NPI there was a significant increase in half recovery time from 20%MVC to 80%MVC ( $p<0.0001$ ).

We found a typical reduction of MBF in participants with NPI in the VL muscle at high working loads, a reduction that we attributed to the interference with the MBF, resulting from the massive activation of motor units. In participants with CP, however, the greater force did not restrict MBF in the VL because of a low contractility.

We assume that the MBF increases in the RF due to increased regional MBF coupled with even more limited contraction in the RF muscle. This assumption is reinforced by the fact that the TSI at 80%MVC decreased more in the NPI participants than in participants with CP, suggesting a greater imbalance between oxygen demand and supply in NPI participants. Between the groups, there was no difference in mVo<sub>2</sub> at 20% and 80% MVC. Yet, dividing the mVo<sub>2</sub> by torque (i.e. muscle efficiency) for NPI participants suggests that the muscle construction is more efficient in the NPI group.

## Significance

The NIRS was able to capture differences in muscle hemodynamics and oxygenation in people with CP. These measurements are important to understanding muscle function in order to find treatments and shape training protocols to improve CP lifestyle.

## Acknowledgments

This research was supported by Kreitman School of Advanced Graduate Studies Found at Ben-Gurion University of the Negev. The use of NIRS technology was supported by Yogev Koren from Physical Therapy Department at Ben-Gurion University of the Negev.

## Dynamic Joint Stiffness During Single Leg Drop in FAIS Participants

Jennifer Perry<sup>1</sup>, Kate Jochimsen<sup>1</sup>, Rich Willy<sup>2</sup>, and Stephanie Di Stasi<sup>1</sup>,

<sup>1</sup>OSU Sport Medicine Research Institute, The Ohio State University, Columbus, OH, USA

<sup>2</sup>School of Physical Therapy & Rehabilitation Sciences, University of Montana, Missoula, MT, USA

Email: [jennifer.perry@osumc.edu](mailto:jennifer.perry@osumc.edu)

### Introduction

Femoroacetabular impingement syndrome (FAIS) preferentially afflicts young, athletic individuals and is associated with functional deficits, pain, and altered movement strategies during functional tasks<sup>3</sup>. Joint stiffness is a valuable tool to assess the interaction between changes in joint torques and changes in joint motion during loading phases. In other populations with intra-articular pathology, elevated joint stiffness is often observed during dynamic tasks, such as landing. Understanding limb and joint stiffness patterns in FAIS may provide valuable insight into syndrome-specific impairments. As such, the purpose of this study was to compare the total limb and dynamic joint stiffness of the hip, knee, and ankle between the symptomatic and asymptomatic limb of those with FAIS during a single leg drop (SLD) task. We hypothesized that the symptomatic limb would demonstrate greater hip joint and total limb stiffness during landing.

### Methods

Twenty athletes with FAIS (22.9±9.1 years old; 11 female) performed 5 SLDs on each limb from a 31cm box on to a force plate while 3-dimensional motion data were collected. The last 3 trials for each limb were selected for analysis. Dynamic sagittal plane joint stiffness during the initial landing phase was calculated for each joint. Initial landing phase was defined as initial contact to time of peak joint moment. Joint stiffness was calculated as the angular coefficient of the linear regression line when joint moment is plotted as a function of joint angle<sup>3</sup>. Total limb stiffness was calculated from initial contact to lowest center of mass during landing. Total limb stiffness was also calculated as peak vertical ground reaction force divided by vertical displacement of the center of mass during landing (ie. initial contact to lowest center of mass).

Wilcoxon Signed-Rank tests were performed to compare dynamic joint stiffness and total limb stiffness between limbs. Alpha was set to 0.05. Probability of Superiority for dependant measures (PS<sub>dep</sub>) was defined as the number of observations where the involved limb variable of interest was greater than the uninvolved limb divided by sample size.

### Results and Discussion

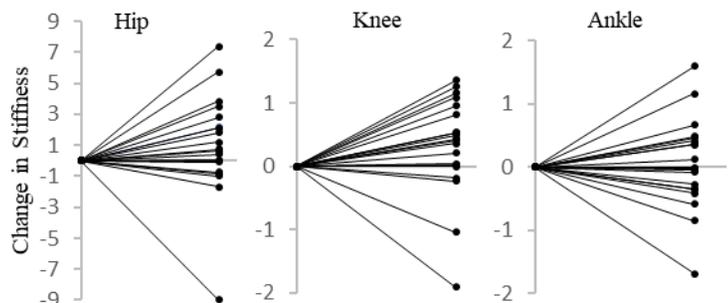

Subjects with FAIS demonstrated an increased dynamic joint stiffness at the knee on the involved limb compared to the uninvolved limb during a SLD. There was a PS<sub>dep</sub> of 75% for joint stiffness of the knee, meaning there was a 75% chance that knee stiffness was greater on the involved side. There were no significant differences between limb found at the hip, ankle, or total limb stiffness. However, there was a 70% chance that hip stiffness was greater on the involved side compared to the uninvolved side.

Increased load on the symptomatic limb has been previously reported during gait in those with FAIS<sup>1,2</sup>. The increased dynamic knee joint stiffness on the involved side during the SLD task identified in the current study may be a protective measure

employed to adapt to increased joint moments. Alternatively, the increased dynamic knee joint stiffness may be resultant of a decreased sagittal knee excursion. Future studies should evaluate both joint kinematics and kinetics to understand contributing factors to alterations in joint stiffness.

	Limb	Median	IQR	<i>p</i>	<i>PS<sub>dep</sub></i>	<i>r</i>
Hip	Involved	4.82	(3.08, 6.23)	.073	.70	-.283
	Uninvolved	4.28	(3.07, 6.13)			
Knee	Involved	5.08	(4.29, 6.60)	.028	.75	-.348
	Uninvolved	4.75	(4.12, 6.30)			
Ankle	Involved	4.28	(3.51, 5.13)	.737	.45	-.053
	Uninvolved	4.44	(3.41, 5.05)			
Total Limb	Involved	19.31	(14.57, 20.71)	.126	.65	-.242
	Uninvolved	16.70	(15.37, 19.42)			

**Table 1:** Median dynamic joint stiffness during landing of involved and uninvolved limb for hip, knee, and ankle (\*significant difference for  $p < 0.05$ ).

**Figure 2:** Participant-level limb differences in joint stiffness for hip, knee, and ankle. Positive values indicate higher involved limb stiffness.

Based on participant-level data, some individuals demonstrated higher hip joint stiffness on the symptomatic side. This may or may not correspond with higher knee and/or ankle stiffness; kinematics and joint moments would further explain what is influencing these patterns. With larger samples, including healthy controls, the implication of altered hip stiffness on functional performance can be fully examined. Understanding such strategies may provide critical clinical insight into variations in functional performance and inform rehabilitation strategies.

### Significance

Persons with FAIS show asymmetrical dynamic knee joint stiffness between limbs during the dynamic task of SLD. Whether or not this is an effective strategy to maintain sports participation in the presence of hip pain or could negatively impact knee function or future knee injury is unknown.

## Are Lower Back Demands Optimal in People with Unilateral Amputation?

Jacob J. Banks<sup>1</sup>, Ryan D. Wedge<sup>2</sup>, Graham E. Caldwell<sup>1</sup>, and Brian R. Umbeger<sup>3</sup>  
<sup>1</sup>Department of Kinesiology, University of Massachusetts, Amherst, MA, USA

<sup>3</sup>School of Kinesiology, University of Michigan, Ann Arbor, MI, USA  
Email: jbanks@umass.edu

### Introduction

People with unilateral lower limb amputation (PULLA) often walk asymmetrically with a prosthesis<sup>1</sup>. Asymmetric gaits are usually more inefficient with a greater cost of transport (CoT)<sup>2</sup> and may also be responsible for secondary disorders that impact quality of life<sup>3</sup>. Lower back pain (LBP) is a frequently cited complication, with twice the reported prevalence of the able-bodied population<sup>3</sup>. The increased LBP prevalence coupled with a growing number of amputations<sup>4</sup> have led to studies concerning the demands placed on the lower back during gait in PULLA<sup>2,5</sup>.

Lower back vertebral compression forces have been reported to be up to 40% greater in PULLA than in able-bodied controls<sup>5</sup>. These increased spinal demands have been attributed to residual limb and prosthetic limitations that lead to more lateral trunk flexion during stance on the prosthetic leg, greater forward trunk lean, and sustained erector spinae activity<sup>2</sup>. A question of clinical importance is whether these lower back demands could be reduced with more symmetrical gait. To address this question, we compared lower back compression forces in PULLA and able-bodied participants at different levels of enforced (a)symmetry. We hypothesized that compression forces are already optimized at the preferred (natural) gait asymmetry level for both the able-bodied and PULLA, as is the case for CoT<sup>6</sup>.

### Methods

PULLA and able-bodied participants (Table 1) took part in this study<sup>6</sup>, approved by the institutional review board. PULLA were limited to transtibial ambulators capable of variable cadences (i.e. >K3) from non-vascular causes at least 1-year post amputation.

All participants attended two sessions, with the first session used to determine preferred walking speed (PWS), preferred asymmetry level, and to acclimate them to the protocol. Whole-body kinematic data were collected in session 2. During both visits, participants walked on a motorized treadmill with up to eight different conditions of gait (a)symmetry (-15% to 15% in 5% increments [0%=symmetry] and preferred) for five minutes at PWS, with foot targets to aid gait asymmetries. Real-time visual feedback of (a)symmetry performance was provided from insole foot switches. Gait (a)symmetries level was defined as the difference between intact (dominant) and prosthetic (non-dominant) leg stance times relative to the combined stance time<sup>1</sup>.

Peak L5/S1 compression forces were calculated for each asymmetry level from a modified full-body OpenSim model<sup>7,8</sup> and expressed relative to bodyweight and PWS. Static optimization<sup>9</sup> was used to estimate individual muscle forces and their contribution to the derived lower back joint moments. For each participant, the minimum L5/S1 compression force across asymmetry conditions was calculated from a quadratic best-fit curve (Fig. 1). For each group, a paired t-test was used to compare ( $\alpha < .05$ ) the peak L5/S1 compression force at the predicted minimum with the force at the preferred level of asymmetry. A pooled t-test compared the between-group differences at preferred asymmetry levels.

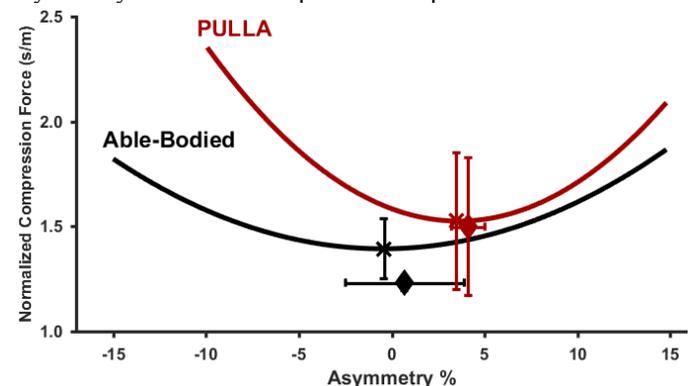

**Table 1:** Participant (PULLA n=5; able-bodied n=5) demographics by group. Asterisk (\*) significant difference between group's preferred walking speeds (PWS).

	Mass (kg)	Height (cm)	Age (years)	PWS (m/s)*
PULLA	84.8±22.0	178.6±10.0	38.6±11.6	1.1±0.3
Able-Bodied	74.1±13.4	177.2±8.3	29.6±6.4	1.4±0.1

### Results and Discussion

PULLA preferred to spend more time on their intact leg and therefore exhibited more stance time asymmetry (~4%) than able-bodied (~1%;  $p=.05$ ), which supports previous work<sup>1,2</sup>. The between group L5/S1 compressive loads were ~20% greater in PULLA for the preferred asymmetry conditions, but this trend was not significant ( $p=.10$ ) due to a large between-subject variability in the PULLA group. The peak L5/S1 compressive force at preferred asymmetry did not differ from the predicted optimal (Fig. 1) for either group, supporting our hypothesis.

Study limitations include low participant numbers, the use of static optimization to compute muscle forces, variability in task execution strategies, and the brief acclimation to the gait asymmetry conditions compared to the preferred.

**Figure 1:** PULLA (maroon) and able-bodied (black) group's normalized peak L5/S1 compression across different (a)symmetric gait conditions. Curves represent the average quadratic fit, crosses the predicted minimum, and diamonds the preferred asymmetry for each group.

### Significance

Our results suggest that training PULLA to walk more symmetrically may not reduce lower back demands, as both PULLA and able-bodied participants already locomote at a preferred level of asymmetry that minimizes peak L5/S1 compression forces.

## Introduction

Peripheral artery disease (PAD) is a cardiovascular disease that manifests from atherosclerotic blockages in the extremities. Lower extremity PAD results in intermittent claudication, a debilitating leg pain caused by insufficient blood flow to the lower-limb muscles during physical activity. PAD severely impacts patients' ability to complete daily living tasks and negatively affects their quality of life. A key functional limitation caused by PAD is reduced ankle power during late stance compared to healthy, aged-matched adults [1]. Previous literature suggests that this reduced ankle power during late stance could correlate to an increase in negative work during early stance [2]. Work is the amount of energy expended over time with a unit definition of joules. Positive work corresponds towards forward progression while negative work corresponds to braking or slowing of joint rotations[2]. We hypothesized that revascularization surgery to restore blood flow to the affected lower-limbs would lead to improved walking mechanics as demonstrated by increased mechanical walking efficiency. Increased efficiency is defined as increases in positive work produced during late stance and a decrease in negative work produced during early stance.

## Methods

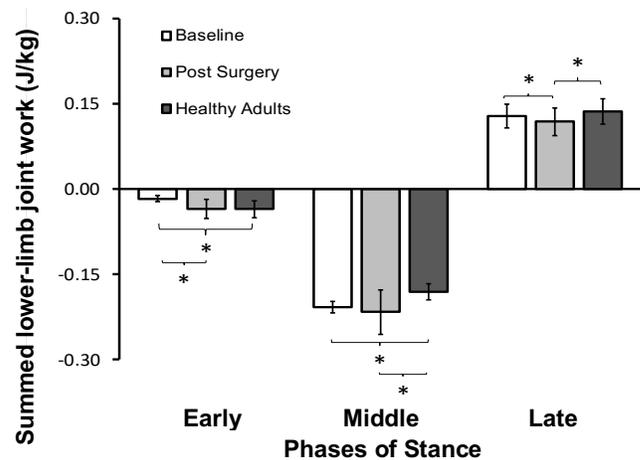

Thirty-four patients with PAD were recruited by the Nebraska-Western Iowa Veterans' Affairs Health Care System as well as 24 healthy, aged-matched adults from the University of Nebraska Medical Center. Patients completed over-ground walking trials at their self-selected speed before and 6-months following revascularization surgery. All participants walked over eight in-ground AMTI force plates until six quality foot-to-force plate contacts were recorded for each leg. Three-dimensional kinematics were collected using 17 motion capture cameras (Cortex 5.1, Motion Analysis Corp, Santa Rosa, CA) with retro-reflective markers placed at specific anatomical locations [3].

Lower-limb joint powers were calculated from heel contact to toe-off using Visual3D (Visual3D, Germantown, MD, USA). Ankle, knee, and hip joint work was calculated as the integral of joint power utilizing MATLAB 2018a for each phase of stance. Phases of stance were defined as early (0-28%), middle (29-74%), and late (75-100%) [2]. For each phase of stance, work was summed for the ankle, knee, and hip. A one-way analysis of variance was used to test for significance of summed joint work for each stance phase across groups: patients with PAD at baseline, patients with PAD 6-months following surgery, and healthy adults. A Bonferroni corrected  $\alpha$ -level of 0.0167 was used to correct for repeat assessment. As post hoc, Tukey test was implemented to assess significant differences between groups.

## Results and Discussion

Contrary to our hypothesis, patients with PAD produced more negative work during early stance and less positive work during

late stance following surgery ( $p < 0.01$ ). This suggests that patients with PAD walk less mechanically efficient following revascularization. The acute improvement to circulatory blood flow most likely does not translate to immediate improvement in the systemic muscle and passive tissue damage sustained from years of continual and degenerative ischemia.

**Figure 1:** Summed lower-limb joint work performed by patients with peripheral artery disease before and 6-months following revascularization surgery as well as healthy, age-matched participants. Stars indicate statistical significance between groups ( $p < 0.01$ ).

## Significance

Revascularization did not improve walking gait efficiency 6-months following surgery in patients with PAD. These findings should not diminish the importance of revascularization surgery for patients but instead, should emphasize the need to develop rehabilitation strategies following surgery. These results support further work investigating supplemental therapies such as exercise and assistive devices following revascularization to maximize the circulatory improvement.

**Introduction**

Multiple Sclerosis (MS) has different disease courses that can be broadly categorized into relapsing-remitting (RRMS) and progressive (PMS). Gait impairment is common in MS, and the timed 25-foot walk test (T25FW) is a clinical tool often used to track the level of disability in people with MS. The T25FW is associated with long-term disease outcomes.<sup>1</sup> Interestingly, spatiotemporal gait parameters do not differ between RRMS and primary PMS at preferred speeds when matched for age and disease disability<sup>2</sup>, but this has not been examined at the “fast and safe as possible” speeds generally used for the T25FW.<sup>3</sup> There may be spatiotemporal gait performance differences at brisk speeds that may be able to characterize differences in mobility performance (measured by spatiotemporal gait parameters) between MS subtypes.

The objective of this study was to determine if there are group differences in RRMS, PMS, and non-MS healthy controls (HC) in gait performance during T25FW. We hypothesized that gait performance will be more impaired (i.e. shorter steps spatially and longer stride times to increase stability) in PMS compared to RRMS, and in MS groups compared to HC.

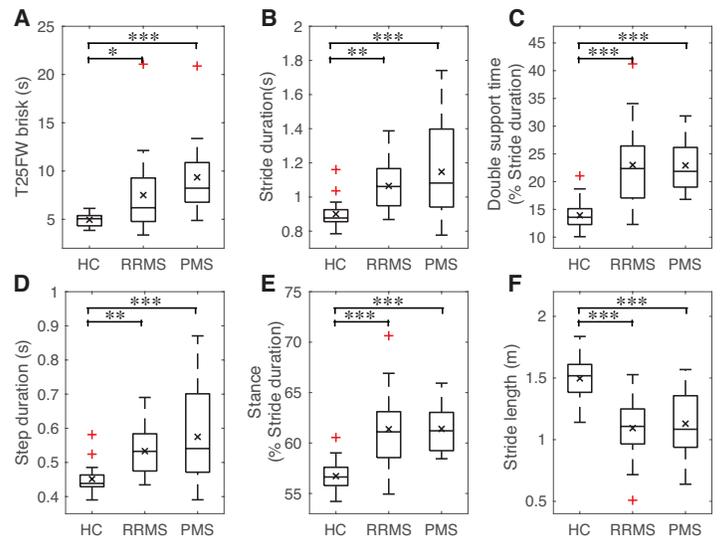

**Methods**

Twenty-four HC (54.8 ± 12.6 yrs), 16 RRMS (52.6 ± 11.0 yrs) and 17 PMS (59.1 ± 6.9 yrs) adults participated in this study. All MS participants walked without any walking aids. Participants completed the T25FW at a “fast and safe as possible” pace, while wearing inertial sensors on both feet equipped with a tri-axial accelerometer, gyroscope, and magnetometer (Opal, APDM, Inc., Portland, OR; 128 samples/s). Spatiotemporal gait variables were extracted using APDM Mobility Lab (version 2) software. This method has been validated in healthy young and older adults, and in people with Parkinson’s disease.<sup>4,5</sup> Our spatiotemporal gait variables were: stride duration (s) double support time (% stride duration), stride length (m), step duration (s), and stance time (% stride duration). One-way analysis of variance and post-hoc independent t-tests with unequal variance were used to examine differences between groups.

**Results and Discussion**

T25FW time was shorter in HC than RRMS and PMS, but not significantly different between RRMS and PMS (Fig. 1A, Table 1). Similarly, stride duration, double support time, step duration, and stance time were shorter, and stride length was longer in HC than RRMS and PMS, but were not significantly different between RRMS and PMS (Fig. 1B-F, Table 1).

The differences between HC and both MS groups shows that even in persons with MS who walk without aids, speed is slower and spatiotemporal parameters are modified, presumably to increase stability. The lack of differences between MS subtypes in these parameters is consistent with a study by Dujmovic and colleagues that examined spatiotemporal variables at preferred speed.<sup>2</sup> This suggests that even at brisk pace, spatiotemporal gait parameters may not characterize differences between MS subtypes in those walking independently without walking aids.

**Figure 1:** T25FW time (A) and spatiotemporal gait parameters (B-F). Black ‘X’ indicates mean, and red crosses indicate outliers. \*: p = 0.010-0.050; \*\*: p = 0.001-0.009; \*\*\*: p < 0.001

	ANOVA	HC-RRMS	HC-PMS	RRMS-PMS
T25FW	< 0.001	[-4.4, -0.7]	[-6.3, -2.5]	[-4.4, 0.7]
Stride duration	< 0.001	[-0.2, -0.1]	[-0.4, -0.1]	[-0.3, 0.1]
Double support time	< 0.001	[-13.3, -4.4]	[-11.6, -6.4]	[-4.6, 4.7]
Step duration	< 0.001	[-0.1, -0.04]	[-0.2, -0.1]	[-0.1, 0.04]
Stance time	< 0.001	[-6.9, -2.4]	[-6.1, -3.3]	[-2.4, 2.4]
Stride length	< 0.001	[0.2, 0.6]	[0.2, 0.5]	[-0.2, 0.2]

**Table 1.** ANOVA p-values and 95% confidence intervals for differences between group means.

**Significance**

Our results are important because current clinical tests to track disability in MS rely largely on mobility as a key outcome measure. The small spatiotemporal gait differences between independently walking RRMS and PMS demonstrates that gait may not be the best clinical test to characterize MS subtypes. Future analyses should assess the link between these spatiotemporal gait variables and stability in MS subtypes.

### Introduction

Fixed grab bars, which must be capable of sustaining a minimum of 1.3kN [1], are recommended to secure bathtub transfers of individuals with chronic mobility impairments. Individuals with a temporary need for assistance (e.g.: post surgery or palliative care) may prefer installing suction cup grab bars.

However, clinicians are reluctant to recommend suction cup grab bars for bathtub transfers because they question their sturdiness. Indeed the forces applied to a grab bar during complete bathtub transfers (step into the bathtub, sit down into the bottom, stand up and step out) are unknown, so an evidence-based decision is impossible.

We thus determined the magnitude and duration of the force applied to a grab bar during complete bathtub transfers, and the factors influencing this force.

### Methods

A three factorial repeated measures design was used in an experimental environment including a bathtub, padded walls, instrumented fixed grab bars and a safety harness.

Seven healthy young adults (four women) stepped into the bathtub, sat down into the bottom, stood up and stepped out (three trials), with or without a slippery surface (with or without lubricating gel [2]), grabbing onto four grab bar configurations (vertical, angled, horizontal low, horizontal high).

Maximum force magnitudes and durations applied on the grab bar during complete bathtub transfers were measured by two six degrees of freedom load cells sampled at 2 KHz, for each of the 16 conditions (4 grab bar configurations \* 2 surfaces \* 2 directions of bathtub transfer).

Separate three-way ANOVAs with repeated measures were used to study main effects and interactions on the magnitude and duration of the force applied to a grab bar. Post-hoc two-way ANOVAs and paired t-tests were then computed.

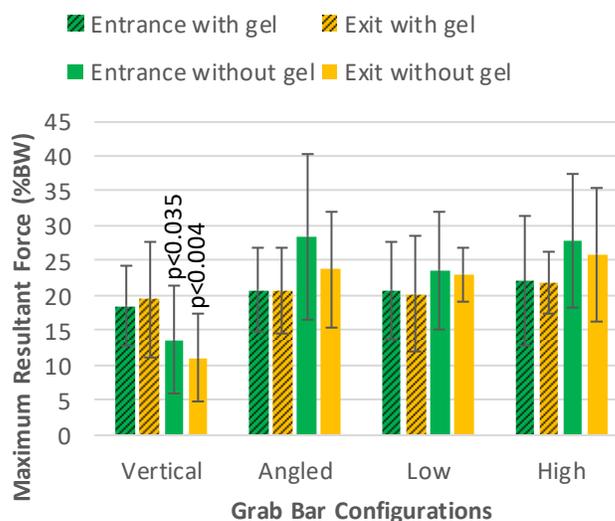

### Results and Discussion

On average, 23.2±6.4% of body weight was applied on the grab bar during complete bathtub transfers.

Maximum resultant forces were not influenced by grab bar configuration, presence of a slippery surface or direction of bathtub transfer (entrance or exit), except for the vertical configuration without a slippery surface. In this configuration, the maximum resultant force was smaller than for the three other configurations, in both directions.

Transferring on a slippery surface also increased the time participants applied a force on the grab bars across all configurations and directions.

Therefore, grab bars used during complete bathtub transfers should be capable of sustaining a minimum of 23.2% of body weight, to which a factor of safety of 1.5 should be added [3], regardless of the grab bar configuration.

**Figure 1:** Mean ± standard deviation maximum resultant force applied on the grab bar during complete bathtub transfers (N=7).

For example, a manufacturer whose suction cup grab bar fails at 60kg should claim to sustain a maximum of 60kg / 1.5 = 40kg. Therefore, a 95<sup>th</sup> percentile male would apply 110.7kg \* 23.2% = 25.7kg on the grab bar, which is well below the 40kg of our hypothetical suction cup grab bar and would in fact have a factor of safety of 60kg / 25.7kg = 2.33.

Unfortunately our study cannot confirm the loads that grab bars should be capable of sustaining if a fall occurs, as no falls occurred during testing.

### Significance

All grab bars, fixed and removable suction cup grab bars, used during complete bathtub transfers with no loss of balance should be capable of sustaining a minimum of 23.2% of body weight, to which a factor of safety of 1.5 should be added [3], regardless of the grab bar configuration. These results could thus be used to support evidence-based recommendations regarding the safe use of suction cup grab bars to secure bathtub transfers, when it is not feasible or desirable to install a fixed grab bar into the wall.

## Introduction

People with unilateral lower limb amputation have a greater prevalence of knee osteoarthritis (OA) in the intact limb compared to people without amputation<sup>1</sup>. Greater OA prevalence may be due to greater load magnitude or stance time duration on the intact limb compared with the prosthetic limb<sup>2</sup>, leading to greater cumulative loading, which has been linked to OA<sup>3</sup>.

Walking speed has opposite effects on knee joint load magnitude and duration. Slower walking speeds reduce peak knee loads<sup>5</sup>, therefore that may be why people with amputation generally walk slower than able-bodied people<sup>4</sup> even though it increases stance time. It is unclear how these combined consequences of walking speed affect per-step loads, and loads over a given distance. The purpose of this preliminary study was to understand tibiofemoral joint loading between the prosthetic and intact limbs across gait speeds.

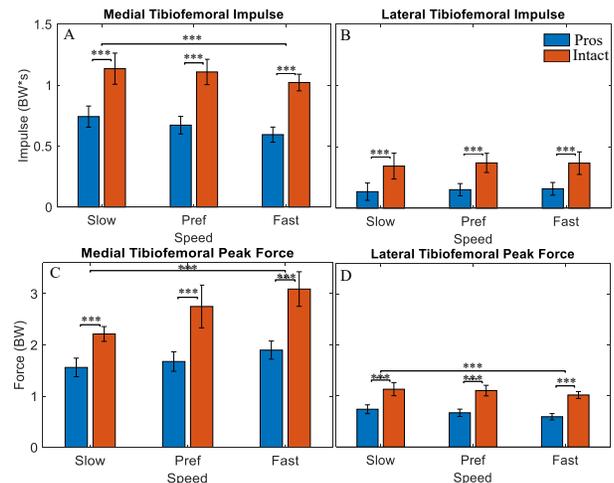

## Methods

Four people with unilateral transtibial amputation from non-vascular causes that were either K3 or K4 ambulators (2 female; mass:  $65.6 \pm 9.1$  kg; height  $177.2 \pm 9.2$  cm; years  $38.5 \pm 9.9$  years; preferred walking speed:  $1.24 \pm 0.04$  m·s<sup>-1</sup>) participated in this institutional review board approved study. Participants walked overground at preferred and  $\pm 20\%$  preferred speed with motion capture marker data collected at 240 Hz and ground reaction force data collected at 2400 Hz. Preferred speed was determined by timing 6 m in the middle of a 10 m walk for 3 trials<sup>6</sup>.

Tibiofemoral contact forces were estimated with an established model<sup>7</sup>. Briefly, joint kinematics and kinetics were calculated using an inverse dynamics approach. Muscle force estimates for the quadriceps, hamstrings and gastrocnemius were derived from the resulting net joint moments across stance phase using published muscle moment arms as a function of joint angle and muscle cross sectional areas. Muscle forces and joint reaction forces were combined to yield total tibiofemoral joint axial force, which was distributed to the medial and lateral proximal tibia in a manner to achieve the calculated frontal plane knee joint moment. The gastrocnemius was removed when estimating joint contact force on the prosthetic limb because the gastrocnemius does not perform the same biomechanical role after a transtibial amputation. We performed a two way (limb x speed) ANOVA ( $\alpha=0.05$ ) to test for differences in medial and lateral tibiofemoral joint contact peak force and force impulse.

## Results and Discussion

The intact limb had significantly greater peak force ( $p<0.001$ ) and significantly greater impulse ( $p<0.001$ ) than the prosthetic limb during stance across speeds, except for the lateral impulse speed effect ( $p<0.508$ ) (Figure 1a-d). Medial tibiofemoral peak forces had a significant ( $p<0.002$ ) interaction between limb and speed, indicating that intact and prosthetic limb medial

**Figure 1:** Medial and lateral tibiofemoral stance phase joint force impulse (A & B) and peak force (C & D) for prosthetic (Pros-blue) and intact (orange) limbs across three speeds (slow, preferred (Pref), fast). Braces indicate limb and speed main effects. \*\*\* indicates  $p<0.001$ . The intact limb had greater impulses and forces than the prosthetic limb for both medial and lateral tibiofemoral compartments across three speeds.

compartment peak forces increased with greater speeds, but only for the intact limb (Figure 1C). Greater tibiofemoral peak force and force impulse have been associated with medial knee OA in able bodied<sup>3</sup> and people with unilateral amputation<sup>8</sup>. Based on our preliminary results, people with unilateral amputation generally experience both greater peak force and force impulse on the intact limb than the prosthetic limb regardless of walking speed. Interventions to reduce inter-limb loading asymmetry during walking may reduce this OA risk factor. However, the effects of such interventions on other aspects of walking such as gait stability and metabolic cost of transport require further study.

## Significance

People with unilateral amputations utilizing prostheses have greater knee loads on the intact limb that may promote OA onset or progression. Minimizing inter-limb loading asymmetry through gait re-training may prevent secondary disability.

# Depth of Squat Influences the Two-Dimensional Analysis of Knee, Hip, and Pelvis Frontal Plane Motion in Pain-Free Women

David M. Bazett-Jones<sup>1</sup>, Marina Cabral Waiteman<sup>1,2</sup>, Neal R. Glaviano<sup>1</sup>

<sup>1</sup>University of Toledo, Toledo, OH, USA

<sup>2</sup>São Paulo State University (UNESP), Presidente Prudente, Brazil

Email: [david.bazettjones@utoledo.edu](mailto:david.bazettjones@utoledo.edu)

## Introduction

Excessive frontal plane motion of the lower extremity is related to lower limb injuries.<sup>1,2,3</sup> Frontal plane measurements of the lower extremity and trunk during functional motion are easily measured with 2-dimensional (2D) motion analysis and these values are clinically relevant.<sup>3,4</sup> In this context, the squat task is a practical tool able to evaluate frontal plane motion related to knee injuries development and interventions. However, methodological differences in squat depth are reported and have resulted in varying results.

Studies have reported a minimal depth knee angle ( $\geq 60^\circ$ ),<sup>3</sup> a standardized step height (i.e. 21 cm),<sup>4</sup> a knee angle range ( $45^\circ$ - $60^\circ$ ),<sup>5</sup> and a knee angle that was standardized (i.e.  $60^\circ$ ).<sup>6</sup> Each of these methods can result in differing squat depths and resulting knee flexion angles. However, it is unknown if frontal plane trunk, pelvis, hip and knee frontal plane motion is influenced by squat depth. Therefore, the aim of this study was to investigate knee valgus (KV), hip adduction (HADD), pelvic drop (PD), and lateral trunk flexion (LTF) at different knee flexion angles during a single-leg squat in pain-free women. We hypothesized that as knee flexion angle increased, all other 2D angles would also increase.

## Methods

Twenty pain-free women (age= $22.3 \pm 1.1$  years, height= $1.68 \pm 0.06$  m, mass= $63.1 \pm 11.7$  kg) were recruited from the local university. Markers were placed on the anterior superior iliac spines, greater trochanter and center of the patella. Participants performed three single leg squats to the lowest depth comfortable while keeping pace with a metronome (2s down, 2s up). Frontal and sagittal plane videos were recorded during SLS and images were extracted at  $30^\circ$ ,  $45^\circ$ ,  $60^\circ$ ,  $75^\circ$  and  $90^\circ$  of knee flexion. Average values for KV, HADD, PD, and LTF during knee flexion angles were analyzed. Positive values indicate greater KV, HADD, PD, and contralateral LTF. Four repeated measures analysis of variance with Sidak pairwise comparisons were used to investigate differences in frontal plane motion across knee flexion angles. Significance was set to  $p \leq 0.05$ . Effect sizes (ES) for each comparison were also calculated (Cohen's  $d < 0.40$ : small effect, 0.41 to 0.70: moderate effect,  $\geq 0.71$ : large effect).

## Results and Discussion

Significant differences for KV ( $F=33.95$ ,  $p < 0.001$ ), HADD ( $F=67.77$ ,  $p < 0.001$ ), and PD ( $F=51.98$ ,  $p < 0.001$ ) among  $30^\circ$ ,  $45^\circ$ ,  $60^\circ$ ,  $75^\circ$  and  $90^\circ$  of knee flexion were found. Post-hoc analyses revealed significant differences for most comparisons. KV significantly increased at every increase of knee flexion angle ( $p \leq 0.05$ , ES: 0.54-1.95), as did PD ( $p \leq 0.05$ , ES: 0.61-3.03). HADD was significantly increased ( $p \leq 0.05$ , ES: 0.64-3.85) at every knee flexion angle except between  $30^\circ$  and  $45^\circ$  ( $p=0.158$ , ES: 0.52). No differences in LTF were found ( $F=2.73$ ,  $p=0.085$ , ES: -0.29-0.08). Means and standard deviations for trunk, pelvis, hip and knee frontal plane motion across knee flexion angles are presented in Table 1.

Our findings show that as knee flexion angles (i.e. squat depth) increase, frontal plane motion of the knee, hip, and pelvis also increased. Analysis of squatting using 2D motion analysis is common among clinicians but no standardized methods for collecting this information have been recommended. More studies investigating the different methodologies of 2D measurement of the single-leg squat seem warranted. Since this study was performed in healthy individuals, future studies should include pathological groups for which front plane motion is important. It could be that groups with pain may limit their motion, thus dampening the relationship found in our study; or it they could demonstrate a greater influence of knee flexion on frontal plane measures. In conclusion, pelvis, hip, and knee motion in the frontal plane are influenced by knee flexion angles during 2D analysis of a single-leg squat task.

## Significance

Our results highlight the importance of standardizing squat depth during research and clinical practice ensure appropriate comparisons across time and assessors. Caution would be advised when comparing the KV angles obtained at different angles of knee flexion, both in research and clinical practice.

# Muscle Forces of the Lower Extremity During Dynamic Tasks in People With and Without Chronic Ankle Instability

Hoon Kim<sup>1</sup> and Kristof Kipp<sup>1</sup>

<sup>1</sup>Program in Exercise and Rehabilitation Science, Department of Physical Therapy, Marquette University, Milwaukee, WI, USA  
Email: \*[hoon.kim@marquette.edu](mailto:hoon.kim@marquette.edu)

## Introduction

Ankle ligament sprains are common musculoskeletal injuries, and people who sprain their ankle ligaments may develop chronic ankle instability (CAI).<sup>1</sup> Although people with CAI exhibit neuromuscular deficits, muscle forces have not been studied.<sup>1,2</sup> Although measuring muscle forces directly is difficult, musculoskeletal modelling and simulations can help estimate individual muscle forces. Knowing muscle forces in CAI patients would provide a better understanding of the neuromuscular deficits in people with CAI and may improve targeted rehabilitation protocols. Furthermore, investigating muscle forces would be a first step to understand how muscle forces contribute to the development of ankle osteoarthritis, which is a critical issue in CAI patients.<sup>3</sup> The purpose of this study was to estimate individual muscles forces in the lower extremity and compare these estimates between people with and without CAI during landing, and anticipated and unanticipated cutting tasks.

## Methods

Eleven people with CAI and 11 people without CAI participated in this study. Each participant performed a landing, anticipated cutting, and unanticipated cutting task while the position of reflective markers (240 Hz), muscle activity (1200 Hz), and ground reaction force (1200 Hz) were recorded.<sup>4</sup>

A musculoskeletal model was scaled in OpenSim.<sup>5</sup> Inverse kinematics was used to calculate joint angles. Static optimization was used to estimate muscle activity and forces. Results were validated by comparing simulated activations with EMG of the soleus (SL), fibularis longus (FL), tibialis anterior (TA), medial gastrocnemius (MG), and lateral gastrocnemius (LG). Peak muscle forces were normalized by body weight. The SL, MG, LG, TA, FL, TP (tibialis posterior), FB (fibularis brevis), VAS (vastus muscles), RF (rectus femoris), GX (gluteus maximus), GM (gluteus medius), HAMS (biceps femoris long and short heads, semimembranosus, semitendinosus) muscles were considered for statistical analyses. Separate two-way ANOVAs were used to compare muscle forces across group and task. For significant interaction or main effects, Fisher's least significant difference test was used to examine pair-wise differences. The  $\alpha$  levels were set to 0.05. Effect-sizes ( $\omega^2$ ) were also calculated.

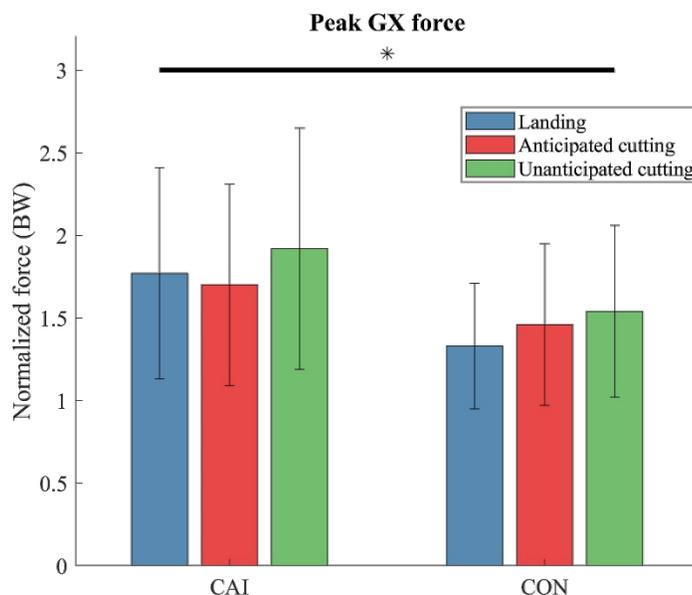

## Results and Discussion

We observed moderate to strong similarity between simulated muscle activation and EMG data for all participants and tasks.

There were no significant group by task interactions for any peak muscle forces. There was, however, a significant group main effect for peak GX force ( $p = 0.018$ ) with medium effect size ( $\omega^2 = 0.08$ ). Specifically, CAI patients generated approximately 24% greater GX peak force regardless of task compared to the control group.

The result indicates that people with CAI exhibit greater proximal muscle forces (e.g., GX). Similarly, Kim et al. (2019) showed that CAI patients exhibited greater EMG in proximal muscles (e.g., GX) during the eccentric-to-concentric transition phase during jump landing/cutting tasks.<sup>6</sup> In addition, Simpson et

al. (2020) reported that CAI patients exhibited greater stiffness in the hip joint than healthy controls.<sup>7</sup> The authors of these studies suggested that greater proximal muscle activations and stiffness compensate for neuromuscular deficits in distal muscles. Collectively, these results suggest that people with CAI cope with distal neuromuscular deficits through proximal compensatory mechanisms aimed to perhaps increase postural control of the larger trunk and upper body segments.

**Figure 1:** Normalized peak gluteus maximus (GX) force for people with chronic ankle instability (CAI) and control group (CON) during landing, anticipated cutting, and unanticipated cutting tasks.

## Significance

The current study is the first to use musculoskeletal modelling to estimate muscle forces in people with CAI. The finding of greater GX muscle force across a variety of tasks agrees with other results. Since ankle osteoarthritis is a critical issue in CAI patients,<sup>3</sup> investigating if and how proximal changes affect ankle joint contact force should be considered in future studies.

## Introduction

Research on exoskeletons designed to augment human activities, and the attendant exoskeleton industry, is growing rapidly. However, progress in the field is currently being hindered by a lack of understanding regarding human–exoskeleton interaction. At present, the main method applied understanding this interaction is to build and test prototypes [1] or end-effectors (that simulate the devices) [2], but this is a very time-consuming and costly process. To improve the time and cost inputs for this process, numerical simulation and optimizations were recently used to design an exoskeleton for a standing long jump [3]. In this study, we aimed to simulate passive exoskeleton–human interaction during a vertical jump, with a view to using it as a tool for exoskeletons design.

## Methods

Using the simulation, we performed a numerical optimization procedure to determine the muscle excitation and starting postures that would give the maximum jump height. The simulation used a planar 4-DOF dynamic model, where the ankle, knee and hip joints on both sides are considered to be symmetric, and thus each of the joints could be represented by one torque actuator. The torque actuators were modeled on the flexor and extensor muscles of each joint, and passive torque represented the properties of tendons and muscles [3]. We then simulated jumps with a passive knee exoskeleton (two devices) at five different values of maximum torque, with the aim of studying the exoskeletons' effects on jump height. The springs were modeled as linear, with total values of 0, 35, 70, 105, and 140 Nm (for both devices), at a 90° knee bend.

The optimal excitation for the maximum jump height was found by using a genetic algorithm (GA). To improve our optimization results, and to test the convergence of the GA solution for each of the five exoskeleton conditions, the GA optimization was performed 500 times (we then used the best solution).

## Results and Discussion

The jump heights converged for all five exoskeleton conditions in less than 450 GA runs. The result revealed an increase in jump height as the spring became stiffer (0, 2.8, 5.3, 10.4, 15.1 cm). The analysis of total work for each of the joints revealed that the hip increased by 7.5% and the ankle decreased by 8%; the total knee work increased by 90%, and the biological knee work decreased by 16.5% (Fig. 1). To gain a better understanding of what happens at joint level during a jump, we compared the torque joints with the maximum torque capability of the joint. For the knee, the torque is comprised of exoskeleton torque and biological knee torque (Fig. 2). At the beginning of the jump there is low biological torque, and most of the total knee torque is provided by the exoskeleton. At 0.15 s, the biological torque reaches its maximum value; thus, for the rest of the jump the human knee is working at maximum capacity. This last statement is true for the ankle and hip as well.

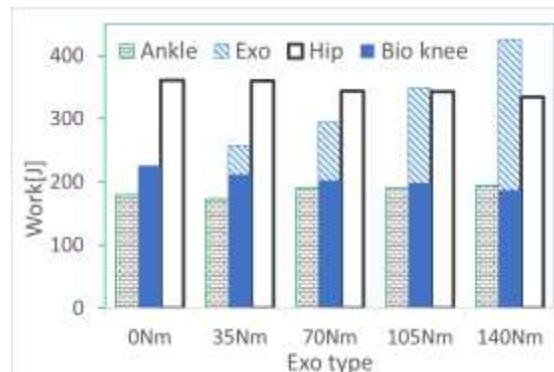

Figure 1: Work at the joints and at the spring, for each of the spring conditions

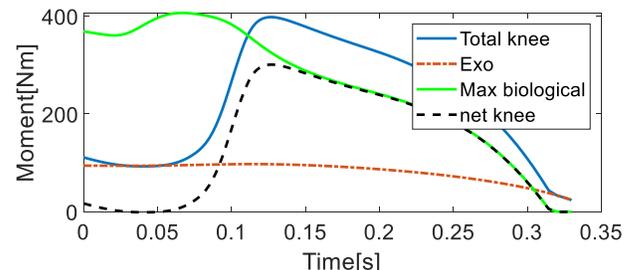

Figure 2: Torques at the knee with a 70-Nm exoskeleton: total torque and maximum torque available at the given angle and velocity

Analysis of the exoskeleton work under the 140 Nm condition revealed that 68% of the energy stored in the spring of the exoskeleton was transferred into energy causing an increase in jump height.

## Significance

This research shows that a passive spring can enhance human performance for certain physical actions. It can also improve understanding of how to build and utilize (modifying jump technique) such a device.

# A Computational Gait Model With Lower Limb Loss and a Semi-Active Variable Stiffness Foot Prosthesis

## Introduction

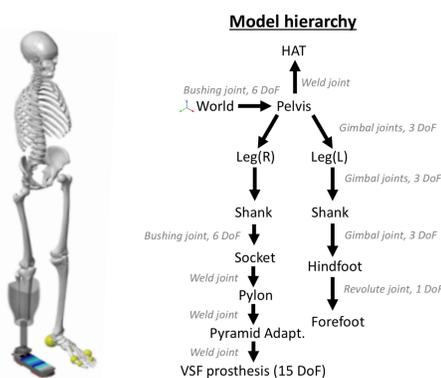

Passive energy storage and return (ESR) foot prostheses are the current high-performance standard for mimicking the energy absorptive and propulsive properties of a lost limb. However, the fixed stiffness behavior of these devices contrasts that of the healthy foot-ankle complex, which modulates stiffness in response to varied gait conditions (e.g. velocity and terrain). A recently developed variable stiffness foot (VSF) prosthesis [1] was designed with an actuated keel support fulcrum to semi-actively control sagittal forefoot stiffness and thereby adapt to different gait conditions with low power.

The potential effects of implementing a novel ESR prosthesis may be evaluated using simulations based on computational gait models. Simulations have been used previously to investigate the probable effects of prosthesis design on gait mechanics among persons with lower limb loss [2]. However, these models do not account for the ESR properties of the prosthetic foot, thus limiting their ecological validity. The purpose of this study was to incorporate the variable ESR properties of the VSF in a gait model of a lower limb prosthesis user.

## Methods

A model of the VSF was developed in Simscape Multibody (Mathworks, Inc.) (Figure 1). Keel elasticity was modeled as a 16-element lumped parameter cantilever beam. Fulcrum position (i.e. variable stiffness) is controlled through a custom MATLAB script. Foot-ground contact consists of 24 sphere-to-plane contact models parameterized to represent the geometry and dynamics of the VSF's foam base. A least squares optimization approach was applied when determining contact parameters to improve resultant ground reaction force (GRF<sub>x</sub>) predictions.

**Figure 1:** Gait model with the VSF (left) and model hierarchy (right). Sphere-to-plane contact models are depicted in yellow (intact foot) and red (VSF).

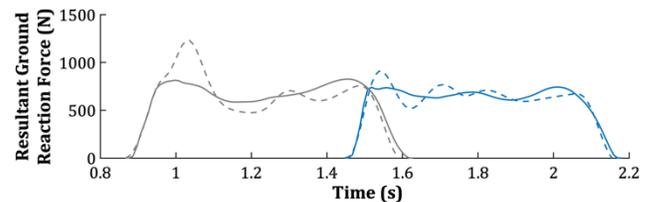

An anatomic gait model (Figure 1) was developed in Simscape Multibody using skeletal 3D surface geometry data from Mitsuhashi et al. [3]. Each segment is independently scalable to match subject-specific anthropometrics. The tibia and fibula were transected and encapsulated within a prosthetic socket to represent a transtibial amputation. The residual limb and prosthetic socket were connected via a high stiffness bushing joint to assess 6 DoF socket-residual limb interface dynamics.

Stiffness of the VSF was validated by simulating static compression tests for five discrete fulcrum positions (66, 87, 108, 129, and 151 mm) which span the full continuous range of

possible positions. Stiffness was calculated as the slope of the linear fit to the load-displacement data above 200 N [1], and displacement was calculated at the midpoint of this range. Simulation-derived values were compared to those from static compression tests of the physical VSF [1] via correlation and RMSE. To investigate the model's ability to predict GRF<sub>x</sub> using joint angles as inputs, a kinematically-driven gait simulation was computed for one male subject with a unilateral transtibial amputation (181 cm, 79 kg, fulcrum position: 66 mm). Simulated kinematics and GRF<sub>x</sub> were compared to experimental motion capture data of the subject walking with the VSF [1].

## Results and Discussion

Simulated VSF stiffness reproduced experimental stiffness across the five fulcrum configurations ( $R^2 = 0.99$ , RMSE = 1.31 N/mm). Mid-range displacement also matched well ( $R^2 > 0.99$ , RMSE = 1.08 mm). Simulated gait demonstrated a similar kinematic profile for all joints (mean  $R^2 > 0.98$ , mean RMSE = 2.0 deg). Model-predicted GRF<sub>x</sub> aligned well in the time domain but showed amplitude discrepancies for both the intact foot and VSF ( $R^2 = 0.87$  and  $0.97$ , RMSE = 129 and 56 N) (Figure 2).

**Figure 2:** Simulated (dashed) and experimental (solid) GRF<sub>x</sub> for the VSF (blue) and intact (grey) sides.

Data from simulated compression tests indicate that the ESR properties of the VSF were modeled with high fidelity. Simulated gait kinematics show that the model is numerically stable when driven by joint kinematics measured during gait with the VSF. However, amplitude discrepancies in GRF<sub>x</sub> highlight the need for further optimization of the foot-ground contact models.

## Significance

The present results show promise for simulating gait with a VSF prosthesis. Data from these simulations will improve our understanding of how humans interact with foot prostheses and may provide a framework for predictive modeling of human adaptation to variable stiffness. Future efforts include further contact model optimization, validating the generalizability of these methods for additional subjects, and studying how variable stiffness can be used to optimize gait.

## Introduction

“Rigging” is a technique commonly used in computer animation, which involves computing weights for each vertex in a mesh that govern how the vertices move based on movement of each segment in an associated articulated skeleton, or rig. Rigging methods could be useful for efficient repositioning of finite element (FE; e.g., tetrahedral) meshes representing human anatomy for applications such as thermal analysis or assessment of protective equipment. However, few tools exist to apply rigging methods to FE meshes. We propose a fully automatic method for calculating influence weights for FE meshes. The method is designed to increase the accuracy of deformations in rigged FE meshes. Here, we compare two different methods for computing vertex weights: a material-naïve distance-based method and a novel material-informed distance-based method.

## Methods

We start with an articulated FE mesh with labeled materials. We use custom software to load the surface mesh along with a skeleton containing motion data. The skeleton is then rigged by manually placing joint centers at their desired locations and defining segments which connect them. The articulated FE mesh is loaded in at which point distance-based bone-influence weights are calculated one of two ways: using a material-naïve method and a material-informed method where all bone weights are set to the maximum value and Laplacian diffusion is used to ensure a continuous displacement field [1]. The meshes are then morphed into a t-pose, where we examine deformations by comparing change in tetrahedra volume of bone within mesh.

**Figure 1:** Undeformed bone (red) and muscle (blue) labeled mesh

## Results and Discussion

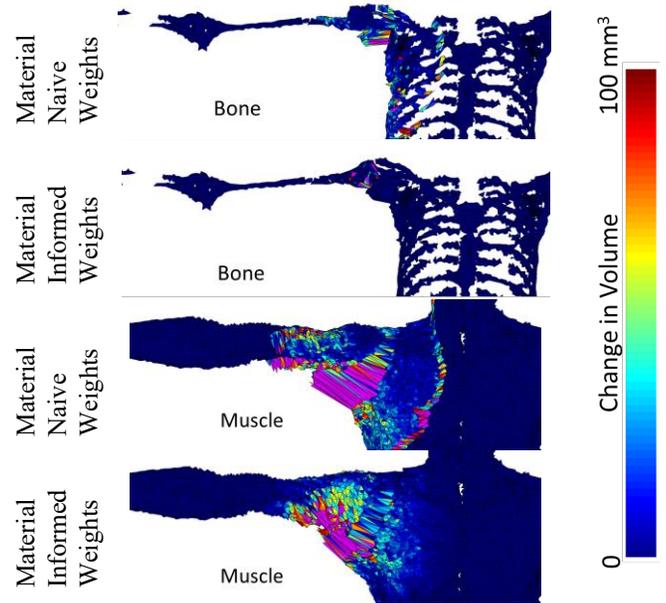

Table 1 shows the mean change in volume for both bone and muscle. Much more deformation occurs in bone when using the material-naïve method as opposed to the material-informed method. However, the difference is less pronounced for muscle.

Mean Change in Material Tetrahedra Volume (mm <sup>3</sup> )	Bone	Muscle
Material Naïve	0.99	3.24
Material Informed	0.32	3.20

**Table 1:** Average change in tetrahedral volume for bone and muscle.

The original undeformed mesh (muscle and bone) is shown in Figure 1. A comparison of naïve and informed weights are shown in Figure 2. Here, we can see that the overall deformation in bone is much less using the informed method than naïve. Using the naïve method results in significant changes in tetrahedral volumes in the torso along with minor changes in volume along

the humerus. Additionally, there are large deformations at the edge of the influence of the segment. Large deformations in the informed method only occur near the joint center, leaving much of the humerus and torso bone undeformed.

**Figure 2:** Comparison of change in volume from undeformed pose of tissue naïve and informed methods. Purple indicates change of greater than 100 mm<sup>3</sup>.

The overall deformation in muscle does not change much with the use of material-informed weights (Table 1). However, the distribution of deformed tetrahedra in muscle is more desirable with the material-informed method (Figure 2).

## Significance

Our results indicate that using material-informed weighting in articulated FE meshes greatly reduces the deformation of specified materials (e.g., bone). This method can be generalized to any FE mesh composed of different materials which are properly labeled. Compared to a material-naïve method, the material-informed method results in more anatomically realistic deformation of 3D medical models for applications such as thermal or projectile penetration analysis.

### Introduction

Neurological impairments, like cerebral palsy (CP), result in altered motor control as well as secondary musculoskeletal impairments, like contracture and weakness. Combined, these impairments cause abnormal gait patterns that impact function in daily life [1]. However, improving function remains difficult as understanding relative effects neurological and musculoskeletal impairments have on gait, and their implications for treatment, remains challenging [2].

Computational models enable rapid evaluation of hypotheses regarding neuromusculoskeletal impairments and gait [3]. Yet, few frameworks simultaneously consider the impacts of altered motor control and physiology. Recently, a case study using neuromusculoskeletal simulations of a child with CP suggested that musculoskeletal impairments, rather than altered control, played a larger causal role in impaired gait [4]. Whether these conclusions extend to a larger population or prevent individuals with CP from achieving a typically developing (TD) gait pattern remains unknown. We have previously shown that reduced motor control complexity can prevent an unimpaired gait pattern, but only with severe impairment [5]. The goal of this study was to investigate the combined impact of altered motor control and weakness, one of the most common secondary impairments in CP. We hypothesized that muscle weakness would require more complex motor control to achieve TD walking.

### Methods

A dynamic sagittal plane musculoskeletal model consisting of seven rigid body segments (thigh, shank, feet, and torso) and 9 degrees-of-freedom was used for analysis [6]. Each limb was actuated by eight Hill-type musculotendon units. Direct collocation optimal control tracked joint trajectories of TD gait while minimizing kinematic error and neural excitation effort.

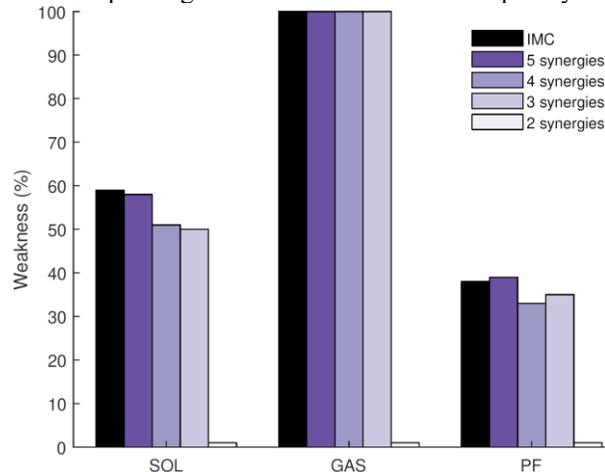

Simulations were performed with two motor control strategies: individual muscle control (IMC), where each muscle was independently activated, and synergy-based control, where sets of 2-5 synergies dictated which muscles could be activated together in fixed ratios (NNMF). Synergies have been used extensively to model simplified motor control and have been shown to have reduced complexity in CP [7].

Plantarflexor weakness was incorporated by reducing the maximum isometric force of the soleus (SOL), gastrocnemius (GAS), or both plantarflexor muscles (PF). Weakness was varied from 0-100% of nominal TD values and its effect on the model's ability to replicate TD walking was examined with IMC and synergy-based control. We evaluated the amount of weakness the model could tolerate until the optimization no longer identified a feasible set of muscle activations to replicate TD gait.

### Results and Discussion

The simplest control (2 synergies) was unable to replicate TD walking (**Figure 1**) with any weakness severity, similar to prior results [5]. The GAS could be completely removed (100% weakness) and still achieve TD gait with all control strategies

except 2 synergies. The model was more sensitive to SOL weakness and tolerated less weakness with simplified control: weakened by 59% with IMC but only 50% with three synergies. The model could tolerate less weakness of both PF muscles (33-39%), suggesting that weakness, when severe enough, may prevent unimpaired gait no matter the control complexity.

**Figure 1:** Weakness tolerable in soleus (SOL), gastrocnemius (GAS), and both plantarflexors (PF) for varying levels of control complexity.

Increased plantarflexor weakness required increased motor control complexity eliciting compounding mobility restrictions from interplay between impaired system and control. However, differences in tolerated weakness across control complexities were minimal, indicating that musculoskeletal properties may be a primary determinant of TD walking. Future investigations should examine the combined effects of these impairments across a broader range of impairments and gait patterns.

### Significance

This study illustrates that plantarflexor weakness and simplified control, when coupled, create more adverse effects on gait capacity than either alone. Future investigations of populations with neuromusculoskeletal impairments should consider both impaired system and control during predictive simulations. As strength appears to inhibit TD walking, with soleus weakness having a large effect, strengthening may take precedent during therapeutic interventions.

## Introduction

In static conditions, a larger moment arm amplifies the force capacity of a muscle while a smaller moment arm amplifies the output lever displacement. However, in dynamic lever systems driven by muscle contraction, inertia and muscle force-velocity effects confound the relationship between lever geometry and output speed. We hypothesize that in a muscle-driven lever system there is an optimal mechanical advantage above muscle force-velocity properties limit output velocity. Since force-velocity effects are proportional to muscle fiber length [1] and a function of the resistive forces acting on the system, we hypothesize additionally that the optimal mechanical advantage will be a function of muscle optimal fiber length and the inertia of the system.

## Methods

To test our hypotheses, we built a computational model of a simple lever system using OpenSim V. 4.0 scripted in Matlab. Our model consisted of an output lever which pivoted around a pin joint, and a muscle acting across the joint with a moment arm defined by the radius of a wrapping surface. The muscle implemented was a Millard2012EquilibriumMuscle muscle model with a non-compliant tendon and a fixed pennation angle of zero. Gravity was not included in the model. We welded a mass to the end of the lever and constrained the range of motion of the lever to 150 degrees with a joint limit force stiffness of 20, damping of 5 and transition range of 2.5°. We generated 3600 modifications of this model with different muscle optimal fiber lengths, OFL, moment arms, starting normalized muscle lengths and driven masses. The volume of the muscle was held constant across changes in OFL such that the muscle force capacity scaled inversely with square root of length. For each modified model, we simulated motion resulting from 100% activation of the muscle model across the full range of motion of the joint in 0.0005 second time steps and extracted

the maximum velocity of the driven mass, muscle contractile velocity, normalized contractile distance, total muscle impulse and work.

## Results and Discussion

In line with our hypothesis we found that for every muscle simulated, there existed a mid-range moment arm that optimized output speed. We explain the shape of the output velocity-moment arm plot as the interaction of two opposing factors: mechanical advantage and force-velocity effects. At small moment arms, large muscle force capacity is offset by a small mechanical advantage, minimizing torque. At large moment arms, large mechanical advantage is offset by small muscle force capacity due to large muscle contraction velocities.

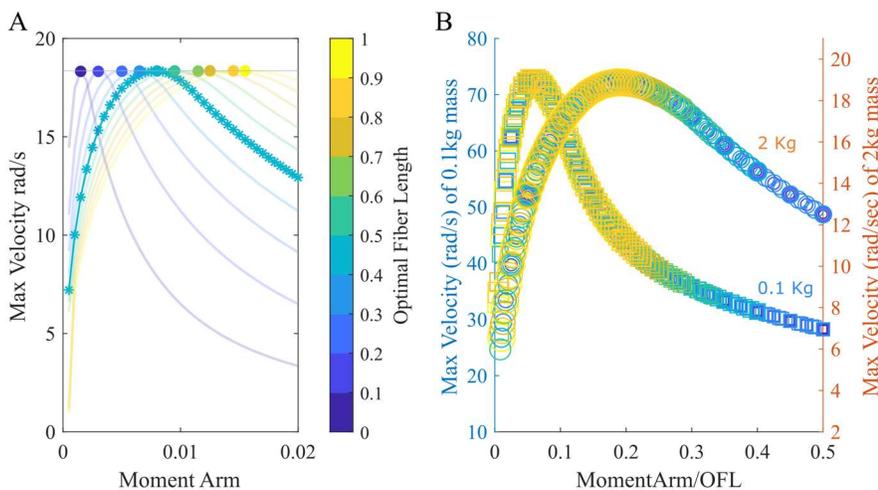

The optimal moment arm increases linearly with muscle OFL (Fig. 1A). Plotted against normalized moment arm (moment arm/OFL), the data collapses to fall along one curve (Fig. 2B). This implies that changes in moment arms can be compensated for by changes in muscle fiber length, as predicted by Zajac [1]. Further, the optimal normalized moment arm increases with driven mass (Fig. 2B) and starting muscle length. Therefore, even for a single individual, changing joint posture (i.e. starting muscle length) or the resistive forces acting on the system (i.e. throwing a different sized ball) can change the moment arm which will maximize output velocity.

## Significance

Here we show that the functional consequences of differences in moment arm are dependent on muscle properties and the resistive forces of the system. This suggests that inferences about how variations in moment arm will influence performance could be erroneous if muscle and inertial properties are not accounted for in analyses.

## References

[1] Zajac, F (1992). *J.Hand Surgery*, 17(5):799-804.

**Figure 1:** (A) Maximum velocity as a function of moment arm for a system driving a 2 kg mass. There is an optimal moment arm for each muscle and it varies by optimal fiber length. (B) Maximum velocity as a function of OFL normalized moment arm for systems driving both 2kg (circles) and 0.1 kg masses (squares). The data from A collapses such that there is an optimal moment arm/OFL ratio that generates maximum output velocity. That optimum ratio changes with driven mass. In both plots, optimal fiber length is represented by color.

# A Subject-Specific Finite-Element Musculoskeletal Model for Analysis of Lower Limb Biomechanics

Shihao Li<sup>1</sup>, Liming Shu<sup>1\*</sup>, Jiang Yao<sup>2</sup>, and Sugita Naohiko<sup>1</sup>

<sup>1</sup> Department of Mechanical Engineering, The University of Tokyo, Tokyo, Japan

<sup>2</sup> Dassault Systemes Simulia Corp., Johnston, RI, USA

\*Email: l.shu@mfg.t.u-tokyo.ac.jp

## Introduction

Musculoskeletal (MS) modeling is a versatile computational method that gives a great insight into neuromuscular biomechanics of human movement (Delp et al., 1990, 2007). To understand the subject-specific tissue-level mechanics, researchers have developed various workflows that utilize the output of the MS model as the boundary condition of the finite element (FE) model. This unsynchronized feature, however, prevents the detailed changes in the FE model from being reflected into the whole workflow, thus lowering the computation accuracy. In this research, we proposed a subject-specific FE-MS workflow that can concurrently predict the tissue and body level biomechanics.

## Methods

The generic FE-MS model developed in Abaqus CAE (Dassault Systems Simulia Corp., Providence, USA) is shown in Figure 1(a). Muscles were modeled as 1D axial connector elements (CONN3N2). The insertion coordinates and parameters of the three-component Hill-type muscle model were obtained from ISB (Delp and Loan, 1995). The model scaling & positioning were executed according to the mass and the marker position extracted from the motion capture data of each subject, thus turning the generic model to a subject-specific model. Then the inverse kinematics & dynamics were implemented using Abaqus Implicit Solver. The whole workflow including scaling & positioning, inverse kinematics & dynamics, and muscle-tendon force optimization was integrated under Isight. While contact and detailed tissues can be easily coupled with the model (Shu et al., 2018), all the joints were simplified as connectors with all the contact ignored in this research. The patient data of JW and DM who underwent total knee replacement with instrumented knee prosthesis from the grand challenge competition (Fregly et al., 2012) were used to verify the proposed model from the aspects of muscle activation, joint kinematics, and joint contact force.

## Results and Discussion

The computation time for a single gait cycle on a desktop computer took approximately 30min. The flexion-extension rotations of the knee joint were well predicted, while the prediction for internal-external (IE) and abduction-adduction (Ab-Ad) rotation has failed. The failure might be caused by soft tissue artifact. It is thus necessary to compensate for the Ab-Ad and I-E rotations during the simulation. The muscle activation results of flexor-extensor muscles for both subjects JW and DM showed good consistency on trend with electromyography. Figure 1(b,c,d) shows the comparison of the knee contact force between simulation and experiment. Good agreement on trend and magnitude were found not only in the superior-inferior (SI) tibiofemoral (TF) contact forces but also in anterior-posterior (AP) and medial-lateral (M-L) TF contact forces.

Overall, the proposed subject-specific FE-MS model presented a good prediction accuracy in terms of knee joint

kinematics, dynamics, and muscle-tendon forces. It provides an approach for concurrent prediction of the body-level neuromuscular biomechanics and the tissue-level biomechanics.

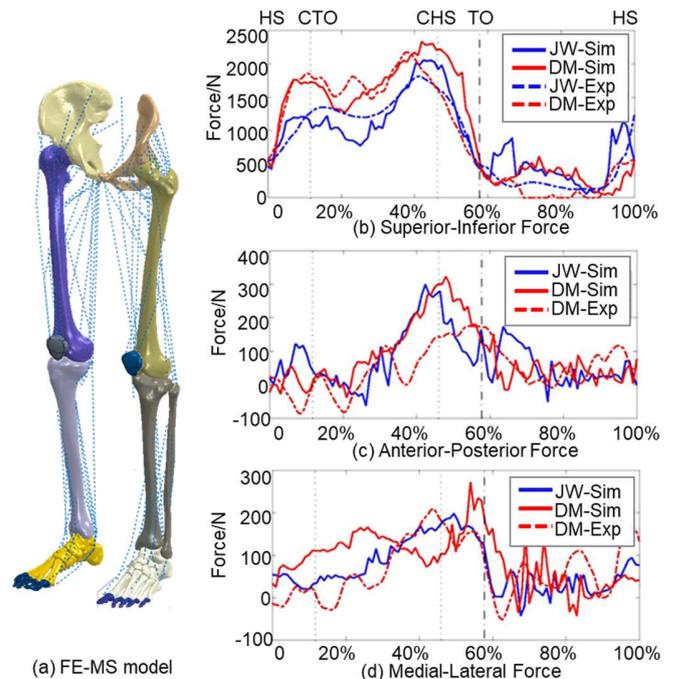

Figure 1: (a) FE-MS model; (b,c,d) knee contact force

## Significance

We proposed a finite-element-solver based 3D subject-specific human lower extremity musculoskeletal model which allows synchronized calculation in the FE-MS workflow with reasonable computation time and accuracy. Good agreement on knee joint rotations, muscle-tendon forces, and knee joint contact forces with experimental data indicated that the model has a high potential for the application to investigate the biomechanics of lower extremity, subjective surgical planning and the design of customized prostheses.

## Introduction

Developmental dysplasia of the hip (DDH) is characterized by altered acetabular and femoral geometries, which result in altered joint loading and increased risk for early hip osteoarthritis (OA) [1-2]. Pre-OA damage in dysplastic hips includes labral tears, which are largely influenced by habitually increased joint loading near the acetabular edge, most commonly in the anterior and lateral regions [3]. Joint loading, whether healthy or pathologic, is dependent on joint kinematics [4]. Movement training to correct kinematics may help normalize both the magnitude and location of joint mechanics without the need for surgery. We recently demonstrated the effect of simulated movement training on hip joint reaction force magnitudes in patients with DDH [5]; yet the direct relationship between altered kinematics and the location of intra-articular joint loading in hips with DDH remains unknown. Using a probabilistic framework, the objective of this study was to identify how kinematic perturbations change the acetabular location of hip joint reaction forces in patients with DDH.

## Methods

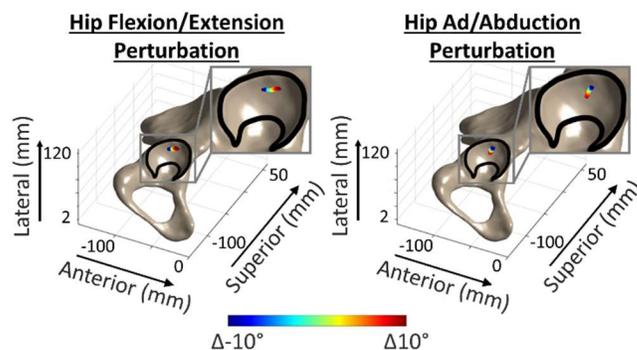

With IRB approval, MRI (psoas origin to knee) and treadmill gait data were collected from one female patient diagnosed with symptomatic and radiographic DDH (age: 22 y/o; BMI: 25.9 kg/m<sup>2</sup>; lateral center edge angle: 7°). An existing musculoskeletal model [6] was modified by including subject-specific pelvis/femoral geometries, hip musculature origins/insertions from MRI, and subject-specific isometric strength values.

The effect of movement training on the acetabular location of the hip JRF was assessed using 2,000 Monte Carlo (MC) simulations and high throughput computing [7]. In each simulation, the sagittal (flexion/extension) and frontal (adduction/abduction) plane hip angles were perturbed by  $\pm 10^\circ$  relative to baseline [4]. Computed muscle control was used to estimate muscle forces throughout the gait cycle, which were used to estimate the hip JRF. The location of the intersection point between the peak hip JRF and the acetabular geometry was determined using a ray-triangle intersection algorithm and expressed relative to the model global origin (mid-ASIS) [8]. Sensitivity factors between the degree of kinematic perturbation and the intersection point coordinates ( $x$ -anterior/posterior and  $z$ -medial/lateral) were calculated using Pearson correlation coefficients ( $r$ ) (strong:  $0.6 \leq |r| < 1.0$ ). The slope of each sensitivity factor was multiplied by  $\pm 10^\circ$  to predict the effect of a  $10^\circ$  change in hip angles via movement training on the location of hip joint loading within the acetabulum.

## Results and Discussion

The  $x$ - and  $z$ -acetabular intersection coordinates of the peak hip JRF (12% of gait cycle) were strongly sensitive to perturbations in both the hip flexion/extension ( $r_x = 0.99$  and  $r_z = 0.83$ , respectively) and adduction/abduction angles ( $r_x = 0.98$  and  $r_z = 0.97$ ). Increasing the hip flexion angle by  $10^\circ$  shifted the acetabular intersection location by 4.5 mm posteriorly and 0.8

mm medially. Shifting the hip abduction angle by  $10^\circ$  (i.e. shifted the acetabular intersection location by 1.1 mm anteriorly and 2.6 mm medially (Fig. 1). We have previously shown that increases in hip flexion and abduction angles reduced the overall magnitude of hip JRF by upwards of 30% of the total body weight [5]. The current results indicate that those *magnitude* changes can occur with only minor alteration ( $<5$  mm) to the *location* of peak joint reaction forces within the acetabulum.

**Figure 1.** Acetabular intersection location at the point of peak hip JRF in 2,000 MC simulations that perturbed the hip flexion/extension and abduction/adduction angles between  $\pm 10^\circ$  relative to baseline.

## Significance

We identified that increasing the hip flexion angle during walking shifted joint loading posteriorly, whereas increasing the hip abduction angle shifted joint loading medially. Because the location of acetabular labral tears are most common in both the anterior and superior regions in patients with DDH [3], these results could be used to inform patient-specific intervention planning dependent upon the location of damage. For example, a patient with an anterior labral tear and elevated joint loading near the anterior acetabular edge should adopt increased hip flexion during walking to prevent further labral damage caused by joint overloading. Future work will involve coupling joint reaction force alterations with cartilage contact modelling to clarify how movement training and other nonsurgical interventions may change articular stress patterns in dysplastic hips.

# A Comparison of Ligament Strain Estimations Using Bone Pins and Skin Markers

Jeff H. Mettler<sup>1</sup>, Erin Ward<sup>2</sup>, and Timothy R. Derrick<sup>1</sup>

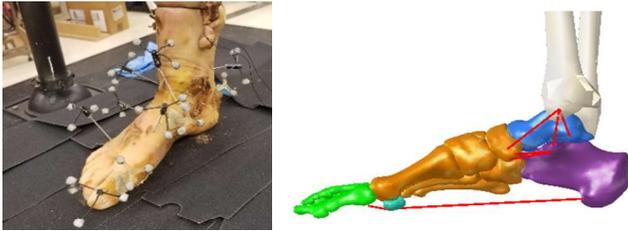

<sup>1</sup>Department of Kinesiology, Iowa State University, Ames, IA, USA

<sup>2</sup>Central Iowa Foot Clinic, Perry, IA, USA

Email: [jmettler@iastate.edu](mailto:jmettler@iastate.edu)

## Introduction

Skin-mounted markers are frequently used to estimate the position, velocity, and acceleration of the underlying bones. However, previous research on the foot has reported significant kinematic differences between skin markers and bone pins [1]. Bone pins are invasive and impractical to use in many situations. Therefore, the purpose of the study is to compare the estimated ligament strains between bone pins and skin markers. A further purpose is to compare the estimated strains to the measured strains from a manual digitizer to validate the current model.

**Figure 1:** Bone pins and skin markers were used to estimate effects of a tibial axial load on ligament strains using a musculoskeletal model.

## Methods

8 cadaver feet were analyzed for the study. An experienced podiatrist dissected the foot to expose the spring and deltoid ligaments, and pins were placed at the origin and insertion of each ligament. Each cadaver was placed with an axial load of 10N on the tibia. A manual digitizer (Microscribe G2, Revware Inc., Raleigh, NC, USA) was used to define the origin and insertion of each ligament. Simultaneously, kinematic data were collected using a 12-camera motion analysis system (Qualisys Oqus 600+, Qualisys NA, Inc., Buffalo Grove, IL, USA). Bone pins and skin marker triads were placed on the calcaneus, navicular, and hallux. Following digitization of the ligaments and the kinematic collection, the axial load was increased to 250N, 500N, 750N, and 1000N, and the process was repeated at each load.

A five-segment model of the foot (calcaneus, talus, forefoot, hallux, and sesamoids) was used to measure the foot position at each load. Movement of the model ankle joint was limited to sagittal plane, and frontal and transverse plane motions at the ankle were attributed to the subtalar joint. Strains of the spring (2 slips) and deltoid (3 slips) ligaments were estimated as the percentage change in length relative to the baseline 10N load condition. Pearson's R correlation coefficients were calculated to investigate the relationship between ligament strains estimated from the model and the strains measured with the digitizer.

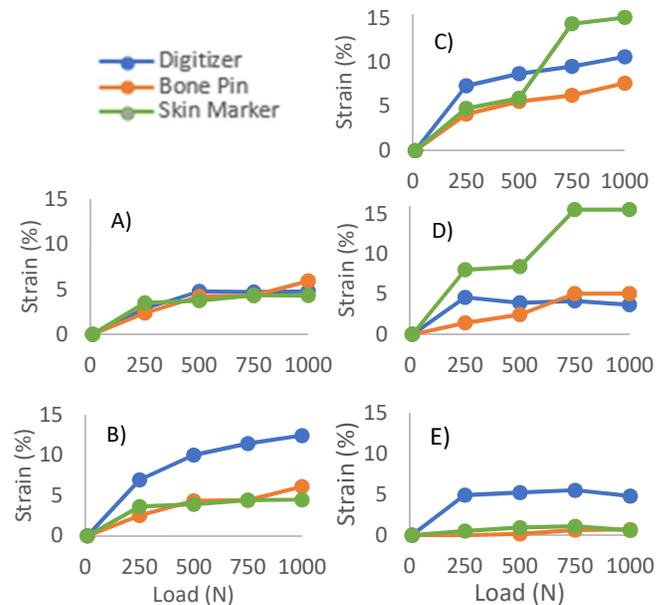

Table 1: Pearson's R correlation coefficients between the ligament strains estimated using the musculoskeletal model and the ligament strains measured using the manual digitizer.

Ligament	Digitizer – Bone Pins	Digitizer – Skin Markers
Spring – Superior	0.95	0.96
Spring – Inferior	0.98	0.97
Tibionavicular	0.99	0.85
Tibiocalcaneal	0.60	0.76
Tibiotalar	0.48	0.88

## Results and Discussion

Ligament strains estimated using both the bone pins and skin markers were strongly correlated to the ligament strains directly measured by the manual digitizer for both aspects of the spring ligament and the tibionavicular aspect of the deltoid ligament (Table 1). Weaker relationships were noted for the tibiocalcaneal and tibiotalar aspects of the deltoid ligament. Coefficients were larger between the manual digitizer and skin markers than they were between the manual digitizer and bone pins for both the tibiocalcaneal and tibiotalar aspects of the deltoid ligament.

The results show that the ligaments crossing the midtarsal joint of the foot can be estimated using a musculoskeletal model. Furthermore, the high correlations between the strains measured using the digitizer and the strains estimated using skin markers suggest that skin markers placed on the surface of the foot can be used to accurately estimate ligament strain.

**Figure 2:** Ligament strains at each axial load for the A) spring – superior, B) spring – inferior, C) deltoid – tibionavicular, D) deltoid – tibiocalcaneal, and E) deltoid – tibiotalar.

## Significance

The results from the study will allow us to estimate ligament strains in a living population using a musculoskeletal model. Doing so provides us with the potential to more fully understand soft tissue foot injuries that are related to ligament strains, such as posterior tibial tendon disorder and plantar fasciitis.

# Walking with a cane alters plantarflexor muscle forces during walking in individuals post-stroke

Todd J. Leutzinger<sup>1</sup>, Erica A. Hedrick<sup>1</sup>, Brian A. Knarr<sup>1</sup>

<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE USA

Email: [tleutzinger@unomaha.edu](mailto:tleutzinger@unomaha.edu)

## Introduction

Stroke is the leading cause of prolonged disability in the United States [1]. A prominent issue in gait post stroke is decreased propulsive force generation from the paretic leg [2]. This decreased propulsion force is caused by a reduction in ankle plantarflexor activation [3] and results in metabolically inefficient gait patterns [4] as well as decreased community ambulation, a measure correlated with quality of life [5]. Moreover, the use of a cane is prominent in individuals post stroke to help improve balance and overall walking ability. The purpose of the current study was to utilize musculoskeletal modeling to investigate how ankle plantarflexor forces change between walking with versus without a cane post-stroke. Additionally, the authors sought to determine how the model's residual actuators adjusted when the subject walked with a cane, without accounting for the forces of the cane in the model. The authors hypothesized ankle plantarflexor forces would decrease and residual actuator forces would increase with cane use to match the force output of the cane.

## Methods

One subject (mass: 101.34 kg, height: 1.8 m) performed walking trials with and without a cane at a self-selected speed across eight in-ground force platforms. Seventeen motion capture cameras sampling at 100 Hz were used to track a full body marker set of 65 retroreflective markers and 6 additional markers placed on the cane. The subject performed four trials in each condition. A single, clean foot contact from the subject's paretic limb was used for analysis in each condition. Data were exported from Visual 3D (Germantown, MD, USA) to OpenSim [6] where all analyses were performed. The model was scaled to fit the subject based on the Visual 3D scale set and inverse kinematics were performed in Visual 3D for both conditions. Residual Reduction Analysis (RRA) was performed to decrease the effects of modeling and marker processing errors. The RRA solution of the cane trial was then compared to the ground reaction forces of the cane. Computed Muscle Control (CMC) was used to calculate the muscle actuator forces used to drive the model forward while tracking the desired kinematics. The medial gastrocnemius (MG), lateral gastrocnemius (LG), and soleus (SOL) muscles of the paretic limb were used for comparison between the two trials.

## Results and Discussion

During the cane condition, the average vertical ground reaction force of the cane was within 14% of the average vertical residual force from RRA when the cane was in contact with the force plate. This result is aligned with previous research demonstrating OpenSim's ability to account for handrail use during walking [7]. During the no cane condition, the model displayed a 21.4% and 49.8% increase in peak actuator force of the MG and LG respectively compared to the cane condition. The model also demonstrated a 21.5% decrease in peak actuator force of the SOL compared to the cane condition. Average actuator force in the no cane condition for the MG, LG, and SOL were 27.6%, 56.0%, and 32.6% greater compared to the cane condition, respectively.

The results of this abstract are in accordance with previous literature indicating muscle forces are reduced when walking with versus without a cane in an individual post stroke [8]. Neptune et al. reported that the SOL and MG provide trunk support during early stance and the SOL promotes trunk acceleration during late stance [9]. During early stance, SOL and MG muscle actuator forces are present when not using the cane but are not present when using the cane (Figure 1). This suggests the subject used the cane, not their MG or SOL, to support their trunk. Research has shown canes are able to increase an individual's braking force during walking [10]. The increase in SOL force during the cane condition is likely a result of the subject increasing forces in the SOL to overcome the increased braking force provided by the cane and accelerate the trunk forward.

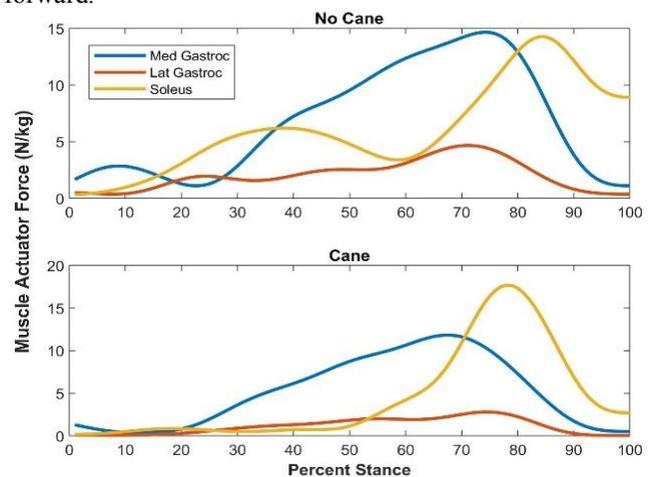

Figure 1: Muscle forces of ankle plantarflexor muscles of the paretic limb when walking with versus without a cane.

## Significance

The results of this study indicate ankle plantarflexor muscle force of the paretic leg decreases with the use of a cane, and OpenSim's RRA tool is able to compensate for residual forces not accounted for in the model. Future work is necessary to implement the cane in the simulation to more accurately account for it in the model and determine how the model responds to this external force.

# Between-session Reliability of Subject-Specific Musculoskeletal Models of the Spine Derived from Optoelectronic Motion Capture Data

Katelyn A. Burkhart<sup>1</sup>, Daniel Grindle<sup>2</sup>, Mary L. Bouxsein<sup>1</sup>, and Dennis E. Anderson<sup>1</sup>

<sup>1</sup>Center for Advanced Orthopedic Studies, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston MA

<sup>2</sup>Division of Engineering Mechanics, Virginia Polytechnic Institute and State University, Blacksburg VA

Email: [kburkhar@bidmc.harvard.edu](mailto:kburkhar@bidmc.harvard.edu)

## Introduction

Optoelectronic motion capture data are often used for scaling of musculoskeletal models to an individual's anthropometry. However, there is known error in optoelectronic motion capture due to inherent system performance<sup>1</sup> and more notably due to variation in marker placement on anatomical landmarks<sup>2-4</sup>. While these concerns have been well studied in gait models, there has been limited prior investigation into how this variation might affect marker-estimated spine models and spinal loading predictions.

Therefore, the aim of this study was to investigate how variation in the placement of anatomical markers affects the reliability of body segment scaling, estimated spine curvature, and resulting compressive spine loading outcomes when creating subject-specific musculoskeletal models.

## Methods

Nineteen healthy participants aged 24-74 years underwent the same set of measurements on two separate occasions. Retroreflective markers were placed on anatomical regions, including C7, T1, T4, T5, T8, T9, T12 and L1 spinous processes, pelvis, upper and lower limbs, and head. We created full-body musculoskeletal models with detailed thoracolumbar spines, and scaled these to create subject-specific models for each individual and each session. Models were scaled from distances between markers, and spine curvature was adjusted according to marker-estimated measurements. Using these models, we estimated vertebral compressive loading from T1 to L5 for five different standardized postures: neutral standing, 45° trunk flexion, 15° trunk extension, 20° lateral bend to the right, and 45° axial rotation to the right. Intraclass correlation coefficients (ICCs) and standard error of measurement were calculated as measures of between-session reliability and measurement error, respectively.

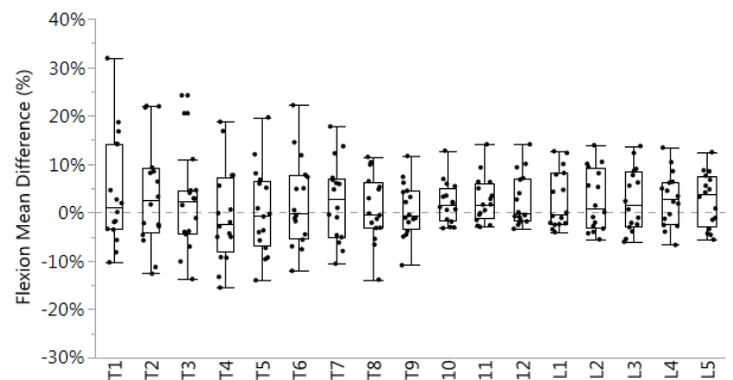

## Results and Discussion

Of the nineteen healthy subjects, two subjects were excluded from analysis due to non-visible retroreflective markers on the pelvic ASIS or on the L1 vertebra. For body segment scaling, segment lengths were not different between sessions ( $p > 0.05$ ). The measurements with excellent reliability ( $ICC > 0.75$ ) were the head and neck length and width, humeri and radii, spine and foot length and width. All other scaling measurements had fair reliability with ICCs ranging from 0.46 – 0.75. Spine curvature was not different between sessions, however the variability was larger for lordosis than kyphosis. Both measures had excellent reliability with  $ICCs > 0.75$ . Bland Altman plots of between session measures showed no systematic differences or proportional biases.

Subject-specific spine loading between sessions was not significantly different for all activities. Interquartile ranges and total range of mean difference were similar across all levels of the spine for all simulated activities. Mean difference in compressive spine loading during flexion between sessions is

shown in Figure 1. The ICC values of spine loading from T1 to L5 were mostly excellent, with 91% of ICC point estimates being greater than 0.75 for all activities.

This is the first study to determine the reliability of spine loading determined from marker-based subject-specific musculoskeletal models. We found that larger differences in spine loading between sessions ( $>15\%$ ), at any level, were corresponding to larger differences ( $>10\%$ ) in lordosis or kyphosis between sessions. This indicates much of our spine loading differences can be ascribed, at least in part, to differences in spine curvature, and that precise and accurate assessment and implementation of spine curvature is crucial for creating subject-specific musculoskeletal models of the spine.

**Figure 1:** Mean difference in compressive spine loading for flexion between sessions. Box plots show median and interquartile range, and black dots represent individual data points.

## Significance

Overall, this information is a necessary precursor of using motion capture data to estimate spine loading with subject-specific musculoskeletal models, and suggests that marker data will deliver reproducible subject-specific models and estimates of spine loading. This informs the conduct and interpretation of future studies on dynamic spine loading, which are important for gaining insight into mechanisms contributing to back pain, vertebral fractures and other musculoskeletal injuries.

# A self-correcting spiking network model for motor unit coordination during force production

Brianna M. Karpowicz<sup>1</sup>, and Lena H. Ting<sup>1,2</sup>

<sup>1</sup> The Wallace H. Coulter Department of Biomedical Engineering at Georgia Tech and Emory University, Atlanta, Georgia 30322-0535

Email: brianna.karpowicz@emory.edu, lting@emory.edu

## Introduction

We do not understand how commonly observed and mathematically described properties of motor force output arise from neural circuitry. For example, motor outputs exhibit signal dependent noise, in which force variability increases with force magnitude. Further, the motor system exhibits the ability to robustly maintain a force, such that variability in the output of individual motor units or muscles does not directly affect the variability in force output. This has been extensively described in the motor literature as the “uncontrolled manifold,”<sup>1</sup> or optimal feedback control.<sup>2-3</sup>

Here, we developed a model of a motor neuron pool based on principles of an efficient spiking network, which has been used to understand firing properties of cortical neuronal populations. In an efficient spiking network, the neurons cooperatively produce an output with a balanced distribution of activity across neurons.<sup>4-6</sup> We hypothesize that this balance enables stable force production despite variability in individual neural firing. Provided various desired force trajectories, we tested whether the model output would exhibit signal-dependent noise and robustness to perturbations in its motor neuron firing.

## Methods

The model was composed of a network of  $N=100$  leaky integrate-and-fire neurons in an efficient balanced network. The model was given a desired time-varying input force vector  $x$  (Fig 1, red). The neurons in the network fire if their firing reduces the error of the system, which is represented by:

$$\mathcal{L} = \langle \|x - \hat{x}\|^2 + \mu \|r\|_2^2 \rangle$$

where  $\hat{x} = \sum_i w_i r_i$  is the network’s estimated force output,  $w_i$  are the fixed weights of the connections between neurons,  $\mu$  is the cost of firing, and  $r$  is the filtered spike train  $s$ , where  $\dot{r} = -\lambda r + s$  and  $\lambda$  is the neuron’s leak coefficient. This loss function minimizes error in the produced force while ensuring that spiking activity is distributed across neurons. A neuron in the network fires when its membrane voltage  $V_i = w_i(x - \hat{x}) - \mu_i r_i$  crosses the firing threshold. Each neuron’s contribution to  $\hat{x}$  is reflected in its inhibitory connections (weighted by  $w_i$ ) to other neurons. This simulates the effects of interneurons, including Renshaw cells, where each motor neuron inhibits itself and all other motor neurons.

We used this architecture to create two models. First, we simulated a force-sharing network in which the contribution of each neuron to the total force was equal ( $w_i = w_j$  for all pairs of neurons  $i, j$ ), and each neuron had an equal firing threshold. The second model was a motor unit recruitment network; the contributions of each neuron in this network to the total force output increased linearly such that “larger” motor units needed to reach a higher membrane voltage to fire and contributed more to overall force. That is,  $w_i < w_j$  for all pairs of neurons  $i, j$  such that the size of neuron  $i$  is less than the size of neuron  $j$ .

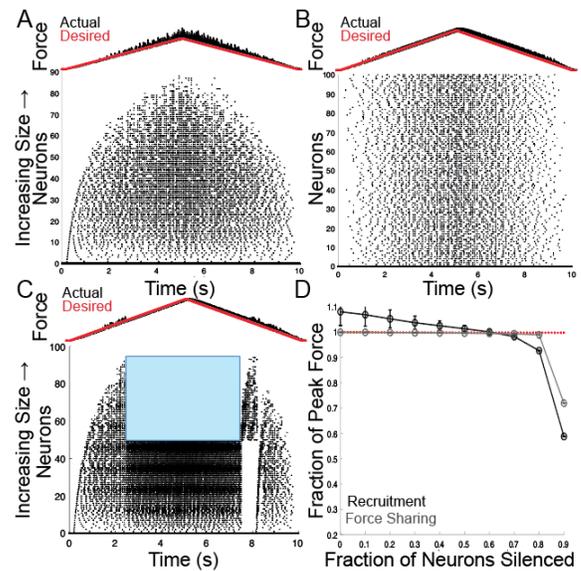

We fed time-varying force trajectories to each network and observed the resultant variance and magnitude of the force output to assess the presence of signal-dependent noise. To test the robustness of the model output to neural variability, we created a drastic change in neural firing by silencing a large fraction of neurons and

measuring the mean and variance of the force output.

## Results and Discussion

Both network models were able to simulate a desired force input (Fig. 1a, b). With respect to signal-dependent noise, only the motor unit recruitment network exhibited an increased variance with an increased magnitude of force output (Fig 1, insets).

Both networks were robust to massive perturbations (Fig 1c), i.e. the destruction of a large fraction of its neurons. Notably, we found that the networks were able to sustain force production by distributing force production amongst the remaining available neurons until the destruction of 60-80% of the neurons (Fig 1d). Across motor pool simulations with successful force production, force output varied by 7%, while the firing of the remaining individual neurons changed by  $467 \pm 99\%$ .

**Figure 1: Network Outputs.** (A) Raster plot of motor unit recruitment network producing a ramping force. (B) Raster plot of force sharing network producing a ramping force. (C) Representative raster plot showing a fraction of silenced neurons (blue box). (D) Fraction of desired force reached across various fractions of silenced neurons.

## Significance

We have developed a biologically plausible model of how motor output may be regulated by a self-correcting network to maintain task level goals despite variability in individual motor neuron output. Such a framework may inform our mechanistic understanding of compensation in debilitating motor impairments.

# Fracture resistance analysis in human dentin microstructure

Ebrahim Maghami<sup>1</sup>, Ahmad R. Najafi<sup>1,\*</sup>

<sup>1</sup>Department of Mechanical Engineering and Mechanics, Drexel University, Philadelphia, PA 19104, USA

Email: \*[arn55@drexel.edu](mailto:arn55@drexel.edu)

## Introduction

Dentin has a unique hierarchical structure containing mineral crystals embedded in a protein matrix [1]. Fracture behavior in such a biological composite is of great importance for the restorative dentistry. At the microscale level, an important feature is the existence of dentinal tubules. The tubules are surrounded by highly mineralized cylindrical cuffs of peritubular dentin (PTD) [1]. PTDs are embedded in a protein matrix known as intertubular dentin (ITD). The density and diameter of tubules near the pulp tissue are larger than those of near the dentin enamel junction (DEJ) [2]. There is also an increase in the thickness of PTD from the pulp tissue to the DEJ.

The microstructural features have considerable effects on the mechanical resistance of dentin and the hierarchical structure of dentin is associated with various toughening mechanisms [1]. In the present study, we investigate the influence of variations in PTD thickness, the tubules' diameters, and materials properties through dentin on the crack growth. In order to capture different toughening mechanisms, we use a brittle model of the phase-field method to analyze the crack growth.

## Methods

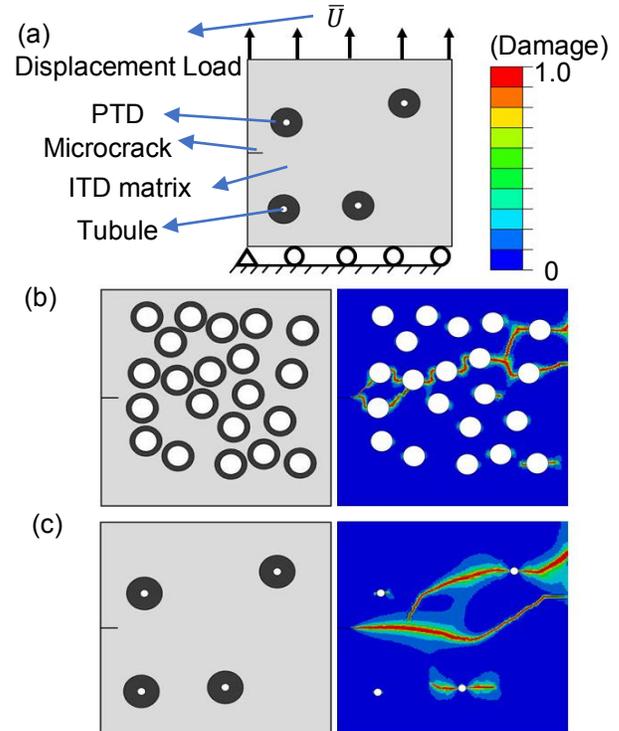

At the microscale level, dentin can be considered as a fiber-reinforced composite structure. PTDs are considered as hollow fibers with the inner diameter  $d_t$  and thickness  $t_p$  and embedded in ITD matrix (Figure 1). To create the models, we use the geometrical information reported by Chu *et al.* [2]. The boundary conditions of the models are shown in Figure 1. We investigate the mechanical response and damage propagation in dentin under 2D plain-strain conditions. To study the region-dependent fracture behavior of dentin, we consider the density and the diameter of dentinal tubules and the PTD thickness at the crown and root parts of dentin. We also evaluate the influence of mechanical properties of ITD and PTD on crack growth. We adopt a brittle model of the phase-field method developed by Molnár *et al.* [3]. We implement the brittle model into a subroutine using Abaqus software.

## Results and Discussion

Our results show that microcracking in PTD is found as an effective toughening mechanism in all simulations. The rate of microcracking increases by decreasing the critical energy release rate of PTD. However, microcracking in PTD is not significantly dependent on the elastic moduli of ITD and PTD. We also observe crack branching in our models. Crack branching is determined as one of the toughening mechanisms in the region near to the pulp tissue. Our results also reveal that the toughness of the dentin microstructure is dependent on the density of tubules. Due to a decrease in the density of tubules in the location near to the DEJ, cracks propagate through the ITD matrix with few barriers in head of the cracks in this region (Figure 1).

Our results also indicate that crack deflection is decreased by a decrease in the density of tubules. In this study, we also evaluate the important role of the interface between PTD and ITD in crack deflection. By decreasing the critical energy release rate of the

interface (i.e., decreasing the resistance of the interface to fracture), the cracks are arrested along the interface.

**Figure 1:** (a) A schematic representation of the microstructural features within dentin including the applied load and the boundary conditions. 2D models of two different locations within dentin and their fracture patterns: (b) near the pulp tissue and (c) near the DEJ. Damage with 1.0 shows the crack path and the zero value presents that there is no damage.

## Significance

The findings of the present research show the region-dependent fracture behavior of dentin. This dependency on the regions helps us to develop the dentine-adhesive restorative materials. We can also predict the probability of failure in various regions within dentin. This provides technical information on fracture behavior of dentin for the dental restorations. Our models also enable us to capture various toughening mechanisms such as microcracking, crack deflection and branching in a composite structure.

# MODELING SITE-SPECIFIC WOVEN BONE FORMATION IN RESPONSE TO EXOGENEOUS PURE BENDING OF RAT TIBIA

Ajay Goyal, Jitendra Prasad\*

Department of Mechanical Engineering, Indian Institute of Technology Ropar, Punjab, India 140001

\*Email: [jprasad@iitrpr.ac.in](mailto:jprasad@iitrpr.ac.in)

## Introduction

Osteocytes are the mechano-sensors that initiate variety of signaling pathways (such as  $Ca^{2+}$ /NFAT, BMP, WNT etc.) within lacunae-canaliculi network in response to exogenous mechanical loading [1]. These signals induce stimuli within the bone matrix which produces proportionate new bone formation at bone's periosteal and endocortical surface [1]. Induced stimuli must surpass a threshold level to deposit lamellar bone [2]. However, woven bone gets generated in haphazard manner if induced stimuli exceed another higher threshold level [2]. This study presents a mathematical model that fits site-specific woven bone generation for rat tibia mid-section exposed to pure bending. In particular, this model is an extension of an existing model that predicts site-specific lamellar bone for different loading regimens [1]. The model has potential to predict lamellar as well as woven bone distribution for different loading regimens at rat and mice tibial mid-section.

## Methods

The current model is an extension of existing mathematical model [1]. Induced strain at location of any osteocyte should surpass a threshold level ( $\epsilon_1$ ) to allow flow of stimulus to its neighboring osteocyte. Stimuli generated by osteocytic network within lacunae-canaliculi network will reach lining cells and deposit proportionate lamellar bone to stimuli. However, once lining cell gets differentiated into mature osteoblast and exceeds another higher threshold level of strain ( $\epsilon_2$ ), then woven bone will be generated in haphazard manner. Therefore, we added that osteoblasts not osteocytes play significant role to predict woven bone when they are exposed to heavy loads. Hence, this modified model can fit both lamellar and woven bone. In addition, osteoblasts behave differently to tensile and compressive loading. Accordingly, the optimization function ( $f$ ) has been modified as follows:

If  $\epsilon_{ob_j} - \epsilon_2 < 0$

$$f = \sum_{j=1}^{n_{ob}} (t_{ob_j} - k S_{ob_j})^2$$

Otherwise;

$$f = \sum_{j=1}^{n_{ob}} [t_{ob_j} - \{k_i r (\epsilon_{ob_j} - \epsilon_2) (NB)^{1/b}\}]^2$$

$\epsilon_{ob_j}$ ,  $t_{ob_j}$  and  $S_{ob_j}$  represents the induced strain, in-vivo new bone thickness and stimulus from osteocytic network at  $j^{th}$  osteoblast located at bone periosteum respectively.  $N$  and  $B$  represents number of loading cycles/day and number of bouts per week respectively.

“ $k$ ”, “ $b$ ” and “ $r$ ” are constants adapted from [1]. Proportionality constants “ $k_i$ ” ( $i=1, 2$ ) and  $\epsilon_2$  (threshold strain value for woven bone generation) are variables to be optimized.

## Results and Discussions

The modified model has been tested at periosteal surface for Sprague Dawley rat tibia mid-section exposed to pure bending [3]. Required input data has been collected/calculated from the literature [3]. Figure 1 shows the in-vivo vs. analytical woven bone distribution. Watson U2 goodness of fit test (p-value = 0.76 and independent two sample Student's t-test (p-value=0.61) suggested a good fit between analytical and in-vivo woven bone distribution.

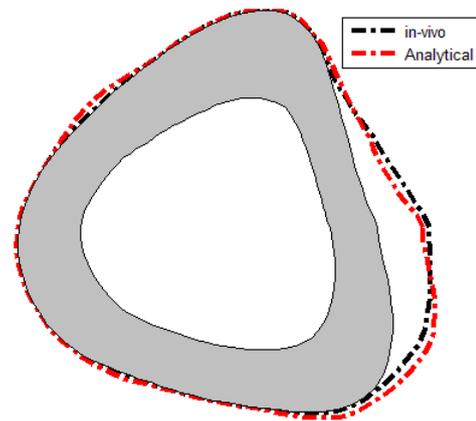

Figure 1: In-vivo vs. analytical woven bone distribution at periosteal surface of 9 months old rat mid-section tibia exposed to pure bending with peak induced strain of  $3010\mu\epsilon$ . The loading was done using 504 nos. sinusoidal loading waveform (2Hz) at 64N amplitude in 12 days.

## Significance

The model closely predicts site-specific woven bone distribution at least for pure bending cases. The model has potential to predict both lamellar and woven bone distribution for different loading regimens.

**Introduction**

Robustness of movement in the presence of internal (sensorimotor noise) and external perturbations results from the interaction between neural control and musculoskeletal mechanics. It has been shown that humans use both delayed sensory feedback control [1], and adapt joint impedance by co-contracting muscles [2] to stabilize movement. However, it is yet unclear how those strategies are combined. Simulations might give insight in how task goals and task constraints shape the control strategy. Optimal control explains many features of human movement. However, due to the high computational cost, available approaches require either deterministic open-loop trajectory optimization in case of complex musculoskeletal models, or stochastic feedback control with simpler models and linear [3] or open-loop stable dynamics [4].

We previously proposed an optimal control framework based on direct collocation that enables rapid predictive simulations of movement [5]. Here, we extended our trajectory optimization framework to a generally applicable robust optimal control framework. We then applied the framework to predict muscle co-contraction and sensory feedback for a reaching task in a divergent force field [3].

**Methods**

Consider a system with dynamics  $\dot{x} = f(x, u, w)$ , with  $x$  the states,  $u$  the controls and  $w$  a set of zero mean Gaussian disturbances (noise). To account for uncertainty, we augment the state-space by adding the state co-variance matrix  $P$ . We describe the propagation of the co-variance matrix by the continuous Lyapunov equation [1]:  $\dot{P} = AP + PA^T + C\Sigma_w C^T$ , with  $A = \partial f(x, u, 0)/\partial x$ , and  $C\Sigma_w C^T$  the effect of noise with  $C = \partial f(x, u, w)/\partial w$  and  $\Sigma_w$  the noise co-variance matrix. In our robust optimal control framework, we solve for controls that minimize a task-related cost using direct collocation.

We modeled a reaching task in a divergent force field as performed by Franklin et al. [3]. The musculoskeletal model is a 2-dof planar arm model driven by four mono-articular Hill-type muscles. Muscle excitations ( $e_m$ ) consist of a feedforward term and linear feedback of the deviation from the optimal hand trajectory:  $e_m(t) = e_{ff,m}(t) + K(t) \cdot (p_h(t) - p_h^*(t))$ , with  $p_h$  the hand's position and velocity in the 2D plane and  $p_h^*$  the deterministic trajectory generated by the optimal feedforward controls. We implemented a lumped neuromechanical delay of 100ms. The divergent force field is modelled as an external horizontal force acting on the hand that is dependent on hand position:  $F_x = 100 \frac{N}{m} \cdot x_{hand}$ . Sensory noise is modeled as Gaussian noise with standard deviation of 2mm and 4mm/s on respectively hand position and velocity respectively. Motor noise is modeled as Gaussian noise with standard deviation of 0.3Nm added to the shoulder and elbow torques. Starting pose (0,0), end pose (0,0.25m) and movement duration 0.5s are prescribed. We solve for feedforward excitations  $e_{ff,muscle}(t)$  and feedback gains  $K(t)$  that minimize a trade-off between effort and variance of the end-point position of the hand.

**Results and Discussion**

We evaluated feedforward muscle excitations, hand trajectories and the end-point error ellipses (95% confidence ellipse

resulting from 1000 stochastic forward simulations) under three types of control: (1) feedforward control minimizing effort ('ff nominal'), (2) robust feedforward control minimizing effort and end-point variance ('ff robust') and (3) combined feedforward and feedback control minimizing effort and end-point variance ('ff + fb robust').

Our robust optimal control model predicts co-contraction and delayed sensory feedback as mechanisms to stabilize the musculoskeletal dynamics during a reaching movement in an unstable environment in the presence of sensorimotor noise (Figure 1). Robust feedforward control leads to co-contraction to mitigate the effects of interactions between motor noise and the destabilizing force-field. However, without feedback the motion is not stable and the end-point error ellipse is larger than experimentally observed [3]. Adding sensory feedback leads to end-point variance similar to what is experimentally observed [3]. In agreement with experimental results, co-contraction is still present, due to the limited performance of sensory feedback in presence of delays and noise.

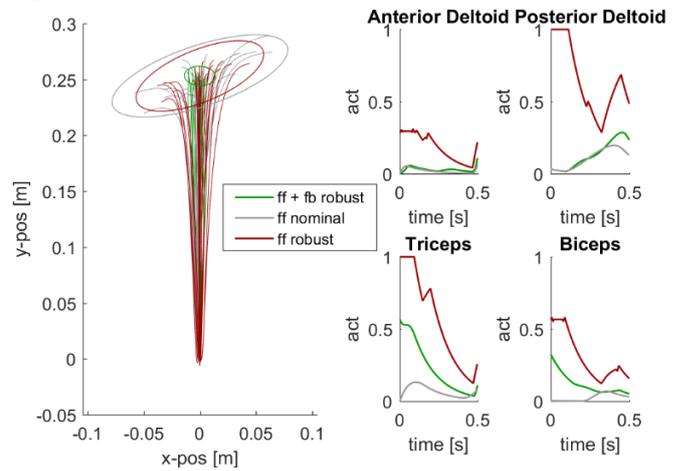

Figure 1: Reaching trajectories and muscle activations for shoulder antagonists (anterior and posterior deltoid) and elbow antagonists (triceps and biceps). Note that co-contraction (simultaneous activity in antagonist muscles) is large in the absence of feedback (red) but still present when feedback is added (green).

**Significance**

We present a generally applicable robust optimal control framework and demonstrate that optimal control can explain both sensory feedback and co-contraction as strategies to cope with sensorimotor noise in an unstable environment. Importantly, our ability to use complex muscle-driven models allows us to account for the interaction between the intrinsic stabilizing properties of the musculoskeletal system and motor control when studying how uncertainty shapes movement patterns, muscle co-activation, and feedback control.

#### Introduction

In designing a prosthetic foot, the relationship between the mechanical properties (e.g., stiffness and damping) and the gait biomechanics should be considered to have human-like ambulation. One of the critical factors is the toe joint stiffness, which can provide a general feeling of springiness in toe-off step. Several studies have attempted to implement the toe stiffness in the prosthetic foot design; however, their designs were complex to be manufactured [1], [2]. Also, the aforementioned designs usually require an additional mechanical part for the toe joint, leading to the heavier weight of the foot. In this study, we propose the 3D printable foot structure (i.e., re-entrant and honeycomb structure [3]) to mimic human foot characteristics, specifically the toe stiffness. We also propose a composite material, called “onyx”, to enhance the elasticity and strength.

#### Methods

To analyze the toe stiffness properties, two finite element analysis (FEA) models (a: re-entrant, b: re-entrant honeycomb) were established (Figure 1). In Figure 1(a), the re-entrant structure was applied in the forefoot. To investigate the effect of the foot material, two different materials (i.e., ABS and onyx) were compared using the identical structure in the simulation. On the other hand, in Figure 1(b), the combined structure of the re-entrant and honeycomb was applied in the forefoot to release stress concentration of the re-entrant model. Then, to analyze toe bending characteristics, a simulation was conducted with and without the bending zone (BZ). For a toe bending simulation, a rigid plate was placed at the bottom of the forefoot and approached gradually with 10° inclination in the re-entrant model, and 15° inclination in the re-entrant honeycomb model to confirm reinforcement of the latter model. All numerical simulation was done with ABAQUS (v6.14, ABAQUS Inc., Vélizy-Villacoublay, France).

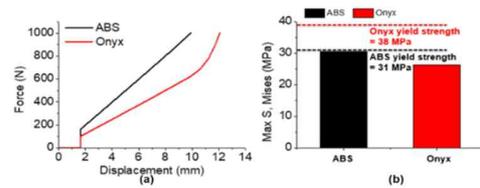

**Figure 1:** FEA models (a) the re-entrant structure was applied in the forefoot; (b) the combined structure of the re-entrant, honeycomb, and BZ was applied in the forefoot

#### Results and Discussion

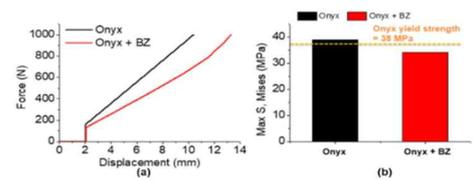

Figure 2 shows the FEA results of the re-entrant model. As it is shown in the force-displacement (F-D) graph (Figure 2(a)), the stiffness (i.e., slope of F/D curve) of the onyx increased while that of the ABS was constant. Note that the nonlinearly increasing toe joint stiffness is desired for the prosthetic foot due to the human gait biomechanics. In addition, the onyx showed lower maximum stress and higher yield strength than the ABS (Figure 2(b)). Since the onyx has high elasticity and strength, it may have

performed variable stiffness characteristics while having a proper strength characteristic.

**Figure 2:** The FEA results of the first model: re-entrant structure (a) F-D graph; (b) maximum stress

However, when the toe bending angle was over 15°, the maximum stress of the re-entrant structure exceeded the yield strength. For this reason, the re-entrant honeycomb model was designed to reduce the maximum stress. Since it resulted in a deterioration of the stiffness characteristics, BZ was used to compensate it. The FEA results are depicted in Figure 3. The characteristics of the stiffness and the strength were enhanced when the BZ is considered. The curved surface of the BZ released the stress concentration, resulting in the enhancement of the bending characteristics.

**Figure 3:** The FEA results of the second model: re-entrant honeycomb structure (a) F-D graph; (b) maximum stress

#### Significance

This study shows that numerous mechanical properties can be obtained by modifying the structure of the prosthetic foot. Further, the desired characteristics can be obtained by the optimization process. Since the proposed foot is 3D printable, it is easy to manufacture the prosthetic foot while considering individuals’ characteristics. We expect that the proposed re-entrant honeycomb structure and onyx will lead to simplicity in manufacturing, the reduction of the cost and the weight, and enhancement of gait biomechanics.

## Introduction

In the past years, the design of prosthetic feet has been widely studied for the lower extremity amputees. One of the critical design challenges is the impact reduction at the heel strike [1]. To carefully manage the impact load at the heel strike, a prosthesis design using a lattice structure was considered. The auxetic structure has received an attention due to its excellent mechanical properties, such as increased shear resistance and energy absorption [2]. Specifically, the re-entrant honeycomb structure exhibits an increased energy absorption capacity compared to the conventional honeycomb [3]. In this study, we propose the re-entrant structure for the prosthetic foot to enhance the energy absorption at the heel strike.

## Methods

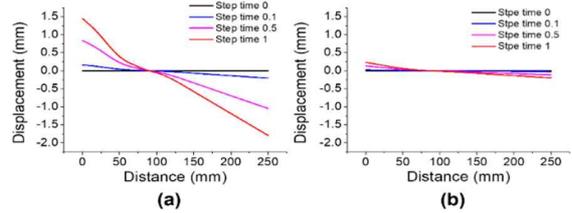

Structural behavior analysis was conducted using ABAQUS (v6.14, ABAQUS Inc., Vélizy-Villacoublay, France). The foot shape was approximated as rectangular with a length of 250 mm and a width of 120 mm. The geometry was meshed with 8-node hexagonal elements and the material properties were set as acrylonitrile butadiene styrene copolymer (ABS). One of the design parameters is the relative density (RD) of a structure, which is the ratio of the volume of all struts in a unit cell to the apparent volume of the unit cell. The finite element analysis (FEA) was conducted using two types of foot with RD of 0.35 and RD of 0.55. In the FEA, the ankle connection part was constrained from moving in the x, y, and z directions. Then, the load was applied normal to the heel (red line in Figure 1 (b)) during the step time of 1 sec as pressure with the total force of 1,000N. All experiments were done numerically in the ABAQUS.

**Figure 1:** Stress analysis of the prosthetic foot at step time 1; (a) structure relative density of 0.35, (b) structure relative density of 0.55

## Results and Discussion

As a result of FEA, the stress distributions of the prosthetic foot are shown in Figure 1. The plastic deformation did not appear in both cases. The stress was evenly distributed in heel part of the foot with RD 0.35. However, in the foot with RD 0.55, the stress was largely concentrated in the area near the ankle connection part. Therefore, the local failure (e.g., brittle failure), not as an elastic deformation, would be expected in foot with RD 0.55. The instability deformations are further described as following. The displacement of the bottom surface of each foot is analyzed as shown in Figure 2. The distance in x-axis means the foot length (0 mm: the end of the hindfoot or heel, 250 mm: the end of the forefoot or toe tip).

**Figure 2:** Displacement distribution of prosthetic foot according to the step time; (a) RD 0.35, (b) RD 0.55.

Under the same load condition, the foot with RD 0.35 deformed 6.3 times larger than the foot with RD 0.55. Also, the deformation of the forefoot was much larger in the foot with RD 0.33 than that of the foot with RD 0.55 due to the bending deformation. Through these deformations, the foot with RD 0.35 shows more stable energy absorption. This is because the re-entrant structures exhibit the significant energy absorption capacity at bending deformation [3]. However, with the higher RD (e.g., RD 0.55), the slenderness ratio of the strut increases, which makes the structure more brittle. The brittle properties of the foot with RD 0.55 can lead to instability behaviour, such as local failure due to stress concentration as shown in Figure 1. Therefore, the decision of an appropriate RD is important to enhance the energy absorption behavior of the prosthetic foot for stable deformation at the heel strike.

## Significance

The longer-term purpose of this study is to manufacture the prosthetic foot using 3D printing technology as a single part. This may make the manufacturing process simpler while enhancing the performance of the prosthetic foot. To achieve the shock-absorbing property at the heel strike, we applied the novel re-entrant structure to the prosthetic foot. Also, we investigated the effect of the structure's RD by comparing two different RD cases in the simulation. We expect that, via biomechanical studies of prosthetic walking, a stable heel strike can be achieved by using the proposed auxetic structure with optimal RD for the prosthetic foot.

Email: jente.willaert@kuleuven.be

## Introduction

A common symptom in neurological disorders is joint hyper-resistance to passive stretch, which results from neural and non-neural contributions. Neural contributions are involuntary muscle activity (muscle tone) and stretch hyperreflexia. Non-neural contributions are due to changes in mechanical tissue properties. However, it is challenging to distinguish these contributions based on clinical tests<sup>1</sup>. Neuromechanical models that explicitly model these contributions may be useful in dissociating the various contributions to joint hyper-resistance in instrumented clinical tests<sup>2</sup>. The pendulum test is such a test where the lower leg is dropped from a horizontal position and features of limb motion are evaluated<sup>3</sup>. The first swing excursion is especially sensitive to the presence of spasticity. We found that it was important to model muscle short-range stiffness (SRS) and its interaction with muscle tone and hyperreflexia to capture the reduced first swing excursion in simulation<sup>2</sup>. SRS is a steep increase in muscle force upon stretch of an isometric muscle that is proportional to muscle tone. Our recent experimental results confirm the contribution of SRS. Moving the leg, which is known to reduce SRS, instead of keeping it isometric before releasing it in the pendulum test increased first swing excursion and reduced reflex activity. Here, we tested whether our model allows identifying individual-specific contributions of hyperreflexia, muscle tone, and damping (resulting from passive tissues) to hyper-resistance based on pendulum test kinematics. To this aim, we assessed (1) the quality of the fit between measured and simulated kinematics, (2) differences in parameters between children with CP and typically developing (TD) children, and (3) whether the effect of pre-movement on pendulum test kinematics could be predicted based on parameters identified from pendulum test kinematics in the isometric condition.

## Methods

First, model parameters were identified by fitting pendulum test trajectories for 1 TD child and 4 children with CP (Table 1).

**Table 1:** Modified Ashworth Scale (MAS) and pendulum kinematics (Measured first swing excursions (FS) (range) and increased FS due to pre-movement (mean), simulated increase due to pre-movement (range)).

	TD1	CP1	CP2	CP3	CP4
MAS (Quadriceps-Hamstrings)	0-0	0-1	0-1	0-1	0-3
Measured FS (°)	106-122	103-104	67-70	26-55	45-54
Measured increase in FS (°)	-4	5	0	22	41
Simulated increase in FS (°)	2-3	3-5	3-10	40-53	19-36

The model consists of a planar lower leg segment actuated with a passive torque, due to damping, and an active torque, representing torque from muscle tone, SRS proportional to muscle tone, and reflex activity modeled as linear feedback from force<sup>2,5</sup>. Parameters (damping, muscle tone and reflex gain) for

each child were estimated by tracking 2-3 trials of kinematic data in the isometric condition. Estimated parameters were normalized to leg mass multiplied by leg length. Next, we used these parameters to predict the effect of pre-movement on pendulum test kinematics. Pre-movement was modeled by removing the torque due to SRS from the model.

## Results and Discussion

Preliminary results demonstrate that our model can fit a wide range of pendulum test kinematics across children (e.g. Fig 1a). Damping was variable across subjects (Fig 1c). Muscle tone and reflex activity were higher in children that had a smaller first swing excursion (Fig 1de, CP2-4). The identified parameters have predictive value, as they captured the effect of pre-movement on pendulum test kinematics (Fig. 1ab, Table 1). Although none of the children with CP had quadriceps spasticity according to Modified Ashworth Scores (Table 1), we observed large differences in first swing excursion and the effect of pre-movement on first swing excursion. Our best fit model parameters also suggest different contributions from muscle tone and reflex activity in these children. In CP3 and CP4, reduced first swing excursion might be due to increased muscle tone and reflex excitability, whereas in CP2, reduced first swing excursion might be primarily due to increased damping, consistent with the lack of an effect of pre-movement on first-swing excursion.

**Figure 1:** Simulated (no PM: black; PM: red) and experimental (no PM: grey; PM: orange) pendulum trajectories for a child with only minor spasticity (a) and a child with severe spasticity (b). Simulated parameters were damping (c), muscle tone (d) and reflex activity (e).

## Significance

Our neuromechanical model combined with an instrumented spasticity assessment revealed abnormal contributions to hyper-resistance that were not identified in clinical tests. Model parameters may be useful to improve diagnosis and guide treatment selection in children with spasticity.

## Introduction

Spasticity refers to velocity dependent hyperreflexia, where involuntary muscle activation is caused by passive muscle stretch. However, the mechanisms underlying spasticity and its consequences on movement are still unclear.

In a recent study we developed a computational model to simulate pendulum test kinematics in children with spastic cerebral palsy (CP)<sup>1</sup>. The pendulum test is a diagnostic method that consists in evaluating the pattern of lower leg movement after release from the horizontal. Our simulations show that increasing muscle tone and short-range stiffness, with increased reflex strength could explain key kinematic outcomes of the pendulum test that are associated with spasticity in children with CP.

Here, our **objective** was to test the relative contributions of increased muscle spindle sensitivity to stretch versus increased reflex gain to abnormal pendulum test kinematics. We integrated a biophysical model of a muscle spindle<sup>2</sup> with a biomechanical model of the lower limb, increased muscle spindle sensitivity (i.e. sensory signal per unit stretch) is due to gamma motor neuron activity, i.e. gamma drive, increasing tension in intrafusal muscles within the muscle spindle. And reflex gain refers to the transformation of the sensory signal to a motor output within the spinal cord (i.e. reflex torque per unit sensory signal).

We **hypothesized** that increasing gamma drive versus reflex gain would cause different kinematic outcomes in clinical-relevant motor behaviors. Specifically, we simulated two leg motor behaviors commonly used for clinical assessment, the pendulum test and the knee tendon jerk reflex.

## Methods

We integrated a biophysical model of muscle spindles<sup>2</sup> with a single-link, torque-driven model of the lower limb<sup>1</sup> with passive damping (Fig. 1). Muscle spindle sensory signals were modeled by simulating cross-bridges in intrafusal muscle and converting the resultant force and yank to simulated afferent neuron driving potentials causing sensory signals. Gamma drive ( $k_\gamma$ ) modulates the number of available actin binding sites, increasing the force in the intrafusal fiber. Reflex gain ( $k_r$ ) modulates the amount of torque produced per unit of muscle spindle sensory feedback.

The knee jerk reflex was simulated by imposing a stretch of the extensor muscle that elicited an initial reflex torque equal to 12Nm in the baseline condition. The pendulum test was simulated as a leg drop from a starting angle of 0°. The number of oscillations (N) and first swing excursion ( $\theta_1$ ) were used to evaluate the effects of increasing  $k_\gamma$  or  $k_r$  on kinematics.

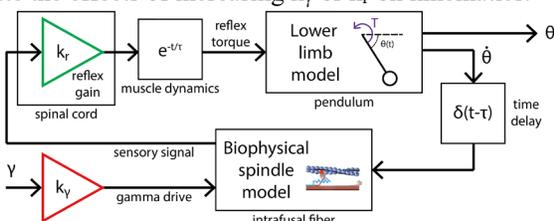

Figure 1: Block diagram of the neuromechanical model.

## Results and Discussion

Different limb movements emerged when modulating gamma drive versus reflex gain.

In knee jerk reflex simulations, the reflex torque caused a oscillatory movement of the leg (Fig. 2A). Increasing gamma drive ( $k_\gamma$ ) or reflex gain ( $k_r$ ) increased the first swing excursion, but higher gamma drive *reduced* the number of oscillations whereas higher reflex gains *increased* the number of oscillations.

In pendulum test simulations (Fig. 2B) higher gamma drive *decreased* both first swing excursion and number of oscillations. Higher reflex gain *decreased* the first swing excursion but did not change the number of oscillations. The torque profiles suggest that higher gamma drive causes increased reflex sensitivity to the dynamic component of muscle stretch (narrow peaks), and earlier reflex activity.

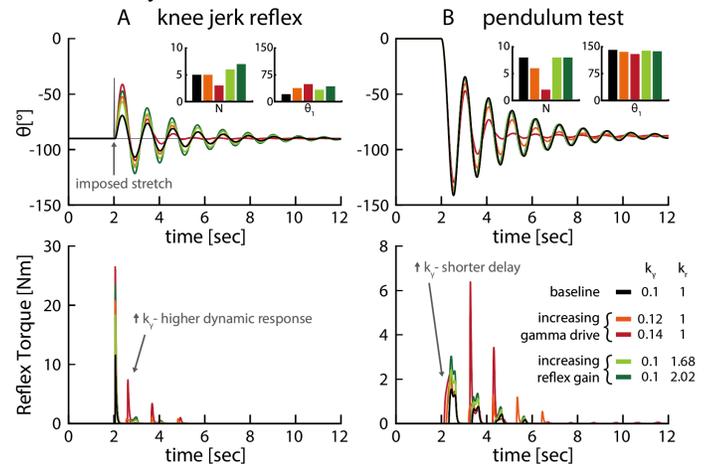

Figure 2: Simulations of knee jerk reflex (A) and pendulum test (B).

## Significance

Our neuromechanical simulations including muscle spindle sensory feedback in clinical behaviors provide a framework to dissociate gamma drive from central reflex gain as mechanisms underlying hyperreflexia. Neuromechanical simulations could be used to identify the underlying mechanisms of hyperreflexia from experimental data in patients, understand how physiological and pharmacological factors affect sensorimotor behaviors in health and disease, and guide personalized interventions and novel therapeutic approaches to neurological movement disorders.

# Identifying the Role of Residual Gastrocnemius in Isometric Knee Flexion of Below Knee Amputees

Joseph M Dranetz<sup>1</sup>, Sepehr Ramezani<sup>1</sup>, Matt S. Stock, Michael Carroll, Michael Varro, Woon-Hong Yeo<sup>2</sup>, Yun-Soung Kim<sup>2</sup>, Ulas Bagci, Heather Cornnell, and Hwan Choi<sup>1</sup> Email: [hwan.choi@ucf.edu](mailto:hwan.choi@ucf.edu)

<sup>1</sup>Department of Mechanical and Aerospace Engineering, University of Central Florida, Orlando

<sup>2</sup>George W. Woodruff School of Mechanical Engineering and Institute for Electronics and Nanotechnology, Georgia Institute of Technology

## Introduction

The role of residual gastrocnemius in gait for transtibial amputees remains relatively unexamined. During the transtibial amputation surgery, the distal end of the gastrocnemius is typically wrapped around the distal end of the limb. As the apparent role of the muscle changes after an amputation, understanding the characteristics of the residual gastrocnemius and nature of these acquired functions can inform the development of surgical and rehabilitative strategies. Study of the electromyographic activations of the residual gastrocnemius during gait show that activation patterns vary greatly between but not within transtibial amputees.<sup>1</sup> This suggests that transtibial amputees develop different strategies for their gastrocnemius during gait. Developing subject specific models that account for unique physiology of the residual gastrocnemius could better elucidate the character and function of the muscle given the variance observed in electromyographic data.

The goal of this study is to collect data from individual intact and residual gastrocnemii in order to construct subject specific musculoskeletal models in OpenSim. From these models we can assess the character and function of the muscle. In this study we demonstrate that the contribution of the gastrocnemius muscles in knee flexion decrease in an amputated leg.

## Methods

A 37 year old male transtibial amputee performed maximal effort isometric knee flexions at knee angles of 0, 30, 60, and 90 degrees in a Biodex System 4 human dynamometer. During these trials, surface electromyographic (EMG) sensors were placed over the muscle bellies of 3 knee flexors and 3 knee extensors, digital goniometers were placed across the knee and ankle joints (if present), and an ultrasound probe was placed over the muscle belly of gastrocnemius muscle. The experiment was repeated done on both the subject's amputated and intact side.

An OpenSim model developed by Rajagopal et al. was adapted to model the seated isometric flexions.<sup>2</sup> Using scaling measurements taken of the subject's segment lengths, an intact model of the subject was created. Next the model was cut at the shank based on subject measurements and all muscles of the shank were removed except for the gastrocnemii, whose paths were modified based on the ultrasound images. New values for tendon slack length, optimal fiber length, pennation angle were modified based on the ultrasound images (isokinetic flexions of the knee were done to identify the optimal fiber length) and the maximum isometric force of the muscle was scaled based on the physiological cross section of subject's muscle.

Static optimization was performed on the model using kinematic data and external forces from the goniometers and the Biodex respectively. Individual muscle contributions are estimated based on their mean activity (and corresponding force contribution) across the duration of the force production. These results are summed and compared to the experimentally measured net knee moment. The EMG data is rectified/filtered and the resultant linear envelope is compared to the predicted muscle activity.

## Results and Discussion

On average the moment contribution of the of the medial gastrocnemius dropped from 41% to 11% moment contribution from the unaffected leg to the affected leg, and the lateral gastrocnemius decreased from 12% to 3% moment contribution. The model simulated the experimental net torque with a percent error between 5% and 14% for the affected limb and between 11% and 34% for the unaffected limb. The normalized linear EMG envelopes had a similar shape to the predicted muscle activity curves for most of the muscles, but were less representative in the gastrocnemii in particular.

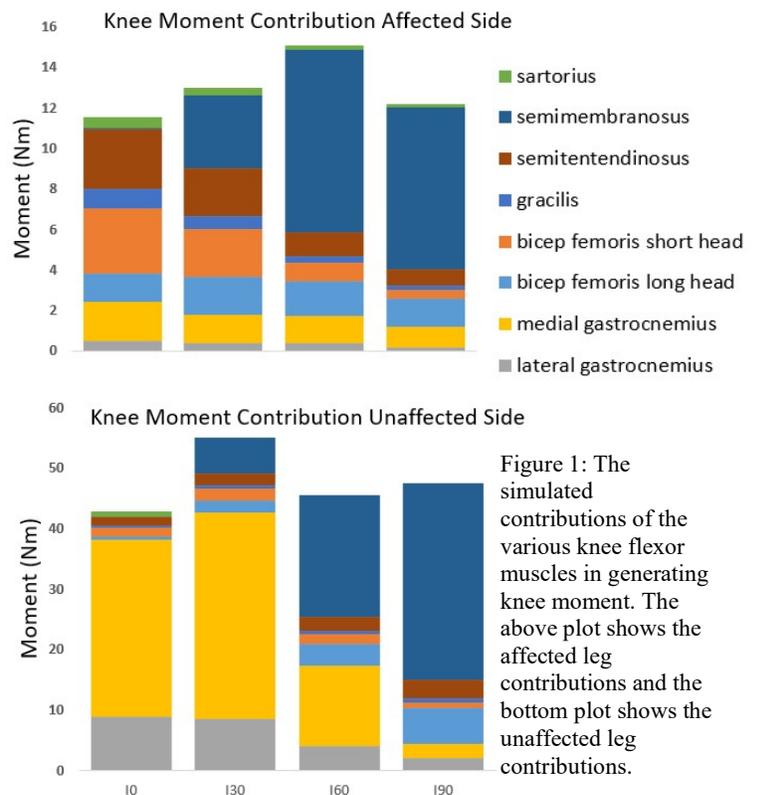

Figure 1: The simulated contributions of the various knee flexor muscles in generating knee moment. The above plot shows the affected leg contributions and the bottom plot shows the unaffected leg contributions.

## Significance

The generated model demonstrates the change in relative muscle contribution in knee flexion for transtibial amputees. Through the use of a subject specific model, we were able to account for both macroscopic changes the shape of the gastrocnemii as well as internal changes in muscle properties. The outcome of this study is useful in furthering the understanding of the character of the residual gastrocnemius in dynamic tasks.

# Effects of End-User and Design Parameters on Shear Wave Propagation: A High-Throughput Parametric Modeling Study

Jonathon L. Blank<sup>1</sup>, Darryl G. Thelen<sup>1</sup>, and Joshua D. Roth<sup>1,2</sup>

<sup>1</sup>Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, WI

## Introduction

Shear wave tensiometry is an emerging technique capable of quantifying tendon<sup>1</sup> and ligament<sup>2</sup> loading noninvasively. In shear wave tensiometry, the shear wave propagation speed in the tissue of interest scales predictably with the axial tissue stress. These measurements are made *in vivo* using a handheld or wearable sensor. However, measured shear wave speeds may be sensitive to sensor design and end-user variability in performing these measurements.

We have developed a parametric, dynamic finite element model<sup>3</sup> of a multibody tensiometer that predicts shear wave speeds that agree with an analytical tensioned beam model<sup>1</sup> (FEBio v2.9.1).<sup>4</sup> Using this parametric model, we can vary tensiometer application force, internal tensiometer stiffness, and the tensiometer component mass. Hence, the purpose of this study was to characterize the effect of these parameters on measured shear wave speeds.

## Methods

Our parametric model includes a shear wave tensiometer and a fibrous soft tissue structure. We modeled the tissue as a 60-mm long cylinder with a radius of 3 mm. The tissue mechanical behaviour was governed by a transversely isotropic Mooney-Rivlin constitutive relationship with uniformly distributed fibers aligned axially. The tensiometer was modeled using a set of rigid cylinders, representing a piezoelectric tapper and two accelerometers, in contact with the tissue surface (Fig. 1). Each cylinder was prescribed a finite mass and attached to a displacement controlled block by a spring-damper.

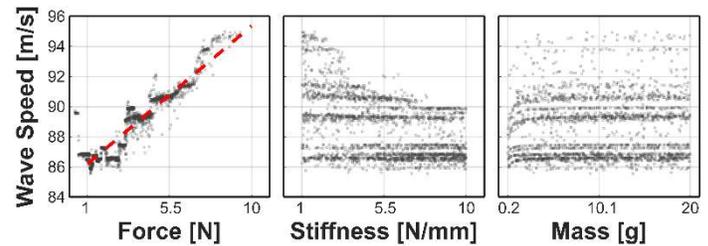

**Figure 1:** The parametric tensiometer model was used in a dynamic analysis to determine the effects of tensiometer design parameters on measured shear wave speeds.

A shear wave was excited in the tissue via a ramp displacement of the actuator calibrated to the dynamic behaviour of piezoelectric tappers used in our wearable tensiometers.<sup>1</sup> Shear wave speed was calculated using a normalized cross-correlation of the transverse tissue motion at the two accelerometer blocks.

Monte Carlo simulations ( $n = 2,400$  at each strain level) were run on a high-throughput computing grid with tensiometer mass (0.2-20 g), stiffness (1-10 N/mm), and application force (1-10 N per component) randomly selected from uniform distributions.

## Results and Discussion

The model-predicted shear wave speeds increased with axial tendon strain as predicted by our analytical model.<sup>1</sup> When the tissue was strained to 3%, the shear wave speeds did not scale predictably with tensiometer mass, stiffness, or application force. However, when 6% strain was applied to the tissue, measured wave speeds were highly correlated with application force ( $R^2 = 0.84$ ), with shear wave speed increasing by 1.02 m/s for a 1 N increase in application force (Fig. 2).

**Figure 2:** Measured shear wave speeds are sensitive to tensiometer application force at the 6% strain level.

The dependency of measured shear wave speeds on the tensiometer application force could be a result of an increase in the localized tissue stress due to tissue deformation. This would suggest that tensiometer application force should ideally be kept low to mitigate its effect on shear wave propagation within the tissue, which might lead to an over-estimation of the *in situ* stress.

## Significance

Shear wave tensiometers enable the noninvasive measurement of ligament and tendon loading. However, the sensor relies on mechanical contact with the tissue of interest, and hence has the potential to alter how waves propagate locally. Our novel parametric model presents a platform by which tensiometer design factors can be studied. High-throughput computing allows us to fully explore the tensiometer design space. The insights gained are important for designing tensiometers that are best suited for targeted applications in orthopedic surgery and wearable kinetics.

### Introduction

An understanding of the resonant frequency of the human body would be beneficial in designing machinery, buildings, and transportation so that exposure to vibrations close to the human body's resonant frequency may be avoided. However, that requires first understanding the mechanical effects and properties of the human body undergoing these vibrations. The human body is a complicated system of interconnected masses, elasticities, and viscous dampers (Coermann 1962). It would be difficult to describe the mechanical properties of this system and almost impossible to find the natural frequency of one part of the body without generating the whole-body resonances (Randall 1997).

The current investigation used a mannequin specially designed for the training of spinal manipulation and has characteristics of human soft tissue, with a 3-D-printed spine, pelvis, and skull connected by anatomically accurate articulating joints and are covered with a silicon skin; stiffness of the lumbar and thoracic regions can be controlled with nylon cords accessible in the chest cavity. This mannequin has been previously examined in static stiffness experiments, to be reported separately. The method of investigation in the present study has been used with inanimate objects and materials; the current investigation is a step in studying its feasibility with humans.

### Methods

A vibration fitness machine was used for generating harmonic excitation. The mannequin was laid prone while the data was collected. The machine was run at seven different speed settings corresponding to each hertz reading level, and the mannequin was tested in conditions of "soft", with the cords on slack, and "stiff" with the cords pulled to tension.

Figure 1: Mannequin lying on top of the vibration plate

Two accelerometers (PCM Model Number 352C65) were used during testing. One accelerometer was attached to the top of the lumbar spine using a strap and the other accelerometer was attached to the base. The machine was turned on and the data was collected from the accelerometers via LabVIEW SignalExpress software. The data collection period was 5 seconds. The calibration factor for the accelerometer is 100 mV/g. The dynamic model of the mannequin is given in Eq. (1) where  $m$  is the mass of the lower waist (Lumbar spine region,  $m = 20.4$  kg),  $c$  is the damping coefficient,  $k$  is the stiffness and  $y = Y \sin(\omega t)$

is the amplitude of the harmonic excitation and  $\omega$  is the forcing frequency.

$m\ddot{x} = f(t) = c(\dot{y} - \dot{x}) + k(y - x)$  where the velocity,  $\dot{x} = -\omega x$  and the acceleration is  $\ddot{x} = -\omega^2 x$ . The damping coefficient,  $c$  was calculated using Eq. (1). The natural frequency,  $\omega_n$  is found from the largest peak obtained in the power spectrum.

### Results and Discussion

The resonance frequency (Fig. 2) of a soft mannequin was 6.4 Hz while the stiffer one had the resonance frequency of 8.6 Hz. This rise in the resonance is in accordance with the Eq.  $k = m\omega_n^2$ . The displacement amplitude is higher for the stiffer as compared to the soft mannequin (Fig. 2). The table shows the stiffness,  $k$ , the damping coefficient,  $c$  and the damping ratio,  $\xi$ . The damping ratio which is the ratio of actual damping to the critical damping is the system property and it is 0.5 which means it's an underdamped system.

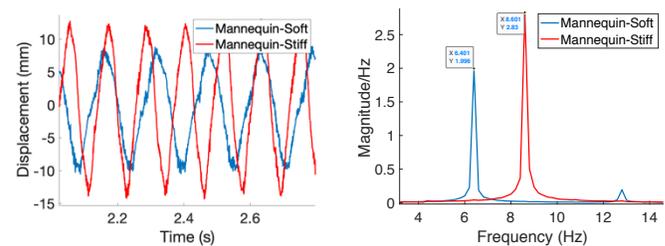

Figure 2: The displacement and the power spectrum

Table: System parameters.

	Stiffness	Damping Coefficient	Damping ratio
<b>Mannequin</b>	<b>k (N/m)</b>	<b>c (N-s/m)</b>	<b><math>\xi</math></b>
<b>Soft</b>	32967	820	0.5
<b>Stiff</b>	59528	1103	0.5

### Significance

The method was able to differentiate between soft and stiff conditions of the mannequin and thus may be able to assess stiffness for humans with differences in spinal stiffness and body morphology. This method may be used in future studies of human spinal stiffness and outcomes of spinal manipulation.

## Introduction

EMG-driven musculoskeletal modeling uses optimization to calibrate musculotendon model parameter values to subject movement and EMG data. The objective function minimizes the sum of squares of errors between inverse dynamic joint moments and the joint moments estimated by the EMG-driven model. While necessary, this objective function is not sufficient to produce unique model parameter values. Consequently, unrealistic solutions sometimes occur where a muscle generates unreasonably large passive force, even when published passive joint moments for sagittal plane joints are also tracked in the cost function [1]. Previous research has shown that to avoid injury during walking, muscles likely operate primarily on the ascending or early descending region of their active force-length curves, thereby producing relatively low passive forces [2, 3]. To address over-estimation of muscle passive force, this study investigated how EMG-driven model calibration results change through the addition of passive muscle force minimization to the optimization cost function.

## Methods

Previously published gait data collected from the non-paretic leg of a subject post-stroke performing treadmill walking were used to scale a generic OpenSim (v3.3; [4]) model and calibrate lower body joint positions and orientations [1]. The OpenSim model possessed  $N_m = 35$  muscles controlling  $N_j = 5$  degrees of freedom (DOFs) (2 hip DOFs, 1 knee DOF, and 2 ankle DOFs), where muscles were treated as Hill-type models with a rigid tendon. EMG-driven model calibration was performed using 10 gait cycles collected at the subject’s self-selected and fastest speeds (5 gait cycles for each speed) by optimizing activation dynamics and Hill-type muscle model parameter values ( $P$ ). The optimization cost function was formulated as:

$$\min_P J \triangleq (1 - \mu)J_{TrackMom} + \mu J_{PassiveF} \quad (1)$$

$$J_{TrackMom} \triangleq \frac{1}{N_j} \sum_{i=1}^{N_j} (M_i^{mod} - M_i^{exp})^2 \quad (2)$$

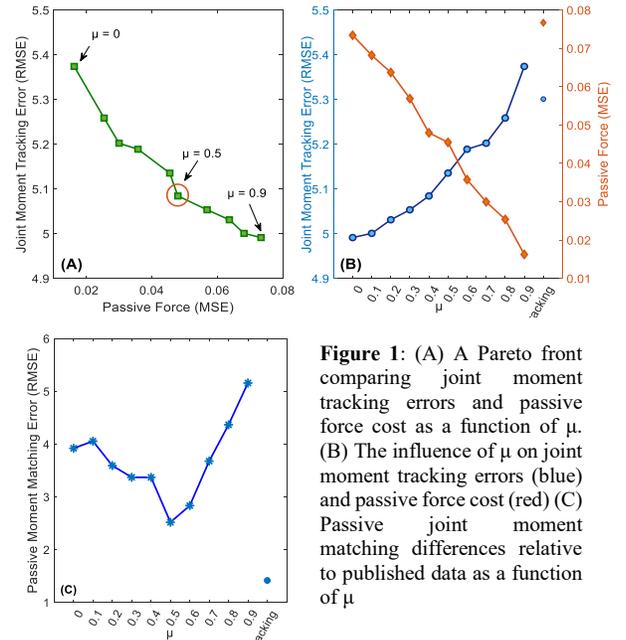

$$J_{PassiveF} \triangleq \frac{1}{N_m} \sum_{j=1}^{N_m} (F_j^{Passive} / F_j^{mo})^2 \quad (3)$$

$J_{TrackMom}$  minimizes for errors in matching joint moments from inverse dynamics,  $J_{PassiveF}$  minimizes total normalized passive force cost, and  $\mu$  is a weighting factor that defines the relative importance of each sub-objective. The sensitivity of the solution to  $\mu$  was investigated when  $\mu$  was increased incrementally from 0 to 0.9.

$M_i^{mod}$  and  $M_i^{exp}$  represent calculated and experimental joint moments around joint  $i$  respectively.  $F_j^{Passive}$  defines model-predicted passive force of muscle  $j$ , which was normalized to maximal isometric muscle force ( $F_j^{mo}$ ). For each solution, the resulting joint passive moments for the three sagittal joints were also compared with the passive joint moment measurements reported in the literature [1,5].

## Results

A Pareto front (Fig.1 (A)) showed the trade-off between joint moment tracking error and passive force cost, where increasing the weight factor  $\mu$  led to decreased passive force magnitude and increased joint moment tracking error (Fig.1 (B)). Furthermore, passive moment difference relative to published passive joint moments for different values of  $\mu$  followed a v-shaped curve with a minimum near  $\mu = 0.5$  (Fig.1 (C)), which was close to the elbow of the Pareto front. Passive force minimization reduced passive force cost and joint moment tracking errors simultaneously relative to a solution that tracked published sagittal plane passive joint moments in the cost function (see ‘Tracking’ in Fig.1 (B)).

**Figure 1:** (A) A Pareto front comparing joint moment tracking errors and passive force cost as a function of  $\mu$ . (B) The influence of  $\mu$  on joint moment tracking errors (blue) and passive force cost (red) (C) Passive joint moment matching differences relative to published data as a function of  $\mu$

## Significance

EMG-driven model calibration was influenced by passive muscle force minimization, which tended to increase optimal muscle fiber parameter values while decreasing joint moment tracking errors. Matching published average passive joint moments during model calibration may hinder EMG-driven model calibration [1, 5]. The proposed approach showed the potential to reduce the occurrence of unrealistically high passive muscle forces while simultaneously producing passive joint moments that exhibit trends consistent with published data.

## Introduction

Enhancement of human performance while minimizing energy expenditure are common goals for assistive device design. For human-in-the-loop design, a subject’s metabolic cost is evaluated as device design and control parameters are varied. However, human-in-the-loop optimization [1] is an inefficient and time/cost intensive process due to several experimental iterations.

Predictive gait optimizations performed using neuro-musculoskeletal (NMS) and metabolic cost models could potentially replace human-in-the-loop optimizations to identify metabolically optimal device designs more rapidly and easily. However, the accuracy of model-based metabolic cost estimates is influenced by the choice of metabolic cost model [2] and possibly by NMS model parameter calibration as well.

This study evaluated how NMS model calibration impacts estimated metabolic cost during walking as calculated using two common metabolic cost models.

## Methods

This study analyzed walking data previously collected from high functioning (79 yr, lower limb Fugl-Meyer score of 32) and low functioning (62 yr, lower limb Fugl-Meyer score of 25) male subjects post-stroke with right-sided hemiparesis.

Three modeling approaches were investigated to determine the influence of NMS model calibration on metabolic cost estimates. The first approach used a scaled generic OpenSim model and found muscle activations via static optimization (*SO-Gen*). The second approach used a calibrated EMG-driven model [3] with calibrated functional axes [4] to find muscle activations. The third approach used the calibrated NMS model but found muscle activations via static optimization (*SO-Cal*).

Muscle activation estimates were used to calculate each subject’s cost of transport (CoT) at different gait speeds using metabolic cost models published by Umberger [5] and Bhargava *et al.* [6].

The calculated CoT values for the two subjects and two metabolic cost models were compared with experimental CoT values for individuals post-stroke as reported by Finley *et al.* [7].

That study reported a strong negative linear association between CoT and gait speed ( $r = -0.98$ ). Thus, for the present study, the Pearson correlation coefficient ( $r$ ) between CoT estimates and gait speed was calculated for each modeling approach and metabolic cost model.

## Results and Discussion

Of the three modeling approaches, the EMG-driven model predicted the strongest negative correlation between CoT and gait speed for both subjects and both metabolic cost models (Table 1). Umberger’s model predicted larger CoT estimates but with a higher correlation to gait speed compared to Bhargava’s model, where the difference in magnitude was expected as previously observed [1]. Also, Bhargava’s model predicted CoT values within the statistical range ( $\pm 3$  SD) of the mean reported in Finley *et al.* [7].

## Significance

Based on these results, we recommend using calibrated EMG-driven NMS models to estimate muscle activations if metabolic cost estimates are to be made. Furthermore, our results suggest that Bhargava’s model is the most realistic metabolic cost model since it produced CoT estimates that were of comparable magnitude to published experimental values.

# IS MY MUSCULOSKELETAL MODEL COMPLEX ENOUGH?

*The Implications of Six Degree of Freedom Lower Limb Joints  
for Dynamic Consistency and Biomechanical Relevance*

Owen D. Pearl<sup>1</sup> and Daniel A. Jacobs<sup>1</sup>

<sup>1</sup>Mechanical Engineering, Temple University, Philadelphia, PA, USA

email: owen.pearl@temple.edu, web: <https://sites.temple.edu/rise/>

## Introduction

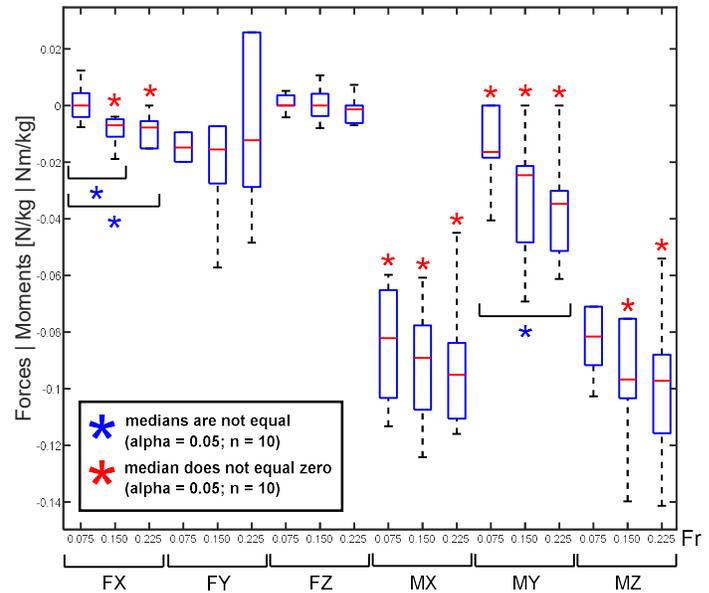

In the United States, one in every eight adults suffers from a gait impairment that restricts their mobility [1]. Proper diagnosis and treatment of these impairments requires an accurate understanding of an individual's motion and the forces that produce their motion. Musculoskeletal modeling is an essential technique for non-invasively acquiring these kinematic and dynamic estimates [2]. At present, most musculoskeletal models assume that the biomechanical effects of soft-tissues like skin, cartilage, and ligaments are negligible [3]. However, studies have shown that neglecting soft-tissues in these instances can incite errors known as soft-tissue artifacts (STAs) in estimates of joint kinematics [4], and dynamics [5] that limit the accuracy of musculoskeletal models. Research has shown that adding degrees of freedom (DOF) to the joint definitions between the lower limb segments of a human model can improve the estimation of joint forces, work, and power [5, 6]. However, the effect of increasing joint DOF on a model's satisfaction of Newton's Second Law of Motion is unclear. Our aim was to determine if increasing the DOF of specific joints reduces the artificial residual wrench applied at the pelvis during inverse dynamics routines to satisfy Newton's Second Law, and whether reductions in these residual forces and moments correlate with walking speed or BMI.

## Methods

We recruited ten subjects with no history of neurological or musculoskeletal impairment (8 male, 2 female; age  $21.6 \pm 2.87$  years; BMI  $25.1 \pm 5.1$ ; mean  $\pm$  s.d.) and recorded walking data at three speeds normalized by Froude number (Fr) using optical motion capture and an instrumented treadmill. We systematically added DOF to the lower limb joints of OpenSim's 23 DOF lower body and torso model (gait2354). For each model, we calculated the magnitude of the pelvis residual forces and moments for a single, representative subject trial (BMI = 24.0, Fr = 0.15). Finally, we simulated all 30 trials with both models and calculated median differences in residual wrench components using a non-parametric ranked sum test. Then, we tested for correlations using multiple linear regression models. All statistical analyses were completed using JMP Pro.

## Results and Discussion

A 35 DOF model (gait3554) resulted in the lowest residuals for the representative subject trial. The gait3554 comprised 6 DOF at each hip, 4 at each knee plus 2 constraints, and 1 at each ankle. Our results showed statistically significant reductions in four of the six residual components with the proposed model (Figure 1). However, for half the subjects, the model did not converge to solutions which respected joint constraints. Incorporating more relevant constraints or including additional modeling elements such as ligaments could improve the effectiveness of the IK algorithm on models with higher DOF. For the subjects where the model converged, the FX and FZ residuals possessed statistically

**Figure 1: Average RMS Residual Shifts.** The changes in mean RMS residual pelvis residuals after switching to the edited model. Each box plot is ten subjects walking at one speed. A negative value indicates a reduction in residuals and an improvement in dynamic consistency. Nonparametric signtests of the medians reveal four of the six residual categories' medians are below zero, while Wilcoxon rank sum tests reveal that slight differences occur due to speed.

significant ( $\alpha = 0.05$ ) negative correlations with Fr, while no correlations existed with BMI.

## Significance

To practically overcome STA by adding DOF, methodologies for subject-specific model tuning must be improved. Adding DOF to the lower limb joints can improve a model's dynamic consistency and biomechanical accuracy, and models of higher speed behaviors are more likely to benefit from adding DOF. Future work will include the development of methods for automatically tuning the inverse kinematics step to better model individuals with higher STA by eliminating the requirement for suboptimal, manual IK tuning for each DOF that is added.

# Minimizing Angular Momentum Yields More Robust Walking Trajectories in Five-Link Biped

Christian DeBuys<sup>1</sup> and Pilwon Hur<sup>1</sup>

<sup>1</sup>Texas A&M University

Email: [pilwonhur@tamu.edu](mailto:pilwonhur@tamu.edu)

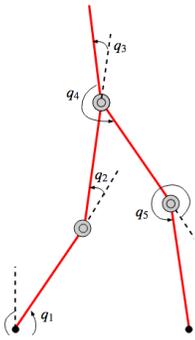

## Introduction

In the field of humanoid robots, walking motions are typically achieved by calculating desired trajectories and using controllers to help the robot follow those trajectories. The manner in which these trajectories are obtained is critical, since even the best controllers cannot yield a stable walking gait if the trajectories which they track are of poor quality.

In this study, a trajectory optimization via direct collocation is performed to generate desired joint trajectories for a single step of a five-link biped. The trajectories are examined in a forward simulation for their robustness to impulsive disturbances. Prior research has shown that angular momentum  $H$  about the whole body center of mass (COM) is highly regulated during human walking [1]. Since human walking is seemingly robust to disturbances and has very low  $H$  throughout the gait cycle, it is reasonable to suspect that trajectories with reduced  $H$  would be more robust to disturbances than those without. Thus, terms which facilitate the minimization of  $H$  are added to the cost function, and the performance of base-line trajectories is compared to the performance of trajectories which also minimize  $H$ . It is hypothesized that the trajectories which minimize angular momentum will be more robust to disturbances.

## Methods

The simulated walking robot is the five-link biped shown in Figure 1(a). It has dimensions, masses, and inertias similar to that of a human for the shank and thigh, and uses the head-arms-torso (HAT) approximation for the upper body [2].

$$\begin{aligned} \min \quad & \sum \tau^2 + \alpha H_{spin}^2 + \beta H_{orb}^2 \\ \text{s.t.} \quad & \text{Dynamics} = 0 \\ & \text{ImpactDynamics} = 0 \\ & \text{JointRange} \leq 0 \\ & \text{TorqueLimit} \leq 0 \\ & \text{StepLength} \leq 0 \\ & \text{ImpactVelocity} = 0 \end{aligned}$$

**Figure 1:** (a) Five link biped (b) Optimization formulation. Note that all inequality constraints are expressed with “ $\leq 0$ ”

The joint trajectories are generated via trajectory optimization using direct collocation, in which the desired optimal trajectories are discretized and used as the decision variables in the optimization [3]. In this case, the accelerations, post-impact velocities, and impact forces are included with the decision variables in addition to those shown in [3]. The optimization is done in Julia (v1.3) using JuMP as an interface and IPOPT as the solver. The Hermite-Simpson method is used for the direct collocation [3]. The base-line cost function is the sum of the squared joint torques  $\tau^2$ . This cost function is augmented with the spin angular momentum squared  $H_{spin}^2$  (i.e.,  $\alpha = 1, \beta = 0$ ), with the orbital angular momentum squared  $H_{orb}^2$

(i.e.,  $\alpha = 0, \beta = 1$ ), or with both  $H_{orb}^2$  and  $H_{spin}^2$  (i.e., the total angular momentum squared,  $\alpha = 1, \beta = 1$ ).  $H_{orb}$  is the angular momentum of a segment COM (point mass) in the reference frame of the whole-body COM.  $H_{spin}$  is the angular momentum of a segment about its own COM (in its own reference frame). The optimization includes many constraints such as those for respecting the dynamics, a minimum step length of 0.2 m, periodicity constraints so that the step behavior is repeatable, limits on the joint angles, and impact at the heel strike. A formulation of the optimization with these constraints is given in Figure 1(b). The details of these constraints can be found in [4].

A forward simulation is conducted in which a horizontal impulsive force is applied at 1.0 sec at the hip joint for a duration of approximately 0.4 sec, against the direction of the step. The biped is tasked with walking 10 steps without falling over. A PD controller is used for all simulations to track the trajectories, and center of mass forward progression is used as the phase variable (i.e., time parameterized by state variables).

## Results and Discussion

The maximum force the biped withstands without falling over for a given cost function’s set of optimal trajectories is reported in Table 1. When the step length was left unconstrained except for the minimum required length of 0.2 m, the optimizer chose this minimum value. To rule out the potential effects of step lengths on the maximum force, trajectories were generated for different fixed step lengths as well.

**Table 1:** Maximum force (N) of perturbation without falling for sets of trajectories with different cost functions and step lengths.

Step Length [m]	$\tau^2$	$\tau^2 + H_{spin}^2$	$\tau^2 + H_{orb}^2$	$\tau^2 + H_{spin}^2 + H_{orb}^2$
0.200	222	657	536	536
0.241	221	586	563	551
0.272	unstable	477	570	547

Adding angular momentum into the cost function improved the maximum force tolerated in all cases. For  $H_{spin}^2$ , the maximum force decreased for increasing step length. The opposite trend is seen for  $H_{orb}^2$ . Surprisingly, the maximum force for the cost function with both terms was lower for the shorter two step lengths. These results suggest that it may be advantageous to include one type of angular momentum over the other depending on the desired step length.

## Significance

These results support the idea that human walking tends to have low angular momentum because it allows human gait to be more robust to disturbances.

### Introduction

Grip strength is sensitive to wrist posture, and the preferred wrist posture is extended and ulnarly deviated [1]. Grip strength is significantly reduced as the wrist moves away from this optimal posture [1]. Previous work from our group demonstrated that grip strength in this self-selected posture could be successfully predicted through a forward-dynamic optimization for healthy adults [2]. Before our simulations of grip strength can be generalized to other conditions, we need to validate that our model displays a sensitivity to wrist posture. Our hypothesis is that predicted grip strength would decrease as wrist posture moved away from the optimal posture in any direction.

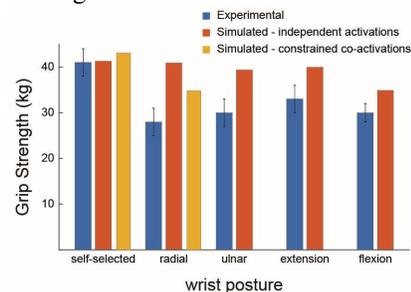

### Methods

A previously developed OpenSim [3] musculoskeletal model of the hand and wrist [1] that incorporated all five digits and 38 Hill-type muscle-tendon actuators (both intrinsic and extrinsic) was used in the simulations. Grip strength was modeled as contact between the skin of the phalanges (cylinders overlaid on the bone geometries) and a massless elliptical cylinder representing the dynamometer. Contact parameters from the literature were used for the skin [4] and the dynamometer. A simulated annealing optimization was used to determine muscle activations that maximized contact force along the long axis of the ellipse during a forward-dynamic simulation. The optimization encourages the wrist to maintain the initial posture with an additional penalty term. A total of 5 wrist postures (self-selected, radially deviated, ulnarly deviated; extended, and flexed) corresponding to postures evaluated in O'Driscoll et al [2] were evaluated to determine the simulations sensitivity to wrist posture.

### Results and Discussion

For every wrist posture, the model was able to maintain the initial wrist posture within 0.2°; however, the model's grip capacity was not sensitive to wrist posture. Reductions in predicted grip strength were less than 2kg for 3 of the 4 other postures (Figure 1) whereas experimental reductions ranged from 8 to 13kg [1]. The model predicted the largest reduction for the flexed posture, but this was still above the experimental reduction. This flexed posture had the model's lowest flexion (13.4Nm) and highest extension (29.2Nm) moment capacity at the wrist of all the postures tested (average 28.6 and 13.9 Nm for flexion and extension respectively of other postures). This large difference in moment capacity at the wrist may have contributed to why the largest reduction was seen in the flexed posture. One potential reason why predicted grip strength was not sensitive to wrist posture is that the muscle compartments of flexor digitorum profundus (FDP) and extensor digitorum communis (EDC) were considered as independent actuators. A previous study has shown that voluntary activation of the middle compartment of FDP and EDC causes similar coactivation in the index compartment of the same muscle [5]. For the self-selected posture, the activation of

the individual compartments were fairly consistent across these muscles; however, for other postures, the model selectively activated certain compartments while leaving others inactive. For example in ulnar deviation, the model activated the little, ring, and index compartments of FDP (activations of 0.88, 0.51, and 0.55 respectively), but left the middle compartment inactive (activation of 0.16). This ability to selectively activate certain compartments during maximal grip may not be possible *in vivo*. To confirm that involuntary coactivation among muscle compartments would increase sensitivity to wrist posture, we reran the simulations in the self-selected and radial posture with the compartments of FDP and EDC constrained to be within 5% of the activation of the middle compartment. Requiring coactivation reduced grip strength in the radial posture from 40.9 to 34.8 kg, but increased grip strength in the self-selected posture from 41.3 to 43.1 kg.

**Figure 1:** Grip strength measured experimentally (blue) [2] and grip strength predicted by the musculoskeletal model (orange – independent activations, yellow constrained co-activations).

### Significance

Without requiring coactivations of FDP and EDC compartments, the model's predicted grip strength was not sensitive to wrist posture. The constraints on coactivation in the resimulation were simplistic and somewhat arbitrary. Furthermore, in actuality, involuntary coactivation of muscles extends beyond individual compartments of singular muscles [5]. Future work is needed to quantify involuntary coactivation of muscles during grasping.

## Introduction

Studying complex behavior through the lens of simple models allows fundamental concepts and control strategies used by humans in well-practiced tasks to be revealed. One such well-established example is the spring-loaded inverted pendulum (SLIP) to model walking and running [1] that is used here to capture regulation of linear and angular motion during land and stop tasks. Our aim is to validate the SLIP model with experimental data during a series of landings where the participant intentionally regulated the magnitude of the reaction forces during the initial impact phase of the landing. We expected that the control implemented by the individual could be characterized by determining spring and damper coefficients for the model under each landing condition through an optimization procedure. These spring coefficients,  $k_\phi$  and  $k_r$ , along with damping coefficients,  $c_\phi$  and  $c_r$ , could then be used as representations of impedance control implemented in the task performance.

## Methods

A female participant with a background in gymnastics provided informed consent and performed a series of land and stop tasks with a range of peak reaction force during the initial impact phase (soft 2.6kN, normal 3.0kN, and hard 4.8kN) from a 0.445 meter platform. Kinematic data in the sagittal plane was captured at 11000 frames per second with a 1.5mm/pixel resolution. Ankle, knee, hip, and shoulder points are tracked with available Matlab software [2]. A cubic smoothing spline is applied to the raw data to attenuate high frequency noise.

## Modeling

The dynamics of the SLIP can be described by

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{G}(\mathbf{q}) = \mathbf{u}$$

where  $\mathbf{q} = [\phi, r]^T$ . By choosing the control to be

$$\mathbf{u} = \mathbf{G}(\mathbf{q}) - \mathbf{K}_p\mathbf{q} - \mathbf{K}_d\dot{\mathbf{q}}$$

where  $\mathbf{K}_p = \text{diag}(k_\phi, k_r)$  and  $\mathbf{K}_d = \text{diag}(c_\phi, c_r)$ , asymptotic stability of the origin can be analytically shown using Lyapunov theory [3]. To determine the control coefficients  $\mathbf{K}_p$  and  $\mathbf{K}_d$ , the following cost function is minimized.

$$J = \sum_i^n \left( \frac{\phi_{d,i} - \phi_{m,i}}{\phi_{d,range}} \right)^2 + w \left( \frac{r_{d,i} - r_{m,i}}{r_{d,range}} \right)^2$$

where  $\phi_{d,i}$  is the  $i$ th angular position data value,  $\phi_{m,i}$  is the  $i$ th angular position model value,  $\phi_{d,range}$  is the range of angular position data, and  $w$  is a scaling factor. The same notation is used for the deflection coordinate,  $r$ .

## Results and Discussion

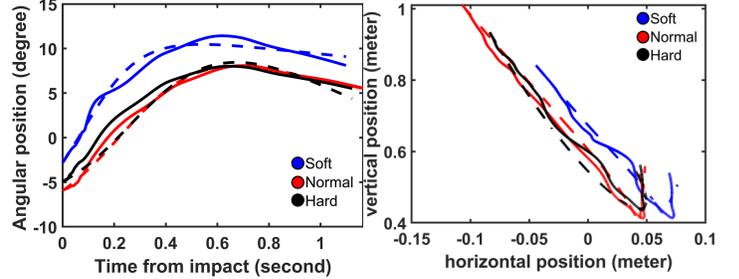

Figure 1: Solid lines: experimental data. Dashed: model. Left: angular position of center of mass (CM). Right: Cartesian position of CM with respect to the ankle.

	$k_\phi$ (N·m/deg)	$k_r$ (N/m)	$c_\phi$ (N·m·s/deg)	$c_r$ (N·s/m)
Soft	5.7	173.4	175.7	412.0
Normal	71.7	182.9	107.0	161.2
Hard	116.2	174.8	65.4	288.9

The model satisfactorily reproduces the kinematic behavior of all three impact landing conditions. Also, one can observe the increase of torsional spring coefficient values for the different landing conditions. This demonstrates the ability of the nervous system to modulate the body impedance for drop landings. The translational spring constant does not demonstrate significant difference across landing cases, as seen in the table. Furthermore, all three landing cases exhibit about the same vertical displacement upon landing (Figure 1). This suggests that various impact landing conditions from the same drop height directly affect the angular position more than the vertical displacement of the body center of mass.

## Significance

With only two degrees of freedom, the SLIP model can capture the essential kinematics of human drop landings under various conditions. This is of importance because it shows the versatility of the model; it has been used for running, walking, and now drop landings. Previously, drop landings have been modeled as a series of spring-mass systems, performing translational motion and were unable to capture the angular kinematics. Lastly, the control signal consists of a gravity compensation term, linear stiffness and linear damping terms. Thus, allowing for straightforward stability analysis.

# Optimal Bipedal Walking Gaits Found with Different Direct Collocation Settings

Veronica Knisley<sup>1</sup> and Pilwon Hur<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Texas A&M University, College Station, TX

Email: [ver96@tamu.edu](mailto:ver96@tamu.edu)

## Introduction

Applications of bipedal robotics include the navigation of uneven terrain [1] and the development of assistive devices like prostheses [2]. These devices may require an optimal reference trajectory. In order to find such a continuous-time gait, it is helpful to transcribe this problem into a discretized nonlinear program (NLP). One technique, direct collocation, does this by satisfying the system's dynamics at only a few discrete points along the trajectory [3].

This method can be implemented in many different ways. Some studies have compared the specific collocation method chosen in terms of time or accuracy [4], and some have compared differentiation methods in a variety of contexts, including other forms of trajectory optimization [5]. However, such studies have not been completed for the low degree-of-freedom (DOF) bipedal walking models sometimes used by roboticists, such as the two-DOF compass walker and the five-DOF kneed biped with torso. This study [6] addresses this gap in the literature and compares factors such as CPU time for optimal gaits generated with different implementation settings.

## Methods

NLPs were developed for finding an optimal trajectory for the two walkers mentioned above. For both models, the objective function was the integral of the sum of squared input torques. Constraints included periodicity constraints, constraints on the initial orientations of the models' legs, and dynamic constraints. For the five-link walker, constraints were also used to prevent the hyperextension of the knees and to ensure foot clearance.

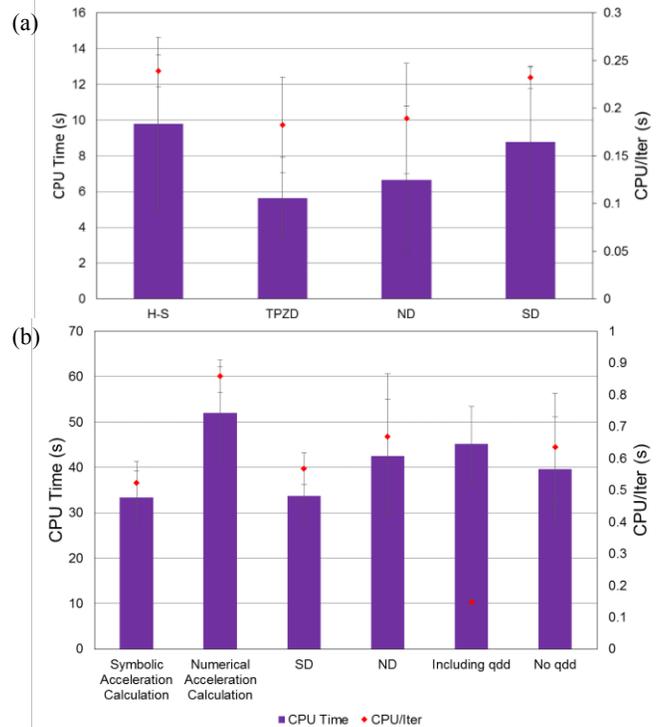

Trapezoidal (TPZD) and Hermite-Simpson (H-S) collocation were used in the objective function and collocation constraints of the compass walker, while only the former was used with the five-link biped. The gradient of the objective and Jacobian of the constraints for the compass walker were found either numerically (ND)—using the central difference approximation—or symbolically (SD). For the five-link walker, these were found using ND, except for the Jacobian of the collocation constraints, which varied in method. Also, for this walker, the joint accelerations were either found numerically or symbolically, or they were included in the decision variables.

Optimizations were performed using the mexIPOPT [7] package for MATLAB. One-hundred optimizations for each of four settings were run for the compass walker with random initial guesses and eleven collocation points. Twenty optimizations were run for each of four settings of the five-link walker. The data were analyzed using an analysis of variance (ANOVA).

## Results and Discussion

Figure 1(a) shows the mean and sample standard deviation of two time-related measures for the compass walker. ND was significantly faster than SD, so this differentiation method was considered to be ideal. TPZD was selected over H-S, also for its speed, although there was a slight tradeoff with accuracy.

Similar types of data are shown for the five-link walker in Figure 1(b). It was recommended that accelerations be included in the decision variables due to the rapid per-iteration CPU time

**Figure 1:** Total CPU time and average CPU time per iteration for (a) compass walker, (b) five-link walker with 21 collocation points. [6]

and a suggested robustness. This was at the expense of the overall CPU time. It was also determined that the joint accelerations should be calculated symbolically due to speed and that ND should be used due to the high complexity of the symbolic expressions required for SD.

In summary, varying the implementation of a direct collocation-based walking trajectory optimization resulted in changes in solution efficiency and, in some cases, accuracy. By analyzing tradeoffs, it was possible to determine potential best practices for performing such optimizations.

## Significance

Since many applications of bipedal robotics, such as powered assistive devices, may require a reference trajectory, these results could help to expedite the requisite optimizations. On a wider scale, this study could be combined with those in other fields to see if best practices are similar for multiple types of NLPs with collocation methods. That would extend the value of these results to a far wider range of fields which require the solution of NLPs.

## Acknowledgments

The authors would like to thank recent graduate Dr. Kenneth Chao, who introduced one of the authors to direct collocation.

# A 3D Computational Model to Simulate 2D Ultrasound Measurements of Medial Gastrocnemius Architecture

Adrienne Williams<sup>1</sup>, William H. Clark<sup>2</sup>, Jeroen B. Waanders<sup>3</sup>, Jason R. Franz<sup>2</sup>, and Silvia Blemker<sup>1</sup>

<sup>1</sup>University of Virginia, Charlottesville, VA, USA, <sup>2</sup>UNC Chapel Hill & NC State University, Chapel Hill, NC, USA

<sup>3</sup>University of Groningen, Groningen, the Netherlands. Email: \*[afw6gf@virginia.edu](mailto:afw6gf@virginia.edu)

## Introduction

Real-time two-dimensional (2D) ultrasound (US) is commonly used to non-invasively study skeletal muscle architecture and muscle-tendon interactions *in vivo*. Though informative and fast, the efficacy of 2D US to examine changes in muscle architecture with contraction is limited. For example, these 2D measurements of three-dimensional (3D) architecture capture fascicle length and pennation angle measurements within only a small region of the muscle in the probe's field-of-view (FOV), and rely on identifying a fascicle that appears in the US FOV at a given time.

We aim to examine these limitations by (i) creating a 3D simulation of the medial gastrocnemius (MG) during an isometric contraction, (ii) comparing the model predictions with US measurements, and (iii) analyzing the model to examine how sampling muscle fascicles within the region of an US probe influences fascicle length change predictions.

## Methods

MR images were used to create the 3D geometry of a MG muscle. The geometry was scaled to the average thickness of the MG muscles of 6 young adults (age:  $23.7 \pm 4.9$  years, 2 females), then meshed and assigned a muscle material [1] for finite element (FE) analysis. Computational fluid dynamics was used to assign vectors from a laminar flow simulation within the geometry as fiber directions to the model's elements [2]. Based on these fiber directions, streamlines generated (in MATLAB [3]) were used to define representative fascicles (Fig. 1A). Muscle-tendon junction displacement collected by US during a maximum voluntary isometric contraction (MVC) defined the boundary conditions at the distal MTJ. After the FE simulation, we sampled the model fascicles in the region that represented the volume of the muscle that is captured in the FOV of the US probe (L:60mm x W:15 mm x D:24 mm) – Fig. 1B. We assume that the region's thickness is the same as the probe width. Lastly, the 3D trajectories of the fascicles were projected on the 2D plane of the probe (Fig. 1C), to represent what would be visible in the US image.

## Results and Discussion

The predicted fascicle arrangement within the probe field of view was qualitatively similar to the ultrasound images (Fig. 1C&D). Of the 367 representative fascicles in the 3D model (Fig. 1A), 86 (23.4%) fascicles at rest and 84 (22.9%) fascicles at MVC had at least two points within the probe volume. Of those 86 fascicles, one fascicle had all points from the 3D model within the probe volume when the muscle was relaxed (Fig 1B,C), while no fascicles were completely within the volume at MVC, as fascicles shifted medially out of the region with contraction. Between rest and MVC, the average length change of all fascicles in the modelled probe region were comparable to the average *in vivo* data, but with a large standard deviation, representing all the fascicles within that image. We see from our model that many fascicles are curved, while ultrasound image analyses typically assume fascicles are straight lines. Future work will account for the curvatures observed in our model fascicles, as we evaluate pennation angles and fascicle curvatures.

## Significance

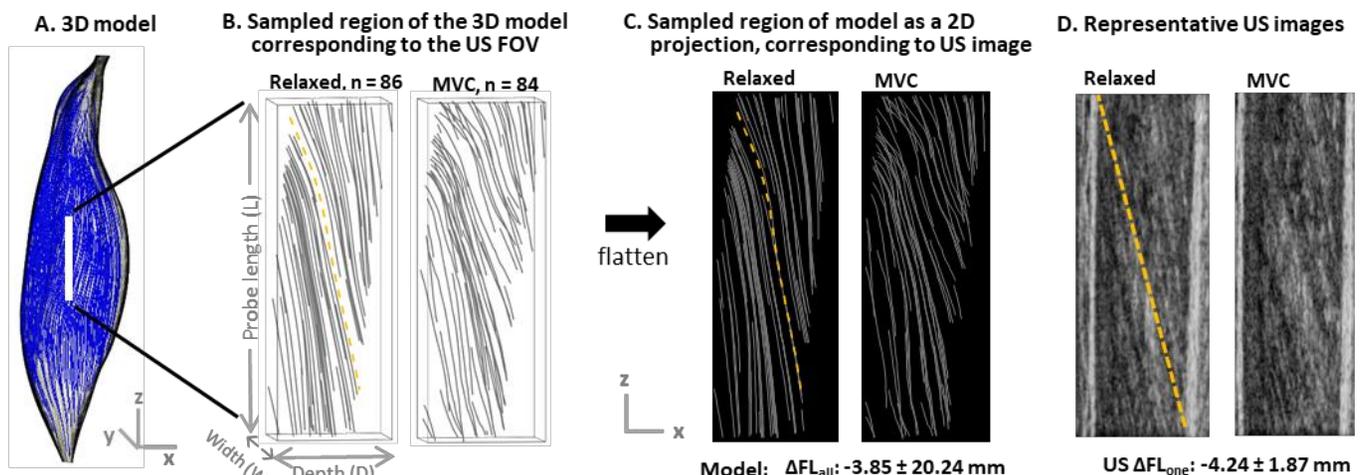

Ultrasound imaging has become a ubiquitous tool in biomechanics to understand *in vivo* muscle function. Our work aims to augment those measurements with 3D modeling to explore the 2D assumptions made with US and investigate issues such as how probe placement (location, tilt, and rotation) influences measurements.

# The Contribution of Spinal Erector Muscle Strength and Facet Contact in Reducing Disc Herniation Risk During Forward Bending

Stephanie Rossman M.S.<sup>1,2</sup>, Eric Meyer Ph.D.<sup>1</sup>, and Steven Rundell Ph.D.<sup>2</sup>

<sup>1</sup>Lawrence Technological University

<sup>2</sup>Explico Engineering

Email: \*[rossman@explico.com](mailto:rossman@explico.com)

## Introduction

Disc herniations occur in a biomechanical environment consistent with forward bending, i.e. compression and flexion. It is generally believed that facet contact is not relevant in loading modes that place the spine in flexion, such as forward bending. This belief is supported by the use of a compressive follower force to simulate the spine's musculature. This assumes a perfect balance between flexor and extensor muscle activation. However, it is possible, and encouraged by athletic trainers and physical therapists, to activate the spinal extensor muscles during forward bending, i.e., maintaining a flat back.

Activation of these spinal erector muscles during bending may encourage facet contact, which could effectively offset compressive and shear loading from the disc to the facets. This may be an effective way to protect the disc during forward bending activities.

Therefore, the objective of the current study was to utilize a finite element model of a lumbar motion segment to evaluate the association between spinal extensor muscles, specifically the erector spinae (ES) muscle, and facet contact force in reducing disc herniation risk during forward bending. We hypothesized that the presence of intact facets and increased ES muscle force would result in increased sagittal balance and decreased disc pressure, disc stresses, and nuclear extrusion forces compared to no facets.

## Methods

A previously developed and validated finite element model of a L4-5 lumbar motion segment was utilized for the current study[3], [6], [7]. Forward bending was simulated by rotating the motion segment 30° and applying 343 N of axial compression 15 mm anterior to the center of the L4 bony endplate. The inferior bony endplate of L5 was fixed rigidly in space. A surface-to-surface contact was established between the L4 and L5 posterior elements. To simulate the removal of facets, the contact between the posterior elements was turned off. The ES was simulated by attaching bi-lateral force elements between the spinous processes approximately 5.5 cm posterior of the joint center. Varying amounts of ES force was applied. The disc pressure, disc 1<sup>st</sup> principal stress and shear stress, nuclear extrusion forces, facet contact forces, and L4 vertebral x-axis rotations were recorded.

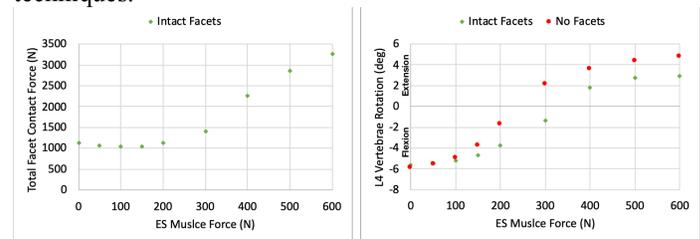

## Results and Discussion

Results of the study confirmed our hypothesis that the presence of intact facets resulted in lower disc pressure, disc stresses, and nuclear extrusion forces during forward bending. The greatest reduction in loads on the disc occurred when balance was restored due to increased ES muscle activation. At the point of maximum reduction in disc loads, there was an increase in facet contact force, consistent with the facets offsetting loads in the disc.

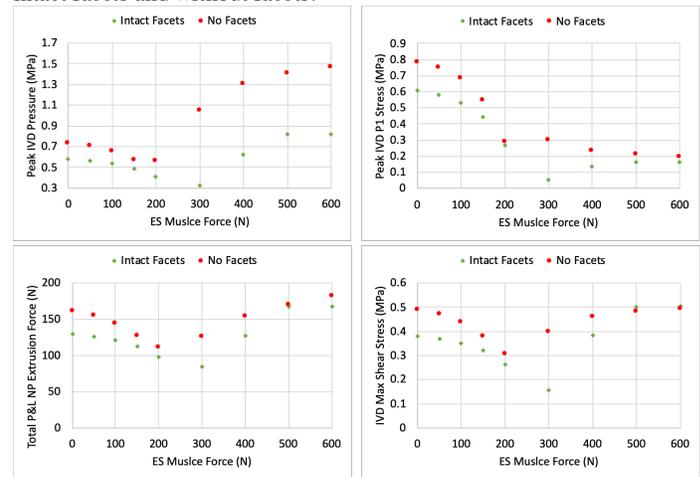

## Significance

The current study demonstrated the importance of ES muscle strength and facet contact contribution to maintaining a healthy

disc environment. This has clinical significance in the surgical realm due to the current practice of removal of facets during decompression techniques for the treatment of disc herniation. Future studies involving the current finite element model may be conducted to evaluate the risk for re-herniation following decompression surgery. Additionally, if the facet joints must be removed, the current study demonstrates increased ES muscle activation may not result in a healthy disc environment, which has many implications in post-surgical physical therapy techniques.

**Figure 1:** Facet contact force and L4 vertebral x-axis rotations with intact facets and without facets.

**Figure 2:** Disc pressure, shear stress, 1<sup>st</sup> principal stress, and nucleus extrusion force in the posterior and lateral aspect of the disc with intact facets and without facets.

# Discrepancy Modeling for Human Locomotion

Megan Auger<sup>1</sup>, J. Nathan Kutz<sup>2</sup>, and Katherine M. Steele<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, University of Washington, Seattle, WA

<sup>2</sup>Department of Applied Mathematics, University of Washington, Seattle, WA

Email: [mauger@uw.edu](mailto:mauger@uw.edu)

## Introduction

Despite our ability to model the human system, accurately predicting locomotion when idealized musculoskeletal model dynamics differ from reality remains challenging. While first-order, physics-based models describing human motion generally capture salient characteristics of locomotion, physical systems are not ideal. Thus, models are unable to capture the complete dynamics observed in experiment, i.e. simulation does not match experiment [1, 2]. The inability to represent such discrepancies can have significant impact on model predictions.

Discrepancies can arise from a variety of factors often ignored in idealized models, such as with parameter mismatch (subject-specific musculotendon properties, segment mass estimation error) or missing physics (unmodeled body segments, motion artifacts, soft tissue mechanics). These discrepancies are typically unique to an individual and must be learned and quantified as such. Taking inspiration from perturbation theory [3], we develop a mathematical architecture based upon sparse regression that discovers interpretable, data-driven discrepancy models to augment first principles dynamics that may help predictions and guide future experimental studies. To evaluate the feasibility of discrepancy models in human locomotion, we used a simple dynamic walking model in an ideal simulation environment and hypothesized our simulation framework would recover small nonlinear discrepancies from the model's locomotion dynamics.

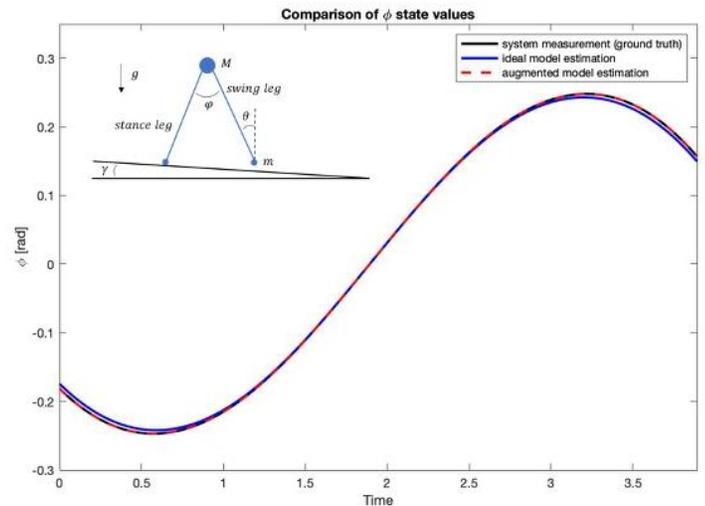

## Methods

The sparse identification of nonlinear dynamics (SINDy) algorithm [1] uses sparse regression to discover a parsimonious representation of nonlinear system dynamics from measurement data. An important assumption about the model structure is that there are only a few salient terms governing the dynamics; this ensures system interpretability and avoids overfitting. Recently, this framework has been used to identify discrepancy models between empirical data and model outputs of a system [2]. Discrepancy models can analogously be thought of as a first-order perturbation model. Our solvable problem ( $A_0$ ) is an oscillatory 2-link pendulum [4] with collision constraints, and the first-order perturbation solution ( $\tilde{A}$ ) includes small nonlinear contributions to equations of motion  $A \approx A_0 + \tilde{A}$  where  $\tilde{A} \ll 1$ .

We used a simple passive dynamic walking model described by two states:  $\theta$  (angle of stance leg w.r.t. vertical) and  $\varphi$  (relative angle between legs) (Fig. 1).  $N = 1000$  trials were performed. Each trial generated a random polynomial discrepancy (max. order 5) and randomly added the discrepancy to a system state. Kinematics were evaluated for stability (10+ steps) before using SINDy to recover the discrepancy model.

## Results and Discussion

SINDy recovered first-order physics with high fidelity, correctly identifying 88.6% of the discrepancies. No discrepancy model was identified for the remaining 11.4% due to an inappropriately high sparsity regularization parameter. This could be rectified in future analyses via hyperparameter tuning.

**Figure 1:** Model parameter  $\varphi$  for one step. Ideal model estimation (blue) fails to fully capture measured system dynamics (black). Discrepancy model augments the ideal model (dashed red) to recover system physics.

While this initial investigation used a simple toy model to investigate the use and accuracy of discrepancy modeling for recovering locomotion dynamics, including system-specific corrections to an idealized model can help close the gap between experiment and simulation.

## Significance

This work is a critical first step in improving the integration of heterogeneity into musculoskeletal models to improve prediction accuracy. Developing subject-specific models will be crucial for predicting effects of treatments or interventions computationally. This is especially true when an individual has a motor impairment and does not subscribe to the same assumptions about musculoskeletal properties as unimpaired individuals.

# Which Muscles are Most Responsible for Tremor? Principles from Computer Simulations

Spencer A. Baker<sup>1</sup>, Daniel B. Free<sup>1</sup>, Steven K. Charles<sup>1,2</sup>

<sup>1</sup>Mechanical Engineering and <sup>2</sup>Neuroscience, Brigham Young University, Provo, UT

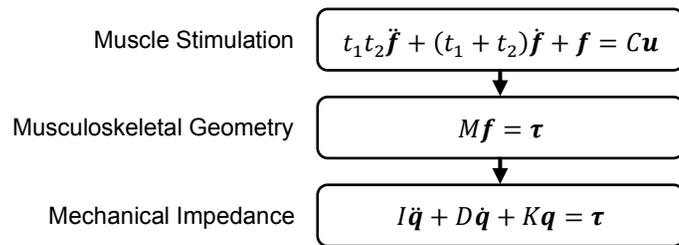

Email: [skcharles@byu.edu](mailto:skcharles@byu.edu)

## Introduction

Tremor is the most common movement disorder. Essential Tremor alone affects approximately seven million people in the United States [1]. Tremor’s debilitating effects and lack of satisfactory treatments accentuate the need for new tremor-suppressing methods. Peripheral treatments are possible but are presumably more effective when applied to the muscles that are most responsible for the tremor [2]. Determining which muscles cause tremor is a complex challenge. Tremor in the arm “propagates” (spreads) tremorogenic muscle activity to multiple degrees of freedom (DOF), and each muscle-DOF relationship is unique. Past studies have examined tremor propagation from the 15 major superficial muscles of the upper limb [3], but this is only a subset of the muscles capable of causing tremor. The purpose of this research was to expand the previous studies to include all 50 muscles of the upper limb, to discover principles of tremor propagation, and to determine which of these muscles are most responsible for tremor.

## Methods

We modeled the upper limb as a linear, time-invariant, multi-input-multi-output system. Inputs are the neural drive in one or multiple arm muscles. Outputs are the displacements in the seven DOF from the shoulder to the wrist. The model simulates tremor propagation in three phases (Figure 1).

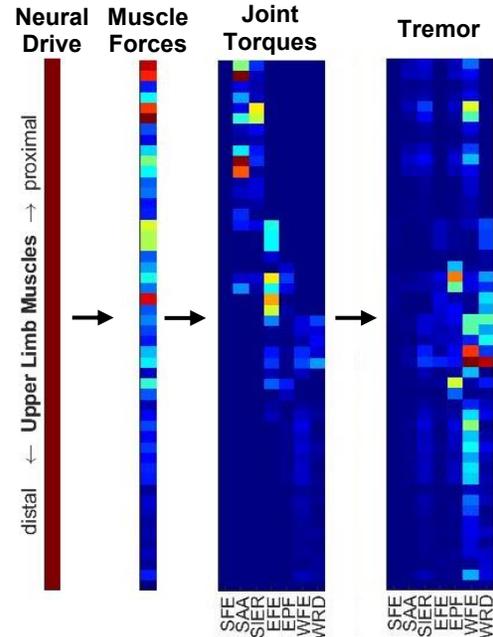

**Figure 1:** Summary of the model and the relationships between neural drive ( $\mathbf{u}$ ), muscle forces ( $\mathbf{f}$ ), joint torques ( $\boldsymbol{\tau}$ ), and DOF movement ( $\mathbf{q}$ ). Model parameters are the muscle-excitation time constant ( $t_1$ ), muscle-contraction time constant ( $t_2$ ), muscle strengths ( $C$ ), musculoskeletal geometry ( $M$ ), inertia ( $I$ ), damping ( $D$ ), and stiffness ( $K$ ). Default parameter values were obtained from prior studies [3-4].

Bode analyses were used to investigate tremor magnitude and spreading on each muscle-DOF relationship in the tremor band (4-12 Hz).

In addition, we conducted a sensitivity analysis to account for error in our parameter values and variability between subjects.

## Results and Discussion

Simulations showed that if all muscles had the same amount of tremorogenic input, the proximal muscles produce the most force and joint torque, but the forearm and wrist muscles produce the most tremor (Figure 2). We found that tremor will predominantly affect one or two DOF. The DOF with the most tremor were always distal.

**Figure 2:** Tremor propagation at 8 Hz from neural drive (plot 1) to muscle forces (plot 2), joint torques (plot 3), and DOF movement (plot 4). The rows represent muscles. The columns in plots 2 and 3 represent the DOF: shoulder flexion-extension (SFE), shoulder adduction-abduction (SAA), shoulder internal-external rotation (SIER), elbow flexion-extension (EFE), forearm pronation-supination (FPS), wrist flexion-extension (WFE), and wrist radial-ulnar deviation (WRUD). Magnitudes are indicated by shades of blue (low) to red (high).

We found that while tremor magnitude depends on exact model parameter values, tremor propagation patterns are robust to parameter errors and subject variability.

Our investigation confirms previous findings that musculoskeletal dynamics spread tremor narrowly (i.e. input in a muscle causes tremor mostly in a small number of DOF) but not necessarily locally (e.g. input in a proximal muscle may cause its greatest tremor in a distal DOF) [1]. We also found that wrist and forearm muscles produce the greatest tremor (for a given tremorogenic input), and that most of the tremor produced (by all muscles together) occurs in the DOF of the wrist and forearm.

## Significance

These findings provide principles of propagation for estimating which muscles are most responsible for tremor. This understanding can be used by researchers and clinicians to optimize peripheral tremor-suppression methods, facilitating the innovation of tailored and effective treatments.

## Acknowledgments

This research was supported by NSF grant 1806056.

# The Importance of Spinal Erector Muscle Strength and Facet Contact in Establishing Sagittal Balance and Reducing Disc Loads During Standing and Forward Bending

## Introduction

During normal standing and forward bending, the lumbar spine is exposed to compression and anterior shear due to upper body weight[1]. Additionally, the line of gravity is anterior to the center of the vertebrae resulting in development of a flexion moment. The extensor muscles of the spine, primarily the erector spinae (ES), counter-act the anteriorly biased body weight, and re-establish sagittal balance. Paradoxically, despite the increased amount of loading, it is generally believed that strong spinal extensor muscles provide a biomechanically healthier environment for the discs. We hypothesize that the benefits of extensor muscle activation are the direct result of increased facet engagement. Specifically, strong spinal extensor muscles increase facet force and thereby align the vertebrae, restore sagittal balance, and generally reduce loading on the disc.

The current study involved applying upper body weight (compression, anterior shear, and flexion) to a single finite element lumbar motion segment to evaluate the effect of ES muscle activation in engaging the facets and re-establishing sagittal balance during simulated standing and forward bending.

## Methods

A previously developed and validated finite element model of a lumbar motion segment was utilized for the current study[2]. Axial compression of 343 N was applied 15 mm anterior of the center of the L4 superior bony endplate to simulate standing[3]. Forward bending was simulated by rotating the motion segment 30° and applying 343 N of axial compression 15 mm anterior to the center of the L4 bony endplate. The inferior bony endplate of L5 was fixed rigidly in space. A surface-to-surface contact was established between the L4 and L5 posterior elements. To simulate the removal of facets, the contact between the posterior elements was turned off. The ES was simulated by attaching bilateral force elements between the spinous processes approximately 5.5 cm posterior of the joint center. Varying amounts of ES force was applied. The L4 vertebral x-axis rotations, facet reaction forces, and disc pressures were recorded.

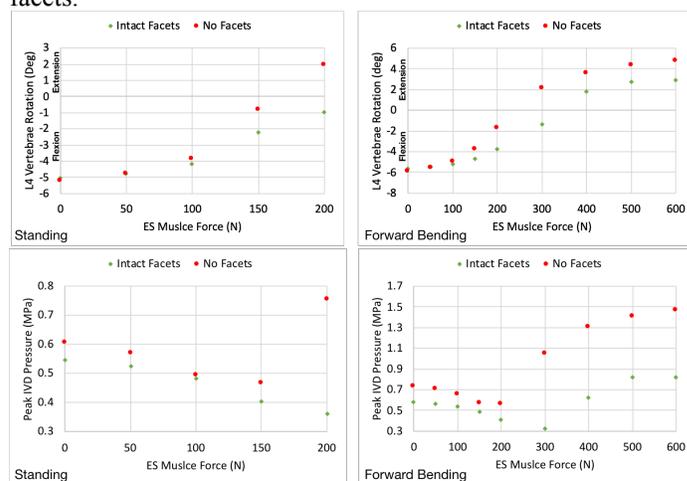

## Results and Discussion

Results of the study confirmed our hypotheses that an increase in ES force would engage the facets, restore sagittal balance, and decrease loading on the disc. In general, the absence of facet contact resulted in greater mobility of the joint. These results indicate the facet joints play a role in stabilizing the lumbar spine in the sagittal plane. As the ES muscle force increased, an extension moment was created to offset the flexion generated by upper body weight. Facet joint engagement resulted from increased amounts of ES muscle activation, which in turn resisted the compressive and shear components of body weight. The greatest reduction in disc pressure resulted when sagittal balance

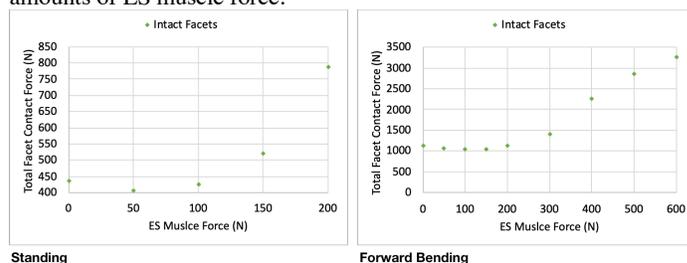

was restored. Without intact facets, higher ES muscle loads resulted in increased disc pressures and extension rotation suggesting an inherently unstable condition (marble perched on a hill) for spines with jeopardized facets.

## Significance

The current study demonstrated the importance of the facet joints and ES muscle strength in maintaining sagittal balance and reducing the loading on the disc. This study provides the foundation for understanding the relationship between the spinal extensor muscles and the facets and the contribution of these anatomical structures to maintaining a healthy disc environment. This has clinical significance due to the current trend of surgical removal of the facets during decompression techniques used to treat disc herniations. The current finite element model may be used to study the effects of those surgical techniques on disc health and to evaluate how maintaining strong spinal extensor muscles can contribute to disc health after surgical removal of the facets.

**Figure 1:** L4 vertebral x-axis rotations and disc pressures during standing and forward bending, with and without facets, for varying amounts of ES muscle force.

**Figure 2:** Total facet contact force during standing and forward bending for varying amounts of ES muscle force.

## Using System Identification to Determine how Tremor Propagates in the Upper Limb

Sydney B. Ward<sup>1</sup>, Jing-Song Huang<sup>1</sup>, Sadie Cutler<sup>1</sup>, C. Paul Curtis<sup>1</sup>, Steven K. Charles<sup>1,2</sup>

<sup>1</sup>Mechanical Engineering and <sup>2</sup>Neuroscience, Brigham Young University

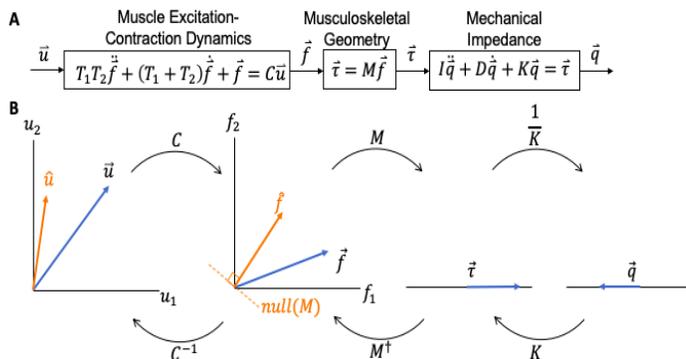

Email: [Sydney.ward30@gmail.com](mailto:Sydney.ward30@gmail.com)

### Introduction

Essential Tremor (ET) is one of the most common movement disorders, affecting 5% of adults over 60 years old. ET involves involuntary shaking of the hands, arms, head and/or other body parts during voluntary movement and postural stances. Common treatment options include medications and neurotherapy, such as deep brain stimulation and MRI guided focused ultrasound. Unfortunately, the side effects and risks associated with these options cause many people with ET to opt out of treatment altogether. Peripheral tremor suppression options, such as wearable orthotics and weighted utensils, are also available, but one limitation to the effectiveness of these options is we do not currently know where in the upper limb the tremor originates or how the tremor propagates. The purpose of our research is to determine the mechanical origin and propagation of tremor throughout the upper limb.

### Methods

Tremor propagation was previously simulated [1] using a linear, time-invariant (LTI) model of the upper limb neuromusculoskeletal system, which takes in muscle activity and outputs joint displacements through a series of three subsystems: muscle activity to muscle force; muscle force to joint torque; and joint torque to joint displacements (Figure 1.A). Also, we previously collected muscle activity and joint displacement data in 15 major superficial muscles and 7 joint degrees of freedom in the upper limb while 24 ET patients assumed multiple postures and performed various movements. Combining the model and measured data would allow us to estimate which muscles are most responsible for a patient's tremor. However, this model includes many unknown patient-specific parameters (muscle time constants, moment arms, joint impedances, etc.). Therefore, we are applying system identification to estimate the physically significant parameters of the upper limb neuromusculoskeletal system based on the model, muscle activity input, and joint displacement output data. We will then apply superposition techniques to the model to determine which muscles are most responsible for each patient's tremor.

**Figure 1:** A. LTI model relating tremorgenic muscle activity to joint displacements.  $u, f, \tau,$  and  $q$  represent muscle activity, muscle force, joint

torque, and joint displacements;  $T_1$  and  $T_2$  represent muscle time constant diagonal matrices;  $C$  and  $M$  represent the diagonal muscle gain matrix and the moment arm matrix; and  $I, D,$  and  $K$  represent positive definite impedance matrices. B. Simplified version of the LTI model (2 inputs, 1 output; derivative terms not included) represented as a series of linear transformations. The inverse transformation from  $q$  to  $u$  requires the inverse of the wide matrix  $M$ . The pseudoinverse of  $M$  finds the force vector that is perpendicular to the null space of  $M$ , which is not necessarily the true force.

### Results and Discussion

We have approached this problem using a least-squares method in the time domain and have faced three significant challenges: 1. Combining the three subsystems into a single system results in a fourth-order ODE that forces least-squares minimization of the residual error of the (very noisy) muscle activity input instead of the residual error of the (smoothed) joint displacement output; 2. Combining the three subsystems into a single system also forces the least-squares solution to perform the inverse transform, which involves calculating muscle forces from joint torques (Figure 1.B); unfortunately, the usual assumptions used to perform this underdetermined inversion (e.g. minimizing effort) do not apply to tremor; 3. The system is linear with respect to the parameter matrices but is not linear with respect to the nonzero, non-repeating elements of the parameter matrices.

Consequently, we are currently investigating other system identification methods to avoid or minimize these three challenges. The issues of minimizing the input residual errors and performing the inverse transform may be resolved by implementing system identification in the frequency domain instead of in the time domain. Frequency domain system identification assumes steady-state, periodic input, which is an appropriate assumption for tremor. The problem of nonlinearities with respect to significant elements of the parameter matrices can be resolved by applying an iterative search method, such as Gauss-Newton, steepest descent, or Levenberg-Marquardt. The drawback of iterative search methods is a more complicated algorithm that carries the risk of getting trapped in local minima when searching for optimal parameters.

### Significance

Our work will result in a method for determining the physical parameters of the tremorgenic upper limb neuromusculoskeletal system. We will use parameters generated from this method to determine which muscles are most responsible for a patient's tremor and therefore where peripheral tremor suppression techniques should be applied for maximum tremor reduction.

## Introduction

Clinical ankle assessment and treatment has become much more sophisticated over the last two decades as treatment for end-stage ankle arthritis has shifted to total ankle arthroplasty (TAA), compared to the traditional ankle arthrodesis (AA).<sup>1</sup> A motivating factor in this is the improvement in the ankle replacements being used in the TAA procedure. However, little work has been done to examine how TAA affects the motion of the foot. This is made difficult by a lack of knowledge of what typical foot motion looks like as well as the lack of technical uniformity between various existing foot models.<sup>2</sup> This case study compares three foot models, all modelling the same step to illuminate differences in the existing models, and propose critical components in the use and development of foot models moving forward.

## Methods

3D motion capture data was collected on one healthy, 22 y.o., male subject. Markers were applied to complete the marker sets necessary for the Plug-in-Gait (PiG), Oxford Foot (OXF), and KU Leuven (KUL)<sup>3</sup> models. The subject walked at his self-selected, comfortable walking speed along a 15 m walkway. A single step was isolated and exported to OpenSim 4.0. The 4-segment OXF model was created in OpenSim by fixing the midfoot(MF)-forefoot(FF) joint in the 5-segment KUL model, then replacing all existing joints in the model with ball joints aligned to the anatomical planes. To allow for comparison between PiG, OXF, and KUL the off-axis MF-FF joint of the KUL model was replaced with overlaid revolute joints to report flexion and inversion. With these changes all models report flexion in the sagittal plane, inversion in the frontal plane, and internal/external rotation in the transverse plane. The same step

**Figure 1.** Kinematics of multiple foot models, overlaid on Lundgren's (2008) corridors for internal foot motion (blue shaded).

was then modelled by each of the three models. All kinematics were normalized to the static position of the subject standing still. Outputs were compared to Lundgren<sup>4</sup> foot motion for reference.

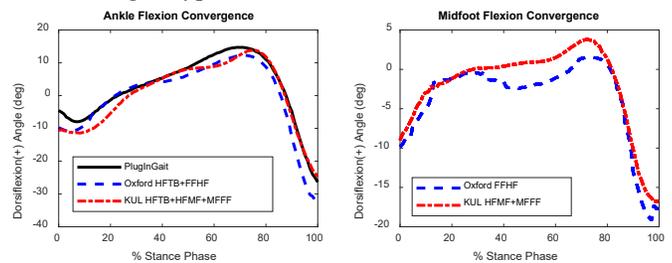

It is implied that the angles reported by the multi-segment models (OXF, KUL) should converge to the angle reported by the model with the least segments (PiG). The convergence of the models was analyzed by summing all of the joints contributing to flexion and comparing the result to the fewer segment models.

## Results and Discussion

All models represent the total sagittal motion between the ankle and the foot (*Fig. 2*). However, to investigate more degrees of freedom through the foot, it is shown that the PiG model cannot give any more information, as it is only one segment.

*Figure 1* shows how the total motion is distributed along the foot. Flexion within the foot is captured by two joints in the KUL model and only one in the OXF model. The result of this is matching reports of the MF-hindfoot(HF) angle between OXF and KUL. However, if the MF-HF angle from OXF is used to capture MF-FF motion, the result falls outside of the Lundgren<sup>4</sup> corridor and varies largely from the result of the KUL MF-FF joint motion (*Fig 1, Row 3*). Lack of uniformity in the midfoot is important to note, as it shows the hypothesis that more segments are necessary to accurately describe the motion of the foot.

When considering the convergence of the models (*Fig. 2*), it can be seen that the models do converge well in the sagittal plane. However, there are still differences seen in the resulting curves, further suggesting that we do not yet have a complete understanding of typical foot motion.

**Figure 2.** Convergence of joint flexion. PiG solid black. Oxford Foot dashed blue. KU Leuven dot-dashed red.

## Significance

We expect the motion of the ankle to change with TAA, so we need a method to analyze this change and ultimately design better ankle replacement mechanisms. These results highlight the importance of a multisegment model for understanding internal foot motion. This comparison also begins to lay the ground work for determining the optimal degrees of freedom needed from a ankle joint model.

### Introduction

Reliable estimation of muscle forces during human movement could facilitate the development of improved interventions for disorders such as stroke [1]. Muscle forces cannot be measured noninvasively using standard experimental methods, nor can they be computed via rigid body dynamics alone due to the muscle redundancy problem (i.e., more muscles than degrees-of-freedom (DOF) in the human musculoskeletal system). Because of its simplicity, static optimization (SO) is frequently used to resolve the muscle redundancy problem. However, generic musculoskeletal modeling frameworks have shown to be incapable of accurate estimation of muscle activations and, therefore, muscle forces [2].

Model personalization has been applied as one big step forward in personalizing neuromusculoskeletal parameters, especially in pathologic cases, such as stroke [3]. However, to estimate muscle activations/forces more accurately, personalization of the muscle redundancy problem seems necessary. This study explored the customization of the static optimization formulation for an individual post-stroke and how it affects the estimation of muscle activation and force.

### Methods

Walking data (Motion, ground reaction, and EMG of 50 trials—5 speeds, 10 trials each) from a previous study of a patient post-stroke were used [3]. A modified OpenSim (v4.0; [4]) model with 31 degrees of freedom (DoFs; 5 per each leg) and 35 leg muscles was used for the initial musculoskeletal analysis, including scaling and inverse kinematics and dynamics. An EMG-driven musculoskeletal model calibrated musculotendon parameters [3]. Standard static optimization was formulated as  $\min \sum_{i=1}^{33} a_i^2$ , subject to  $M_j = \sum_{i=1}^{33} r_{ij} F_i^T$  ( $j = 1, \dots, 5$ ) and  $0 \leq a_i \leq 1$  ( $i = 1, \dots, 33$ ) where  $M$  is joint moment,  $F^T$  is musculotendon force, and  $a$  is muscle activation. The inverse optimization problem was defined as

$$\max_{w, a^{Bg}} \sum_{k=1}^N \sum_{i=1}^{33} R_{ij}^2(a_{ik}, a_{ik}^{EMG})$$

subject to muscle weight parameter  $w \geq 0$  and muscle

background activation level  $0 \leq a^{Bg} \leq 1$  where  $N$  is the number of trials,  $a^{EMG}$  are the target muscle activations from the EMG-driven model, and activations  $a$  are estimated from the inner loop problem, which is a custom SO [4,5]:

$$\min_{a_{ik}} \sum_{i=1}^{33} w_i (a_{ik} - a_i^{Bg})^2$$

subject to  $M_j = \sum_{i=1}^{33} r_{ij} F_i^T$  ( $j = 1, \dots, 5$ ) and  $0 \leq a_i \leq 1$ .

Several sets of trials were used for the inverse optimization problem to assess the sensitivity of the training set on the optimal parameters.

### Results and Discussion

The mean of the Pearson correlation between the estimated activations and processed EMG increased from 0.68 for SO to 0.93 for the inverse optimization framework (Figure 1). Optimal weight and background activation parameters resulting from different training sets were robust ( $R^2 > 0.95$ ).

### Significance

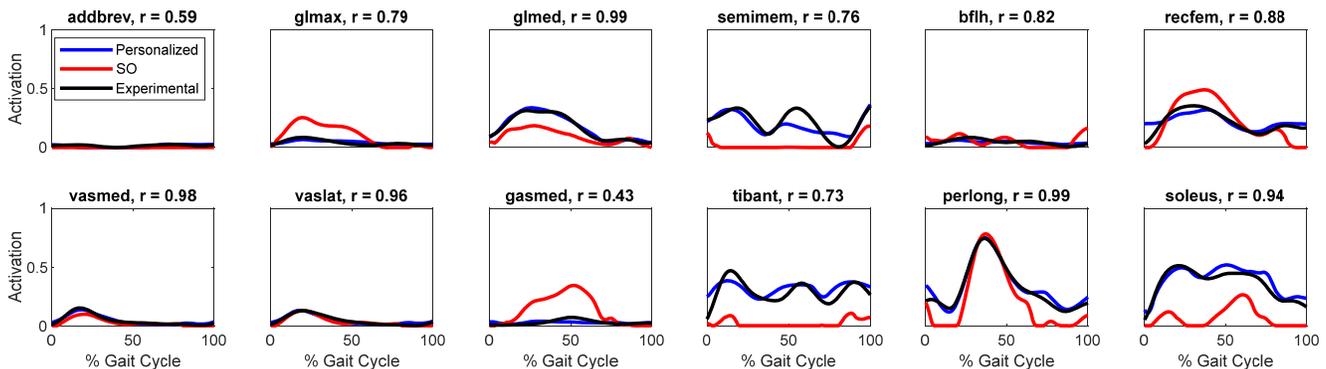

This study showed that personalizing an objective function for the muscle redundancy problem of a patient post-stroke is necessary. Although traditional static optimization is not accurate in estimating muscle activations, we showed that personalized custom static optimization could have the potential to be used for such estimations, which can have a great impact on how the interventions are designed in pathologic populations.

# A Framework for Bipedal Walking Research in Biomechanics from Robotics

Pilwon Hur

Department of Mechanical Engineering, Texas A&M University, College Station, TX

Email: pilwonhur@tamu.edu

## Introduction

Bipedal walking has been a research topic in biomechanics for many years [1]. After this, many research on human bipedal walking has been conducted. Most common methods require laboratory environments with motion capture systems and force platforms. Measured data were, then, entered into bipedal walking models for further analysis. Even though this method is considered the golden rule in biomechanics, there exist limiting factors including experimental artifacts, time constraints, intractability to change experimental conditions, etc.

In robotics literature, techniques of trajectory optimization have been widely used to produce a set of joint trajectories that minimize a cost function while satisfying constraints. The benefits of these techniques include no need of experiments, no time constraints, ease of changing system parameters, to name a few. Trajectory optimization is beneficial in the biomechanics research for the following reasons. First, no experiments with subjects are needed, which involves with time, cost and, unforeseen safety issues. Second, system parameters can be easily updated without the need of repeated (or paired) experimental design, which is important for research with people with impairments. For example, the optimal reference trajectory for transfemoral amputee patients are not known due to amputation, weakening the usage of the reference trajectory from healthy subjects. Third, perturbation studies and motor control research can be easily conducted. The results from the trajectory optimization can be easily combined with various controllers in the forward simulation to perturb the walking or to test several motor control ideas (e.g., uncontrolled manifold, equilibrium hypothesis, free energy principle). Even though the results from the models need to be validated with the experiments, these can provide the intuition about the human motor control of bipedal locomotion. More importantly, the intuition learned can facilitate the expensive experiments in the more meaningful and successful directions.

In this abstract, we introduce the framework for bipedal walking research that's used in HUR group at Texas A&M University.

## Methods

**Trajectory optimization:** There exist several approaches in the optimal control problems including Pontryagin's minimal principle (MP), dynamic programming (DP), shooting methods (SM), and direct collocation method. Each has its own benefits and disadvantages. While MP, DP and SM can provide accurate solution, they cannot be easily scaled up to cases with higher dimensions and complicated constraints. Direct collocation, however, can provide more efficient computation by discretizing the infinite dimensional domain into lower finite dimensions and using nonlinear programming algorithms (e.g., IPOPT). The compromised accuracy can be remedied by increasing the collocation points or algorithms.

**Transcription methods:** Both trapezoidal (TPZD) collocation and Hermite-Simpson (HS) collocation methods are used. HS is more accurate than TPZD. However, HS is slower than TPZD. Therefore, depending on the complexity of the model, either method can be selected [2]. Appropriate differentiation methods (e.g., numerical, symbolic, automatic) for dynamics and constraints need to be chosen for the best performance. When the complexity of the model increases, acceleration can be used as separate decision variables.

**Dynamic models:** Euler-Lagrange (EL) formulation is the usual choice for modeling the bipedal walker. EL formulation can also

provide intuitive information including energies in the system, and generalized momenta. If the slipping is required, extra generalized coordinates need to be introduced at the slipping foot (note it can be anywhere in the body) and appropriate constraint dynamics should be formulated by introducing Lagrange multipliers.

**Cost functions:** Several cost functions have been used in the literature including cost of transport, torque squared. Depending on the complexity, relaxation terms for constraints can be added in the cost. Recently, we reported that adding extra terms (e.g., stepping time uncertainty, angular momentum) in the cost enhanced the robustness of the bipedal walking to perturbation [3,4].

**Control in the forward simulation:** Once optimal reference trajectories are determined, appropriate controller should be chosen. PD control is the usual choice for tracking the reference trajectories. However, more complicated control schemes are needed in many cases: i) the system is underactuated. ii) perfect trajectory tracking is needed. iii) impedance control is needed, iv) and more. In addition to PD control, we use impedance control, and hybrid zero dynamics (HZD)-based control. Specifically, HZD-based control requires the feedback linearization via desired output functions. HZD approach is useful since it can handle underactuated systems, and provides rapidly exponentially stable trajectory tracking. Lastly, it is more beneficial to use a state-based phase variable (i.e., parameterized time) to track the trajectories rather than time-based control since any perturbed movement will unrealistically correct the errors if time-based control is used. Horizontal whole body COM position normalized by the desired walking speed is a reliable phase variable.

**Other considerations:** When muscle activation is involved, muscle models should be included in the modeling. Direct collocation can efficiently solve this problem with muscle models included in the optimization due to its strength in scalability. In our research group, muscle models are not considered except the direct EMG measurement. Please refer to OpenSim Moco [5].

## Results and Discussion

Using the introduced framework, we could generate human-like walking trajectories for healthy people [6,7] and transfemoral amputees [8,9]. We could also show that human balance and walking tried to minimize the entropy (e.g.,  $H_\infty$  vs.  $H_2$ ) due to free energy principle [10]. Robustness to perturbation could be enhanced by appropriate choice of cost function. Optimization performance varied depending on the optimization settings and the complexities of the problems.

## Significance

The introduced framework can facilitate the biomechanics and motor control research for human bipedal walking.

# ANALYSYS THE STRAIN OF PLANTAR FASCIA WITH DIFFERENT PLANTAR FASCIA THICKNESS AND TENDON LOADING IN 3-D FINITE ELEMENT FOOT MODEL

Jinhyuk Kim, Stacie I. Ringleb, Sebastian Y. Bawab,  
 Old Dominion University, Norfolk, VA, USA  
 email: [sringleb@odu.edu](mailto:sringleb@odu.edu)

## Introduction

The plantar fascia transfers loads from the Achilles tendon to the forefoot during walking [1]. Thus, both Achilles tendon loading and plantar pressure may contribute to the strain in the plantar fascia. In the case of in patients with plantar fasciitis and diabetes, the plantar fascia is typically thicker than healthy asymptomatic [2, 3]. Specifically, the average thickness of healthy plantar fascia is  $2.0 \pm 0.5\text{mm}$ , while plantar fasciitis and diabetic plantar fascia is  $5.71 \pm 1.3\text{mm}$  and  $3.1 \pm 1.0\text{mm}$  [2, 4], respectively. In addition, the properties of plantar fascia are different between healthy and injured or diabetes plantar fascia [5]. However, finite element models of the foot typically keep the plantar fascia at a constant thickness (i.e., 2mm or the cross-sectional area of  $3.2\text{mm}^2$ ) [1]. The purpose of this study was to examine the strain of the plantar fascia with different plantar fascia thickness and Achilles tendon loading in 3-D finite element foot model.

## Methods

A finite element (FE) model was developed using 3DSlicer (Slicer), Geomagic Design X (3D Systems, Rock Hill, SC), Hypermesh (Altair, Troy, MI), and FEBio (FEBio, Salt Lake City, UT) segmented from CT images obtained from one cadaver (Figure 1). The plantar fascia was modeled with three different thickness (3mm, 4mm, and 6mm). The foot was modeled with 4-node quadratic tetrahedral elements (TET4) and homogeneous isotropic elastic materials [6]. Tied surface to surface contact was applied to the bones, cartilage and plantar fascia. A 0 and 700N axial load was applied to the top surface of tibia and fibula, as the Achilles tendon force was increased from zero to 500N to simulate in midstance (Fig 1).

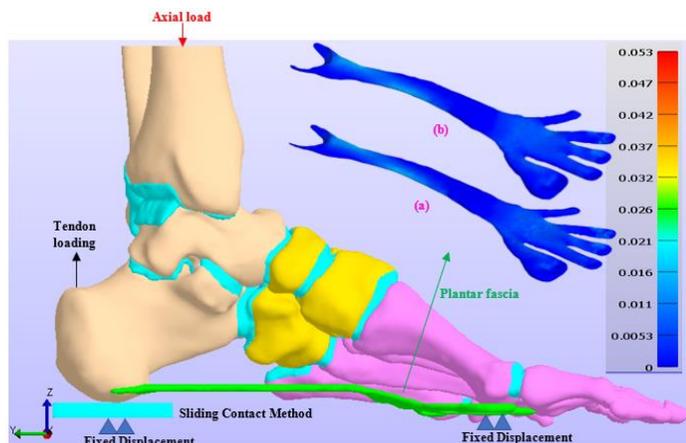

Figure 1 FE model of foot during standing contains; bones, cartilages (aqua), 3mm thickness plantar fascia (green) and strain in. 4mm (a) and 5mm (b) thick plantar fascia.

## Results and Discussion

The strain of the 3D FE models, when only the Achilles tendon loading was loaded from 0 to 500N, increased linearly from 0 to 0.0331. In an in vitro experiment with the same loading, the strain increased non-linearly from 0 to 0.023 [7]. Depending on the

thickness of the plantar fascia, the difference between the model and in vitro experiment varied by 6-17% before reaching 300 N of loading. Because of the linear elastic properties of the model, the variation increased to 36% difference from 300-500N of Achilles tendon loading at 5mm thickness plantar fascia (Fig 2). With the 700N axial load and for tendoachilles force varying from zero to 500N, the strain value ranged from 0.0214 to 0.0502 (Fig 2), and the percent increase in strain was also calculated 51% at 3mm thickness plantar fascia, 38% at 4mm thickness plantar fascia, and 29% at 5mm thickness plantar fascia. According to the simulation, the strain was decreased more with thicker plantar fascia and Achilles tendon loading. Therefore, further investigation of the characterization of soft tissue in this model must be conducted to analyze the plantar pressure and stress on hindfoot and forefoot. This model was also limited because it was only axially loaded and should be tested with off axis loads, and with non-linear and pathology specific material properties.

Plantar Fascia Strain with/without axial load

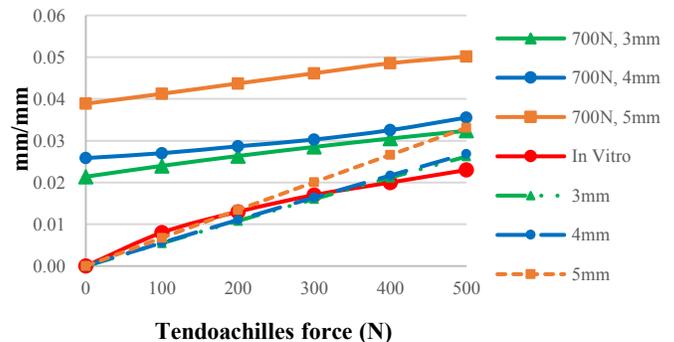

Figure 2 the strain results based on three different thickness plantar fascia compared with an in vitro experiment, with increasing ACH loading, but no axial load.

## Significance

A 3D finite element model with varying plantar fascia thicknesses was developed to understand the effect of plantar fascia thickness for a patient with plantar fasciitis and diabetes because a thicker plantar fascia was measured from the patients. Results indicated that, plantar fascia strain decreased with thickness of the plantar fascia, which suggests that this should be further investigated while examining aspects such as plantar pressure and peak stress on the soft tissue. In future iterations of the model, plantar soft tissues will be not included as well as non-linear and pathology specific material properties.

# Investigating Whole-Leg Contributions to Center-of-Mass Acceleration During Gait

Michael C. Rosenberg<sup>1</sup>, Katherine M. Steele<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, University of Washington, Seattle, WA

Email: [mcrosenb@uw.edu](mailto:mcrosenb@uw.edu)

## Introduction

The ability to effectively accelerate the center-of-mass (COM) is fundamental to walking performance and emerges as a combination of musculoskeletal dynamics, motor control, and control objectives [1, 2]. Predicting a clinical intervention’s impact on an individual’s capacity to accelerate the COM may inform treatment planning. However, the high-dimensional, nonlinear interactions of often-uncertain dynamics and motor control make quantifying intervention effects on an individual’s strategy and capacity for controlling COM acceleration challenging, particularly when uncertainty in such parameters exists. “Template” models, which encode high-dimensional COM acceleration strategies in low-dimensional lumped-parameter representations, may facilitate the interpretation of acceleration strategies without assumptions about uncertain physiological parameters [2]. However, if and how template models reflect COM acceleration strategies remains unclear.

We investigated the ability of a template walking model to elucidate whole-leg contributions to COM acceleration in a stroke survivor with left-leg hemiparesis, compared to unimpaired individuals. If an individual accelerates their COM asymmetrically, the template dynamics describing each leg’s contribution to COM acceleration should also differ. Therefore, we hypothesized that the dynamics representing the stroke survivor’s impaired leg’s contributions to COM acceleration would differ from their unimpaired leg, while unimpaired individuals’ legs would exhibit similar acceleration dynamics.

## Methods

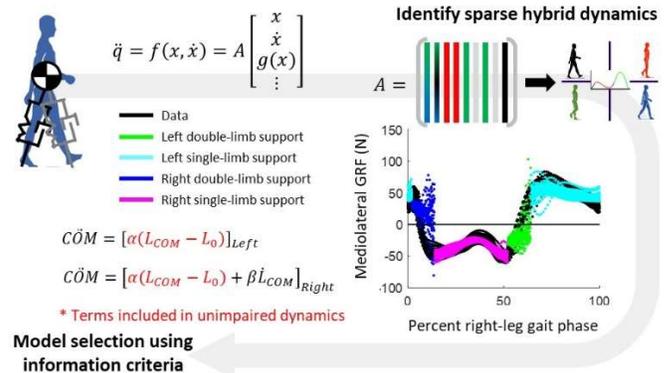

To identify differences in unimpaired and impaired control, we collected marker trajectories and ground reaction forces from seven unimpaired individuals (5F/2M, age = 23.7±2.3 yrs), for whom we expected similar control, and one stroke survivor with left-leg hemiparesis (F, age = 23 yrs), walking at a self-selected speed on a split-belt treadmill for three minutes. We computed COM positions, velocities, and accelerations in OpenSim 3.3 [3].

To identify COM acceleration dynamics for each participant, we used an algorithm that automatically identifies and validates low-dimensional hybrid dynamics capable of explaining, in this study, GRFs from kinematic data [4]. We modeled whole-leg control using variables based on a modified hybrid spring-loaded inverted pendulum: COM position and velocity, leg lengths and leg angles in 3D (Fig. 1) [5]. We identified and compared different candidate dynamics describing COM acceleration strategies (e.g. with or without velocity terms) using a two-minute training dataset and validated on a held-out thirty-second test dataset. Only dynamics with high prediction accuracy and low complexity were considered *plausible* strategies for COM acceleration. We compared the structure of the plausible dynamics over different gait phases across participants.

## Results and Discussion

For each phase of the gait cycle, one to two sets of plausible dynamics were identified among over 500 models generated from

the training data, supporting that the plausible models best reflected each participants’ acceleration strategies, given the candidate model dynamics. Plausible models predicted single-limb support GRFs well ( $r^2=0.70\pm0.37$ ) (Fig. 1), though prediction accuracies were reduced ( $r^2=0.23\pm0.28$ ) during double-limb support.

**Figure 1: Perimeter:** Pipeline for identifying plausible dynamics. Center: Model single-limb support dynamics (left) and predictions (right) for mediolateral COM acceleration in the stroke survivor.  $L$  and  $\dot{L}$  terms denote position and velocity control, respectively.

The stroke survivor’s unimpaired limb’s COM acceleration dynamics resembled those of the unimpaired participants, whose dynamics were symmetric. Leg position and velocity variables appeared in 100% and 42% of plausible anterior-posterior and mediolateral single-limb support dynamics, respectively, suggesting a heterogeneous reliance on velocity-based control during walking. Interestingly, the stroke survivor’s anterior-posterior and mediolateral dynamics included damping only in the unimpaired limb (Fig. 1), suggesting an increased reliance on position-based (elastic) control in the impaired limb. Unimpaired COM acceleration strategies appear to differ between individuals but remain symmetric, while template dynamics reflected asymmetric strategies in the stroke survivor.

## Significance

This work supports hypotheses that template models’ may elucidate how motor impairments alter COM acceleration strategies. Embedding these template models in physiologically-detailed dynamics may identify mechanisms that are associated with COM acceleration, informing predictions of response to interventions targeting those mechanisms.

# Bungee Method for Augmenting Human Treadmill Running

John R Rogers<sup>1</sup>

<sup>1</sup>Department of Civil and Mechanical Engineering, United States Military Academy, West Point, NY USA

Email: [john.rogers@westpoint.edu](mailto:john.rogers@westpoint.edu)

## Introduction

Researchers and designers of mechanical augmentation systems will benefit from improved understanding of the benefits and challenges of a simple augmentation system for running, regardless of whether their purpose is to enhance performance, to rehabilitate, or to replace lost function. This abstract describes a mechanical augmentation system that can be modelled in OpenSim to validate simulation-based prediction of metabolic expenditure in the presence of mechanical augmentation.

## Methods

This abstract describes methods of a study in progress. Subjects will run on a treadmill both with augmentation and without. Investigators will monitor the subjects' oxygen consumption, forces exerted by the augmentation system, and ground reaction forces detected by the treadmill. Body kinematics will also be monitored using anatomical markers and video motion capture. The experimental protocol will be reviewed by the US Military Academy Collaborative Academic Institutional Review Board. All subjects will provide written informed consent before they participate.

Leg swing during running will be augmented by the forward-acting force of latex rubber surgical tubing ("bungees") attached to the subject above the knees. The opposite end of the bungees will be anchored in front of the runner. The bungees act as springs which assist hip flexion. The subject self-adjusts the spring tension by moving forward or backward on the treadmill, backward to increase force, forward to reduce force (Fig. 1). The above-the-knee location is selected to emulate an exoskeleton prototype that was developed at USMA. The bungee force will vary from zero to a self-selected maximum, approximately 10% of body weight.

Metabolic power will be calculated from VO<sub>2</sub> measurements. Motion and force histories collected during trials will be input into OpenSim to simulate the running motion and to calculate the metabolic rate.

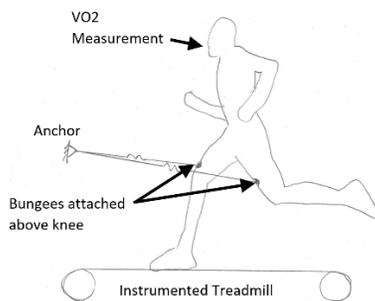

Figure 1: Experimental setup.

## Results and Discussion

Pilot data for a 92 kg male running at 3.4 m/s clearly indicate a metabolic benefit similar to running downhill. Metabolic rate in the pilot run was 740 W, 8.0 W/kg augmented, and 1250 W, 13.6 W/kg not augmented. The metabolic difference attributable to augmentation was 510 W. The bungee force (Fig. 2), peaked at

80 N per side; the average sum of left and right was 97 N. The equivalent mechanical work as if over-ground (force \* velocity) was 814 W.

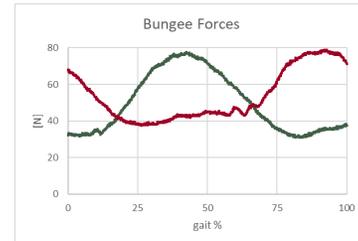

Figure 2: Augmentation force for one gait cycle. Peak force is 9% of body weight. (Pilot data.)

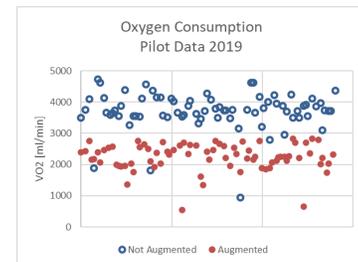

Figure 3: Metabolic data. Two minutes were allowed for VO<sub>2</sub> stabilization, then data were collected for five minutes. (Pilot data.)

Data (Fig. 3) show that the bungee cord augmentation provides a substantial metabolic benefit.

## Significance

The results of this study are expected to inform researchers, clinicians, and device designers in the field of mechanically-augmented human motion by providing insight about how external work replaces muscle work and thereby contributes to changes in metabolic rate. Robotic-assisted therapy is used in stroke rehabilitation. Exoskeletons and orthoses are used to augment human economy, strength, and endurance. Exoskeletons are used to assist with load carriage.

The project is relevant to any system that modifies human energy expenditure by mechanical means, including robotic rehabilitation. Augmentation could eventually help people with spinal cord injury or stroke to return to running.

## Acknowledgments

This project is supported by the USMA-ARL research fund. Thanks to Shane Murphy and Dr. Greg Freisinger of USMA. Additionally, thanks to Dr. Crowell and Mr. Tweedell of ARL.

# Predicted Gait Alterations due to Reduced Paretic Leg Muscle Synergy Complexity

Marleny Arones<sup>1</sup>,Carolynn Patten<sup>2</sup>, and Benjamin J. Fregly<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Rice University, Houston, TX, USA

<sup>2</sup>Department of Physical Medicine and Rehabilitation, University of California, Davis, CA, USA

## Introduction

Muscle synergies may provide a helpful avenue for predicting patient function following clinical interventions, such as those arising from neurorehabilitation or orthopedic surgery. Theoretically, muscle synergies reduce the achievable control space, making predicted muscle forces and consequently predicted motions more unique. In individual’s post-stroke a reduced number of muscle synergies has been associated with a deterioration in walking function [1] and an increase in metabolic cost [2].

This study predicted the effect of reducing the number and complexity of paretic leg muscle synergies on walking function for an individual post-stroke. Walking changes were quantified using predicted spatiotemporal symmetry measures.

## Methods

This study analyzed data from previously collected walking trials from a male subject suffering from stroke walking dysfunctions. The subject’s neuromusculoskeletal components were represented using four modeling elements: a kinematic model, an EMG-driven model, a foot-ground contact model, and a motion prediction model using the concept of muscle synergies; see [3] for more details.

The subject-specific neuromusculoskeletal model was used to develop four predictions for how the subject would walk after the number of synergies controlling the paretic leg were reduced from the calibrated case of five to two. In the *first* optimization, the two muscle synergies controlling the paretic leg were free to vary (*FCFW*). In the *second* optimization, the two synergy vectors of the paretic leg were constrained to be a linear combination of the original five synergy vectors while the synergy commands were free to vary (*FCCW*). In the *third* optimization, the paretic leg synergy commands were constrained to be a linear combination of the original five synergy commands while the synergy vectors were free to vary (*FWCC*). In the *fourth* optimization, the two muscle synergies controlling the paretic leg were constrained to be a linear combination of the original five paretic leg muscle synergies (*CCCW*).

After running all four predictions, the cost of transport (CoT) was calculated using Umberger’s model [4] along with ratios describing spatial and temporal symmetry.

## Results and Discussion

When walking motion was predicted using two synergies to control the paretic leg, an increase in CoT and a decrease in spatial symmetry were observed (Table 1, read from top to bottom). However, temporal symmetry did not follow the same pattern, consistent with Finley et al.’s 2017 [5] finding that temporal asymmetry was a poor predictor of CoT changes. These findings are consistent with the observation that individuals post-stroke have a more difficult time correcting spatial asymmetry than temporal asymmetries [6]. When the model’s paretic leg was controlled by two constrained muscle synergies (*CCCW*, the most limiting case), the model experienced hip hiking, the largest decrease in paretic knee range of motion, and the largest increase in paretic toe drop (Figure 1), which are consistent with clinical observations of hemiparetic gait.

**Table 1:** Cost of transport, and spatial and temporal symmetry measures

	CoT	Spatial	Temporal
5 Synergies	13.68	0.47	0.52
FCFW	15.89	0.39	0.53
FCCW	17.23	0.37	0.52
FWCC	19.08	0.23	0.42
CCCW	19.14	0.17	0.43

## Significance

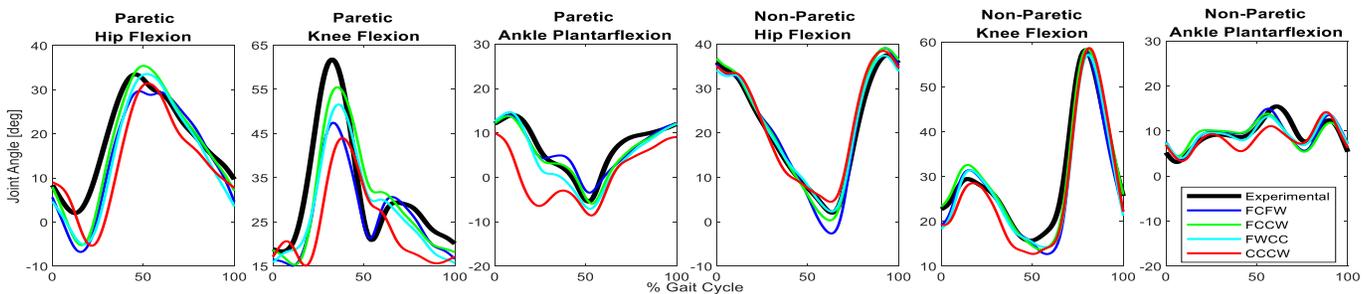

Our findings support the idea that less complex neural control building blocks may not be the reason for the degeneration of walking function. Rather, constraints on the remaining neural control building blocks may be the main problem.

# The Influence of Inter-joint Force-dependent Feedback on Whole Limb Impedance Over a Range of Frequencies

Thendral Govindaraj<sup>1</sup>, T. Richard Nichols<sup>2</sup>, and Gregory S. Sawicki<sup>1,2</sup>

<sup>1</sup>Woodruff School of Mechanical Engineering, Georgia Tech

<sup>2</sup>School of Biological Sciences, Georgia Tech

Email: tgovindaraj3@gatech.edu

## Introduction

Neural feedback pathways arise from a variety of sensory receptors. Muscle spindles measure changes in length and velocity, while Golgi tendon organs measure contractile force. Understanding the functions of these pathways is important because they become disrupted in stroke and Spinal Cord Injury. While length and velocity-dependent pathways are relatively localized, force-dependent feedback is asymmetric and can be widely distributed within the limb.

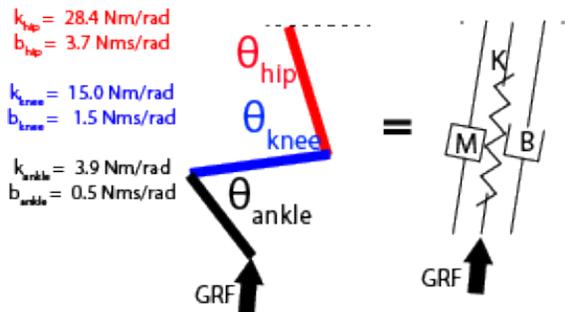

Although the muscle-level distributions of force feedback have been measured under different conditions, it is not known how these distributions regulate limb mechanics (stiffness and interjoint coordination). We analysed the frequency dependent impedance properties and interjoint coordination of a cat hindlimb with intrinsic musculoskeletal impedance. Our hypothesis was that force feedback would reduce whole limb impedance and promote proportional coordination between the knee and ankle.

## Methods

We developed a three segment model with realistic lengths and masses [1], with muscles represented as rotational springs and dampers, whose values are based on our physiological best guess, as shown below. The rest angles of the springs were chosen as weight acceptance during landing as defined in [2]. Force feedback was implemented as a generalized torque at the joints in addition to the spring and damper torques, and the values of these torques were calculated at each time step using the following equation, where  $\tau_{fb}$  is the force feedback torque,  $[\alpha]$  is a 3x3 matrix of force feedback gains,  $[K]$  is the stiffness matrix, and  $[B]$  is the damping matrix:

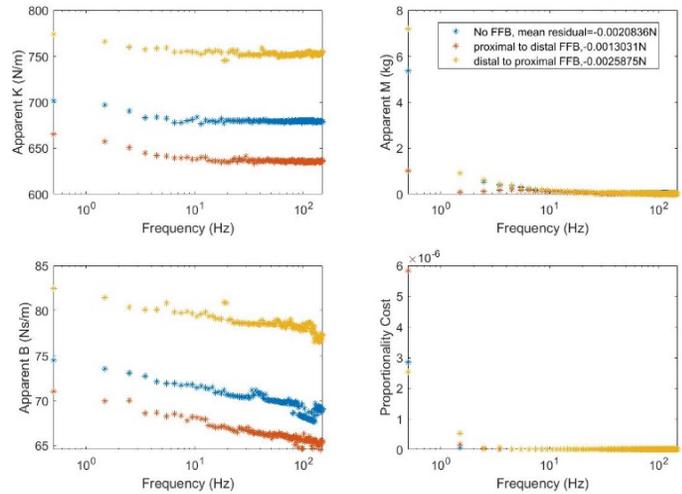

$$\tau_{fb,n} = [\alpha] * ([K]\{\Delta\theta_{n-1}\} + [B]\{\dot{\theta}_{n-1}\}) + \tau_{fb,n-1}$$

We performed a sinusoidal analysis based on the study in [3] adapted here to the whole limb. We applied an endpoint force whose average value was 60N directed at the hip joint center. Using a technique in [4], we calculated the apparent impedance properties and proportionality cost, defined as the integral of  $((\theta_k - \theta_{k0}) - (\theta_a - \theta_{a0}))^2$  over time for one sinusoidal cycle, over a range of frequencies for the uni-articular musculoskeletal distribution and two experimentally observed force feedback distributions between the ankle and knee [5].

These included a proximal to distal distribution, with inhibition directed towards the toes, and a distal to proximal distribution, with inhibition directed towards the knee.

## Results and Discussion

As expected, all of the impedance values were lower for the proximal to distal distribution of force feedback than for the uni-articular musculoskeletal distribution without force feedback. However, contrary to our hypothesis, these impedance values were higher for the distal to proximal force feedback distribution than for the uni-articular musculoskeletal distribution. Examining how force feedback influences the relative contributions of the joint torques to the overall limb force response will elucidate the reason for this outcome. Also contrary to our hypothesis, the proportionality cost was lowest for the uni-articular musculoskeletal distribution without force feedback.

## Significance

Patients with stroke and Spinal Cord Injury have impaired knee and ankle coupling compared to able-bodied humans. Therefore, understanding how force feedback influences interjoint coordination, and not only limb impedance, could inform the design of therapeutic and rehabilitation techniques (ex. robotic devices, drug therapies, surgeries).

# A Novel Closed-Loop MIMO Model for Studying the Effect of Spinal Afferents on Tremor

Ian Syndergaard<sup>1</sup>, Daniel B. Free<sup>1</sup>, Steven K. Charles<sup>1,2</sup>

<sup>1</sup>Mechanical Engineering and <sup>2</sup>Neuroscience, Brigham Young University, Provo UT

Email: ians@byu.net

## Introduction

Tremor is the most prevalent movement disorder in the world today; yet despite decades of research, the mechanisms of tremor propagation are not yet fully understood. Recent investigations of the mechanisms of essential tremor generation have provided strong evidence that tremor originates centrally. However, it remains unclear what role spinal afferents play in tremor modification and propagation.

Tremor propagation refers to the way a neural signal in one muscle creates movement in each degree of freedom (DOF) and to the interactions between movement in each DOF. Previous studies have explored the effects of spinal afferents in a single DOF, but did not model interactions between DOF. Other studies have investigated interactions between the DOF of the arm to determine fundamental principles of tremor propagation [1], but did not model afferent feedback. Thus, we present here a novel closed-loop multiple-input multiple-output (MIMO) model of the upper limb, which may provide much-needed insight on the role of spinal afferents in tremor.

## Methods

This model expands an open-loop model by Davidson et al. [1] and Corie et al. [2] as summarized in *Error! Reference source not found.*

The input to the model is a set of descending neural signals ( $u_{\text{descending}}$ ) to the 15 major superficial muscles of the arm. The forward path models the transformation of these descending neural signals to muscle forces ( $f$ ), then to joint torques ( $\tau$ ), and finally to joint displacements ( $q$ ) in the 7 DOF of the upper limb.

The inner loop models the effects of the Golgi tendon reflex. The outer loop models the effects of muscle spindles (both type Ia and type II). In the outer feedback path, joint displacements are transformed to muscle stretch ( $\Delta\lambda$ ), which is both multiplied by a reflex gain matrix (representing type II muscle spindles) and by  $s$  (to differentiate) and a reflex gain matrix (representing type Ia muscle spindles).

$C$  models the maximum voluntary contraction of each muscle.  $M$  represents the muscle moment-arm matrix.  $I$ ,  $D$ , and  $K$  model the inertia, damping, and stiffness of the joints, respectively. The  $G$  matrices model the reflex gains between homonymous and heteronomous muscle pairs.

Tremor was simulated by feeding the model a synthetic tremorogenic neural signal. An example output is shown in *Figure 2*. Outputs were processed by computing the power spectral

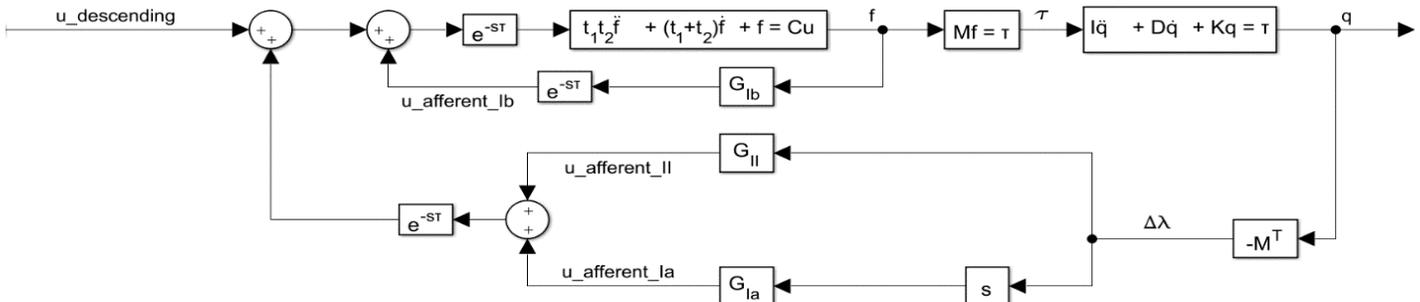

Figure 1 – A novel closed loop multiple-input multiple-output model of the upper limb.

density (PSD), then integrated over tremor frequencies (4-12 Hz) to find total tremor power. Reflex gains were multiplied by a range of scalar values and tremor power recalculated to determine the robustness of the simulated findings.

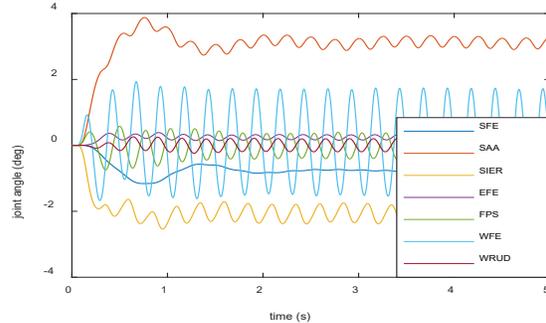

Figure 2 – An example simulation output for a 4 Hz neural signal input in the posterior deltoid.

## Results and Discussion

Simulation showed that reflexes generated by Golgi tendon organs did not significantly affect tremor power. The effect of muscle spindles changes depending on the frequency of the descending neural signal. At low input frequencies, spinal afferents tended to greatly attenuate limb motion. However, at tremor frequencies, reflexes between most muscle pairs did not significantly affect tremor. Ongoing research is attempting to identify all muscle pairs which have a reflex relationship that alters tremor at each tremor frequency.

## Significance

Optimal tremor treatment requires an understanding of the fundamentals of tremor propagation. This model provides valuable insights on the role of spinal afferents in tremor propagation, and may eventually lead to greater knowledge of where to intervene in the tremor pathway, thus improving tremor treatment and quality of life for those who suffer from this debilitating disorder.

# Validation of Musculoskeletal Models Using Single Degree of Freedom Analysis

Sepehr Ramezani<sup>1</sup>, Joseph Dranetz<sup>1</sup>, Matt S Stock<sup>2</sup>, and Hwan Choi<sup>1\*</sup>

<sup>1</sup>Department of Mechanical and Aerospace Engineering Department, University of Central Florida

<sup>2</sup>School of Kinesiology, University of Central Florida,

Email: \*[hwan.choi@ucf.edu](mailto:hwan.choi@ucf.edu)

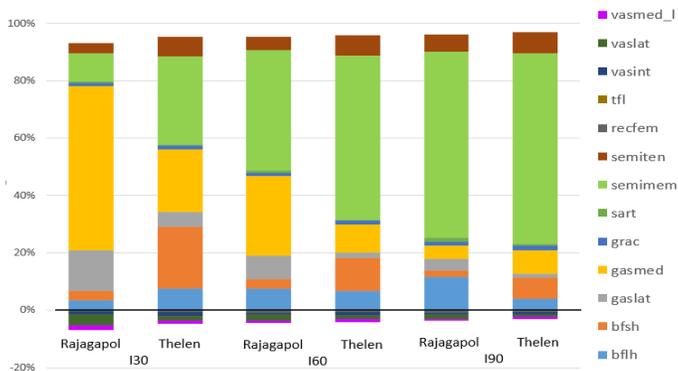

## Introduction

Musculoskeletal modeling is known as a non-invasive and cost-effective method for analyzing human motion and musculoskeletal function. Accurate data is required to develop valid models which are representative of the actual test conditions. Additionally, these analyses are extremely challenging due to the complex nature of musculoskeletal function. Thelen et al. measured muscle function and structure from cadavers in order to develop models for musculoskeletal analysis [1]. Although this model represents muscle activity and dynamics during walking reasonably well, there are some discrepancies with certain muscles. More recently, Rajagapol suggested another model which includes: muscle functions from previously conducted muscle experiments, muscle geometry from magnetic resonance image (MRI) of healthy young adults, and improvements to the calculation of muscle force [2]. These models are used to calculate muscle contributions during walking. Because analysis of muscle contribution in walking requires data on the complex motion and contact forces involved, it is difficult to compare the validity of each model. Therefore, in this study, we used two different musculoskeletal models to simulate motion with one degree of freedom, isometric knee flexion, and assessed the contributions of each muscle.

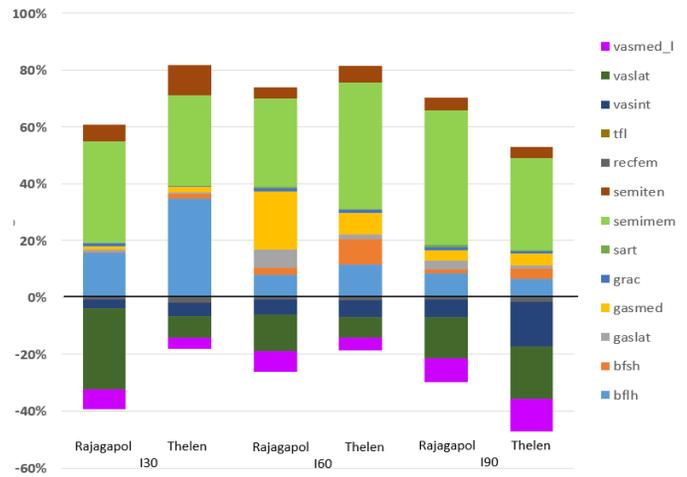

## Methods

Experimental data is collected from a 37 year old 196.7 cm height, 104 kg weight male. The subject performed isometric knee flexions at knee angles of 30, 60, and 90 degrees in a Biodex System 4 human dynamometer (Biodex Medical Systems, Shirley, NY). All the trials were randomized. The duration of isometric exercise was 20 seconds in each trial and the participant had 5 minutes resting between trials.

Two musculoskeletal models of Rajagopal et al. and Thelen et al., were used in Opensim to compare knee extensors and flexors in each testing condition. Anthropometric data of the participant were measured and in input into each generic musculoskeletal model for scaling.

**Figure 1:** SOP calculation of different muscle torque contribution of the knee joint moment represented in percentages.

**Figure 2:** CMC calculation of different muscle torque contribution of the knee joint moment represented in percentages.

Then, we used static optimization (SOP) and computed muscle control (CMC) to calculate muscle forces for the two different musculoskeletal models. For these methods, kinematic data and external force were acquired from goniometer and Biodex respectively.

## Results and Discussion

Both models obtained a small residual actuation moment, lower than  $3e^{-3}$  Nm, verifying our simulation. In both figures, the positive and negative percentages represent flexion and extension respectively. In figure 2, CMC employed more extensor muscles compare to SOP because CMC calculation uses forward dynamics to simulate muscle co-contraction.

By comparing each of the models in figure 2, the Rajagopal model dedicated a higher percentage of the total torque to extensor muscles in I30 and I60 conditions than the Thelen model. Another significant observation is the increased muscle contribution of the gastrocnemius at I60.

## Significance

In this experiment, muscle co-contraction plays a pivotal role in creating muscle forces. It is highly recommended to use the CMC tool when co-contractive muscle forces are expected.

The outcome of this study can be used as a guide for selecting the proper model and method when estimating muscular contribution to torque production.

Email: [brad.wham@colorado.edu](mailto:brad.wham@colorado.edu), [aldrich.valerian@colorado.edu](mailto:aldrich.valerian@colorado.edu), [zdenek.krobot@unob.cz](mailto:zdenek.krobot@unob.cz)

## Introduction

Occupant safety in the realistic car crash accident is typically solved as a problem of human body interaction with airbags and vehicle structure (vehicle seats, vehicle body parts, and others). There is also a situation when an unsecured object placed in the vehicle causes the injury of the vehicle occupant. The unsecured object can be described as a bottle, tablet, or laptop.

These unsecured objects are acting in the vehicle during its crash like projectiles, and they have a very significant potential to harm the vehicle occupant if they interact with their bodies.

An experimental investigation was performed to explain what can happen if the unsecured object interacts with the human body and what is the injury risk if this case happens. As a critical human body part was selected human head and as the traffic accident situation was taken frontal vehicle impact.

The hypothesis on which the whole experimental project was build on takes into account: The human head rear part interacts only with the unsecured object and nothing else (airbags, etc.); The seat head restraint is not present; The unsecured object is stiff and has initial speed during the crash similar as the vehicle crash velocity (friction effect is negotiable); The injury effect is blunt.

## Methods

Head injury experimental investigation was performed using equipment: Airgun (with pressure vessel and optical measuring barriers); Nylon body projectiles with different mass (0.5 [kg], 1 [kg], 1.5 [kg]) and hard rubber impact part; High-speed camera; Hybrid III 50<sup>th</sup> percentile male dummy with instrumentation; Vehicle seat with restraint system; DAQ system DEWE A4.

The computation of HIC (see Eq. (1) [2], and Eq. (2)) was done through Software NI DIADEM (Crash Analysis Toolkit).

The symbol  $a$  in Eq. (1) represents resultant head acceleration, and it is calculated from Eq. (2) where  $a_x$ ,  $a_y$ , and  $a_z$  are representing components of "resultant" acceleration. Symbols  $t_1$  and  $t_2$  are describing a time interval for the HIC calculation process (15 [ms]).

$$HIC = \max_{t_1, t_2} \left\{ \left( \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} a \, dt \right)^{2.5} (t_2 - t_1) \right\} \quad (1)$$

$$a = \sqrt{a_x^2 + a_y^2 + a_z^2} \quad (2)$$

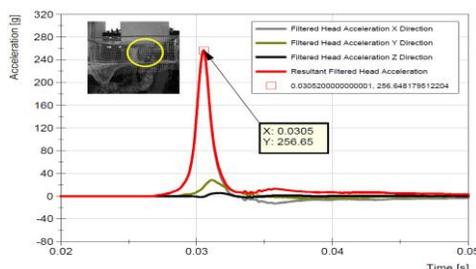

Figure 1: Filtered Impulse from Hybrid III Dummy Head – HIC Input

## Results and Discussion

Experimental data show (see Figure 2 and Table 1) that the dangerous speed of an unsecured object in the vehicle during frontal vehicle impact is around 50 [km/h] (HIC = 1000 [-]) [1]. The length of the impulse is short (approx. 1.5 [ms]), and other tools must be used to verify the injury potential calculated through HIC (Blunt Criterion usage).

The results show that the increasing mass (from 0.5 [kg] to 1.5 [kg]) of the unsecured object has a significant effect on the critical object speed (mass increases = dangerous unsecured object speed decreases – see Table 1).

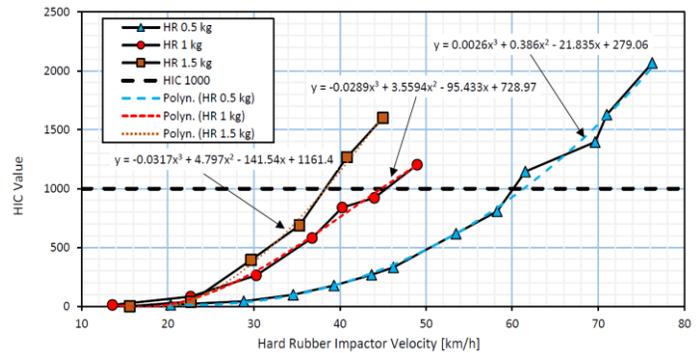

Figure 2: Interpretation of Critical Speeds of Unsecured Object Regarding Computed HIC (15 [ms]) – Comparison with HIC 1000

Projectile Velocity [km/h]	Resultant HIC [-] Projectile 0.5 [kg]	Projectile Velocity [km/h]	Resultant HIC [-] Projectile 1 [kg]	Projectile Velocity [km/h]	Resultant HIC [-] Projectile 1.5 [kg]
58	808	44	921	35	687
62	1144	49	1204	41	1266

Table 1: Critical Speeds of Unsecured Object Regarding Computed HIC (15 [ms]) – Comparison with HIC 1000

The experimental work is focused only on human head interaction (rear part) with unsecured stiff objects. In reality, the transported unsecured objects have different stiffness, and they can act differently than unsecured rigid objects.

## Significance

The significance of the experimental research lies in the description of how unsecured objects may act as projectiles during a vehicular crash. Many people are interested only in passive vehicle safety (airbag interaction) and don't care much about the objects they are transporting in the vehicle even that these objects may cause serious injury during the vehicular crash.

# Evaluation and Modeling of Falls onto Poured Rubber Playground Surfaces

Kyle B. Van Housen<sup>1</sup>, Matthew Lara<sup>1</sup>, and Sean D. Shimada, PhD<sup>1</sup>

<sup>1</sup>Biomechanical Consultants

Email: \*[sean@motionsandforces.com](mailto:sean@motionsandforces.com)

## Introduction

It is reported that emergency rooms treat approximately 200,000 playground injuries annually. Three-fourths of these injuries are from falls, mostly affecting the hand and wrist [1]. In recent years, poured rubber (PR) has become a popular choice for surfacing playgrounds. Its smooth look, vibrant coloring, low maintenance, and drainage properties give it clear advantages over other surfacing options, but how effective is it at preventing injuries?

PR is made from two layers: a base layer that provides springiness and a wear layer that protects from abrasion and light damage. Deterioration of the wear layer through overuse can potentially diminish its protective quality, but to what extent? This paper uses a combination of experimental and mathematical methods to determine an estimate for the safe fall heights of children onto PR surfaces both with and without the wear layer intact.

## Methods

### Experimental

A series of drop tests were performed in order to determine the response of PR to impact forces comparable to those that would cause an injury in children. Because of a lack of available data, Davidson et al. [3] developed an equation to predict fracture tolerance of the distal radius in children. For children ages 3 -7, 8-10, and 11-15, the compressive bone strengths calculate to 1390, 1849, and 2738 N, respectively. A metal shotput was dropped onto a Kistler (model 9286BA) force plate with a 15.2x15.2x5.1 cm section of PR securely attached. The shotput was dropped from heights that exceeded the compressive strengths given above. The force was recorded and the PR was found to closely match the response of a linear spring, where spring stiffness is a function of impact speed ( $p < .05$ ). The wear layer was removed and the experiment was repeated. The spring constants calculated from this experiment were then input into the mathematical model to accurately simulate the PR response for both conditions.

### Mathematical

Our model is based on previous work done by Chui and Robinovich [2], who developed a two-mass, spring, and damper system for falls onto an outstretched arm. Our model includes the addition of an extra spring layer that represents the PR surface. Deriving the equation of motion allows us to then make use of the MATLAB Simulink software package to simulate and plot the force on the palm/wrist as it makes contact with the PR.

The model requires inputs for the spring and dampeners that mathematically represent the joints in the arm. These values were experimentally determined by Chiu and Robinovich [2]. The mass  $m_1$  is the weight of the entire arm unit and the mass  $m_2$  is approximately 50% of the total body weight of an average 7 year old. The simulation was run with fall heights ranging from 1.2-1.8 m (4-6 ft) with and without the wear layer (Fig. 1).

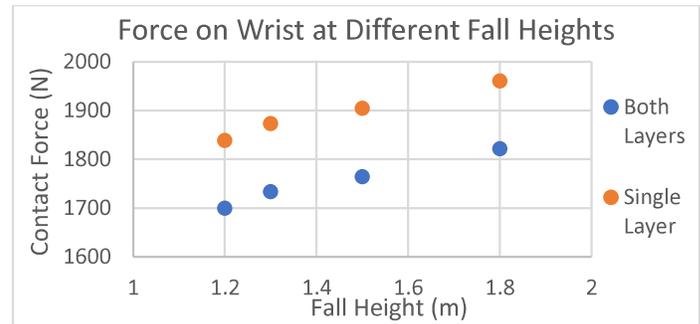

Figure 2: Peak force on the wrist with base and wear layer intact

## Results and Discussion

Our mathematical model predicts that falls of the body's center of mass (COM) from heights of 1.2-1.8 m (similar to the height the COM would fall from monkey bars) generate enough force to cause a distal radius compression fracture in children 3-7 years old. When you remove the wear layer, forces were found to increase by approximately 8% for all fall heights. This increase puts the 8-10 year olds at risk for heights exceeding 1.2 m. The wear layer is shown to provide a small but important layer of protection from falls. These results provide a tentative threshold value for safe fall heights onto PR, but are limited because they lack the inclusion of rotational forces and use averaged or mathematically obtained values for physiological properties.

## Significance

The mathematical model used here is applied in a novel application to simulate falls onto PR surfacing with an outstretched arm. Values for the stiffness of PR surfacing with and without the wear layer provide information on how the safety of playgrounds change with constant use. These results stress the importance of continual maintenance of playground facilities in order to minimize risk of injury to children. This is only one scenario that can be simulated using this method, by changing spring values and physiological parameters you can simulate falls for a variety of different ages and ground materials.

## Introduction

Shoulder pain and injuries are prevalent in manual wheelchair users due to the high, repetitive loads required [1]. Weaker shoulder muscles are correlated with shoulder pain development [2] and a recent modeling study found that compensating for weakened shoulder adductors results in increased muscle stress in the rotator cuff muscles [3]. In addition, those that use a single-loop (SL) hand pattern experience the highest overall muscle power and stress compared to the other patterns, particularly in the middle deltoid and rotator cuff muscles [4]. Although previous research found no correlation between hand pattern and future pain development [5], this may have been due to analyzing propulsion at self-selected speeds. Fast wheelchair propulsion may exacerbate underlying poor mechanics due to the higher loads experienced that may not be seen during self-selected conditions.

The purpose of this study was to determine whether the hand pattern used during fast wheelchair propulsion correlates with shoulder pain development. A secondary purpose was to determine whether shoulder adductor strength correlates with the hand pattern used during fast propulsion. We expect that individuals who develop pain use more over-rim (e.g., SL) hand patterns and that weaker shoulder adductors will be correlated with more over-rim patterns.

## Methods

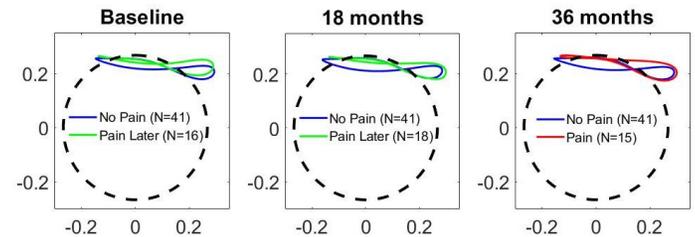

Kinematic, kinetic and strength data from 60 individuals with paraplegia (56 men, 4 women; age=35.9±8.31 yrs; time since injury=10.1±5.86 yrs; height=1.74±0.10 m; mass=76.8±16.0 kg) were analyzed from a previously collected dataset [2]. Data were collected at baseline, 18 and 36 months after baseline during propulsion at their fastest comfortable speed. Participants were asymptomatic for shoulder pain at baseline, and self-reported shoulder pain at the follow-up assessments. The no pain group were pain-free at all time points, while the pain group had shoulder pain at only the 36-month time point.

Strength was measured as the maximum isometric torque from the shoulder adductors, abductors, flexors, extensors, internal rotators and external rotators. Hand patterns were quantified using net radial thickness (NRT) and total radial thickness (TRT) of the closed-curve hand path. NRT indicates the hand's displacement above the handrim, and TRT indicates the absolute distance between the hand and handrim [6]. Linear mixed-effects models were used to determine if the hand pattern and shoulder strength were significantly different between the pain and no pain groups. An additional model was created to determine if weaker shoulder adductors correlates to using a more over-rim pattern (e.g., higher NRT values).

## Results and Discussion

There was a trend for the pain group to use more over-rim patterns (e.g., SL) than the no pain group (Fig. 1), however there were no significant differences between NRT and TRT between groups at any time point. Higher NRT values (e.g.,

more over-rim patterns) significantly correlated with lower shoulder adduction strength ( $p=0.042$ ). Of the strength measures, only adduction strength was significantly lower in the pain group ( $p=0.036$ ). In addition, internal rotation strength significantly decreased over time, regardless of whether they developed pain or not ( $p=0.004$ ).

**Figure 1:** Hand patterns across time for the no pain (blue; NRT for all times =  $-0.01 \pm 0.06$  m) and pain (green = pre-pain, red = pain present, NRT for all times =  $0.02 \pm 0.05$  m) groups.

Contrary to our expectations, individuals that developed pain did not use a hand pattern that was more over-rim than the no pain group during fast wheelchair propulsion. Even though the SL pattern requires higher muscle power and stress [4], cadence and handrim forces [7] than other hand patterns, the results of this study suggest that simply changing hand pattern is not sufficient to prevent shoulder pain development. Weaker adductors were significantly correlated to more over-rim hand patterns, which would suggest that the use of the SL hand pattern during fast propulsion may be indicative of shoulder muscle weakness. However, the marginal  $R^2$  value of the correlation between shoulder adductor strength and NRT was low ( $R^2=0.019$ ), highlighting the large variability across subjects.

## Significance

This study showed that the hand pattern used during fast wheelchair propulsion does not predict shoulder pain development. However, more over-rim patterns were correlated to weaker shoulder adductors, although this correlation had large variability. Therefore, further research is needed to verify this relationship before we can use hand pattern as an indicator of shoulder adductor weakness.

# Relationship Between Blood Perfusion and Pressure: A Study with Wheelchair Users and Able-Bodied Individuals

Justin Scott<sup>1</sup> and Tamara Reid Bush<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Michigan State University, East Lansing, USA

Email: [reidtama@msu.edu](mailto:reidtama@msu.edu), [scottju5@msu.edu](mailto:scottju5@msu.edu)

## Introduction

Pressure ulcers (PUs) are a pressing issue for wheelchair users, with 47% of individuals affected [1]. PU development is linked to sustained, external pressures. These pressures lead to reduced capillary blood flow, or perfusion, in the loaded tissues [2]. A third of PUs in wheelchair users occur in the buttocks; thus strategies to relieve pressure and increase perfusion to this region are critical [3]. Currently, the most common movements for pressure relief in wheelchairs are recline of the back and whole body tilt [4].

Studies that investigated pressure relieving movements had limitations. No studies investigated changes in pressure and blood perfusion in the buttocks while using pressure relieving movements, even though both have been shown to be linked to PUs. Further, most seated load data were collected from able-bodied people, while the majority of people who experience PUs use wheelchairs. Research has shown differences between pressure distributions in wheelchair users and able-bodied individuals, thus it is important the wheelchair user population be included in studies evaluating pressure relieving strategies [5].

Therefore, the goals of this work were to quantify trends in pressure and perfusion data on the buttocks of wheelchair users during three movements: 1) whole body tilt, 2) back recline and 3) isolated seat pan tilt, during which the anterior edge of the seat pan is higher than the posterior edge.

## Methods

Twenty able-bodied people (ten males, ten females) and ten male wheelchair users volunteered for this study (IRB#15-889). An articulating chair was created with independent seat pan tilt and back recline to test combinations of the two movements.

Data were gathered on seated participants as the articulating chair moved through nine positions, with three angles of seat pan tilt (0°, 15°, 30°) and three angles of back recline (0°, 10°, 20°). Positions in which there were both a seat pan tilt and back recline created a whole body tilt. A perfusion sensor attached on the skin over the ischial tuberosity collected data in all positions. A pressure mat recorded data on the seat pan for each position, and data were split into two regions, buttocks and thighs (back and front halves of the mat).

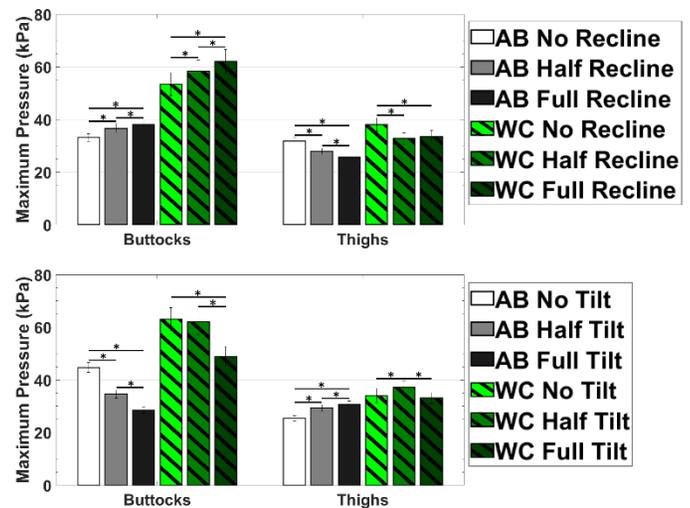

## Results and Discussion

Trends in perfusion values differed between the two groups. Perfusion in able-bodied people increased with seat pan tilt ( $p = 0.0006$ ) and decreased with back recline ( $p = .046$ ). No significant trends in perfusion emerged in wheelchair users.

The maximum pressures in wheelchair users were larger than those in able-bodied people, but trends in maximum pressures in each region with respect to chair position were consistent in both groups. Maximum pressure in the buttocks increased with recline and decreased with seat pan tilt for both groups ( $p < .0001$  for all). Maximum pressures in the thighs decreased with back recline ( $p < .0001$  for both) and increased with seat pan tilt in able-bodied people ( $p < .0001$ ).

**Table 1:** Perfusion values for each group in each seat pan tilt and back recline, normalized by the maximum value within each participant. Perfusion in able-bodied individuals increased with seat pan tilt and mixed trends were seen in wheelchair users.

	Able-bodied			Wheelchair User		
	0° Tilt	10° Tilt	20° Tilt	0° Tilt	10° Tilt	20° Tilt
0° Recline	0.42	0.48	0.69	0.50	0.39	0.50
10° Recline	0.37	0.50	0.53	0.55	0.41	0.46
20° Recline	0.35	0.42	0.52	0.49	0.54	0.46

**Figure 1:** Magnitudes of the maximum pressures, by recline angle (top) and seat pan tilt (bottom). Able-bodied (AB) data are solid bars, and wheelchair user (WC) data are striped. Maximum pressure increased in the buttocks with back recline and decreased with seat pan tilt (\* indicates significant differences). Opposite trends were seen in the thighs.

## Significance

This work indicated that the movement most commonly used to relieve pressure on the buttocks while seated (i.e., recline) was not effective in relieving pressure or restoring perfusion. However, increasing the seat pan tilt relieved pressure on the buttocks of both groups and increased perfusion in able-bodied individuals. Thus, seat pan tilt has the potential as a strategy for reducing PUs. Because each movement decreased pressure in one area while increasing it in another, these movements may need to be cycled through to reduce overall PU risk in every region.

# Females Exhibit Higher Hamstring Activation Prior to Landing and Reduced Activation After Acute Fatigue

David Phillips, Bridgette Buckalew, Jacklyn S Alencewicz, Bridget Keough  
Department of Exercise Science and Physical Education, Montclair State University  
Email: phillipsdav@montclair.edu

## Introduction

Anterior cruciate ligament (ACL) injuries occur more commonly in females compared to males. Possible intrinsic risk factors can be found in the areas of strength, anatomy, biomechanics (kinematics and kinetics parameters), fatigue, and neuromuscular coordination. The hamstrings receive particular attention as they help counteract the shear forces generated by the quadriceps during landing [1]. This reduces the load borne by the ACL. Because ACL injuries happen rapidly, how athletes activate their hamstrings prior to landing may influence their landing mechanics and injury risk. This activation and coordination can also be affected by the fatigue state of the athlete.

The purpose of this study is to investigate hamstrings activation characteristics prior to landing before and after a fatigue protocol. We hypothesize that males will have a higher hamstrings activation than females and that hamstrings activation amplitude will increase after fatigue.

## Methods

Twenty four subjects (13 males, 11 females) participated in the study. Maximum vertical jump was used to estimate peak lower extremity power and quantify fatigue. Subjects performed 3 trials of a drop vertical jump from a 30 cm box onto 2 force plates. Electrodes were placed bilaterally on the biceps femoris muscles. Data were sampled from the force plates and EMG synchronously at 2000 Hz. Subjects then performed a fatigue protocol of bodyweight squats at 60 Hz until exhaustion. Immediately after the fatigue protocol (<1min), subjects performed a maximum vertical jump and 3 successful drop vertical jumps. Two dimensional video was recorded from the sagittal and coronal planes. Dependent variables included max vertical jump power, normalized peak vertical ground reaction force (vGRF), time to peak vGRF, Landing Error Scoring System (LESS), and hamstrings muscle activation 200 ms, 150 ms, 100 ms, 50 ms, & 0 ms before landing.

EMG data was band-pass filtered, 20 Hz – 500 Hz, and smoothed using a 50 ms root-mean-squared window. EMG data were normalized to a MVC contraction and maximum activity measured during the non-fatigue jumps. Force plate and LESS variables were assessed using a mixed 2x2 ANOVA with fatigue (within subjects factor) and sex (between subjects factors). Hamstrings activation was assessed with a mixed 2x5x2 ANOVA with fatigue and time before contact (within subject factors) and sex (between subject factor). The effect of fatigue on peak vertical jump height was assessed with a dependent *t*-test.

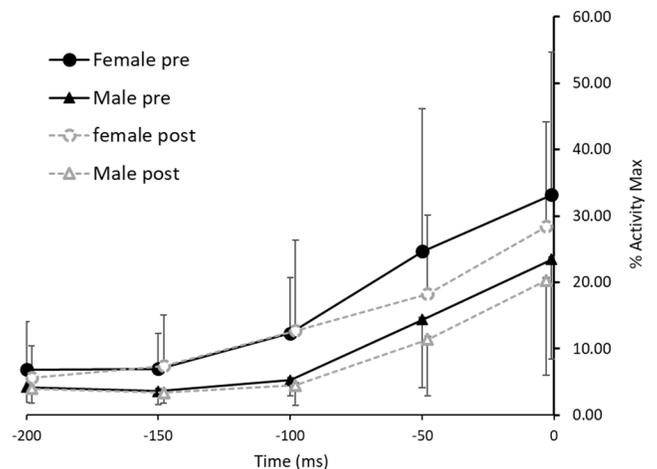

## Results and Discussion

There was a 63% reduction in max vertical jump height after fatigue ( $p < 0.001$ ). No significant effects were found for normalized peak vGRF or time to peak vGRF. For hamstring activation, there were significant main effects for fatigue ( $p = 0.02$ ), time ( $p < 0.001$ ), and sex ( $p = 0.038$ ) (Figure 1). In both sexes, hamstring activation increased until contact, with males

having lower activation compared to females. Fatigue reduced hamstring activation similarly between sexes.

Females had 2.3, 1.7, & 1.4 times the hamstring activation of males at 100 ms, 50 ms, and 0 ms respectively before fatigue. The increased activation remained similar to these amounts after fatigue, but both sexes saw reduced overall activation at 50 ms and 0 ms.

These results are opposite to our hypothesis. We expected females to have lower activation because of the higher incidence of ACL injury. Lower activation would mean less preloading of the hamstrings prior to landing and more shear force being placed on the ACL at landing. Three of the four studies examining hamstring pre-activation, including this study, found higher hamstring pre-activation whereas only one found lower hamstrings pre-activation in females prior to landing [2]. There appears to be a sex-related difference in lower extremity coordination when preparing to land. Acute fatigue affects the landing strategy similarly between sexes with a reduction in hamstring activation.

**Figure 1:** Hamstring prior to landing before and after fatigue, normalized to maximum EMG activity during prefatigue jump landings. Error bars are standard deviation.

## Significance

These results support the continued investigation of the hamstrings muscle group as a factor in ACL injuries and as a target for preventative intervention strategies. Caution should be exercised when directly linking to ACL injuries as the activation differences may be due to anatomical differences that require different motor patterns for a landing rather than a pathological origin. As acute fatigue shows an effect on hamstrings activation, clinicians and coaches could choose muscle activation as a potential evaluative method for interventions or training status.

# A Threshold-based Algorithm for the Detection of Pre-impact Falls-from-Height

Haneul Jung, Bummo Koo, Yejin Nam, Taehun Kim, Gyoobaek Cho and Youngho Kim\*  
 Department of Biomedical Engineering and Institute of Medical Engineering, Yonsei University, Korea  
 Email: \*[younghokim@yonsei.ac.kr](mailto:younghokim@yonsei.ac.kr)

## Introduction

The mortality rate of falls-from-height (FFH) is the highest among accidents occurring in construction site. According to BLS data, 366 of 971 construction fatalities were caused by FFH in 2017 [1]. Even though many fall prevention trainings have been provided to workers and supervisors in order to prevent these fall accidents [2,3], they did not reduce fall accidents significantly. Recently, some researches regarding the wearable airbag have been conducted to minimize the damage of inevitable fall accidents [4,5]. Therefore, the algorithm for the detection of pre-impact FFH is essential to guarantee enough lead time (the time interval between the detection and the collision) for inflating the airbag. A threshold-based algorithm for the detection of pre-impact FFH was developed in this study.

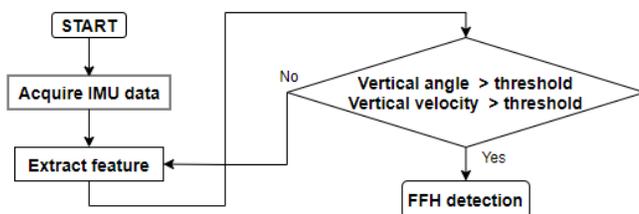

## Methods

Totally 20 healthy male volunteers (age:  $24.75 \pm 1.37$  years, height:  $174.05 \pm 4.86$  cm, weight:  $73.7 \pm 10.05$  kg) participated in the study and were equipped with an IMU sensor on thoracic vertebrae 6 (T6). They performed nine different types of non-fall motions and one FFH (Table 1). FFH was performed on a 40cm mattress for the safety. The present study was approved by the Yonsei University Research Ethics Committee (1041849-201911-BM-166-01), and the written informed consent was obtained from every experiment participant.

**Table 1:** List of experimental motions.

1. Sit quickly and get up	6. Working with pickaxe
2. Sit on the floor and get up	7. Lifting (Front)
3. Stair up and down	8. Lifting (Back)
4. Ladder up and down	9. Lifting (Side)
5. 0.7m height jump	10. 0.7m height forward fall

Due to the safety issue, the actual FFH experiment was performed only from 0.7m height. Instead, a ball-jointed doll was used to perform FFH motions from the heights of 1.5m, 2m and 3m. In addition, Pam-Crash (ESI Group, France) program and human model (HARB) were used to simulate FFH motions in computer. Vertical angle was calculated using the complementary filter with proportional integral controller [6], and vertical velocity was determined by integrating vertical acceleration. Vertical acceleration was obtained by the Euler transformation of 3-axis accelerations [7]. A threshold-based algorithm for the detection of pre-impact FFH is shown in Figure 1.

**Figure 1.** The flow chart of FFH detection algorithm.

The thresholds were set using the receiver operating characteristic curve with randomly selected 10 participants' data. The rest of 10 participants' data was used to test the algorithm.

## Results and Discussion

The present algorithm resulted in 100% accuracy of pre-impact FFH detection. Table 2 shows the lead time obtained from the experiment and the simulation for different heights of falls. Since the inflation time of our wearable airbag system was about 200ms [5], it can be said that enough lead time was obtained in this study. In addition, results from the simulation and the experiment were in good agreement.

**Table 2:** Lead times from the experiment and the simulation (unit: ms).

Fall height	0.7m	1.5m	2m	3m
Experiment	324.3±46.7	380±10.9	462±11.7	592.5±17.8
Simulation	320	340	430	570

However, the number of subjects in this study was relatively small and the number of non-fall motions was insufficient to represent actual activities in construction site. A wearable airbag system to protect workers from inevitable fall accidents has been developed and it is necessary to evaluate the algorithm with various activities in construction site.

## Significance

The construction site has many dangerous works and environments. In particular, many activities at high place are inevitable in construction and FFH frequently occurs. Many efforts have been made to prevent these accidents including safety training and installing guardrail and safety net, but a high incidence of FFH still remains. A wearable airbag system has been developed to minimize serious damages caused by FFH. The present threshold-based algorithm for the detection of pre-impact FFH would be essential in developing the wearable airbag system.

# A Predictive Model for Stress Fractures in Runners

Yannis K. Halkiadakis<sup>\*,1</sup>, Helia Mahzoun Alzakerin<sup>1</sup>, Kristin D. Morgan<sup>1</sup>

<sup>1</sup>Department of Biomedical Engineering, College of Engineering, University of Connecticut, Storrs, CT, USA

Email: \*[Yannis.Halkiadakis@uconn.edu](mailto:Yannis.Halkiadakis@uconn.edu)

## Introduction

Up to 50% of all running injuries are attributed to stress fractures [1]. Milner et al. (2006) found that vertical loading rate was greater in female runners with history of tibial stress fractures [1]. Additionally, elevated impact peak has also been reported in individuals suffering from stress fractures [2]. These findings suggest an inability to attenuate tibial shock. While loading rate and impact peak are often analyzed independently, this study explored the relationship between these variables during running to determine if a combined metric could more effectively delineate between those with and without stress fractures. We hypothesized that the relationship between loading rate and impact peak would be a better feature to help differentiate and more accurately classify between runners with and without a history of stress fractures than either feature on its own.

## Methods

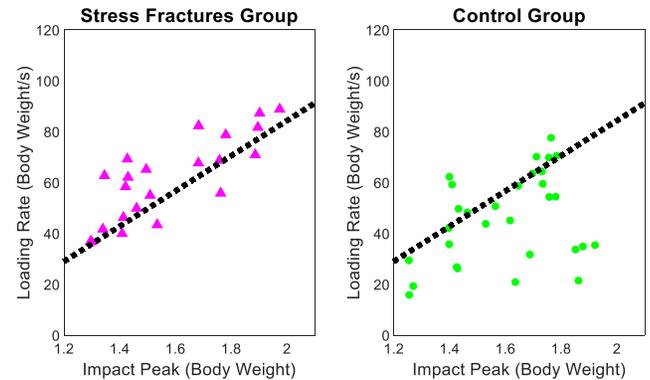

Fifteen controls (age  $19.1 \pm 0.8$  yrs; height  $1.78 \pm 0.08$  m; mass  $64.7 \pm 8.7$  kg) and 11 individuals with history of stress fractures (age  $19.4 \pm 0.8$  yrs; height  $1.77 \pm 0.08$  m; mass  $63.7 \pm 6.9$  kg) participated in a running protocol. Each participant provided written consent to participate in the study in accordance with the institutional review board. Participants ran on an instrumented split-belt treadmill (Bertec Corporation, Columbus, Ohio). Participants started with a two-minute warm-up period where they ran at 2.5 m/s followed by running at 3.3m/s for 30 seconds. Running parameters were then extracted from the vertical ground reaction force (vGRF) data that was collected at 1200 Hz and low-pass filtered at 35 Hz using a 4<sup>th</sup> order Butterworth filter.

The variables of interest were impact peak, loading rate and loading rate to impact peak ratio. The impact peak is the first vGRF peak during each stride. The loading rate is the slope between 20 and 80% of the vGRF data between foot strike and impact peak [1]. Both impact peak and loading rate were normalized to individuals body weight (BW). The ratio was created by dividing the loading rate by the impact peak. An unpaired t-test determined if the means of the variables of interest were significantly different between the two groups ( $\alpha=0.05$ ). Then each single feature was tested as the predictor using a Linear Support Vector Machine algorithm to classify between the two groups. A more advanced model was created by fitting a linear regression model to the control impact peak and loading rate data that provided upper and lower 99% confidence limits. The upper 99% confidence limit served as a dividing line to delineate between the control and stress fracture individuals.

## Results and Discussion

Both loading rate and the ratio were significantly greater in the stress fracture individuals than controls ( $p<0.01$ ;  $p<0.01$ ) (Table 1). No significant difference was found in impact peak ( $p=0.68$ ) (Table 1). The assessment of the linear relationship and associated classification line successfully placed 81% of the stress fracture individuals in the injured region (Fig. 1). The overall model accuracy of appropriately classifying individuals in either the stress fracture and control groups was 75%.

The results support the hypothesis that the ratio of loading rate over impact peak is a more impactful feature than loading rate or impact peak on their own. Impact peak showed a 58% classification accuracy (sensitivity = 0.50, specificity = 0.63, AUC = 0.57), loading rate showed a 65% classification accuracy (sensitivity = 0.59, specificity = 0.7, AUC = 0.68), and loading rate over impact peak showed a 71% accuracy (sensitivity = 0.64, specificity = 0.77, AUC = 0.75). This shows that the relationship between impact peak and loading rate can be considered as a more significant feature than either on their own.

**Figure 1.** Comparison of the scatter plots of impact peak versus loading rate for the stress fracture and control groups. The line is the stress fracture classification line, which is the upper 99% confidence limit for a linear regression model based on the control individuals.

## Significance

This model furthers the understanding of how stress fractures impact the gait patterns of runners and has potential to be used as a real-time, gait retraining tool to help runners lower their risk of stress fractures [3]. A limitation of this study is that it was performed on Division I athletes. Future studies will evaluate how this relationship applies to runners of all levels.

## Acknowledgments

We would like to acknowledge Dr. Brian Noehren for providing the data for this study.

## Pressure Relief in Wheelchair Users with Static Posture Changes

Paige Cordts<sup>1</sup>, Justin Scott<sup>1</sup>, Tamara Reid Bush<sup>1</sup>, PhD

<sup>1</sup>Michigan State University College of Engineering

Email: cordtspace@msu.edu, reidtama@msu.edu

### Introduction

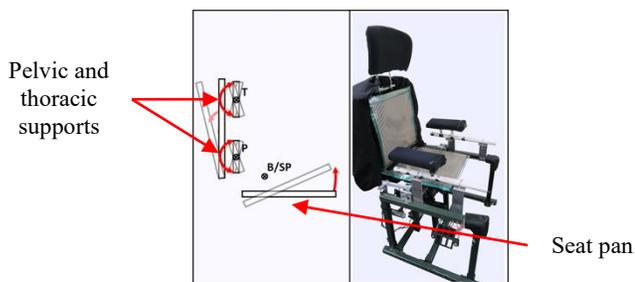

Many wheelchair users experience pressure ulcers (PUs), caused by prolonged periods of external loading and high pressures on the body. PUs can result in infections, longer hospital stays, and increased healthcare costs<sup>1</sup>. The seated posture generally produces concentrated pressures around the buttocks, distal thigh, sacrum, and shoulders, thus making these high risk regions for a PU formation<sup>2</sup>. To relieve the pressure on high risk regions of the body, we investigated a large set of postures to identify those that would be able to shift where pressure is concentrated on the legs and back while seated.

### Methods

Twenty able-bodied adults (10 male, 10 female) volunteered for this study. A chair was constructed with independently tilting pelvic and thoracic supports on a reclining back, and an independently tilting seat pan. All three supports were mounted on six-axis load cells (AMTI, Watertown, MA) and each driven by independent motors.

Pressures on the thighs, buttocks, and back were measured via pressure mats (Tekscan, Boston, MA) mounted to the seat pan and back of the chair. 27 postures were tested on each participant, each held for one minute to allow settling to occur. These postures were defined by the following angles: (1) back recline 0° (vertical), 15°, 30°, (2) seat pan tilt 0° (horizontal), 15°, 30°, and (3) back posture 0° (vertical) thoracic and pelvic tilt, 5° thoracic tilt and -15° pelvic tilt, 5° pelvic tilt and -15° thoracic tilt. Posture order was randomized for each participant to correct for possible influence from testing fatigue.

Pressure data collected from each of these postures were visually analyzed to determine postures with high and low pressure on specific regions of the body: the distal thighs, buttocks, lower back, middle back, and upper back.

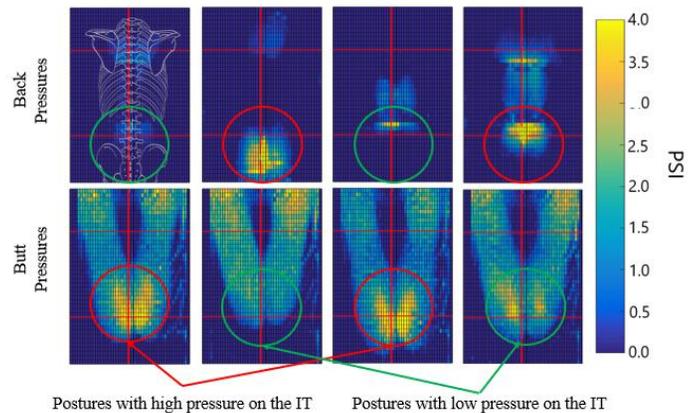

**Figure 1:** Prototype of the articulating wheelchair used for testing selected postures. Separate motors were used to control the seat pan tilt, recline, and thoracic and pelvic tilts.

### Results and Discussion

Areas of highest and lowest pressure were determined for each of the 27 postures. A sample set of postures were identified that could significantly shift pressures from one region to another. Pressure shifts occurred from the butt to distal thigh, and between

low, mid, and high back regions. These identified trends were used to determine which static postures would be ideal for offloading specific regions of the body.

**Figure 2:** Sample set of postures used to demonstrate areas of high and low pressure. An emphasis was placed on shifting pressure away from commonly loaded areas for a given posture. Areas loaded in each posture are indicated with red circles, while green circles indicate relief or absence of loading in subsequent postures.

### Significance

These data are significant for wheelchair design and use, as they show that there is a correlation between position of articulating wheelchair segments and pressure in the buttocks, thighs, and back. With these data, we have identified postures that could be used to offload pressure in a specified region of the body in order to prevent the long periods of external loading that cause PUs. These postures all emphasize placing loading on one region of the body, while attempting to reduce pressure on the other high-risk regions. While the body cannot be completely unloaded while seated, these varying postures reduced loading, thus reducing the likelihood of tissue necrosis and PU formation. Future work will determine how long each posture needs to be held for effective pressure relief.

## Bilateral Differences in Lumbopelvic-Hip Complex Kinematics during the CKCUEST

Jeff W. Barfield.<sup>1,\*</sup>, Nicole M. Bordelon<sup>2</sup>, Kyle W. Wasserberger<sup>2</sup>, and Gretchen D. Oliver<sup>2</sup>

<sup>2</sup>Sports Medicine Movement Lab, School of Kinesiology, Auburn University; Auburn, AL, 36849

Correspondance Email: \*[jbarfield@lander.edu](mailto:jbarfield@lander.edu)

### Introduction

The closed kinetic chain upper extremity stability test (CKCUEST) is a reliable test used by clinicians and coaches to assess an athlete's recovery from an upper extremity injury by examining lumbopelvic-hip complex (LPHC) and upper extremity stability.<sup>1</sup> In particular, the CKCUEST is a beneficial assessment for overhead athletes participating in unilateral rotational sports which require the body to perform efficiently as a kinetic chain. For example, baseball pitchers repeatedly rotate towards their non-throwing side which, over time, can result in asymmetric LPHC and upper extremity movement patterns.

Clinicians and coaches can benefit from understanding the effect of chronic unilateral rotational motion on LPHC stability, which in turn, impacts upper extremity movement efficiency.<sup>2,3</sup> Therefore, the purpose of this study was to examine how LPHC kinematics differed between dominant and non-dominant hand touches during the CKCUEST in a group of baseball pitchers. We hypothesized that LPHC kinematics observed on a dominant hand touch would differ from the non-dominant hand touch. Specifically, greater compensatory movement patterns, evidenced by increased LPHC kinematic deviation from neutral, would be observed upon a non-dominant hand touch compared to a dominant hand touch.

### Methods

Kinematic data from nineteen baseball pitchers (17.71 ±1.98 yrs; 184.92 ± 6.02 cm; 81.75 ±13.78 kg) performing three trials of the CKCUEST<sup>1,4</sup> were collected at 240 Hz with an electromagnetic tracking system. Data from all three trials of the CKCUEST were averaged at the middle touch as determined by Tucci and colleagues.<sup>4</sup> Dominant hand was indicated by the participants' throwing arm. The inverse value of left hip ab/adduction was used for analysis so that data would be relatable to right hip ab/adduction data. Paired samples t-tests were used to assess differences in LPHC kinematics upon dominant and non-dominant hand touching. Specifically, stance width, pelvic axial rotation, and bilateral hip ab/adduction between dominant and non-dominant hand touching were the LPHC kinematics analysed. Cohen's d was used to assess effect size. Testwise error was set at  $\alpha=0.05$ .

**Table 1:** Mean (SD) of dominant and non-dominant LPHC kinematics.

Variable	Dominant	Non-Dominant
Stance Width (m)	0.16 (0.09)	0.15 (0.09)
*Pelvic Axial Rotation (°)	-2.09 (5.73)	-5.58 (6.40)
*Touching Side Hip Abduction (°)	-2.63 (9.64)	-12.76 (10.40)
*Stance Side Hip Adduction (°)	0.40 (9.04)	11.34 (9.74)

Note: \* denotes significant difference at  $p<0.05$ . Stance width = ankle joint center displacement.

### Results and Discussion

Descriptive statistics can be found in Table 1. Differences were observed between dominant and non-dominant hand touches in pelvic axial rotation ( $t(18) = 2.45, p = 0.025, d = 0.56$ ), stance leg side hip adduction ( $t(18) = -3.70, p = 0.002, d = -0.85$ ), and touching side hip abduction ( $t(18) = 2.91, p = 0.009, d = 0.67$ ). Upon dominant hand touch, significantly less pelvic axial rotation, touching side hip abduction, and stance side hip adduction was observed when compared to a non-dominant hand touch. These results support our hypothesis that differences in LPHC kinematics would be observed between bilateral hand touching during the CKCUEST.

During non-dominant hand touching, the pitcher's dominant hand should act to support stabilizing the body on the ground. Interestingly, more LPHC movement was observed in this position compared to when the non-dominant hand was stabilizing. This potentially indicates less LPHC stability while the dominant hand was in a closed chain position. We speculate that experiencing a repetitive unilateral open-chain pitching motion may affect dominant side closed chain stability. However, less LPHC stability during the non-dominant hand touch may be a product of muscular weakness or lack of neuromuscular coordination not related to the pitching motion.

Our results indicate that baseball pitchers appear more stable performing a dominant hand touch as evidenced by decreased kinematic compensations within the LPHC.

### Significance

In order to achieve efficient proximal to distal energy transfer, stability of the LPHC is necessary.<sup>2,3</sup> Greater stability was observed during dominant hand touching, indicating a discrepancy between sides that can impact training and rehabilitative programs. Clinicians and coaches should take this information into account when designing programs for baseball pitchers. Since the baseball pitch requires proximal stability for efficient energy transfer, future research should determine whether the observed asymmetry is a result of LPHC or upper extremity instability stemming from the baseball pitching motion. Additionally, future research should examine the effect this asymmetry has on performance and risk of injury.

# ACUTE EFFECT OF AN INTERVENTION TO IMPROVE ANKLE DORSIFLEXION AMONG INDIVIDUALS WHO DISPLAY MEDIAL KNEE DISPLACEMENT

Rebecca Ban<sup>1</sup>, Feng Yang<sup>1</sup>

<sup>1</sup>Department of Kinesiology and Health, Georgia State University, Atlanta GA, 30303

## Introduction

Knee valgus has been identified as an important risk factor for lower extremity injury, specifically non-contact anterior cruciate ligament injury<sup>1</sup>. Dynamic knee valgus is the combination of excessive femoral adduction and internal rotation, and tibial abduction and external rotation<sup>1</sup>. These motions are influenced by joints proximal and distal to the knee, including the hip and ankle<sup>1,2</sup>. Clinically, excessive knee valgus, visually demonstrated as medial knee displacement (MKD), is described as the midpoint of the patella passing medial of the great toe<sup>3</sup>.

Recently, numerous studies have reported limited ankle dorsiflexion range of motion (ROM) to be a contributor to excessive knee valgus<sup>2,4</sup>. However, no direct evidence shows an improvement in frontal plane knee motion after an intervention to increase ankle dorsiflexion ROM. The purpose of this study was to examine if an intervention designed to increase ankle dorsiflexion ROM in persons who display MKD acutely reduces MKD in an overhead squat task.

## Methods

Sixteen participants were randomly assigned to the intervention (n = 8, mean ± standard deviation age: 21.3 ± 4.7 years, mass: 63.7 ± 16.8 kg, height: 163.2 ± 7.9 cm) or control group (n = 8, age: 22.3 ± 3.3 years, mass: 67.3 ± 12.6 kg, height = 164.3 ± 8.8 cm). All participants were screened using the double-leg squat assessment to verify the presence of MKD<sup>3</sup>. Specifically, the assessment consists of five consecutive squats in a standardized position: feet shoulder width apart, toes pointing forward, arms overhead with elbows locked straight<sup>3</sup>. If MKD is observed, heel lifts are placed under the heels and five additional squats are performed. This movement screen can theoretically differentiate between dysfunction at the hip or ankle as the primary contributor to MKD. If application of the heel lifts rectifies knee alignment, the primary contributor to MKD is reduced ankle dorsiflexion ROM<sup>2</sup>.

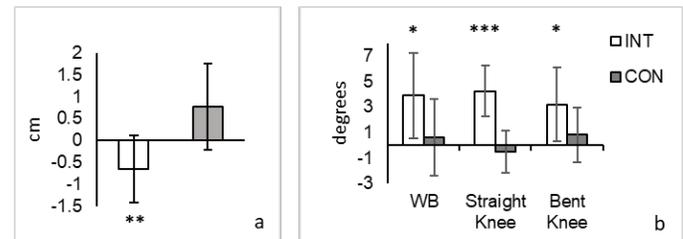

After screening, qualified participants underwent a pre-test assessment. Ankle dorsiflexion ROM was measured in three conditions: passive straight knee, passive bent knee, and a weight-bearing lunge. Subjects then performed five consecutive double-leg squats in the standardized position and the average was used for analysis. After the pre-test assessment, participants completed the assigned intervention protocol. For the training group, the intervention protocol was developed using procedures from the National Academy of Sports Medicine corrective exercise strategies textbook<sup>5</sup>. Participants used a high-density foam roller embedded with a vibrating motor to perform self-myofascial release of the gastrocnemius and soleus. Participants then performed a weight-bearing static stretch of the gastrocnemius and soleus. Isolated activation of the posterior tibialis and heel raises with the toes internally rotated for two sets of 10 repetitions was completed. Lastly, participants performed single leg squats for two sets of 10 repetitions. Participants in the control group walked on a treadmill at a self-selected speed in lieu of the intervention

program. Immediately following the intervention, the measurements performed during the pre-test assessment were repeated for all participants. During the squat task, lower extremity kinematic data were gathered through 23 markers using an 8-camera motion capture system (Vicon, UK).

The changes from the pre-training to the post-training assessments were calculated for each of the four outcomes (ankle dorsiflexion ROM under three conditions and MKD during the overhead squats for the affected leg). Independent *t*-tests were used to compare the changes between groups. SPSS 24 (IBM) was used and a significance level of 0.05 was applied.

## Results and Discussion

The intervention group significantly reduced MKD ( $p = 0.003$ , Fig. 1a), and increased all dorsiflexion ROM measures compared to the control group: passive straight knee ( $p < 0.001$ ), passive bent knee ( $p = 0.04$ ), and weight-bearing ( $p = 0.03$ ) (Fig. 1b). A significant correlation was observed between the changes in ankle dorsiflexion ROM and MKD ( $r = -0.548$ ,  $p = 0.014$ ). Our most important finding was that an increase in dorsiflexion ROM could reduce MKD during an overhead squat task in individuals who displayed MKD that was corrected with a heel lift.

**Figure 1** Between-group comparisons for the intervention-induced changes in a) MKD (cm), and b) ankle dorsiflexion ROM (deg) under three testing conditions. WB: weight bearing. \*:  $p < 0.05$ ; \*\*:  $p < 0.01$ ; \*\*\*:  $p < 0.001$  between groups.

## Significance

To our knowledge, this is the first study to examine the effects of an intervention aimed to increase ankle dorsiflexion ROM on mediolateral knee motion. Our results indicate that an increase in ankle dorsiflexion ROM has the potential to diminish MKD. Dynamic knee valgus is a modifiable risk factor for knee injury. Intervention programs have previously focused on plyometric training and strengthening hip musculature to reduce knee valgus. Based on our findings, we recommend that interventions to improve dynamic knee valgus include exercises to increase ankle dorsiflexion ROM.

# Increased Ankle Range of Motion Reduces Knee Loads during Landing in Healthy Adults

Lauren E. Schroeder<sup>1</sup>, Joshua T. Weinhandl<sup>1</sup>

<sup>1</sup>The University of Tennessee, Knoxville, Knoxville, TN, U.S.A.

Email: [lschroel@vols.utk.edu](mailto:lschroel@vols.utk.edu)

## Introduction

Decreased dorsiflexion range of motion (DROM) has been associated with abnormal knee mechanics during landing [1] and may identify those at an increased risk of anterior cruciate ligament (ACL) injury. Fortunately, DROM can be easily modified using both plantarflexor static stretching (SS) [2] and talocrural posterior joint mobilizations (JM) [3]. Both interventions have shown to produce acute increases in DROM after a single bout and may attenuate known sagittal and frontal plane knee ACL injury risk factors during dynamic tasks. However, it is not known how these interventions compare to each other and how they alter knee landing mechanics.

The purpose of this study was to determine the acute effects of SS and JM interventions on pre to post-intervention DROM measurement changes ( $\Delta$ DROM) and right-leg drop jump knee landing mechanics. We hypothesized that  $\Delta$ DROM would be different between interventions, and that there would be favorable knee biomechanical changes after both interventions.

## Methods

Seven males (age: 25.1 $\pm$ 3.1yrs; height: 1.80 $\pm$ 0.08m, mass: 85.69 $\pm$ 17.84kg) and 18 females (age: 21.7 $\pm$ 2.5yrs; height: 1.65 $\pm$ 0.06m, mass: 63.96 $\pm$ 8.56kg), all healthy and recreationally active, completed SS on day 1 of testing and JM on day 2 of testing. On both days, right-leg passive and active DROM, the weight-bearing lunge test, the anterior reach portion of the Star Excursion Balance Test, and a motion capture right-leg box landing task were completed both before and after the intervention. For the box landing task, participants stood on a 30cm tall box, placed a distance equal to half of their height away from the center of the force plate, jumped off of their left foot and landed on their right foot until stable.

3D marker coordinate data were collected using a 12-camera Vicon system (200Hz), and ground reaction forces were collected with one AMTI force plate (2000Hz). 3D knee sagittal and frontal plane kinematics and internal moments, as well as peak anterior shear force (ASF), normalized to body mass, were calculated.  $\Delta$ DROM was calculated as the difference between post and pre-intervention DROM measurements. Pairwise dependent *t*-tests were performed for

$\Delta$ DROM and 2 $\times$ 2 (time  $\times$  intervention) repeated measures ANOVAs were performed for initial contact (IC) and peak knee angles, peak knee moments, and peak ASF ( $\alpha$ =.05).

## Results and Discussion

No significant differences were present in  $\Delta$ DROM between SS and JM interventions (passive: SS = 3.2 $^\circ$ , JM = 2.9 $^\circ$ , active: SS = 1.9 $^\circ$ , JM = 2.2 $^\circ$ , WBLT: SS = .86 cm, JM = .84 cm, anterior SEBT: SS = .00 cm, JM = .01 cm,  $p$ >.05). There were significant time main effects for peak knee flexion ( $p$ =.005,  $\eta_p^2$ =.28) and abduction ( $p$ =.004,  $\eta_p^2$ =.30) angles, peak knee adduction moment ( $p$ =.001,  $\eta_p^2$ =.40), and peak ASF ( $p$ <.001,  $\eta_p^2$ =.42). Additionally, significant intervention main effects were present for IC abduction angles ( $p$ =.023,  $\eta_p^2$ =.20) and peak adduction moments ( $p$ =.001,  $\eta_p^2$ =.39) (Table 1).

Increases in dorsiflexion measurements did not significantly differ between interventions, indicating both were effective in improving DROM. Peak ASF significantly decreased after both interventions, possibly due to the increased peak knee flexion angles exhibited after both interventions. However participants experienced greater frontal plane excursions after both interventions during the jump landing task, warranting further investigation as to why this occurred.

## Significance

Ankle DROM is a potential modifiable ACL injury risk factor that can be improved using either SS or JM interventions. Our results demonstrated that not only were SS and JM interventions effective in increasing DROM, they also improved knee flexion angles and ASF during landing, both of which are known ACL injury risk factors. Plantarflexor SS may be a more practical treatment for those at an increased risk of ACL injury due to the ability to completed the intervention without the assistance of another individual.

# Force and Rate Metrics Provide Return-To-Sport Criterion after ACL Reconstruction

Helia Mahzoun Alzakerin<sup>1</sup>, Yannis Halkiadakis<sup>1</sup>, and Kristin D. Morgan<sup>1\*</sup>

<sup>1</sup>Department of Biomedical Engineering, College of Engineering, University of Connecticut, Storrs, CT, USA

Email: \*[kristin.2.morgan@uconn.edu](mailto:kristin.2.morgan@uconn.edu)

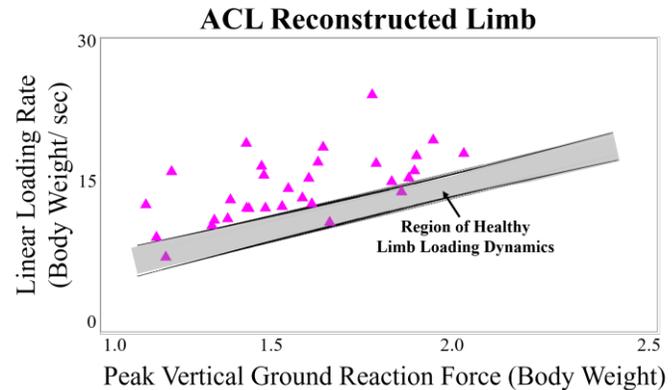

## Introduction

An anterior cruciate ligament (ACL) injury is a common sport's injury that impacts over 250,000 individuals each year and often requires surgical intervention and rehabilitation [1-2]. A goal of post-ACL reconstruction (ACLR) rehabilitation is to restore an individual's neuromuscular control to healthy, pre-injury levels to enable a rapid return-to-sport (RTS) [3]. However, the challenge resides in defining universal benchmarks to quantify the restoration of healthy motor control. Andriacchi et al. (1977) found that gait speed and peak force are linearly related and that this relationship could be used to differentiate between the gait of healthy individuals and those after total knee replacement [4]. Given that elevated peak vertical ground reaction force (vGRF) and linear loading rate are often found to be indicative of altered limb loading, we sought to investigate and exploit the linear relationship between peak vGRF force and linear loading rate to develop a criterion to aid in the individualized assessment of post-ACLR individuals. We hypothesized that there would be a strong linear relationship between the peak vGRF and the linear vGRF loading rate using the data from the healthy controls and post-ACLR non-reconstructed limbs. We will then use the healthy control data to develop a linear regression model to define a region of healthy limb dynamics to aid in the classification of altered limb dynamics in the post-ACLR individuals reconstructed limb.

## Methods

Thirty-one post-ACLR individuals (mean  $\pm$  standard deviation; age:  $20.4 \pm 6.2$  yrs; height:  $1.8 \pm 0.1$  m; mass:  $71.7 \pm 11.1$  kg; running speed:  $2.7 \pm 0.3$  m/s; Tegner (post-ACLR at 6 months):  $6.4 \pm 1.8$ ; 16 males and 15 females) and 31 healthy controls (age:  $20.9 \pm 3.4$  yrs; height:  $1.7 \pm 0.1$  m; mass:  $65.2 \pm 13.8$  kg; running speed:  $2.7 \pm 0.4$  m/s; Tegner:  $6.9 \pm 1.3$ ; 18 males and 14 females) performed a running protocol. All post-ACLR individuals participated in the study 6 months after surgery and were cleared to RTS by their physician. All of the control participants were injury free for the six months prior to the study and had no history of knee surgery. Participants provided informed written consent prior to their participation.

Participants performed a running protocol where they ran at a self-selected speed on an instrumented treadmill (Bertec Corporation, Columbus, Ohio). Ground reaction force data was collected at 1200 Hz and filtered using a zero-lag, fourth-order Butterworth filter with a 35-Hz low-pass cutoff frequency. Peak vGRF and linear loading rate, defined as the slope from foot strike to peak vGRF were extracted from 10 running strides. A correlation analysis was conducted to measure the strength of the linear relationship between the peak vGRF and linear loading rate for the control right and left and ACLR reconstructed and non-reconstructed limbs. The region of healthy limb dynamics was defined as the upper 99% confidence limit based on the model fit to the control right, control left and ACLR non-reconstructed limb data. All of the statistical analyses were conducted in MINITAB (MINITAB, Version 18, State College, PA, USA).

**Figure 1:** Scatter plot of the peak vertical ground reaction force (vGRF) data versus the linear vGRF loading rate data for ACL reconstructed limbs. The black lines represent the upper and lower 99% confidence limits based on the healthy control and non-reconstructed limb data.

## Results and Discussion

There was a strong linear correlation between the peak vGRF and linear vGRF loading rate for the control right ( $R=0.90$ ), control left ( $R=0.91$ ) and post-ACLR non-reconstructed limb ( $R=0.88$ ). A weaker relationship was reported in the post-ACLR individuals reconstructed limb ( $R=0.61$ ). A linear regression model was fit to the control and non-reconstructed limb data ( $R^2 = 0.81$ ) (Eq. 1).

$$\text{Linear vGRF Loading Rate} = 0.06 + 7.90 * \text{Peak vGRF} \quad (1)$$

The 99% upper confidence limit obtained from the linear regression model served as a boundary line to demarcate between the healthy and abnormal limb dynamics (Fig.1). This boundary line successfully classified 90% of the 31 reconstructed limbs as having abnormal limb dynamics. Overall, 83% of the 124 limbs in the study were correctly classified.

The results supported the hypothesis that there was a strong linear relationship between peak vGRF and linear loading rate that could be used to denote abnormal limb dynamics. The deviation from this relationship in the reconstructed limb suggests an inability to properly control the force produced in the that limb which could be attributed to altered neuromuscular control. This analysis is significant because it suggests that there the relationship between these variables can be used as a benchmark by clinicians and researchers to quickly detect individuals with abnormal limb dynamics.

# DYNAMIC JOINT STIFFNESS OF THE ANKLE IN CHRONIC ANKLE INSTABILITY PATIENTS

Jaeho Jang<sup>1</sup>, Kyeongtak Song<sup>1</sup>, and Erik. A Wikstrom<sup>1</sup>

<sup>1</sup>University of North Carolina Chapel Hill, NC, USA

Email: [jaeho@live.unc.edu](mailto:jaeho@live.unc.edu)

## Introduction

Between 30-40% of patients with a lateral ankle sprain (LAS) experience one or more residual symptoms, which are considered to be hallmark characteristics of a condition referred to as chronic ankle instability (CAI). CAI patients have altered spinal reflex and muscular activity patterns, as well as aberrant movement strategies, which could lead to alterations in joint stability and development of pathomechanical loading at the ankle joint. Consequently, altered joint loading threatens cartilage health and is thought to contribute to the development of ankle posttraumatic osteoarthritis (PTOA).

While decreased dorsiflexion excursion and increased plantar flexion moments during a stance phase of walking are commonly found in CAI patients [1], the interaction between these is not fully understood. This interaction, referred to as stiffness, has been studied during various dynamic activities (i.e. landing and cutting) in CAI patients and thought to reduce joint stability at the ankle [2]. However, little attention has been placed on stiffness during gait, limiting our understanding of how the most common dynamic task during daily life affects ankle cartilage health. Dynamic Joint Stiffness (DJS) is defined as the resistance developed by joint structures during inter-segmental displacement in response to an external moment [3]. DJS is more comprehensive measure than stiffness as it distinguishes ankle behaviors across three distinctive and continuous sub-phases. Thus, DJS is better suited to capture alterations that could modify the visco-elasticity of the joint and lead to reduced joint stability; factors that could facilitate PTOA development. Therefore, the purpose of this study was to compare DJS at the ankle joint between CAI patients and healthy control.

## Methods

Forty-five healthy control (age:  $20.24 \pm 3.90$  years, weight  $67.06 \pm 13.18$  kg, height:  $169.32 \pm 8.39$  cm) and forty-five CAI patients (age:  $20.71 \pm 2.07$  years, weight  $72.65 \pm 14.65$  kg, height:  $169.87 \pm 7.43$  cm) participated. CAI inclusion criteria were in accordance with the International Ankle Consortium guidelines. Kinematic (120Hz) and ground reaction force data (1200Hz) were collected while participants completed five gait trials with self-selected speed. The sagittal ankle joint angle and moment during stance phase was normalized to percentages of the stance cycle. Ankle DJS was represented by the slope of the joint moment plotted as a function of the joint angle. The entire curve was split into three sub-phases of ankle behaviors during ground contact: controlled plantar flexion (CPF), controlled dorsiflexion (CDF), and powered plantar flexion (PPF). Least-squares linear regression models were used to determine the corresponding slopes. The coefficient of determination ( $R^2$ ) was also calculated to determine how accurately data fit a linear model. Average values from the five collected trials were used to compare between groups using independent *t*-tests with the significance level of 0.05.

## Results and Discussion

A lower DJS was observed in the CAI group during CPF as seen in Table 1. No group differences were observed during the CDF or PPF phases, and the  $R^2$  was not different across all sub-phases.

CPF is characterized by the initiation of heel contact with a plantar flexion movement and moment. Although CPF is brief, it controls the impact with the ground. The lower slope during CPF in those with CAI is thought to represent their inability to control the plantar flexion moment associated with their plantar flexion excursion. This is consistent with the previous literatures that specified a lack of control of the eccentric contraction of the dorsiflexor muscles in CAI patients [4]. While the exact relationship between kinetic variables and cartilage health remain unknown, the observed DJS alteration might expedite the initiation of ankle cartilage degeneration via increased compressive forces at a more susceptible area of the ankle joint cartilage as muscle force is a contributor to total joint contact force [5].

	CAI (n =45)	Control (n = 45)	Differences
	Mean (SD)	Mean (SD)	p-value
CPF (Nm kg <sup>-1</sup> /°)	0.022 (0.011)	0.028 (0.011)	0.016
CDF (Nm kg <sup>-1</sup> /°)	0.089 (0.018)	0.093 (0.023)	0.397
PPF (Nm kg <sup>-1</sup> /°)	0.060 (0.010)	0.062 (0.009)	0.442
CPF – R <sup>2</sup>	0.980 (0.028)	0.971 (0.041)	0.256
CDF – R <sup>2</sup>	0.904 (0.050)	0.874 (0.113)	0.111
PPF – R <sup>2</sup>	0.977 (0.023)	0.982 (0.012)	0.163

Table 1. Dynamic joint stiffness comparison between those with and without chronic ankle instability (CAI); CPF: controlled plantar flexion sub-phase; CDF: controlled dorsiflexion sub-phase; PPF: powered plantar flexion sub-phase.

## Significance

Our study indicates that CAI patients have altered ankle DJS during initial ground contact while walking. This inability to control impact with the ground may contribute to cartilage degeneration.

# Kinematic and Kinetic Differences Pre- and Post-Femoral Stress Reaction Injury: A Case Study

Kathryn A. Farina<sup>1</sup>, Seth R. Donahue<sup>1</sup>, and Michael E Hahn<sup>1</sup>

<sup>1</sup>University of Oregon, Department of Human Physiology, Bowerman Sports Science Clinic, Eugene, OR, USA

Email: kfarina@uoregon.edu

## Introduction

Femoral stress fractures account for 10% of stress fractures in runners [1] that are prone to complications and, if left untreated, may require extensive rehabilitation or surgery [2], highlighting the importance of early detection. Stress reactions occur due to repetitive stress, and without rest, may advance to a stress fracture [2], making identification of stress reactions vital to rapid recovery. Few prospective studies have focused on femoral stress reactions or fractures, consisting of case study analysis of imaging, diagnoses, and return to sport [3]. It remains that little is known about how to identify potential risk factors from kinematic and kinetic variables associated with femoral stress injuries. The purpose of this case study was to examine biomechanical variables before and after a femoral stress reaction in a trained female distance runner.

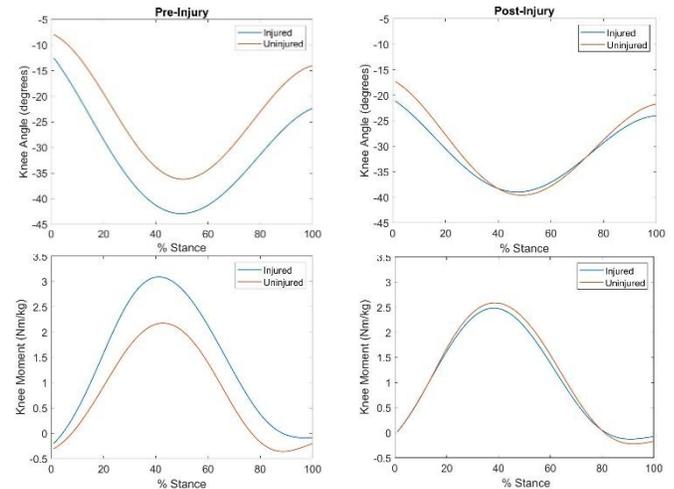

## Methods

One collegiate female distance runner suffering a Grade 3 femoral neck stress reaction to the right side was evaluated before and after injury. Assessments were one year apart. Injury occurred roughly two months after the first test. The subject ran at 3.83 m/s for twenty strides on a force instrumented treadmill ( $f_s=1000\text{Hz}$ ) (Bertec, Columbus, OH) while segmental position and orientation data were collected ( $f_s=200\text{Hz}$ ) from both lower limbs (Motion Analysis Corp., Rohnert Park, CA). Inverse dynamics calculations were performed in Visual3D (C-Motion Inc., Germantown, MD). Kinematic and kinetic variables were exported to MATLAB (The MathWorks, Natick, MA), averaged across twenty strides at both time points, and peak values were extracted for analysis. Symmetry Index (SI) was calculated for peak values as  $SI = (X_{right} - X_{left}) / (0.5(X_{left} + X_{right})) * 100\%$ . SI of an uninjured collegiate female runner of similar demographics was included as a healthy control comparison.

## Results and Discussion

Sagittal plane peak angles, moments, and powers for the ankle, knee, and hip joints, along with SI, are presented in Table 1. The largest asymmetries pre-injury were ankle angle, knee moment, knee power, and hip power. These discrepancies decreased post-injury, and were more similar to SI values of the

healthy control. For example, the knee on the injured side showed an increased angle and moment throughout stance phase prior to injury, but appeared closer in value to the uninjured side post-injury (Figure 1).

**Figure 1.** Average sagittal plane knee angle and moment during stance, running at 3.83 m/s: Pre-Injury on left, Post-Injury on right.

## Significance

This case study provides a brief examination of sagittal plane mechanics before and after returning from a Grade 3 femoral neck stress reaction. These data indicate a possible link between asymmetry of sagittal plane joint kinematics and kinetics and the development of a femoral stress injury, and demonstrate resolution of asymmetries almost a year after injury. Further study of similar injuries, and variations in limb asymmetry in injured and uninjured runners should provide more insight into the role of asymmetric limb loading on bone stress injuries.

## Modeling of Feet First Falls into Protective Water Pits in the Context of OCRs

Rachel Tanczos<sup>1</sup>, Kyle B. Van Housen<sup>1</sup>, Sean D. Shimada, PhD<sup>1</sup>

### Introduction

Obstacle course races (OCRs) are a relatively new sporting event that involves competitive completion of physically demanding activities or “obstacles.” Many of these obstacles utilize a water pit to reduce injury potential from a fall. The buoyant and drag forces of water oppose a person’s downward motion, reducing the participant’s velocity and ground impact force. The force applied to a falling contestant is principally dependent on the drop height, water depth, and the person’s anthropometric characteristics. The purpose of the study is to propose a method to assess lower extremities injury risk during OCR events by determining the ground impact velocity when falling into a body of water.

### Methods

This study utilizes calculated estimates for velocity, acceleration, buoyant force ( $F_b$ ), and drag force ( $F_d$ ) of a person falling perpendicular to a non-fully submersing body of water. The simulation allows for modification of total fall height, water depths, and a person’s anthropometric characteristics. A force balance for a vertically falling body was used to determine the equation for acceleration as seen in (1), where  $g$  is acceleration due to gravity and  $m$  is the mass of the person. This equation was numerically integrated for velocity and displacement using a time step of 0.005s.

$$a = -g + \frac{F_b}{m} + \frac{F_d}{m} \quad (1).$$

For the computation of drag force, the cross-sectional area facing the fluid was estimated as the combined area of the subject’s feet. The value of the drag coefficient was taken to be the same as a skydiver falling feet first with a closed chute [1]. By implementing these parameters, velocity of the falling body was then used to calculate drag force.

To determine buoyant force, the vertical displacement of the falling body was used to calculate the volume of displaced water, which was estimated based on a geometric representation of a body developed by Hanavan [2]. Anthropometric dimensions were used to model components of lower limbs and torso as either an ellipsoid or conical frustrum. From the displaced volume calculations, buoyant force was then computed.

### Results and Discussion

The described method was conducted for a fifty-percentile male falling from a total height of five feet (1.52 m), measured from the ground to the bottom of the subject’s feet. Water depths were tested from one foot (0.30 m) to four feet (1.22 m), in one-foot increments. The simulation output revealed a 19.4% decrease in maximum velocity attained between depths of one foot to four feet (Fig. 1).

A threshold velocity for various lower extremity injuries can be determined based on injury tolerances from literature. Funk et al. reports a 50% risk of injury to the foot/ankle complex for an 8.3 kN blunt axial force [3]. Estimating an 88 millisecond time interval of impact [4], the terminal velocity needed to achieve this force (for a fifty-percentile male) is

calculated to be 9.9 m/s. With the highest output velocity of 5.13 m/s for the simulated water depth of 1 foot, the simulation suggests low injury risk of the foot/ankle complex for all presented simulation conditions.

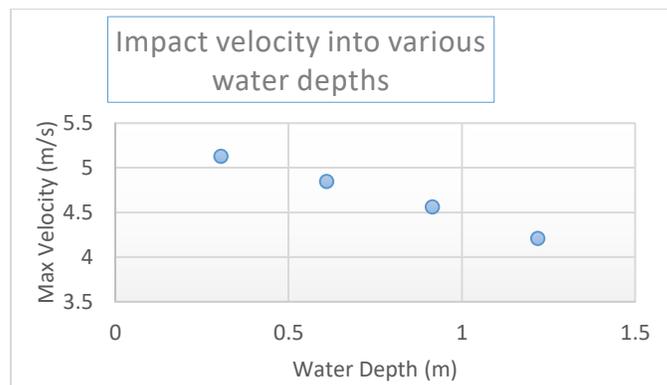

Figure 1: Impact velocity for 1.52 m total fall height into water

### Significance

The proposed simulation allows for modification of fall conditions and anthropometric characteristics. The ability to readily conduct analyses for multiple parameters can be used to create safer water pits and obstacles through the evaluation of lower extremity impact velocities and forces.

With OCRs growing in popularity, recent steps have been taken to create safety standards for obstacle implementation. Recently, the World OCR has released guidelines that involve consultation with a qualified medical planner, risk assessor, and engineer [5]. Our simulation could be applied as a standardizing tool by qualified personnel to evaluate obstacle designs and to prepare the level of required medical personnel. Beyond OCRs, the flexibility to change input parameters allow this simulation to be used to model and assess injury risk in other activities such as cliff and splash diving. This analysis is currently limited to feet first, perpendicular water entry; however, future models will include oblique and head first entry to expand applications to platform and swim start diving.

# Prophylactic Ankle Braces Did Not Elicit Changes Associated with Injury or Compromise Performance in Sports Specific Movements

Christian N. Sanchez<sup>1</sup>, and Jeffery D. Eggleston<sup>1</sup>

<sup>1</sup>Department of Kinesiology, The University of Texas, El Paso, TX, USA

Email: [cnsanchez4@miners.utep.edu](mailto:cnsanchez4@miners.utep.edu)

## Introduction

Previous research has demonstrated limiting sagittal plane ankle range of motion, such as with a prophylactic ankle brace, causes increased frontal plane knee moments while performing various jumping tasks followed by a secondary movement [1]. Limiting ankle range of motion (ROM) during a landing task increases knee adductor moments which is associated with increased risk of injury during various sporting events [2]. Performing a secondary movement upon landing, such as a countermovement jump (CMJ), may also be associated with increased injury risk [3,4,5]. Currently, frontal plane knee angle and moment have not been quantified at initial peak ground reaction force (vGRF) upon landing followed by a secondary task. The purpose of this study is to examine frontal plane knee angle and moment at peak vGRF, and jump height while performing a jumping task followed by a secondary movement under braced and non-braced conditions to assess injury risk. It is hypothesized that vGRF, frontal plane knee moment and angle would increase while jump height would be decreased in the braced condition.

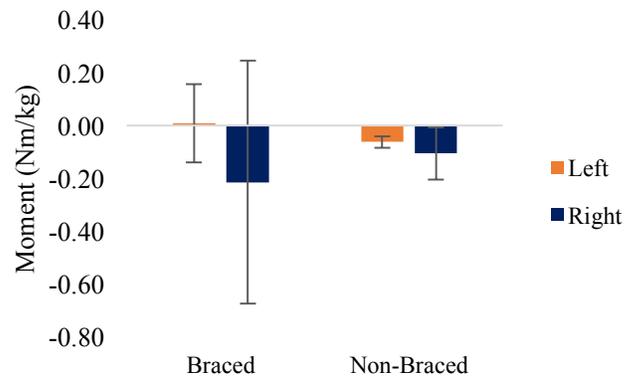

## Methods

3 healthy adults (1 female, 2 males, 23.67±2.08 years of age; 1.70±0.06m; 73.3±3.02 kg) were recruited for participation in this study. Participants performed three standing broad jumps followed by a maximal effort countermovement jump upon landing with and without wearing non-rigid Ankle Stabilizing Orthosis (ASO) braces. During the jumps, simultaneous three-dimensional lower extremity kinematic (200 Hz, Vicon Nexus Ltd., Oxford, UK) and kinetic data (1000 Hz, Advanced Mechanical Technology, Inc. Watertown, MA, USA) were obtained. Raw trajectory and force data were exported to Visual 3D for processing where digital low-pass Butterworth filters were applied (12 and 50 Hz, respectively). Variables of interest include frontal plane knee angle and frontal plane knee moment at vGRF, vGRF, and jump height. Kinetic data were normalized to participants' body mass for comparison. Jump height was computed through the impulse-momentum relationship. A two (limb; left/right) by two (condition; braced/non-braced) analysis of variance ( $\alpha=0.05$ ) was used to test for statistical significance for each variable. If an interaction was detected, dependent *t*-tests ( $\alpha=0.05$ ) were used for both unilateral comparisons between conditions and between-condition comparisons. If no interaction was detected, limb and condition main effects were examined after applying the Sidak adjustment. A dependent *t*-test ( $\alpha=0.05$ ) was used to test for statistical significance for vGRF and jump height between conditions.

## Results and Discussion

Frontal plane knee angle did not have a significant interaction ( $F(1,8)=0.01$ ,  $p=0.923$ ,  $\eta^2=0.00$ ) or condition or limb main effect ( $p=0.297$  and  $p=0.661$ , respectively). Frontal plane knee moment did not have a significant interaction ( $F(1,8)=0.40$ ,  $p=0.545$ ,  $\eta^2=0.05$ ) or condition or limb main effect ( $p=0.896$  and  $p=0.379$ ) (Figure 1). Vertical jump height and peak vGRF were not statistically different between conditions ( $p=0.459$  and

$p=0.562$  respectively). A lack of statistically significant differences indicates that performing braced standing broad jumps followed by a maximal effort countermovement jump may have no adverse effects on knee landing mechanics or jump performance between conditions, as observed in previous literature [1].

**Figure 1:** Frontal plane knee moment at peak vGRF during braced and non-braced conditions. Positive knee moment = abduction.

Results indicate that performing a jumping task (broad jump), immediately followed by a secondary movement (CMJ), upon landing while wearing prophylactic ankle braces did not elicit changes in frontal plane knee angles or moments, vGRF, or jump height in healthy individuals. This may suggest risk of injury is not elevated when performing a secondary movement upon landing. Additionally, vertical jump height was not significantly different between conditions, suggesting performance was not compromised during braced jumping. Thus, use of ankle braces may provide additional support for the individual without increasing forces on the knee and hindering performance. Specifically, during activities that require various jumping tasks succeeded by secondary task; such as a broad jump immediately followed by a maximal countermovement jump upon landing.

## Significance

The effects of restricted ankle ROM on the knee during specific athletic movements are currently unknown. This study contributes to the literature of how the knee may be affected when performing subsequent jump-landing tasks while wearing ankle braces that mimic sport-specific movements during game situations. Understanding jumping and landing mechanics while wearing prophylactic ankle braces may allow individuals to confidently wear them during sporting events without fear of increased injury risk or decreased performance.

## Introduction

Hamstrings muscle strains (HSMS) are a common musculoskeletal condition for basketball players with high rates of re-injury [1]. Risk factors such as weaker hamstrings (HAM) muscular strength and low flexibility (range-of-motion: ROM) can be mitigated by implementation of targeted dynamic warm-up programs during team practice sessions [2,3]. Recently, additional factors such as ultrasound-based shear wave elastography (SWE) stiffness have been explored [4]. Dynamic warm-up programs for prevention of HSMS commonly consist of eccentric hamstring resistance exercise, balance/core/hip exercise, sprinting/jumping techniques, and active/dynamic stretching [5]. Basketball coaches and players are interested in how such warm-up programs could influence their jump height performance. Therefore, the purpose of this study was to examine the effects of a targeted neuromuscular dynamic warm-up program on HAM muscle strength, ROM, SWE stiffness, and jump performance in high school basketball athletes.

## Methods

A total of 31 high school basketball athletes with no recent musculoskeletal injuries (11 females / 20 males, Age: 15.5±1.4years, HT: 176.8±11.3cm, WT: 75.7±22.5kg) from the same high school participated in the study. Pre- and post-intervention tests were conducted at school. For the quadriceps (QUAD) strength testing, subjects sat on a table with the knee flexed to 75°. For HAM strength testing, subjects were prone on a table with the knee flexed to 30°. Subjects were asked to push as hard as they could against a hand-held dynamometer for 3 seconds. Peak force was recorded in kilograms and normalized to their body weight for analyses. Strength ratio of HAM over QUAD (H/Q) was analysed. ROM was recorded using a digital inclinometer (placed on the shaft of the tibia) during passive ROM clinical tests (straight leg raise: SLR and knee extension: KE). For SWE stiffness, the first examiner scanned the biceps femoris while subjects were supine with their hip stabilized at 90° and the second examiner stretched subject's lower leg at 60% and 40% of the maximum KE ROM values. For jump performance, subjects placed their hands akimbo and performed a maximum countermovement jump (CMJ) and drop vertical jump (DVJ) from a 31-cm box onto a force plate. For both jump types, jump height was calculated based on flight time. For all variables, an average of three trials was used for analyses. Descriptive statistics and paired t-tests (or Wilcoxon tests) were used for statistical analyses (P<0.05).

An investigator-led dynamic warm-up program was performed twice a week throughout the season (total: 14 wks/28 sessions). Warm-up sessions were 15 minutes in duration at the beginning of practice. It consisted of dynamic stretching (2min), skipping/hopping/jumping exercises in each direction (2min),

eccentric Nordic hamstring exercise x 10 rep), balance/hip/core exercises (3min), stretching (3min), and sprinting (3min).

## Results and Discussion

Strength and ROM significantly increased after the intervention (P=0.001-0.008; **Table 1**). Significance was not seen in SWE stiffness and jump performance (P=0.100-0.845).

**Table 1. Descriptive statistics and effects of intervention on strength, ROM, SWE stiffness, and jump height performance.**

Strength (%BW)	PRE	POST	P
HAM Left	32.3 (7.0)	51.3 (12.4)	0.001
HAM Right	34.0 (8.5)	39.2 (8.6)	0.001
QUAD Left	58.1 (17.2)	72.3 (19.1)	0.002
QUAD Right	58.6 (17.0)	63.0 (15.6)	0.001
H/Q Ratio Left (%)	57.6 (10.8)	73.0 (14.3)	0.001
H/Q Ratio Right (%)	60.0 (12.4)	63.2 (7.3)	0.092
ROM (°)	PRE	POST	P
SLR Left	71.3 (10.1)	73.9 (10.7)	0.008
SLR Right	68.3 (9.8)	71.6 (10.5)	0.001
KE Left	50.9 (7.3)	53.8 (8.1)	0.005
KE Right	52.7 (8.0)	58.1 (8.8)	0.001
SWE (kPa)	PRE	POST	P
SWE 60% Left	69.5 (33.7)	65.0 (38.4)	0.845
SWE 60% Right	83.2 (37.1)	75.2 (36.0)	0.159
SWE 40% Left	70.1 (32.9)	57.6 (29.2)	0.100
SWE 40% Right	63.2 (33.5)	59.8 (29.7)	0.845
Jump Height (cm)	PRE	POST	P
CMJ	29.9 (7.3)	30.3 (6.5)	0.430
DVJ	35.8 (10.1)	34.0 (6.9)	0.109

## Significance

Although a lack of control group is a major limitation in the study, the current findings confirm the effectiveness of a simple 15-minute dynamic warm-up on key risk factors of HSMS. There is a trend of less SWE stiffness after intervention; however, clinical significance is not yet known. Prospective studies should follow to examine if such a program could reduce incidence and severity of HSMS.

## Introduction

Blunt impact test methods are an important tool used to examine the ability of helmets to reduce head rotational acceleration and subsequently the risk for brain injury due to blunt force trauma. However, some studies have reported that angular acceleration of the headform can be greater with than without a helmet [1]. Such results are contradictory to those of others [2] and may be influenced by impactor geometry. Thus, the purpose of this study was to investigate the difference in angular acceleration of an anthropomorphic test device (ATD) headform with and without an urban bicycle helmet using a small and large radius impactor. We hypothesized that a larger radius impactor would result in angular accelerations that at some impact locations were greater during blunt impacts with a helmet than without one, but this effect would not be present with a smaller radius impactor.

## Methods

A pneumatic linear impactor was used to impact a male 50% Hybrid III head and neck ATD (Humanetics, Huron, OH) outfitted with a nine accelerometer array package [3] at 3 locations (front boss, left side, and rear) at 4 m/s. The bare headform was impacted 6 times at each location with both an impactor that had a small (29.9 mm) and large (127 mm) radius convex impact surface. Both impactors were of similar configuration to that described by ND-081 [4]. Twelve commuter bicycle helmets (CM-1, Retrospec, CA) were also impacted once at each location with a large (n = 6) and small (n=6) radius impactor. Acceleration signals were resolved into peak resultant angular acceleration (PAA) [3]. High-speed video of the impacts (3000 fps; Phantom- V611; Vision Research, NJ) were recorded and used for qualitative analysis (Cineviewer v. 3.3, Vision Research, NJ). A 2 x 2 x 3 (Impactor, Helmet, Location) repeated measures ANOVA was used to make comparisons within groups. Simple effects analyses were used to explain interaction effects. Independent samples t-test were used to compare PAA between the barehead and helmeted condition at each location-impactor condition (SPSS v. 25.0, IBM, NY). We used a modified Bonferroni adjustment to correct the  $\alpha$ -level of 0.05 for multiple comparisons ( $\alpha = 0.01$ ). Values are presented as mean  $\pm$  1 SD.

## Results and Discussion

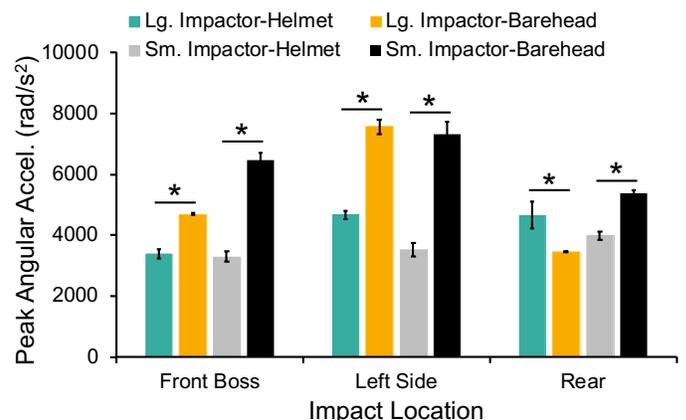

Highspeed video analysis revealed that for impacts to the front boss location of the bareheadform the large radius impactor made contact with its lower portion. For all other conditions the apex of the impactors made contact with the headform.

A significant interaction between Impactor, Helmet and Location was observed ( $p = 0.001$ ). Simple effects analyses indicated that the small radius impactor had greater PAA values for the barehead condition than the large radius impactor at the front boss ( $p < 0.001$ ) and rear impact locations ( $p < 0.001$ ), but not at the left side impact location ( $p = 0.125$ ).

For impacts with the small radius impactor PAA was less for the helmeted compared to barehead conditions at all

locations ( $p < 0.001$ ). For impacts with the large radius impactor PAA was less for the helmeted compared to barehead condition at the front boss ( $p < 0.001$ ) and left side locations ( $p < 0.001$ ). However, for the large radius impactor condition PAA was greater for the helmeted compared to the barehead condition at the rear location ( $p = 0.001$ ). See Figure 1.

These results are similar to Rousseau et al. [1], which showed PAA values were greater in helmeted compared to bare conditions for a subset of helmets and impact locations. The results also support of our hypothesis as we observed that impactor head radius altered whether PAA was greater in the helmeted or barehead condition. This seemed to occur because the smaller radius impactor typically increased the PAA of the barehead condition. However, the reason the large radius impactor produced lower PAA in the barehead than helmeted conditions remains unclear. It is possible such findings are the result of the headform used, which is more rigid than a human head. Future work should explore the influence of headform rigidity and the transfer of force from the impactor to the head as well as the potential for this effect to be observed on other kinematic measures associated with brain injury.

**Figure 1:** Peak resultant angular acceleration (PAA) for blunt impacts to the ATD headform at three locations. \* Indicates significance difference between helmet and barehead condition.

## Significance

Our results indicate that impactor geometry has a substantial influence on ATD headform rotational acceleration and should be considered when interpreting blunt impact test results as well as during the design of helmets.

### Introduction

The position and orientation (pose) of an anthropomorphic test device (ATD) headform has been shown to influence its impact response[1]. However, no study has shown how the pose of the headform influences the impact performance of American football helmets, or if any effect is helmet specific. This is especially important as two main test methods; 1) National Operating Committee on Standards for Athletic Equipment (NOCSAE) method ND-081 and 2) the National Football League (NFL) test protocol, are used to certify and set limits on the performance acceptability of football helmets for use in the NFL, but use different ATD poses [2, 3]. Because of differences in the relative location of the neck rotation joint, the poses set forth by NOCSAE put the ATD neck in a flexed position, whereas the NFL protocol often require lateral bending of the neck. Therefore, the purpose of this study was to evaluate the influence of the NOCSAE and NFL poses on the kinematic responses of an ATD donning modern football helmets during blunt impacts test performed at the NOCSAE prescribed locations.

### Methods

Two Xenith Shadow and X2E+ (Xenith, Detroit, MI) American football helmets were fit to a medium NOCSAE head attached to a male 50% Hybrid III neck (Humanetics, Huron, OH) outfitted with a nine accelerometer array package [4]. Each helmet was impacted at 6 m/s using a pneumatic linear impactor. Helmets were impacted 4 times at side, rear boss centric (RBCG), rear boss non-centric (RBNC), rear, front boss (FB), and front locations [2]. One set of Shadow and X2E+ helmets were impacted with ATD pose set according to the NOCSAE method, while the other set was impacted with the ATD pose set according to the NFL method. Note, for all impacts the impact location was the same. Acceleration signals were resolved into peak resultant linear and angular accelerations (PLA and PAA) and peak resultant angular velocity (PAV). For each measure the difference between the NOCSAE and NFL methods (NOCSAE – NFL) was calculated. Statistical analyses were performed on these difference scores (dPLA, dPAA, and dPAV). A 2 x 6 (Helmet x Location) repeated measures ANOVA was used to make comparison within groups. Simple effects analyses were used to explain interaction effects (SPSS v. 25.0, IBM, NY). Significance was set at an  $\alpha$ -level of 0.05. Values are presented as mean (95% CI) unless otherwise specified. Difference scores whose 95% CI include the zero value indicate no statistical difference exists between the NOCSAE and NFL poses.

### Results and Discussion

A significant interaction between Helmet and Location was observed for each dependent variable ( $p < 0.001$ ;  $\eta^2 \geq 0.64$ ). A main effect for helmet was also observed for dPLA ( $p < 0.001$ ;  $\eta^2 = 0.92$ ) and dPAV ( $p = 0.004$ ;  $\eta^2 = 0.766$ ), but not for dPAA ( $p = 0.221$ ;  $\eta^2 = 0.24$ ). Mean difference scores for the dependent variables are reported in Table 1.

**Table 1.** dPLA, dPAA, and dPAV mean difference scores for each impact location for the X2E+ and Shadow Xenith helmets. \* Indicates values in which the 95% CI did not include the zero value.

Loc.	dPLA (g)		dPAA (rad/s <sup>2</sup> )		dPAV (rad/s)	
	X2E+	Shdw.	X2E+	Shdw.	X2E+	Shdw.
Side	13.0*	18.1*	237*	520*	-2.9*	-2.4*
RBCG	11.1*	-3.4	249	425	-6.5*	-5.3*
RBNC	16.5*	0.8	737*	224	-2.5*	1.2*
Rear	19.0*	-14.5*	424*	-1355*	-6.0*	-5.5*
FB	9.7*	-0.3	718	1561*	2.8*	-8.9*
Front	0.4	-2.8	524*	160	2.5*	1.0

Averaged across impact locations mean dPLA was 11.6 g (9.10 – 14.1 g) for the X2E+, but was 0.34 g (-2.83 – 2.16 g) for the Shadow. At all locations except for the front location dPLA for the X2E+ helmet was greater than zero. However, for the Shadow dPLA was 18.1 g (12.0 – 24.3 g) for the side location, but was -14.5 g (-19.8 – -9.1g) for the rear location. At all other locations dPLA for the Shadow included the zero value.

Averaged across impact locations dPAA was 482 rad/s<sup>2</sup> (196– 767 rad/s<sup>2</sup>) for the X2E+, but was 256 rad/s<sup>2</sup> (-30 – 542 rad/s<sup>2</sup>) for the Shadow. At the side, RBNC, and rear locations dPAA for the X2E+ was greater than zero. Similarly, at the side and FB locations dPAA was greater than zero, but at the rear location dPAA was -1355 rad/s<sup>2</sup> (-1611 – -1098 rad/s<sup>2</sup>) for the Shadow.

In contrast to acceleration values dPAV averaged across impact locations was -2.1 rad/s (-2.6 – -1.6 rad/s) for the X2E+ and was -3.3 rad/s (-3.8 – -2.8 rad/s) for the Shadow. Furthermore, at the side, RBCG, and rear locations both the X2E+ and Shadow helmets dPAV values were below zero.

These results indicate that despite identical impact locations the pose of a headform influences its kinematic response, but differently depending on the model of football helmet worn and location of impact. Furthermore, it seems that while acceleration responses tend to be greater for the NOCSAE style pose, angular velocity was typically greater for the NFL style pose.

### Significance

ATD pose is a critical factor in assessing a helmet's ability to manage blunt impact forces and how its performance compares to other helmets. Furthermore, the results highlight the need for ATD pose to be reported in manuscripts and standards.

# Loading Asymmetry Before and After Metatarsal Stress Fracture: A Case Study

Ryan S. Alcantara<sup>1</sup> & Alena M. Grabowski<sup>1</sup>

<sup>1</sup>University of Colorado, Boulder, CO, USA

Email: [ryan.alcantara@colorado.edu](mailto:ryan.alcantara@colorado.edu)

## Introduction

Metatarsal stress fractures are a running-related overuse injury that comprise 23% of all stress fractures affecting collegiate cross country athletes [1]. Stress fracture recovery can take several months, often preventing an athlete from training or competing. Determining biomechanical changes that precede an injury like metatarsal stress fractures could inform coaches and athletes of an increased injury risk.

Previous research suggests that runners with a history of metatarsal stress fractures have similar peak vertical ground reaction forces (vGRFs) as those without a history of injury, but a causal relationship between peak vGRF and metatarsal stress fractures in runners is lacking [2]. A history of running-related overuse injuries may be associated with increased vertical loading rate, but to our knowledge, no prospective work has established an association between increased loading rate and metatarsal stress fractures in runners [3]. We measured peak vGRF and loading rate for each leg over the freshman year of collegiate running during which an athlete sustained a metatarsal stress fracture.

## Methods

Data from one male athlete (18 yrs, 75 kg, 1.85 m) were analysed for this case study. The athlete ran on a force-measuring treadmill (Treadmetrix, Park City, UT) at 3 speeds (3.8, 4.1, 5.4 m/s) for 30 seconds each during the fall, winter, and spring competition seasons. The athlete was diagnosed with a Grade 3 bone stress injury of the 2<sup>nd</sup> metatarsal between winter and spring data collections. The fall data collection was 20 weeks prior to injury, winter data collection was 3 weeks prior to injury, and spring data collection was 11 weeks after injury.

Kinetic data were filtered using a lowpass zero-lag 4<sup>th</sup> order Butterworth filter with a 14 Hz cutoff. We analyzed the final 10 sec of each trial and used a 30 N threshold to determine stance phase. The athlete was a habitual forefoot strike runner. Peak vGRF was calculated as the maximum value during stance phase. We calculated loading rate as the average slope of vGRF versus time from 10-20% of stance phase because no transient impact peak was visually present.

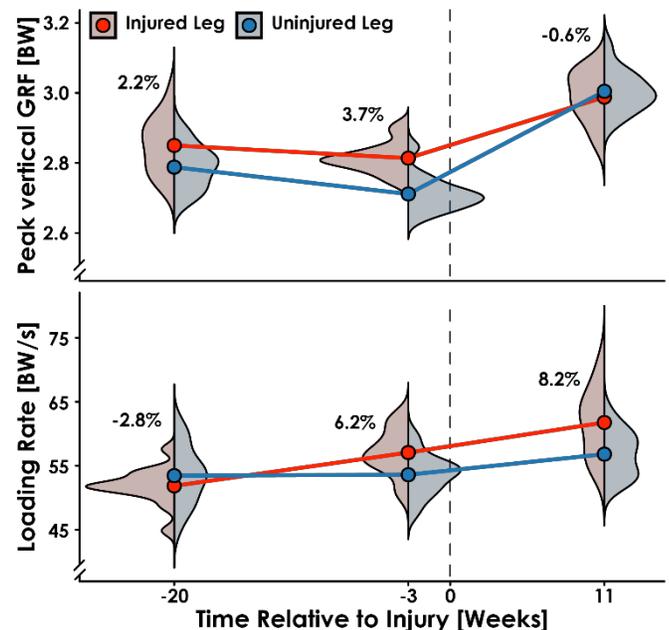

We calculated the percentage difference in peak vGRF and loading rate for the injured and uninjured leg (Fig. 1). A positive percentage difference indicates a greater magnitude of the given variable for the athlete's injured leg.

## Results and Discussion

We observed similar trends across speeds and report the results for the fastest speed (5.4 m/s). We found that the percentage difference between the injured and uninjured leg changed over time for peak vGRF and loading rate (Fig. 1). Peak vGRF of the injured leg was 2.2-3.7% greater than the uninjured leg prior to injury. However, the difference between peak vGRF of the injured and uninjured leg was only 0.6% 11 weeks after metatarsal stress injury (Fig. 1). In addition to these changes in peak vGRF asymmetry, peak vGRF values for the injured and uninjured leg increased 0.2 and 0.3 BW from 3 weeks prior to injury to 11 weeks after injury. Between step

variation in peak vGRF was qualitatively similar between legs over the year.

The loading rate of the injured leg was 2.8% lower than the uninjured leg 20 weeks prior to injury, but 6.2% greater than the uninjured leg 3 weeks prior and 8.2% greater than the uninjured leg 11 weeks after metatarsal stress injury. In addition to changes in loading rate asymmetry, loading rate values for the injured and uninjured leg increased 4.7 and 3.2 BW/s from 3 weeks prior to injury to 11 weeks after injury. Between-step variability in loading rate was qualitatively similar for the injured and uninjured leg at 3 weeks prior to injury and 11 weeks after injury, but differed at 20 weeks prior to injury.

**Figure 1.** Peak vertical ground reaction force (GRF) and loading rate for the injured and uninjured leg across three data collection sessions. Violin plots illustrate the distribution of values across steps, colored dots represent the mean, with percentage differences between the injured and uninjured leg annotated.

## Significance

These preliminary findings suggest peak vGRF asymmetry may differ before and after a metatarsal stress fracture, but it is unclear if loading rate is associated with prospective metatarsal stress fractures. This work provides insight into changes in asymmetry and between-step variability before and after sustaining a metatarsal stress fracture. Future work is planned to quantify how leg-specific external loading metrics predict running-related overuse injuries.

### Introduction

Army paratroopers have historically experienced traumatic brain injuries (TBI) at a rate significantly greater than the general soldier population [1]. Paratroopers are particularly vulnerable to posterior helmet-to-ground impact during parachute landing falls. Additionally, helmet-to-ground impacts are a significant risk in recreational football [2]. The purpose of this study was to evaluate head kinematics occurring in a simulated backfall experiment and assess the ability of a standardized rotation-inducing impact method (pneumatic ram) to reproduce the severity of measured backfall head kinematics.

### Methods

In the first series of tests, a simulated backfall impact was performed with a Hybrid III anthropomorphic test device (ATD). The ATD torso, arms, neck and head were rigidly attached to pendulum swing arm that falls to ground due to gravity. A 57.5 lb ballast mass was added to the pelvic region of the swing arm to represent the mass of the lower torso. Impact occurs onto a stack of foam and rubber materials that mimic the impulse delivered by an athletic turf field [3]. Head kinematics were measured with 3 linear accelerometers and 3 angular rate sensors.

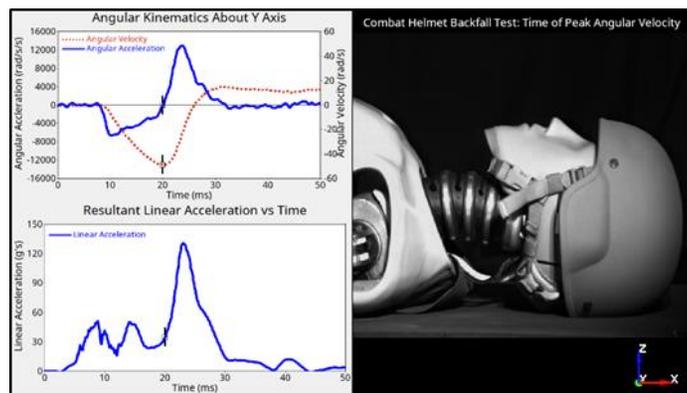

**Figure 1:** Backfall (A) and pneumatic ram (B) impact setups.

The second series of tests used a Biokinetics pneumatic ram (linear impactor) to determine whether this method could reproduce the severity of head kinematics observed in the backfall test. The pneumatic ram with NOCSAE impact tip was used to impact a Hybrid III neck and head with a nine accelerometer array package. The headform orientation with respect to ground, just prior to impact, was translated from the backfall test to the pneumatic ram setup. Impacts were performed at velocities equal to and greater than the impact velocity observed in the backfall test. A recently developed head kinematic assessment metric that rapidly estimates maximum principal strain (MPS) of brain tissue, DAMAGE, was used to compare the relative severity of each impact [4].

### Results and Discussion

The backfall experiment produces severe head kinematics from a combination of inertial and impact loading, illustrated in Figure 2. The headform experiences peak angular velocity as it contacts the ground followed by a change in velocity of 65 rad/s in less than 10 milliseconds as it rebounds from impact. The whipping

motion of the head during the backfall test format leads to an increased severity of rotational head kinematics.

**Figure 2:** Angular and linear kinematics resulting from the backfall test using a Hybrid III head-neck-torso fitted with a combat helmet.

Measurement	Pneumatic Ram		Backfall	
Helmet Impact Velocity (ft/s)	21.9	25.4	29.4	22.0
Peak Linear Acceleration (Res) (g)	152	227	241	132
Peak Angular Acceleration (Y) (rad/s/s)	5,205	5,249	5,973	12,948
Peak Angular Velocity (Y) (rad/s)	36.8	45.3	45.8	49.9
DAMAGE (Predicted Brain MPS)	0.32	0.42	0.43	0.58

**Table 1:** Results from backfall and pneumatic ram experiments.

In contrast, the pneumatic ram method did not capture the inertial loading of the head-neck that occurs in a backfall test as the torso impacts. Moreover, the peak angular head kinematics in the pneumatic ram format did not reach the same levels as in in the backfall test even as impact velocity was increased (Table 1).

### Significance

Head-to-ground impact is a significant source of TBI in the military as well as among athletes. Standardized impact testing methods like the pneumatic ram format, used to certify professional and collegiate football helmets, effectively measure head kinematics resulting from combined linear and rotational loading scenarios. However the pneumatic ram format was not able to replicate the severity of head kinematics or DAMAGE assessment as observed in the backfall test, suggesting a complimentary test specific to head-to-ground impacts may have value in the helmet testing community.

### Introduction

The purpose of this study was to investigate the influence of friction at the head-helmet pad interface on the rotational kinematic responses of an anthropomorphic test device (ATD) headform when fitted with advanced combat helmets (ACH) with a standard issue foam pad suspension system. We hypothesised that lower head-helmet pad interface friction conditions would illicit lower magnitude angular kinematic responses.

### Methods

Five head-helmet pad friction conditions (Polytetrafluoroethylene; PTFE, human hair wig, bald, skullcap, and hook and loop) were used for impact testing on 2 new ACHs. The coefficient of static friction ( $\mu_s$ ) for each condition was determined using the incline plane method [1]. Helmets were fitted to a 50% male hybrid III head and neck (Humanetics, Huron, OH) instrumented with a nine accelerometer array [2] and impacted four times at 7 locations (crown, front, rear, left side, right side, left nape, and right nape) on a pneumatic linear impactor at 14 ft/s [3]. Acceleration signals were resolved to determine peak angular acceleration (PAA), peak angular velocity (PAV) as well as to compute the DAMAGE metric [4]. Separate  $5 \times 7$  (friction condition  $\times$  location) repeated measures ANOVAs were used to make comparisons within groups (SPSS v25, IBM, NY) for each dependent variable. A Huynh-Feldt adjustment was used when sphericity was violated. Simple effects analyses were used to explain interaction effects. Significance set at  $\alpha$ -level of 0.05.

### Results and Discussion

The  $\mu_s$  for each condition is shown in Table 1. Rotational kinematic responses and DAMAGE measure for each condition are reported in Table 2.

Coefficient of Static Friction ( $\mu_s$ )				
PTFE	Human Hair	Bald	Skullcap	Hook
0.15	0.7	1.38	2.68	$\infty$

Table 1: Average  $\mu_s$  for each material measured on the incline plane.

	Angular Acceleration (rads/s <sup>2</sup> )					Angular Velocity (rads/s)					DAMAGE				
	PTFE	Wig	Bald	Skullcap	Hook	PTFE	Wig	Bald	Skullcap	Hook	PTFE	Wig	Bald	Skullcap	Hook

Front	4195	4099	4457	4475	4801	27	27	27	28	27	0.18	0.18	0.16	0.18	0.16
Rear	2430	2931	2867	2827	2725	31	32	31	32	29	0.27	0.28	0.30	0.30	0.26
LSide	4979	5084	5014	5202	5521	22	21	22	22	21	0.17	0.16	0.15	0.16	0.16
RSide	5185	4814	5153	5139	5972	22	22	23	24	21	0.16	0.16	0.15	0.15	0.16
LNape	4849	5049	4593	4846	5235	26	25	25	25	24	0.21	0.22	0.19	0.19	0.20
RNape	4832	4721	4814	4789	4904	26	27	25	27	25	0.22	0.23	0.21	0.22	0.22

Table 2: Mean angular acceleration, angular velocity, and DAMAGE for each head-helmet pad  $\mu_s$  condition at each impact location.

An interaction effect was found for friction condition  $\times$  location for PAA ( $p < 0.001$ ). Significant differences were found between friction conditions at crown ( $p = 0.012$ ) front ( $p = 0.006$ ), rear ( $p < 0.001$ ), and right side ( $p < 0.001$ ). Pairwise comparisons revealed that greater PAA values were not always associated with greater  $\mu_s$  values. However, at the front location hook resulted in significantly higher PAA compared to wig and PTFE ( $p < 0.027$ ).

An interaction effect was found for friction condition  $\times$  location for PAV ( $p < 0.001$ ). Significant differences were found for friction condition at all locations. The hook condition was found to have the lowest PAV for all locations but a clear response pattern was not observed for the other friction conditions and locations.

An interaction effect was also found for friction condition  $\times$  location for DAMAGE ( $p < 0.001$ ). Significant differences were found for friction conditions at all locations. Similar to the PAV results a clear response pattern was not observed for PAV across the friction conditions and locations.

Our hypothesis was not supported. Rotational kinematic responses and DAMAGE varied by location and  $\mu_s$ , but lower friction conditions did not typically result in lower kinematic or DAMAGE responses.

### Significance

Variation in  $\mu_s$  of the head-helmet pad interface for impacts representative of collisions found in sport did not consistently result in lower magnitude kinematic responses.

## Dorsiflexion shoes affect landing mechanics related to lower extremity injury risk

Gina L. Garcia<sup>1\*</sup>, Mia Caminita<sup>1</sup>, Jessica G. Hunter<sup>1</sup>, Ross H. Miller<sup>1</sup>, Hyun Joon Kwon<sup>1</sup>, Jae Kun Shim<sup>1</sup>

<sup>1</sup>Department of Kinesiology, University of Maryland, College Park, MD, USA

### Introduction

Traditional athletic footwear is designed with the heel elevated above the forefoot, putting the ankle in a plantarflexed position (positive drop). Conversely, research suggests that elevating the forefoot above the heel (negative drop), could take advantage of musculotendinous structures in the calf to improve jump height (1). It is unknown, though, if dorsiflexion shoes (negative drop) also affect landing mechanics related to lower extremity injury risk, particularly patellofemoral pain (PFP) and anterior cruciate ligament (ACL) injury which are two of the most common and debilitating injuries experienced in jumping sports (2).

The purpose of this study was to investigate if shoes that vary in midsole drop (negative [NEG], neutral [NTRL], positive [POS]) affect kinetics and kinematics related to lower extremity injury risk during landing. We hypothesized that NEG will illicit jump-landing mechanics associated with PFP and ACL injury compared to NTRL and POS. Decreasing the available ankle dorsiflexion range of motion (ROM) will have a cascading effect on proximal joint ROM, energy absorption, and joint loading. Specifically, peak knee valgus, peak knee abduction moment (KAM), and peak impact forces will be greater in NEG, and sagittal joint displacement and total eccentric work will be less in NEG compared to NTRL and POS.

### Methods

Three trials of maximum effort vertical countermovement jumps were performed by 16 females in shoes with negative, neutral, and positive drops (-1.5°, 0°, and 8° respectively) (Figure 1). Kinematic data of the center of mass and at the joint level were collected using a 13-camera motion capture system (VICON, Centennial, CO). Two embedded force plates recorded 3-dimensional GRF data (Kistler, Amherst, NY). A custom Visual3D script (C-Motion, Inc, Germantown, MD) was used for analysis. One-way repeated measures ANOVAs with correction for sphericity determined the main effect. Post-hoc Tukey contrasts with a Bonferroni correction assessed differences between conditions. A critical  $\alpha$  of 0.01 determined significance.

**Figure 1:** A lateral view of the three shoe conditions. From the left; NEG, NTRL, and POS. Red lines indicate approximate midsole drops.

### Results and Discussion

Peak impact force was similar between shoe conditions. However, shoe condition did affect total eccentric work, where NTRL resulted in significantly less eccentric work than POS. There were no effects of shoe condition on both KAM or knee valgus. Eccentric ankle work was greater in NTRL compared to POS, while knee work was greater in POS compared to both NEG and NTRL. Knee flexion displacement during landing was significantly greater in POS compared to NEG and NTRL, due to greater peak knee flexion in POS (Table 1).

**Table 1.** Mean  $\pm$  SD and  $p$ -value for total (T), ankle (A), knee (K), and hip (H) eccentric work and joint displacement during landing.

	NEG	NTRL	POS	$p$
Eccentric Work (J/kg)				
T	-1.89 $\pm$ 0.51	-1.85 $\pm$ 0.46	-2.02 $\pm$ 0.53	0.029 <sup>b</sup>
A	-0.54 $\pm$ 0.27	-0.57 $\pm$ 0.28	-0.47 $\pm$ 0.23	0.005 <sup>b</sup>
K	-1.24 $\pm$ 0.44	-1.14 $\pm$ 0.42	-1.42 $\pm$ 0.47	<0.001 <sup>ab</sup>
H	-0.11 $\pm$ 0.12	-0.14 $\pm$ 0.17	-0.13 $\pm$ 0.14	0.27
Joint displacement (deg)				
A	60.39 $\pm$ 10.02	58.91 $\pm$ 11.31	58.91 $\pm$ 9.53	0.486
K	-59.57 $\pm$ 12.90	-58.94 $\pm$ 12.72	-63.54 $\pm$ 14.32	0.001 <sup>ab</sup>
H	35.79 $\pm$ 14.48	35.5 $\pm$ 14.85	35.49 $\pm$ 14.23	0.963

<sup>a</sup> Significant difference between NEG-POS ( $p < 0.05$ )

<sup>b</sup> Significant difference between NTRL-POS ( $p < 0.05$ )

We hypothesized that the dorsiflexion induced by NEG would pose a greater risk for PFP and ACL injury by limiting sagittal joint displacement and energy absorption, which was supported by our results. The greater energy absorption in POS, quantified as eccentric work, was primarily driven by greater knee joint work and peak knee flexion. Peak knee flexion ROM, an active form of impact dissipation, can be used to identify stiff landings (3). Small knee flexion ROM during stiff landings increases the strain on passive joint structures, especially the patellofemoral ligament and ACL, to absorb impact. This and can increase injury risk for athletes whose sport involves repeated jumping (2).

However, our results did not support our hypothesis that knee valgus, knee abduction, and peak impact forces would be greater in NEG. Landing on a negatively sloped surface of -3.6° has previously been shown to increase knee valgus and impact forces, suggesting midsole drops greater than -1.5° are needed to affect knee valgus and external loads (4).

### Significance

To our knowledge, this is the first study to examine if dorsiflexion shoes affect landing mechanics related to PFP and ACL injury. We found an immediate effect of shoe drop on knee joint flexion, joint-level eccentric work, and total eccentric work. These are variables associated with increased strain on ligaments in the knee, but in the absence of increased peak KAM, peak knee valgus, and peak impact forces, athletes can be moderately confident that dorsiflexion shoes with drops of -1.5° or less do not increase risk of knee injury. However, caution is advised if using shoes with greater degrees of dorsiflexion as research has yet to determine their effect on injury-related landing mechanics.

# Evaluating Limb Stiffness and Local Dynamic Stability in Cutting and Landing Movements of Female Athletes

Jacob Larson<sup>1</sup>, Michael Zabala<sup>1</sup>,

<sup>1</sup>Department of Mechanical Engineering, Auburn University, Auburn, AL, USA

Email: [jsl0043@auburn.edu](mailto:jsl0043@auburn.edu)

## Introduction

It is well established that the risk of anterior cruciate ligament (ACL) reinjury is higher than the initial risk of injury [1]. Additionally, several studies have suggested that high limb asymmetry increases the risk of injury [5]. A previous internal study found that the combined left and right legged local dynamic stability (LDS) of global knee adduction during a repetitive vertical jump was able to effectively identify previously injured subjects when compared to uninjured subjects using a logistic regression, with a receiver operating characteristic (ROC) = 0.8036 [2]. As this study is a continuation of a previous study investigating local dynamic stability, the goal of this experiment was to compare results from the vertical jump tests to cutting and dynamic landing movements, with the hypothesis that limb stability would differ for cutting and landing movements between injured and uninjured subjects.

## Methods

This study collected the biomechanics of fourteen female D1 soccer, D1 basketball, and club soccer athletes from Auburn University (height = 171.2 ± 8.9 cm, weight = 66.3 ± 8.6 kg, age = 19.8 ± 1.9 yr). The two main metrics in this study are local dynamic stability and maximum limb stiffness during a trial. Local dynamic stability was calculated using the Rosenstein method [3], and limb stiffness was calculated as the change in virtual leg length divided by the resultant ground reaction force [4]. The Limb Symmetry Index (LSI) of these metrics was analyzed using the following formulation:

$$LSI = \left( \frac{Max(Llimb, Rlimb) - Min(Llimb, Rlimb)}{Llimb + Rlimb} \right) * 100\%$$

Participants were screened into two groups: the first having undergone ACL reconstruction in the past two years, and the second for having no previous history of ACL reconstruction. All subjects were active members of their respective sport who were cleared to participate in their sport at the time of testing. All subjects signed informed consent forms approved by the Auburn University Internal Review Board.

## Results

Table 1 shows that the symmetry index of limb stiffness during a landing error scoring system (LESS) jump has a strong and highly significant correlation with the sagittal plane stability of the hip and ankle joints. Additionally, there is a highly significant correlation between the LSI in the right and left limb during a run to cut (RTC) movement.

## Discussion

There are several conclusions to be drawn from the results shown in Table 1, namely that local dynamic stability of the hip and

ankle are strongly correlated with high limb stiffness symmetry during a landing event. This indicates that individuals with a high limb stiffness symmetry also have high stability in the sagittal plane. This conclusion may be tempered due to how much motion occurs in the sagittal plane during a LESS jump, and this relationship should be further explored during vertical drop landing and single-leg landings in future studies.

The second conclusion which can be drawn from Table 1 is that high limb stiffness symmetry during the RTC indicates a decreased local dynamic stability in ankle inversion. This finding is especially interesting, as it suggests that highly symmetric limb stiffnesses could result in lower dynamic stability during a cutting motion. As most studies find that limb symmetry is beneficial to subject health, and high dynamic stability indicates that a subject has a high degree of control over their motion, this finding seems to conflict with both pieces of information. The explanation behind this correlation is currently unclear to the authors, but the finding should be explored further in future studies.

**Table 1.** Bivariate correlation between symmetry indices and combined local dynamic stability

		LDS Hip Flexion	LDS Ankle Flexion	LDS Ankle Inversion
LSI LESS	r	<b>0.5892*</b>	<b>0.6464*</b>	-0.3085
	P	<b>0.0266</b>	<b>0.0125</b>	0.2832
LSI RTC	r	0.1703	-0.3569	<b>-0.6988**</b>
	P	0.5604	0.2103	<b>0.0043</b>

\*\* Significance of p<0.01

\* Significance of p<0.05

## Significance

This research is important to the field of biomechanics because there is much to learn about local dynamic stability, which is seen especially in the correlation between high LSI and low LDS in the ankle. If high LSI and high LDS indicate good subject health, then the negative correlation between these two metrics is one that needs to be reconciled in future studies. Additionally, if this study can further explore correlations between commonly used metrics and local dynamic stability, it will be easier to implement local dynamic stability measures into future research, as well as make the concept of local dynamic stability more easily comprehended to athletes, researchers, and clinicians alike.

### Introduction

Disorders and musculoskeletal injuries affecting the knee are common and limit activity in athletes and the elderly [1]. Current technologies used to diagnose knee problems such as computed tomography and magnetic resonance imaging are limited to clinical environments. Studying the vibratory behavior of the knee when subjected to an external stimulation can reveal information regarding the structure of the joint. Researchers have investigated the vibration characteristics of various parts of the human body such as the skull [2], arm [3], and hip [4]. In this work, vibration transmission through the human knee is used as a tool to determine the presence of meniscus tear in the joint.

### Methods

Six fresh frozen cadaver legs with an initial tear on the lateral meniscus were used in this study. The legs were placed on an adjustable frame at a flexion angle of 30° and fixed with two Velcro bands. The setup consisted of a permanent magnet shaker (LDS V201, Brüel & Kjær, Nærum, Denmark) equipped with a load cell (Honeywell model 31, Honeywell International Inc., Charlotte, NC) and an impedance head sensor (8001, Brüel & Kjær, Nærum, Denmark) at the driving point. Two accelerometers (3225F, Dytran Instruments Inc., Chatsworth, CA) were placed medial and lateral to the patella proximal to the knee joint. The experimental setup is shown in Figure 1. A frequency-sweep sine excitation signal with frequencies from 100 Hz to 4200 Hz and a total length of 180 sec was sent to the shaker, and the transmitted vibration through the joint was recorded using the two accelerometers. Measurements were carried out at three stages: initial (baseline), after sham surgery, and after a simulated medial meniscus tear. For the sham stage, a 3-cm cut was made just anterior to the medial collateral ligament to expose the medial meniscus. The frequency response function (FRF) of the accelerometers with respect to the input acceleration was calculated and compared for all the legs. Student's t-test was used to determine statistical differences in the measured vibration data between different stages of the tests for all the legs.

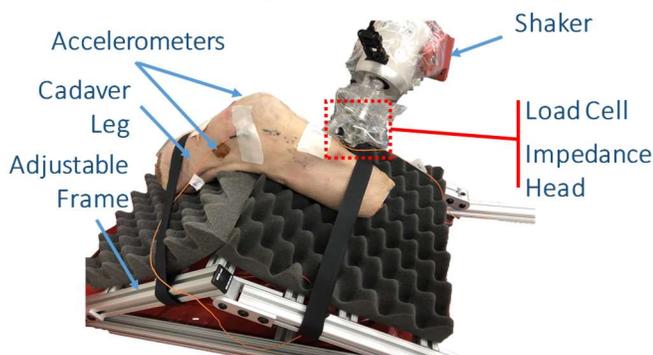

Figure 1. Knee joint vibration stimulation setup.

### Results and Discussion

Initial investigation of FRF diagrams revealed a noticeable change in the magnitude of FRF amongst samples at the

frequency ranges of 2.8 to 3.2 kHz and 2.2 to 2.6 kHz for the medial and lateral accelerometers, respectively. To measure the differences in FRF results, the root-mean-square deviation (RMSD) values of FRF quantities for the meniscus tear case and the sham case with respect to the initial case were calculated. Results for the six legs are presented in Figure 2. Across-specimen mean values of 0.11 and 0.22 were obtained for the sham and meniscus tear, respectively. The meniscus tear demonstrates a significantly higher RMSD compared to the sham with a p-value < 0.01. The results show that altering the structure of the knee joint by cutting the meniscus results in a significant change in the vibration transmission through the joint. However, the changes are only traceable in specific frequency ranges. Similar behavior has been previously observed in studying the vibration transmission in knee implants with loosening [5].

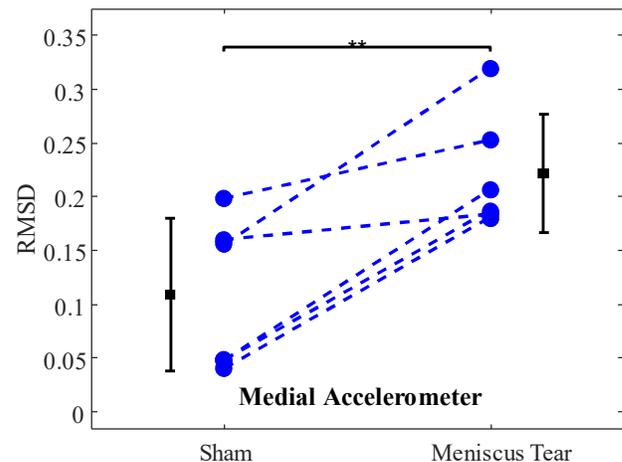

Figure 2. RMSD values for the sham and meniscus tear stages with respect to the initial stage (\*\* indicates  $p < 0.01$ ).

### Significance

This work demonstrates the promising potential of external vibration stimulation as a noninvasive method of monitoring the structural health of the knee joint. Given the available technologies for miniature vibration actuators, the vibration technique can be used to develop wearable devices capable of tracking joint health outside of clinical settings. In addition, such a measurement system can reduce the cost and inconvenience of current diagnostic technologies.

## Kinematic Evaluation of Return-to-Play Hop Tests in a Healthy Population

Kimi D. Dahl<sup>1</sup>, Jacqueline N. Foody<sup>1</sup>, Sarah A. Wilson<sup>1</sup>, Grant J. Dornan<sup>1</sup>, Matthew T. Provencher<sup>1</sup>, and Scott Tashman<sup>1</sup>  
<sup>1</sup> Steadman Philippon Research Institute, Vail, CO, USA  
 Email: stashman@sprivail.org

### Introduction

While return-to-play (RTP) testing is standard practice after ACL reconstruction, there is debate on which tests and criteria to use for effectively assessing an athlete's readiness for safe return to sport [1]. Hop tests remain a standard part of RTP testing batteries. However, passing scores are based only on side-to-side discrepancies in performance (e.g., differences in jump distance); the quality of the movement is rarely assessed. [3] The purpose of this study was to determine the extent of kinematic asymmetry in a healthy population performing standard, RTP hop tests and secondarily to determine the reliability of kinematic measurements from trial to trial.

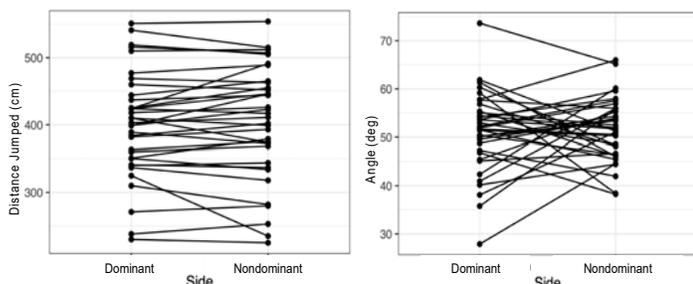

### Methods

Thirty-five healthy adults (28±5yrs; 72.4±11.4kg; 1.75±0.08m; 14 female) were recruited for this study. Participants were pain-free, without any lower extremity or back injury that affected their movement. This study was approved by an IRB, and all participants provided informed consent. Trunk and lower extremity kinematics were captured using eight wearable inertial measurement unit (IMU) sensors (128Hz, APDM). Participants performed three trials of standard-of-care RTP tests, including a single-leg triple hop and a single-leg triple crossover hop for both legs. Consistent with standard test scoring, the trial with the maximum distance achieved from three attempts was used to evaluate asymmetry [2] in the landing phase of the middle hop, and comparisons were made between the dominant and nondominant legs for each test. Correlations and side-to-side difference (SSD) for initial and maximum flexion at both the knee and hip joint were compared. For SSD, legs were considered asymmetric if the measured differences were >10%.

### Results and Discussion

The maximum jump distance occurred on the final trial for 57% of participants for the triple hop on both dominant and nondominant limbs. For the crossover, this was 57% on the dominant and 60% on the nondominant limb. This shows a learning effect that may need to be taken into consideration for patient populations.

For both the triple hop and the crossover hop, healthy volunteers had nearly identical maximum hop distances on both the dominant and nondominant legs. However, for both hop tests, a pattern of high kinematic dissimilarity was seen in initial and max flexion at the hip and knee joints. While the max distance

**Figure 1:** Comparison of dominant to nondominant leg similarity for distance jumped (left) and max knee flexion (right) for the triple jump.

jumped on the dominant leg was strongly correlated with that of the nondominant leg ( $\rho=0.96$ ,  $p<0.001$ ), this correlation was substantially less when assessing kinematic variables (Figure 1). Even though there was dissimilarity between dominant and nondominant legs, there was moderate to good agreement in the reliability of the measurements within a participant between trials for each leg (Table 1). However, the poor symmetry of kinematic variables in this healthy population suggest these measures a) are not the correct metrics to evaluate or b) are not being acquired and identified reliably. In particular, values found at initial landing may be susceptible to variance due to identifying landing timing based only on IMU accelerometer spikes.

**Table 1.** Reliability for variables in both hops (ICC [95% CI])

	Limb	Triple Hop	Crossover Hop
<b>Distance Jumped</b>	Dominant	0.94 [0.90-0.96]	0.92 [0.83-0.95]
	Nondominant	0.94 [0.88-0.97]	0.96 [0.93-0.97]
<b>Initial Knee Flexion</b>	Dominant	0.80 [0.68-0.88]	0.81 [0.70-0.89]
	Nondominant	0.77 [0.57-0.88]	0.77 [0.65-0.90]
<b>Initial Hip Flexion</b>	Dominant	0.84 [0.75-0.90]	0.88 [0.78-0.93]
	Nondominant	0.76 [0.61-0.86]	0.83 [0.64-0.90]
<b>Max Knee Flexion</b>	Dominant	0.61 [0.40-0.78]	0.72 [0.57-0.84]
	Nondominant	0.69 [0.55-0.80]	0.66 [0.52-0.80]
<b>Max Hip Flexion</b>	Dominant	0.83 [0.74-0.89]	0.85 [0.75-0.90]
	Nondominant	0.79 [0.58-0.89]	0.83 [0.66-0.89]

Lastly, SSD in initial knee flexion corresponded to SSD in initial hip flexion for both the triple ( $r=0.58$ ,  $p<0.001$ ) and crossover ( $r=0.50$ ,  $p<0.01$ ) hops. Asymmetry in max knee flexion corresponded to asymmetry in max hip flexion only in the triple hop ( $r=0.43$ ,  $p<0.05$ ). These results encourage the inclusion of exercises and tests that address asymmetry not only of the affected joint but also of the surrounding joints.

### Significance

RTP testing efficacy has been debated in the literature for patients recovering from an ACL injury. However, the tests used and scoring systems remain largely unchanged. Simple symmetry assessments (e.g., jump distance) did not correlate with kinematic symmetry in a healthy population. Thus, basic movement evaluation may not provide information that is as valuable as clinicians may believe. Instead, this study supports the trend toward whole movement pattern evaluation such as Statistical Parametric Mapping to evaluate overall quality of movement. Furthermore, attention should be given to joints surrounding the injury to ensure additional asymmetries are not present.

## Introduction

While return-to-play (RTP) testing is common after ACL reconstructions, there is debate on which tests and criteria to use [1] as well as whether the tests provide a good determination for the patient's readiness to return to sport. Hop tests and strength assessments remain a standard part of RTP testing batteries. However, passing scores are quantitative, and the quality of the movement is rarely assessed. [4] The goals of this study were to determine 1) if kinematic measures from standard RTP hop tests are correlated with maximum jump distance in a healthy population, and 2) if strength and maximum muscle power are correlated with maximum jump distance.

## Methods

Thirty-five healthy adults (28±5yrs; 72.4±11.4kg; 1.75±0.08m; 14 female) were recruited for this study. Participants were pain-free, without any lower extremity or back injury that affected their movement. This study was approved by an IRB, and all participants provided informed consent. Trunk and lower extremity kinematics were captured using eight wearable inertial measurement unit (IMU) sensors (128Hz, APDM).

A power test was performed on a leg press machine (Keiser AIR300) with separate foot plates for comparisons between limbs. A hand-held dynamometer was used to measure isokinetic knee extension strength on each leg. Participants also performed three trials of indoor, standard-of-care RTP tests, including a single-leg triple hop and a single-leg triple crossover hop for both legs. Per standard clinical guidelines, [2] a passing score was defined as a maximum dominant versus nondominant limb difference in hop distance of <10%, and consistent with standard test scoring, [3] kinematics were extracted from the trial with the maximum distance achieved from three attempts. Spearman's Rho correlations were made between this, the maximum power output, and the sum of three isometric knee extension repetitions. Correlations were also made between distance jumped and the kinematic variables of initial and max flexion of the hip and knee joints during the landing phase of the middle hop.

## Results and Discussion

Based on the 10% asymmetry criterion, three participants (8%) failed the triple hop while eleven failed the crossover hop (31%). In a healthy population, it is expected that most, if not all, of the participants would pass; the high failure rate in crossover hop indicates that a passing score indicating a high degree of limb-to-limb symmetry may poorly represent "normal" function and may not be an ideal measure for readiness to return to play.

For both the dominant and nondominant legs, maximum power and the sum of isometric knee extensions were correlated with maximum distance jumped for both hops (Table 1). While it is not surprising that greater strength and power correlate with a larger hop distance, it does bring into question whether total distance jumped, and the capacity to execute it within 10% of the uninjured leg, are appropriate criteria on their own to clear athletes for return to sport. Instead, since strength and power are moderately correlated with jump distance, RTP tests could remove one of these components and add a task that would focus

on movement quality. This may allow for diversity in movement strategy to be analyzed and potentially corrected.

There were no strong correlations between knee joint kinematics and maximum hop distance achieved. However, for the triple jump, maximum hip flexion was moderately correlated

**Table 1.** Spearman's Rho correlation between maximum hop distance and same-side maximum power and isometric knee extension strength.

	Limb	R-statistic Max Power	R-statistic Isometric Extension
Triple Hop Distance	Dominant	0.72 (p<0.001)	0.58 (p<0.001)
	Nondominant	0.78 (p<0.001)	0.58 (p<0.001)
Crossover Hop Distance	Dominant	0.64 (p<0.001)	0.47 (p<0.01)
	Nondominant	0.74 (p<0.001)	0.60 (p<0.001)

with jump distance ( $r=0.19$ ,  $p<0.05$ ). For the crossover hop, initial and max hip flexion were moderately correlated with distance jumped on the dominant side ( $r=0.19$ ,  $p<0.05$  and  $r=0.20$ ,  $p<0.05$ , respectively). For the nondominant leg, only max hip flexion was correlated with jump distance ( $r=0.21$ ,  $p<0.05$ ). These results suggest that jumping technique at the hip may be a factor when completing RTP tests. Thus, it may be advantageous to include exercises and tests in physical therapy that address asymmetry not only of the affected joint but also of the surrounding joints. Within the same jump for each hop test, initial and max knee flexion were highly correlated for both the dominant and nondominant legs. The same was true for initial and max hip flexion.

In conclusion, power, strength, and hip kinematics are factors associated with jump distance on RTP hop tests. Within a jump, the total range of motion at the hip and knee joint depends on the initial joint flexion at landing.

## Significance

Standard single-leg hop RTP tests are scored on distance symmetry and do not incorporate a kinematic analysis. This study shows that a diversity of kinematic patterns may be employed to pass standard RTP tests. Based on the correlations seen for strength and power, an ACLR patient could use brute force to pass their test, while risk factors in their kinematic pattern at the knee and hip joints could go unnoticed. This study adds to the growing body of literature supporting a more comprehensive approach for determining when a patient is ready to return to sport, using criteria that goes beyond achieving an external pass/fail score and instead looks at the quality of the kinematic movement.

# The effect of landing coordination and amputation on high limb loading during bilateral landings

Sarah C Moudy<sup>1,2\*</sup>, Neale A Tillin<sup>1</sup>, Amy R Sibley<sup>1,3</sup>, Siobhan Strike<sup>1</sup>

<sup>1</sup>University of Roehampton, London, UK, <sup>2</sup>University of North Texas Health Science Center, Fort Worth, TX, USA, <sup>3</sup>London South Bank University, London, UK, \*Email: [sarah.moudy@unthsc.edu](mailto:sarah.moudy@unthsc.edu)

## Introduction

High impact forces when landing from a jump are thought to be associated with an increased risk of injury [1]. Previous research has suggested that in-phase flexion coordination strategies and increased trunk flexion may be important for mediating forces upon landing [2]. For individuals with unilateral transtibial amputations (ITTAs), ankle joint mechanics and lower-limb coordination strategies are disrupted in the affected limb [3]. The ankle joint is believed to be crucial for attenuating load such that reduced ankle dorsiflexion has been associated with increases in peak vertical ground reaction force (vGRF). As such, ITTAs are discouraged from participating in sports involving jumping. However, it is unclear how the altered affected limb mechanics may effect the landing coordination by the intact limb. There is limited research to suggest that the intact limb experiences a greater load when landing and thereafter is at a greater risk of injury compared to able-bodied controls. **Thus, the purpose of this study was to examine differences in joint coordination and trunk angles between those who experience high versus low load and if the landing strategy is affected by amputation.**

## Methods

8 recreationally-active ITTAs and 21 controls hung from a custom hanging bar frame with their heels 30 cm off the ground. Bilateral drop landings were performed with each foot landing on a separate force platform. vGRF was time-normalized to 100% from touchdown to maximal knee flexion in the intact limb or dominant control limb (i.e. absorption phase). Ankle, knee, hip, and trunk flexion angles were extracted and coupling angles ( $\theta$ ) were calculated for ankle-knee, knee-hip, and hip-ankle joint pairs using the following equation:

$$\theta_t = \tan^{-1} \left( \frac{Y_{t+1} - Y_t}{X_{t+1} - X_t} \right)$$

where  $t$  = time,  $Y$  = distal joint angular position, and  $X$  = the proximal joint angular position. The average  $\theta$  value from touchdown to peak vGRF was used in further analysis. Trunk flexion range of motion (ROM) was calculated as the maximum change during the absorption phase. Lastly, the duration of the absorption phase was calculated in seconds.

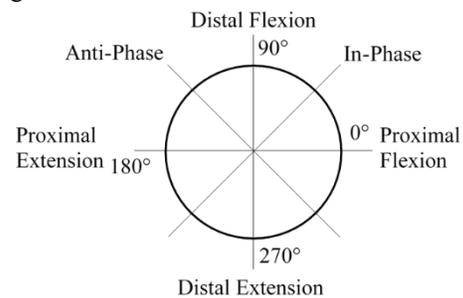

ITTA and control participants were treated as a single cohort to identify high versus low loaders based on peak vGRF. A 10% threshold around mean peak vGRF was used to identify groups. 3 control participants were within this threshold, identified as a middle group, and removed from further analysis.

*Statistical analysis:* Independent  $t$ -tests were performed

between loading groups for each joint pair, trunk flexion, and absorption duration. Hedge's  $g$  effect sizes were calculated and interpreted as  $\geq 0.2$  = small,  $\geq 0.5$  = medium, and  $\geq 0.8$  = large.

## Results and Discussion

Identification of high and low loaders was confirmed with significant and large effects for peak vGRF (Table 1) suggesting comparisons were made on divergent groups. Low loaders landed with a significantly longer absorption duration (Table 1). Coordination strategies found both groups performed in-phase flexion (Figure 1) with low loaders performing greater flexion in the distal segments (i.e. ankle and knee) and greater trunk flexion. While not all comparisons were significant, medium to large effects were found (Table 1). Results suggest that reduced load can be achieved through increasing the time to attenuate load by increasing trunk flexion and ankle and knee flexion.

**Figure 1.** Interpretation of coupling angle values

ITTAs and controls were represented equivalently in both loading groups suggesting that increased vGRF is not dependent on the presence of an amputation rather on landing coordination.

## Significance

The results suggest that 1) ITTAs can adapt their intact limb mechanics similar to an able-bodied control, which is consistent with previous research [4] and 2) high limb loading is dependent on landing coordination rather than amputation. Further, it is possible that the intact limb of ITTAs is not at any greater risk of injury than able-bodied controls.

# Bilateral Asymmetry in Leg Stiffness During Dynamic Activities

William Taylor<sup>1</sup>, Abigail Jacobs<sup>1</sup>, Jacob Larson<sup>1</sup>, Michael Zabala<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Auburn University, Auburn, AL, USA

Email: [wat0011@auburn.edu](mailto:wat0011@auburn.edu)

## Introduction

Many of the injuries sustained by athletes in contact sports are preventable soft tissue injuries which occur during deceleration and change of direction movements, such as cutting or landing [1]. Leg stiffness is important to understanding deceleration during these events because an individual's leg stiffness determines the response to generated ground reaction forces in dynamic movement. This study aimed to provide pilot data on tests that involved cutting and landing movements and to identify whether stiffness differences existed between an injured and uninjured population in either movement. A difference in the bilateral limb stiffness between injured and uninjured subjects was expected.

## Methods

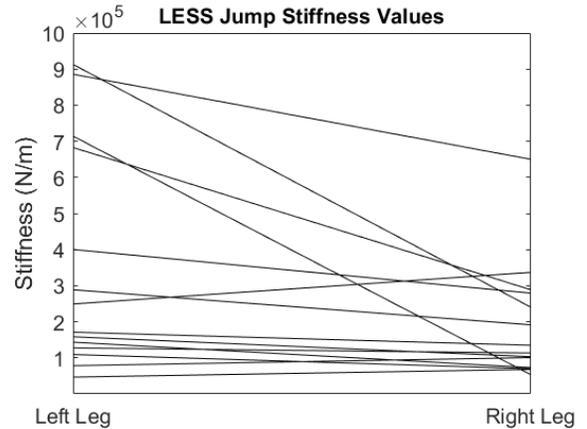

This study retrospectively reviewed the kinematics of run-to-cut (RTC) and Landing Error Scoring System (LESS) jumps from fourteen female subjects who participated in D1 soccer, D1 basketball, or club soccer teams from Auburn University. To participate in the study, all subjects had to be cleared to participate in their respective sport. Out of the 14 athletes, two had previous bilateral ACL injuries, two had previous unilateral ACL injuries, 3 had other previous surgically repaired knee injuries, and 7 did not have any previous knee injuries. Each subject signed informed consent forms approved by the Auburn University Internal Review Board. Leg stiffness was defined as the resultant vertical ground reaction force divided by the change in the distance between the calculated hip joint center of the leg and the center of pressure of the foot during contact with an AMTI force plate [2]. Paired *t*-tests were used to compare right to left and injured vs uninjured legs.

## Results

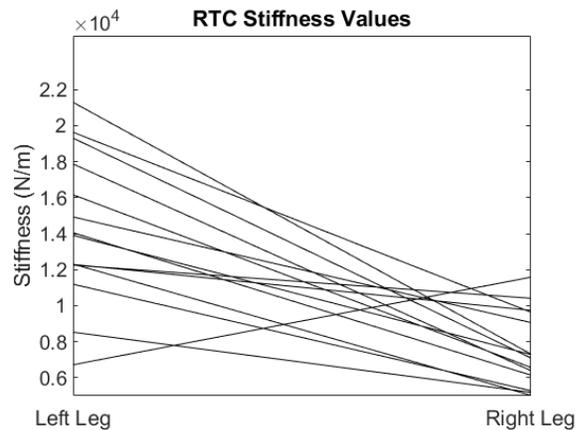

The *t*-tests showed that the left leg was more stiff than the right leg for all subjects performing the LESS jump, and that the left leg was more stiff than the right in RTC for every subject but one. Data from these tests is shown in Figures 1 and 2. Results did not show significant differences between previously injured and uninjured legs.

## Discussion

This study identified a significant difference in bilateral leg stiffness in both LESS and RTC tasks but did not identify any significant difference between injured and uninjured populations. These findings contradict the initial hypothesis and the results of a previous study that found a significant difference in bilateral leg stiffness between injured and uninjured professional Australian football players [3]. The differences in results could be attributed to a different selection in dynamic movement, less specific injury classification, and a small sample size. These issues could be addressed in future studies by comparing affected and unaffected limbs and testing further subjects.

**Figure 1:** Difference in Stiffness Values for the Left and Right Legs in LESS trial (Mean Difference =  $1.81 \times 10^5$  N/m;  $p=0.0278$ )

**Figure 2:** Difference in Stiffness Values for the Left and Right Legs in a RTC Trial (Mean Difference =  $7.39 \times 10^3$  N/m;  $p=0.0002$ )

## Significance

This is important to the field of biomechanics because the results in this study contradict those of another and bring up a discussion about whether bilateral limb stiffness is a reliable indicator of injury. This study expected that bilateral limb stiffness would be different for injured and uninjured. However, it did not find that to be the case. Future studies should further investigate the difference in bilateral limb stiffness for injured and uninjured populations performing various movements, and thus determine whether differences in bilateral limb stiffness is indicative of injury.

## Introduction

Reserve Officer Training Corps (ROTC) cadets regularly participate in physical training (PF) and physical fitness tests (PFT). PFT are field-based tests evaluate multiple cadets at the same time using minimal equipment, providing scores used by the United States military as an approach to injury prevention [4]. However, the current field-based tests lack the ability to deliver accurate assessments of fitness or predict the likelihood of injury [4]. Meanwhile, clinical assessments of physical health and fitness are considered to be more reliable and valid [4]. The prevalence of lower extremity (LE) injuries with cadets has raised concerns about the efficiency of PT and PFT scores when it comes to injury prevention [1,2,3]. This concern led to a structural adaptation of the PFT in each of the branches. Therefore, the purpose of this study was to evaluate the relationship between traditional field-based PFT scores and clinical assessments of physical health and fitness.

## Methods

The study was divided into two sessions. A total of 225 cadets from various ROTC branches were recruited for field assessments similar to the PFT (*Session 1*). Participants completed a performance test consisting of 2-minute split lunge jumps, 2-minute up-down planks, and a shuttle run. The performance testing was scored by how many split-lunges or plank up-downs the participants completed within two minutes. The shuttle run was timed once and consisted of a back and forth sprinting pattern.

Twenty-eight cadets (*20 males*: 183cm ( $\pm 5.3$ ), 88.4kg ( $\pm 12.6$ ), 21.8yrs ( $\pm 3.4$ ); & *8 females*: 167cm ( $\pm 5.2$ ), 59.6kg ( $\pm 7.4$ ), 20.7 ( $\pm 1.8$ )) participated in additional clinical and laboratory tests (*Session 2*). The branches represented were: Air Force (11 cadets), Army (4), Marines (5), & Navy (8). Participants completed a full-body Dual-Energy X-Ray Absorptiometry (DEXA) scan (Hologic, Marlborough, MA), a lower and upper quarter Y-Balance test, and isokinetic testing (CSMi, Stoughton, MA). The isokinetic testing involved five repetitions of bilateral knee flexion/extension (90 & 120°/sec), hip abduction/adduction (60 & 180°/s), and ankle plantar/dorsiflexion (60 & 120°/s). All data were recorded or extracted via Microsoft Excel and imported to MATLAB (MathWorks, Natick, MA) for further analysis. Following session 2, the most current PFT scores were collected from the respective cadre leadership. The PFT (branch specific) consisted of three exercises: push-ups (or pull-ups), sit-ups/curl-ups, and a 1-mile run (or 1.5-mile run).

Pearson product-moment correlation coefficient analyses were conducted to evaluate the relationship between PFT scores and clinical assessments. Statistical analyses were completed via SPSS version 25.0 (IBM, Armonk, NY).

## Results and Discussion

The main finding of the present study was the overall weak relationship between clinical assessment scores and ROTC PFT

scores. On average, neither Y-Balance, nor DEXA scans, or isokinetic strength test results yielded significant correlations between the three field-tests ( $r < 0.5$ ). Both bone mineral density and lean mass also showed a weak correlation to PFT scores. Similarly, none of the isokinetic strength test results were found to be related to PFT scores. Nevertheless, a significant difference was found between right and left lean mass (kg), as well as relative knee extensor and flexor peak torque (Table 1).

Table 1

Right vs. Left Lower Extremity Differences (Mean & SD)

	Lean Mass (kg)	Extension PT 90°/s (Nm)	Flexion PT 90°/s (Nm)
Air Force	0.34 ( $\pm 0.33$ )†	0.75 ( $\pm 0.35$ )†	0.50 ( $\pm 0.22$ )†
Army	0.32 ( $\pm 0.35$ )	0.72 ( $\pm 0.24$ )†	0.49 ( $\pm 0.35$ )
Marines	0.31 ( $\pm 0.2$ )†	0.75 ( $\pm 0.11$ )†	0.71 ( $\pm 0.22$ )†
Navy	0.34 ( $\pm 0.19$ )†	0.82 ( $\pm 0.22$ )†	0.67 ( $\pm 0.32$ )†

† statistically significant difference ( $p < 0.05$ )

positive difference shows right LE values greater than left LE values

This finding suggests a discrepancy between the right and left LE and warrant further investigations, specifically regarding the injury rate within the ROTC population. Interestingly, while lean mass and isokinetic knee strength displayed a weak relationship ( $r < 0.1$ ), fat mass and isokinetic knee strength had a moderately strong negative relationship ( $r = -0.64$ ). This implies that the amount of fat mass may affect strength more than the amount of muscle mass.

Overall, the results indicate that clinical assessments are not promising predictors of performance in ROTC field-based physical fitness tests, yet may be useful as additional screening tool for injury prevention.

## Significance

The weak relationship between PFT scores and clinical assessments suggests that field-based test scores, such as push-ups, sit-ups, pull-ups, or distance runs may inherently not have the same injury screening capabilities as their clinical counterparts. This was partly shown by the significant bilateral difference in both lean mass and knee extensor and flexor knee torque. Field-based test would not be able to provide such information. Future research should focus on the occurrence of lower extremity injuries and the correlation to bilateral weaknesses revealed by clinical assessments.

## Acknowledgments

We would like to thank the Army ROTC, Air Force ROTC, and Navy ROTC cadres of the University of Idaho and Washington State University for their support and willingness to participate in this research study.

# No Difference in Knee Biomechanics During Landing Between Individuals with and without a History of Concussion

## Introduction

Recreationally active individuals who are 3 years post-concussion have a higher rate of anterior cruciate ligament (ACL) tear compared to individuals without a history of concussion [1]. Limited research has investigated the effects of concussion on lower extremity mechanics during landings, which are commonly associated with lower extremity injury risk. Individuals with a history of concussion had greater trunk flexion during cutting an average of 124 days post-concussion [2]. Moreover, individuals who were an average of 3.1 years post-concussion exhibited less knee varus and external rotation during a jump cut maneuver compared to individuals without a history of concussion [3].

The purpose of this study was to examine the influence of concussion history on lower extremity biomechanics during a double leg landing. It was hypothesized that individuals with a history of concussion would have greater vertical ground reaction force, greater vertical loading rate, lesser peak knee flexion angle, greater knee abduction angle, and greater external knee abduction moment compared to individuals without a history of concussion.

## Methods

Twenty-five individuals with a history of concussion (BMI=24.5 (3.5) kg/m<sup>2</sup>; 21.6 (1.5) years), and 25 individuals without a history of concussion (24.8 (3.4) kg/m<sup>2</sup>; 21.8 (2.1) years) participated and were matched on sex (13 females, 12 males), age ( $\pm 3$  years), and body mass index ( $\pm 1$  kg/m<sup>2</sup>). Participants were included if they were recreationally active and between 18-30 years old. Participants with concussion were included if they had sustained a concussion within the last 6 years [4]. Participants were excluded if they had an acute concussion (preceding 6 months) [3], lower extremity injury in the preceding 6 months, any history of lower extremity surgery and/or traumatic injury, neurological conditions that may alter balance, or currently using medication that may alter balance. Concussion history was assessed via 2 questions: (1) "have you ever been diagnosed with a concussion by a medical professional?" (2) "have you ever sustained a head injury with concussion like symptoms not diagnosed by a medical professional?" If they answered "yes" to either question, they were placed in the history of concussion group [4].

Participants jumped from a standardized 30cm box half the participants' height away from 2 AMTI forceplates. Marker trajectories were sampled at 240 Hz, and force plate data were sampled at 2400 Hz. All data were exported to Visual 3D for model construction. Marker position and force plate data were low pass filtered using a zero-phase lag fourth-order Butterworth filter at 12hz [5]. Peak angle and external moments are reported during the landing phase. Values from both limbs from 3 trials were averaged for analysis. Joint moments were normalized to a product of bodyweight and height (BW\*height), and forces were normalized to bodyweight (BW). A one-way multivariate analysis of variance was used to compare landing outcomes between individuals with and without a history of concussion.

## Results and Discussion

There was no difference in landing outcomes based on group ((F<sub>5, 44</sub>)=0.966, p=0.431, Wilk's  $\Lambda$ =0.898) (Table 1).

Table 1: Summary of Results

Variable	Concussion (mean $\pm$ SD)	Control (mean $\pm$ SD)
Vertical Ground Reaction Force (BW)	1.89 $\pm$ 0.25	1.83 $\pm$ 0.28
Vertical Loading Rate (BW/sec)	59.33 $\pm$ 13.60	52.39 $\pm$ 11.62
Knee Flexion Angle (degrees)	-93.40 $\pm$ 11.97	-91.22 $\pm$ 9.16
Knee Abduction Angle (degrees)	11.75 $\pm$ 6.18	10.41 $\pm$ 6.11
Knee Abduction Moment (BW*Height)	0.035 $\pm$ 0.019	0.033 $\pm$ 0.014

Lynall et al. found that individuals who were 124 days post-concussion had greater trunk flexion compared to individuals without a history of concussion [2]. Additionally, individuals an average of 49.9 days post-concussion had greater hip stiffness, and lower knee and leg stiffness compared to their pre-season baseline scores [6]. The individuals with a history of concussion in this study were an average of 3.3 years post-concussion. It is possible that neuromuscular control is resolved in individuals who are approximately 3 years post-concussion. Previous research found lower knee varus and external rotation during a jump cut maneuver in individuals who were 3.1 years post-concussion compared to those without a history of concussion [3], and greater rates of ACL tear have been found 3 years post-concussion [1]. The discrepancy in results may be due to the different tasks performed, or the simultaneous use of a Flanker task [3].

## Significance

Individuals with a history of concussion may not have aberrant drop vertical jump biomechanics. Lower extremity injury risk following a concussion may be due to other factors such as the inability to simultaneously process proprioceptive and external stimuli. Future research is needed to determine clinical methods for assessing this inability to process multiple stimuli, and if this deficit may contribute to injury following concussion.

# Lower Extremity Stiffness is Altered During Decision-Making Drop Jumps in Males and Females

## Introduction

Leg stiffness associates with measures of athletic performance and injuries, making it a versatile and applicable neuromuscular control measure in coaching and rehabilitation (1,2,6). Drop jumps are commonly used to study neuromuscular control mechanisms, like leg stiffness, to identify performance and injury mechanisms (5). However, cognitive constructs important for sports (i.e. reaction time, visual processing speed) may be linked to non-contact injuries and landing mechanics during drop jump protocols simulating cognitive game-like demands (4,8). Thus, adding a cognitive task to drop jump activities may mimic more game-like settings (3,4,6). Importantly, reported sex differences in neuromuscular control of landing indicates reason to analyse sex differences during cognitively loaded drop jump (6). Thus, the purpose of this study was to determine differences in ankle, knee, hip, and leg stiffness among drop jump of varying cognitive demands and between males and females. Secondly, measures accessible to coaches, clinicians and researchers, like ground contact time and jump height performance, were analysed in relation to leg stiffness to provide potential applicable training and rehabilitation implications.

## Methods

Thirty healthy, active young adults (males=12, females=18 age=20±1yr, height=1.7±0.1m, mass=69.8±11.0kg) performed drop jump and drop lands under four conditions from a 0.3m box placed one-half the participant's height from the force plates (7). The standard condition involved asking participants to perform a drop jump or drop land. The choice condition allowed participants to volitionally choose between a drop jump or drop land. Visual and auditory conditions involved decision-making through reactions to visual or auditory cues presented while the participant was in mid-air. Three jumps and one land were randomized in each condition. Leg stiffness equaled the ratio of peak vertical ground reaction force and change in leg length between foot strike and time of minimum leg length. Leg length equaled the distance between the lateral malleolus and greater trochanter. Joint stiffness equaled the ratio of the change in joint moment and angular displacement between foot strike and time of minimum joint angle. All stiffness was normalized to body mass. A 5n threshold identified ground contact time and vertical center of mass position displacement identified jump height. A 2x4 (sex x condition) repeated measures MANOVA with post-hoc Bonferroni adjustments identified differences in lower extremity stiffness and performance outcome variables. Pearson product correlations were performed among dependent variables within conditions.

## Results and discussion

There was no significant interaction between sex and condition. There was a significant main effect of condition ( $\eta^2=0.703$ ,  $F(12,206.660)=2.977$ ,  $p=0.005$ ) and sex ( $\eta^2=0.440$ ,  $F(4,24)=2.977$ ,  $p=0.008$ ). Standard drop jump ankle stiffness was larger than visual drop jump ( $p=0.044$ ), and overall leg stiffness was larger during audio drop jump compared to the standard drop

jump ( $p=0.005$ ). Females exhibited lower ankle stiffness compared to males ( $p<0.001$ ).

Auditory drop jumps exhibited longer ground contact time ( $0.63\pm0.13s$ ) compared to visual ( $0.57\pm0.09s$ ,  $p<0.001$ ), choice ( $0.55\pm0.11s$ ,  $p<0.001$ ) and standard drop jump ( $0.53\pm0.10s$ ,  $p<0.001$ ). Audio drop jump height was lower compared to standard drop jumps ( $p=0.013$ ), and visual drop jump height was lower compared to choice and standard drop jumps. Males jumped higher than females ( $p=0.011$ ).

Increased leg stiffness was related to decreased ground contact time during standard drop jump with a large effect relationship ( $r=-0.523$ ,  $p=0.003$ ) and decreased choice drop jump with a moderate effect ( $r=-0.383$ ,  $p=0.037$ ). However, this relationship was not statistically significant during audio and visual drop jumps.

Our results indicate ankle and leg stiffness are influenced during the drop jump in the presence of reactive decision-making and between males and females. Females are reported to exhibit decreased leg stiffness during hopping (5). Although increased stiffness is related to enhanced athletic performance, too much or too little stiffness, allowing for increased forces or excessive joint motion, may both relate to injury (2,5,6). Our results of decreased ankle stiffness in females during drop jumps support previous findings and may contribute to increased lower extremity laxity postulated to influence injury mechanics (5).

## Significance

Differences in drop jump mechanics between different decision-making stimuli and sex have the potential to provide enhanced rehabilitation and coaching tools. Understanding the lack of relationship between ground contact time and leg stiffness during reactive-decision making can allow coaches to monitor ground contact time while implementing auditory and visual stimuli specific to a particular sport. Cues focusing on ground contact time are reported to change leg stiffness (1,2). Thus, considering cues during reactive-decision making drop jumps may contribute to specific stiffness training goals and improve return-to-play protocols specific to a sport. Considering programs that emphasize ankle stiffness in females may benefit both training, rehabilitation and high rates of injuries like anterior cruciate ligament injuries.

# The Effects of Foot Position on Gluteus Maximus Activation During Jump Tasks

Jason Brunet, Emma Grote, Paige Janka, Tanner Strommen, Mostafa Hegazy  
Southwest Minnesota State University, Marshall, MN, USA

## Introduction

The primary function of the GMAX during sprinting is trunk and hip control on the stance leg side, as well as decelerating the swing leg [1]. For many individuals the GMAX is often weak or inactive. Inability to properly activate the GMAX has been termed “gluteal amnesia”. This phenomenon can be attributed to prolonged periods of sitting [2]. Thus, activation of the GMAX is often the focal point of many training programs. Plyometric tasks involving forward movement stimulate activation of the GMAX in order to stop this forward movement. The use of plyometric training is very popular in sports that involve sprinting such as baseball and softball. It is commonly believed that landing on the heels will produce the greatest amount of GMAX activation. However, there are no studies that have reported this idea. Kovacs et al. (1999) reported no difference in GMAX activation when performing forefoot and heel-toe landing during a drop jump[3]. The Tensor Fasciae Latae (TFL) and Gluteus Medius (GMED) are both hip abductors, however, overactivation of the TFL has been linked to different lower limb disorders. An ideal GMAX exercise would be one that maximizes its activity as well as that of the GMED while reducing activity of the TFL. Thus, the purpose of this study was to determine if foot position during landing affects the activation of the GMAX in Division II baseball and softball players. A secondary purpose was to determine how foot position affects activation of the GMED and TFL.

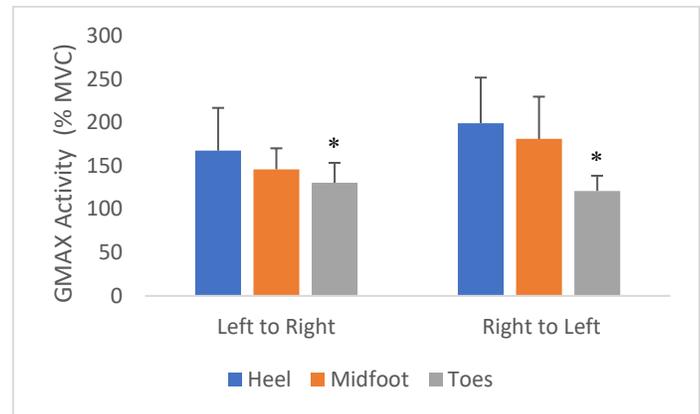

## Methods

Fifteen male baseball players and fifteen female softball players from Division II teams participated in this study. Upon arrival, participants had EMG electrodes (Delsys Trigno Avanti Sensors, Natick, MA) placed on their right and left GMAX, GMED, and TFL. Participants performed three different plyometric tasks, each with three different landings on toes, flatfoot, and on heels with each condition repeated 3 times. The plyometric tasks used were as follows: broad jump (9 trials), forward leap on the right and left side (9 trials per side), and leap with a 90-degree turn on the right and left side (9 trials per side). Task distance was the length of their lower limb for all trials. Muscle activation during landing were calculated as a percent of maximum voluntary contraction. Mixed design ANOVAs with landing type as the within subjects factor and gender as the between subjects factor were conducted.

## Results and Discussion

Heel and flatfoots landing led to a significantly greater GMAX activation when compared to toe landings during both right and left forward leaps ( $F(2, 56) = 4.038$  ( $p < 0.05$ ) and  $3.614$  ( $p < 0.05$ ) for landing on the left and right foot, respectively; Figure 1). Kovacs et al. (1999) reported an increase in plantar flexor activity during drop landings on the toes compared to heel landing [3]. They suggested landing on toes allows the plantar flexors to absorb the impact force. When landing on heels, plantar flexor moment arm is too small for them to be effective, thus control is shifted to the hip, where the GMAX plays a major role. Similarly, it is likely that heel and midfoot landings shifted the load away from the plantar flexors in the forward leap task. Kovacs et al.

(1999) did not find a difference in GMAX activation. However, during a forward leap, the GMAX needs to be more active than during a drop jump to control forward trunk flexion.

**Figure 1:** Softball player gluteus maximus activity as a percent of maximum voluntary contraction (%MVC). \* Indicates significantly lower activity ( $p < 0.05$ ).

Foot placement during landing from the 90 degree-turn leap showed no significant difference in GMAX activation ( $p > 0.05$ ). In case of the 90 degree-turn leap, the task is novel for most individuals. Thus, like any new motor skill, participants tended to be stiff during landing regardless of foot placement to reduce degrees of freedom[4]. We hypothesize the outcome may have been different had it been a task participants are familiar with. Foot placement during landing from the broad jump showed no significant difference in GMAX activation ( $p > 0.05$ ). Compared to the leap, the broad jump used two feet. Since the distance used was similar in both cases, it is likely forward momentum during the broad jump was not high enough to elicit a difference for this task and perhaps doubling the distance was warranted. There was no significant difference in GMED and TFL activation during all landings for all tasks ( $p > 0.05$ ) nor was there a gender difference ( $p > 0.05$ ).

## Significance

In this study there was evidence found to support the need to land on heels or midfoot during a forward leap when the aim is to maximize activation of the GMAX. We found no evidence to suggest landing on heels or midfoot would increase GMAX activation during a forward leap with a 90-degree turn or during a broad jump. Thus, when performing such task there may be no need to instruct individuals to land on their heels. However, further examining the effect on jump distance and task novelty is warranted.

## Acknowledgments

We would like to thank the Southwest Minnesota State University baseball and softball teams their participation.

## Do inclined sleeping surfaces impact infants' upper body muscle activity and movement?

Junsig Wang, Safeer F. Siddicky, John L. Carroll, Brien M. Rabenhorst, David B. Bumpass, Brandi N. Whitaker, Erin M. Mannen  
University of Arkansas for Medical Sciences, Little Rock, AR  
Email: [Jwang3@uams.edu](mailto:Jwang3@uams.edu)

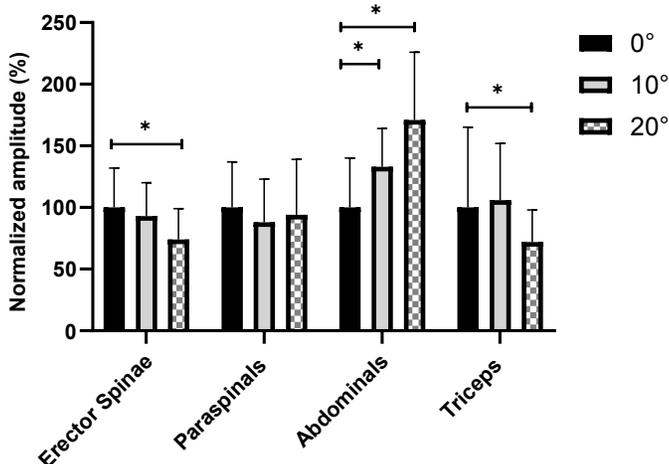

### Introduction

The infant sleep environment has been highlighted due to an increase in the tragic incidence of Sudden Infant Death Syndrome (SIDS). However, commercial infant products evolve quickly, and over the past ten years, infants have been placed to sleep in the relatively new class of Inclined Sleep Products, designed to keep an infant supine at a 10° to 30° incline. Parents are advised to always use restraints in the products and to discontinue use once an infant has the ability to roll over. This implies that the design of infant inclined sleep products may have additional suffocation hazards when infants find themselves prone in the product. However, no published study has investigated how babies move and use their muscles in different inclined surface conditions. Thus, the purpose of this study was to assess upper body muscle activity and kinematics while normal healthy infants were placed on different inclined crib mattress surfaces (0° vs. 10° vs. 20° vs. 30°) during prone positioning.

### Methods

Fifteen healthy full-term infants (age: 17.7±4.9 weeks; 8M, 7F; length: 61.5±4.1 cm; weight: 6.5±1.0 kg) were recruited for this IRB-approved study. The participants were placed prone on the customized crib mattress at 0°, 10°, and 20° for 60 seconds. The 30° incline was excluded since we observed babies were not able to maintain a stable lying posture due to sliding down the incline. Surface EMG (Delsys Inc., Natick, MA; 1000Hz) was recorded from cervical paraspinal, abdominal, erector spinae, and triceps muscles. A motion analysis system with 10 high-resolution cameras (Vicon Nexus, Oxford, UK) was used to collect three-dimensional kinematic data at 100 Hz during each testing condition. Sagittal plane range of motions of neck and trunk as well as the number of neck and trunk angle peaks were calculated. Repeated Measures ANOVAs and Bonferroni post-hoc adjustments were performed to test the effect of incline angles.

### Results and Discussion

**Figure 1:** Effect of Incline (0° vs. 10° vs. 20°) on EMG: erector spinae, cervical paraspinals, abdominals, and triceps. \* indicates  $p < 0.05$  when compared to 0° or 10°.

**Table 1.** Effect of Incline (0° vs. 10° vs. 20°) on kinematic variables

Variable	0°	10°	20°	Main effect p value
Neck ROM (deg)	40±17	44±15	45±15	0.628
Trunk ROM (deg)	26±11	24±11	26±9	0.678
# of neck peaks per 10s	1.4±0.9	1.5±0.7	1.9±1.7	0.459
# of trunk peaks per 10s	0.7±0.6	1.0±0.8	0.9±0.6	0.453

Erector spinae and triceps muscle activity was decreased by 26% and 28% when comparing to 20° to 0° ( $p = 0.019$ ,  $p = 0.036$ ; Figure 1). Abdominal muscle activity was increased by 33% and 71% when comparing when comparing 10° and 20° to 0° ( $p = 0.037$ ,  $p = 0.006$ ; Figure 1). No significant differences on cervical paraspinal muscle activity and kinematic parameters (neck and trunk ROMs; number of neck and trunk angle peaks) were found (Table 1).

The babies were not moving their heads or trunks more or less often on an inclined surface, yet the muscle activity profile was significantly different. Inclined surfaces (especially 20°) require greater abdominal muscle activity while decreasing erector spinae and triceps muscle activities. The core muscles (abdominals) require 71% more activity to maintain a prone lying position, indicating that muscle fatigue of the abdominals could occur more quickly at an incline (20°) compared to a flat surface (0°). Thus, this situation could likely result in expedited muscle fatigue as the baby attempts to reposition and self-correct.

### Significance

The biomechanics of infants is grossly understudied and scarce compared to older children and adults. To the best of our knowledge, this study is the first to determine the effect of different inclined surfaces on infants' upper body and core muscle activity as well as upper body kinematics. During prone positioning, the 20° inclined surface resulted in significantly higher muscle activity of the trunk core muscles (abdominals), which may exacerbate fatigue and contribute to suffocation if infants cannot self-correct.

## Introduction

Repetitive mechanical loading of the musculoskeletal system can result in accumulation of damage to bone microarchitecture. These overuse injuries are referred to as bone stress injuries (BSI). BSIs account for virtually 20% of all injuries reporting to sports medicine clinics [1]. BSIs of the metatarsals have been reported to account for 65% of total BSIs in military recruits [2]. In a recent chart review of athletes diagnosed with metatarsal BSI, we found a 2:1 ratio between women and men. BSIs are most frequently found in the second and third metatarsals [3]. Several biomarkers for BSI risk have been proposed, including low areal BMD and weakness of intrinsic foot muscles. We hypothesized that female runners have lower bone strength and weaker foot muscles compared to men. In this study, we characterized the bone structure and muscle strength in a group of healthy runners.

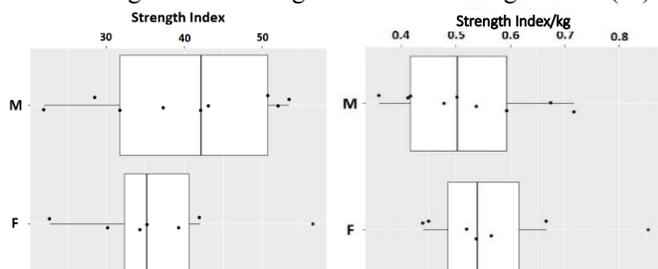

## Methods

Sixteen runners (9 male, 7 female, age=25±8 yrs) volunteered for participation for this institutionally approved, ongoing study. Subjects were screened for metabolic disorders, previous BSIs, and weekly running distance (≥16 km/week for the past 12 months). Arch strength was assessed using a doming exercise described previously [4, 5]. Quantitative computed tomography (XtremeCT; Scanco, Switzerland) was performed on all subjects. CT images (246 x 246 x 246 μm voxels) were taken of the entire metatarsal volume.

**Figure 1:** Reconstruction of the forefoot (left) with cross-sectional bone density displayed (middle). Lines show density-weighted center of mass and principal moments of the second metatarsal shaft (right).

Integral masks of the right, second metatarsals were imported into MATLAB (MathWorks; Natick, MA). Bones were aligned along the longitudinal axis. Geometric characteristics were calculated for each individual, including principal moments of inertia and a geometric strength index. The strength index (SI) at

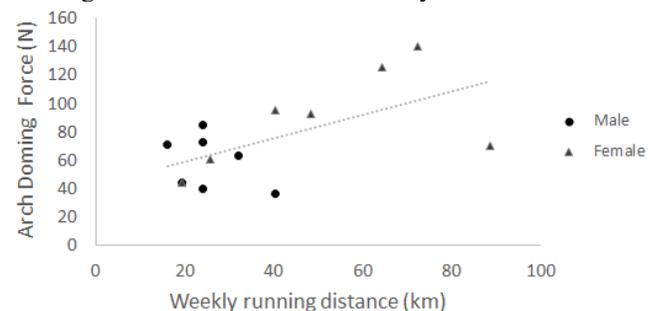

**Figure 2:** (Left panel) Men had higher second metatarsal SI (mm<sup>3</sup>). SI normalized to body mass were similar by sex (mm<sup>3</sup>/kg, Right panel).

the mid-shaft was calculated as the ratio of polar moment of inertia and metatarsal width [6].

## Results and Discussion

Second metatarsal SI was significantly correlated with body mass ( $r=0.532$ ,  $p=0.03$ ). Both raw and normalized SI values to body mass are summarized in the whisker plots in Figure 2. After normalization, SI was not different between men and women ( $p=0.42$ ). SI is only a single metric calculated at one discrete location, and may not be adequate to discern differences in mechanical integrity of spatially complex shapes such as metatarsal bones.

Arch doming strength was not significantly different between sexes ( $p=0.06$ ); however, athletes with greater weekly running distance tended to have greater arch muscle strength (Figure 3). Arch strength was not associated with body mass.

**Figure 3:** Peak force recorded during maximal voluntary arch doming contraction increased with running activity ( $R^2 = 0.35$ ,  $p=0.05$ ).

Neither geometric bone strength nor arch doming strength were different between male versus female healthy runners. Although bone strength scaled with body mass, arch doming strength did not. Collectively, these data support the concept that healthy musculoskeletal systems adapt to the mechanical demands placed on them.

## Significance

Our preliminary findings suggest that the increased rate of BSI in female runners cannot be explained by deficits in these measures of bone or muscle strength. In this healthy group, arch muscles were stronger in those who ran more. Applying this method to measure characteristics within athletes with metatarsal BSI may help understand risk factors and management of these injuries.

# SEX AND LEG DIFFERENCES IN ACL STRESS DURING UNILATERAL DROP LANDING

Jake A. Melaro & Joshua T. Weinhandl

Department of Kinesiology, Recreation & Sport Studies, University of Tennessee, Knoxville, TN, USA

Email: [jmelaro@vols.utk.edu](mailto:jmelaro@vols.utk.edu)

## Introduction

Of the estimated 120,000-400,000 anterior cruciate ligament (ACL) injuries reported annually, roughly 70% are the result of noncontact causes [1]. Athletes consistently exposed to dynamic landing movements are at greater risk of ACL injury. Further, women incur ACL injuries at rates 2-8x greater than men [2]. The link between ACL injury and leg dominance has been investigated but remains unclear. Previous research has shown that non-dominant (ND) compared to dominant (D) leg landings may increase ACL injury risk while being further influenced by sex [3]. The purpose of this study was to investigate the influence of sex and leg dominance on ACL Stress during unilateral landings. We hypothesized that greater ACL stress would be observed in the women and during ND leg landings.

## Methods

Forty active participants (20 men, 20 women) performed unilateral drop landings on both their D and ND legs. Participants stepped off a 40 cm box onto a force platform while wearing reflective markers so that force and 3D positional data could respectively be collected. OpenSim static optimization was used to simulate all D and ND leg landing trials whereby specific muscle forces for the quadriceps, hamstrings, and gastrocnemius were estimated and then input into a 3D knee model to estimate ACL stress [4] normalized to body mass. A 2x2 (sex x leg) mixed model ANOVA was run to assess differences in ACL stress. 3D knee joint kinematics and kinetics were also analyzed. Cohen's *d* effect sizes were calculated to determine the magnitude of differences between groups.

## Results and Discussion

A significant sex x leg interaction effect was observed for ACL stress ( $p=.046$ ). Post-hoc comparisons revealed differences between legs in the women ( $p=.005$ ,  $d=0.64$ ) but not the men. Women experienced higher ACL stress than men in the D ( $p<.001$ ,  $d=2.47$ ) and ND ( $p<.001$ ,  $d=1.77$ ) leg.

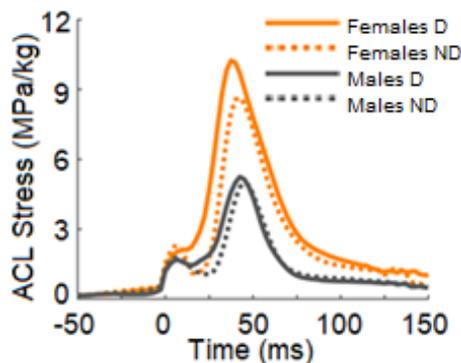

Figure 1: ACL Stress during unilateral drop landings

These results show that women undergo greater ACL stress than men during unilateral drop landings. Further, women experience greater ACL stress during these landings on their D leg. These discrepancies may be due to anatomical differences and different neuromuscular landing strategies that could partially explain why women are at greater risk of noncontact ACL injury than men.

Furthermore, the only leg main effect observed was for knee rotational moments ( $p=.001$ ) as the ND legs for both men ( $d=0.57$ ) and women ( $d=1.00$ ) were subjected to greater peak internal rotation moments than the D legs.

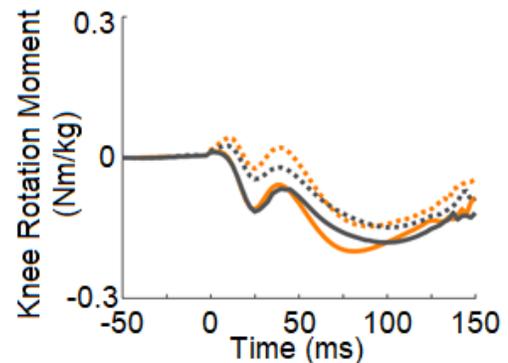

Figure 2: Knee rotation moment during unilateral drop landing

## Significance

The magnitudes of the differences observed equated to women experiencing 89 and 71% greater ACL stress during the landings in their D and ND legs, respectively. Further, women were exposed to approximately 17% greater ACL stress in their D leg compared to their ND leg. These data reveal a link between biological sex and leg dominance and their respective influences on ACL stress during single-leg landing tasks. Leg Differences in leg strength, proprioceptive response, and neuromuscular landing strategies between sexes and legs may potentially explain the variance observed in ACL Stress in this study.

## Introduction

Soccer is the most popular sport world-wide and has seen recent growth in the United States, which has been associated with increased lower-extremity injuries. Recent studies have investigated the influence of core muscular strength and endurance on sports injuries (Leetun, et al., 2004; Wilkerson, et al., 2012), but only one has done so in soccer players (Abdallah et al., 2019). Considering the majority of injuries occur later in game situations, it is likely that injured athletes generally have the needed muscle strength but are unable to sustain the needed level of force production as games progress, thus, have lower muscle endurance. Specifically, male soccer players with lesser prone- and side- bridge times experienced more injuries (Abdallah et al., 2019). To our knowledge, this type of investigation has never been conducted in female soccer players.

The purpose of this study was to compare pre- and post- season core muscle endurance of Division II female soccer players who sustained injuries during the season to those who did not.

## Methods

Twenty-two female Division II soccer players ( $19.5 \pm 1.22$  years;  $67.4 \pm 7.42$  kg;  $166 \pm 4.88$  cm) participated in this study. Participants completed a series of four muscular endurance tests: hip abduction, hip external rotation, prone-bridge, and side-bridge. Participants performed repeated hip abduction and external rotation against gravity to exhaustion. These tests were conducted bilaterally with participants performing movements paced using a metronome at 30 bpm. Tests ended once participants were unable to keep pace. The number of repetitions participants were able to perform were recorded. Static side- and prone- bridge tests were conducted with participants maintaining these positions. The length of time participants maintained these positions were recorded. Testing ended when form could not be maintained. All lower limb and trunk injuries that resulted in time away from practice and/or games throughout the season were recorded. One tailed independent t-tests were conducted to compare injured and uninjured players.

## Results and Discussion

Eleven players sustained a lower limb and/or trunk injury during the season. Preseason left hip external rotator endurance was significantly lower in injured players ( $p < 0.05$ ), while the right external rotator endurance approached significance ( $p = 0.09$ ). Postseason right hip external rotator endurance was significantly lower in injured players ( $p < 0.05$ ), while the left external rotator endurance approached significance ( $p = 0.06$ ). No other significant differences between the groups were observed. Leetun et al., (2004) were able to predict lower extremity injury status over the course of one season in basketball and track athletes from hip external rotator weakness. In our study, we did not measure muscle force production but we measured muscle endurance. As muscles fatigue, they are unable to continue providing the force needed to maintain stability. This reduced

force predisposes players to injuries by altering trunk and lower extremity mechanics (Calston, 2012). Specifically, sufficient external rotator force product can prevent excessive internal rotation, thus, reducing the chance of the knee going into dynamic knee valgus.

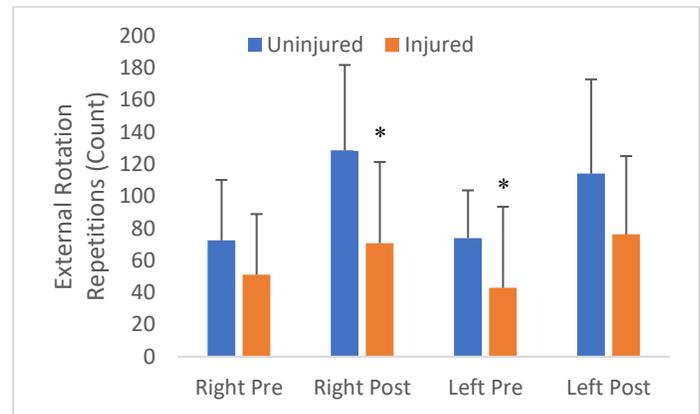

Figure 1. Hip external rotator endurance for injured and uninjured players. \*  $p < 0.05$

Professional male soccer players have been found to experience more injuries when they have lesser side- and prone- plank times (Abdallah et al., 2019). This may be due to structural differences between genders as well as the level of play in our study. Although not part of the purpose of the study, we noticed that hip external rotation endurance improved over the season, which may have resulted from the season fitness program with emphasis on gluteus maximus muscle endurance. It may also be related to repeated concentric activation of external rotators on the kicking side and eccentric actions of the non-kicking side while controlling pelvic movement during a kick throughout the season.

## Significance

Hip external rotator endurance may play a role in reducing injury in Division II women soccer athletes and therefore should be considered by coaches and athletic trainers when designing conditioning programs.

## Acknowledgments

We would like to thank the SMSU Soccer team for their participation and efforts in this study. We would also like to thank the SMSU athletic training staff for assistance with injury data collection.

<sup>2</sup>United States Marine Forces Special Operations Command, Camp Lejeune, NC, USA

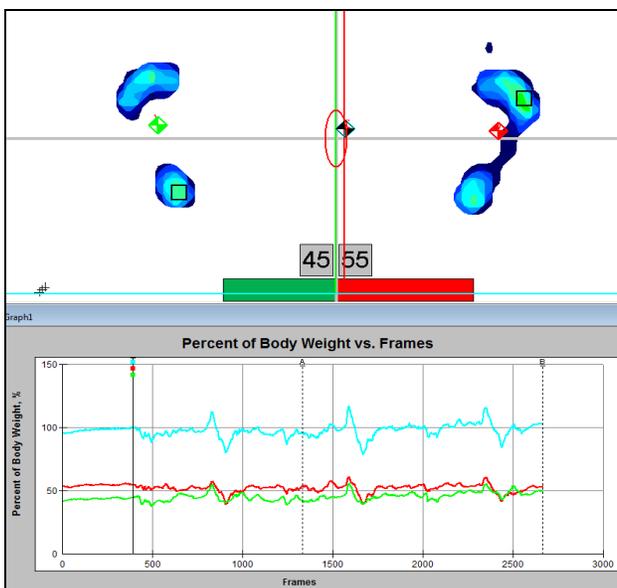

Email: [joshua.winters@uky.edu](mailto:joshua.winters@uky.edu)

## Introduction

Military training is rigorous in nature placing great demand on the musculoskeletal (MSK) system, resulting in significantly high rates of MSK injuries across all military services.<sup>1</sup> Although MSK injuries may occur as a result of an acute traumatic incident, many result from cumulative loading, or overuse.<sup>2</sup> Overuse injuries, including pain, are commonly reported in the low back.<sup>3</sup> Therefore, the purpose of this analysis was to examine weight bearing asymmetries in active military personnel prior to deployment and compare those with a history of low back injuries to those without a history of MSK injury.

## Methods

Loading patterns were collected from 94 Marine Forces Special Operations Command (MARSOC) personnel (age:  $28.59 \pm 5.17$ , height:  $178.28 \pm 6.59$  cm, mass:  $86.38 \pm 12.14$  kg) prior to deployment. Weight bearing ratios (WBRs) were calculated from the average of three consecutive unweighted overhead squats performed on a pressure mat (Tekscan, Boston, MA). Pressure was converted to Force (N) and normalized to bodyweight (%BW) for both the dominant (DOM) and non-dominant (NOND) limbs (Figure 1). Participants also completed a self-report injury history questionnaire. Those who reported a previous injury to the back or pain that restricted training for at least one day (LBP, n=10) and those who reported no history of MSK injuries (Controls, n=26) were included in additional between limb WBR analyses.

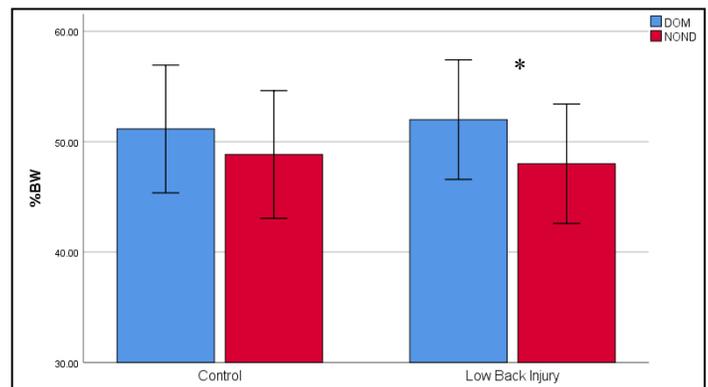

**Figure 1.** Weight bearing ratios calculated from a pressure mat during an unweighted overhead squat assessment.

Paired samples t-tests were used to evaluate weight bearing asymmetries between the DOM and NOND limbs. Significance level was set at  $\alpha = 0.05$ . Effect sizes were calculated for all comparisons using Cohen's  $d$ .

## Results and Discussion

Paired samples t-tests indicated statistically significant pre-deployment WBR asymmetries across all MARSOC personnel ( $p < 0.001$ ,  $d = 0.69$ ). The LBP group also exhibited statistically significant WBR asymmetries ( $p = 0.044$ ,  $d = 0.738$ ) but not the control group ( $p = 0.053$ ,  $d = 0.40$ ), (Figure 2).

**Figure 2.** Weight bearing ratios by group

## Significance

Prior to deployment, MARSOC personnel demonstrated significant asymmetrical WBRs, loading the DOM with 3.66 %BW more on than the NOND during an unweighted squat. These asymmetries were further exaggerated in the LBP group and though the between limb difference was only 4.0 %BW, it was nearly double the 2.3%BW asymmetry in the control group and had a greater effect size ( $d = 0.74$  vs  $d = 0.40$  respectively). Due to the physicality and cumulative effects of the day-to-day workload during deployment, improving loading symmetry during military training may reduce the warfighter's risk of sustaining a MSK injury while on deployment.

## Peak Elbow Angles in Independent Wheelchair Transfer: A Prelim Study

Ashleigh Fults, Stephen Sundarrao MS, and Stephanie L. Carey PhD  
 Center for Assistive Rehabilitation and Robotics Technologies, University of South Florida  
 Email: alf3@mail.usf.edu

### Introduction

For individuals with spinal cord injuries (SCI) who utilize manual wheelchairs for mobility and recreational wheelchairs for an adaptive sport, it is necessary to transfer into and out of their wheelchairs to compete. These transfers can be easily accomplished with the help of a caretaker or transfer device, but independent transfers, wherein an individual transfers himself or herself unaided using only their upper limbs and torso, have been found to promote rehabilitation and improved mental health over assisted transfers. [1]

Because of the frequency of the transfers, improper movements over time can cause pain, lead to musculoskeletal pathologies, or exacerbate pre-existing damage to the individual's upper limbs. [2] Therefore, it is necessary to develop an optimized transfer technique, especially for transfer into a recreational wheelchair. From the literature, a transfer is broken into three phases. The phase of interest for this study is the lift phase, since it is the weight-bearing phase of transfer. [3] The purpose of this study was to first examine the current transfer technique used by wheelchair athletes to determine if it changes depending on the height of the recreational wheelchair.

### Methods

For this study, kinematics were collected using the motion capture system, Vicon Nexus with Nexus 1.8.2 software, and passive, reflective markers adhered to the subject's upper limbs and torso. The recreational wheelchair used was the Top End Eliminator Racing Wheelchair with Open V Cage (Racer). The subject was a 38 year old male manual wheelchair user of more than two years with a SCI at T12 who participates in para ice hockey. The subject was asked to arrange and angle his personal wheelchair and the racer as they would in an everyday situation. The subject was instructed to independently transfer from his personal wheelchair into the racer as they normally would three times with the racer seat height equal to, and then 10 centimeters below, that of his personal wheelchair.

Joint angles were calculated with the biomechanics analysis software, C-Motion Visual 3D, and the joint coordinate system used for the elbow was that recommended by the Standardization and Terminology Committee of the International Society of Biomechanics. [4]

### Results and Discussion

The start and end of the lift phase was defined as the time at which the subject's pelvis moved off the seat to when subject's pelvis was placed on the seat of the racer. The mean and standard deviation of the maximum and minimum elbow angle was calculated for each arm from the three trials and displayed in Table 1. For the elbow angles reported, 0 degrees is defined as the neutral position with the elbow in neither flexion nor extension. Elbow flexion is reported as positive degrees from the neutral position, and elbow extension is reported as negative degrees from the neutral position.

Descriptive statistics shows a difference between the maximum and minimum elbow angles of the of the leading arm

between the two conditions. The elbow angles of the leading arm may be smaller, closer to neutral, when the racer seat is lowered, to compensate for the greater distance that arm must reach from the subject to the racer seat. Since there is no change in the subject's personal wheelchair, the trailing arm shows no difference in maximum and minimum elbow angle.

	Equal Seat Height		Lower Seat Height	
	Leading Arm	Trailing Arm	Leading Arm	Trailing Arm
Max Flex(+)/Ext(-)	51.8 ± 6.0*	34.0 ± 6.8	42.0 ± 2.5*	31.4 ± 6.3
Min Flex(+)/Ext(-)	14.2 ± 3.7*	-1.0 ± 1.4	3.6 ± 6.7*	2.0 ± 2.1

**Table 1:** Mean ± standard deviation of maximum and minimum elbow angles (°) during lift phase of transfer for leading arm and trailing arm. \*No overlap in mean ± one standard deviation between the conditions

### Significance

Although a case study, these results show that there may be some difference in an individual's movement pattern during transfer. Continuation of this study will show if this holds true in additional subjects as well. Furthermore, examining the shoulder and wrist angles during transfer may reveal similar differences. If there are consistent differences in joint angles, the next step is determining if these differences may do the individual harm with repeated occurrences, and, if so, how can the technique be improved to prevent that harm.

### Acknowledgments

This study was partially funded by the Florida Department of Education, Rehabilitation Engineering and Technology Program.

## Introduction

Tendon and ligament injuries in the lower limb are a significant cause of poor performance and attrition of show jumping horses [1]. These injuries are typically the result of high cyclic tendon and ligament strains and strain rates [2]. Due to limb anatomy, tendon and ligament strains and strain rates are highly correlated with fetlock joint angle and the rate of change of fetlock angle.

Fetlock joint angle is affected by the force transferred to the limb when the hoof interacts with the ground [3-4]. Relationships between force and gait, force and activity, and force and speed have been quantified for show jumping horses; however, it is unclear how force is modified by properties of the arena surface. This study evaluates relationships between mechanical properties of arena surfaces and biomechanical properties of the fetlock of show jumping horses in order to identify surface property variables which reduce the risk of injury.

## Methods

A repeated measures study design was used to collect data from 4 horses jumping 3 times over a 1.1 meter jump on each of 12 arena surfaces (5 dirt and 7 synthetic).

High contrast motion capture markers were placed on the left forelimb of each horse to quantify joint angles at takeoff and landing using monochrome high-speed video. Palpable anatomic landmarks verified by radiographs were used for marker placement. Limb marker positions were digitized using kinematic software to determine maximum fetlock angle (**Figure 1**) and fetlock angular velocity during motion.

**Figure 1:** Fetlock Angle Definition.

Vertical impact force and horizontal shear force of each arena surface were measured immediately following biomechanical data collection of each horse using a custom designed arena impact device (AID) and quasi-static linear shear tester (STD) respectively (**Figure 2**). The AID features a triaxial accelerometer, 6-axis load cell, and laser displacement sensor and was dropped from a height of 31.3 cm to achieve physiologically equivalent limb accelerations upon landing after a jump. Data were collected at 4,545 Hz. The STD features a single axis load cell, two string potentiometers to measure displacement in horizontal and vertical directions, and a linear transducer. Tests were run under displacement control (0.017 m/s) with data collected for 5 normal loads (50 to 225 lbs) at 1,613 Hz. All data were collected in LabVIEW and processed using custom MATLAB software.

**Figure 2:** Arena Impact Device (AID) and Quasi-Static Linear Shear Tester Setup (STD).

An analysis of variance accounting for repeated measures was used to assess differences in fetlock motion between takeoff and

landing and surface type (dirt, synthetic) and differences in surface properties between surface type (dirt, synthetic). Differences were considered significant at  $p < 0.05$ . Spearman correlation statistics were also examined to determine relationships between fetlock motion and surface properties.

## Results and Discussion

Landing exhibited significantly higher maximum fetlock angles ( $4.8^\circ$ ) than takeoff indicating that tendon strain and injury risk is likely to be maximized during landing. The rate of fetlock extension was also  $668^\circ/\text{s}$  higher at jump landing indicating high soft tissue strain rates. Since soft tissues become less elastic at high loading rates (high stiffness and less elongation before failure), high loading rates are predicted to increase the risk of injury to soft tissue structures.

Surface type (dirt, synthetic) exhibited no statistically significant effects on motion at the fetlock. Similarly, ground reaction force and shear force were unaffected by surface type. Historically, the effect of surface type on mechanical properties has involved extremely low sample sizes (one of each type of surface) [5]. Therefore, we believe that categorizing arena surfaces by type does not sufficiently describe the underlying mechanical properties of the surface which affect joint motion and is not a sufficient predictor for injury risk to the horse.

However, this does not mean that mechanical surface properties are not important factors for injury risk. Significant Spearman correlations between arena surface shear forces and rate of fetlock extension were found for both takeoff ( $r=0.35$ ) and landing ( $r=0.31$ ). These results indicate a positive correlation between shear forces and rate of fetlock extension. Thus for the range of shear properties observed in this study injury risk appears to increase as shear forces of arena surfaces increase.

## Significance

The results of this study are expected to quantify the relationship between surface properties and joint angle biomechanics of show jumping horses. Since overextension of joint angles correspond to high tendon and ligament strains which are risk factors for injury, results from this study could help determine ideal surface property values that minimize these risk factors and reduce the rate of injury. In this way, the safety of performance horses while training and competing would be improved.

## Spatiotemporal Gait Parameters in Middle Age Adults with Persistent Ankle Pain

Mohammed S. Alamri<sup>1</sup>, Kazandra M. Rodriguez<sup>2</sup>, Emily E. Gerstle<sup>1</sup>, and Stephen C. Cobb<sup>1</sup>

<sup>1</sup>Department of Kinesiology, UW-Milwaukee, Milwaukee, WI, USA

<sup>2</sup>Department of Kinesiology, University of Michigan-Ann Arbor, Ann Arbor, MI, USA

Email: [msalamri@uwm.edu](mailto:msalamri@uwm.edu)

### Introduction

The prevalence of persistent ankle pain peaks in middle-aged adults and is associated with decreased mobility and health-related quality of life [1,2]. Spatiotemporal parameters (STPs) during walking gait can be used to evaluate the functional condition of individuals with chronic knee pain and chronic ankle instability (CAI) [3,4]. Further, individuals with chronic foot pain have demonstrated increased double support time compared to those without chronic foot pain [5]. Although the previous studies have improved the understanding of CAI and chronic foot pain, they have primarily focused on young active adults, or defined groups that included both young and middle-age or middle-age and older adults.

The purpose of this study was to investigate walking gait STPs in middle-aged adults with persistent ankle pain. We hypothesized that those with persistent ankle pain would walk with: decreased stride length, uninvolved limb step length, and involved limb single limb stance duration; and increased double limb support time compared to middle-aged adults without persistent ankle pain.

### Methods

Nineteen middle-aged (45 – 64 years old) adults participated in the study (Table 1). Persistent ankle pain group participants (PAIN) had a history of at least 1 significant lateral ankle sprain, experienced pain for the previous three months, and complained of at least slightly troublesome ankle pain on most days during the past month [6]. Uninjured participants (CON) were age, sex, and BMI classification matched with PAIN participants, had not had an acute lower extremity injury within the previous 3 mos., had no history of ankle sprain in the previous 12 mos., and no complaints of ankle pain in last 3 mos.

Following written informed consent, each participant performed 10 barefoot overground walking trials at self-selected speeds along a 15 m walkway with 3 embedded force plates sampling at 1000 Hz. The STP variables calculated are defined in Table 2. Independent t-tests were performed to investigate group differences (SPSS,  $\alpha = 0.05$ ).

**Table 1** Study Participant Demographics (Means  $\pm$  SD).

Group	Age (years)	Sex (F/M)	Height (cm)	BMI (kg/m <sup>2</sup> )
Pain	54.4 $\pm$ 5.8	9/1	168.0 $\pm$ 5.1	27.3 $\pm$ 7.1
Control	53.0 $\pm$ 5.8	8/1	168.2 $\pm$ 6.1	26.5 $\pm$ 7.4

### Results and Discussion

We postulated that the PAIN group would alter their gait STPs to decrease single limb stance time on the painful limb. The hypothesized differences between groups were not supported (Table 2). The significant decrease in involved limb step length in the PAIN group was not anticipated, but was consistent with a previous study that investigated the influence of CAI on STPs [4] (Table 2). Persistent ankle pain may be associated with the initial ground impact and/or loading rate. If this is the case, a shorter step length of the involved limb may act as compensatory

mechanism to decrease the initial impact force and/or loading rate.

With respect to the lack of significant group differences between the other STP variables investigated in the current study and previous studies investigating the effect of CAI or foot pain on gait STPs; the results are consistent with some [7,8] and inconsistent with others [4,5,8]. Comparisons across the studies is difficult given the differences in participant demographics (e.g. age, BMI, activity level), inclusion/exclusion criteria, footwear conditions, and gait speeds.

**Table 2** Mean (SD) PAIN and CON Group STPs.

STP	Group		P	$\eta^2$
	PAIN	CON		
Gait speed (m/s)	1.19(0.1)	1.21(0.1)	.79	.00
Stride length (m)	1.36(0.1)	1.39(0.1)	.20	.09
Cadence (steps/min)	105.2(6.4)	104.0(9.8)	.75	.01
In. Step length (cm)	64.5(6.0)	70.1(4.3)	.03*	.23
In. Single support (%GC)	39.3(1.5)	39.1(1.5)	.76	.01
In. Double support (%GC)	23.2(3.1)	22.6(3.2)	.66	.01
Un. Step length (cm)	71.4(6.6)	69.3(6.9)	.51	.03
Un. Single support (%GC)	37.5(1.8)	38.4(2.0)	.34	.05

In. = Involved limb; Un. = Uninvolved limb

\*statistically significant group difference

### Significance

Middle-aged adults with persistent ankle pain demonstrate decreased involved limb step length during walking gait. The assessment of STPs may be used to identify the presence of gait dysfunction and as an outcome measure to assess the effectiveness of an intervention aimed at improving the mobility of patients with persistent ankle pain. However, additional research is needed to identify the lower extremity kinematic and neuromuscular function changes that lead to decreased involved limb step length during walking in middle-aged adults with persistent ankle pain.

# Effect of Targeted Hamstrings Intervention on Vertical Ground Reaction Force Asymmetries during Takeoff and Landing

Nathaniel A Bates<sup>1</sup>, Takashi Nagai<sup>1</sup>, Ryo Ueno<sup>1</sup>, Luca Rigamonti<sup>1</sup>, Rena F. Hale<sup>1</sup>, Timothy E. Hewett,<sup>2</sup> Nathan D Schilaty<sup>1</sup>  
<sup>1</sup>Department of Orthopedic Surgery, Mayo Clinic, Rochester, MN, USA; <sup>2</sup>Sparta Science, Menlo Park, CA, USA  
Email: [batesna@gmail.com](mailto:batesna@gmail.com)

## Introduction

Side asymmetry, limb dominance, and hamstrings:quadriceps strength ratios are factors associated with increased risk of lower extremity injury during athletic participation. [1,2] Targeted training interventions have proven adept in the reduction of modifiable biomechanical risk factors in high-risk athletes. [3] The objective of this study was to assess the efficacy of a targeted hamstrings training on the reduction of ground reaction force asymmetries in female basketball athletes across a single season. The hypotheses tested was that trained athletes would exhibit less asymmetry compared to controls at the end of the season.

## Methods

Female high school basketball athletes (n=43; Age 15±1 yrs; Height = 171±17 cm; Mass = 65.2±12.2 kg) completed both pre- and postseason biomechanical evaluations that were used for analysis. Athletes were divided into intervention groups (control vs. trained) by team. The trained group completed dynamic hamstring exercises twice per week during their standard team warmup throughout the season. The control group received no additional training. Females were selected as they are at higher risk for noncontact lower extremity injury than males. Dominant side was determined by asking which leg an athlete would use to kick a ball. Dual force platforms continuously collected vertical ground reaction force (vGRF) separately for each leg at 1000 Hz during countermovement jump tasks. Data was filtered through a lowpass 4<sup>th</sup> order Butterworth filter with a 50 Hz cutoff and used to calculate rate of force development (RFD) before takeoff and after landing (LAND). RFD was calculated as the peak force divided by the time between this peak and zero force. Side asymmetry was assessed for both RFDs as well as peak force before takeoff and after LAND. Each athlete completed three jump trials and a mean was calculated. The hypothesis was tested via repeated measures ANOVA as collection was repeated pre- and postseason with an intervention (control/trained) factor.

## Results and Discussion

For asymmetry in peak takeoff force, a time\*intervention interaction effect was significant ( $P<0.01$ ) as asymmetry shifted toward the non-dominant leg from pre- to postseason in controls ( $P<0.01$ ; Figure 1), but remained unchanged in trained subjects ( $P=0.85$ ). For asymmetry in takeoff RFD, no significant effects were observed ( $P\geq 0.29$ ). For asymmetry in peak LAND force, a time\*intervention interaction was significant ( $P=0.02$ ) as asymmetry shifted toward the non-dominant leg from pre- to postseason in controls ( $P<0.01$ ), but remained unchanged in trained subjects ( $P=0.89$ ). For asymmetry in LAND RFD, a time\*intervention interaction effect was not observed ( $P=0.34$ ).

In basketball, the non-dominant leg is often the launch or pivot limb, which may develop a strength imbalance during the course of a season. This was observed in the current study as control group vGRF asymmetries during takeoff and landing favored the non-dominant leg in postseason testing. This trend was absent in the trained group, which indicated that interventional effects were present. Thus, the hypothesis was supported for a female cohort as development of peak force asymmetries over the course of a season were prevented in the training group.

## Significance

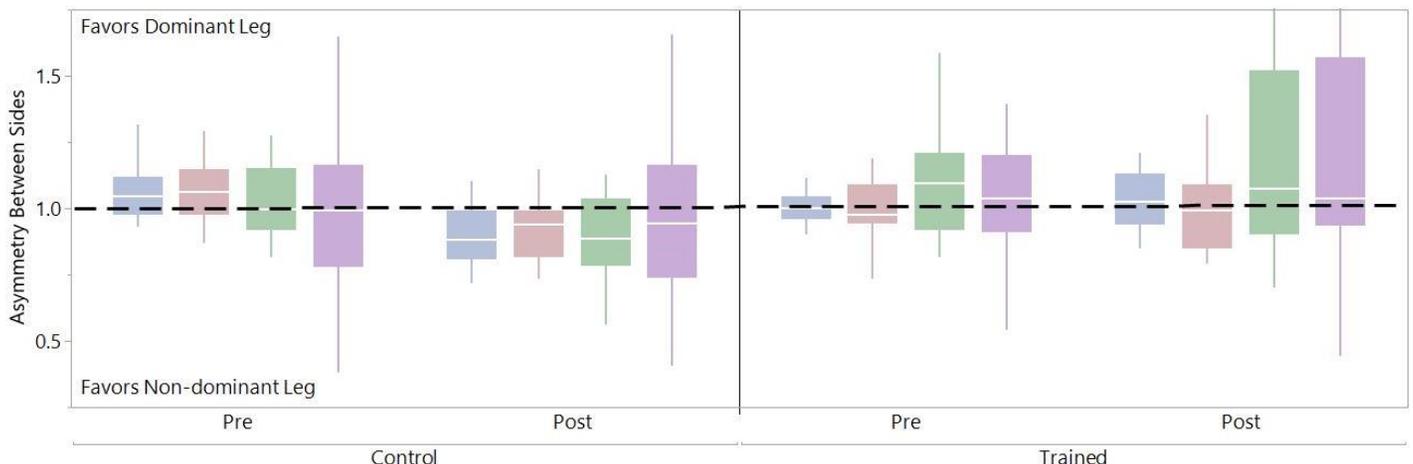

These results indicate that targeted hamstrings interventions can influence limb asymmetries during athletic tasks and may be efficacious for high-risk athletes who are predisposed to develop vGRF asymmetries.

3. Webster KE, Hewett TE. 2018. J Orthop Res; 36(10).

**Figure 1:** Side to side asymmetry for peak takeoff force (blue), takeoff RFD (red), peak LAND force (green) and LAND RFD (purple). Outcomes are separated by pre-/postseason and intervention. Asymmetry >1.0 indicates favoring of the dominant leg, while asymmetry <1.0 indicates favoring of the non-dominant leg. Increased asymmetry toward the non-dominant leg was observed in controls, but not trained subjects.

# Bad vibes? Preliminary data on shock attenuation in injured and uninjured runners

Dovin Kiernan<sup>1</sup> and David Hawkins<sup>1</sup>  
<sup>1</sup>University of California, Davis, Davis, CA, USA  
Email: [dahawkins@ucdavis.edu](mailto:dahawkins@ucdavis.edu)

## Introduction

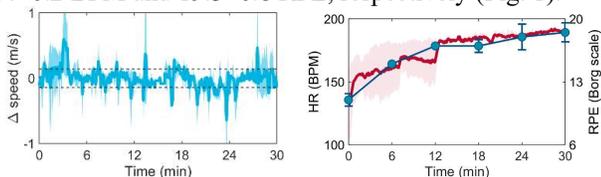

Running is associated with high injury rates and, with millions of Americans running, preventing these injuries is critical. One proposed injury risk factor is an inability to attenuate the high frequencies imposed on the musculoskeletal system with each step [1]. Some runners may be less capable of attenuating these frequencies or may lose the ability to attenuate these frequencies with fatigue, predisposing them to injury. There is, however, no direct evidence connecting reduced attenuation with injury and the relationship between attenuation and fatigue is equivocal. Here, we investigate whether: (1) shock attenuation changes across a prolonged run, and (2) previously injured runners display altered patterns of attenuation compared to uninjured controls.

## Methods

Based on *a priori* sample size calculations, previously injured ( $n = 15$ ) and uninjured ( $n = 15$ ) rearfoot strike runners will be recruited. To date, one runner per group has been collected. Inertial measurement units (IMUs; Inertia Technology ProMove MINI;  $\pm 100$  g,  $\pm 2000$  deg/s, 1000 Hz) were fixed to runners' distal tibiae and foreheads. Runners performed calibration movements, ran 0.5 km to warm up, then ran for 30 min at their maximum pace. An experimenter biked beside runners to ensure speed remained within  $\pm 0.14$  m/s (Garmin Edge 520 Plus). Heart rate (HR) was collected continuously (Polar H10) and ratings of perceived exertion (RPE) were collected every 6 minutes [2]. IMU data were rotated to segment local coordinate systems [3] and vertical accelerations from each stance from the 30-min run were isolated [4]. For each stance, the signal was de-trended and -meaned and attenuation was calculated by taking the log-ratio of head and tibia power spectral densities in 1 Hz bins from 0 to 500 Hz [5]. Attenuation was summed across a 10-20 Hz bin of interest and compared across the duration of the run.

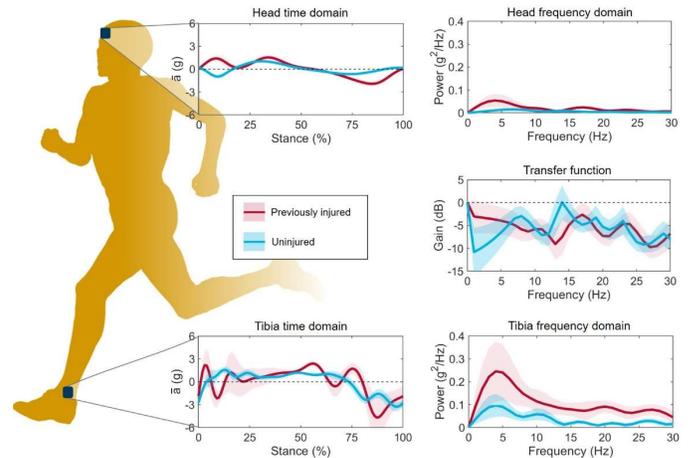

## Results and Discussion

Current results are preliminary and are limited by sample size but across the 30-min run, runners neared maximal exertion while maintaining relatively constant speeds. Speed remained within a mean absolute difference of 0.14 m/s from target speed. In contrast, HR and RPE increased throughout the run, ending at  $190.4 \pm 0.2$  BPM and  $19.3 \pm 0.8$  RPE, respectively (Fig. 1).

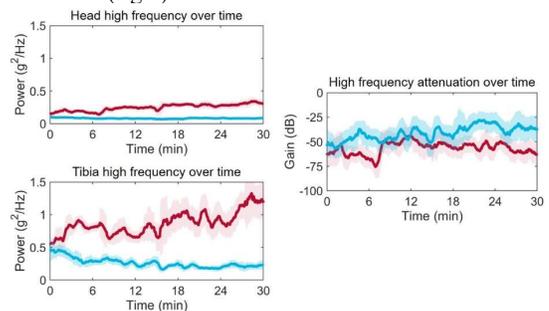

**Figure 1:** Mean $\pm$ SD change in speed (left), heart rate (right; red), and Borg rating of perceived exertion (right; blue).

Tibia and head accelerations and signal powers were higher for the injured runner, likely because their target speed was higher (Fig. 2). Attenuation in the 10-20 Hz frequency bin decreased across the run for the uninjured runner while remaining relatively stable for the injured runner (Fig. 3). The stability in the injured runner's attenuation did, however, hide a marked increase in both head and tibia signal power.

**Figure 2:** Mean $\pm$ SD head and tibia de-trended and -meaned vertical accelerations in the time domain (left) with frequency domain and transfer function (right).

**Figure 3:** 60-second moving mean $\pm$ SD sum of signal power in the 10-20 Hz bin for the head (top left) and tibia (bottom left) across the run. Attenuation of the 10-20 Hz bin (right).

Though limited by a small sample and retrospective design, these preliminary results suggest a link between running injury and the propagation of high frequency content up the kinetic chain. Interestingly, attenuation, calculated as the log-ratio of head and tibia frequency content, was not suitable to capture this propagation as both head and tibia high frequency content increased in the injured runner. These results also join an equivocal literature and suggest that fatigue may cause changes to high frequency signal power and/or attenuation. Future work will increase the sample size to further investigate these effects.

## Significance

If high frequency content and attenuation are related to running injury and can be non-invasively monitored throughout a run, they may provide a means to monitor runners' injury risk.

## Comparison of trunk neuromuscular control strategies between athletes with and without a shoulder injury

Courtney M. Butowicz<sup>1</sup>, Andy S. Camp<sup>2</sup>, and Sheri P. Silfies<sup>1</sup>

<sup>1</sup>Department of Exercise Science, University of South Carolina, Columbia, SC

<sup>2</sup>United States Navy, Norfolk, VA

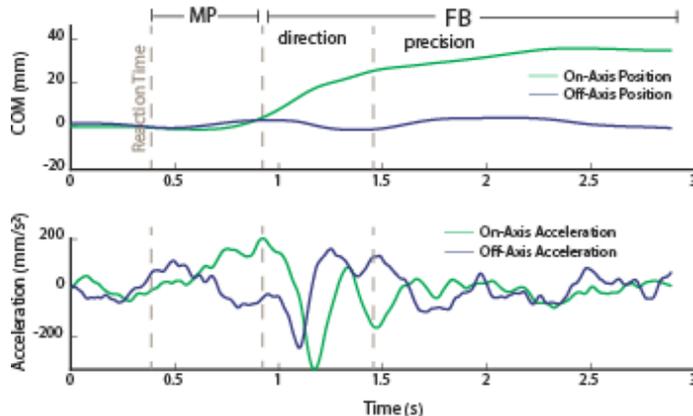

Email: butowicz@mailbox.sc.edu

### Introduction

Shoulder injuries account for up to 40% of athletic injuries.<sup>1</sup> It is posited that impairments or variations in trunk control strategies perhaps influence force dissipation and upper extremity movement patterns, contributing to athletic injury. For example, diminished trunk neuromuscular control was associated with an increased risk of injury that resulted in missed days in professional baseball pitchers.<sup>2</sup> However, recent work suggests athletes with shoulder injuries may not demonstrate trunk control deficits when assessing motor performance, thereby challenging established theories of upper extremity injury mechanisms.<sup>3</sup> Trunk neuromuscular control assessments have mainly quantified specific performance parameters (e.g., postural sway, muscle endurance), yet rarely, consider the underlying system control strategy. Thus, the purpose of this study was to compare trunk neuromuscular control strategies between athletes with and without a shoulder injury. We hypothesized that athletes with a shoulder injury would demonstrate altered motor planning and feedback control strategies, corresponding to altered movement timing and accuracy during a goal-directed, unstable sitting task.

### Methods

Ten athletes with a current shoulder injury (4 females; age: 22±4 years, mass: 78±19 kg, stature: 174±10 cm) and 10 sex, age, mass, stature, and sport-matched healthy controls consented to the study. Athletes sat on an unstable chair while force platform data were sampled (2400Hz), converted to COP trajectories, and displayed in real-time on a monitor. Athletes were directed to reposition the trunk-pelvis, which tilted the chair, resulting in movement of the COP. Precise changes in trunk-pelvis segments were required to quickly and accurately move the COP trajectory toward 8 targets (radius 35mm). Targets were displayed sequentially (clockwise); after target acquisition (or 12s, whichever occurred first), athletes returned to a central target. Control strategies were defined as (Figure): Motor planning (MP) control bounded by the reaction time (RT) and a local maximum in COP acceleration. Feedback (FB) control began at the end of MP and ended with target acquisition. FB control was further divided into a region that reflected control of movement toward a target (*directional control*) and a region where the goal shifted to target acquisition (*precision control*). A spike in polar velocity was used to separate FB phases. Duration and accuracy in each control strategy were calculated. *MP*, *FB directional*, and *precision time* were defined as the duration of the respective regions. *MP accuracy* was defined as off-axis error at the local maxima. *FB directional accuracy* was calculated as normalized RMSE between an idealized (second-order transfer function) and actual COP trajectories. *FB precision accuracy* was quantified with a 50% confidence ellipse area around each target. Performance measures of RT, time to target acquisition (TA), and number for missed targets (MT) were also recorded. Parameters were averaged across targets for each athlete. Independent t-tests were used to determine group differences ( $p \leq .05$ ).

**Figure:** Representative COP (top panel) trajectory and accompanying COP acceleration data (bottom panel) with control regions identified.

### Results and Discussion

Task performance did not differ between groups [*RT* ( $p=.31$ ), *TA time* ( $p=.53$ ), *MT* ( $p=1.0$ )]. In contrast with our hypothesis, *MP time* ( $p=.81$ ), *MP accuracy* ( $p=.60$ ), *FB directional time* ( $p=.62$ ) and *accuracy* ( $p=.94$ ), *FB precision time* ( $p=.80$ ) and *accuracy* ( $p=0.27$ ) were not different between groups. These results indicate that trunk control performance, nor underlying control strategies, differed between athletes with and without a shoulder injury. Our findings support recent evidence suggesting isolated trunk neuromuscular control performance does not differ between athletes with and without shoulder injuries.<sup>3</sup> Utilizing a dynamic systems approach to identify trunk control strategies has been previously validated comparing individuals with and without low back pain.<sup>4</sup> Both groups in the current study appear to employ similar control strategies in this the goal-oriented task.

### Significance

While trunk neuromuscular control is often incorporated into athletic injury prevention and rehabilitation paradigms, the results of the current study are in concert with recent work suggesting that impairments in trunk control may not be associated with shoulder injuries. Assessing trunk control by characterizing strategies for task achievement is a novel approach to identify potential impairments in an athletic population. Though trunk control is likely an important factor in athletic performance, impairments in control may not be present in athletes with a shoulder injury, perhaps challenging the kinetic chain theory.

# An investigation into the head accelerations and forces experienced by clay-target shooters

Suzanne M. Konz, Holly Cypert, and Robert O. Powell  
Marshall University, Huntington WV, USA  
Email: [konz@marshall.edu](mailto:konz@marshall.edu)

## Introduction

Much attention has focused on the long-term effects of concussion in contact sports. CTE and other degenerative brain disorders have been identified in the brains of contact sport athletes and thought to result from repetitive exposure of the brain to acceleration-deceleration forces. Hunting and trap shooting are popular with the U.S. general population at 4.3 million.[4] School shooting teams are popular, increasing from 60 teams in 2009 to over 32,000 in 2019.[4,5] Clay-target shooters document shooting above 50,000 rounds per year. The military established recoil limits and firearm use protocols, limiting the number of rounds per level of recoil energy to reduce soldier injury risk due to recoil exposure.[1,2] What remains uncertain is the level of recoil energy of the brain during civilian sports. Indeed, the developing brain of high school shooters is of particular concern with the high-frequency head acceleration exposure. Research is needed to understand how high-frequency recoil exposure affects the brain. The purpose of this study was 1) to determine the differences in accelerations and forces encountered by clay-target shooters and 2) to compare the accelerations and forces that the head of clay target shooters' experience to norms from contact sports.

## Methods

Subjects ( $n=35$ ,  $82.38 \pm 21.142$ kg) agreed to participate in this IRB approved study. Participants were randomized into a 25-shot or 100-shot group. 100-shot participants were given a 5-minute rest every 25 shots. Firearm and shooter kinematics were determined via inertial movement sensors (IMU's). Participants had an IMU secured behind the ear of the non-shooting shoulder. An IMU was also affixed to the stock of a 12-gauge shotgun. Data was processed using a custom Matlab code. The IMU outcomes of interest were gunstock, shoulder, and head accelerations. Other variables of interest were calculated with custom processing software to include the average and peak shot acceleration, shot force, shot impulse, and shot jerk experienced with each shot as well as the summation of all shots. Descriptive statistics and one-way ANOVA analyzed the day with significance set at the .05 level.

## Results and Discussion

The single-shot averages at the gunstock for all shooters were as follows: duration ( $0.19 \pm 0.04$  sec), average acceleration ( $2.32 \pm 0.23$ g), peak acceleration ( $7.09 \pm 0.94$ g) were minimal, as expected. The accumulated totals at the gunstock for all shooters were as follows: duration ( $8.63 \pm 6.64$  sec), average acceleration ( $106.91 \pm 50.34$ g), and peak acceleration ( $106.91 \pm 84.18$ g). The gunstock of the 25-shot subjects experienced  $2.29 \pm 0.22$ g average acceleration and  $7.24 \pm 0.89$ g peak acceleration over  $0.20 \pm 0.04$  sec while the gunstock of the 100-shot subjects experienced  $2.38 \pm 0.22$ g average acceleration and  $6.72 \pm 0.99$ g peak acceleration over  $0.18 \pm 0.05$  sec for a single shot.

One-way ANOVA indicated no significance for the single-shot variables from the gunstock, but accumulated gunstock variables were significant.

The single-shot averages for all shooters at the ear was as follows: duration ( $0.20 \pm 0.08$  sec), average acceleration ( $1.34 \pm 0.13$ g), peak acceleration ( $2.29 \pm 0.55$ g) were minimal, as expected.

The accumulated totals at the ear for all shooters were duration ( $10.27 \pm 8.74$  sec), average acceleration ( $68.17 \pm 50.34$ g), and peak acceleration ( $118.05 \pm 96.04$ g). 25-shot subjects experienced  $41.58 \pm 29.49$ g average acceleration and  $69.53 \pm 53.52$ g peak acceleration over  $7.27 \pm 8.32$  sec while 100-shot subjects experienced  $118.92 \pm 42.42$ g average acceleration and  $210.67 \pm 92.10$ g peak acceleration over  $15.99 \pm 6.57$  sec.

One-way ANOVA indicated no significance for the single-shot variables from the ear sensor between the 25-shot and 100-shot groups. But, a one-way ANOVA indicated that the single-shot variables of average force ( $F(1,30) = 12.06$ ,  $p = .00$ ) and peak force ( $F(1,30) = 12.70$ ,  $p = .00$ ) were significant between the shooting groups. The one-way ANOVA determine the accumulated ear sensor variables of duration ( $F(1,30) = 9.06$ ,  $p = .01$ ), average acceleration ( $F(1,30) = 36.61$ ,  $p = .00$ ), peak acceleration ( $F(1,30) = 30.35$ ,  $p = .00$ ), average force ( $F(1,30) = 41.39$ ,  $p = .00$ ) and peak force ( $F(1,30) = 29.66$ ,  $p = .00$ ) were significant.

The significance of the accumulated ear sensor variables between the groups needs to be viewed with caution as an increase in repetition will increase the accumulated accelerations and forces encountered. Football athletes experience peak linear forces at the 50<sup>th</sup> percentile at 20.3g and 62.2g at the 95<sup>th</sup> percentile.[3]

## Significance

The g-forces encountered by individuals are low for a single shot and are not of concern. However, the accumulated totals for g-forces for all clay target shooters rose to levels where the brain could be influenced due to the repetitive nature of impact and the short duration of the exposure during shooting.

# The Influence of Concussion History on Reactive Balance Performance

Amanda Morris<sup>1</sup>, Benjamin Cassidy<sup>1</sup>, Ryan Pelo<sup>2</sup>, Lee Dibble<sup>2</sup>, Peter C. Fino<sup>1</sup>

Departments of Health, Kinesiology, and Recreation<sup>1</sup> and Physical Therapy and Athletic Training<sup>2</sup>, University of Utah, Salt Lake City, UT, USA

Email: amanda.morris@utah.edu

## Introduction

Concussion history has been associated with worse outcomes after future injuries, such as increased recovery time [1] and persistent symptoms [2], as well as neurocognitive [3] and motor deficits, such as increased intracortical inhibition [4] and a more conservative gait [5]. Standard clinical testing may be insufficient to detect lingering deficits associated with previous concussions [6].

Athletes frequently need to recover balance after an external disturbance, but little is known about the effects of concussion on reactive balance, and reactive balance is not currently part of standard clinical testing. While some studies have indicated lifetime incidence of concussion (i.e., concussion history) can impair postural control [7], there is little research on reactive balance performance in regard to concussion history. Therefore, the goal of this study was to examine the relationship between concussion history and reactive postural responses in collegiate athletes.

## Methods

Reactive postural responses in 107 collegiate athletes (F=48, 19.30 (1.61) years, 23.49 (3.19) kg/m<sup>2</sup>) were assessed using the Push and Release (P&R) in four directions (forward, backward, right, left), with eyes closed, under single (ST) and dual task (DT, concurrent cognitive task) conditions. Inertial sensors (Opal, APDM, Portland, OR; 128 Hz) on the sternum, lumbar, right tibia, and feet were used to assess step initiation latency and time to stabilization (TTS). A sensor on the tester's hand was used to determine release time. Participants were sorted into groups based on number of lifetime concussions (Table 1) and time since last concussion (Table 2). ANOVAs ( $\alpha=0.05$ ) were used to compare latency and TTS, under each condition (ST, DT), between groups.

**Table 1.** Participants separated by number of lifetime concussions.

	0 (n=69)	1-2 (n=34)	3+ (n=4)
Age mean (SD)	19.19 (1.64)	19.42 (1.48)	20.25 (2.22)
Female (%)	25 (36)	20 (59)	3 (75)

**Table 2.** Participants with concussion history separated by time since last concussion.

	Within 1 year (n=8)	1-5 years (n=20)	5+ years (n=10)
Age mean (SD)	20.25 (1.91)	18.95 (1.07)	20 (1.76)
Female (%)	7(88)	13 (65)	3 (30)

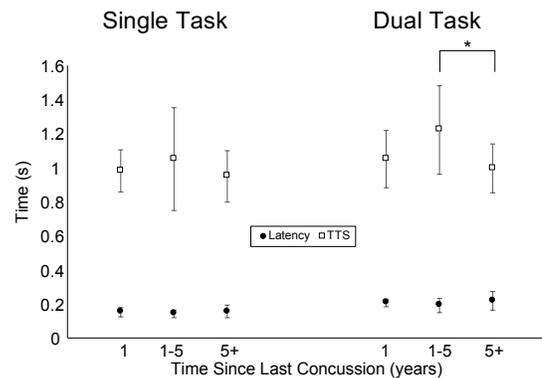

## Results and Discussion

There were no significant differences between groups of lifetime concussions in any of the outcome measures (Table 3). There were also no significant differences between groups of time since concussion in ST latency ( $p=0.39$ ), ST TTS ( $p=0.44$ ), or DT latency ( $p=0.32$ ). However, there was a significant difference in DT TTS ( $p=0.03$ ) between the group that experienced their last concussion 1-5 years ago and the over 5 years ago group (Figure 1). Similar to previous studies that demonstrated a negative

influence of concussion history on physical and cognitive performance, these results suggest that concussion may have long-lasting effects on reactive postural responses.

**Table 3:** Mean (SD) latency and time to stabilization (TTS) separated by number of lifetime concussions and task.

Number of Concussions	ST Latency (ms)	DT Latency (ms)	ST TTS (ms)	DT TTS (ms)
0	149 (26)	199 (53)	973 (173)	1143 (227)
1-2	150 (28)	200 (43)	1028 (250)	1133 (245)
3+	130 (9)	208 (58)	884 (164)	1040 (125)
<i>p</i>	0.35	0.95	0.23	0.73

**Figure 1:** Latency and time to stabilization (mean, SD) separated by time since last concussion and task. \* $p=0.03$

## Significance

These findings suggest that lifetime history of concussion may impact reactive balance performance in collegiate athletes. However, the relationship between concussion history and balance performance, especially across sport-relevant tasks, remains unclear. Future research should examine both reactive, dynamic, and static balance performance in relation to acute concussion and concussion history.

## Introduction

Stress fractures are common in female running athletes and military recruits. Risk for stress fracture is multifactorial including both mechanical and biological factors, with high rates for risk of subsequent fracture<sup>1</sup>. Previous research has linked higher external impact loading during running to history of stress in rearfoot strike (RFS) runners<sup>2</sup>. It is unknown, however, if running impact variables differ between those with a history of single versus multiple stress fracture, and relative to controls. In addition, it is unclear how these variables change in response to fatigue, and if individuals with history of stress fracture elicit larger changes. Previous study has reported on increased impact loading with fatigue in the present cohort, however it was difficult to draw conclusions due to heterogeneity in foot strike pattern and its influence on impact variables with fatigue<sup>3</sup>. The purpose of this study was to investigate change with fatigue between female running athletes who exhibit a RFS with a history of one stress fracture, multiple stress fractures, and those with none. We hypothesized those with a history of stress fracture will show greater changes with fatigue. In addition we hypothesized those with multiple stress fractures to have the largest change.

## Methods

Thirty-one female subjects between the ages of 18-40 years who self-reported running a minimum average of 15 miles/week were included in this study. All subjects were classified as RFS using sagittal plane 2D digital video (125 Hz) during treadmill running at a standardized speed (2.7 m/s). Subjects were categorized on number of previous stress fractures; no stress fractures (CON, n=11), one (1SFX, n=11), and 3 or more (3SFX, n=9). A fatigue run protocol was conducted on a force instrumented treadmill at a subject determined 5 km race speed and terminated when rating of perceived exertion reached  $\geq 18$  out of 20. Vertical average (VALR) and instantaneous (VILR) loading rate, along with vertical stiffness during impact (KIL) were calculated at a standardized speed (2.7 m/s) and the subjects' 5 km race speed at the beginning and end of the fatigue run. Change scores (post – pre) were compared separately for both speeds using one-way ANOVAs ( $\alpha < 0.05$ ).

## Results and Discussion

All subjects ran faster at their 5 km race speed than the standardized speed (MED: +0.67 m/s, MIN: +0.23 m/s, MAX: +1.79 m/s). No differences were seen between groups in age, mass, miles per week, years running, chosen 5km race speed, or

time to fatigue. No differences were detected in impact loading or stiffness change scores at the standardized speed. At the 5 km race speed there was a group effect for KIL, with post-hoc analysis showing the 3SFX group was stiffer than CON ( $p = 0.026$ , see Table). 3SFX also showed the largest positive changes for VILR and VALR at the 5 km race speed, followed by the 1SFX, but were not statistically significant.

## Significance

Our fatigue protocol did not elicit large changes in impact variables between groups, on average. Variation in magnitude and direction of change was observed, suggesting individualized response. It should be noted that “fatigue state” was captured using an exertion scale and not a subjective measure of fatigue, along with a lack of an objective measure of fatigability. This highlights the need for development of validated fatigue protocols and measures specific to running that are linked to the performance changes we expect to observe<sup>4</sup>. Despite this, time to fatigue and race speeds were similar between groups and the 3SFX showed the largest changes as hypothesized, but only during race like speeds. This could potentially be due reduce muscle capacity to attenuate impact loads and stiffness during early stance, resulting in more external loads applied to the skeletal system. This finding could be considered during injury screening and evaluating runners at potentially higher intensity speeds with fatigue. Interestingly, the CON group showed small-to-negative changes at both speeds suggesting an ability to compensate by reducing impacts with fatigue. While further investigation would benefit from being more adequately powered, these results warrant strategies to optimize mechanics and prevent fatigue-induced increases in impacts, particularly in those at risk of subsequent stress fracture.

## Introduction

Ankle sprains are a common injury among military Service members, leading to DoD mandated use of semirigid braces during high risk activity [1]. However, conventional designs are inadequate; mechanical response is invariant to task demands, often too restrictive or bulky, and therefore disuse rates are high [1]. Next-generation solutions are needed, although studying injury occurrence is challenging, albeit necessary to assess design efficacy. Dynamic, musculoskeletal simulation has prior been applied to reveal the role of ankle passive flexibility/laxity in sprain occurrence [2], and separately to highlight potential of preparatory co-activation and stretch-reflexes to prevent sprains [3]. This study aimed to estimate likelihood and sensitivity of sprain occurrence during a simulated drop landing within a single framework, given variance in neuromuscular and external loading factors. We expected that co-activation and drop height would be most influential, followed by ankle passive stiffness, reflex strength, and ground surface characteristics, respectively.

## Methods

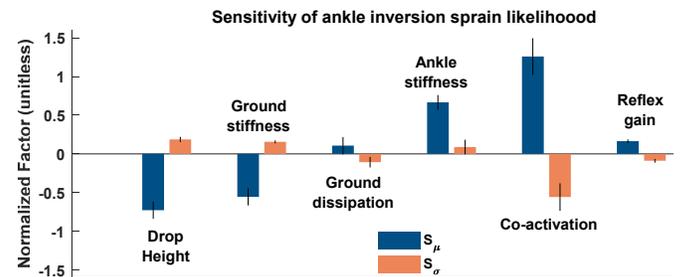

An established framework was adapted for this study [3]. Briefly, authors implemented custom stretch-reflex muscle controllers in a whole-body musculoskeletal model scaled to a single subject (F, 68kg, 1.8m), and tuned control parameters to track experimental kinematics during a 0.4 meter drop onto an inclined surface. After verifying simulation reproducibility, we assigned probability distributions to six model parameters suspected to influence sprain occurrence; with mean equivalent to baseline value, and variance meant to span physiologic neuromuscular ranges or realistic drop heights and surface characteristics (Table 1). Similar to [4], virtual scenarios were instantiated for a 5000-trial Monte Carlo simulation using Latin hypercube sampling (NESSUS, v9.8.0, SwRI), and executed via the MATLAB API (OpenSim v3.3). Since baseline, scaled model anthropometry and posture were kept constant, these scenarios represent a single subject with varied neuromuscular properties and control dropping from different heights onto varied surface stiffness. Peak subtalar inversion angle was extracted and assessed versus a 35±6 degree threshold where ligament failure may initiate [3]. Across all scenarios, subtalar angle cumulative response probability was calculated, as well as Pearson correlation versus each input variable. Scenarios with a response likelihood less than 5% were discarded from consideration. Lastly, probabilistic sensitivity factors were computed for each input 'x' as  $(\partial p / \partial x * \sigma / p)$ , and averaged over the [29,41] degree sprain range. These factors then identify how sprain likelihood varies with a change in each input's mean ( $S_\mu$ ) or variance ( $S_\sigma$ ).

**Table 1:** Probabilistic drop landing simulation inputs and Pearson correlation versus peak subtalar angle across 5000 scenarios.

Model parameter	Distribution	$\mu$	$\sigma$	Correlation
Initial drop height (meters)	lognormal	0.30	0.15	<b>0.36</b>
Ground contact modulus (MPa\meter)	lognormal	34	15	0.28
Ground contact dissipation (sec\m)	lognormal	5	4	0.04
Ankle passive stiffness ( $\pm\%$ scale from baseline)	normal	0%	40%	<b>-0.39</b>
Co-activation (invertor\evetor)	lognormal	30%	20%	<b>-0.63</b>
Reflex strength (controller gain)	lognormal	5	3	-0.05

## Results and Discussion

Across all scenarios, peak subtalar angle ranged 9-46 degrees, and likelihood of a peak greater than [29, 41] degrees was [36, 10]% respectively. Confirming expectations, sprain occurrence was most sensitive to co-activation, indicated by a positive  $S_\mu$  roughly double that of ankle stiffness (Fig. 1). This indicates increased co-activation decreased sprain likelihood twice as much as an equivalent increase in ankle stiffness. In contrast, reflex gain and ground contact dissipation had negligible influence. This corroborates prior work, which suggested 60% co-activation could prevent a sprain, but even the fastest reflexes could not [3]. Drop height and ground contact stiffness had a similar, but opposite, influence magnitude versus ankle stiffness ( $S_\mu$  Fig. 1). Sprain likelihood was generally insensitive to input variance  $S_\sigma$ , with exception of co-activation, which had a moderate negative sensitivity, indicating increased co-activation variance increased sprain likelihood, with similar magnitude as increased drop height and ground stiffness over simulated ranges.

**Figure 1:** Probabilistic sensitivity factors for peak subtalar angle in response to changes in mean ( $S_\mu$ ) and variance ( $S_\sigma$ ) of model input parameters (Table 1). Continuous factor trajectories were reduced to mean(std) over the 35±6 degree range where ligament failure is likely to initiate [3]. A *positive* factor indicates decreased sprain likelihood via a *negative* response correlation (Table 1); *negative* factor vice-versa.

## Significance

Our findings suggest relative, theoretical importance of key neuromuscular and external loading factors in sprain prevention. Such data are useful to guide focus of continued simulation and experimental validation studies; ultimately aimed at informing stiffness design requirements for next-generation ankle braces.

## Introduction

The rat hindlimb is one of the most highly utilized model systems for pathologies whose healing requires functional recovery. However, most studies focus on indirect functional measurements such as force generation and kinematics of the hindlimb to quantify the quality of their treatment, providing only a partial picture. To fully understand the impact of a treatment on the functional recovery of an animal it is necessary to acquire and compare joint and muscle kinetics.

In order to quantify the effects of volumetric muscle loss on movement function we have previously developed a model and methodology to measure the kinematics and kinetics of rodent gait. We investigated the tibialis anterior (TA) and employed our motion capture approach to evaluate a 20% (by mass) volumetric muscle loss (VML) injury<sup>1</sup>. This work resulted in statistical differences between the injured and healthy animals at all post-surgical timepoints. This was significant considering the low gait impact of the TA, as it is solely responsible for ankle dorsiflexion and toe clearance during swing. We have leveraged that previous work into the investigation of injuries to a major gait contributor in the lateral gastrocnemius (LG). The LG is important, as ankle plantarflexion is the primary means of propulsion in walking. The LG also has the added complexity of being a two-joint muscle.

## Methods

8 twelve-week old male Lewis rats were given a 20% by mass VML injury to their right LG with no repair (LGNR). Animals were labeled with motion capture markers and recorded using Vicon Nexus software as they voluntarily walked down an instrumented walkway at -1, and 12 weeks (W12) relative to their surgery date. Before testing sessions, rats were shaved to allow accurate placement of 4mm reflective markers on the bony landmarks. All motion data was normalized to 100% of a complete gait cycle (heel strike), with a minimum of three cycles averaged for each rat. Simulations were performed on subject specific versions of a modified OpenSim 3D rat hindlimb model<sup>1,2</sup> to calculate kinematics, kinetics and muscle length over a gait cycle. Force testing consisted of LG stimulation

**Figure 1:** Labeled rat in the walkway (left), OpenSim model scaled to the individual rat (right).

via a nerve cuff on the tibial nerve, with the distal portion of the LG tethered to a load cell to record maximum isometric torque.

## Results and Discussion

Force testing at the W12 timepoint showed a significant deficit in the injured vs. contralateral LG muscle's ability to generate force at the ankle. Baseline kinematics<sup>1,3</sup> and GRFs<sup>3</sup> were similar to reported data of normal gait in rats. W12 kinematics showed significant changes in the hip motion in stance and pre-stance, with increased extension, abduction, and external rotation. While not significant, there was a trend at the knee for increased knee extension throughout stance. Surprisingly, there was little difference at the ankle joint. Joint kinetics of the injured limb demonstrated little differences compared to the baseline moments. There was an increased hip abduction and knee extension moments in stance. Again, surprisingly, there was no difference in the moment generated about the ankle.

Post hoc analysis of the medial and lateral gastroc musculotendon unit length adds some insight as to how the rats were able to generate the normal ankle moment with injured LG. Simulations show that the rats LG and MG musculotendon unit was longer at the W12 tests. This moved the force length curve to the right increasing the contributions of the passive portion of the muscle, enabling the rats to generate the required moment with reduced active muscle capacity. This can also be seen in the kinematics where the knee and hip were extended allowing the LG and MG to operate in a more advantageous position.

**Figure 2:** Muscle tendon unit length (mm) over one gait cycle.

Baseline black  
Week 12 red

## Significance

The development and implementation of robust dynamic models of the Lewis rat musculoskeletal system offers new perspective on how animals adapt to new and novel neuromuscular pathology. Understanding how activation and loads change for a given movement adaptation will help to inform cutting edge methods for VML repair. This includes defining the material properties of engineered regenerated muscle fibers, in addition the models offer a method for testing possible rehabilitation methods to optimized functional recovery.

# Variability of Spatiotemporal Gait Metrics in Middle-Aged Adults with Persistent Ankle Pain

Stephen C Cobb<sup>1</sup>, Kazandra M Rodriguez<sup>2</sup>, Mohammed S Alamri<sup>1</sup>, and Emily E Gerstle<sup>1</sup>

<sup>1</sup>Department of Kinesiology, University of Wisconsin-Milwaukee, Milwaukee, WI, USA

<sup>2</sup>Department of Kinesiology, University of Michigan-Ann Arbor, Ann Arbor, MI, USA

Email: [cobbsc@uwm.edu](mailto:cobbsc@uwm.edu)

## Introduction

Persistent ankle pain afflicts an estimated 11.7% of adults over the age of 50 with the prevalence peaking in middle-age [1]. In addition, individuals with ankle pain/ stiffness but no diagnosed OA report similar pain, disability, and decreased QoL as those with ankle OA [2]. Despite the prevalence and adverse impact on QoL, very little research has investigated the influence of persistent ankle pain on gait in middle-aged adults.

Spatiotemporal parameter variability (STPV) may be a sensitive indicator of age- and injury- related changes in the motor control of gait [3,4]. Previous studies have investigated STPV in young adults with chronic ankle instability (CAI) [5] and in middle-old aged adults with chronic lower body joint pain [4], however, persistent ankle pain in middle-aged adults has not been studied.

The purpose of this study was to investigate walking gait STPV in middle-aged adults with persistent ankle pain. We hypothesized that individuals with persistent ankle pain would demonstrate increased spatiotemporal parameter variability.

## Methods

Nineteen middle-aged adults (45-64 yo) provided written informed consent to participate in one of two groups (PAIN, CON). PAIN group participants (n = 10; 9 F, 1 M; mean age: 54.4 ± 5.8 y; mean height: 168.0 ± 5.1 cm; mean BMI: 27.3 ± 7.1 kg/m<sup>2</sup>) experienced pain for the previous 3 months, complained of at least slightly troublesome pain on most days during the past month [6], and had a history of at least one lateral ankle sprain. CON group participants (n = 9; 8 F, 1 M; mean age: 53.0 ± 5.8 y; mean height: 168.2 ± 6.1 cm; mean BMI: 26.5 ± 7.4 kg/m<sup>2</sup>) were matched with PAIN group participants by age (± 5 y), sex, and BMI classification. CON group participants had no complaints of ankle pain in the previous 3 mos., had no history of ankle sprain in the previous 12 mos., and no acute lower extremity injury in the previous 12 mos.

Each participant completed 10 successful self-selected speed barefoot walking trials along a 15 m walkway with 3 embedded force plates (sampling rate: 1000 Hz). For each spatiotemporal metric of interest, variability was expressed as the coefficient of variation (100 x (standard deviation of the metric/mean of the metric) (Table 1). Group differences were investigated using independent t-tests (SPSS,  $\alpha = 0.05$ )

## Results and Discussion

A preliminary analysis of preferred walking speeds revealed no significant differences between the groups (PAIN: 1.19 ± 0.11 m/s, CON: 1.21 ± 0.13 m/s,  $p = 0.786$ ). The hypothesized increase in PAIN group STPV was supported during double support, but not for the other metrics assessed (Table 1). The increased variability during double support may be the result of decreased strength, changes in neuromuscular function, postural

stability, and/or central motor control changes associated with persistent ankle pain [5,7].

The lack of significant difference in stride length and cycle time between the PAIN and CON groups in the current study was consistent with a previous CAI study [5]. Although the results agree, comparison between the studies is difficult given the differing participant ages and inclusion/exclusion criteria. The lack of significant difference in step length variability was inconsistent with a previous study that reported decreased step variability in participants with chronic lower body joint pain [4]. However, the lower body joint pain study included middle-old aged participants with low back, hip, knee and foot pain and suggested the majority of the differences were driven by hip pain. Thus, the effect of chronic pain on STPV may be influenced by the joint(s) affected.

**Table 1** Mean (SD) PAIN and CON Group STPV

STPV (%)	Group		P	$\eta^2$
	PAIN	CON		
Cycle time	2.73 (1.05)	2.67(1.04)	0.904	0.001
Stride length	1.61 (0.56)	1.28 (0.56)	0.222	0.086
Gait speed	2.92 (1.25)	2.81 (0.94)	0.831	0.003
Cadence	2.70 (0.99)	2.63 (0.98)	0.887	0.001
In. Step length	3.62 (1.89)	3.53 (2.77)	0.937	0.000
In. Single support	2.20 (0.85)	2.11 (0.58)	0.794	0.004
In. Double support	4.22 (0.88)	3.13 (0.92)	0.017*	0.292
Un. Step length	3.63 (2.35)	3.33 (1.90)	0.767	0.005
Un. Single support	2.51 (0.73)	2.12 (0.98)	0.339	0.054

In. = Involved limb; Un. = Uninvolved limb

\*statistically significant group difference

## Significance

Middle-aged adults with persistent ankle pain demonstrate increased variability during double support of walking gait. Further study is warranted to investigate pain-related changes in strength, neuromuscular function, postural stability, and/or central motor control in middle-aged adults with persistent ankle pain that may lead to the increased double support variability during walking gait.

## The Effects of Recreational Dance Experience on Landing Mechanics

Cycenas, T. J., Kimberlin, T., Hegazy, M.A, PhD  
Southwest Minnesota State University  
Email: Taylor.Cycenas@my.smsu.edu

### Introduction

Poor landing mechanics expose athletes to increased risk of injury (Harwood *et al.*, 2018). However, dancers experience less acute lower limb injuries than non-dance athletes (Turner *et al.*, 2018). Specifically, research supports that dancers experience substantially reduced ACL injuries compared to team sport athletes (Liederbach, *et al.*, 2008). Reduced injuries may be a result of the extensive training experienced dancers undergo (Orishimo *et al.*, 2014). Although researchers have recommended that non-dance athletes may benefit from doing dance training (Turner *et al.*, 2018), it is unknown how much dance training would be needed to gain similar benefits. While research provides evidence that dancers exhibit superior landing mechanics compared to non-dancers, these findings have been conducted in professional and high level dancers who spend at least 12 hours a week practicing (Turner *et al.*, 2018). Competitive athletes typically have time constraints and it is highly unlikely they will engage in dance with the same commitment as professional and high level dancers that spend long hours on a daily basis. It is unknown if recreational dance experience contributes to better landing mechanics. Therefore, the purpose of this study was to determine if recreational level dance experience provided better landing mechanics to that of non-dancers. If so, it is more practical for non-dance athletes to gain a recreational level of dance experience to improve their landing mechanic.

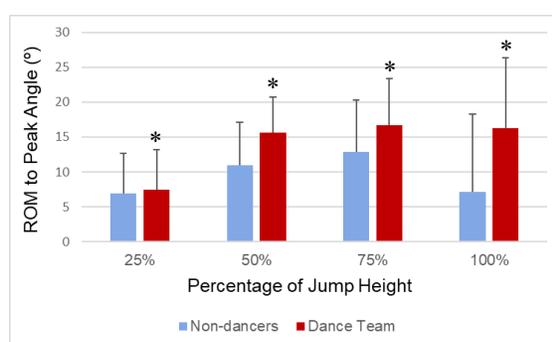

### Methods

We compared landing mechanics of noncompetitive college dance team dancers (n=12; weight=61.71±12.53 kg; height=160.66±8.61 cm; years of experience=12.75±4.16; hours/week=10.75±3.44) to those of non-dancers (n=12; weight=80.34±21.13 kg; height= 165.10±5.86 cm). Loadsol insoles (Novel, St. Paul, Minnesota, United States) were inserted into the participant's shoes to measure GRF and Opal inertial sensors (APDM, Portland, Oregon, United States) were secured to the participant's body to collect kinematic data. A 5-minute warmup on an elliptical machine was performed prior to the jumping tasks. Participants then performed 3 maximal countermovement vertical jumps using a vertical jump measuring device, from which their 75%, 50%, and 25% sub maximal values were calculated. Participants then performed three jumps from each submaximal height in a counterbalanced order.

### Results and Discussion

No significant differences in normalized peak vertical GRF or peak loading rate were found between groups ( $p>0.05$ ). However, dancers displayed greater peak hip flexion range of motion to peak GRF in both left and right hips with ( $F(1, 22) = 5.06$ ,  $p<0.05$  and  $11.09$ ,  $p<0.05$ , for the left and right hips, respectively; Figure 1). In addition, dancers also showed a significantly lesser knee valgus angle than non-dancers with ( $F(1, 22) = 4.93$ ,  $p<0.05$  and  $4.79$ ,  $p<0.05$ , for the left and right knees, respectively). Increase in hip flexion during landing increases the moment arm for the ground reaction force vector at the hip and reduces it at the knee. Thus, the demand on hip extensors to control the

downward movement increases, while that on knee extensors would decrease (Powers, 2010). Turner *et al.*, (2018) reported that dancers achieved greater gluteus maximus activation and reduced knee valgus angles compared to non-dancers in a drop landing task. However, dancers in their study practiced for a minimum of 12 hours a week and were members of a university dance program. In our study, dance team members with less weekly practice time than typically reported in the literature showed superior landing biomechanics to non-dancers. The landing patterns observed may protect against acute lower extremity injury.

**Figure 1:** Left hip ROM to peak joint angles of dance team and non-dancers at 25%, 50%, 75%, and maximal jump heights. \* $p<0.05$

### Significance

In this study we found sufficient evidence to support that non-dance athlete may benefit from implementing dance training at a recreational level. However, dancers in our study spent approximately 10 hours of practice every week, which is less than professional dancers but more than what a typical non-dance athlete may be able to do given time constraints. Thus, future studies should focus on identifying key components of dance training for non-dance athletes to implement. Another direction would be to study landing mechanics of individuals who engage in dance for less than five hours a week. However, finding participants that meet this criteria may prove difficult.

### Acknowledgments

We would like to thank the SMSU Dance team.

## Introduction

At NASA Johnson Space Center, engineering evaluations of prototype exploration spacesuits and spaceflight analog environments have been led by the Human Physiology, Performance, Protection, and Operations (H-3PO) Laboratory in collaboration with the Anthropometry and Biomechanics Facility (ABF) to advance the current understanding of crewmembers' capabilities and limitations in suited planetary extravehicular activities (EVAs). We have been conducting simulated planetary EVA operations using the Mark III spacesuit [1] in the Active Response Gravity Offload System (ARGOS). While partially offloading subjects' weight to simulate Lunar gravity, 1/6 of Earth's gravity (1/6-G), we are characterizing activities and postures during EVAs to provide both quantitative and subjective data for work-domain and metabolic characterizations as well as engineering evaluations of next-generation spacesuits and tools.

## Methods

Subjects conducted EVA-like tasks, such as deploying science experiments on the lunar surface, which enabled efforts toward classifying when subjects were standing, bending over, kneeling, walking, etc. For example, subjects performed each experimental package deployment (i.e., while bending over or kneeling) then ambulated on a treadmill with various incline grades to simulate translation paths to the next deployment site (Figure 1).

For kinematic assessments, we donned 7 Opal™ (APDM, OR, USA) wireless inertial measurement units (IMUs) on the spacesuit: one on the chest; one each on left and right upper hip bearing; left and right mid hip bearing; and left and right ankle bearing. The chest IMU measured the torso tilt angle in the sagittal plane. Specifically, accelerometer, gyroscope, and magnetometer data were fused into quaternion rotation matrices via a gradient descent algorithm [2]. The quaternion rotation matrices were then transformed into Euler angles using custom scripts programmed in MATLAB® (R2019a, Mathworks, MA, USA). The lower limb IMUs discriminated translation (walking), standing activities, and kneeling activities. We utilized an ensemble learning method to capture each activity type. Specifically, activities were first characterized and verified by direct observation using Boris event-logging software [3]. Afterwards, we used ensemble learning on the labeled dataset and enlisted classifier models including linear discriminant analysis and support vector machine that are strategically combined to reduce computational cost while improving the performance compared to a single classifier [4]. We provided a rejection criteria for all pseudo-kinematic motions that were not strictly considered translation (i.e., at least three consecutive gait cycles must be demonstrated for both legs) and kneeling down (i.e., at least three-second kneeling down posture must be maintained).

## Results and Discussion

Table 1 and Table 2 show the duration and percentage of each activity type and its corresponding torso tilt angle in the sagittal plane. For example, during a 38-minute experimental package deployment task, the subject spent 32.6%, 50.5%, and 16.9% of the task time translation, standing, and kneeling, respectively.

**Figure 1:** Examples of activities and postures: (left) translation (walking) on the treadmill, (middle) standing and bending over, (right) non-standing (kneeling with both knees) and bending over.

**Table 1:** Duration and percentage of each activity (unit: minute [%]).

Total	Translation (walking)	Standing activities	Kneeling activities		
			Both	Right	Left
38.2 (100.0)	12.4 (32.6)	19.3 (50.5)	2.5 (6.6)	3.4 (8.8)	0.6 (1.5)

**Table 2:** Duration and percentage of the torso tilt angle in the sagittal plane during standing and kneeling activities (unit: minute [%]).

Posture	0-10°	10-20°	20-30°	30-40°	40-50°	50-60°	60-70°	70-90°
Standing activities	9.6 (49.7)	2.8 (14.5)	1.8 (9.3)	1.7 (8.8)	1.7 (8.8)	1.5 (7.8)	0.2 (1.0)	0.0 (0.0)
Kneeling activities	0.4 (5.2)	0.4 (5.2)	0.5 (6.5)	0.6 (7.8)	0.7 (9.1)	1.9 (24.7)	2.2 (28.6)	1.0 (13.0)

Suited subjects were demanded kinematic adjustments during EVA-like tasks at the ARGOS environment, which were depicted by the varying degrees of torso tilt in the sagittal plane (i.e., past 20 degrees). The lack of flexibility in the hard upper torso (HUT) may have caused subjects to increase torso tilt to beyond 60 degrees in the kneeling activities. Advanced materials and joint bearings have allowed room for rotation at the hips and bending of the knees to coordinate these tasks. The modified Extravehicular Mobility Unit (EMU) gimbal limited arm movement during translation, however, subjects could ambulate at a range of speeds and inclination angles without discomfort.

## Significance

Mobility and energy expenditure of crewmembers on the lunar surface are of prime interests in any lunar EVA. On Apollo missions, the hopping and falling behaviors were attributed to restricted movement due to the inflexibility of the Apollo suits. However, in this study, the Mark III spacesuit that includes multiple bearings and convolutes at the hip and thigh provided greater mobility. The results should be generalizable to the Exploration EMU (xEMU) for the Artemis astronauts who will be working on the moon. Future work will include the validation study of characterized activities and postures with the xEMU suit. These methods also will be used as part of a metabolic rate task characterization study to determine the physical workload associated with partial gravity EVAs.

# Assessing Postural Control with Smartphone Accelerometry in People with Multiple Sclerosis

Katherine L. Hsieh<sup>1</sup> and Jacob J. Sosnoff<sup>1</sup>

<sup>1</sup>University of Illinois at Urbana-Champaign, Urbana, IL

Email: [klhsieh3@illinois.edu](mailto:klhsieh3@illinois.edu)

## Introduction

Falls are a major health concern for people with Multiple Sclerosis (pwMS). One in two pwMS will fall in a three-month period, and up to 50% of falls result in an injury.<sup>1</sup> Impaired postural stability is one of the most important risk factors for falls in MS and affects over 50% of pwMS.<sup>1</sup> Postural stability can be assessed with clinical scales, but these do not always capture underlying balance impairments in pwMS.<sup>2</sup> Technology-based assessments (i.e., force plates, motion capture) can capture minute changes in posture but require expensive equipment.

One alternative solution is to use leverage the power of smartphone technology. Smartphones are embedded with an accelerometer that can potentially be used to assess postural control. Smartphones are also affordable, ubiquitous, and portable, offering potential for home-based assessments. The purpose of this study was to determine whether smartphone accelerometry can measure postural control in pwMS compared to a research grade accelerometer and force plate measures during standing balance tasks. We also determined whether smartphone accelerometry was capable of discriminating between assisted device users and non-assisted device users, as assisted device usage is a strong predictor of falls in pwMS.<sup>3</sup>

## Methods

Twenty-seven individuals with MS participated. All participants underwent static balance assessments while standing on a force plate (Bertec Inc, Columbus, OH) and holding a smartphone (Samsung Galaxy S6, Seoul, South Korea) medially against the chest along the sternum. A research grade accelerometer (Opal, APDM, Portland, OR) was attached to the smartphone.

Two trials of five standing balance tasks were performed on the following order for 30 seconds each: 1) eyes open, 2) eyes closed, 3) semi-tandem, 4) tandem, and 5) single leg. Acceleration from the smartphone and Opal in the mediolateral (ML), anteroposterior (AP), and vertical directions were exported and processed, and Root Mean Square (RMS) acceleration in the ML and AP directions and 95% area ellipse were calculated. Center of Pressure (COP) data from the force plate was exported and processed, and RMS in the ML and AP directions and 95% area ellipse were calculated.

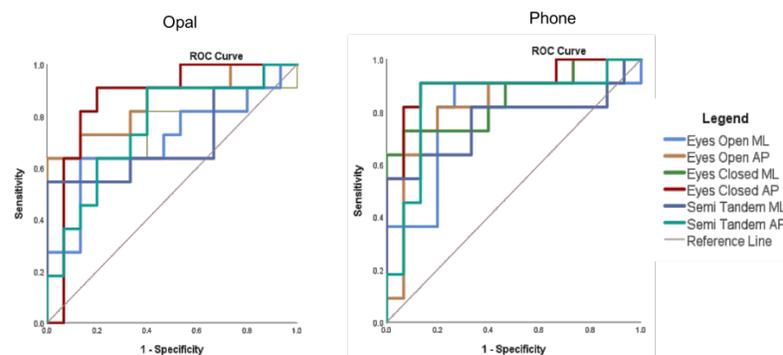

COP and acceleration measures were averaged for the two trials for each condition. Validity between measures derived from the force plate, smartphone accelerometer, and Opal accelerometer were assessed with Spearman's correlations for all balance conditions. Receiving operating characteristic (ROC) curves were constructed and the area under the curve (AUC) was calculated to determine the level of discrimination between assisted device users and non-assisted device users.

## Results and Discussion

Of the 27 participants, 12 were assisted device users and 15 were non-assisted device users. Assisted device users had significantly greater Expanded Disability Status Scale scores, suggesting greater disability ( $p = 0.01$ ). There were no differences in age between groups ( $p = 0.11$ ).

There were moderate to strong correlations between the smartphone accelerometer and Opal accelerometer for RMS ( $\rho = 0.66 - 0.97$ ;  $p = 0.001 - <0.001$ ) and 95% area ellipse ( $\rho = 0.72 - 0.94$ ;  $p = <0.001$ ). As anticipated, there were weak to moderate correlations between the smartphone accelerometer and force plate for RMS ( $\rho = 0.45 - 0.87$ ;  $p = 0.02 - <0.001$ ) and 95% area ellipse ( $\rho = 0.48 - 0.72$ ;  $p = 0.01 - <0.001$ ). These findings suggest that smartphone accelerometry is comparable to measure postural control compared to gold-standard devices in pwMS.

ROC curves were constructed to determine the classification accuracy between assisted device users and non-assisted device users (Fig. 1). For RMS ML, AP and 95% confidence ellipse acceleration from the smartphone, the AUC was statistically significant ( $p < 0.001 - 0.02$ ). For RMS AP and 95% confidence ellipse acceleration from the Opal accelerometer, the AUC was statically significant ( $p = 0.002 - 0.03$ ). There was no statistical significance for RMS ML from the Opal accelerometer. For COP outputs from the force plate, the AUC was statistically significant ( $p = 0.004 - 0.05$ ). These results suggest that smartphone accelerometry can be used to classify MS assisted device users and non-assisted device users. Because assisted device usage is a strong predictor of falls and a proxy of postural instability, smartphone accelerometry may provide an insight to understanding those who are at a high risk for falls.

**Figure 1.** Receiver Operating Characteristic (ROC) curves for Root Mean Acceleration from the Opal and Smartphone.

## Significance

There is potential to leverage smartphone accelerometry to provide an objective assessment of standing balance in pwMS. Smartphones are affordable, ubiquitous, and portable, and over 80% of pwMS own smartphones. These finding provide preliminary results to support the development of mobile health app to measure fall risk for those with MS.

## Introduction

Machine learning (ML) algorithms for the estimation of biomechanical variables have been implemented in the highly controlled settings of the laboratory. However, one of the ideals of these tools is to take biomechanical analysis into a less constrained environment [1]. In gait biomechanics the accurate measurement of ground reaction forces is crucial for solving inverse dynamics. In the laboratory Inertial Measurement Unit (IMU) data has been input into ML algorithms to estimate ground reaction forces, joint moments and powers [2,3]. These studies have been limited in their real world applicability because only a small number of locomotion modes or speeds were tested.

The purpose of this project was to examine the accuracy of a long short term memory (LSTM) network to estimate the vertical ground reaction force waveform (vGRF) of subjects across multiple locomotion modes (level ground walking, running, ramp and stair, ascent and descent) from data collected in a real world environment. We expect that estimation error, (root mean square error (RMSE)) of the predicted vGRF data will be the lowest for walking, and that running will have the highest RMSE of the locomotion modes.

## Methods

Data were collected from 14 subjects (8 male and 6 female,  $32.7 \pm 15.2$  years,  $175 \pm 7.9$  cm,  $67.8 \pm 9.0$  kg) over a two day protocol. All analyses were performed in custom Matlab programs (Mathworks, Natick, MA). Lightweight IMUs (Vicon, Centennial, CO) mounted on the dorsal aspect of each participant's dominant foot and shank recorded linear accelerations and angular velocities at 500 Hz. Vertical ground reaction force data were recorded with Loadsol inserts (Novel Electronics, St. Paul, MN) at 100 Hz.

On the first day of the protocol participants performed 6 locomotion tasks; stair ascent and descent, level ground walking, ramp ascent and descent (slopes  $<5^\circ$ ), and running. The second day of the study utilized a protocol adapted from Long and Srinivasian [5]. The range of target average speeds was 1.3 to 3.0,  $m s^{-1}$  (1.30, 1.51, 1.73, 1.94, 2.15, 2.36, 2.58, 2.79, 3.00  $m s^{-1}$ ) on a 90 m course. Participants received feedback at the half-way time point and with five seconds remaining in the trial. Trial order was randomized to minimize learning effect. Vertical ground reaction forces were normalized to body mass. Data were synchronized, resampled to 100 Hz and split into training (70%), validation (15%) and test (15%) sets.

An LSTM network consisting of 4 layers was built to estimate vGRF from IMU data. Inputs to the network were linear acceleration and angular velocity data from single footfalls with swing phase data included from before and after the period of foot contact, from which the network determines gait events. Output from the LSTM was a single vGRF waveform. Ramp, stair and running footfalls were bootstrapped. A Bayesian hyperparameter search was completed to determine optimal hyperparameters for the LSTM. The estimated vGRF waveforms were then filtered

with a 6<sup>th</sup> order low-pass zero lag butterworth filter ( $f_c=15$  Hz). Estimation error of vGRF was quantified using RMSE.

## Results and Discussion

The overall RMSE for estimation of vGRF was 1.1 N/Kg (Table 1). These are similar to RMSE values reported in previous studies (1-2 N/Kg) [3,4].

**Table 1:** RMSE (N/Kg  $\pm$  SD) between the measured and estimated vGRF for raw and filtered waveforms.

	Raw RMSE	Filtered RMSE
Walking	1.11 $\pm$ 0.49	1.06 $\pm$ 0.49
Running	2.18 $\pm$ 0.88	2.09 $\pm$ 0.88
Stair Ascent	1.02 $\pm$ 0.28	0.97 $\pm$ 0.28
Stair Descent	1.25 $\pm$ 0.45	1.19 $\pm$ 0.46
Ramp Ascent	0.99 $\pm$ 0.32	0.94 $\pm$ 0.32
Ramp Descent	0.99 $\pm$ 0.25	0.93 $\pm$ 0.25

The results of this study demonstrate that vGRF can be accurately estimated in a real-world environment, across multiple locomotion modes and self-selected speeds. The estimated running vGRFs had the largest RMSE, followed by ramp ascent and descent and then level ground walking. Level ground walking speeds were more variable during the second day of the protocol which may explain why the RMSE is larger for level ground walking compared to ramp walking. Filtering the output vGRF data reduced RMSE, as expected. These filtered outputs can be used to calculate spatiotemporal parameters and gait events with the development of clear rules.

A limitation of this work is that only vGRF waveforms were estimated from the input IMU data. A more complex model may be needed to estimate joint moments across locomotion speeds and modes. For example, other basic measures such as anterior-posterior GRF may be needed for this model to accurately estimate joint forces and moments.

## Significance

This work has shown the estimation of a mechanical variable in a real world environment is possible. Our findings can lead directly to the estimation of basic spatiotemporal variables for a variety of locomotion modes and speeds. Additionally, these findings could also inform locomotion mode estimation using IMU data.

E-mail: [aldering@gvsu.edu](mailto:aldering@gvsu.edu)

### Introduction

The hip is modeled as a spherical joint with its center (HJC) frequently estimated using predictive [1,2,3,4] or functional methods [5]. Although functional methods are relatively robust, medical imaging is considered the gold standard for determining the HJC [6]. Of the predictive methods, Harrington's (HARR) appears to be most accurate [2,6]. Recently, Hara et al. have provided an alternative algorithm, dependent only on leg length, with HJC results that were comparable to Harrington [4]. Leboeuf et al. compared Hara and Harrington's predictive methods with ultrasound imaging and favored Hara's method because it reduced errors along the anterior-posterior pelvic axis. Leboeuf cautioned that HJC differences influenced hip kinetics [7], as reported elsewhere [8,9], but findings are somewhat discrepant. Therefore, the purposes of this study were to compare Hara and Harrington predicted HJC locations and to examine potential differences in net hip moments during stance in gait.

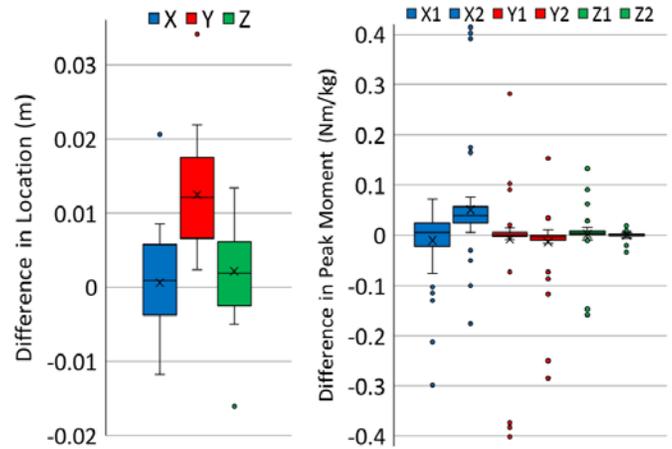

### Methods

Thirty active healthy individuals (13 females; 46.4±26.0 yrs; 1.71±0.01 cm; 69.7±11.5 kg) performed walking trials at self-selected speeds. Approval was obtained from the Grand Valley State University Human Research Review Committee (IRB#14080-H). Eight Vicon MX-T40 cameras (120 Hz) and Nexus software (V2.5, Oxford Metrics) were used to track full-body, modified PIG and Oxford Foot Model trajectories (Woltring filter, MSE 15). Ground reaction forces were collected (1200 Hz, 4<sup>th</sup>-order, zero lag Butterworth filter, 6 Hz) using floor-embedded AMTI force platforms (Advanced Mechanical Technology, Inc.). Visual3D (v6, C-Motion) was used to determine HJC location and hip kinetics, where the original PIG model was modified to reflect the Hara and HARR derived HJC locations (pelvic frame; +x lateral, +y anterior, and +z superior). Modifications were performed in the commonly used PIG model in order to maintain ancillary model definitions other than HJC calculations.

Right HJC locations and net internal hip moments, from three randomly selected gait cycles, were exported for statistical analysis. Peak stance moments of each pelvic frame were examined. Based on normality testing, paired t-tests for HJC locations and Signed-rank tests for HJC moments (SAS JMP) were used to assess for differences in coordinate positions and net hip joint moments among HJC methods ( $p < .05$ ). Cohen's D method was used to determine effect sizes.

### Results and Discussion

There was a significant difference in HJC location along the y-axis ( $p < .0001$ ), suggesting HARR HJCy (red) was more posterior compared to Hara. HJCx (blue) and HJCz (green) locations were similar between the two methods (Figure 1); effect sizes were: HJCx (0.09), HJCy (0.88), and HJCz (0.33).

**Figure 1.** Difference in HJC location between HARR and Hara. **Figure 2.** Difference in HJC moments (1<sup>st</sup> and 2<sup>nd</sup> peak).

Hara and HARR predictive models have been shown to minimize mean absolute error [4]. Leboeuf et al. demonstrated that HARR's equations were best for medio-lateral HJC location, while Hara's were best in the antero-posterior location [7]. Our data agree with Leboeuf's findings that HARR HJC is more posterior. Leboeuf et al. found that neither Hara nor HARR improved the supero-inferior HJC location. This could be related to the fact that neither method accounts for the pelvic height relationship to HJC [10].

Second peak moments in the sagittal (X2) and frontal planes (Y2), and the first peak in the transverse plane (Z1) were different between the two methods ( $p < .0001$ ) (Figure 2). Our findings are consistent with others [8,9] who have reported differences in hip moments during gait.

### Significance

The small significant differences in selected hip moments likely will not impact clinical diagnoses or treatment recommendations. Hara may be the preferred HJC predictive method because of its use of leg length, which minimizes error secondary to soft tissue artefact.

# Frequency Characterization of Thigh Soft Tissue Artifact During a Relaxed and Activated State

Scot Carpenter<sup>1</sup>, Michael Zabala<sup>1</sup>, Jacob Larson<sup>1</sup>, Anthony Marino<sup>1</sup>, and Edmon Perkins<sup>1</sup>

<sup>1</sup>Mechanical Engineering, Auburn University, Auburn, AL, US

Email: [zabalme@auburn.edu](mailto:zabalme@auburn.edu)

## Introduction

Marker-based motion capture systems are commonly used for biomechanical analyses to measure human movement by tracking the positions of reflective markers placed on the surface of the skin. A 3-D model of the subject can be created using the data from the markers. This provides an approximate location of the position and orientation of the underlying bones during a particular movement. A well-known limitation of this method of data collection, however, is the relative movement of skin and other soft tissue over the bone [1]. This type of error is known as *soft tissue artifact* (STA). In order to accommodate for this discrepancy, low-pass filters can be used to remove frequencies deemed to be too high for human volitional movement, thus lowering the likelihood of error due to STA. For general data collections, a common method of filtering at 6 Hz has shown to be somewhat effective at removing STA [2] and has been used as the typical low-pass filter. However, the frequency at which data should be filtered has been shown to depend on the movement type as well as various subject characteristics [3]. For this study, we hypothesized that STA frequency will be affected by muscle activation level. Thus, the objective of this study was to analyze how the STA frequencies of the thigh differ based on an activated and relaxed state of the thigh musculature.

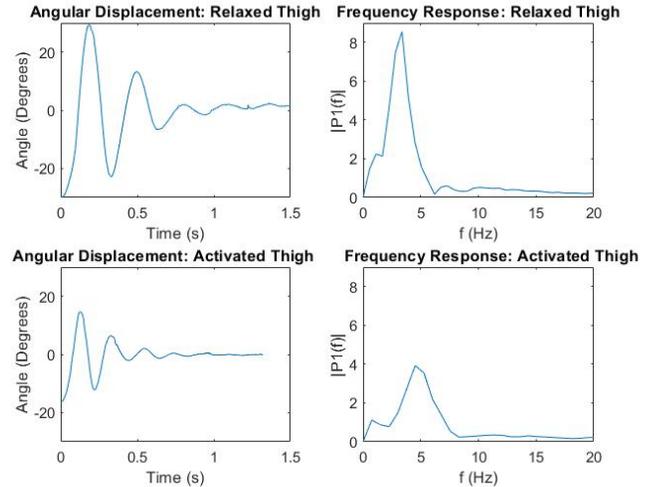

## Methods

Four human subjects participated in this study, having given IRB-approved informed consent. A 10-camera VICON motion capture system was used during data collection, and reflective markers were placed on each subject using a 79 marker set based on the point cluster technique [4]. The test consisted of subjects standing with their right foot on a platform which was raised to a height such that the knee was at 90 degrees of flexion. The subject was instructed to relax the thigh and perturb the skin by twisting the thigh with one hand about the femoral longitudinal axis to its maximum possible angle and quickly releasing, allowing the soft tissue to oscillate freely. The subject was then asked to repeat the procedure, while activating the musculature of the thigh. Three trials were taken for both conditions. The marker trajectories were gap-filled in Nexus software and further processed in MATLAB by creating an anatomical reference frame on the thigh and tracking movement of the centroid of the 9-marker thigh cluster relative to the origin of the segment. The angle of twist about the femur was calculated for each trial. This data was then converted to the frequency domain with a Fast Fourier Transform (FFT) to analyze the frequency components of the signal.

## Results

The angle of twist and frequency plot for a relaxed and activated state in one subject is shown in Fig. 1. The upper left plot shows the time history of the oscillations of the thigh's soft tissue, when it is in a relaxed state. The upper right plot shows the FFT of this data. The lower plots show the same information for an activated thigh. Table 1 shows the mean and standard deviation of frequencies for the activated and relaxed thigh. The mean

difference between the two sets of frequencies is shown and is statistically significant with a p-value of 0.022.

**Figure 1:** Time history and frequency response plot for a single subject.

**Table 1:** Frequency statistics based on one data set from each subject.

	Frequency (Hz)	STDEV	Mean Difference
Relaxed Thigh	4.04	0.697	1.55 Hz, P = 0.022
Activated Thigh	5.60	0.749	

The data shows that the average frequency for a relaxed thigh is lower than that of an activated thigh. Also, the maximum angular deflection is much higher in the relaxed thigh, as compared to the activated thigh.

## Discussion

The results indicate that the angular frequency of the thigh increased with muscle activation, which can be seen with a higher frequency and a lower maximum amplitude in Fig. 1. More importantly, the average frequency is less than 6 Hz regardless of activation. This means that some STA might not be removed from motion capture data when the typical 6 Hz cutoff frequency is used.

## Significance

The results of this study have indicated the possibility of allowing STA into motion capture results while using a 6 Hz lowpass filter. Future work in determining the relationship between STA and physical traits of the subject, such as age, weight, sex, and percent body fat, is needed to further determine STA frequencies for various subject characteristics.

# Application of quadratic regression model in the calculation of lower extremity joint stiffness

Youngmin Chun<sup>1</sup>, Joshua P. Bailey<sup>1</sup>

<sup>1</sup>Department of Movement Sciences, University of Idaho, Moscow, ID

Email : \*[y.chun@uidaho.edu](mailto:y.chun@uidaho.edu)

## Introduction

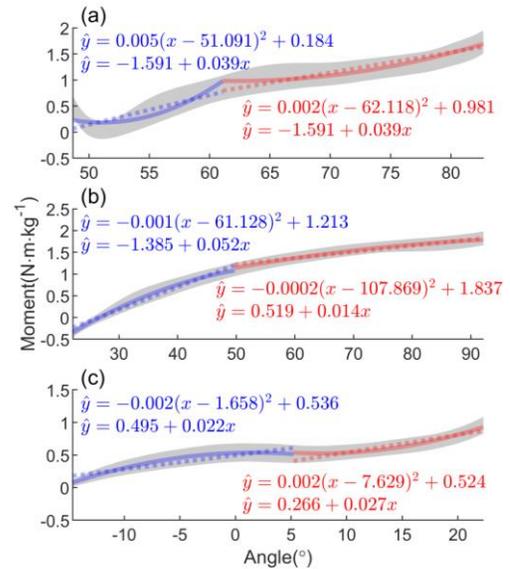

Lower extremity stiffness is an effective measure to relate load and deformation characteristics in sport-related activities attempting to evaluate performance [1,2] and identify potential injury risk [3,4]. Investigating lower extremity stiffness can be achieved through a spring-mass model [2,3] calculating leg stiffness or vertical stiffness, or by investigating individual joint stiffnesses in the sagittal planes [1,3]. Traditional methodology for representation of joint stiffness is through the line of best fit using simple linear regression model of the landing phase [1,3,4]. It is debated if this linear regression modelling is the most accurate way to represent such a non-linear relationship of joint position and moments. Therefore, the purpose of this abstract is to demonstrate how using a quadratic regression line of best fit model represents joint stiffness more accurately than a linear regression model. A secondary purpose is to demonstrate the importance of dividing the landing task into phases of interest prior to the identification of the line of best fit regression model.

## Methods

Thirty healthy college students participated in this study (15 males: age = 25.8 ± 6.6 yrs, height = 1.82 ± 0.04 m, mass = 82.4 ± 12.1 kg; 15 females: age = 25.2 ± 9.2 yrs, height = 1.71 ± 0.09 m, mass = 64.5 ± 11.2 kg). Fifteen drop vertical jumps from 30 cm of box were collected using 3D motion capture system (Vicon, 250 Hz) synchronized with two force platforms (1000 Hz). The obtained data of preferred limb (kicking limb) were exported to Visual 3D software and lowpass filtered at 15 Hz with 4<sup>th</sup> order Butterworth filter. The initial contact (IC) was identified if the vGRF of the preferred limb was greater than 20 N. The descending phase (IC to lowest COM position) was divided into loading (IC to peak vGRF) and absorption (peak vGRF to lowest COM position) phases [5]. Sagittal plane joint stiffnesses were calculated using both linear and quadratic regression models. The coefficient of determination ( $r^2$ ) of each model was also calculated to determine which model represents a better fitted line. Multiple independent *t*-tests ( $\alpha < .05$ ) were performed to compare the  $r^2$  values between models.

## Results and Discussion

The  $r^2$  of the quadratic model was significantly greater than the  $r^2$  of linear model in all joints and phases (Table 1). Figure 1 shows the moment-angle mean curves with lines of best fit calculated by both simple linear and quadratic models.

**Figure 1.** Mean hip (a), knee (b), and ankle (c) sagittal angle-moment graphs with lines of best fit models for each phase. The shaded area with gray color represents mean ± 95% CI of the moment-angle curve, blue and red lines represent the lines of best fit for the loading phase and absorption phase, respectively. *Solid lines* indicate the quadratic models, and *dotted lines* are simple linear models.

## Significance

The quadratic regression models provide more accurate lines of best fit than the simple linear models for each joint and each phase. Thus, the given model represents the joint stiffness more accurately. Additionally, the coefficient of  $x^2$  in the quadratic model estimates the slope. Therefore, using this model may indicate changes in joint stiffness.

Email: [dchiasso@sjtu.edu.cn](mailto:dchiasso@sjtu.edu.cn)

## Introduction

Wearable human movement information from inertial measurement units (IMU) is critical for a variety of applications including virtual reality, wearable electronics, physical therapy and human performance. However, techniques for representing this class of multimedia information has received little attention compared with the mature fields of image, audio, and text. Developing compressed representations of kinematic data will allow for higher sampling rates, greater data throughput, more nodes, and more data stored in a limited space. Compression is a key element to enabling previously unfeasible applications particularly those which experience limited transmission bandwidth or data storage. We hypothesised that the most efficient compressed representation format would utilize the interrelated nature of rotation and orientation information in the accelerometer and gyroscope.

## Methods

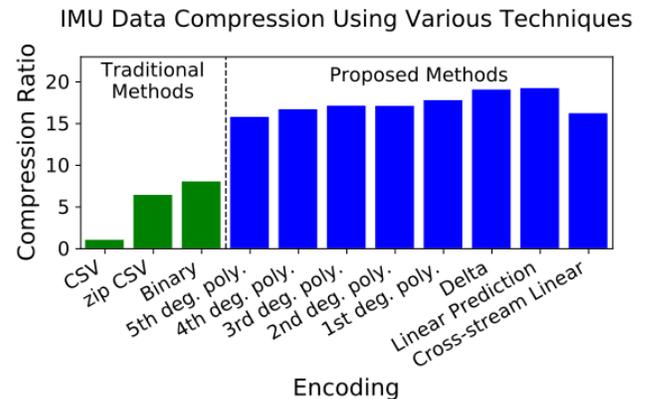

For this study, the Human Gait Database (HuGaDb)[1] is used to meaningfully and repeatably demonstrate the performance of various compression techniques. HuGaDb is a public dataset of six-axis IMU signals collected from six different body segments of 18 healthy subjects performing 12 different movement activities.

Eight lossless compression techniques are proposed and compared with three traditional methods which are already in widespread use. The first six techniques which fall under polynomial regression, are borrowed from the field of audio compression. These techniques extrapolate a polynomial regression of the past  $n$  data samples where  $n$  is an integer greater than the polynomial degree. The last two techniques are the optimal linear predictors of training data which were computed via Lasso regression. The cross-stream linear compression technique additionally considers past samples of other dimensions and sensor modality. The data collected from three random subjects was designated as training data, and only data from the remaining 15 subjects was used in our results.

The traditional method of comma separated value (CSV) is selected as the baseline size when computing compression ratio (CR). CR is computed by dividing the size of the CSV file by the size of the compressed file. In addition to CSV, two other traditional techniques are included for further context: ZIP compression, and efficient binary representation. All proposed compression techniques are implemented as FIR filters using 16.16 fixed point computation.

## Results and Discussion

All proposed compression techniques far outperformed traditional representation methods in size efficiency (Fig. 1). This is likely due to the proposed methods' ability to utilize time auto-correlation and sparsity of the sensor sample space. Delta encoding (zero-degree polynomial) proved to be the best

**Figure 1:** Compression ratios relative to CSV. Higher is better. Proposed methods compressed IMU data 15-20 times more than standard CSV formatting and 2-3 times more than traditional compression methods.

performing polynomial regression technique (CR=19.0), with each additional degree performing worse. This is likely because higher degree polynomial predictors suffer from poor white noise attenuation [2].

The linear prediction filter (CR=19.2) proved to be slightly better than delta encoding. Investigation of the coefficients showed that the per-stream FIR had learned an approximation of Delta encoding.

Cross-stream linear prediction (CR=16.2) unexpectedly performed significantly worse than linear prediction or delta encoding which fails to support our hypothesis. We expect that this was due to accumulation of error from 16.16 arithmetic. The cross-stream predictor involved two orders of magnitude more computation than delta encoding.

## Significance

Using these techniques, kinematic data can be compressed to almost one-twentieth the size of the current de-facto standard. This enables a range of applications which experience stringent requirements such as real-time data streaming, wireless communications, or limited storage space.

# Magnetometer-Free, Inertial-Sensor-Based Foot Progression Angle Estimation

Tian Tan<sup>1</sup>, Zachary A. Strout<sup>1</sup>, and Peter B. Shull<sup>1</sup>

## Introduction

Foot progression angle (FPA) is a critical walking gait parameter for assessment and intervention in a wide variety of movement-related diseases. Measurement of FPA is traditionally performed with an optical motion capture system. Previous approaches to estimate FPA via a foot-worn magneto-IMU (3-axis accelerometer, 3-axis gyroscope, 3-axis magnetometer) typically rely on magnetometer signals to correct the drift in the estimated sensor heading direction [1]–[3], which can be sensitive to magnetic distortion.

The purpose of this study was to develop an FPA estimation algorithm solely based on an inertial sensor consisting of a 3-axis accelerometer and a 3-axis gyroscope. To avoid drift problems, the sensor heading direction was estimated from the peak foot deceleration during the swing phase rather than from gyroscope integration as in previous approaches. We hypothesized that the proposed algorithm would enable accurate estimation of the FPA for normal, toe-in, and toe-out gait patterns.

## Methods

Three coordinate systems were used, including a sensor frame  $S$ , a changing reference frame  $C$ , and an intermediate frame  $F$ . The frame  $S$  is aligned with the foot via sensor placement. The frame  $C$  is aligned with the foot heading vector and updated after each mid-stance. The Euler angle roll and pitch of frame  $F$  with respect to frame  $C$  are both 0, while the yaw is the same as the yaw of frame  $S$  (sensor heading direction). For each step, the FPA is defined by the angle between the foot vector and the foot heading vector, so it is equivalent to the yaw of frame  $F$  with respect to frame  $C$  at mid-stance. The algorithm (Figure 1) consists of three components: 1) roll and pitch angle estimation via gyroscope integration (drift is corrected by the measured gravity vector during mid-stance), 2) estimated orientation conversion into a rotation matrix to transform the foot acceleration from frame  $S$  to frame  $F$ , and 3) FPA estimation using the relationship between different acceleration axes in frame  $F$  as follows:

$$\text{FPA} = \text{yaw} = \arctan\left[\frac{a_x^F}{a_y^F}\right], \quad (1)$$

where  $l$  is the sample with the largest acceleration magnitude during the last 50% of the swing phase.

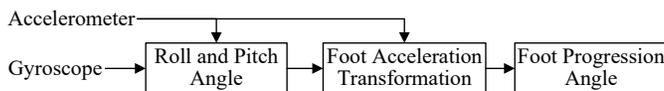

Figure 1: Flow chart of the proposed FPA estimation algorithm.

Twelve healthy subjects (age:  $25.8 \pm 3.3$ ; height:  $1.72 \pm 0.07$  m; weight:  $59.2 \pm 8.8$  kg, all male) participated in this study after providing informed consent. A motion capture system (Vicon, Oxford, UK) and two reflective markers placed on the calcaneus and the head of second metatarsal were used to collect ground-truth FPA measurements at 100 Hz. A synchronized inertial sensor was embedded in the heel of each subject's left shoe, and inertial data was collected at 100 Hz.

Subjects performed seven walking trials (large toe-in, medium toe-in, small toe-in, normal, small toe-out, medium toe-

out, and large toe-out) at a self-selected speed ( $1.16 \pm 0.06$  m/s) on a treadmill. A paired t-test was used to determine if there were significant differences between the FPA estimated by the proposed algorithm and the ground-truth FPA for all seven different gait patterns. The level of significance was set to 0.05.

## Results and Discussion

The hypothesis was supported that the FPA estimated by the proposed algorithm closely matched the ground-truth FPA (Figure 2). The overall mean absolute error, mean error, and Pearson's correlation coefficient across all walking gait patterns were  $3.1 \pm 1.3$  deg,  $0.3 \pm 2.7$  deg, and  $0.99 \pm 0.00$ , respectively. The mean absolute error for large toe-in, medium toe-in, small toe-in, normal, small toe-out, medium toe-out, and large toe-out trial were  $2.6 \pm 1.2$  deg,  $2.7 \pm 1.3$  deg,  $2.4 \pm 1.0$  deg,  $2.6 \pm 1.1$  deg,  $3.8 \pm 2.4$  deg,  $3.8 \pm 2.5$  deg, and  $4.0 \pm 2.0$  deg, respectively. There was no significant difference between FPA estimated by the proposed algorithm and ground-truth FPA for any of the seven gait patterns (Figure 2).

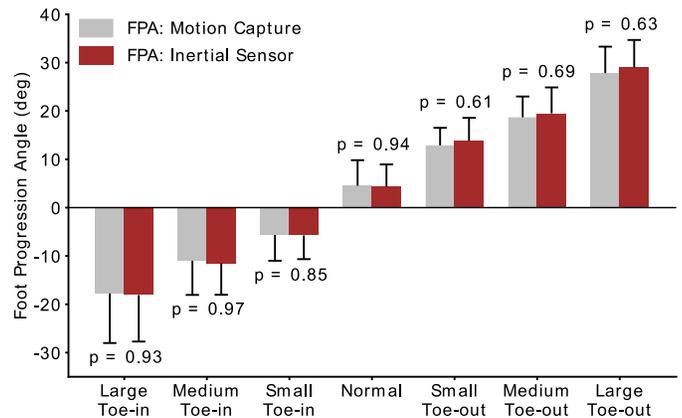

Figure 2: Average FPA grouped by walking gaits. There was no significant difference between FPA: Motion Capture and FPA: Inertial Sensor for any gait pattern.

When based solely on an inertial sensor, regular orientation estimation algorithms are prone to experience drift from angular velocity integration. In our case, the drift in roll or pitch was corrected via the gravity vector measured by the accelerometer, while there was no drift in yaw or FPA because it was estimated via the peak foot deceleration using Equation (1) without integration.

## Significance

The orientation of the foot with respect to walking direction can be estimated via a magnetometer-free inertial sensor during gait. The proposed algorithm may be useful for situations requiring wearable FPA assessment that are prone to magnetic distortion.

## Introduction

Soccer involves various functional movement patterns that require high velocity cutting, pivoting, and acceleration-deceleration maneuvers that can generate large lower extremity accelerations and impacts. Wearable inertial measurement units (IMUs) can capture accelerations of the lower extremity experienced during these high velocity movements. More importantly it can provide clinicians with the ability to estimate lower extremity impact loads during sport related tasks (1).

Previous work has identified the ability of these sensors to reliably measure impact load during running and their ability to predict running related injuries (2-4). To date, there is little information on the reliability of these sensors for capturing impact load metrics during more functional, individual sport specific soccer movements (i.e. cutting, pivoting, kicking). Thus, the purpose of this study is to determine the reliability of the Blue Trident IMU sensors in measuring impact load and step count during a series of soccer related functional tasks to assess its potential use in field-based sporting events.

## Methods

Ten healthy individuals (age :27.9 ± 2.18; height: 69.80 ± 4.022; mass: 79.02 ± 13.07; sex: 6 males, 4 females) were recruited and asked to complete a three-visit study where they performed 3 trials of the following standardized tasks during each session: 1) acceleration-deceleration, 2) plant and cut, 3) change of direction and 4) ball kick. Participants were instructed to perform the ball kick task using their dominant limb. Order of tasks was randomized for each participant and tasks were completed in the same order during each session. Test sessions were approximately 7-10 days apart (average 7.95 ± 1.06 days) and all sessions were collected on an outdoor, grass field. All participants currently or had previously participated in recreational ball sport activities (i.e. soccer, basketball, rugby, football etc). Participants were excluded if they had sustained a musculoskeletal injury within the last 6 months or had previous history of lower extremity surgery.

Bilateral impact load and total number of steps during the 4 tasks were collected using two IMUs secured via soft athletic pre-wrap and self-adhesive overwrap to the participant's distal, medial tibia just above the medial malleolus. IMU data was sampled using VICON IMeasureU Blue Trident dual-g sensor

(Low-g 1125Hz/High-g 1600 Hz). Impact load was calculated using IMeasureU Step platform where impact load = (#of steps x 1g) + (# steps x 2g) + (# of steps x 3g) + ... = Total # of steps \* g's. Outcome variables were averaged across the 3 trials during each session and intraclass correlation coefficients (ICC3,1) with 95% confidence intervals were used to assess between day reliability across the 3 sessions.

## Results and Discussion

ICC values for right and left impact load during each task are presented in Table 1. ICC values for total impact load were good to excellent (0.743-0.911). ICC values for right, left and total step count were good to excellent during the acceleration-deceleration task (0.728-0.837), change of direction (0.734-0.955) and plant and cut maneuver (0.701-0.866) and fair to good during the ball kick (0.588-0.683).

The high ICC values in the present study demonstrate the ability of the Blue Trident dual-g sensor to reliably measure bilateral lower extremity impact load and step count across an acceleration-deceleration, change of direction, plant and cut and ball kick task. Although the ball kick task demonstrated lower reliability in the number of steps taken, this is likely due to the inherent variability associated with executing the task.

## Significance

These results suggest that wearable sensors can reliably measure the cumulative impact load across a variety of athletic functional movements in an outdoor environment. Measuring impact load in the field expands the ability to capture more ecologically valid data. This work can serve as a stepping stone for future research aimed at evaluating impact load metrics over the course of games and practices. This information can help to inform athlete load monitoring strategies targeted towards injury prevention.

# Description and Validation of a Ground Reaction Force Triggered Treadmill Protocol for Simulation of Tripping Falls

Hui-Ting Shih<sup>1\*</sup>, Szu-Ting Yi<sup>1</sup>, Yo Shih<sup>1</sup>, Szu-Ping Lee<sup>1</sup>

<sup>1</sup>Department of Physical Therapy, University of Nevada Las Vegas

Email: \*[shihh1@unlv.nevada.edu](mailto:shihh1@unlv.nevada.edu)

## Introduction

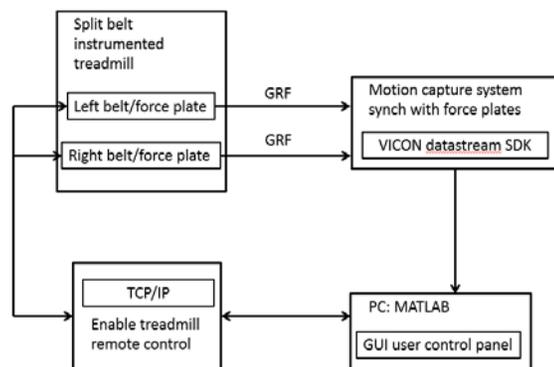

Falls frequently happen during perturbed walking as a result of tripping in community-dwelling middle-aged and older and even in young adults.<sup>1,2</sup> Previous protocols have used concealed obstacles, tether-based obstruction, and the acceleration and deceleration of a treadmill to simulate trips.<sup>3</sup> Each current protocol has its strengths and limitations. The obstacle and tether-based protocol obstructs one limb at a time during swing phase to simulate tripping. However, the timing of the perturbation delivery is difficult to control, leading to less replicable fall trials. The treadmill protocol which utilizes ground reaction force (GRF) to precisely deliver the trips, but so far is mostly limited to perturbing both legs together and therefore less realistic.

The novel protocol examined in our study aims to enable reproducible, unilateral trips. We validated the protocol by examining how the protocol can be used as an assessment tool to differentiate the trunk trip recovery responses<sup>5</sup> between young and middle-aged to older adults.

## Methods

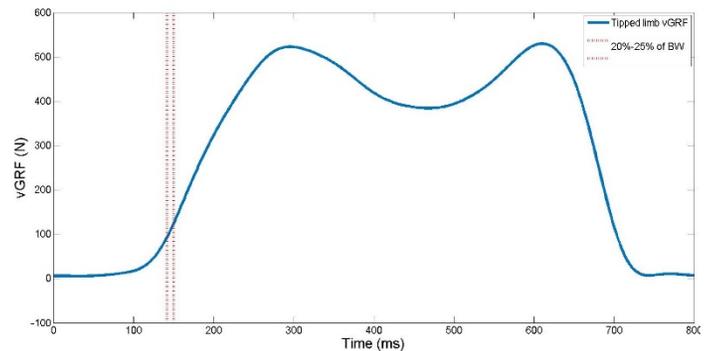

The system consists of three main components: 1) Bertec side-by-side split-belt instrumented treadmill (Model ITC-11-20L-4, Bertec Corp., Columbus, OH), 2) VICON motion capture system and Datastream Software Development Kit (SDK) (Oxford Metrics, Oxfordshire, UK), and 3) MATLAB (MathWorks Inc., Natick, MA).

The instrumented treadmill is equipped with one force plate underneath each belt. The force plate data were synchronized with the motion data in real-time and streamed by the SDK. We utilized MATLAB as an interface to communicate between Datastream SDK and the treadmill controller. MATLAB program read the vGRF from Datastream SDK and remotely employed the pre-programmed perturbation to the treadmill via Transmission Control Protocol/Internet Protocol (TCP/IP) port through which the program triggers the tripping perturbation by decelerating/accelerating the treadmill motor.

**Figure 1:** System apparatus.

Triggering criteria were based on the vGRF in order to deliver the perturbation during early stance phase right after initial contact of the tripped limb. First, the vGRF of the tripped side had to be between 20-25% of the person's body weight. Second, the vGRF of the selected frame in criterion 1 had to be greater than the value of the frame that is 10ms before it to ensure the vGRF is in the ascending limb of stance phase.

**Figure 2:** Triggering criteria. Blue vGRF line is from the tripped limb; pink dash lines represent triggering criteria.

During the perturbation, the belt on which the early stance phase occurs, either left or right, would decelerate from the comfortable walking speed (CWS) for 50ms, consecutively accelerate for 270ms, and then decelerate again for 220ms, resuming CWS.<sup>4</sup> Two acceleration levels are used to simulate the more and less severe tripping falls. The acceleration was linearly and positively scaled by the CWS.

## Results and Discussion

Of the 12 included participants, 6 were young and 6 were middle-aged to older adults (20.83 vs 58.17 y/o). Significant age group and severity main effects were found in peak trunk flexion angle and velocity, indicating that the protocol was able to discern the two age groups. Besides, both groups exhibited greater response following more severe trips.

	Trunk flexion angle (degree)		Trunk flexion velocity (degree/s)	
	Mild trip	Severe trip	Mild trip	Severe trip
Young (n = 6)	12.10 ± 5.59	23.95 ± 8.17†	81.81 ± 32.68	172.53 ± 61.08†
Old (n = 6)	20.66 ± 7.21*	33.65 ± 11.95*†	98.82 ± 37.80	179.45 ± 55.46†

**Table 1:** Peak trunk flexion angle and peak trunk flexion velocity in young and middle-aged to older adults.

## Significance

Since falling due to external perturbation is one of the most common causes of injury in older adults, having a tool that allows researchers to evaluate fall response and even train the participants under a realistic and safe environment is necessary. Our data show that this protocol can serve as a valid assessment tool for populations with high fall risks.

## Introduction

One limitation to measuring human movement patterns from inertial measurement units (IMUs) is the susceptibility of magnetometer readings to ferromagnetic interferences. To address this limitation, we recently proposed the use of deep neural networks to predict joint angles directly from inertial data, without relying on noisy magnetometer readings [1]. To further improve the accuracy and generalizability of these models, here we introduce a new framework that combines deep learning with top-down optimization.

## Methods

To train the deep neural networks, we used treadmill running data from 586 subjects and walking data from 384 subjects collected at the University of Calgary using an optical motion tracking system. Synthetic IMU data (linear acceleration and angular velocity) were generated by placing virtual IMUs on the segment marker clusters. Sensor noise was modelled synthetically by adding Gaussian noise [1], while sensor placement variability was modelled using data augmentation techniques [2]. As a baseline, we built deep neural networks to predict the joint angles,  $\alpha_i$  ( $i \in \{1, 2, 3\}$ ), and orientations of the adjacent segment sensors,  $q^S = \{q^{S1}, q^{S2}\}$ , from the inertial data.

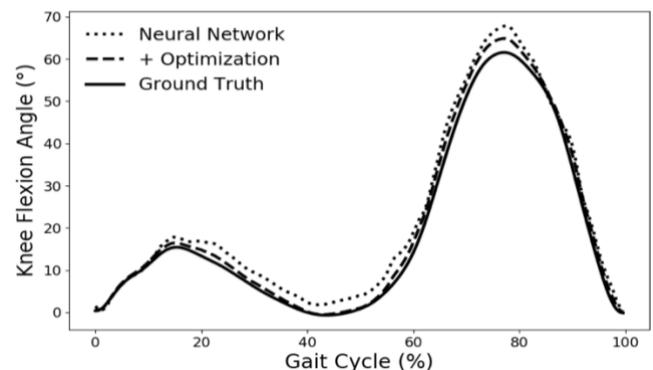

We then implemented a top-down optimization algorithm, which updated the orientation of each adjacent segment until the discrepancy between the inertial data associated with these predicted orientations and the “true” inertial data from the virtual sensors was minimized. The result of the optimization ( $\beta_i$ ) was defined as the angle between two optimized sensor orientations. To derive final angle prediction ( $\theta_i$ ), we used weighted average of two prediction results  $\alpha_i$  and  $\beta_i$ , where  $\theta_i = w_i\alpha_i + (1 - w_i)\beta_i$ . We set terminal stance of the predicted angle as zero and express the subsequent predictions as a function of the angle at that pose. We call this process passive pseudo calibration, since it does not require user engagement but is effective in reducing prediction error in subjects with atypical limb alignments.

## Results and Discussion

Walking kinematics could be predicted with a mean ( $\pm$  STD) RMSE of less than  $2.95^\circ$  ( $\pm 0.82^\circ$ ), while running kinematics could be predicted with a mean RMSE of less than  $3.24^\circ$  ( $\pm 1.12^\circ$ ). During walking, flexion/extension was the most accurate degree of freedom, with a mean RMSE of less than  $1.07^\circ$  ( $\pm 0.37^\circ$ ) across the ankle, knee, and hip joints, followed by ab/adduction with a mean RMSE of less than  $1.98$  ( $\pm 0.97$ ) and internal/external rotation with a mean RMSE of less than  $2.95^\circ$  ( $\pm 0.82^\circ$ ). Similarly, during running, flexion/extension was the most accurate degree of freedom, with a mean RMSE of less than  $1.29^\circ$  ( $\pm 0.40^\circ$ ) across the ankle, knee, and hip joints, followed by ab/adduction with a mean RMSE of less than  $2.33^\circ$  ( $\pm 0.84^\circ$ ), and internal/external rotation with a mean RMSE of less than  $3.24^\circ$  ( $\pm 1.12^\circ$ ). The higher RMSE in internal/external rotation may be explained by the lack of magnetometer data, which, when undisturbed, contribute toward heading estimation. Further,

optical motion tracking, which was used as ground truth here, exhibited similar accuracies across degrees of freedom.

Optimization improved prediction of knee flexion by over 15%, hip flexion by over 10%, and ankle flexion by over 15%. When passive pseudo-calibration was applied, optimization had an even larger effect on final kinematics. In this case, prediction of knee flexion improved by over 45%, hip flexion by over 60%, and ankle flexion by over 40%, compared to the neural network outputs. Using this pseudo-calibration framework the predictive accuracy of the algorithms can be tuned passively after a few gait cycles, without requiring attention from the user. Also, because we trained the models on augmented data, sensor placement errors did not significantly degrade the predictive accuracy of the overall framework. While validation with true sensor data is a necessary follow-up step, the accuracy of the presented framework is a promising advance toward prediction of joint kinematics from wearable sensors without relying on ferromagnetic interference, drift-prone algorithms, and/or error-prone calibration techniques.

**Figure 1:** Knee flexion over a representative gait cycle for a test subject computed from marker data (solid), predicted from a deep neural network (dash), and adjusted with top-down optimization (dotted), demonstrating how optimization improves joint angle estimation.

## Significance

Wearable sensors offer a promising alternative for motion analysis in natural environments by overcoming some of the limitations of traditional marker-based techniques: spatial limitation, expensive equipment, and need for human expertise. The hybrid deep learning and top-down optimization approach presented here brings us a step closer toward accurate estimation of kinematics from IMUs. Progress in this direction should enable large-scale studies and new insights into disease progression, patient recovery, and sports biomechanics.

# Comparing IMU and Motion Capture Kinematics for Jumping Jacks

Eric D. Brannock<sup>1</sup>, Kayt E. Frisch<sup>1</sup>

<sup>1</sup>George Fox University, Department of Mechanical, Civil, and Biomedical Engineering

Email: kfrisch@georgefox.edu

## Introduction

Inertial Measurement Units (IMUs) are a promising new tool for biomechanics research, providing the opportunity to move experiments “into the wild.” IMU systems have limitations, particularly for short duration motions, that are typically documented by the manufacturers [1], but studies seem to be choosing a system without attention to these details [2]. The goal of this abstract is to compare an IMU system with motion capture (MoCap) for a simple motion which the IMU system is probably not “tuned” for: jumping jacks.

## Methods

9 healthy subjects (4 female, 5 male, avg. age 21) took part in the study. Subjects were instrumented with a fullbody XSense Awinda IMU system, and then a full body biomechanics reflective marker set was applied. IMU (60Hz) and MoCap (120 fps, 8-Vicon T40 cameras) data were collected simultaneously while the subject performed two trials of 15 jumping jacks. Center Of Mass (COM) position, hip angle, and shoulder angles were computed for both data sets. MoCap position data was filtered (10Hz, 4th order Butterworth) and angles calculated in the coronal plane using Matlab. All IMU data was based on post-processing calculations performed within the XSENS software.

## Results and Discussion

There was a notable difference between the IMU and MoCap data sets. In the jumping jack trials, where both the subject’s feet left the ground simultaneously, the IMU system struggled to maintain the correct position in the transverse plane, with the IMU’s COM position drifting noticeably compared to the corresponding position of the MoCap LV5 (Fig. 1). Some IMU systems solve this problem by including a GPS system in their sensor suite, though the system used in this study is not one of them [1].

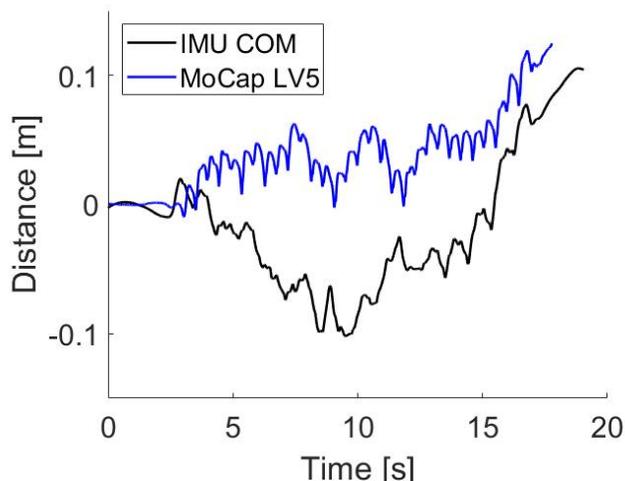

Figure 1: Magnitude of the COM drift distance in the transverse plane over 15 jumping jacks for a single representative subject.

In general the IMU and MoCap joint angles agreed. The greatest divergence occurred at points of impact (Fig. 2), presumably corresponding to high transient accelerations, which would result in data that could not be sampled by a system with a max sampling frequency of 60 Hz. Typical recommendations for data collection rates for high-impact activities (running, and presumably jump jacks landing) is a minimum of 400 Hz [3].

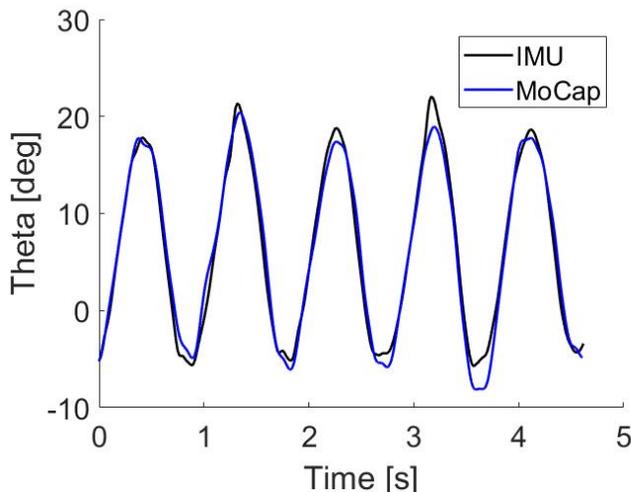

Figure 2: Hip angle over middle 5 jumping jacks for a single subject.

## Significance

IMU systems have exciting potential to move biomechanics experiments out of the lab, however, these preliminary findings suggest that the functionality of the particular system should be carefully considered and matched to the task being analysed. In particular, these specific IMUs seem to be accurate for slow movements, but face challenges for measuring impacts or long-term position tracking. Researchers should take care in selecting a system, paying attention to the sampling rate and tracking limitations as related to their particular context. Using an IMU system in place of motion capture should be done cautiously, and the validity should be checked carefully before a wholesale shift in methodology is adopted.

## sEMG-based Finger Posture Recognition Considering the Electrode Shift

Jongman Kim, Taehee Kim, Bummo Koo, Haneul Jung, Yejin Nam and Youngho Kim\*

Department of Biomedical Engineering and Institute of Medical Engineering, Yonsei University, Republic of Korea

Email: \*younghokim@yonsei.ac.kr

### Introduction

sEMG-based pattern recognition algorithms have been developed to recognize the user's motion or intention. Most previous studies developed sEMG-based gesture recognition systems, and they used sEMG sensors attached to specific muscles to avoid misclassification due to the electrode shift [1]. However, they were difficult to use by non-experts and did not perform well due to the electrode shift when the sensors were worn again in daily life [2]. Furthermore, the selection of feature vectors based on classification performance was not efficient in considering the cost and time to train and evaluate the classifier [1]. This study presents the sEMG-based finger posture recognition algorithm for non-experts and method to select the feature vector considering the electrode shift.

### Methods

Ten healthy adults were recruited to perform twelve finger postures in MVC of 20% (rest, spread, V-sign, O.K.-sign, scissor-sign, finger-pointing, thumb-up, palmar pinch, lateral pinch, tip pinch, cylindrical grasp, spherical grasp). Each subject wore a pre-developed armband-type sEMG sensor [3] on the right lower arm, and the electrode of the mainboard was placed on the top of the flexor carpi radialis. The subjects performed each finger posture for five seconds and all finger postures were repeated twice. These sessions were repeated ten times with donning and doffing of the sEMG-based armband sensor. Twenty-one feature vectors in time domain were calculated using the band-passed (10-250Hz) signal. Pearson's correlation coefficients (PCCs) were used to analyse the correlation of inter-gesture and inter-session. In PCCs, the values ( $r$ ) between  $0 < r \leq 0.3$ ,  $0.3 < r \leq 0.7$  and  $0.7 < r \leq 1.0$  indicate weak, moderate and strong linear relationship (LR), respectively. An artificial neural network (ANN) classifier with a single feature vector was used to classify finger postures. For each subject, nine sessions were used for training (TRN) the ANN classifier, and the other session for the testing in the MATLAB Neural Network Toolbox.

### Results and Discussion

In all feature vectors, the ANN classifier using 9 training data showed higher classification accuracy than the classifier using 1 training data. The accuracy of the classifier was high in the order of WAMP( $6.7 \pm 6.5\%$ ), ZC( $66.7 \pm 7.3\%$ ), WL( $65.8 \pm 6.1\%$ ) in 1 training session, and WL( $83.3 \pm 7.3\%$ ), AAC( $82.9 \pm 8.7\%$ ), IEMG( $81.7 \pm 6.0\%$ ) in 1 to 9 training session. These results mean that the additional training data considering donning and doffing of the sensor can solve the problems of electrode shift. Most feature vectors showed moderate LR of inter-gesture. The feature vectors with high inter-session ( $r > 0.8$ ) showed the classification accuracy of higher than 75%. MYOP and MAVSLP showed mean accuracy of 14.2% and 15.0%, respectively. These feature vectors showed weak LR in inter-gesture and inter-session. PCCs of inter-gesture showed the classification performance of feature vectors. In addition, PCCs of inter-session showed the robustness of the feature vectors regarding the electrode shift by donning and

doffing of the sensor. Both of inter-gesture PCCs and inter-session PCCs were important in evaluating the classification performance of feature vectors, but the results showed that the effect of inter-session was greater than that of inter-gesture.

The present study suggested that various finger postures could be recognized using an armband-type sEMG sensor and the problem of electrode shift could be solved using the feature vectors with a high inter-session PCCs.

**Table 1:** Classification accuracy (CA) and PCCs of inter-session and inter-gesture according to the feature vectors

### Significance

The robustness on the electrode shift by donning and doffing of the sensor is important in sEMG-based pattern recognition system for non-expert and daily life. In this study, classification performance was improved by the additional training data about the electrode shift in all twenty-one feature vectors. The analysis of PCCs showed that the LR of inter-session is more important than the LR of inter-gesture to improve the finger posture recognition.

## A comparison of attachment methods of skin mounted inertial measurement units on tibial accelerations

Caleb D. Johnson, Jereme Outerleys, Adam S. Tenforde, Irene S. Davis

Spaulding National Running Center, Dept. of Physical Medicine and Rehabilitation, Harvard Medical School, Cambridge, MA

Email: cdjohnson@mgh.harvard.edu

### Introduction

Tibial accelerations (TA) during running have been shown to be a valid surrogate for vertical ground reaction force loading rates [1,2], as well as showing associations with running injury [3]. With their recent proliferation, inertial measurement units (IMUs) containing tri-axial accelerometers, have become a common method of measuring TA. These IMUs often come with manufacturer-provided straps, for easy attachment on the skin. However, early work by LaFortune et al. [4] demonstrated systematically lower TA measured with bone- compared to skin mounted accelerometers, due to signal artefact introduced by soft tissue mounting. However, little attention has been given to the method of attaching skin mounted IMUs and its effect on resulting TA measures. Given the findings of LaFortune, it stands to reason that attaching an IMU more securely to the skin will result in lower mean TA. Further, it may also result in lower stride-to-stride variability and better correlations with vertical loading rates.

Therefore, our purpose was to compare two IMU attachment methods: the manufacturer-provided strap and a combination of tape with a neoprene wrap. We hypothesized that the wrap method would be more secure and therefore show lower mean TA, lower stride-to-stride variability, and higher correlations with vertical loading rates compared to the strap.

### Keep Space

#### Methods

18 runners were recruited as part of an ongoing study (10 men/8 women; mean age= 33 ± 11 yrs). An IMU (iMeasureU Blue Trident, Auckland, NZ) was attached to the right distal-medial tibia, 1 cm above the superior border of the malleolus. For the strap attachment method, participants were sized to one of 4 straps provided by the manufacturer for use with the IMU. For the wrap attachment, the IMU was first secured directly to the skin with Kinesio Tape® and then wrapped over top with a neoprene wrap. In both cases, the strap/wrap was secured as tightly as possible without causing significant discomfort.

Participants then ran for 5 minutes at a self-selected pace on an instrumented treadmill (AMTI, Watertown, MA) to warm-up, followed by 16 seconds of data collection (approx. 20 strides). The second attachment method was applied, and these procedures were repeated. Order of attachments was counterbalanced across subjects. Mean comparisons between attachment methods were performed for peak vertical and resultant TA (TA-V, TA-R), the stride-to-stride coefficient of variation for TA-V and TA-R, and vertical and resultant instantaneous ground reaction force loading rates (VILR, RILR). Further, correlations between peak TAs and VILR/RILR were assessed.

### Keep Space

#### Results and Discussion

Results of mean comparisons (Fig. 1) showed significantly lower peak TA-V in the wrap compared to strap condition ( $p=$

0.02,  $d= 0.34$ ). Mean TA-R was not significantly different between conditions ( $p= 0.06$ ). Mean VILR and RILR were found to be almost identical between conditions ( $p> 0.9$ ), indicating that differences in TS-V were due to differences in the IMU attachment, not changes in impact loading. This partially supports our hypothesis, that the wrap condition would more tightly couple the IMU to the skin, resulting in lower peak TAs similar to the results reported by LaFortune [4]. However, the effect size was small.

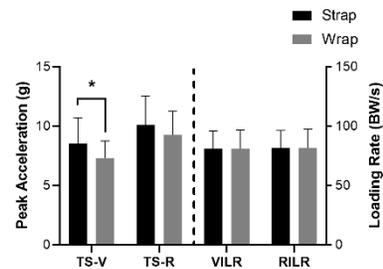

Figure 1: Mean comparisons between strap and wrap conditions

Median stride-to-stride coefficients of variation for TA-V (**Strap:** 8.5%, **Wrap:** 9.6%,  $p= 0.46$ ) and TA-R (**Strap:** 10.3%, **Wrap:** 10.1%,  $p= 0.64$ ) were similar. This was counter to our hypothesis, that the wrap condition would also lower stride-level variability in peak TAs.

Finally, our last hypothesis was also not supported. Correlations between TA-V and VILR/RILR were similar for the strap ( $r_s= 0.91$ ,  $p< 0.01$ ) and wrap ( $r_s= 0.84-0.85$ ,  $p< 0.01$ ) conditions. Correlations were also similar for TA-R (**Strap:**  $r_s= 0.85$ ,  $p< 0.01$ , **Wrap:**  $r_s= 0.79-0.81$ ,  $p< 0.01$ ). Our correlations are stronger than those reported by previous studies ( $r= 0.61-0.82$ ). [1,2] These results indicate that, despite lower mean TAs in the wrap condition, the correlations with ground reaction force loading rates were unaffected by the attachment method.

### Keep Space

#### Significance

Overall, our results provide two key pieces of evidence. For individuals interested capturing the most representative measure of actual TAs during running, a more secure attachment method for skin mounted IMUs may be necessary. This was evidenced by systematically lower peak TA-V in the wrap condition, albeit, with a small effect size. However, many individuals, such as clinicians, may simply be interested in TAs during running as a surrogate for impact loading forces. In these terms, using a simpler method of attaching IMUs (i.e. the strap) appears to be adequate.

## Introduction

Obtaining running data is crucial for managing an athlete's training load [1]. A gait lab can provide accurate position measurements, but simple wearable technologies are helping athletes reduce their costs and allowing the athlete to remain in a setting that is more representative of their typical gait pattern [2]. In particular, stride length can be obtained with the help of Global Positioning System (GPS) wearables. Unfortunately, a GPS may not be feasible due to the signal being deflected by buildings [3]. An alternative may include a Local Positioning System (LPS) since it is highly accurate, covers a large frequency spectrum (equal to or greater than 500 MHz) and consumes little energy, avoiding the disadvantages of GPS. Despite its advantages, an LPS has its limitations in determining gait events. Sensor fusion may be beneficial in this regard as sensor fusion takes inputs from multiple sensors and combines them into a single output. An Inertial Measurement Unit (IMU) can help characterize a gait event such as stride length. In order to get both good gait event data from the IMU and good position data from the LPS, sensor fusion is required. The objective of the study was to compare stride length obtained from a LPS to a motion capture system (MOCAP), the "gold standard".

## Methods

90 recreationally active participants (Age: 27.6 years  $\pm$  5.1, Mass: 70.7 kg  $\pm$  10.6, Height: 173.8 cm  $\pm$  8.7) free of any physical condition that prevents them from running were recruited. The testing session was conducted along a ten-meter running lane. Kinematic data were recorded using reflective markers and eight MOCAP cameras (Vicon, Oxford, UK). The LPS (XCo Tech, Penticton, Canada) consisted of a hub and an IMU sensor equipped with a radio frequency emitter operating in the ultrawide bandwidth (central frequency: 4GHz; bandwidth: 500 MHz). The hub was positioned two meters behind the participant's starting position at a height of one meter. A retroreflective marker was placed on each heel and the IMU was placed on the sacrum. Participants performed three trials at each of a self-selected walk, run and sprint speed. Stride length from the MOCAP was obtained by finding the difference between vertical minima of a heel marker at ipsilateral heel strikes. Stride segmentation was obtained by finding local peaks in the superior-inferior direction of the IMU data and deeming them as heel strikes [4]. Stride length was then calculated as the difference between position in the anterior-posterior direction obtained from the LPS of the heel strike epoch. The stride length in the last stride was used for analysis. A Bland-Altman plot was used to compare stride length between the LPS and MOCAP systems.

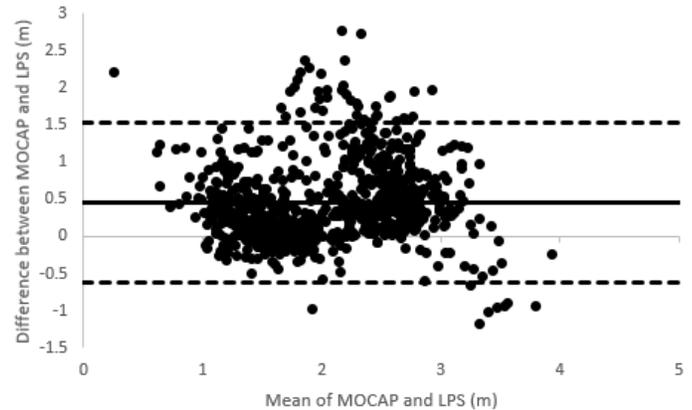

Figure 1: Bland Altman Plot of stride length obtained from the MOCAP and LPS

## Results and Discussion

As shown in Figure 1, the bias in the Bland Altman Plot of stride length is 0.46 m, the upper limit of agreement (+1.96 SD) is 1.53 m and the lower limit of agreement (-1.96) is -0.61 m. Out of 810 trials, 46 (5.68%) stride lengths fall outside of the limits of agreement. The Bland Altman plot of stride length showed a large scatter between MOCAP and LPS data.

## Significance

An LPS equipped with an IMU and operating in the ultrawide bandwidth may not be a valid method to determine stride length. Additional data processing methods, for example machine learning, should be explored to determine if efficacy can be improved.

### Introduction

Optical motion capture systems are often used in studies of human motion and biomechanics but remain expensive and constrained to a calibrated volume. Ambulatory motion sensors are emerging as a cost-effective and mobile alternative. Recent years have witnessed the increasing presence of inertial measurement units (IMUs) in non-laboratory settings for human motion measurement. However, the way these sensors are attached to the human body creates questions concerning subject discomfort, performance interference, and data quality [1]. More recently, a wireless, miniaturized, skin-mounted inertial sensor, BioStampRC (MC10 Inc., Lexington, MA, USA), has been developed, and it overcomes the drawback of conventional IMUs with a soft, flexible design that allows direct body-conforming adhesion to the skin [2]. This sensor integrates an accelerometer, a gyroscope, and a biopotential measurement unit and can be controlled using a tablet without any additional hardware, thus supporting potential ambulatory recording.

This study aimed to establish the viability of flexible sensors for measuring human knee flexion-extension (F/E) kinematics during level walking and develop a corresponding alignment-free auto-calibrating algorithm. We hypothesized that flexible sensors could render joint angle measurement with accuracy comparable to an optical motion capture system. The effects of sensor placement and walking step frequency were also investigated.

### Methods

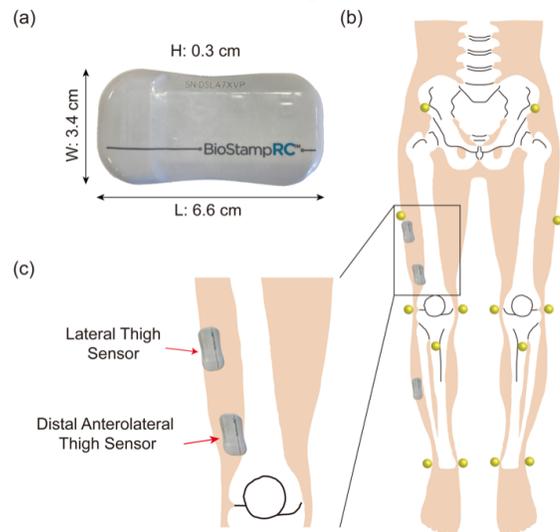

#### Algorithm

The algorithm first estimates the knee F/E axis of rotation by principal component analysis (PCA) of the gyroscopic data of segments (i.e., thigh and shank) articulating at the knee joint [3]. Then, the knee F/E angular velocity is calculated by subtracting the projection of gyroscopic data of two segments onto the knee F/E axis. Integrating the angular velocity results in knee F/E angle, which unfortunately is subject to significant drift caused by sensors random error. In order to compensate for the drift, an acceleration based sensor position estimation method [4] is employed to predict knee F/E angle of terminal stance phase. Finally, a least squares method is used to estimate the offset to be added to the integrated knee F/E, yielding the ultimate measure.

#### Experimental Test and Statistical Analysis

Three subjects were recruited and performed level walking across an eight-meter platform with varied step frequency (80, 100, 120 steps/minute). An optical motion capture system, Qualisys (Qualisys AB, Gothenburg, Sweden), was used to record the movements of a set of markers placed on subjects. The marker position data was imported to OpenSim4.0 to derive knee F/E based on individually scaled musculoskeletal models. Three BioStampRC flexible sensors (Figure 1a) were placed on ipsilateral thigh and shank—two on the thigh and one on the shank (Figure 1b&c)—so that knee F/E could be derived using data either from lateral thigh sensor and lateral shank sensor (LTS), or from distal lateral thigh sensor and lateral shank sensor

(DTS). Thus, the effect of sensor placement could be investigated. The root mean square error (RMSE) between sensor-measured and OpenSim model-derived knee F/E angle was the response variable in ANOVA. Bland-Altman analysis [5] was also employed to examine the agreement between the sensor-measured and marker-measured (OpenSim-derived).

**Figure 1:** Flexible sensors and reflective markers placement: (a) the dimensions of a BioStampRC flexible sensor; (b) front overall view of flexible sensors and reflective markers placement; (c) detailed view of flexible sensors on the thigh.

### Results and Discussion

The overall RMSE were 7.8° and 4.5° for DTS and LTS, respectively. ANOVA indicated that sensor placement had a significant effect on RMSE ( $P < 0.001$ ), while no significant effect of step frequency was detected ( $P = 0.527$ ). Bland-Altman analysis showed that the  $r^2$  of linear regression between DTS and OpenSim is 0.84, and that between LTS and OpenSim is 0.95. Results demonstrate that flexible sensors, based on the proposed algorithm, can generate comparable results to marker-based measurement, and appear insensitive to varied walking step frequency. A significant sensor placement effect is identified, and a more proximal lateral thigh strategy is recommended.

### Significance

Flexible sensors present a novel alternative to acquire human kinematics data in ambulatory or non-laboratory settings, thus extending the capabilities to conduct field biomechanical studies.

# Knee Flexion Prediction from a Neural Network Algorithm with Various Sources of Training Data

Michael Zabala<sup>1</sup>, Jordan Coker<sup>1</sup>

<sup>1</sup>Mechanical Engineering, Auburn University, Auburn, AL, US

Email: [zabalme@auburn.edu](mailto:zabalme@auburn.edu)

## Introduction

Maturation of powered exoskeleton technology would benefit various sectors including military, manufacturing, and healthcare. A key part of this maturity is increased metabolic efficiency of the operator. Most current exoskeleton systems require the operator to “bump into” the device as a means of informing it to move out of the way. However, this impediment of motion is a likely contributor to metabolic inefficiencies [1]. It is critical that the device move prior to contact. In order for this to occur, a prediction of future joint angles is required to actuate the exoskeleton with enough lead time to avoid unnecessary contact with the body. One way to do this is to utilize muscle EMG and current joint angle data in conjunction with trained machine learning algorithms, such as a neural network [2]. However, it is unknown what effect the source of training data has on the prediction error. As such, the purpose of this study was to test the hypothesis that one’s own opposite lower-limb used to train a neural network predictive algorithm would produce less error than either a sex-matched independent population or a non sex-matched independent population.

## Methods

This study collected whole body biomechanics from ten (5 F, 5 M) healthy participants ( $21.5 \pm 2.0$  yrs,  $64.5 \pm 9.8$  kg,  $166.9 \pm 14.5$  cm) during an established gait. A 10-camera Vicon motion capture system was used to capture lower limb kinematics. The marker data was filtered using a 15 Hz lowpass Butterworth filter and knee flexion angle calculated in Visual-3D software. A 6-sensor Delsys Trigno IM set was synchronized to the motion capture system and captured EMG data for the right and left tensor fasciae latae, rectus femoris, vastus medialis, vastus lateralis, biceps femoris, and semitendinosus. Knee flexion angle and EMG signals were split into three training data sets: the opposite limb of the knee being tested, a population of only males or females (whichever sex match the subject), and a general population that included all other nine test subjects. Knee flexion angle predictions for the tested knee 50 ms into the future were obtained using a nonlinear input-output time series neural network algorithm trained using Bayesian regularization with a single hidden layer of ten nodes and a feedback delay set to two. This was performed for each knee of all ten subjects. The RMS errors of the predicted angles vs motion capture determined angles were used to compare the accuracy of the neural networks. An ANOVA was conducted to compare the mean RMS errors from each of the sources of training data to determine significant differences. All subjects provided IRB-approved informed consent to be involved in this study.

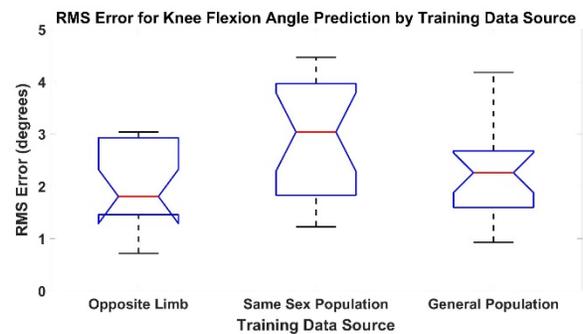

## Results

The RMS error of the predicted knee flexion angle from the three sources of training data are presented in Figure 1 and were as follows: Opposite Limb:  $1.7 \pm 0.7^\circ$ , Sex-Matched Population:  $3.3 \pm 2.4^\circ$ , and Non Sex-Matched Population:  $2.5 \pm 1.6^\circ$  (excluding statistical outliers). The results of the ANOVA analysis (Table 1) showed that there were no significant

differences in the RMS error between all three sources of training data.

**Table 1:** ANOVA results from comparing RMS Error of predicted knee flexion angle for various sources of training data.

ANOVA Table					
Source	SS	df	MS	F	Prob>F
Columns	253.28	2	126.64	1.96	0.1509
Error	3692.25	57	64.776		
Total	3945.53	59			

**Figure 1:** RMS Error for knee flexion angle predicted with data sources of the same subject (opposite limb) and independent populations (same sex, general population). Figure does not represent statistical outliers.

## Discussion

The results of the ANOVA disagreed with our hypothesis that one’s own opposite knee flexion angle used to train a neural network predictive algorithm would produce less error than either a non sex-matched independent population or a sex-matched independent population. This means that there would not be a significant gain for training on an injured persons’ healthy leg to be used on a leg with disabilities.

## Significance

The lack of significant difference in the RMS error between all three sources of training data points to a need for further exploring the implementation of the method that would be easiest to enact. In this case, the non sex-matched independent population would see the widest range of success as it would cover any healthy individual. A single, universal algorithm for all exoskeleton users would significantly expedite the acceptance of exoskeleton technology in numerous applications.

### Introduction

Though wearable movement sensors allow kinematics to be measured in natural environments, it remains challenging to evaluate kinetics outside the laboratory. Instrumented shoes and insoles can be used, but require inverse dynamic models to estimate the underlying tissue loads.<sup>1</sup> This study introduces a wearable sensor for tracking tendon loads during outdoor locomotion. We adapt shear wave tensiometry,<sup>2</sup> based on the relationship between shear wave speed and tension, to a wearable system and assess the viability of tracking fluctuations in Achilles tendon loading during walking on uneven outdoor terrain.

### Methods

The tensiometer unit consisted of a piezoelectric actuated tapper, and two miniature accelerometers mounted 8 mm apart within a silicone mold.<sup>2</sup> The actuator was impulsively driven at 100 Hz via a micro-piezo driver. A vibration data logger was used to condition and record accelerometer and timing signals. Cross-correlation analysis of the accelerometer signals after each tap was used to ascertain the wave delay between the two accelerometers,<sup>2</sup> which is then converted into wave speed. The piezo driver, data logger, an inertial measurement unit (IMU), and a battery were all mounted on a waist pack.

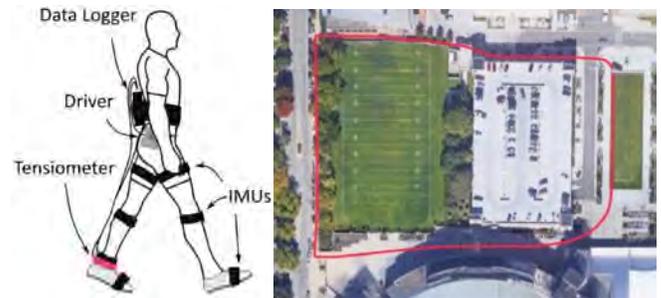

Twelve healthy young adults ( $23.8 \pm 2.3$  years, 5F/7M) were tested, of whom nine are analyzed to-date. The tensiometer unit was positioned over the right Achilles tendon (Fig. 1-left). Subjects first acclimated to the system while walking on a treadmill. Each subject then walked outdoors at a comfortable speed ( $\sim 1.5$  m/s) over a 1-km course that included level walking, inclines, and declines (Fig. 1-right). Whole-body movement reconstructed from wearable inertial sensors was synchronously recorded throughout. A thresholding technique was used to identify heel strikes from the tensiometer accelerometer signal.

To measure terrain slope, we secured an IMU on a bicycle and recorded both position (GPS) and orientation (IMU) as the bicycle was pushed over the 1-km course. This procedure resulted in a topographical look-up table, used to ascertain terrain slope for each stride of a subject by knowing their position along the course. Strides were binned into slopes ranging from -4 to +4 degrees for averaging (Fig. 2).

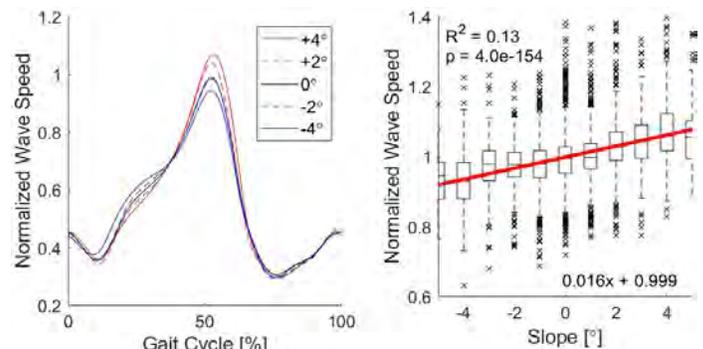

To assess sensitivity of tendon wave speed to slope, a linear regression was performed between peak wavespeed and incline angle of each stride. To further illuminate characteristic differences in loading profiles as a function of incline angle, statistical parametric mapping was used to conduct two-sample t-tests between each binned slope condition and level walking.

### Results and Discussion

Tensiometry detected characteristic changes in tendon loading with terrain slope. Notably, wave speeds increased during mid-stance on declines, and were amplified at pushoff on inclines (Fig. 2-left). Simple regression between terrain slope and peak wave speed over >5000 strides yielded a highly significant ( $p < 0.00001$ ) positive association (Fig. 2-right).

**Figure 1:** Subjects wore a fully portable version of the tensiometer as well as a lower-body set of IMUs. Aerial view of the outdoor course.

**Figure 2:** Normalized, mean Achilles tendon loading at binned inclines. A regression of peak loading against slope yielded a positive association.

Slope-dependent variations in Achilles tendon wave speed patterns concur with biomechanical expectations and are generally consistent with lab-based metrics.<sup>3</sup> However, we did observe considerable variability in the slope-wave speed relationship, which likely arises from the other factors (e.g. walking speed, acceleration, obstacles) that affect locomotion outdoors. We are now coupling tensiometry and IMUs to more fully characterize musculotendinous dynamics. Such analyses could prove useful for understanding biomechanical performance and for quantitatively evaluating overuse injury risk, e.g. in military training activities.

### Significance

This is the first study to uniquely capture identifiable tendon loading profiles during locomotion in the natural environment. Wearable tensiometry allows the study of tasks and behaviors that are not captured by traditional laboratory measures. These findings validate the motivation for developing and utilizing such tools to study locomotion beyond the lab.

# How Accurately Can Motion Capture Identify the Hip Joint Center During Deep Hip Flexion?

Naomi E. Frankston\*, Tom H. Gale, William J. Anderst

Biodynamics Laboratory, Department of Orthopedic Surgery, University of Pittsburgh, Pittsburgh, PA, USA

Email: \*nef22@pitt.edu

## Introduction

Three-dimensional motion capture using skin-mounted markers can be a tool to better understand hip pathology, such as femoroacetabular impingement (FAI), as it relates to dynamic motions. However, motion capture is limited in accuracy due to the movement of skin relative to bone, known as soft tissue artifact (1), and errors in marker placement. Dynamic biplane radiography (DBR) evaluates *in vivo* hip kinematics during dynamic tasks with an accuracy of 0.3 mm and 0.8° (2). Previous studies have evaluated the accuracy of motion capture to measure hip kinematics during gait, hip abduction, rotation, and loaded flexion by comparing motion capture with DBR and found errors up to 54 mm and 9.5° (1,3). However, previous studies did not evaluate motion capture accuracy during deep hip flexion, which is an activity that elicits hip pain in FAI patients. The aim of this study was to determine the error in locating the hip joint center using motion capture compared to DBR during deep hip flexion.

## Methods

Twelve unilateral FAI patients (9 F/3 M, 31 ± 12 years (20-57 years), 23.5 ± 4.0 kg/m<sup>2</sup>) participated in this IRB-approved study. The locations of the bilateral hip joint centers were analyzed during two trials of single-legged standing active hip flexion and two trials of single-legged standing active hip flexion combined with adduction and internal rotation. Motion capture (12-camera Vicon Vantage) and DBR data were captured simultaneously at 100 Hz and 30 Hz, respectively. For Vicon data, the hip joint landmarks were estimated in Visual3D from a Coda pelvis and based on regression equations using the ASIS and PSIS marker locations (4). For DBR, the hip joint centers were based on fitting a sphere onto the femoral head on a subject-specific 3D model generated from a CT scan of the hip. DBR and Vicon hip center locations were filtered with 4<sup>th</sup> and 2<sup>nd</sup> order Butterworth filters with 3 and 12 Hz cutoffs, respectively. The hip joint center locations from motion capture were interpolated to yield data synchronized to the DBR data. Hip joint center locations from Vicon were transformed into the DBR coordinate system. Root mean square (RMS) error was used to calculate the average difference in the medial-lateral (ML), anterior-posterior (AP), and superior-inferior (SI) positions of the hip joint centers between Vicon and DBR systems over the period of synchronized imaging. Differences between trials and sides were tested using paired samples t-tests, and repeatability of trials was assessed with Pearson's correlations.

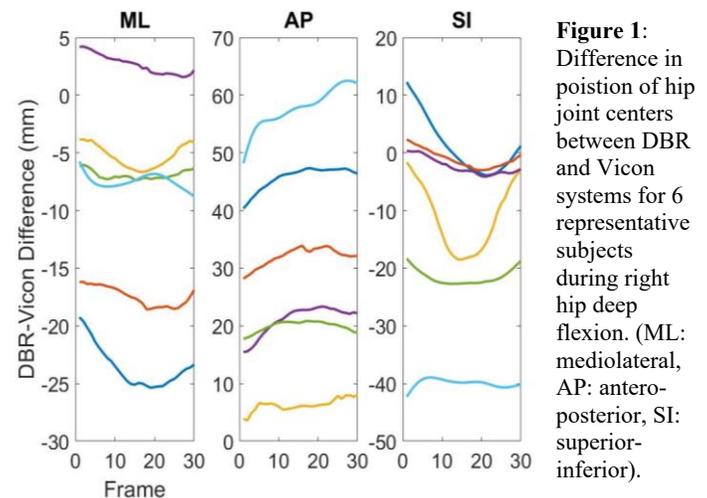

## Results and Discussion

A total of 140 movement trials were included in this analysis. Average peak hip flexion angle across all trials was of 92°. RMS errors ranged from 1 to 74 mm across subjects, trials, and anatomical directions. Our findings are similar to, but slightly larger than those reported by Fiorentino et al. (1) who found mean errors ranging from 3 to 54 mm during walking, hip abduction, and hip rotation.

RMS errors were not significantly different between the symptomatic and asymptomatic legs or between the two trials

( $p > 0.05$ ). The repeatability of error between trials of the same motion were high, with an average Pearson's correlation of  $r = 0.77$ ,  $p = 0.02$  for all trials.

Although errors were fairly repeatable within subjects for a given motion, RMS error varied between subjects and anatomical direction (Figure 1). The average RMS errors for all subjects and all trials were: ML: 11 ± 8 mm, AP: 26 ± 16 mm, SI: 17 ± 13 mm. While Fiorentino et al. analyzed skin-mounted marker and not hip center locations, our average ML-axis findings for all trials are comparable (11 mm). However, our AP and SI errors are higher than theirs (AP: 18 mm; SI: 12 mm), possibly due to the deep flexion movement we studied. RMS errors were also subject-dependent, with standard deviations of RMS errors ranging from  $\sigma = 7$  to 21 mm.

**Figure 1:** Difference in position of hip joint centers between DBR and Vicon systems for 6 representative subjects during right hip deep flexion. (ML: medial-lateral, AP: antero-posterior, SI: superior-inferior).

Researchers should be aware that the error in identifying the hip joint center during deep flexion using motion capture is, on average, a factor of 60 times greater than DBR. An important finding of this study is that this error varies among individuals from 1 mm to 74 mm, making it difficult to develop a single algorithm to correct for the errors from both marker placement and skin motion artifact associated with conventional motion capture.

## Significance

Skin-mounted motion capture systems have error as high as 74 mm in identifying the hip joint center during deep hip flexion. The magnitude and patterns of error vary considerably between subjects, making it difficult to develop a single algorithm to correct for these errors across many subjects.

## Acknowledgments

We thank Camille Johnson, Elliott Hammersley and Jessica Brown for assisting in processing the DBR data.

# The Accuracy of Machine Learning Models for Detecting Propulsion from an Inertial Measurement Unit Worn on the Arm of Manual Wheelchair Users

Brianna M. Goodwin<sup>1</sup>, Omid Jahanian<sup>1</sup>, Stefan I. Madansingh<sup>1</sup>, Beth A. Cloud-Biebl<sup>1</sup>, Kristin D. Zhao<sup>1</sup>, Shivayogi V. Hiremath<sup>2</sup>,  
Melissa M. B. Morrow<sup>1</sup>, and Emma Fortune<sup>1</sup>  
<sup>1</sup>Mayo Clinic, Rochester, MN, <sup>2</sup>Temple University, Philadelphia, PA  
Email: Goodwin.Brianna@mayo.edu

## Introduction

Manual wheelchair (MWC) users with spinal cord injuries (SCI) are four times more likely to have rotator cuff pathology and can experience unbearable shoulder pain after decades of use [1, 2]. Propulsion and upper extremity weight-bearing tasks likely contribute to the increased pain and pathology in this population.

Monitoring of free-living activity combined with activity classification algorithms has the potential to inform the frequency and duration of tasks to aid in understanding how exposure to specific tasks contributes to shoulder pathology. Machine learning (ML) techniques have been used to detect propulsion in the field using wearable-sensors on the body and MWC; however, this includes passive propulsion such as coasting and being pushed [3, 4]. To understand shoulder health in MWC users, accurate detection models are required to quantify the time the shoulder is engaged in active propulsion. The purpose of this study was to compare the performance of six ML models with three feature selection methods (total of 18 models) to detect MWC propulsion using inertial measurement unit (IMU) data collected from one upper arm of MWC users.

## Methods

After IRB approval and informed participant consent, MWC users donned two wireless IMUs (Emerald, APDM, Portland, OR) on their bilateral arms. IMU data (128 Hz) and video data (60 Hz) were synchronized and collected while participants performed six activities of daily living (counter-height reaching, overhead reaching, cross-body lifting, transfers, and level and simulated ramp propulsion on passive rollers). Video data from both arms were coded as propulsion or non-propulsion for each second by two raters; inter-rater reliability: 0.85.

114 normalized temporal and spatial features were calculated from acceleration and angular velocity data for each second for both arms. Data from both arms were used in the model independent of each other. Data were separated into training and testing sets; all data from six of eight randomly selected participants were used as training data (75%), and the data from the remaining two participants made up the testing data. Correlation-based feature selection (CFS), ReliefF (statistical method using k-nearest neighbours), and least absolute shrinkage and section operator (LASSO) were implemented as feature selection methods in MATLAB

(Mathworks, Natick, MA). The MATLAB classificationLearner and neural network pattern recognition applications were then used to create the 10-fold classification models: naïve bayes, linear support vector machine (SVM), Gaussian K-nearest neighbour, ensemble boosted tree, logistic regression, and neural network (18 models total). The accuracies of the models were compared.

## Results and Discussion

Eight MWC users with SCI (7 males, 39.4±12.6 years, 9.6±11.3 years since injury, C5-T6 injury levels) participated in the study. The highest accuracy was observed for linear SVM with LASSO feature selection (Figure 1). Selected features included spatial and temporal features calculated from the acceleration and angular velocity data. Reported accuracies were slightly higher than a previous study using a neural network model with thirteen manually selected features estimated from the same data as the current study [5]. Future work will incorporate full day free-living data to estimate total daily propulsion time.

## Significance

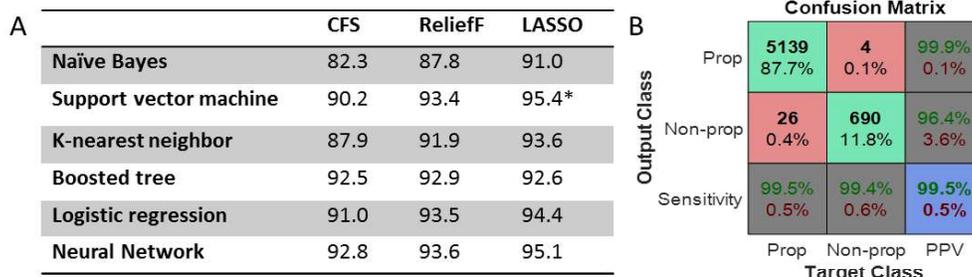

Detection of propulsion in the free-living environment can give insights into the daily exposure of motion and loading experienced by MWC users. As part of another study, authors are currently collecting free-living data alongside shoulder magnetic resonance imaging (MRI). Investigation of the association between daily propulsion time and shoulder MRI findings may lead to better understanding of how MWC propulsion contributes to increased pathology for this population. The models presented in the current study were trained with data collected in the lab and, thus, will be improved with the inclusion of free-living data.

## Acknowledgments

## Introduction

Patients with musculoskeletal disorders often have difficulty performing daily activities like rising from a chair [1]. Performance on the sit-to-stand (STS) test is influenced by leg strength and power [2], as well as joint limitations caused by musculoskeletal pain [3]. Altered body kinematics (i.e. trunk inclination) and slower transfer speed during STS are reported among patients with musculoskeletal pain [4]. Unfortunately, traditional lab-based assessment methods (3D motion capture, forceplate) are infeasible in the routine clinical setting, and test measurement with a simple stop-watch is not sufficiently accurate for diagnostic use. Alternatively, wearable technology, in particular the inertial measurement unit (IMU), has great potential to provide an accurate and sensitive assessment of body kinematics in a low-cost manner.

This study aims to use a single hip-mounted IMU sensor to evaluate the STS performance between healthy controls (HC) and patients with musculoskeletal pain (Lumbar Spinal Stenosis - LSS and Knee Osteoarthritis - KOA), and to explore the feasibility of using sensor-derived features for better disease phenotyping.

## Methods

Thirty participants were enrolled in the study with equal distribution of patients in each of the 3 groups (10 KOA, 10 LSS, and 10 HC, age and gender matched). Each participant completed the 30-second STS test wearing a Shimmer3 IMU sensor (Shimmer, Germany) on the right hip. For each trial, only the first 5 STS cycles were analyzed to ensure signal quality consistency. After IMU orientation correction, the trunk inclination angle (TA), the vertical acceleration, and the sagittal angular velocity were extracted from each STS cycle. The range of each derived measure, as well as the cycle-by-cycle variation of each derived measure (measured by the mean Euclidean distance of the signal profile between STS cycles, using the Dynamic Time Warping method—DTW) were analyzed as the primary outcome measures. The association between each primary outcome and other pertinent clinical outcome measures (i.e. 36-item Short Form health survey, SF-36 [5], etc.) were analyzed using the Pearson correlation. Group difference was analyzed using one-way ANOVA.

**Figure 1:** Scatter plot of the STS TA cycle variation (measured by the DTW mean Euclidean distance of TA profile) against the SF-36 Body Pain score (higher score indicates less daily pain reported).

## Results and Discussion

As expected, patients with musculoskeletal pain exhibited slower STS movement (longer duration per cycle, smaller vertical acceleration) than HC. An increased TA range per STS cycle was also observed ( $65.1^\circ \pm 20.1^\circ$  for LSS,  $76.2^\circ \pm 19.6^\circ$  for KOA) in comparison with HC ( $52.9^\circ \pm 17.4^\circ$ ,  $p=0.044$ ). Additionally, the cycle-by-cycle variation (DTW Euclidean distance) for TA was found to be significantly different ( $p=0.02$ ) between HC ( $771.6 \pm 343.5$ ) and patients with musculoskeletal pain (LSS:  $1678.8 \pm 868.2$ , KOA:  $1901.2 \pm 1240.9$ ). Yet the cycle-by-cycle variation for vertical acceleration and sagittal gyroscope signal did not reach statistical significance ( $p=0.08$ ) for group comparison. As shown in Figure 1, the TA cycle-by-cycle variation was also associated ( $\rho=-0.45$ ,  $p<0.01$ ) with the perceived pain while doing daily activities (SF-36 Bodily Pain). These findings suggest that the Trunk Inclination Angle as well as its cycle-by-cycle variation during STS, can potentially be used as an additional key parameter for altered mobility detection in patients with musculoskeletal pain. Further work investigating the trunk inclination dynamic to phenotype patients with different musculoskeletal pain mechanisms is underway.

## Significance

The results from this work highlight the significance of trunk inclination dynamic during sit-to-stand movement among patients with musculoskeletal pain. The range of trunk inclination and its variation among each sit-to-stand cycles were identified as key features that may be uniquely sensitive to the sit-to-stand test evaluation among musculoskeletal pain patients. These findings could facilitate further feature selection and result interpretation for sensor-based sit-to-stand evaluation in the clinical setting.

## Introduction

In recent years, wearable sensors have attracted considerable interest among the general public due to increased awareness in personal health and wellness management [1]. Technologies as such can be particularly beneficial to industries related to virtual reality, sports performance, military, and healthcare. However, most wearable sensors available today are still based on bulky, inconvenient, electronic devices. Furthermore, they are also limited to discrete sensing at designated points.

On the contrary, sensors in the form of patches are more conformable to the human body and are capable of distributed sensing. For this reason, the objective of this study is to develop a flexible, skin-like sensor capable of continuous physiological and motion monitoring. The approach was to integrate strain-sensitive nanocomposites with commercial kinesiology tape (K-Tape) as the substrate. The sensing properties of these Smart K-Tapes were characterized using a load frame and then tested on subjects performing different activities and movements.

## Methods

Wearable Smart K-Tape sensors were fabricated by integrating piezoresistive graphene-based thin films with kinesiology tape. First, graphene nanosheets (GNS) [2] were dispersed in a 2 wt.% ethyl cellulose ethanol solution by ultrasonication. Airbrushing was employed for depositing GNS-EC thin films on commercial fabric transfer, before they were ironed onto K-Tape. Electrodes based on silver paste and conductive threads were formed at opposite ends of the rectangular GNS-EC thin films. These Smart K-Tapes were then mounted in a load frame for characterizing their sensor performance and affixed onto a subject's wrist for validating human motion monitoring.

## Results and Discussion

First, Smart K-Tapes were mounted in a Test Resources 100R load frame for characterizing their strain sensing performance. Tensile cyclic strains were applied, while a digital multimeter (DMM) recorded the electrical resistance ( $R$ ) of the specimen at 2 Hz. Fig. 1 shows a representative resistance time history of a Smart K-Tape specimen, where repeatable and high signal-to-noise ratio sensing response was observed. The strain sensitivity or gage factor was calculated to be  $\sim 26$ , which is  $\sim 13$  times higher than the sensitivity of a foil-based strain gage.

Second, Smart K-Tapes (Fig. 2 left) were also mounted onto a subject's wrist. As the subject bent the wrist to different angles and back-and-forth,  $R$  of the Smart K-Tape was recorded using the DMM. Fig. 2 (right) plots the resistance time history of the sensor's response. It can be seen that changes in resistance was observed depending on different angles of the wrist, which induced different magnitudes of strain on the Smart K-Tape and its integrated GNS-EC sensing element. The repeatable nature of

the sensor signals validated sensor performance and showed promise for applications in human motion monitoring.

## Significance

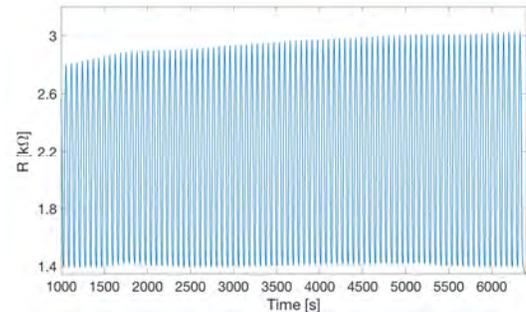

In summary, the results validated that commercially available K-Tape can be engineered with added sensing functionality. The wearable sensors exhibited high strain sensitivities, low-noise, and were highly repeatable over multiple cycles of loading. Not only can Smart K-Tape be used for human and physiological monitoring in various settings, they can also be used for assessing their efficacy from clinical/therapeutical perspectives or if they are even properly applied (or prestretched before affixing) onto the skin.

# IMU-based Kinematic Estimates for a Simplified Model of the Human Lower-limbs: Simulation and Experiment

Michael V. Potter, Stephen M. Cain, Lauro V. Ojeda, and Noel C. Perkins  
University of Michigan, Ann Arbor, USA  
Email: mvpotter@umich.edu

## Introduction

Inertial measurement units (IMUs) present an attractive solution for measuring human kinematics outside of the laboratory due to their small size, portability, low cost, and ease of use. Estimation of kinematics from IMU data requires integration of noisy sensor signals and then correcting the estimates for drift errors. We propose a method for estimating human lower limb kinematics from an array of body-worn IMUs (one on each major segment). As a first step, in this study we present this method for a simplified 3-body model (two legs connected by a pelvis) of the human lower limbs and then assess the fidelity of the estimates via simulation and experiment.

## Methods

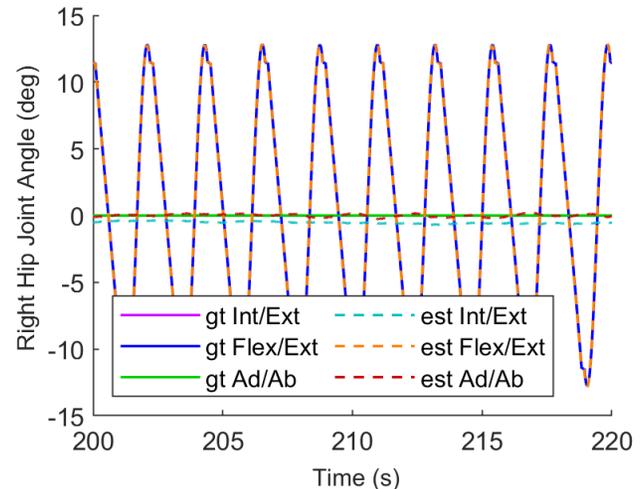

We utilize an error-state Kalman filter (ErKF) similar to [1] to estimate positions and orientations of the body segments. Kinematic constraints (i.e., joint constraints) are utilized to reduce relative drift between segments [2]. Additionally, known kinematic states (i.e., zero-velocity updates and gravitational tilt corrections) reduce drift errors between the lower-limb system and a fixed world reference frame.

We apply our method to a simplified 3-body model of the lower-limbs (two legs and pelvis) that reveals the key challenges that must be addressed to develop a full 7-body lower-limb model. We first consider noise-free IMU data as created numerically from a walking model. We then add known noise to test the fidelity of the ErKF estimates. The model, created in OpenSim [3] with attached virtual IMUs, generates noise-free IMU data for a 4-minute walk. Noise is then added (commensurate with commercially available IMUs) to generate simulated IMU data. The simulated data is input to the ErKF to yield estimates of lower-body kinematics to compare to the prescribed trajectories of the original model. Because the algorithm requires known sensor-to-segment alignments, we also use OpenSim to investigate the impact of errors in measured sensor-to-segment alignment. In addition to these simulations, we evaluate the performance of this simplified model for a human subject walking overground with stiff legs.

## Results and Discussion

Figure 1 shows a comparison of ground truth and estimated right hip joint angles for a representative 20-second sample for the walking simulations. Root-mean-square errors (RMSE) for the joint angles remain below 0.3 degrees on both hips and on all three axes. Additionally, stride parameters were accurately estimated with RMSE of 2% for stride length and 1.3% for stride width. Table 1 summarizes resulting stride width errors with prescribed misalignment between the leg and leg-mounted IMUs about the hip adduction axis. These results demonstrate significant sensitivity of stride width on sensor-to-segment misalignment. Experimental results with stiff-legged human walking also demonstrate good agreement between estimates and ground truth for stride length and stride width (mean errors of -8 cm and -5 cm, respectively). These results will likely improve

with improved measurement of sensor-to-segment alignment (as demonstrated in Table 1).

**Figure 1:** Comparison of ground truth (gt) and estimated (est) joint angles for the right hip over a representative 20-second time sample of walking simulations.

**Table 1:** Mean and standard deviation (SD) of errors in estimated stride width (SW) due to sensor-to-segment misalignment (from simulation). Misalignment is positive about hip adduction axis.

Misalignment (deg)	-10	-5	0	5	10
Mean SW error (%)	79	40	0	-40	-79
SD SW error (%)	1.0	1.0	1.2	1.0	1.5

## Significance

The results presented support extending this approach to a full lower-limb model incorporating seven segments (feet, shanks, thighs and pelvis). Doing so will provide a powerful means to estimate kinematics outside of traditional laboratory environments, thereby enabling research in broad contexts including human health, worker safety, and human performance. Importantly, the method makes no assumptions about the terrain (e.g., ground need not be level) nor is it constrained to low dynamical movement; thus, allowing the method to be used for a wide range of task analyses.

### Introduction

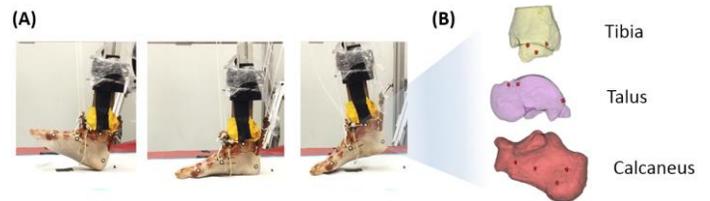

An accurate description of bone motion is essential for understanding motion-related joint pathomechanics. Our in-house, intensity-based centroid detection algorithm for marker-based tracking has been used to track isolated bones using biplane fluoroscopy [1]. However, footwear, which may contain irregular shapes and variable material density, potentially contributes to the image noise level and may influence the tracking performance. The purpose of this study was to use our in-house bead tracking software and evaluate its performance in different footwear conditions. We hypothesized that the tracking performance would be worse in shod and ankle-foot orthoses (AFO) conditions compared to barefoot, as shoes and other devices may attenuate more X-ray compared to the barefoot condition.

### Methods

One cadaveric foot specimen (male, 97 years, BMI = 25.1 kg/m<sup>2</sup>) without known ankle or foot pathology was used for this study. Extrinsic muscles were dissected and attached to nylon ropes with a Krackow suture (Figure 1A). Ten radio-opaque stainless steel beads (diameter: 3mm) were implanted in the cortices of the tibia (3 beads), talus (3 beads), and calcaneus (4 beads) (Figure 1B). The beads were secured with cyanoacrylate adhesive after implantation. A computed tomography (CT) scan of the specimen was conducted (Siemens Biograph 16, 130kV, variable current, voxel size: 0.867 x 0.867 x 0.7 mm).

A custom designed loading apparatus was used to simulate tibial progression during the stance phase of gait. The cadaveric foot was moved through our biplane fluoroscopic imaging system (Figure 1A), consisting of two modified Philips BV Pulsera C-arm fluoroscopes (Philips Medical Systems, 70-72kV, 19mA) with high-speed cameras (Phantom v5.2, Vision Research, frame rate: 500Hz, exposure time 0.0018s) [1]. One operator controlled the tibial motion and another operator applied tension through the nylon ropes to the muscles to regulate foot posture (Figure 1A). Four footwear conditions were tested; one barefoot condition and three shod conditions (control shoe or CS (New Balance 928), CS with an AFO (CS-AFO), and rocker bottom shoe (RB)). A strain gauge mounted to the floor was used to indicate when the foot was being loaded; stance phase was determined by a 10% increase in the signal range for each trial. A total of 20 trials (5 for each condition) were collected and analyzed.

The data underwent imaging distortion and flatfield correction, and 3D localization of the system was conducted [1]. Then 3D space frame-by-frame bead (marker) location reconstruction was conducted using an in-house program written in MATLAB (Mathworks, Natick MA). Pairwise intermarker distances were calculated for each bead pair in the tibia, talus, and calcaneus in different footwear conditions. A total of 12 intermarker distances were calculated over at least 885 video frames per condition. The standard deviations for each pair were used to represent the tracking performance.

**Figure 1:** (A) The loading apparatus with a four-bar linkage simulates the tibial progression angle during the stance phase of the gait cycle. Foot positions were controlled through the nylon ropes to the muscles. (B) Ten stainless steel beads implanted in the hindfoot bones.

One-way analysis of variance (ANOVA) was used to test the difference in means of the standard deviation between footwear conditions (barefoot, CS, CS-AFO, RB), with a value of  $p < 0.05$  considered significant.

### Results and Discussion

The mean of the standard deviation was 0.18 mm (range 0.10-0.33 mm) among all intermarker distances in all testing conditions. For each condition, the standard deviation of the intermarker distances [mean (minimum-maximum)] were 0.20 (0.13-0.33) mm (barefoot), 0.18 (0.13-0.28) mm (CS), 0.15 (0.11-0.22) mm (CS-AFO), and 0.18 (0.10-0.26) mm (RB). The ANOVA showed that there was no significant difference across the footwear conditions ( $p = 0.2$ ), suggesting that the marker tracking performance was not significantly influenced by the selected footwear and orthosis.

Marker-based tracking was used as the gold standard to describe bone motions in other fluoroscopic validation studies [1,2]. However, the effect of footwear on fluoroscopic imaging has not been fully considered. This study is a baseline for our later markerless bone tracking procedures. As we only tested one cadaver, one shoe model, and one AFO, the results may not be generalizable to other footwear designs or conditions.

### Significance

Any materials that potentially attenuate X-ray energy may have resulted in worsened fluoroscopic images. The design and materials used in shoes may affect the marker tracking performance. We confirmed that our in-house marker tracker did not perform differently in barefoot and shod conditions. This enables us to use marker-based tracking as the gold standard for subsequent markerless bone tracking analyses.

# Optimization Tool for the Classification of Human Movement

Kathryn Akmal<sup>1</sup>, Corey Pew<sup>1</sup>

<sup>1</sup>Department of Mechanical and Industrial Engineering, Montana State University, Bozeman, MT  
Email : \*Corey.Pew@montana.edu

## Introduction

Classification and prediction of human movement has become an important research topic in the field of biomechanics and health.<sup>1</sup> Quantitative interpretation of an individual's motions in real-time is necessary for the control of robotic prosthetics, orthotics, and exoskeletons and is useful for clinical identification of abnormal gait or adverse events such as falling.<sup>2,3</sup> Body-worn sensors are often used to collect data used to classify human movement, however, the interpretation of data varies considerably among researchers.

Two main hurdles exist when processing sensor data: 1) feature selection and 2) machine learning algorithm selection. First, when processing sensor information, features of the data (such as mean, max, standard deviation, etc.) are analyzed. In addition, these features are often analyzed over time using sliding windows, where the size and overlap of the windows can affect feature usefulness.<sup>4</sup> Second, the processed data is analyzed with machine learning techniques to relate data patterns to varying activity classifications. With a multitude of combinations between feature selection and machine learning methods the same data set can be analyzed in different ways with varying results.<sup>2,4</sup> Finally, the use of machine learning techniques requires the collection of large amounts of human subject data on which to base the algorithm. Often, the collection of human subject data requires significant investment, and the data of multiple researchers is generally incompatible. This makes it difficult to perform new research or to utilize data from others to augment a data pool.

The objective of this project was to create a stand-alone software application to enable automated processing and analysis of data from body worn sensors to accurately classify human movement. In addition, we propose the use of a standardized data format to facilitate data sharing.

## Methods

Software development utilized the MATLAB App Designer and the Statistics and Machine Learning Toolbox. The standalone application can upload a single, standardized text file that contains experimental motion data for analysis. The user then guides the application to select data groups and extracts labeled classifications contained within the file. They then choose calculated features (mean, min, max, and standard deviation) that are generated by the application. Calculated features are determined over a time window length and overlap that is optimized as part of the process. The user initially indicates a minimum and maximum time window range and overlap over which the application will analyze the data as well as specified machine learning algorithms they would like to consider. The application then iteratively compares the various combinations of features, time window size, window overlap, and algorithm type to find a setup that produces the highest classification accuracy. Accuracy is calculated using either

**Table 1:** Comparison of classification accuracy results. **Bold** shows new method had higher accuracy than previous results.

Subject	SVM		KNN		Ensemble	
	Original	New	Original	New	Original	New
A01	96.2	95.0	96.5	<b>99.7</b>	96.2	<b>99.6</b>
A02	95.2	88.2	94.9	<b>99.5</b>	94.8	<b>99.5</b>
A03	90.7	<b>94.0</b>	90.4	<b>98.6</b>	90.3	<b>93.4</b>
A04	92.7	<b>94.2</b>	92.6	<b>99.1</b>	92.1	<b>99.0</b>
A05	93.0	<b>93.9</b>	94.4	<b>99.3</b>	93.8	<b>99.1</b>
Pooled	90.5	<b>93.7</b>	91.2	<b>98.9</b>	90.5	<b>98.8</b>

five-fold cross validation or testing on a percentage of holdout data determined randomly by the application.

Initial testing of the application utilized pre-existing data used to classify turning in lower limb amputees.<sup>2</sup> In the previous study we looked at data from five amputee subjects (both individually and pooled) and classified whether they were turning or walking straight using data from a single inertial measurement unit simulated using motion capture data. The initial testing compared the efficacy of using support vector machine (SVM), K-nearest neighbor (KNN), and decision tree ensemble (Ensemble) algorithms on the classification accuracy and so we limited the scope of this analysis to those three methods.

## Results and Discussion

Results from the previous study compared to the updated analysis are shown in **Table 1**. We found that the new application was able to attain higher classification accuracies (as measured by percentage of correctly predicted data points) than our original analysis for 16 of the 18 conditions. In our original work we also concluded that pooling data resulted in lowered classification accuracy, however, this new method contradicts that with accuracies near 99% for two of the three classifiers using pooled data. The original study made adjustments and accuracy comparisons manually, requiring weeks of work. Our new method ran in 80 minutes for the entire analysis. These results indicate that higher classification accuracies are attainable in far less time using this automated method as compared to manual analysis.

## Significance

This work highlights that reported classification outcomes using machine learning to predict human motion from body worn sensors are highly variable depending on the method of analysis. The development of a standardized method to organize and optimize these analyses is greatly needed. This application will provide a standard analysis, and future work will expand the application's functionality and optimization.

## Pennation Angle Changes During Successive Loading Cycles

Josiah D. Mercer.<sup>1</sup> and Benjamin W. Infantolino<sup>1\*</sup>  
<sup>1</sup>Kinesiology Department, The Pennsylvania State University - Berks  
Email: \*bwi100@psu.edu

### Introduction

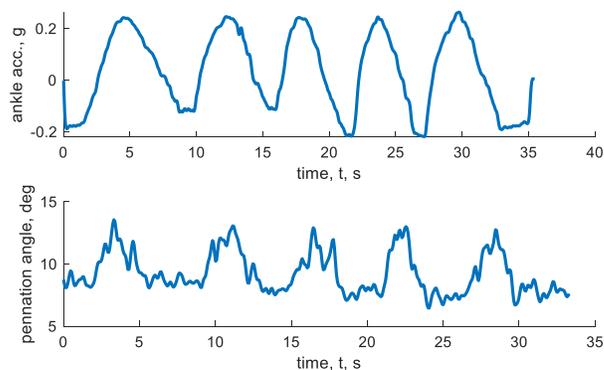

Measuring pennation angle changes during muscle contraction has become relatively common and with a number of automated programs being offered for this purpose these types of measures are only getting more common. Antedoteally, in some instances we (and others) have seen what appears to be pennation angle changes throughout time during a cyclical loading protocol. In these instances, the maximum pennation angle during a contraction cycle is larger than the maximum from the previous cycle. Repeated contractions are standard in lifting activities and therefore investigation of this phenomenon is warranted to first see if it actually exists and then if it does to determine what, if any, functional significance it may have.

In the past, pennation angle has been assumed to change in a fixed relationship with joint angle changes. However, recent literature suggests pennation angle change is also dependent on velocity of contraction [1]. This provides some evidence that pennation angle is dependent on more than just joint angle and therefore could change with successive contraction cycles. The purpose of this study was to describe these anomalies previously seen in research.

### Methods

Five subjects (2 Female, 3 Male,  $21 \pm 1$  years,  $171.7 \pm 8.0$  cm,  $80 \pm 21$ kg) were enrolled in this study. Subjects were asked to plantarflex and dorsiflex through a full range of motion for five cycles while maintaining muscle tension throughout. Subjects maintained a rate of approximately 0.5 Hz while moving through the range of motion. During contractions, ultrasound was used to record the pennation angle of the anterior tibialis and an accelerometer was placed on the dorsum of the foot to verify that the range of motion was consistent throughout all five cycles. Subjects completed three trials each. However, not all trials could be analysed due to ultrasound image quality.

Ultrasound data was processed using a semi-automated custom written Matlab program which identified all fascicle-like objects and then measured the pennation angle for each object. An average pennation angle for each frame of the video was recorded for further analysis. Both accelerometer and pennation angle data were filtered with a first order Butterworth filter with a 2Hz cut-off. The five peaks corresponding to the acceleration vs. time and pennation angle vs. time graphs were selected and a linear regression was used to determine if either peak vs. time regression slope differed from zero.

**Figure 1:** Representative graphs of ankle acceleration vs. time and pennation vs. time graphs for a subject who exhibited a change in pennation angle over time but not in range of motion.

### Results and Discussion

Out of a total of 11 trials, two trials showed no difference in ankle angle over time but showed a difference in pennation angle over time. One showed a difference in both ankle and pennation angle over time and one showed a difference in ankle angle but not pennation angle. The rest of the trials showed no difference in either ankle or pennation angle. While many of these results agree with our previous understanding of how muscle behaves throughout a range of motion, a couple trials do seem to suggest something else maybe occurring. Changing cut-off frequency did not change the results, which seems to indicate that the results are not due to an artifact introduced during processing the data.

Some trials showed that pennation angle changed with successive loading cycles even though range of motion did not. This is an important phenomena as so many of our movements involve cyclical loading of our muscles.

### Significance

Pennation angle changes during cyclical loading could indicate that the muscle is adjusting to the loading condition with each successive cycle. If this is the case, the mechanism responsible for this adjustment needs to be identified. If this adjustment is advantageous for the muscle(s) completing the task, do all individuals exhibit this adjustment? Additionally, which aspect of muscle contraction is now more advantageous with the adjustment?

# Coordinate Projection vs Unscented Filtering for IMU-based Motion Measurement

Benjamin J. Fregly<sup>1</sup>

<sup>1</sup>Department of Mechanical Engineering, Rice University, Houston, TX

Email: [fregly@rice.edu](mailto:fregly@rice.edu)

## Introduction

Inertial measurement units (IMUs) are a promising technology for measuring human movement easily and with low cost outside the laboratory. IMUs measure angular velocity and linear acceleration including gravity. IMU-based motion measurement algorithms integrate angular velocity once and gravity-corrected linear acceleration twice to estimate IMU orientation, position, and velocity. This information is then used in some form of a Kalman filter algorithm to estimate joint kinematics in a human body model [1]. The problem with this approach is that noisy IMU measurements amplify numerical integration drift, resulting in violation of kinematic model joint constraints and ultimately inaccurate estimates of model state.

Thus study compares a traditional unscented Kalman filter approach with a novel coordinate projection approach for estimating kinematic model state from noisy IMU measurements. Coordinate projection [2] is a numerical method that maintains joint constraints in a multibody dynamic simulation utilizing absolute coordinates [3], where each rigid body is simulated independently, similar to IMUs. To reduce numerical integration drift further, this study also explores the use of implicit multi-step numerical integration schemes in place of the more common explicit single-step Euler method.

## Methods

A planar six degree-of-freedom kinematic model of the pelvis, thigh, shank, and foot was developed in MotionGenesis to evaluate the two state estimation approaches. The pelvis was connected to ground by a planar joint, and the hip, knee, and ankle were modeled as pin joints. One IMU was attached to each model segment. Experimental gait kinematics were input into the model to generate 100 Hz synthetic IMU measurements corrupted with white noise representative of actual IMUs.

Implicit multi-step integrators of orders 1 through 3 were used to integrate the noisy synthetic IMU measurements. Implicit integration used measured IMU quantities from the current time frame to find integrated IMU quantities for the same time frame, allowing estimation of kinematic model joint accelerations as well as velocities and positions. IMU angular acceleration was estimated by backward finite differencing.

Following each numerical integration time step, either an unscented Kalman filter or coordinate projection approach was used to estimate kinematic model state. The unscented filter used integrated IMU orientations, positions, and velocities, measured IMU angular velocities and gravity-contaminated accelerations, and differentiated IMU angular accelerations as measurements for estimating kinematic model state. Coordinate projection used the pseudoinverse to find minimum changes to measured, integrated, and differentiated IMU quantities that satisfied linearized position and linear velocity and acceleration joint constraint equations. Kinematic model state was back-calculated analytically from corrected IMU kinematics. For both approaches, one minute of walking (60 gait cycles) was simulated in Matlab (The MathWorks, Natick, MA), and root-mean-square state errors were calculated for the final gait cycle.

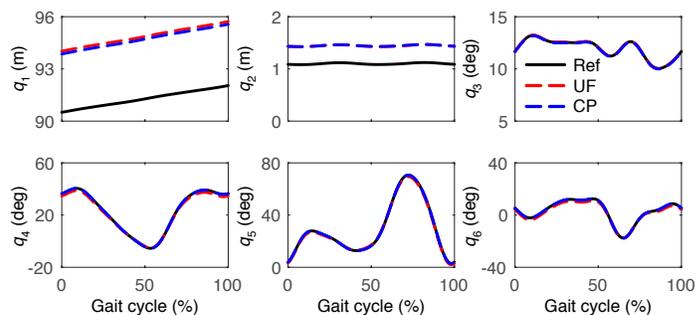

## Results and Discussion

Overall, coordinate projection produced more accurate and robust state estimates than did unscented filtering, with accuracy increasing as the order of the implicit integrator was increased (Table 1). Increasing integrator order to 4 did not improve state estimates further. With the 3<sup>rd</sup> order integrator, both methods produced excellent estimates of not only joint positions (Fig 1 apart from translations) but also joint velocities and accelerations, potentially supporting inverse dynamics analyses.

Compared to unscented filtering, coordinate projection has several advantages. It is faster computationally (25x faster here), requires no tuning of noise variance or other parameters, is more robust to errors produced by low-order integrators, and allows direct calculation of kinematic model state. However, both approaches still require additional measurements to attenuate significant integration drift in joint translations.

**Table 1:** RMS errors in joint positions for final gait cycle from unscented filter (UF) and coordinate projection (CP) using 1<sup>st</sup> through 3<sup>rd</sup> order implicit integrators. Dashes indicate “large” errors.

Solution Method	Integrator Order	q1 (m)	q2 (m)	q3 (°)	q4 (°)	q5 (°)	q6 (°)
UF	1 <sup>st</sup>	---	---	---	---	---	---
	2 <sup>nd</sup>	6.96	2.48	1.47	---	---	---
	3 <sup>rd</sup>	3.59	0.34	0.01	1.26	0.81	1.24
CP	1 <sup>st</sup>	---	1.92	4.13	1.22	---	---
	2 <sup>nd</sup>	3.52	4.83	0.06	0.03	0.18	0.16
	3 <sup>rd</sup>	3.44	0.35	0.04	0.01	0.04	0.08

**Fig. 1:** Joint positions for final gait cycle estimated by unscented filter (UF) and coordinate projection (CP).

## Significance

The novel combination of implicit multi-step integration and coordinate projection may improve IMU-based human motion measurement for real-time applications outside the laboratory such as telerehabilitation and remote patient monitoring. The approach does not require magnetometer data to obtain accurate estimates of joint rotations.

## Preliminary Assessment of Shoulder Activity after Rotator Cuff Repair

Matthew C. Ruder<sup>1</sup>, Rebekah L. Lawrence<sup>1</sup>, Roger Zauel<sup>1</sup>, and Michael J. Bey<sup>1</sup>

<sup>1</sup>Bone and Joint Center, Henry Ford Health System, Detroit, MI

Email: mruder1@hfhs.org

### Introduction

Rotator cuff tears affect about 40% of the population over age 60, with about 250,000 rotator cuff surgeries performed annually [1]. Unfortunately, repair tissue healing after surgery is a major clinical problem, with 42-78% of re-tears occurring within 12 weeks after surgery [2-4]. Risk of repair failure is associated with increasing patient age, tear size, and fatty degeneration, but these factors do not fully explain the high incidence of failure. Another factor that likely influences healing is loading of the repair tissues that occurs during post-operative rehabilitation, but physical therapy accounts for only a small portion of a patient's post-operative life. Moreover, even with the shoulder protected in a sling, activities of daily living (e.g., dressing, self-care, walking) likely results in subtle shoulder motion which may compromise repair tissue healing. However, the extent to which post-operative shoulder activity influences repair tissue healing is unknown. As an initial step toward understanding the relationship between shoulder activity and repair tissue healing, the purpose of this study was to determine if differences in shoulder activity could be detected between rotator cuff repair patients and control subjects using a wearable sensor. We hypothesized that control subjects would have greater shoulder activity than rotator cuff repair patients.

### Methods

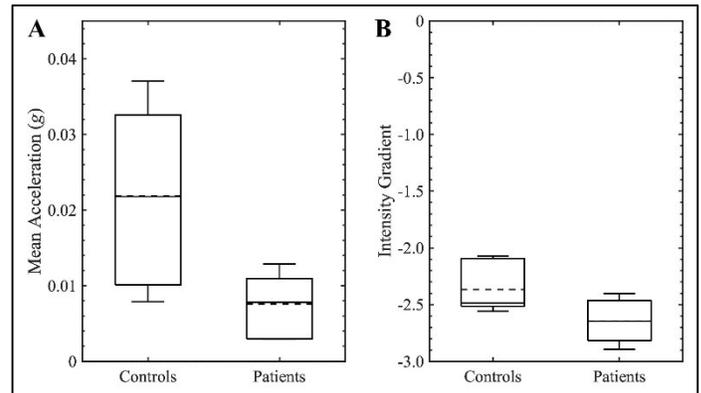

Following IRB approval, six patients who had undergone rotator cuff repair (age: 56.2±9.0) and six asymptomatic control subjects (age: 61.3±9.4) were recruited. Each participant wore a wrist-based activity sensor (3-axis accelerometer) that collected data at 10 Hz (GENEActiv Original, Activinsights). Patients wore the sensor on their affected side for 1 week within the first 3 months after surgery, while control participants wore the sensor on their dominant wrist for 1 week. Participants wore the activity sensor except when sleeping, bathing, or swimming.

To quantify shoulder activity, the acceleration data were calibrated to 1 g (i.e., acceleration due to gravity) [5] and the acceleration magnitude was calculated as the Euclidean norm of the acceleration signals minus one g. Next, the volume of activity was estimated by calculating the mean acceleration [6]. To estimate the intensity of activity, we calculated the intensity gradient, defined as the slope of the regression line relating the natural log (ln) of acceleration frequency to the ln of acceleration magnitude in 10 milli-g bins [6]. A shallower (less negative) slope of this regression line indicates more high intensity activities, whereas a steeper (more negative) slope indicates fewer high intensity activities. Differences in mean acceleration and intensity gradient between rotator cuff repair and control groups were assessed using a *t*-test. The magnitude of potential differences were also assessed using effect sizes and 95% confidence intervals [7]. Significance was set at  $p \leq 0.05$ .

### Results and Discussion

The difference in activity volume between control subjects ( $0.022 \pm 0.012$  g) and rotator cuff repair patients ( $0.008 \pm 0.004$  g) was statistically significant (Fig. 1A,  $p=0.03$ , effect size=1.50,

95% CI: 0.15, 2.84). Similarly, the difference in intensity gradient between controls ( $-2.37 \pm 0.22$ ) and rotator cuff repair patients ( $-2.64 \pm 0.20$ ) was statistically significant (Fig. 1B,  $p=0.05$ , effect size=1.19, 95% CI: -0.09, 2.48).

**Fig. 1:** Control subjects had greater volume ( $p=0.03$ , A) and intensity ( $p=0.05$ , B) of activity than rotator cuff repair patients.

These findings are encouraging and provide preliminary evidence that differences in activity levels between rotator cuff repair patients and control subjects can be detected using a commercially available wearable sensor. We anticipate that the experimental approach described here will also demonstrate that the volume and intensity of patients' activity will increase over time after surgical repair. However, the six patients whose data are reported here were recruited at various stages after surgery (1 week, 6 weeks, and 12 weeks post-surgery), and therefore this limited sample of patients prevents a rigorous analysis of changes in activity levels over time.

Future efforts will build upon this preliminary work by refining the data processing protocol and recruiting additional patients and control subjects. We expect these efforts will provide objective evidence regarding the role of post-operative shoulder activity on repair tissue healing and clinical outcomes. Understanding the role of shoulder activity on repair tissue healing will decrease the prevalence of failed repairs, improve clinical outcomes, and decrease medical costs associated with this common and debilitating condition.

### Significance

This preliminary study is significant, because it provides initial insight into shoulder activity levels in patients during the critical 3-month healing period after rotator cuff repair.

## Comparison of Dynamic Stability Measures Based on Planar Torque Versus Ground Reaction Force

<sup>3</sup>Western Washington University, Bellingham, WA, <sup>4</sup>University of Montana, Missoula, MT

Email: [kurt.otto.buchholz@gmail.com](mailto:kurt.otto.buchholz@gmail.com)

### Introduction

Dynamic stability assessment is used to quantify the quality of postural control from a dynamic task to a static posture. Traditional stability measures determine a time to signal stability using the ground reaction force (GRF) only [1,2]. This approach introduces limitations during interpretation, including inferences about the control of the center of mass (COM), the ability to assess simultaneously beyond a single axis, and the potential for the task used to inappropriately influence the measure.

While the GRF fluctuations analyzed in these measures are created by movement of the COM above the base of support, stability measures using the GRF alone can only make inferences about the control of COM motion. Stability assessments could be improved by including the position of the COM in the calculation to better quantify control. Furthermore, incorporating multiple components into the assessment can strengthen observed control mechanisms beyond analysis along a single axis [3]. Finally, varying protocols introduce the possibility that the task influenced the resulting stability measure; a higher landing velocity (LV) may artificially produce higher scores, implying worse dynamic postural control.

Based on this reasoning, the purpose of this study was to develop a dynamic stability measure based on the torque about the COM in the sagittal ( $T_S$ ) and frontal ( $T_F$ ) planes during a dynamic task. To validate this torque measure being purely kinetic in nature, kinetic and kinematic estimates of the COM position were compared. Kinetically-derived torque measures were also compared with traditional GRF-based measures. Finally, LV was analyzed for its effect on all measures.

### Methods

Sixteen healthy participants [ $24 \pm 3$  years,  $1.71 \pm 0.09$  m,  $74.5 \pm 14.4$  kg] performed five, 70 cm hops while barefoot over a 15 cm hurdle. After landing on their dominant leg only, they stabilized for 20 seconds. Landing kinetics were collected using a force plate (AMTI, Watertown, MA) and kinematics of the pelvis COM were collected using motion capture (Vicon, Englewood, CO). The COM position was calculated using GRF by double-integration of the acceleration component of the GRF [4].

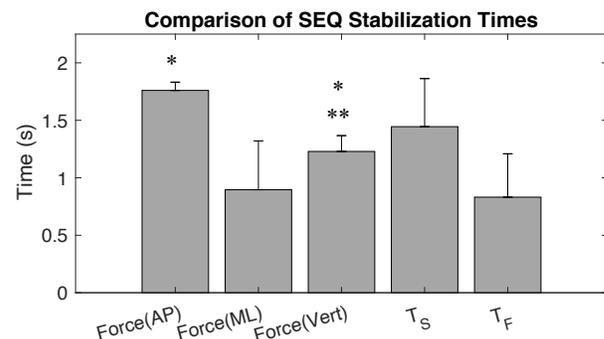

Using the kinetic-derived COM position,  $T_S$  and  $T_F$  were calculated for the 20 second period after landing. To determine the time to stability of the planar torque values, the same determination methods used in sequential estimation (SEQ) [1] and Time to Stabilization (TTS) [2] were applied. For comparison, SEQ and TTS were calculated for the anteroposterior (AP), mediolateral (ML) and vertical (Vert) components of the GRF according to the literature [1,2].

To establish similarity of COM position between the kinetic and kinematic estimates, a correlation was used. SEQ and TTS stabilization times from forces (AP, ML, Vert) and torques ( $T_S$  and  $T_F$ ) were compared using ANOVAs.  $T_S$  stabilization time was compared to AP and Vert force times, while  $T_F$  time was

compared to ML and Vert force times. Finally, LV of the participant was assessed for correlation with all stability measures for potential similarity.

### Results and Discussion

Moderate to strong correlations ( $r_{AP} = 0.89$ ;  $r_{ML} = 0.60$ ;  $r_{Vert} = 0.82$ ) were observed between kinetic and kinematic COM positions. Thus, kinetic estimates of COM position were appropriate for use in the torque calculation.

**Figure 1:** Comparison of all stability times calculated using SEQ methods [1]. Significant differences are noted for GRF stability times from  $T_S$  (\*) or  $T_F$  (\*\*) stabilization time.

Using SEQ, stabilization time of  $T_S$  was different from both AP and vertical axis force stabilization times (Fig. 1).  $T_F$  stabilization time was different from the time calculated using force along the vertical axis, but not the ML axis. Overall, this indicates using SEQ to calculate the amount of time to stability produces significantly different results with the additional benefit of including the COM position in the calculation of stabilization time. Comparison of force and torque stability times using TTS showed no significant differences.

Finally, LV correlated with the stabilization times of TTS ( $r = 0.59$ ), SEQ ( $r = 0.85$ ), and  $T_F$  ( $r = -0.58$ ), but not with  $T_S$  ( $r = 0.02$ ). For  $T_S$ , no correlation with LV indicates the stability time provides a measure of stability in the primary plane of motion that is independent from the LV associated with the task.

### Significance

This torque-based calculation of stabilization time provides a more complex analysis of dynamic stability, as GRF values are used in tandem with COM motion in the calculation. This measure is also independent from the LV in the primary plane of motion. Removing the effect of LV in this plane allows for postural control analysis with reduced protocol-based influences.

# Knee Joint Acoustic Signatures in Healthy Collegiate Athletes: Sex Differences

Caitlin N. Teague<sup>1</sup> and Omer T. Inan<sup>1,2</sup>

<sup>1</sup>School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, GA 30308

<sup>2</sup>Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA 30308

## Introduction

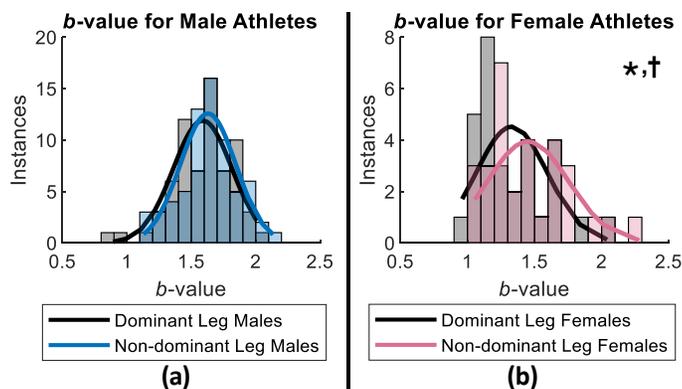

Evaluation of knee joint sounds may provide a non-invasive and quantitative method for determining joint health, which could be leveraged as a metric (e.g., “joint score”) for tracking progress during rehabilitation following an acute injury or deciding on readiness for return-to-play, for example. Knee injury risk and prevalence in females has been well-studied. Given associated risk factors include biomechanical and anatomical factors, it is imperative that possible male-female differences are studied in the emerging field of non-invasive biomarkers of knee health, including those markers derived from joint sounds.

## Methods

The data acquisition protocol is described in [1]. For this work, we analyzed the joint sounds measured from electret microphones placed at the lateral and medial sides of the patella for five seated, unloaded flexion / extension cycles in 49 (N = 15 female) healthy collegiate athletes (male: 28 American football, 6 basketball; female: 7 volleyball, 8 basketball). “Clicks” in the acoustic signal were identified by [1] and used to calculate  $b$ -value according to the equations in [2]. In total, 196  $b$ -values (instances) were found: 49 subjects by two legs (self-reported dominant vs non-dominant leg) at two locations (lateral or medial). A linear mixed effects model was used with sex and leg dominance (LD) treated as fixed effects, subject as a random effect, and microphone location as a covariate (r-project.org). When significant main effects were returned, *a priori* ( $\alpha = 0.05$ ) planned comparisons were completed between (1) sexes at each level of LD and (2) LD at each level of sex using pairwise post-hoc comparisons from the emmeans package in R. These comparisons were repeated for a subset of the data, examining men and women basketball (BB) players (N = 15, 8 females) to complete a direct sport-matched comparison.

## Results and Discussion

For  $b$ -value (Fig. 1), the main effects of sex (collapsed across LD,  $p = 0.09$ ) and LD (collapsed across sex,  $p = 0.74$ ) were not significant. However, the sex by LD interaction was significant ( $p = 0.01$ ). Pairwise comparisons revealed that dominant leg (DL)  $b$ -values were significantly lower ( $p < 0.0001$ ) in females ( $1.14 \pm 0.23$ ) compared to males ( $1.44 \pm 0.31$ ), while non-dominant leg (NL)  $b$ -values were not different (male =  $1.43 \pm 0.25$ , female =  $1.31 \pm 0.37$ ,  $p = 0.10$ ). Furthermore, females had a lower  $b$ -value for the DL compared to NL (by  $0.17 \pm 0.35$ ,  $p = 0.007$ ), but men did not ( $-0.014 \pm 0.24$ ,  $p = 0.75$ ). Similarly, for the BB player analysis, the main effects of sex (collapsed across LD,  $p = 0.20$ ) and LD (collapsed across sex,  $p = 0.48$ ) were not significant, though the sex by LD interaction was significant ( $p = 0.02$ ). Pairwise comparisons of  $b$ -values between men ( $1.34 \pm 0.19$ ) and women ( $1.15 \pm 0.24$ ) BB players’ DLs did not show a significant difference ( $p = 0.08$ ), and the NL  $b$ -values were not significant (men =  $1.26 \pm 0.22$ , women =  $1.39 \pm 0.37$ ,  $p = 0.23$ ) as well. Further, women’s BB players exhibited smaller  $b$ -values for the DL compared to NL (by  $0.25 \pm 0.40$ ,  $p = 0.01$ ), while men’s BB players were not significantly different ( $0.07 \pm 0.16$ ,  $p = 0.50$ ).

**Figure 1:**  $b$ -value for male (a) and female (b) athletes. A significant difference ( $*p < 0.01$ ) was observed between the females’ dominant and non-dominant leg. Further, a significant difference ( $\dagger p < 0.0001$ ) was observed between male and female athletes’ dominant legs.

Previous studies suggest that a lower  $b$ -value is associated with a more “unhealthy” knee when comparing within-subject, within-knee measurements for, perhaps importantly, exclusively (or nearly so) male knees [2, 3]. However, it is unclear from these studies if a one-time, singular  $b$ -value measurement is sufficient to determine joint health—or injury risk—on its own. At this time, we speculate the lower DL  $b$ -value exhibited in females—specifically those participating in sports involving repetitive jumping—may be, in part, attributed to a larger maximum knee valgus angle during drop vertical jump tasks in females’ dominant knee [4]. Notably, models of valgus misalignments show increases in joint contact forces and overall larger and more sustained forces during walking and stair climbing [5], and this larger valgus angle / loading has been associated with increased anterior cruciate ligament (ACL) strain (*in vitro*) [6] and patellofemoral pain as studied in female subjects [7] as well as a potential predictive measure for ACL injury [8].

## Significance

Differences in male and female joint sounds were observed as well as female side-to-side differences, supporting existing knee injury literature. Future work (e.g., powering studies, developing joint score algorithms, etc.) should consider sex disparities.

## Introduction

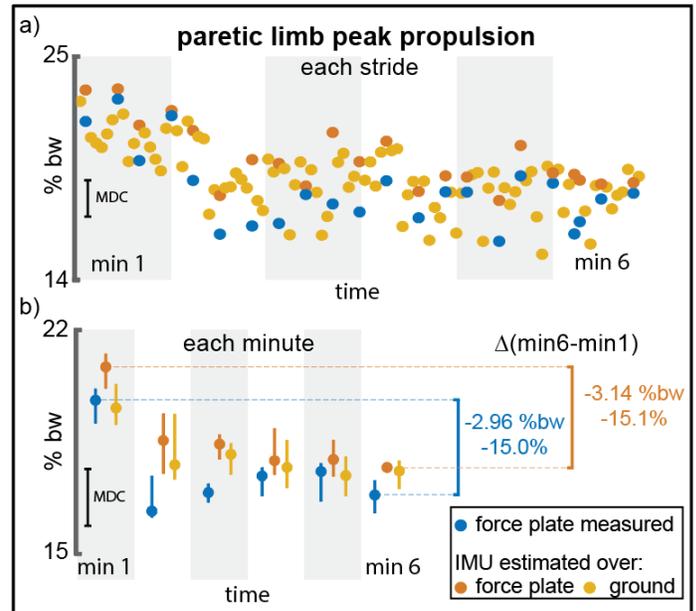

The 6-minute walk test (6MWT) is commonly used across clinical diagnostic groups to measure functional walking capacity<sup>1,2</sup>. The total distance walked<sup>1,2</sup> and the distance-induced change in walking speed<sup>2</sup> measured during the 6MWT are strong indicators of real world walking activity. Although demonstrably valuable, distance-based measurements (e.g., across 6 minutes or per minute) do not account for differences in gait quality that may underlie the impaired performance observed in heterogeneous populations, such as people post-stroke. Indeed, as a timed walk test, the ability to both achieve and sustain a fast walking speed underlies 6MWT performance. Given the relationship between propulsion function and short- and long-distance walking speed<sup>3</sup>, we posit that measurements of propulsion function during the 6MWT may provide crucial diagnostic data that are currently lacking in the distance-based measurements traditionally extracted from the 6MWT, and that can inform targeted gait therapies. In this study, we present the use of a minimal set of wearable inertial measurement units (IMUs) to provide indirect estimates of propulsion function during the 6MWT.

## Methods

Seven individuals with chronic post-stroke hemiparesis completed a 6-minute walk test over a 26.6m walking track instrumented with six forceplates while wearing three IMUs securely attached to the pelvis, thigh, and shank. The forceplates provided direct measurements of the anterior-posterior ground reaction force (AP-GRF) generated during steps with a forceplate strike. In addition, subject-specific models driven by IMU-measured thigh and shank angles and an estimate of body acceleration provided by the pelvis IMU were used to provide indirect measurements of the AP-GRF generated every step<sup>4</sup>. Peak propulsion point metrics were extracted from the direct and indirect estimates of the anterior portion of the AP-GRF and compared. Moreover, the distance walked per minute of the 6MWT was measured using a measuring wheel. Study participants were dichotomized into endurant and non-endurant subgroups, with non-endurant individuals being those who slow down by more than 0.10 m/s between min 1 and min 6<sup>1</sup>. Peak propulsion medians and 95% confidence intervals are reported.

## Results and Discussion

In previous work, we showed that indirect measurements of the AP-GRF time series strongly approximated the direct measurements made by forceplates, with low error and high consistency<sup>4</sup>. The average error between indirect and direct measurements of the peak propulsion magnitude (% bodyweight, %bw) was less than 1.2 %bw—which is lower than the Minimal Detectable Change (MDC) of 1.8%bw<sup>4</sup>. In the present study, four out of seven participants were classified as endurant and the other three were non-endurant. The non-endurant subgroup presented with comparable reductions in speed (-14% [-11%, -16%]) and peak paretic propulsion (-16% [-14%, -38%]) (Ps < 0.05). In contrast, the endurant subgroup did not markedly change speed (0% [-16%, 9%]) or peak paretic propulsion (2% [-8%, 8%]).

**Figure 1:** Change in peak paretic propulsion measured by forceplates and estimated by IMUs during the 6-minute walk test for one exemplar, non-endurant participant on a (a) step by step basis and (b) minute by minute basis. \*Minimal Detectable Change (MDC) = 1.8 %bw.

## Significance

Wearable inertial sensors offer a feasible solution to provide clinically-accessible assessments of propulsion function during the 6MWT. We show that individuals post-stroke who reduce their speed over the duration of the 6MWT (i.e., non-endurant individuals) also present with a reduction in paretic limb propulsion (Figure 1). In contrast, individuals who do not reduce their speed (i.e., endurant individuals) do not reduce paretic limb propulsion. This wearable sensor technology has potential to enable clinicians to co-assess changes in propulsion quality with distance-based performance outcomes that are traditionally evaluated, and may thus provide treatment-shaping diagnostic information not currently available in most clinical settings.

**Introduction**

Deviations in motion control of the whole body center of mass (COM) during walking could imply motor deficits or balance impairments. Moreover, COM acceleration is reported to better differentiate balance control ability in different populations<sup>1</sup>. However, whole-body COM is traditionally calculated with a whole-body reflective marker set and camera-based motion analysis system, which significantly restricts to laboratory settings. Recent advances in wearable motion sensor technologies offer an opportunity to translate laboratory findings to the clinical environment with similar gait balance measures. Inertial measurement units (IMU) combine accelerometers, gyroscopes, and magnetometers into a single sensor and could be used to estimate COM acceleration. The use of wearable sensors to detect mobility impairments has grown rapidly<sup>2,3</sup> and providing a time-efficient and user-friendly measurement of gait and balance performance. The IMU is placed at a fixed body landmark, such as the 5th lumbar vertebra (L5), as a proxy location of COM. However, such a fixed landmark location does not account for any instantaneous changes in body segment alignment that could result in the relocation of whole-body COM. Although kinematic measures derived from both methods have been successfully used to detect gait imbalance, only limited data are available in the literature for comparison of COM accelerations estimated between the conventional motion capture system and wearable sensor technology. The purpose of this study was to demonstrate and compare patterns of COM acceleration during walking estimated using a wearable sensor and a conventional motion capture approach.

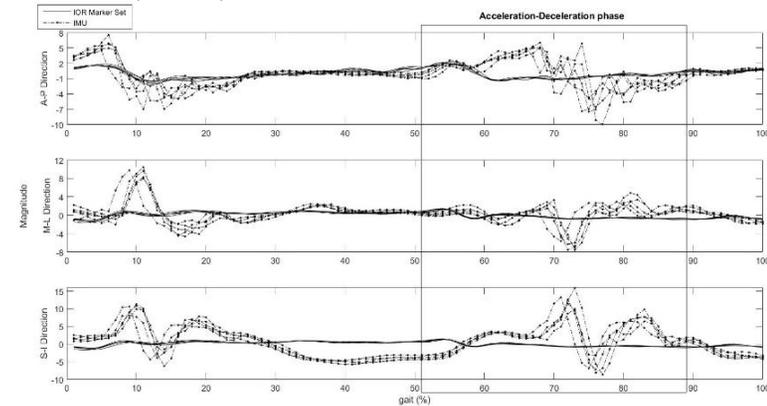

**Methods**

A total of 11 healthy participants (age:  $29.5 \pm 13.3$  years, BMI:  $22.8 \pm 4.8$  kg/m<sup>2</sup>) were recruited so far. Experimental setup for the conventional motion capture system included 12 Oqus infrared cameras (Qualisys AB, Sweden) and forty-nine retroreflective markers placed according to the marker setup<sup>4</sup>. In addition, a single IMU (OPAL, APDM, Portland, OR, USA) was placed at the L5, as the proxy location of COM. Marker trajectory and IMU data of each participant were collected from 10 level walking trials. The whole-body COM position was calculated as the weighted sum of body segments and anthropometric reference data were adopted from the work of Fujimoto<sup>1</sup>. COM acceleration were calculated from the second derivatives of COM positions. For IMU acceleration data, the initial contact (IC) of the gait cycle was determined by transforming the raw acceleration curve to the Gaussian continuous wavelet and identify the maximal value as the point of the start of IC<sup>5</sup>. Data analysis was focused at the time period between 50 and 80% of gait cycle. The 95% confidence intervals for the time when peak accelerations occurred and range of magnitude changes were reported for both approaches.

**Results and Discussion**

Acceleration data in all three anatomical directions obtained from both methods demonstrated a similar overall pattern. However, distinct differences in acceleration magnitudes exist, especially at

the time between heel-strike and mid-stance (Figure 1). A smoother and smaller acceleration data from the camera-based system could be a result of data processing, as data were further smoothed during the calculation of velocity and acceleration. There are also timing differences in when peak accelerations occurred between two methods. This could be due to the instantaneous alignment of IMU deviating from the anatomical directions. (Table 1)

**Figure 1:** Acceleration from IMU at L5 and COM acceleration from conventional motion capture system during walking (x-axis: normalized by 100% gait phase, y-axis: m/s<sup>2</sup>). The anterior, medial and superior direction were denoted as positive values.

**Table 1.** Timing in peak accelerations occurred and magnitude

	IMU [CI]	OTM [CI]
Timing in when peak (%gait)		
A-P Direction	[54.3, 82.1]	[41.5, 64.7]
M-L Direction	[62.6, 84.5]	[50.1, 68.3]
S-I Direction	[65.3, 87.8]	[52.4, 65.4]
Magnitude range (m/s <sup>2</sup> )		
A-P Direction	[15.64, 22.47]	[3.22, 5.76]
M-L Direction	[20.48, 25.02]	[2.63, 3.29]
S-I Direction	[23.11, 28.92]	[2.05, 3.43]

**Significance**

Consistent COM acceleration patterns and magnitudes during walking could be obtained with marker-based motion system and IMU, respectively. Accelerations obtained by the accelerometer are more sensitive to gait events with ground contact, such as heel-strike, when compared with those calculated from the second derivatives of COM positions. Although kinematic markers derived from both methods have been shown to detect clinical populations, users should be mindful about their inherent differences.

## Introduction

Identifying human kinematics is the primary step of biomechanics analyses and clinical evaluation for people with walking disabilities. A typical method for calculating human kinematics is to use a marker-based motion capture system. Such method has a major drawback when capturing motions outside the lab, makes it challenging to measure the various dynamic tasks in daily living. To solve this issue, it has been suggested [1] to use inertial measurement unit (IMU) sensors to capture the motion [1]. However, this method requires attachment of IMU sensors on each body segment. People may feel this is too cumbersome to apply in daily life, limiting the use in real application. Thus, this study aims to investigate the feasibility of capturing the joint angles of lower extremities with a reduced number of IMU sensors using a deep learning algorithm. We hypothesize that if we can train a deep learning model good enough, it can extract the information from a reduced number of IMU sensors for the prediction of kinematics in three dimensions.

## Methods

We recruited a young and healthy participant (31 yrs, 1.75 m, and 84 kg). Two IMU sensors were mounted on the dorsal of both feet of the participant. We calculated non-dimensional slow, normal, and fast walking velocity from the participant anthropometric data [2]. Then the participant walked in the treadmill for approximately 1.5 minutes at three different speeds. We collect the data last 1 minute for data analyses. The motion was captured simultaneously by twelve infrared cameras (Vicon, Oxford, UK), and acceleration and gyroscope data were recorded from the IMU sensor (Avanti™ wireless EMG, Delsys Boston, MA). We used OpenSim, which is an open-source musculoskeletal simulation tool to scale the model according to the participant's anthropometric measurements and calculate the hip, knee, and ankle angle using inverse kinematics. We considered five joint angles for each leg, i.e., hip flexion, hip abduction, hip rotation, knee angle, and ankle angle for the prediction. So, we have an input of 12 features and an output size of 10 joint angles for each timestamp. For the learning algorithm, we stacked two bi-directional Long Short Term Memory (LSTM) deep neural networks, followed by a uni-directional LSTM [3]. Five-fold cross-validation was performed to test the efficacy of the model. For the assessment of the result, the root mean square error (RMSE) and the correlation coefficient was calculated between the ground truth of the test set and prediction of the deep learning model.

## Results and Discussion

Our algorithm enabled us to estimate the joint angles with high accuracy compared with motion capture system. Figure 1 reports the mean and standard deviation RMSE with for five joint angles for both legs (upper subfigure), as well as their correlations (lower subfigure). The mean RMSE remains very low, ranges from ( $1.6^\circ \pm 0.25^\circ$ ,  $1.42^\circ \pm 0.26^\circ$ ) for hip abduction to ( $2.51^\circ \pm 0.2^\circ$ ,  $2.47^\circ \pm 0.24^\circ$ ) for the knee angles on the sagittal plane for left and

right leg. The predicted joint angle shows a higher correlation with the ground truth of the test dataset. However, the correlation was less for hip rotation ( $0.88 \pm 0.024$ ,  $0.88 \pm 0.028$ ). We believe that increasing the number of data from more participants will result in a better deep learning model, helping to achieve higher accuracy and correlation than what we provided in this study. This is left as future work.

## Significance

We have achieved reasonable accuracy with a high correlation using a reduced number of IMU sensors with a specialized deep learning model which supports our hypothesis. Another advantage of our method is to use the dorsal of the foot as the location of the sensor. Reduced number of IMU sensors can be easily mounted to the shoes to monitor kinematics of the athlete and people with gait impairment.

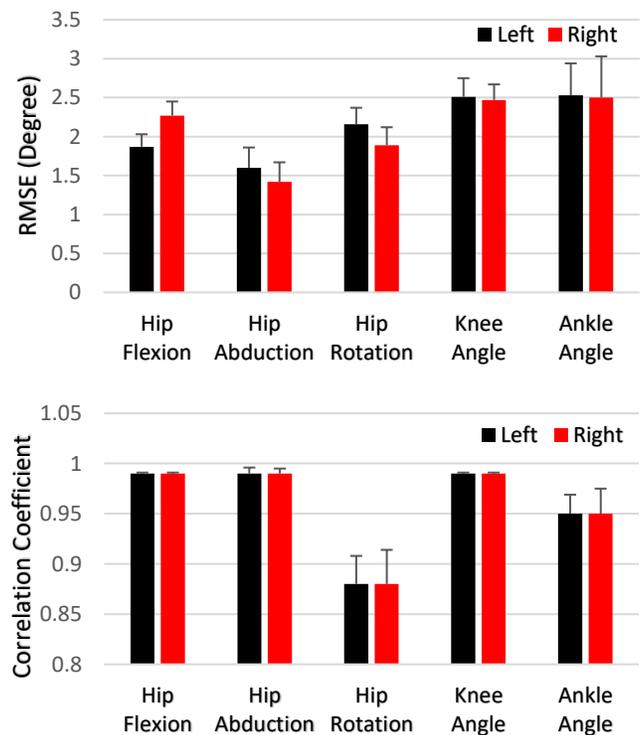

Figure 1: Mean RMSE and Correlation Coefficient with standard deviation for five joint angles for right and left leg.

## Introduction

Motion capture technology is a powerful tool that can be used to create high-fidelity biomechanical models and study movement disorders. Most motion capture systems use sensors mounted to the surface of the skin, and thus suffer from soft-tissue artifact (STA). STA refers to the movement of the skin relative to the skeletal structure. Since the goal of most motion capture efforts is to record the position/orientation of the skeletal structure, measurements from sensors mounted to the skin must be adjusted to better reflect the desired position/orientation of the skeleton.

Understandably, much research has been devoted to STA compensation (STAC); however, most methods have been developed specifically for optoelectronic motion capture systems and, due to inherent differences in methodology, cannot be directly applied to electromagnetic (EM) motion capture systems. To our knowledge there is only one STAC method developed specifically for EM systems [1]; while this method has been shown to be effective, it requires extra data and cannot be applied retroactively to datasets.

The purpose of this research was to develop a STAC method for EM systems that requires no additional experimental procedures or data. Our method adjusts for STA in humeral internal-external rotation (HIER), forearm pronation-supination (FPS), or both, and is based on the method developed by Schmidt et al for optoelectronic systems [2].

## Methods

Our STAC method builds on conventional inverse kinematics algorithms (i.e. algorithms that do not compensate for soft-tissue artifact) for determining global upper limb motion in accordance with the ISB recommendations [3]. These inverse kinematics algorithms are described in detail by Clark et al [4]. This process relates four sensor coordinate systems (SCS) to corresponding body-segment coordinate systems (BCS) of the thorax, upper arm, forearm, and hand. Using these relationships, joint coordinate systems (JCS) can be calculated for the thoracohumeral, humeroulnar and radioulnar (grouped), and wrist joints.

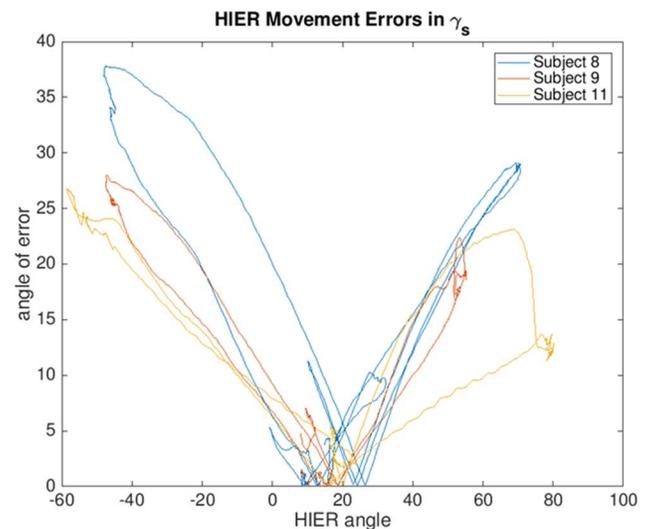

STAC for HIER was approximated based on two critical assumptions: 1) the elbow carrying angle is constant, and 2) STA affects only HIER. Based on these assumptions, HIER can be determined from the orientation of the forearm for most of the range of motion. This calculation only becomes unreliable when the arm approaches full elbow extension, in which case we used weighted averages to approximate HIER [2].

We followed a similar approach to compensate for STA in FPS, but relationships were calculated between the forearm and hand. This calculation is reliable over the full range of motion of the wrist.

We tested our STAC method on 10 subjects. Each subject performed 11 simple tasks that explored both the full and functional ranges of motion of the upper limb. We recorded motion using an EM motion capture system (trakSTAR by NDI, Shelburne, VT) and performed inverse kinematics with and without STAC.

## Results and Discussion

We found that applying this algorithm significantly changed the approximations of HIER and FPS. As seen in Fig. 1, the average maximum difference of HIER calculated with and without STAC was  $29.8^\circ \pm 6.6^\circ$  (mean  $\pm$  SD). In calculating FPS, relative errors of  $1.3^\circ$  in pronation and  $9.3^\circ$  in supination were identified. This data supports the claims that STA has a large impact on joint angle calculations.

**Figure 1:** Error due to soft-tissue artifact in humeral internal-external rotation (HIER). As HIER angle increases in either direction, the error also increases significantly.

Since we measured data and calculated joint angles throughout the workspace of the upper limb, we also confirmed that STA varies with joint configuration and quantified the effect of STA throughout the range of motion of the arm.

Lastly, we explored the effect of STAC on other degrees of freedom. Although our STAC assumed that STA directly affected only HIER and FPS, compensating for STA has indirect effects on other DOF. We found that correcting the approximations of HIER and FPS indirectly affects the angle approximations of elbow flexion, as well as wrist flexion-extension and radial-ulnar deviation.

## Significance

This research presents an STA compensation method for EM systems that can be applied retroactively. It is a relatively simple method that can improve the accuracy of joint angles calculated from EM motion capture used in analysis of movement impairments, biomechanical modelling, and other research and clinical efforts.

## Validity of Peak Tibial Acceleration Obtained from a Wearable IMU during Running

Adriana Miltko<sup>1</sup>, Clare E. Milner<sup>2</sup>, Max R. Paquette<sup>1</sup>

<sup>1</sup>University of Memphis, Memphis, TN, <sup>2</sup>Drexel University, Philadelphia, PA.

Email: [mrpquette@memphis.edu](mailto:mrpquette@memphis.edu)

### Introduction

A growing popularity of wearable technology leads companies to create sensors assessing biomechanical parameters including peak tibial acceleration (PTA) during running. Although development of bone injuries is multifactorial, greater PTA using laboratory-grade accelerometers have been observed in runners with a history of tibial stress fractures in comparison to individuals without lower-limb injury history (1).

Since peak tibial acceleration may contribute to risk factors responsible for tibial stress fractures, using measurements of peak tibial acceleration in runners in the field will allow biomechanists to bridge the gap in our understanding of injury development. However, validity of variables obtained from wearable technology relative to “gold-standard” research-grade instruments is necessary. The purpose of the study was to assess the difference in PTA obtained from wearable inertial measurement units (IMU) and a research-grade accelerometer at different running speeds. We hypothesized that with the device’s specs, the PTA measured with IMUs would be valid in comparison to a research-grade accelerometer at two different speeds.

### Methods

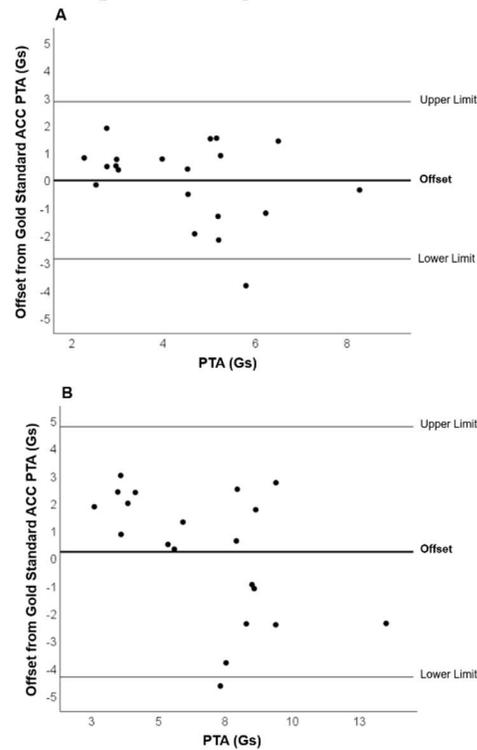

Twenty participants completed 1-2 min treadmill running bouts at 3.0 m/s and 4.0 m/s while wearing standardized footwear. A research-grade tri-axial accelerometer (ACC; PCB Piezotronics) and a 9-axis IMU (Blue Trident, IMeasureU) were secured to the distal tibia to obtain PTA during running. PTA from ACC was obtained while the ACC was placed below and above the IMU (separate trials) at both speeds due to possible position effects. Data were collected for the final 15 seconds of all four running bouts and the average of both positions and both speeds for 10-15 peaks of PTA were used for analyses. Paired t-tests were used to compare mean PTA between sensors at both speeds and the 95% limits of agreement and mean offset was determined (2).

### Results and Discussion

At 3.0 m/s, PTA from ACC ( $4.6 \pm 1.5$  G) and IMU ( $4.7 \pm 1.9$  G;  $p = 0.97$ ;  $d = -0.007$ ) were similar. At 4.0 m/s, PTA from ACC ( $7.0 \pm 2.3$  G) and IMU ( $7.1 \pm 3.4$  G;  $p = 0.64$ ;  $d = -0.08$ ) were also similar.

Further, Bland-Altman plots and 95% limits of agreement demonstrate that 95% of PTAs from the

IMU were within 0.012 G of PTAs from ACC at 3.0 m/s ( $p = 0.972$ ; **Figure 1A**) while 95% of PTAs from the IMU were within 0.25 G of PTAs from ACC at 4.0 m/s ( $p = 0.636$ ; **Figure 1B**).

**Figure 1.** Bland-Altman plots with PTA offset between IMU and ACC including 95% limits of agreement at 3.0 m/s (A) and 4.0 m/s (B).

### Significance

Our findings suggest that the tested IMU (Blue Trident, IMeasureU) provides valid measures of PTA in comparison to research-grade 3D accelerometer. Field testing with validated wearable devices such as IMUs will allow for day-to-day analyses of running biomechanics that can provide a more complete picture of typical external loads experienced by runners during study survey periods.

# Uncertainty propagation in validating bone kinematics using biplane fluoroscopy

Eric Thorhauer<sup>1,2</sup> and William R. Ledoux<sup>1,2,3</sup>

<sup>1</sup>RR&D Center for Limb Loss and MoBility (CLiMB), VA Puget Sound, Seattle, WA; Departments of <sup>2</sup>Mechanical Engineering and <sup>3</sup>Orthopaedics & Sports Medicine, University of Washington, Seattle, WA  
email: [erictor@uw.edu](mailto:erictor@uw.edu)

## Introduction

Biplane fluoroscopy can be a useful tool for biomechanists quantifying in vivo joint motion, however, given the custom nature of these hardware systems and the challenges inherent in imaging dynamic anatomy, these techniques must be validated to ensure data accuracy for each motion and joint of interest. Validation studies utilize anatomical specimens instrumented with fiducial markers. Borrowing from the fields of optical motion capture and Roentgen stereophotogrammetry, general guidelines of maximizing the embedded inter-marker spacing of the required triads of markers are suggested and degeneracy in marker configurations may be quantified with condition numbers [1]. In biplane studies, kinematic curves derived from model-based tracking are compared to “gold standard” marker-based data. Inter-marker distances in the rigid fiducial clusters of each bone have also been used to quantify tracking performance. Many of the foot bones are so small that embedding them with a non-degenerate marker triad is challenging, and the propagated stream of errors arising from marker localization are exacerbated in these joints. The goal of this work was to understand how the placement of validation markers and errors in their localization affects the “gold standard” kinematics in the clinically-important first metatarsophalangeal joint (MTPJ1).

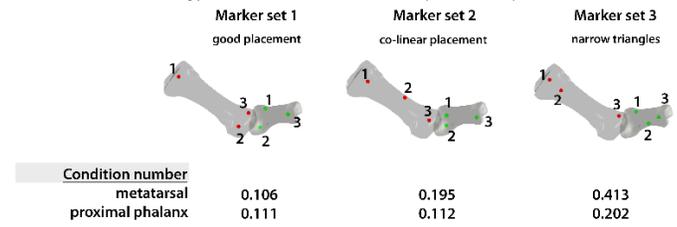

## Methods

A fresh human foot and ankle specimen was prepared by dissecting the great toe flexors and extensors and embedding a set of three 3.0 mm stainless steel marker beads into both the proximal phalanx and first metatarsal bones. The great toe was actuated through ten cycles while biplanar fluoroscopic data were acquired in a standard gait configuration. A computed tomography scan was used to generate models of the bones, establish anatomical coordinate systems, and to localize the markers. Using these data, the ground-truth kinematics of the joint were determined and then low-pass filtered to yield a smooth, but physiologically accurate model of MTPJ1 motion.

Next, various permutations of three virtual fiducial markers simulating different marker installation strategies were generated in a virtual model of the biplane hardware. Set 1 approximated an ideal distribution of markers in both bones. Set 2 simulated a co-linearity condition of markers in the metatarsal. Set 3 simulated placing two markers in each bone in close confinement to each other, yielding a narrow triangle shape. Using the ideal kinematics to drive the bone models in the virtual biplane software, for each frame of data, the virtual markers were projected onto the camera frames. The centroids of the markers were perturbed with varying degrees of uniformly distributed noise (upper limits of 0.25, 0.50, and 1.0 pixels) representing errors in marker localization and imperfect distortion corrections (pixel size for current camera settings = 0.327mm). The bone positions and kinematics were reconstructed for each trial of noisy markers and compared to the ground-truth. This process was repeated for each set of simulated marker installations.

## Results and Discussion

Condition numbers increased as marker distributions became less ideal, with Set 1 having the smallest values (Figure 1). The narrow triangles formed by Set 3’s markers led to the largest condition numbers (Figure 1). Except for the 1.0-pixel perturbations, higher condition numbers (Set 2 and 3) were associated with higher kinematic errors (Table 1).

**Figure 1:** Three example marker configurations for the MTPJ1 joint shown (top) and the respective condition numbers for each bone below. Condition numbers increase with worsening marker distribution.

Between the conditions of 0.25- and 0.50-pixel errors, inter-marker distances were consistent across marker sets and conditions (Table 1). Inter-marker distances cannot discriminate between suboptimal marker distributions and are not correlated to kinematic error magnitudes. Therefore, inter-marker distances alone are not an adequate surrogate metric for kinematic accuracy in biplane bone tracking.

Perturbation limit (pixels)	Marker set 1 good placement			Marker set 2 co-linear placement			Marker set 3 narrow triangles		
	0.25	0.50	1.00	0.25	0.50	1.00	0.25	0.50	1.00
RMS inter-marker error (mm)	0.06	0.03	0.65	0.02	0.03	0.06	0.02	0.03	0.06
Std. dev. of error (deg)									
flexion/extension	0.32	0.70	9.47	0.77	1.55	3.56	1.16	2.83	8.75
adduction/abduction	0.22	0.56	3.69	0.31	0.71	2.02	0.39	1.02	3.39
inversion/eversion	0.26	0.65	4.81	0.30	0.74	2.23	0.48	1.33	4.77

**Table 1:** For each marker set and localization perturbation level, the root-mean-square inter-marker errors (millimeters) and standard deviations of rotational kinematic errors (degrees) are listed for each perturbation range of the marker centroids.

## Significance

This study illustrated how localization errors in the assumed “gold standard” marker tracking can propagate into kinematic errors for small joints like MTPJ1. True validity depends on the marker configuration itself. Establishing these marker distributions in small volumes while balancing marker overlap and occlusion in dense, complex anatomic like the foot can benefit from pre-planning and simulation studies to maximize the validity of the derived kinematics and the overall success of the validation study.

# SURFACE-EXCITED WAVE DISPERSION IN THE ACHILLES TENDON DURING WALKING

Eli Dawson<sup>1</sup>, Dylan G. Schmitz<sup>1</sup>, and Darryl G. Thelen<sup>1</sup>

<sup>1</sup>University of Wisconsin-Madison, WI, USA

Email: [epdawson@wisc.edu](mailto:epdawson@wisc.edu)

## Introduction

The bulk propagation speed of a shear wave in isolated tendon is well described by a tensioned beam model [1]. This observation led to the development of shear wave tensiometers, which are wearable sensors that excite and record wave propagation as a means of gauging loads in *in vivo* tendons [1]. However, waves measured at the skin surface are dependent on the dynamic interaction of tendon and surrounding tissues. This can result in dispersion due to guided wave behavior within the tendon [2], and interaction of tissues of differing stiffnesses [3]. Inherent tissue viscosity can also induce dispersive behavior in which propagation speed, or phase, depends on the excitation frequency [4]. The purpose of this study was to investigate the dispersive nature of wave propagation in the intact Achilles tendon over a range of excitation frequencies.

## Methods

Two subjects walked on a treadmill at 2.5 mph. Each subject also posed statically with their foot in the air and on the ball of their foot to approximate swing-phase unloading and late-stance loading, respectively. A shear wave tensiometer [1] was used to measure wave propagation in the Achilles tendon resulting from Gaussian wavelet excitations (Fig. 1A). Waves were excited using a discrete wavelet frequency for each of 13 walking trials (200-1400 Hz, 100 Hz increments) and an inclusive frequency sweep from 200-1445 Hz for each static trial. Accelerometer signals were bandpass filtered in a narrow range (100 Hz) around each excitation frequency. Wave travel time was computed by finding the lag that maximized the normalized cross-correlation of accelerometer signals [1]. Wave speed was computed by dividing the accelerometer spacing (8 mm) by the travel time. For walking, we detected heel strike from an accelerometer mounted on the treadmill and averaged the wave speed patterns over a minimum of 7 strides at each walking speed (Fig. 1B).

## Results and Discussion

Wave speeds varied with frequency for both the static-loading frequency sweeps and across walking trials using varied excitation frequencies (Fig. 1C). Both subjects showed frequency-dependence, but the pattern was not identical. The frequency-dependence and subject-specificity is likely a result of differing thicknesses of soft tissue layers surrounding the tendon, including skin, adipose tissue, and muscle. Different tissue thicknesses result in unique wave speed vs. frequency profiles for each subject, which is caused by mode conversion due to guided wave behavior across frequencies. The minimas of the frequency profiles are an approach towards the bulk shear velocity of the stiffest layer at that loading level [3] – in this case the tendon.

## Significance

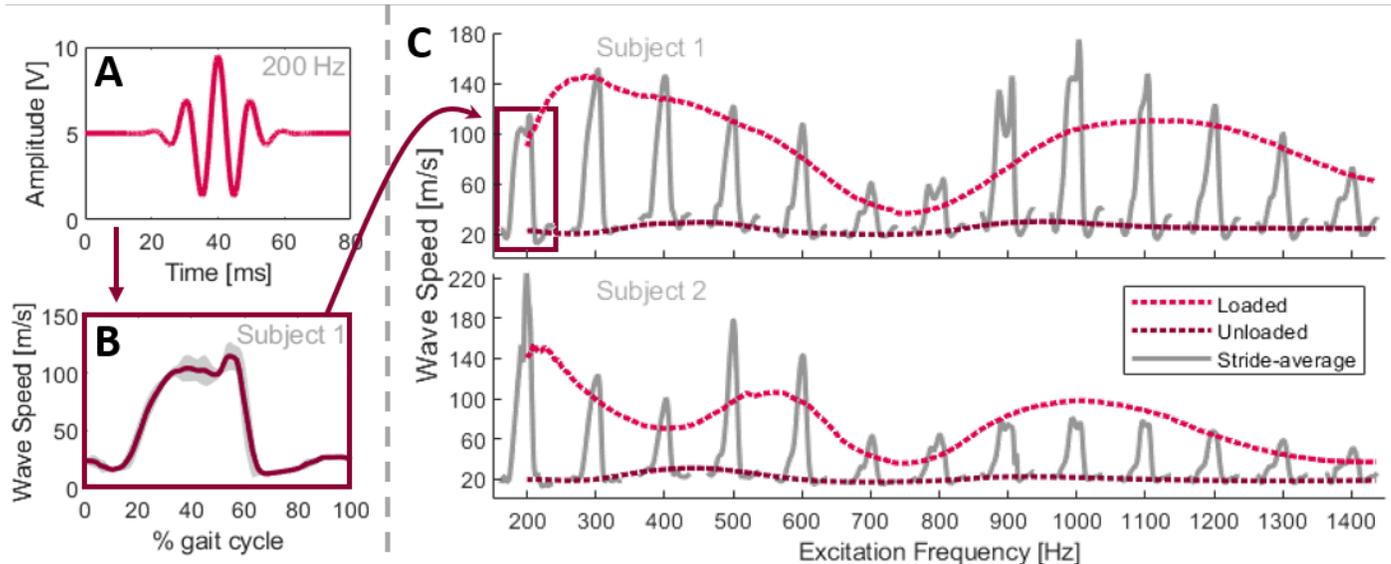

When using wave speed measurements to estimate stress experienced by an individual's tendon, understanding what factors may contribute to subject-specific differences in the wave speed-stress relationship is important. Here, we've shown that measured wave speed is dependent on excitation frequency, especially in the current excitation range used by the tensiometer. Further study of this phenomenon will attempt to link excitation frequency-dependence to subject-specific soft tissue geometry and will guide selection of excitation frequencies that ensure consistent wave speed measurements.

## Introduction

Visual biofeedback of joint kinematics has been explored for its potential to enhance retraining of pathological gait patterns in various populations. The most frequently reported modality for kinematic measurement is camera-based optical marker tracking. This presents challenges to adoption in clinical settings, as it requires considerable setup time as well as compatible space and lighting, and is vulnerable to marker occlusions which are likely to occur during therapist-supervised training. We have developed a visual biofeedback system [1] that provides feedback on knee kinematics measured using small lightweight wearable sensors (inertial measurement units / IMUs). We have designed the system specifically to support retraining of gait deviations in children with hemiplegic CP. To ensure that the feedback provided by the system is based on a robust and valid measure of knee flexion, we report a validation study comparing the knee flexion angle calculated by the system with a gold standard (camera-based) measurement of the same angle.

## Methods

We collected IMU-derived and camera-based data for this study simultaneously as a participant in our pediatric target population performed treadmill walking in a therapy room typically used for clinical training. The participant was an adolescent female with right hemiplegic CP (age 16.2 yrs, height 1.52 m, weight 44.5 kg). Informed consent was provided by the participant as well as a parent in compliance with the regulations of the local Institutional Review Board. Participant safety during treadmill walking was ensured by a pediatric physical therapist (close supervision). Following standard setup methods, three IMUs (MTW Devkit, Xsens, NL) were placed on the participant's right anterior thigh, posterior shank, and heel while standing. (Note: heel sensor data were not used to calculate knee kinematics). The thigh sensor's longitudinal axis was visually aligned perpendicular to the long axis of the thigh, while the sensor outputs were used to guide alignment of the shank sensor to be parallel to the thigh sensor. The IMU-derived knee flexion angles in our system are defined as the difference between the thigh and shank sensors' rotational orientation about their longitudinal axis ('roll'), which were collected at a rate of 60Hz. For the camera-based measure, reflective markers were placed on the greater trochanter, femoral lateral epicondyle, fibular head, and lateral malleolus of the same limb. A 3 camera motion capture system (Optitrack Trio, NaturalPoint, Inc., Corvallis, OR) was used to collect marker positions, and knee flexion angles were calculated as the 3D angle between a femoral vector (epicondyle to trochanter) and a tibial vector (malleolus to fibular head). Marker data were collected at 120Hz.

Four 30 second treadmill walking trials were recorded in total; two at 0.80 m/s, and two at 1.12 m/s. No special instructions or feedback were provided to the participant during these trials.

IMU-derived knee flexion angle data were resampled to 120 Hz and the datasets were aligned in time by the optimization of a variable time offset. Measurement agreement was assessed by linear regressions between the datasets for each trial.

## Results and Discussion

**Table 1.** Trial characteristics and linear regression analysis

Trial number	Speed (m/s)	R <sup>2</sup>	Slope (°/°)	Intercept (°)
1	0.8	0.932	1.26	-31.4
2	0.8	0.935	1.27	-32.7
3	1.12	0.966	1.29	-34
4	1.12	0.947	1.28	-34
Mean ± SD			1.27 ± 0.01	-33.0 ± 1.2

The linear regressions illustrated strong convergent validity of the IMU-derived joint angles with the camera-based joint angles, with correlation coefficients varying between **0.932** and **0.966** across the four trials (Table 1). Predictive equations took the form of (IMU-derived angle) =  $m$  \* (camera-based angle) +  $b$ , with the mean values across trials of the slope  $m$  and intercept  $b$  calculated as 1.27 and -33° respectively. The mean slope indicates that joint angle excursions recorded by the IMU system are somewhat higher than those from the camera data. We observed that this stemmed from movement of the IMUs relative to the overall limb segments. Optical markers are also subject to skin movement artifact, however additional movement of the IMUs may be related to their placement overlying muscles active during gait. During training we used a brief calibration procedure which implements a scaling factor to compensate for this difference and produce appropriate feedback signals. The mean intercept indicates a zero-point measurement offset between the two systems, which is also addressed by the calibration procedure.

## Significance

IMUs are compatible with clinical training environments and can provide robust and valid signals for use in visual kinematic feedback. Future work may include further exploration of sensor placement and attachment methods, feedback formulation, and training paradigms.

## Acknowledgments

This study was funded by Children's Specialized Hospital and Kessler Foundation. Patent pending for visual feedback method.

# Simple and Low-Cost Methods of Computing Joint Angles Using Inertial Measurement Units Without Magnetometers

Seung Yun Song<sup>1</sup>, Yanan Pei<sup>1</sup>, and Elizabeth T. Hsiao-Wecksler<sup>1</sup>

<sup>1</sup>Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, IL 61801

## Introduction

Recent progress made in micro-electro-mechanical systems (MEMS) have allowed Inertial Measurement Units (IMUs) to be more compact, affordable, and accurate. IMUs are now becoming a common tool used in movement and gait analysis. Many biomechanics studies have used expensive IMUs with well-developed software packages. Some research groups have tried to create their own IMU system but have not thoroughly validated their system (e.g., [1]). Most studies only validated their methods using arbitrarily defined movement speeds and ranges of motion, a single rotation axis, and/or short test duration (< 2 min) (e.g., [1]). Also, these studies do not provide open-source material, making it difficult for others to replicate their work.

The goals of this study were to: (1) propose a low-cost joint angle IMU-based measurement system, (2) validate and compare common computational methods of calculating joint angle using IMUs for multiple rotation axes, movement speeds and extended collection times, and (3) provide open-source codes and documentation describing the inner workings of these computational methods to help biomechanics researchers develop low-cost IMU systems.

## Methods

Our system used two IMUs (MPU-6050, TDK-InvenSense). Each IMU has a 3-axis accelerometer and a 3-axis gyroscope, but no magnetometer, built-in digital low-pass filters, and proprietary Digital Motion Processing (DMP™) algorithm for computing quaternion orientation. This IMU costs ~\$10.

We developed a testbed that offered programmable and repeatable rotations to validate the accuracy of our IMU system. The testbed consisted of a stepper motor (NEMA17, 42BY GH3401; Han Ding Motor) with an optical rotary incremental encoder (HEDS-9040#T00; Broadcom). Two microcontrollers were used to ensure consistent data collection at 100 Hz sampling rate (Teensy 3.6; PJRC) and reliable motor control (Arduino Uno; Arduino LLC). One IMU was secured to the motor shaft (moving IMU), and the other IMU was attached to the motor mount (stationary reference IMU). The moving IMU was changed to accommodate rotations about three different axes (yaw, pitch, roll).

Five common methods for computing relative joint angle were investigated: gyroscopic integration (GI), accelerometer inclination (AI), complementary filter (CF), Kalman Filter (KF), and quaternion-based digital motion processing (QDMP). For the QDMP method, we developed a custom calibration and computation protocol, which utilized each InvenSense IMU's DMP-based quaternion data [2]. The other four methods were implemented using previously developed methods from the literature [3]. For yaw calculations, only QDMP, GI methods were used since AI, CF, KF require the rotation axis to be non-parallel to gravity. Open-source code and documentation are available from our group [4].

Nine trials (3 rotation axes x 3 movement speeds (slow 25°/s, medium 100°/s, fast 200°/s)) were performed, each for 25 min and oscillating 180° range of motion. Testing speeds were chosen

to replicate a typical walking gait study for analyzing knee joint kinematics. Root-mean-squared-error (RMSE) was used to compare performance of each method to the gold standard joint angle (encoder-derived angle).

## Results and Discussion

For pitch and roll angles, the AI, CF, KF, and QDMP methods exhibited highest accuracy (RMSE < 6°, acceptable maximum RMSE for biomechanical research studies [5]) at all movement speeds\* and no signs of drift across the entire duration of testing (Fig 1A). (\*AI RMSE = 6.2° at fast speed.) The GI method was the least accurate with rapid divergence. These results suggest that four computational methods (AI CF, KF, QDMP) can be used in biomechanical studies to accurately quantify joint angles for movement speeds up to 200°/s and test durations of 25 minutes.

Computed yaw angles were inaccurate and limiting in terms of available methods (GI, QDMP). After 1.4 and 2.3 minutes, both methods exceeded RMSE 6°, respectively. These methods can only be used for studies lasting less than one to two minutes.

To minimize error, IMUs should be placed close to the rotation axis, and kinematic data during transient regions with high acceleration/deceleration should be analyzed with caution.

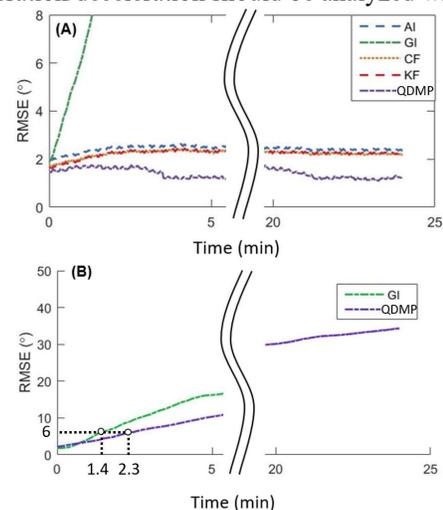

Figure 1: RMSE plots for medium speed for pitch (A) and yaw (B).

## Significance

This study provides information about low-cost IMUs and computational methods, so that other biomechanics researchers can develop their own IMU systems.

## Acceleration Signals and Peaks During Running Vary with IMU Placement

Zachary David Katzman<sup>1</sup>, Dovin Kiernan<sup>1</sup>, Kristine Dunn<sup>1</sup>, and David Hawkins<sup>1</sup>

<sup>1</sup>University of California, Davis, Davis, CA, USA

Email: [dahawkins@ucdavis.edu](mailto:dahawkins@ucdavis.edu)

### Introduction

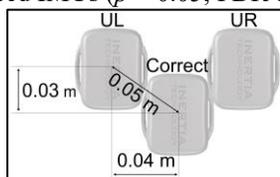

Inertial measurement units (IMUs) provide exciting opportunities to quantify and track biomechanical metrics in the field. To successfully capitalize on these opportunities, however, IMUs must provide repeatable measurements, which may be affected by IMU placement. Understanding the impact of IMU placement is of particular importance when IMUs are placed by end users (e.g. clinicians, coaches, athletes) or where the IMU may move throughout a long data collection. To our knowledge, the effect of IMU placement on repeatability of acceleration measurement during running has not been previously investigated. To address this gap and determine the effects of small changes in IMU placement, we systematically varied IMU placement near several common IMU attachment sites and quantified differences in accelerations.

### Methods

Runners ( $n = 30$ ) ran 25 m overground 60 times at ‘slow’, ‘typical’, and ‘fast’ self-selected speeds while a pair of IMUs simultaneously collected data (Inertia Technology ProMove MINI;  $\pm 100$  g,  $\pm 2000$  deg/s, 1000 Hz). IMUs were either placed ‘correctly’ at one of three commonly used attachment sites (distal tibia, iliac crest, or sacrum) or were ‘misplaced’ 0.05 m to the upper right (‘UR’) or upper left (‘UL’) corner of the correctly placed IMU (Fig. 1).

IMU data were filtered using a 4<sup>th</sup> order 50 Hz low-pass Butterworth filter. The contribution of gravity to the acceleration signal was removed and signals were rotated to a segment local coordinate system [1]. A single stride was isolated from the middle of each trial [2], when the participant was running at an approximately constant velocity.

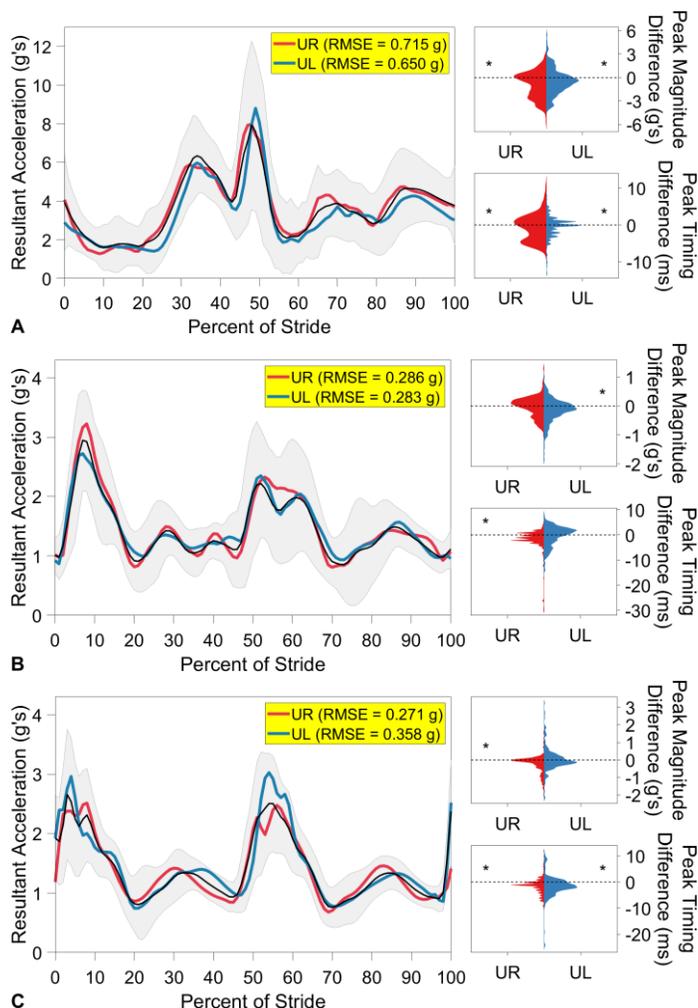

For each stride, RMSE values were calculated between correctly placed and misplaced IMU accelerations. Acceleration peak magnitudes and the difference in timing between peaks were then calculated. Paired t-tests were used to evaluate whether magnitude and timing significantly differed between correctly placed and misplaced IMUs ( $p < 0.05$ ; FDR correction).

**Figure 1:** Location of misplaced IMUs in relation to correct placement.

### Results and Discussion

The 0.05 m shift in placement led to changes in resultant acceleration signals: RMSE values across a stride were between 0.271 and 0.715 g (Fig. 2). RMSE values were largest for the distal tibia location and smallest for the sacrum location. Magnitude and timing differences were particularly pronounced when accelerations peaked. The largest mean difference in peak magnitude of  $-0.856$  g (correct - misplaced) occurred for UR misplacement at the distal tibia (Fig. 2A), while the largest mean difference in peak timing of  $-1.46$  ms was seen for UR misplacement at the iliac crest (Fig. 2B).

**Figure 2:** Distal tibia (A), iliac crest (B), and sacrum (C) mean  $\pm$  SD (black/gray) filtered resultant accelerations, RMSE values across a stride (highlighted in yellow), distributions of correct - misplaced resultant peak magnitude (upper right) and timing (lower right) differences for UR (red) and UL (blue) misplacement. \*misplaced significantly different than correct

### Significance

Researchers, clinicians, and runners interested in accurately measuring resultant accelerations with error less than 0.271 g across a stride should be conscious of placement, as changes in signals and peaks caused by misplacement may impact the repeatability of acceleration-based measurements. Users should be trained to place their devices before collecting running data. Devices such as IMU belts that minimize IMU movement during long runs should be developed to ensure consistent placement.

# IMPROVING CENTER OF PRESSURE ESTIMATION USING A SIMPLE OPTIMIZATION METHOD

Robert A. Creath, Ph.D.

Lewis Human Performance Lab

Department of Exercise Science, Lebanon Valley College

email: creath@lvc.edu

## Introduction

Force plates (FPs) are a crucial component of many biomechanics labs. When purchasing a FP, considerable care is spent determining the degree of accuracy and level of precision needed to produce acceptable research data. However, FP accuracy is dependent on proper installation and it can decline in older FPs rendering error into the data.

Factory recalibration is an ideal yet often impractical solution due to the expense of recalibration and lab downtime.

Several *in situ* calibration methods have been published that achieve accurate and reliable results, but require considerable expertise. For example, Collins et al. (2009) used an instrumented pole and inverse dynamics to model FP error. Reported post-calibration FP error was 5 mm rms.

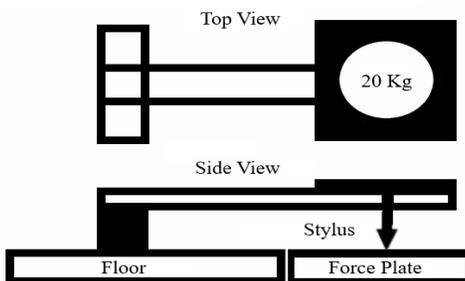

We measured a series of positions using a metric ruler and a weighted metal stylus on two FPs, one new and the other approx. 10 years old. The error values were the differences between measured positions (PMs) and FP data. We assumed the PMs were the desired values and the deviations from true position were the FP data. Error values were reduced by least-squares optimization of a linear function for scaling and offset.

Our goal was to develop a simple yet effective method of optimizing CoP estimation that could be achieved *in situ* and would improve CoP position estimates to levels expected from a factory-installed force plate.

## Methods

Nine evenly-spaced position measurements (3x3 grid) were taken on each of two adjacent 400 x 600 mm AMTI FPs using a pointed metal stylus weighted at approx. 20 Kg. The stylus support structure was made from 2x4 lumbar and 3/4" plywood. The stylus was moved to each of the measurement points on the FP surface which was covered with contact paper to outline the evenly-spaced grid. Figure 1 shows a schematic of the stylus and support structure.

Figure 1: Point application of weight on force plates

PMs were taken and compared to 10-second FP trials for each measured point using the average value for each trial. Forces and moments were processed according to AMTI User Manual standards. CoP position estimation was calculated according to Kwon (1998).

Measurement error between PMs and FP data was calculated as the average (std.dev.) of the x, y, and radial (Euclidean) position differences.

The FP data positions were optimized to the function

$$X_m = B * X_{FP} + \text{offset} \quad (1)$$

Where  $X_m$  was a vector of the PM values,  $X_{FP}$  was a vector of the FP data (10-second trial values),  $B$  was the scaling factor, and offset was the difference between the average of  $X_m$  and  $X_{FP}$ . Y measurements were treated similarly.

Optimization was achieved by the method of least squares using custom MatLab code (fminsearch) with equation 1. The goal was to optimize  $B$  and offset so that  $X_{FP}$  values were a best fit to  $X_m$ . New (optimized) values (OVs) were calculated from  $X_{FP}$  using equation 1 and compared to  $X_m$  and  $X_{FP}$ .

## Results and Discussion

Table 1 compares old and new force plates for average radial errors between OV and  $X_m$  (Optimized), and between OV and  $X_{fm}$  (Pre-optim.).

Table 1 Comparison (mean (std. dev.)) between optimized and pre-optimized average radial displacements errors.

	Old FP	New FP
Optimized	1.0 (0.5) mm	1.6 (1.6) mm
Pre-optim.	6.4 (3.6) mm	12.3 (4.0) mm

In both cases the optimized values were less than the pre-optimized measurements indicating an improvement in accuracy of CoP position estimation.

The large difference errors measured on both plates suggest improper installation which can alter the expected accuracy of the force plates (Collins et al., 2009, AMTI, Inc.). These results suggest the need for professional installation, or as Collins et al. infer, post-installation calibration.

Our goal was to develop a simple, time-efficient *in situ* method to improve CoP position estimation accuracy for embedded force plates. Optimized position estimates were 6.4 to 7.7 times better than the pre-optimization values, but less than AMTI's advertised values of 0.2 mm.

The reader should note this procedure improves CoP position estimates, but not FP forces or moments. For postural control studies, the magnitude of vertical forces far outweighs horizontal forces, so a simple weight calibration could provide adequate ground reaction force values for most studies. If more accurate force and moment values are required, then the method of Collins et al. (2009) should be considered.

**INTRODUCTION** The measurement of physical activity in a clinical setting is often used to predict health outcomes. Hand-timed gait speed, measured during standard clinical gait tests (e.g. 5-meter walk test), is a widespread metric used to quantify physical health. However, there can be measurement noise and bias created by the timing methods and the brevity of these tests. Wearable sensing technologies can be used to complement in-clinic evaluations of movement as they can capture high-resolution kinematic data during free-living. Despite the potential of wearable devices for persistent monitoring, challenges like subject compliance and battery life must be overcome before they can be used regularly in a clinical setting. To address these issues, we use high-resolution measurements of gait kinematics to create subject-specific data-driven models to estimate stride speed from stride frequency. The model is then used to estimate stride speed during daily living from data collected continuously over a week using a low power biologging system.

**METHODS** To collect data from the free-living environment, we used a lightweight (20 grams) accelerometer-based archival sensor (activPAL) secured to the thigh using a stretch adhesive. This sensor offers 7 days of uninterrupted measurement. Custom algorithms were created to extract steady-state walking bouts and calculate stride frequency  $f$ . A data-driven model to estimate stride speed from stride frequency was built using kinematic data estimated from foot-worn inertial measurement units (IMUs) during a prescribed walking task [1]. The walking task consists of a hallway walk, in which a wide range of step frequencies was imposed using a metronome. A power regression model,  $d = a \cdot v^b$ , was used to describe the relationship between stride length  $d$  and stride speed  $v$  [2]. Since  $f = \frac{v}{d}$ , we have the following relationship:

$$f = \frac{v}{d} = \frac{v}{av^b} = \frac{1}{a}v^{1-b} \Rightarrow v = \exp\left(\frac{\ln(af)}{1-b}\right) \quad (\text{Eq. 1})$$

To ensure the model created can be used to accurately estimate speed in the free-living environment, we conducted an experimental verification wearing a foot-worn IMU and the activPAL simultaneously. All protocols used off-the-shelf wearable sensors and were approved by the Institutional Review Board at the University of Michigan.

**RESULTS AND DISCUSSION** The data extracted from the prescribed walking task was used to identify the parameters  $\{a, b\}$  of Eq 1 and derive a subject-specific model of stride speed vs. stride frequency. The resulting model fits the data well ( $R^2 = 0.97$ ), Fig. 1-a. Speed estimates derived from the thigh

worn accelerometer were verified using 14 hours of data collected over 2 days from both a foot-worn IMU and the activPAL. Fig. 1-b. shows the distribution of the speed estimated from the IMU, considered as the true speed, and the estimated speed from the activPAL using our model, as well as their respective fitted Gaussian curves. The mean of the true speed is not statistically different from the mean of the estimated speed ( $p \geq 0.01$ ). These preliminary results support the use of the model to reliably estimate stride speed during daily-living.

## SIGNIFICANCE

Week scale data from a minimally invasive biologging instrument on a single charge

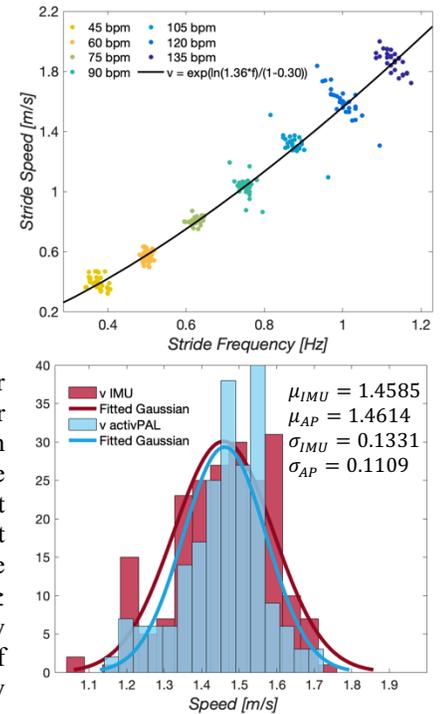

(activPAL) addresses challenges associated with subject compliance and battery life. However, direct measurement of walking speed cannot be estimated from these data. Using a data-driven modeling approach and combining different temporal timescales and resolutions, we were able to leverage this piece of technology to reliably estimate walking speed during free-living, creating the opportunity for clinicians to gain insight on the physical health of an individual in their natural environment.

# Reliability of One-Size-Fits-All In-Shoe Force Sensors Across Various Walking Speeds

Kaleb Burch.<sup>1</sup>, Sagar Doshi<sup>1</sup>, Erik Thostenson<sup>1</sup>, and Jill Higginson<sup>1</sup>  
<sup>1</sup>Mechanical Engineering, University of Delaware, Newark, DE 19711  
Email: kburch@udel.edu

## Introduction

Real-time measurement of ground reaction force (GRF) in unrestricted settings is useful for gait research, clinical assessment, and recreational fitness. One sensing method is the use of force or pressure sensors under the foot. These types of sensor systems can be highly complex, requiring careful sensor placement for each subject [1]. This study seeks to show that one-size-fits-all shoe sensors (SS) can be used to accurately measure both peak GRF and heel strike timing across a range of walking speeds for subjects of various weights and foot sizes.

## Methods

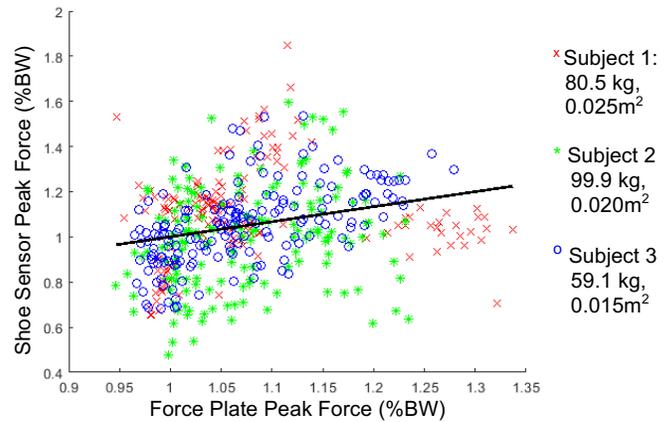

The shoe sensor system in this study consisted of 2 fabric-based nanocomposite sensors located on a sandal under the hindfoot and forefoot regions [2]. This system was worn by 10 subjects (age:  $23.3 \pm 2.5$  years; mass:  $75.2 \pm 18.2$ ; 5 male and 5 female) who participated in calibration trials and walking trials. During calibration trials, subjects performed 3 steps in which they slowly transferred weight onto an individual sensor and then back off the sensor. During walking trials, subjects walked at a given speed (0.5, 1.0, or 1.5 m/s) for 30 seconds. Calibration trials were performed first and then walking trials were performed in a randomized order. Vertical GRF data was collected with an instrumented, split-belt treadmill (Bertec Corp, Worthington, OH, USA) at 2000Hz. Force data was collected from the SS at an average frequency of 28Hz using an Arduino Uno Rev3.

The individual sensors were calibrated against the treadmill during the loading phase of each calibration “step”. Since the sensors do not cover the entire foot, they cannot capture the complete force on the foot. This was accounted for by using a weighted combination of the forces measured by each sensor determined based on a least-squares regression [3]. This regression was performed for all trials. The average coefficients across all walking trials were used to obtain the final forces.

For the walking trials, data was segmented into separate gait cycles using heel strikes. The treadmill force plate (FP) identified heel strikes using a 20N threshold [4]. Heel strikes were identified for the SS as zeros of the third order time derivative of resistance after which a threshold (defined by 23% of the subject-specific resistance range during gait) was crossed. Within each gait cycle, cycle time and forces at both GRF peaks were measured for both FP and SS. All forces were normalized to subject body weight. Linear regression was performed to evaluate peak forces in the shoe sensor versus the force plate.

## Results and Discussion

The SS demonstrated a consistent increase in peak force ( $F_{SS}$ ) that correlated with peak forces ( $F_{FP}$ ) detected by the force plate ( $F_{SS} = 0.665F_{FP} + 0.34$ ,  $r^2 = 0.26$ , Fig. 1). The SS was accurate across a range of speeds (largest average error over 1 speed for a single subject: 0.5 m/s, 5% BW; 1.0 m/s, 11% BW, 1.5 m/s, 5% BW). The heel strike detection algorithm also matched the treadmill algorithm, accurately reproducing gait cycle duration ( $r^2 = 0.996$  when all subjects and trials are included;  $r^2 = 0.76$  to 0.8 per subject on average; largest single trial RMSE < 0.012s).

**Figure 1: Peak Forces Detected by Shoe Sensor vs. Peak Forces Detected by Force Plate.** Peak forces for 3 subjects are depicted, with each symbol corresponding to a different subject. The legend includes subject mass and foot area. The black line represents the linear regression across data from all 3 subjects.

Across speeds and across subjects, the least-squares coefficients were generally not constant (Fig. 2). Nevertheless, taking average values allowed for reasonable force estimates to be obtained.

	0.5 m/s	1.0 m/s	1.5 m/s	Overall
$a_1$	$0.89 \pm 0.02$	$0.89 \pm 0.01$	$1.27 \pm 0.01$	$1.01 \pm 0.20$
$b_1$	$0.57 \pm 0.02$	$0.47 \pm 0.01$	$0.35 \pm 0.01$	$0.46 \pm 0.10$
$a_2$	$1.64 \pm 0.00$	$1.88 \pm 0.26$	$1.83 \pm 0.17$	$1.78 \pm 0.18$
$b_2$	$3.46 \pm 0.24$	$2.99 \pm 0.18$	$3.06 \pm 0.41$	$3.17 \pm 0.32$
$a_3$	$1.87 \pm 0.25$	$1.98 \pm 0.05$	$1.98 \pm 0.02$	$1.95 \pm 0.13$
$b_3$	$0.80 \pm 0.02$	$0.74 \pm 0.01$	$0.65 \pm 0.00$	$0.75 \pm 0.06$

**Table 1: Unitless coefficients (mean  $\pm$  standard deviation) of linear regression used to calibrate sensors.** Subscripts on the coefficients represent corresponding subjects.

With these fabric-based in-shoe sensors, we have demonstrated the ability to estimate peak GRF over a range of walking speeds for a variety of subjects without precise placement of sensors.

## Significance

The sensors evaluated in this study have the potential to impact both research and clinical care. The ability to measure GRF for every step allows the researcher to obtain larger data sets without the restrictions of a laboratory setting. In the clinic, it will be useful to physical therapists could monitor how much load is exerted on patients’ legs. The low cost and simplicity of the sensor implementation make it practical for use in these settings, where more complex systems would require extra setup.

## Introduction

Motion capture systems are used in a number of fields to analyze human movement by collecting data points for motion analysis. Unfortunately, the most widely used motion capture technology (e.g., Vicon) is prohibitively expensive and requires a well-controlled space to be utilized. As a part of an undergraduate education project (i.e., Aggie Challenge at Texas A&M University), in this study, we implemented and verified the feasibility of a design for a smartphone-based motion capture system to analyze the ankle joint kinematics in an easy manner.

## Methods

In this study, we used conventional smartphones to capture the object that we desire. The required number of smartphones is dependent on the number of points to capture. In this case, we used two smartphones to capture four ping-pong balls (Figure 1: green) to analyze the ankle joint. In order to calibrate the motion capture system, we used the direct linear transformation (DLT) method, which relates camera images to real world objects using DLT parameters [1]. A 3D calibration bar with 8 ping-pong balls was used as a global coordinate reference for finding the DLT parameters. Based on the recorded data from two different stationary smartphones, two DLT parameter sets were obtained from each camera by a least squares method. These parameter sets allow us to estimate objects' 3D position from their 2D position in the frame of each camera.

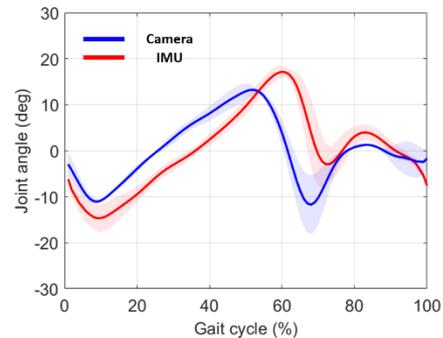

**Figure 1:** Motion capture experiment setup for the ankle joint angle using two independent capture systems: IMU and smartphone-based system.

To validate the system, a treadmill walking experiment was conducted with a healthy young subject (male, 31 yrs. 1.70 m, 70 kg) in order to capture ankle behavior. The subject was asked to walk at his preferred speed (0.5 m/s). During the experiment, four ping-pong balls and two inertial measurement units (IMUs) were attached to the subject's lower leg and foot as shown in Figure 1. The experiment was recorded with the cameras in the same positions as the calibration process. The resulting videos were time-synchronized in post-processing by cross-correlation of the velocity of a ball located at the heel. The IMU system is

commonly used to capture joint kinematics [2] and was used here to verify the proposed smartphone-based system.

After recording the experiment, the movement of each ball was tracked using motion tracking software (OpenCV) to obtain their image plane [u,v] coordinates. Using the DLT parameters from the calibration, the moving image plane data was then converted to three-dimensional coordinates [x,y,z] which were used to calculate joint angles.

## Results and Discussion

**Figure 2:** Ankle joint angle estimation from two different methods: IMU system (red) and camera-based system (blue). Bold lines and shaded regions refer to the average and  $\pm 1$  s.d. of five consecutive steps, respectively.

Figure 2 shows the ankle joint angle in the sagittal plane as measured by the two different methods. This data confirms preliminary feasibility. Compared to the result from the IMU system, the proposed result shows a qualitatively similar trend for the entire gait cycle, especially in showing ankle dorsiflexion and push-off. The discrepancies in angle can be explained by sensitivity to placement both for the IMU sensors and our markers. We expect that we can account for these with modification to the algorithm and marker design, yielding improvements in accuracy. The performance of the improved system will be gauged against the Vicon capture system.

## Significance

This study shows the feasibility of using smartphones for motion capture purposes. Once the accuracy of our motion capture system is improved, it can potentially make motion capture experiments easier, portable, and more accessible, since users only require relatively inexpensive phones with minor preparation for the test. Most importantly, this study provided an educational experience for the undergraduate students at Texas A&M University who completed this work.

# Noninvasive Monitoring of Muscle Metabolic Activity with Near Infrared Spectroscopy and Diffuse Correlated Spectroscopy

Scott Boebinger<sup>1\*</sup>, Rowan Brothers<sup>1</sup>, Sistania Bong, Bharat Sanders, Lena Ting<sup>1</sup>, Erin Buckley<sup>1</sup>

<sup>1</sup>Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology and Emory University

Email: \*sboebin@emory.edu

## Introduction

Resting rate of oxidative muscle metabolic activity may provide a valuable biomarker to assess muscle tone. Numerous disease states are known to influence muscle tone, including Parkinson's disease, yet we lack reliable assessments that quantify muscle metabolic activity.

Near-infrared spectroscopy (NIRS) provides a low-cost, non-invasive means to measure localized oxidative muscle metabolic activity (mMRO<sub>2</sub>)<sup>1,2</sup>. While this optical approach is relatively simple to perform, it requires occluding arterial blood flow. The need for arterial occlusion prevents continuous monitoring and limits the measurements to patients who can tolerate occlusion.

Combining NIRS and diffuse correlation spectroscopy (DCS), which measures blood flow, offers an alternative optical approach to quantify a muscle metabolic activity index (ImMRO<sub>2</sub>) without the need for occlusions. Although NIRS+DCS-measured ImMRO<sub>2</sub> has been reported by several groups<sup>1,2</sup> the measurement itself has never been validated against NIRS-measured mMRO<sub>2</sub>.

We examined the agreement between NIRS (mMRO<sub>2</sub>) and NIRS+DCS (ImMRO<sub>2</sub>) measures of muscle metabolism. Additionally, we address common sources of error associated with the occlusion protocol and present methods to mitigate these errors.

## Methods

**Protocol:** Nine participants (4 men, 5 women) were seated with knee extended while the optical sensor was secured to the medial gastrocnemius of their dominant leg. After a 2-minute baseline to ensure hemodynamic stability, a 30-second venous occlusion of the thigh was performed at 90mmHg tourniquet pressure, followed by a release and 2-minute recovery period. Once large hemodynamic variations stabilized, an arterial occlusion of the thigh was performed at 250mmHg tourniquet pressure, followed by a release and 5-minute recovery period. The sensor was removed. The protocol was repeated 5 times (Figure 1).

Muscle metabolic activity was measured in two ways; 1) a NIRS-only mMRO<sub>2</sub> measure during arterial occlusion and 2) a NIRS+DCS ImMRO<sub>2</sub> measure just prior to the arterial occlusion. mMRO<sub>2</sub> is quantified as the mean rate of change from oxy- to deoxy- hemoglobin during the arterial occlusion. Hemoglobin concentrations were calculated using the modified Beer-Lambert Law<sup>1,2</sup>. ImMRO<sub>2</sub> is quantified via Fick's law by combining NIRS measures of oxygen extraction with DCS measures of blood flow over a 30s interval prior to arterial occlusion.

**Quality Control Criteria:** Data were excluded from trials in which arterial leakage occurred. Arterial leakage was quantified as the slope of total hemoglobin concentration during arterial occlusion. Data were excluded if the slope was greater than 10% of the slope of total hemoglobin concentration during the venous occlusion.

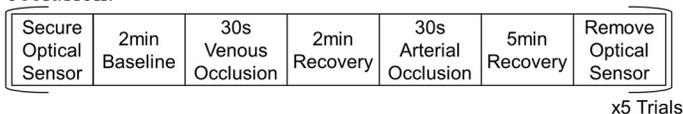

Figure 1: Protocol overview.

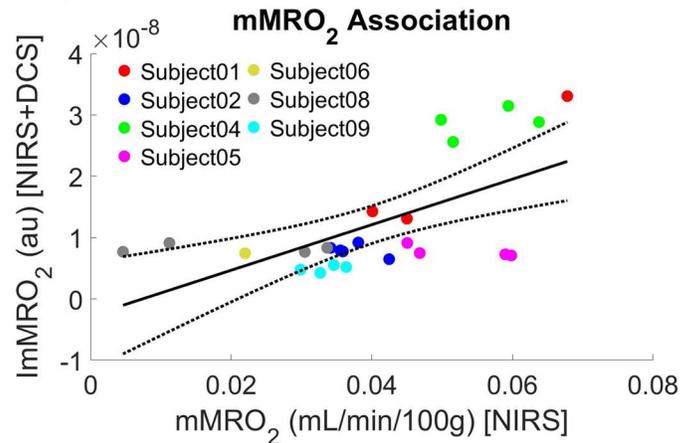

Figure 2: Association between mMRO<sub>2</sub> (NIRS) and ImMRO<sub>2</sub> (NIRS+DCS). Black line and black dotted line show linear regression and confidence intervals, respectively.

## Results and Discussion

Data are reported for 8 out of the 9 participants. Subject 7's data is excluded due to technical difficulties during data collection. Trials 2-5 for subject 6 were excluded as they did not follow the experimental protocol following trial 1.

Out of the 36 trials analyzed 8 did not pass the quality control criterion, none of subject's 3 data passed quality control. Of the eliminated trials there was a significant negative correlation between arterial leakage and metabolic activity for subject 3 ( $R^2 = 0.96$ ,  $p < 0.01$ ). In contrast, there was no significant relation in the reported data in which arterial leakage did not occur. This knowledge could inform future protocols to employ similar quality control criteria to prevent the confounding effect of arterial leakage on mMRO<sub>2</sub>.

Our values of mMRO<sub>2</sub> are similar to those reported in the supine position<sup>1</sup>. Correlations between mMRO<sub>2</sub> and ImMRO<sub>2</sub> were significant ( $R^2 = 0.380$ ,  $p < 0.01$ ) (Figure 2). We found similar variability between trials for both techniques. However, the differences measured across methods was not significantly correlated ( $R^2 = 0.001$ ,  $p = 0.9$ ) (not shown). These preliminary relationships need to be validated with a larger sample size.

## Significance

To our knowledge we are the first to test the association between mMRO<sub>2</sub> and ImMRO<sub>2</sub>. If an association is found in a larger sample size it would suggest that this index may correspond to physiological units. Therefore, NIRS+DCS may be a promising new modality to continuously monitor oxidative muscle metabolic activity during muscle contraction.

## Introduction

Maximum Voluntary Isometric Contractions (MVICs) are an integral part to biomechanics research. Muscles have activation dependent behavior that can cascade from muscle level to whole body biomechanics<sup>1</sup>. Many research questions depend on having reliable and repeatable MVIC measurements in one day and over time. However previous studies have found that even at the same location, having multiple evaluators collect MVICs increased variability<sup>2</sup>. The purpose of this study was to assess different methods for collected MVICs from plantar flexors. We hypothesize that using live biofeedback will improve reliability of MVIC measurements, and that increasing the target value higher than subjects can reach will elicit higher activations.

## Methods

In this preliminary study, we recruited one participant (N=1). All MVICs were collected on a Biodex Dynamometer during isometric contractions of the right leg with the knee fully extended and the ankle fixed at 0° plantarflexion. Electromyography electrodes were placed on lateral gastrocnemius (LG), and soleus (SOL) muscles, and 3D motion capture markers on the medial knee, ankle axis of rotation and head of the 1st metatarsal. For trials with biofeedback a GUI projected torque value as a ball on a graph with a target line. One baseline condition was collected where subjects were instructed to maximally plantar flex. Then, three conditions with at least 3 trials per condition were randomized:

- 1) No biofeedback (NBFB), verbal encouragement
- 2) Biofeedback rampup (RU). The target started as peak baseline torque. Subjects were instructed to beat the target. If they did, the next rampup trial used the new peak torque for the target. This continued until the target could not be beat by more than 5% of the previous trial.
- 3) High biofeedback (HBFB), target was set to 2X higher than the baseline torque. Subjects were instructed to beat the target.

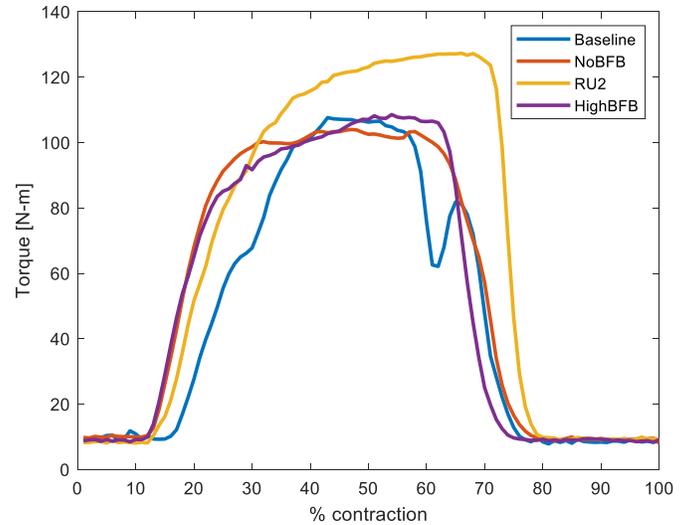

The participant was given a minimum of a two minute rest between each contraction

## Results and Discussion

Preliminary results suggest that the ramp up method elicited the highest torque and activation. Contrary to our hypothesis, there was not a significant difference in the high biofeedback and no biofeedback methods. We anticipate that a target of double the baseline was too high and the participant did not have incentive to reach it. As we get more participants we will be able to draw conclusions on larger scale trends.

Looking to expand these measurements across multiple days, we hypothesize that overtime ramping up will be the best method to produce the highest torques and activations because the participants have a reasonable target to beat. We anticipate that people will get more used to doing contractions so differences between methods will become less apparent overtime.

Although we cannot draw conclusions until the study is complete, results suggest that different tactics even within giving biofeedback yield different results. If a study question relies on MVICs immediately or over time, consideration should be taken on how to collect these data.

**Figure 1:** A) Torque values from baseline, no biofeedback, the highest ramp up condition, and high biofeedback

### Normalized Activation

Ramp-Up	1
Baseline	0.899
NoBFB	0.909 +/- 0.035
HighBFB	0.835 +/- 0.035

**Table 2:** LG EMG values normalized to highest condition (Ramp-Up)

## Significance

MVICs are a common tool in biomechanics research yet the collection method is not standardized. Our results suggest a need for biofeedback to increase efficacy of these measurements. This study is centered on the plantar flexors but similar standards can be developed for each muscle group. Upon completion, this study can provide guidelines for collecting MVICs, providing consistency across labs, participants, and over time.

# Inter-Joint Coordination Variability When Fatiguing With a Repetitive Sit-to-Stand Task

Szu-Hua Teresa Chen<sup>1</sup> and Li-Shan Chou<sup>1,2,\*</sup>

<sup>1</sup>Department of Human Physiology, University of Oregon, Eugene, OR USA

<sup>2</sup>Department of Kinesiology, Iowa State University, Ames, IA USA

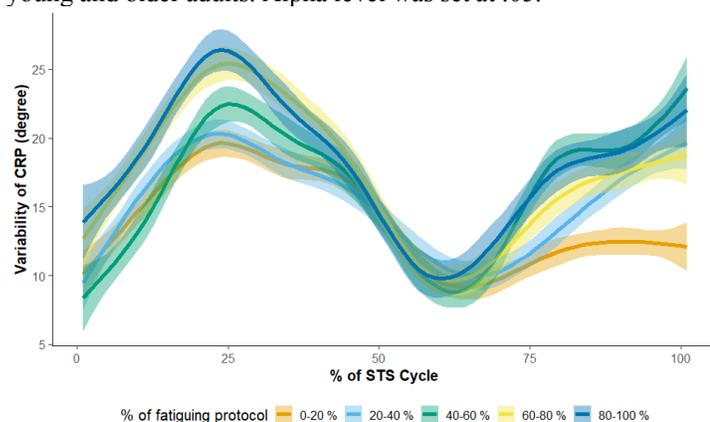

Email: \*[chou@iastate.edu](mailto:chou@iastate.edu)

## Introduction

The repetitive sit-to-stand (STS) task is often used as a fatiguing protocol when studying fatigue effects on gait. However, little is known about the motor adaptation during such fatiguing course. A recent work has reported an increased variability of continuous relative phase (CRP) after fatigue [1], indicating a reduced motor control or a result of compensation. The purpose of this study, therefore, was to examine changes in variability of both hip-knee and knee-ankle CRPs during the STS course

## Methods

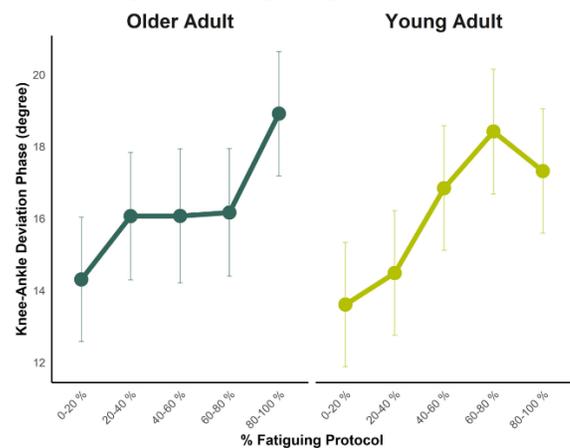

Fifteen young (age:  $26.7 \pm 5.8$ ) and 15 older (age:  $69.3 \pm 5.7$ ) adults were tested. Participants were asked to sit on a regular wooden chair without armrest and perform repetitive STS movements at their comfortable and fixed paces up to 30 minutes. Participants were instructed to keep their feet in place and not to use arm movements for assisting STS movement during the entire protocol. The repetitive STS fatiguing protocol was terminated when 1) participants cannot continue due to exhaustion, 2) when the movement frequency fell below prescribed pace after encouragement, or 3) after reaching 30 minutes. Rating of perceived exertion (RPE) and maximal isokinetic contraction of right knee extensor were examined using a Borg Scale 6-20 scale and a dynamometer, respectively, before and after the fatiguing protocol. Whole body motion data were collected during each minute of the repetitive STS course. Data from 3 consecutive STS cycles from each minute were extracted, and data in each cycle was normalized to 101 points. Hip-knee and knee-ankle CRPs were calculated using methods previously described [2]. Outcome variable was the *deviation phase of CRP*, an average value of all standard deviations calculated from 3 CRP curves for each 101 point. Due to individual differences in STS duration, it resulted in various total numbers of trials being recorded from each participant. Thus, STS trial collected from every minute was time normalized to STS duration and dummy coded as five stages: 0-20, 20-40, 40-60, 60-80 and 80-100% of the course (**Figure 1**). A 2\*5 mixed-effect ANOVA was used to examine changes in variability during different stages of the course in young and older adults. Alpha level was set at .05.

**Figure 1:** Variability knee-ankle CRP during the STS course.

## Results and Discussion

Isokinetic strength was significantly decreased about 18% at post-fatigue with no age-group difference. Both groups demonstrated an increase in RPE from 7 to 18 on average. Older and young adults performed STS protocol to the same degree except for the pace of STS being slower in older adults. No Age x Time interactions were found in neither hip-knee or knee-ankle coordination variability. From sitting to standing, variability of hip-knee and knee-ankle segments did not significantly change along the course nor was there an age effect. In contrast, changes in knee-ankle variability from standing to sitting was dependent on stages,  $p = .01$ . Specifically, knee-ankle deviation phase during the late-stage (80-100 %) was higher than that of early-stage (0-20%) regardless of age (**Figure 2**).

**Figure 2:** Deviation phase of knee-ankle CRP (mean  $\pm$  SEM).

It is argued that the central nervous system makes efficient use of degree-of-freedom abundance in the human body along the course of fatiguing protocol to compensate for deficit and optimize the performance [3]. Compared to non-goal-orientating task (e.g. standing), a timing error during goal-orientating task (e.g. sitting) was well preserved at the expense of coordinative variability [1].

## Significance

The impact of fatigue during repetitive sit-to-stand protocol is not only limited to a decline in force production but also manifested as increasing knee-ankle variability when sitting. Future studies using sit-to-stand movement as a fatiguing protocol could adopt knee-ankle deviation phase as an index of fatigue.

# Autocorrelation and Probability Distributions in Gait-Metronome Synchronization

Ian Sloan<sup>1</sup>, Aaron Likens<sup>1</sup>, Joel Sommerfeld<sup>1</sup> and Nicholas Stergiou<sup>1</sup>  
<sup>1</sup>Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE USA  
email: csloan@unomaha.edu

## INTRODUCTION

Recent studies have shown that the temporal structure of pacing signals (e.g., visual and auditory metronomes) influences the gait dynamics observed when coordinating with those signals [1,2]. Those studies typically involve pacing signals with interbeat intervals that are either constant over time or ‘noisy’, with the latter case referring to a class of signals that vary with respect to their autocorrelation function. To-date, however, no studies have directly examined the role that probability distribution functions play in gait-metronome synchronization. This study examines both structure of autocorrelation functions (ACFs) and the shape of probability distribution functions (PDFs) in noisy metronomes as possible sources of information involved in the synchronization process. Pacing signals varied in terms of both ACF decay and PDF shape. Statistical results support the idea that both the ACF and PDF exert independent effects on the temporal structure of gait.

## METHODS

**Participants.** Ten healthy subjects from the University of Nebraska at Omaha volunteered to participate.

**Apparatus and Procedure.** In this experiment, individual Noraxon FSR SmartLead footswitches (Noraxon USA Inc, Scottsdale, Az) were connected to the heel of each foot of each subject. Then the subject covered the foot switches with their socks and shoes. The footswitches were used to collect stride time intervals. The subject was then instructed to walk around on a track surface for 12 minutes. This baseline trial was self-paced and stride time intervals were collected. The self-paced trial was used to find the average and standard deviation for each subject’s preferred walking speed and variability. Computations were performed using custom MATLAB code (MathWorks, Natick, MA).

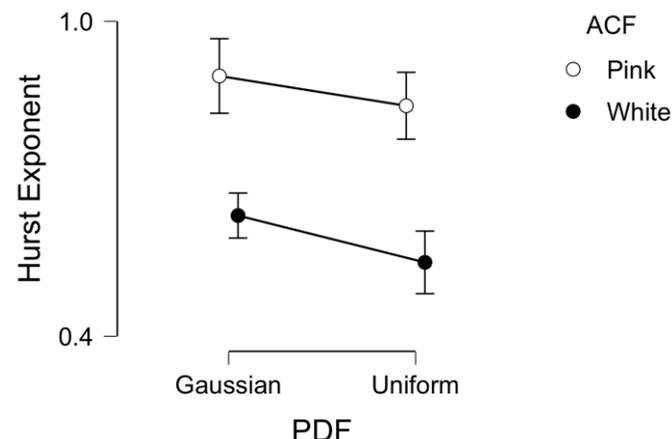

After performing the baseline condition, subjects walked in four pacing conditions. Trial order was randomized. The trials were Pink-Gaussian, Pink-Uniform, White-Gaussian, and White-Noise. Here, Pink and White refer to long-range and zero autocorrelation, respectively. Gaussian and Uniform refer to standard probability distributions. The noises were delivered as a visual stimulus. A small video screen was attached to a pair of glasses to allow the subject to see the screen with their right eye, and the environment with their left eye. The stimulus screen consisted of two fixed horizontal bars, one on the top and one on the bottom of the display. A third moving horizontal bar was placed between the two bars and moved up and down. When the bar reached the top, the subject was instructed to strike with their right heel while walking. The moving bar timing was based on the mean and standard deviation of the subject’s preferred walking speed, and the statistical properties

implied by each experimental condition (e.g., Pink-Gaussian). All trials lasted for 12 minutes.

**Analysis Strategy.** Stride time series were analyzed using Detrended Fluctuation Analysis in order to compute the Hurst exponent, a measure of statistical persistence. Experimental data were analyzed with  $2_W(\text{ACF: Pink, White}) \times 2_W(\text{PDF: Gaussian, Uniform})$  ANOVA.

## RESULTS AND DISCUSSION

That statistical analysis revealed a main effect of ACF,  $F(1,9)=93.16$ ,  $p<0.001$ , as well as a main effect of PDF,  $F(1,9)=6.35$ ,  $p<0.05$ . The two-way interaction was not significant. These results show that the Hurst exponents were larger in the Pink condition than in the White condition. Similarly, Gaussian distributions produced larger Hurst exponents than did Uniform conditions.

**Figure 1:** Hurst exponent as a function of autocorrelation and probability distribution functions.

## CONCLUSIONS

In this study, we investigated the relative influence of autocorrelation and probability distribution functions on gait variability. These results suggest that both ACFs and PDFs provide relevant information that influences the time-varying structure of stride time intervals. Importantly, these properties appear to exert their influence in a relatively independent manner. Future research will investigate a broader range of ACFs and PDFs and their relevance to pathological gait.

## Introduction

The nervous system maintains an internal model that predicts outcomes of current motor commands and plans future movement [1]. After limb loss, this model adapts to changes in the limb and sensorimotor feedback, but deficits and sensory misperceptions remain. For example, affected side toe clearance is less than that on the intact side, and has been linked to tripping [2]. Restoring sensorimotor feedback could help reduce deficits and improve internal model predictions. Our team previously developed a sensory neuroprosthesis (SNP) that delivers electrical stimulation to amputees' residual nerves to induce sensations of foot sole pressure [3]. We used a virtual obstacle crossing task to test the hypothesis that amputees would clear obstacles with their prosthesis more similarly to their intact side when receiving restored sensory feedback.

## Methods

Two below-knee amputees (Par1, Par2) who had received 16-contact nerve cuff electrodes in their residual limbs walked on a split-belt treadmill at their self-selected walking speed while viewing a virtual path (V-Gait, Motek Medical). Each participant's SNP interfaced with their everyday prosthesis. We identified electrode contacts and stimulation parameters that produced somatosensory percepts in the toes and heel of the missing foot. Sensation onset and intensity were linked to pressure readings from matching locations on instrumented shoe insoles. Body position was recorded using a 10-camera motion capture system (Nexus 1.8.5, Vicon). Obstacles of 3 different heights were presented on one side of the virtual path in a random order a total of 7 times each per trial. Two trials each were collected with obstacles presented on the intact and affected sides, and trial order was randomized. Maximum toe height during steps over obstacles was measured. All trials were repeated with the SNP active and inactive. Statistical comparisons for each participant were made with 3-way ANOVAs (leg, obstacle, SNP active/inactive) with Bonferroni-corrected post-hoc tests.

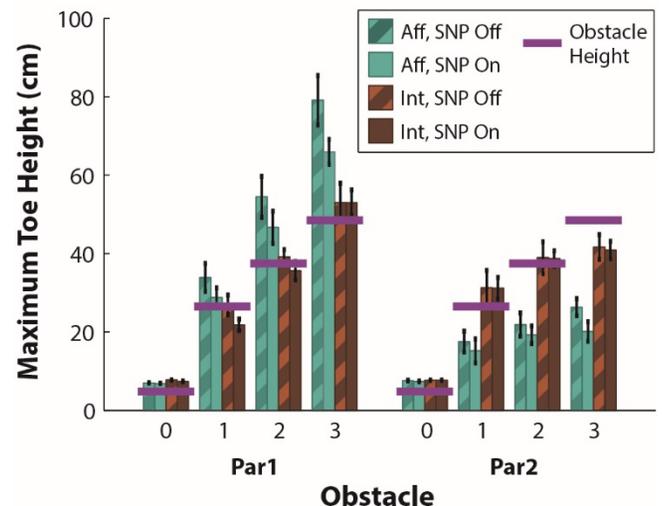

## Results and Discussion

With the SNP off, Par1 stepped higher with his affected limb than with his intact limb, overshooting the obstacles ( $p < 0.001$ , Figure 1). With the SNP on, maximum toe height decreased for both legs, decreasing affected side overshoot of true obstacle height ( $p = 0.0002$ , Figure 1). Par2 undershot obstacles with his affected leg ( $p < 0.001$ ), slightly more so when the SNP was turned on (Figure 1).

Both participants decreased their maximum toe height when receiving SNP feedback. Interestingly, Par2 did this despite already undershooting the obstacles. Par1's affected side toe clearance became more similar to that of his intact side. This suggests that with SNP feedback, amputees' perceived ability to clear obstacles improved (i.e., they felt that they could safely step over an obstacle with their foot closer to it). Able-bodied persons balance minimizing energy expenditure and

maximizing foot clearance when crossing obstacles [4]. It is possible that the amputees shifted away from seeking additional clearance in favor of decreasing energy expenditure while using the SNP. It would be interesting to measure energy expenditure during this task.

The amount that participants lifted their foot to clear a virtual obstacle could be linked to their perception of their foot's location. Amputees often perceive that their phantom recedes proximally [5] and that the leg is shorter than it truly is. Previously, after a month of receiving sensory stimulation, Par1 reported that his missing foot moved from the end of his stump to the floor; Par2 reported that his foot remained tied to the end of his stump [3]. Par2's perception that his leg is shorter than it is may have caused him to undershoot the virtual obstacles.

**Figure 1:** Example toe marker maximum height in unobstructed walking (0) and when stepping over virtual obstacles of different heights (1, 2, 3) for two participants. Results for stepping with the intact leg (brown, Int) and the affected leg (green, Aff) when the SNP was inactive (striped bars, Off) and active (solid bars, On) are shown.

## Significance

Sensory neuroprostheses can provide feedback that influences motor control decisions and movement planning.

## Introduction

Visuomotor adaptation is a learning process that allows us to maintain movement accuracy (e.g., foot placement). We previously showed that visuomotor adaptation to mismatched visual feedback between two legs (i.e., ‘virtual’ split-belt) can alter gait symmetry during treadmill walking.<sup>1</sup> The objectives of the current study were to examine the effects of rewarded and punished reinforcement feedback on ‘virtual’ split-belt adaptation during (1) initial exposure, and (2) re-adaptation 24 hrs after initial adaptation. Based on previous studies using upper limb tasks,<sup>2,3</sup> we hypothesized that rewarded feedback will show greater adaptation and faster re-adaptation compared to those with punished feedback, and those without reinforcement feedback.

## Methods

27 healthy young adults ( $20.4 \pm 2.5$  yrs) walked with visual feedback of toe position and stepping targets, where the visuomotor gain (VM gain; i.e. relationship between treadmill and screen space) was altered for each leg separately. All participants completed two sessions, ~24 hrs apart. Each session consisted of (1) 5 min familiarization (no visual feedback); (2) 300 steps pre-slow baseline (VM gain 0.9:0.9), (3) 300 steps pre-fast baseline (VM gain 1:1), (4) 600 steps adaptation (VM gain 0.9:1) with targets on the side with lower gain moving slower than the other, (5) 600 steps post-adaptation (VM gain 1:1). Participants were randomly assigned to control (CON;  $n = 9$ ; did not receive scores), reward (REW;  $n = 9$ ; received scores that increased by 1 for each accurate step  $\pm 4$  cm target), and punishment (PUN;  $n = 9$ ; received scores that decreased by 1 for each inaccurate step  $> 4$  cm from target) groups. Scores were presented during the adaptation periods.

Normalized step length symmetry was calculated for each stride and averaged across each baseline (first 10 strides), early and late adaptation (first and last 10 strides, respectively), and early and late post-adaptation. We measured the storage of adaptation (i.e., after-effects) as the % ratio between early post-adaptation and late adaptation on day1. The difference ( $\Delta$ ) in symmetry during early-adaptation between day2 and day1 was calculated to quantify difference between initial and re-adaptation.

## Results and Discussion

All participants altered step length symmetry during ‘virtual’ split-belt walking. During adaptation, participants altered their gait mechanics so that the slow leg (VM gain = 0.9) gradually took longer step lengths. During post-adaptation, after-effects were observed, and step lengths gradually returned to symmetry.

Day 1 (initial adaptation): There were no significant group differences in the adaptation of step length symmetry ( $F(2,24) = 1.0$ ,  $p=0.4$ ; Fig. 1a). There were also no significant group differences in %after-effects of step length symmetry ( $F(2,24)=2.9$ ,  $p=0.8$ ; not shown), suggesting reinforcement

feedback does not affect the acquisition phase of walking adaptation.

Day 2 (re-adaptation): PUN showed significantly greater step length symmetry on day 2 compared to day 1 ( $t(8) = 6.0$ ,  $p<0.001$ ). This between-session difference in early adaptation was not significant for CON ( $t(8)=1.9$ ,  $p = 0.1$ ) or REW groups ( $t(8)=-0.4$ ,  $p=0.7$ ). Faster re-adaptation in PUN may reflect consolidation of motor adaptation.<sup>4</sup>  $\Delta$  SL symmetry between day2 and day1 was significantly greater in PUN compared to REW ( $p = 0.014$ ; Fig. 1B). In contrast, previous studies have shown that reward (but not punishment) enhances learning and consolidation of upper extremity motor tasks.<sup>2,3</sup> Our results suggests that reinforcement feedback may affect upper extremity and locomotor adaptation differently.

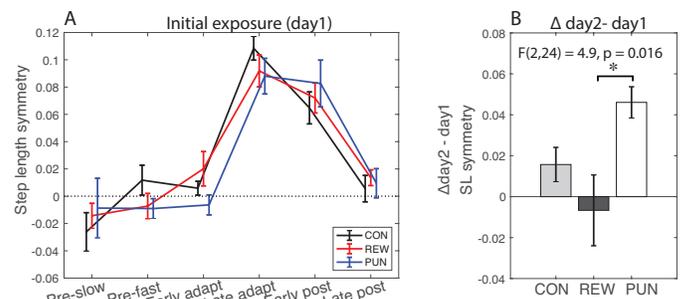

Figure 1: Average SL symmetry during initial exposure (A) and  $\Delta$ SL symmetry between day2 and day1 (B) with SE for CON, REW, and PUN. \* indicates group differences  $p < 0.05$ .

Overall, our results suggest that reinforcement feedback alters re-adaptation, but not initial exposure to visuomotor walking adaptation.

## Significance

‘Virtual’ split-belt paradigm may be a potential alternative intervention to address spatially asymmetrical gait. To maximize the re-learning with repeated exposure to the intervention, it may be beneficial to give punished reinforcement feedback on lower extremity interventions.

## Acknowledgments

We thank Yeun Hiroi, Maia Schlechter, and Adam Lee for assistance with data collection, and support from NSF award #1753026.

## Introduction

To maintain balance and prevent destabilization, humans utilize anticipatory postural adjustments (APAs) prior to the postural perturbations based on predictions and past experience. APAs involve the activation and inhibition of the trunk and leg muscles and a shift of the center-of-pressure (COP) position [1]. The generation of APAs majorly relies on the availability and accuracy of visual information. However, our previous work showed that young adults could rely on an auditory cue only to generate APAs for an external perturbation similar to that when the visual information was available [2]. Older adults generally have diminished APAs and consequently diminished postural control when postural perturbations occur [3]. In this study, we aimed to train older adults to rely on an auditory cue to generate APAs in response to an external perturbation, and examine the retention of this learning effect after 1 week.

## Methods

Five older adults (3M/2F, mean age  $70.3 \pm 6.6$  years) took part in this pilot study. They were instructed to stand on a force plate and be prepared for an pendulum hitting their front shoulders bilaterally. An additional weight (3% of the body weight) was attached to the pendulum. During the first visit, participants received the external perturbation while vision was available (BLV, 5 trials), and while vision was blocked (BLNV, 5 trials). Then they received training (Tr, 50 trials) when vision was blocked but an auditory cue signaling the moment of the pendulum release was provided. After 1 week, retention (Re) was tested when participants received the perturbation with the vision blocked but the same auditory cue was provided (10 trials).

The moment of pendulum impact (T0) was identified using an accelerometer attached to the pendulum. Muscle activities were recorded from the right tibialis anterior (TA), medial gastrocnemius (MG), rectus femoris (RF), biceps femoris (BF), rectus abdominus (RA), and erector spinae (ES). Muscle latency was defined as the first time point within a window of 50 ms that the EMG amplitude was consistently greater (activation) than or smaller (inhibition) than its baseline value (-500 to -350ms)  $\pm$  2SD. The COP

displacements in the anterior-posterior direction at T0 and its peak value after T0 were identified.

Data were organized into 5-trial blocks. Data from the BLV, BLNV, last block of training (Tr10), and two blocks of retention (Re1 and Re2) were used for further analysis. A series of one-way repeated measures ANOVAs were conducted. Statistical significance was set at  $\alpha = 0.05$ .

## Results and Discussion

In BLV condition, latencies of the muscles were detected prior to T0. In the BLNV condition, the latencies were detected mostly after T0. In the Tr10 and Re2 conditions, latencies were comparable to that of the BLV condition. Statistical analysis showed significant differences among conditions for the latencies of TA, MG, RF, BF, and ES (all  $p < 0.05$ ).

When vision was available (BLV), older adults moved their COP posteriorly prior to the perturbation impact (APA phase) and demonstrated a small peak displacement after the physical contact of the pendulum. In the BLNV condition, the COP at T0 was close to 0, and the peak displacement was larger. Statistical analysis showed significant differences among conditions for COP peak ( $p < 0.05$ ).

These results suggest that after only one session of repetitive training, older adults could learn to generate APAs for an otherwise unpredictable postural perturbation relying on an auditory cue, which also resulted in reduced postural disturbance after the perturbation impact. After 1 week, they partially retained this ability; furthermore, after only 5 repetitions of enforcement, they regained this ability to predict external perturbations relying on an auditory cue only.

## Significance

Auditory cues could be used in a training protocol to improve the generation of APAs and consequently to improve overall postural control in older adults.

# Young Adults Can Learn to Predict Unexpected Posterior Perturbations Using an Auditory Cue

Huaqing Liang, Tippawan Kaewmanee, and Alexander S. Aruin  
Department of Physical Therapy, University of Illinois at Chicago, USA  
Email: [vliang@uic.edu](mailto:vliang@uic.edu)

## Introduction

To reduce the effect of an expected postural perturbation, the central nervous system uses anticipatory postural adjustments (APAs), which include the activation and inhibition of the postural muscles and a slight shift of the center-of-pressure (COP) position [1]. The generation of APAs majorly relies on the availability of visual information, and is learned through past experience. Hence, such protective mechanism to maintain balance is not implemented when perturbation comes from one's back unexpectedly. Our previous work showed that young adults could rely on an auditory cue only to generate APAs for a front perturbation similar to that when vision was available [2]. So the purpose was to evaluate whether adults could learn to generate APAs for an external perturbation coming from the back relying only on an auditory cue.

## Methods

Six young adults (mean age  $31.5 \pm 4.1$  years) participated in this pilot study. They were instructed to stand on a force plate, look forward and be prepared for an pendulum hitting their shoulders bilaterally from the back. An additional weight (3% of the body weight) was attached to the pendulum. At first, the participants received perturbation with no cues provided (baseline, BL, 5 trials). Then they received training (Tr, 50 trials) when an auditory cue signaling the moment of the pendulum release was provided via headphones. After a resting period of 5 minutes, they were tested by receiving the perturbation with the same auditory cue (Test, 5 trials).

An accelerometer attached on the pendulum was used to identify the moment of impact (T0). Muscle activities were recorded from the right tibialis anterior (TA), medial gastrocnemius (MG), rectus femoris (RF), biceps femoris (BF), rectus abdominus (RA), and erector spinae (ES). Muscle latency was defined as the first time point within a 50ms window that the EMG amplitude was consistently greater (activation) than or smaller (inhibition) than its baseline value ( $-500$  to  $-350$ ms)  $\pm$  2SD. The COP displacements in the AP direction at T0 and its peak value after T0 were identified.

Data were organized into 5-trial blocks. Data from the BL, one block from the beginning (Tr1), middle (Tr5), and the end (Tr10) of training, and the Test were used for further analysis. A series of one-way repeated measures ANOVAs were conducted. Statistical significance was set at  $\alpha = 0.05$ .

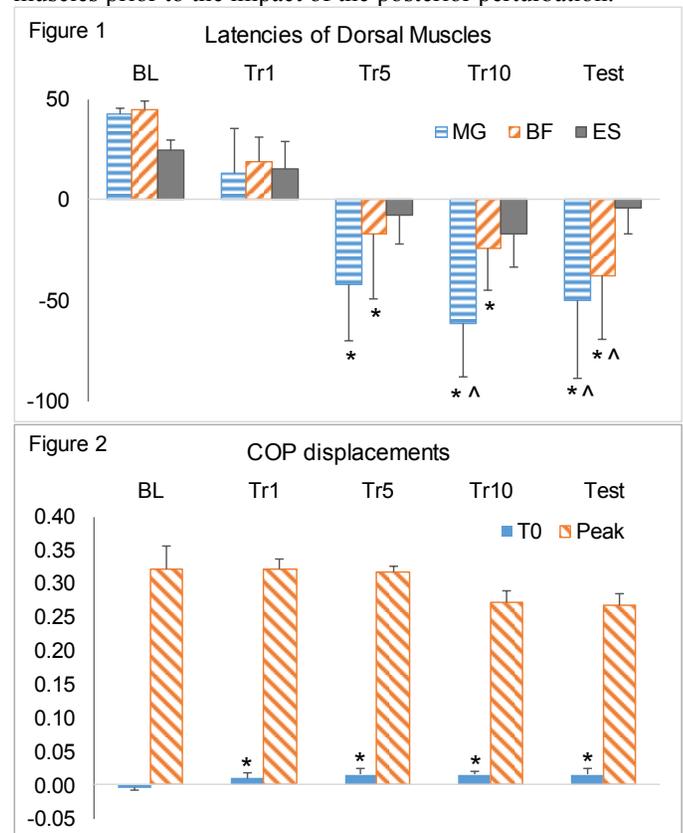

## Results and Discussion

In the BL condition, muscle latencies were detected after T0, COP displacement at T0 was close to zero, and the peak displacement was large. These results suggest that no APAs were generated for an unexpected perturbation coming from the back. After some training (Tr5, Tr10, and Test), muscle latencies were detected earlier and prior to the physical impact of the perturbation, which were more noticeable for the dorsal muscles (Figure 1). Additionally, from Tr1 through Test, a

slight anterior shift of COP was observed at T0 (APA phase), and the peak displacement gradually decreased (Figure 2).

Statistical analysis showed condition effect for latencies of MG and BF, and COP peak displacement (all  $p < 0.05$ ). In Figure 1 and 2, \* and ^ denote a difference compared to the BL and Tr1 condition, respectively.

The activation of frontal muscles and inhibition of dorsal muscles prior to the foreseeable frontal perturbations was reported before [3]. After some training (Tr5, Tr10, and Test), we observed an reverse pattern of early activation of dorsal muscles prior to the impact of the posterior perturbation.

## Significance

After only one session of repetitive training, young adults could learn to generate new APA patterns for an unpredictable postural perturbation relying on an auditory cue. Further study will explore the feasibility of using auditory cues for the generation of APAs and reduction of postural destabilization in response to unexpected external perturbations from the back in individuals with balance problems (i.e. older adults).

## Sex Differences of Motor Units Associated with ACL Injury and Arthrogenic Muscle Inhibition

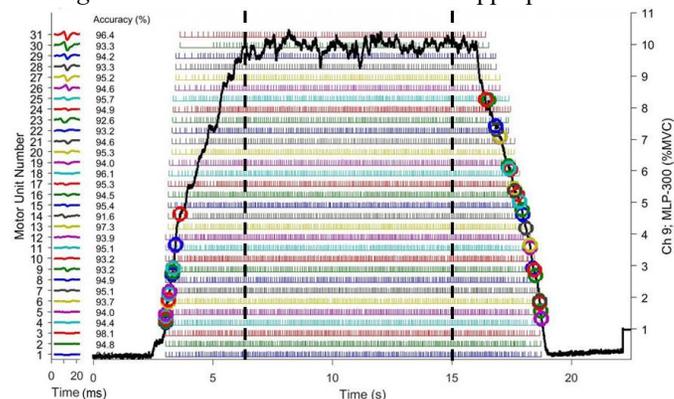

Nathan D. Schilaty<sup>1</sup>, April L. McPherson<sup>1</sup>, Takashi Nagai<sup>1</sup>, Nathaniel A. Bates<sup>1</sup>, Timothy E. Hewett<sup>2</sup>  
<sup>1</sup>Mayo Clinic Biomechanics Laboratories & Sports Medicine Center, Rochester & Minneapolis, MN, USA  
<sup>2</sup>Hewett Consulting, Minneapolis, MN, USA  
 Email: schilaty.nathan@mayo.edu

### Introduction

Females have 4-6x greater risk than males for an anterior cruciate ligament (ACL) injury.<sup>1</sup> ACL injury induces a presynaptic reflex inhibition of joint musculature, termed arthrogenic muscle inhibition (AMI).<sup>2</sup> AMI prevents complete activation of the muscle and may impede long-term recovery. AMI likely manifests differently between sexes and warrants exploration for improved, individualized rehabilitation, especially as females are at higher risk of second injury.<sup>3</sup> The objectives of this study were to determine motor unit (MU) characteristics of thigh musculature between sexes and determine MU adaptations from ACL injury and rehabilitation compared to controls.

### Methods

Decomposed electromyography (dEMG) was acquired with a five-pin array sensor (Delsys *Bagnoli*; Natick, MA) placed on four major thigh muscles from 56 subjects [Female (n=32); Control (n=25)]. ACL subjects were longitudinally assessed at Pre-ACL reconstruction (ACLR), 6-mo, and/or 12-mo post-ACLR. Data was acquired at 20 kHz from isometric contractions (quads, hams) with force measured by a custom load cell apparatus (MLP-300). Acquired dEMG data (band-pass filtered 20 – 1750 Hz) was analyzed with *dEMG Analysis* software to extract average firing rate (Avg FR), inter-pulse interval, recruitment thresholds [% maximal voluntary isometric contraction (%MVIC)], and MU action potential (MUAP) from detected MUs ( $\geq 90\%$  accuracy, **Fig. 1**). Standard least squares analyses were performed in *JMP Pro 14* on data normalized to Force\*Mass (force production dependent on body size). To ensure parametric data for linear regressions, *Cube Root*, *Log*, and *Logit* transformations were selected as appropriate.

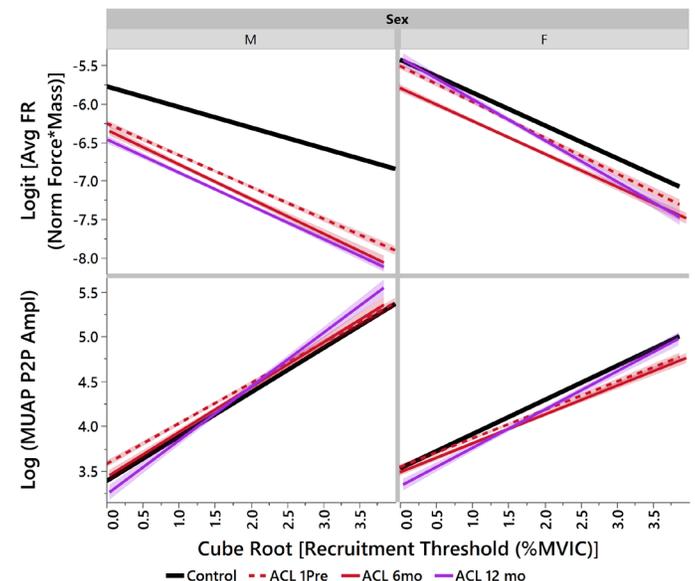

**Figure 1: Isometric Waveform and MU Identification.** With each contraction, the subject followed a trapezoidal waveform with a 3 sec ramp-up, 10 sec hold, and 3 sec ramp-down. The output force is shown (black line). This trial (10% MVC), identified 31 MUs (accuracy  $\geq 90\%$ ). MU recruitment and derecruitment time are denoted by a colored circle while firing pattern is demonstrated by color-matched spikes. Data for this analysis was specifically windowed during the plateau phase of contraction (7–15 sec; dashed lines).

### Results and Discussion

MUs are variably recruited and FR regulated to produce motor control. Regression of Avg FR amplitude by recruitment threshold demonstrated significance of least-squares means for Pre-ACLR, 6-mo, and 12-mo post-ACLR from controls for males and females ( $p < 0.001$ ). Compared to males, females maintained greater Avg FR (**Fig. 2**). Regression of MUAP peak-to-peak amplitude demonstrated significance of higher least-squares means for males at Pre-ACLR ( $p < 0.001$ ) and 6-mo ( $p = 0.02$ ); amplitude was significantly lower for females across all ACLR time points ( $p < 0.001$ ).

### Significance

Decreased Avg FR after injury and across rehabilitation was demonstrated by both sexes, but more prevalent in males. As MUAP amplitude is a surrogate for MU size, females demonstrated smaller MUs than controls. Lack of larger MUs likely leaves females susceptible to further injury with higher demand activities. This information is vital to implement more personalized neuromuscular therapy following ACL injury, especially for females.

**Figure 2: Sex Differences of Quadriceps Avg FR and MUAP Peak-to-Peak Amplitude by Recruitment Threshold.** All  $R^2$  values range between 0.1 – 0.52. Males demonstrated larger MU recruitment and females smaller MU recruitment than controls (MUAP P2P Ampl).

Email: \*[blee24@central.uh.edu](mailto:blee24@central.uh.edu)

## Introduction

The design of shoe-based technologies has the potential to detect hazards leading to falls and alert the user to an impending risk via visual, audible, and/or vibrotactile precues (e.g., [1]). Vibrotactile cueing is possibly the most advantageous because it does not interfere with the visual and auditory cues that also monitor walking. This study evaluates the effect of vibrotactile precues on the user's kinematic recovery performance after unexpected slip perturbations induced by a split-belt treadmill.

## Methods

Our fall-inducing platform incorporating a programmable split-belt treadmill equipped with two force plates (Bertec Corp.) generated slip perturbations by accelerating one of two belts in the anterior direction [2]. A linear vibrating actuator (C2 tactor, Engineering Acoustics Inc.) was placed on the skin of the left lower leg for vibrotactile cueing. A 12-camera motion capture system (VICON, Vicon Motion Systems Ltd.) captured the whole body kinematics from 35 reflective markers.

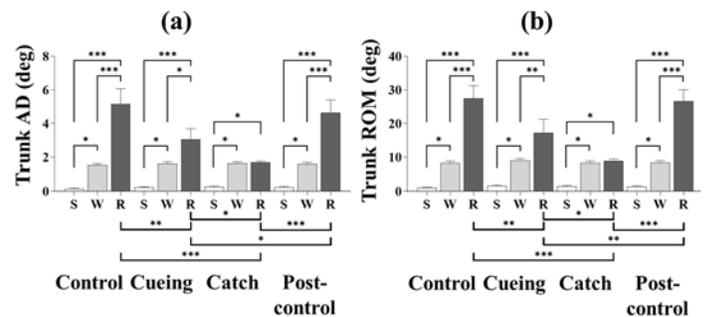

A total of ten healthy young adults (5 females and 5 males) completed 6 experimental trials: 2 consecutive trials without vibrotactile cueing and with a slip perturbation (control trials); 3 trials with vibrotactile cueing (2 trials with the slip perturbation (cueing trial) and 1 trial without the slip perturbation (catch trial)); and 1 trial without vibrotactile cueing and with a slip perturbation (post-control trial). During the control, cueing, and post-control trials, the slip perturbation was randomly applied to the left foot between the 31st and 40th step. Each trial included a standing period, walking period, and recovery period from the perturbation onset to the return to normal walking. The three trials with vibrotactile cueing were randomized.

The Nexus 1.8 ran the Plug-in-Gait model to compute the whole body kinematics. MATLAB (MathWorks) was used to compute trunk angular dispersion (AD) and trunk range of motion (ROM) as an average during the three periods in the sagittal plane. The 2 control trials and 2 trials with vibrotactile cueing were averaged as a function of the period for each participant. Statistical analyses were performed using SPSS (IBM Corp.). A two-way ANOVA determined the main effect of the four trial conditions (control, cueing, catch, and post-control), the three periods, and their interactions for trunk AD and trunk ROM. Post hoc analysis was conducted using the Šidák method.

## Results and Discussion

Figure 1 shows the results of the trunk AD and the trunk ROM, including the statistical significance from the post hoc multiple comparisons. Post hoc analysis showed that trunk AD and trunk ROM were significantly higher during the recovery period than the standing and walking period for the control, cueing, and post-control trials. Post hoc multiple comparisons of trunk AD and trunk ROM were not significantly different between the walking

and recovery periods for the catch trial. Post hoc analysis also showed that trunk AD and trunk ROM were significantly higher during the walking period than the standing period regardless of the trial condition. Post hoc analysis showed that the catch trial had the smallest trunk AD and trunk ROM for the recovery period compared to the other trials.

**Figure 1:** Average trunk AD and trunk ROM as a function of the trial condition and period across all participants. S, W, R indicate standing, walking, and recovery periods, respectively. Error bars indicate standard error of the corresponding mean (\*  $p < 0.05$ , \*\*  $p < 0.01$ , and \*\*\*  $p < 0.0001$ ).

The results confirmed that vibrotactile cueing facilitates the adequate timing of reactive motor responses after a slip perturbation. We assume that a precue constitutes an alert to prepare for motor action in the brain [3]. The results of the catch trial imply that vibrotactile cueing did not trigger anticipatory motor action because the kinematic behavior is not significantly different during the recovery period and the walking period.

## Significance

We believe that our findings can inform the design of wearable technologies that alert users to the risks of falling via vibrotactile cueing, and can assist with developing new gait perturbation paradigms that prompt reactive responses.

# Perceptual Motor Abilities of Professional eSports Gamers

Haneol Kim.<sup>1</sup>, Jianhua Wu<sup>1</sup>

<sup>1</sup>Georgia State University. Email: [hkim162@student.gsu.edu](mailto:hkim162@student.gsu.edu)

## Introduction

eSports is a form of sports primarily using electronic systems (Hamari & Sjöblom, 2017). Players must be able to anticipate a stimulus and react to it as quickly and accurately as possible by manipulating a keyboard and/or a mouse. Playing eSports games demands a high level of perceptual, attentional, cognitive, and fine motor skills (McDermott, et al., 2014). Perceptual motor abilities such as anticipation timing, eye-hand coordination, and peripheral perception are important factors to win a game.

eSports professional players often undergo intensive training at least 10 hours a day. Previous research showed that more experience in playing eSports games enhanced perceptual, attentional, and cognitive skills (Dobrowolski, et al. 2015). However, little is known on the perceptual motor abilities of eSports professional players. Therefore, the purpose of this study was to compare perceptual motor skills between eSports professionals and amateurs. We hypothesized that professionals will show better performance than amateurs in anticipation timing, eye-hand coordination, and peripheral perception.

## Methods

Eight male eSports professionals (age 23.8±1.9 years) and eight male amateurs (24.7±2.1 years) participated in this study. Professionals had an eSports professional experience of 3-10 years. A Bassin anticipation timer was used to provide sequential LED light stimuli at various speeds (1mph, 3mph, 6mph, 9mph). Participants were asked to press a button upon the arrival of the moving stimulus at target. A negative anticipation timing means pressing a button before the arrival of the stimulus and a positive timing means after the stimulus. A rotary pursuit device was used to measure eye-hand coordination: (a) under different directions (clockwise, counterclockwise) and (b) under different tasks (triangle, circle, square). Participants tracked the moving target at 30 rpm with the electronic stylus for 30 seconds and time-on-target was obtained in seconds to quantify eye-hand coordination. Peripheral perception was measured in degrees with a Vienna test system which gave random light stimulus from both the left and right sides and participants responded by pressing the foot pedal. A two-way mixed ANOVA was conducted on anticipation timing and eye-hand coordination duration and a t-test on peripheral perception angle at the significant level of alpha=0.05.

## Results and Discussion

While amateurs generally decreased the anticipation timing with stimulus speed, professionals maintained negative timings (Fig. 1). There was a group by speed interaction ( $p=0.023$ ). A post hoc analysis revealed that professionals had a lower timing than amateurs at 1 mph ( $p=0.001$ ), and amateurs changed the timing from positive to negative from 1mph to 6mph. In general, professional players showed better timing accuracy. Professional eSports players consistently anticipated earlier before the arrival of the stimulus on target across all conditions, which allowed them to defend tactically before the attack of the opponents.

Professionals showed a longer eye-hand coordination duration that amateurs in both clockwise and counter-clockwise directions ( $p=0.014$ , Table 1) and across three tasks ( $p=0.010$ ).

Also, professionals had a wider peripheral perception angle than amateurs ( $p=0.026$ ). The results suggest that multi-year training and playing experience in manipulating a keyboard and/or a mouse rapidly and accurately results in more advanced eye-hand coordination and a wider range of peripheral perception. Overall, the results of this study are consistent with previous studies that professionals show better perceptual motor skills due to their prolonged training and playing.

Fig. 1: Anticipation timing

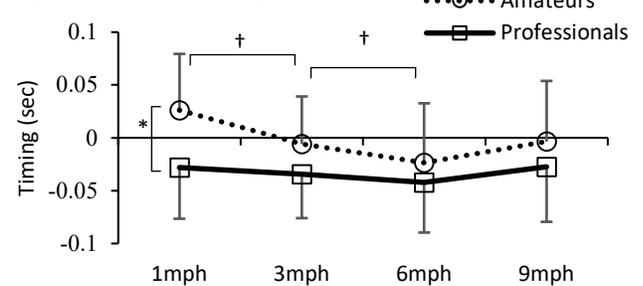

Fig. 1: Means and standard deviations of anticipation timing. Symbol \* denotes a group effect and symbol † denotes a speed effect.

Table 1: Mean (SD) of eye-hand coordination & peripheral perception.

		Professional	Amateur
Direction (sec)	CW	28.92 (1.33)	28.11 (0.83)
	CCW	28.93 (0.97)	27.74 (1.10)
Task (sec)	Triangle	28.90 (1.49)	27.55 (1.65)
	Circle	28.67 (1.19)	27.56 (1.10)
	Square	29.20 (1.10)	28.66 (1.02)
Peripheral perception (°)		165.76 (10.17)	151.34 (12.92)

## Significance

This study provides evidence on advanced perceptual motor abilities in professional eSports players compared to amateurs. This suggests that perceptual motor skills can be manipulated with the number of years and the intensity of training and playing. The improvement in perceptual motor skills can be found in both visual perception and muscular response to a variety of tasks. It is generally recognized that abundant repetitions of motor task training is key to effective training outcomes for individuals with motor deficits. Playing eSports may thus provide a potential rehabilitation paradigm for individuals with perceptual motor deficits. An eSports setting may help increase the enthusiasm of individuals with perceptual motor deficits during training, and the emphasis on timing and accuracy in playing may force these individuals to improve their specific perceptual motor skills.

## Acknowledgments

We would like to thank all the participants.

# The patterning of local variability during the acquisition of a whole-body continuous motor skill in young adults

<sup>1</sup>University of Dayton

Email: mbeerse1@udayton.edu

## Introduction

Initial movement variability when learning a motor skill might enable exploration of the motor space (1). When considering the affect that local variability, e.g. body segment orientation, has on global task variability, e.g. control of center-of-mass (COM), it is possible to partition local variability into two subspaces using an Uncontrolled Manifold (UCM) analysis (2). One subspace of local variability does not affect the global task goal (GEV) and the other subspace of variability affects the global task goal (NGEV). From a motor learning perspective, the GEV represents the implementation of motor solutions to achieve the task goal.

From a motor learning perspective, changes of GEV with practice provide useful interpretations. A reduction of GEV represents a reliance on fewer motor solutions, or exploitation. An increase of GEV represents utilization of more motor solutions. Evidence of both responses have been found, depending on task constraints, for upper limb tasks. However, there is a paucity of evidence for learning whole-body motor skills.

This study aimed to determine how adults modulate local variability during the acquisition of a whole-body continuous motor skill across practice sessions. We evaluated a kettlebell swing because it requires technical proficiency and the hip-hinge motion requires stable COM trajectories across repetitions.

## Methods

Twelve young adults (7F/5M), aged 18-35 years participated. Subjects performed kettlebell swings on five separate days, where we collected data on the first and last day, which were one week apart. We collected data before subjects practiced the kettlebell swing (*no practice*) after subjects performed three practice sets (*immediate*) and one week later after three practice days (*short-term*). The data collection sets consisted of three sets of 20 repetitions and the practice sets consisted of five sets of 20 repetitions. Subjects rested for at least three minutes between sets to minimize fatigue.

For instruction, subjects watched an online video. A sagittal plane view was shown of a demonstration by a skilled individual. The video provided cues of the anterior/posterior (AP) motion of the hips and the vertical motion of the body. Subjects were allowed to view the video as often as they wanted. Subjects received no feedback or cues on their performance.

We collected kinematic data using a Vicon Full-Body Plug-In Gait marker set and a Vicon motion capture system (Oxford, UK). For our UCM analysis we constructed geometric models relating sagittal plane segment angles to AP and vertical COM position. The model consisted of 16 body segment angles, as well as the kettlebell segment angle. We time-normalized each kettlebell swing cycle and conducted a UCM analysis on every 1% of the cycle. Our reference configuration was the average position of the COM at each 1% for that condition.

## Results and Discussion

The position of the COM was more posterior and vertical during the *short-term* condition compared to the *no practice* condition.

Subjects modulated their motor behavior based on the video instruction and in the absence of feedback.

Subjects reduced COM position variance in the vertical direction, but not the AP direction. There might have been a prioritization of the vertical control of the kettlebell swing. Coaching of the kettlebell swing might need to provide cues and feedback on the AP motion, as young adults internally attended to their vertical motion.

Only vertical NGEV decreased from *no practice* to *immediate*. Following initial practice, subjects reduced local variability that affected the vertical COM position, but maintained similar amounts of GEV. This maintenance might represent an exploration of motor solutions that could be beneficial when adapting the motor skill. Interestingly, the subjects who chose to watch the video the most demonstrated the least amount of GEV. This suggests a strategy to adopt a stereotypic movement pattern consistent with the model.

Following *short-term* practice, subjects reduced both AP and vertical GEV. After only a week of practice, subjects began demonstrating a reliance on fewer motor solutions to perform the kettlebell swing. This result suggests a tendency to exploit preferred motor solutions to perform a whole-body motor skill.

	No practice	Immediate	Short-term
AP NGEV	0.004 (0.002)	0.003 (0.001)	0.002 (0.000)
AP GEV	0.026 (0.020)	0.021 (0.021)	0.015 (0.002)*
V NGEV	0.006 (0.002)	0.004 (0.002)*	0.005 (0.001)*
V GEV	0.026 (0.020)	0.021 (0.021)	0.015 (0.018)*

**Table 1:** Mean (SD) of the UCM subspaces for the vertical and AP directions across conditions. \* indicates a significant difference from the *no practice* condition.

## Significance

This study extends the exploration followed by exploitation paradigm, found in motor learning, to a whole-body continuous motor skill. These results could inform motor learning practices for other whole-body tasks, such as locomotion. Considering the tendency for exploitation, identifying techniques to encourage exploration of motor solutions might be pertinent for developing a repertoire of solutions characterized by highly skilled performers (3). In addition, GEV was sensitive to variation of instruction, which would be beneficial when evaluating cueing and feedback techniques for coaching and rehabilitation.

# Adaptation of Leg Forces due to Gradually Introduced Split-Belt Walking in People with Trans-Tibial Amputation

Brian P. Selgrade<sup>1,2,\*</sup>, Young-Hui Chang<sup>1</sup>

## Introduction

People with lower limb amputations exhibit asymmetric step lengths[1], and ground reaction forces [2] during walking. These asymmetries may explain the increased risk of overuse injuries like osteoarthritis on the contralateral, intact side[3].

Split-belt treadmill walking, which involves two side-by-side belts moving at different speeds, has been used to correct baseline step length asymmetries in stroke survivors [4]. These studies use error augmentation, in which the split-belt condition exacerbates the walker's baseline asymmetry. After the split-belt condition is removed, symmetry improves.

We used an error augmentation, split-belt paradigm to induce adaptation of ground reaction forces (GRFs) opposite from a person with amputation's baseline asymmetry. Prior work shows aftereffects in braking GRF, but not propulsive GRF [5]. Since people with amputation adapt to split-belt walking similarly to controls [6], we hypothesized people with amputation and their controls would exhibit aftereffects in braking GRF, but propulsive GRF for both groups would return immediately to baseline levels when the split-belt condition was removed.

## Methods

Eight people with trans-tibial amputation (body weight=77 kg, intact leg length =88 cm) and eight matched controls (body weight=77 kg, leg length =89 cm) gave written, informed consent before participating in this study.

Participants completed a 2-minute, slow baseline trial with both belts moving at 75% of preferred walking speed (PWS) followed by a 90-second fast baseline trial with both belts at 150%PWS and another 90-second slow baseline trial. People with trans-tibial amputation walked with their prosthetic legs on the slow belt as the fast belt was gradually accelerated to 150%PWS from 75%PWS. Participants then walked for 3 minutes with the fast belt at a constant 150%PWS. After a rest, subjects were immediately exposed to both belts at 75%PWS. We compared GRFs, step length symmetry, double support times and stance times of the first 5 steps of post-adaptation to the last 5 steps of the 75%PWS baseline trials using repeated measures ANOVA and post hoc t-tests with Bonferroni corrections (alpha=0.0167).

## Results and Discussion

With the fast (intact) leg, people with amputation and controls had significantly higher peak braking force in early post-adaptation than at baseline (Figure 1), supporting the hypothesis. However, both subject groups also had significantly lower fast leg peak propulsive force in early post-adaptation than at baseline or in late post-adaptation, which does not support the hypothesis and conflicts with previous results on GRF adaptation in healthy people [5]. This indicates that propulsive and braking forces during walking are controlled predictively, and that this control is not impaired by trans-tibial amputation. Thus, this study provides proof of principle that split-belt, error augmentation paradigms can alter kinetic asymmetry in those with amputation.

Overall, people with amputation adapted similarly to their matched controls. Both groups had significant aftereffects of step length symmetry, double support time when the fast leg was leading, and single leg stance time. These data support prior findings that people with amputation adapt to split-belt walking similarly to controls [6, 7] and extend these results to adaptation of temporal, interleg coordination (double support time).

## Significance

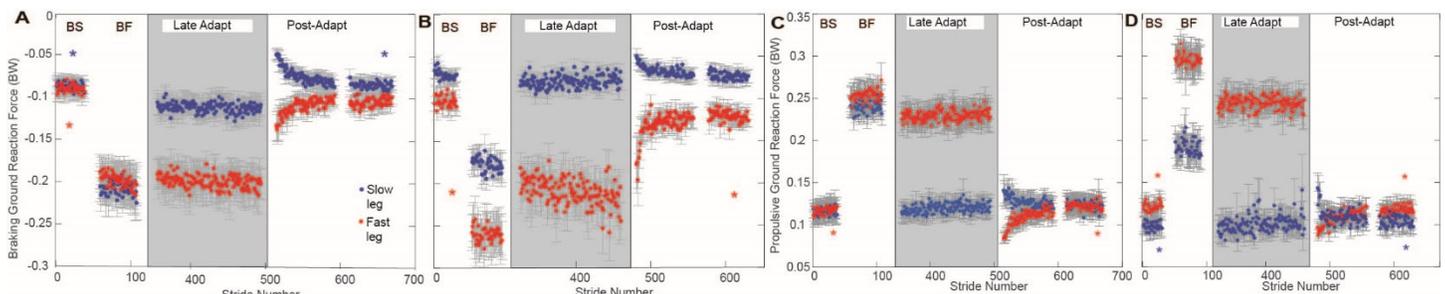

These findings show that people with amputation can adapt their propulsive and braking forces to split-belt walking. Error augmentation caused lower propulsive and higher braking force aftereffects in the intact leg. This may not be preferable clinically, since the intact side, already at risk for osteoarthritis, increased braking force. Future work should determine joint kinetics associated with these changes in GRFs.

### Introduction

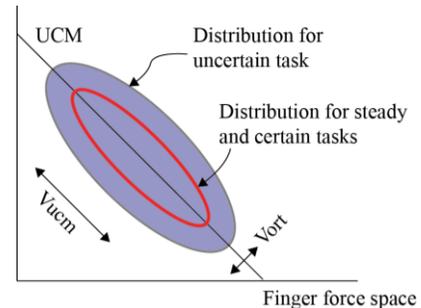

Motor systems are frequently redundant, where numerous input variables contribute to achieve a motor task. Redundant motor systems display compensatory behavior in which errors in some input variables are compensated by changes in others so that the task-specific output variables are stabilized [1]. Such synergistic covariation that stabilizes task variables will also resist any volitional changes in those variables. However, anticipatory synergy adjustments (ASAs) are seen in many tasks: synergies weaken when individuals prepare to voluntarily change their motor state [2]. Furthermore, ASAs occur in response to the mere expectation of an upcoming change, and even when the timing and the nature of the change are uncertain [3]. The mechanisms for weakening a synergy are lower task-preserving covariation in the inputs, increased variability in the inputs that yields higher variability in the task variables, or both. However, it is not known whether such uncertainty in the upcoming motor change influences the magnitude or the mechanism through which ASAs occur. Therefore, the objective of this study was to compare the ASA magnitude in isometric finger force production tasks with and without uncertainty, and to identify whether the ASAs occur via similar mechanisms in both cases.

### Methods

Fourteen right-handed participants (21.6±2.4 yrs) participated in the study. They produced forces with the distal phalanx of their right-hand fingers pressing down on four force sensors (Nano 17, ATI Automation). They produced a total force ( $F_T$ ) – the sum of the finger forces – to track targets presented on a computer screen in three types of tasks. All tasks began with the participant producing 10% of their maximum voluntary contraction (MVC, measured earlier). In the steady task, a square target appeared at the 10% MVC level and never moved. Participants knew that the target will not move for this task. In the uncertain task, trials began with the target at 10% MVC and began moving vertically after a random time interval. The participants knew that the target will begin to move at any time and in any direction. In the certain task, participants first produced 10% MVC force, and then produced a quick  $F_T$  increase after a fixed, predefined time interval. Each task was repeated 15 times.

The finger forces prior to any change in  $F_T$  away from 10% MVC in each task were analyzed using the uncontrolled manifold (UCM) method [1]. The 15 trials for each task yield a distribution in the 4D space of finger forces. The across-trial variance in the forces was partitioned into a component that does not change  $F_T$  (along the UCM,  $V_{UCM}$ ), and another component that changes  $F_T$  (orthogonal to the UCM,  $V_{ORT}$ ). A synergy index was computed as  $\Delta V = (V_{UCM} - V_{ORT}) / (V_{UCM} + V_{ORT})$ , which was then z-transformed ( $\Delta Vz$ ) for statistical analysis.  $\Delta Vz > 0$  implies  $V_{UCM} > V_{ORT}$ , and indicates the presence of a synergy (Fig. 1). Higher  $\Delta Vz$  indicates stronger synergy and vice versa. We computed the change in  $\Delta Vz$  for the certain/uncertain tasks relative to the steady task (i.e., the difference variable  $\Delta\Delta Vz$ ). We also quantified the change in the variance components across the certain/uncertain tasks and the steady task:  $\Delta V_{UCM-certain} = (V_{UCM-$

$certainty - V_{UCM-steady}) / V_{UCM-steady}$ ,  $\Delta V_{UCM-uncertain} = (V_{UCM-uncertain} - V_{UCM-steady}) / V_{UCM-steady}$ , and similarly for  $V_{ORT}$ . One-sample t-tests were used to test if the difference variables  $\Delta\Delta Vz$ ,  $\Delta V_{UCM}$  and  $\Delta V_{ORT}$  were significantly different from zero.  $\Delta\Delta Vz > 0$  will indicate the presence of ASA, and significant changes in  $V_{UCM}$  and  $V_{ORT}$  will indicate the change in the variance structure - the specific mechanism - that yields  $\Delta\Delta Vz$ .

**Figure 1:** Finger force distributions indicating synergies that stabilize total force. Red ellipse is the distribution for the steady and certain tasks. Large ellipse is the distribution for the uncertain task.

### Results and Discussion

$\Delta\Delta Vz$  was not significantly different from zero for either the certain or the uncertain task ( $t_{(13)} > 0.23$ ;  $p > 0.22$ ), indicating that ASA was not observed in our data. This was due to large individual differences, with six of the 14 participants exhibiting ASAs. On the other hand, task uncertainty had a consistent effect on variance structure.  $V_{UCM}$  and  $V_{ORT}$  for the certain task were not different from those for the steady task ( $t_{(13)} > 0.89$ ;  $p > 0.06$ ). In contrast, they were larger for the uncertain task compared to the steady task ( $\Delta V_{UCM-uncertain}$  and  $\Delta V_{ORT-uncertain} > 0$ ,  $t_{(13)} > 2.79$ ;  $p < 0.02$ ). Thus, the absence of ASA for the certain task arose from consistent variance components across the two tasks, whereas the absence of ASA for the uncertain task arose from compatible increases in  $V_{UCM}$  and  $V_{ORT}$  in the uncertain task (Fig. 1). Increased  $V_{UCM}$  has been associated with greater flexibility of task performance, and greater  $V_{ORT}$  has been associated with lower stability of the current task [1,2,3]. Both these mechanisms likely assist in the preparation for the uncertain change in  $F_T$ .

### Significance

Investigating the performance of ill-defined or uncertain tasks provides insights about the control of finger forces. In particular, investigating changes in the variance structure (rather than just ASA) is critical for understanding the influence of task uncertainty on finger force production. Changes in variance components and individual differences in ASAs may be relevant for preventing loss of manual dexterity with aging.

## Effects of asymmetrical footwear height on gait kinetics and kinematics

Sumire Sato<sup>1,2\*</sup>, Maia Schlechter<sup>2</sup>, Adam Lee<sup>2</sup>, Wouter Hoogkamer<sup>2</sup>

<sup>1</sup>Neuroscience and Behavior program, <sup>2</sup>Department of Kinesiology, University of Massachusetts, Amherst

Email: \*[ssato@umass.edu](mailto:ssato@umass.edu)

### Introduction

Asymmetrical stance phases and weight-bearing are common in patients with unilateral impairments such as post-stroke.<sup>1,2</sup> Studies have shown that interventions with unilateral shoe inserts may improve weight-bearing and stance time symmetry, and gait speed.<sup>3-5</sup> However, it has not been established whether humans slowly adapt and store kinetics and kinematics with asymmetrical shoe height. If humans are able to adjust to footwear with asymmetrical height and store new gait patterns this may aid in the development of novel therapeutic footwear.

The objective of this study was to examine adaptations in (1) vertical ground reaction force impulse and (2) stance time imposed by asymmetric shoe heights. Based on previous clinical studies, we hypothesized that early during adaptation with asymmetrical shoe height the leg with the shoe insert will (1) exert less force,<sup>4,5</sup> and be in shorter stance phase,<sup>3</sup> but will regain symmetry later during adaptation.

### Methods

11 Healthy young adults ( $21.2 \pm 3.1$  yrs, 3 males) participated in this study. Participants walked on an instrumented treadmill at 1.3 m/s for four conditions: (1) 5 min with equal shoe height for familiarization on the treadmill, (2) 5 min baseline pre-test with equal shoe height, (3) 10 minutes adaptation with one leg with a 1cm shoe insert in one side (leg with shoe insert = “high leg”; other leg = “low leg”), (4) 10 minutes post-adaptation with equal shoe height. The side with the shoe insert during adaptation was randomized between participants.

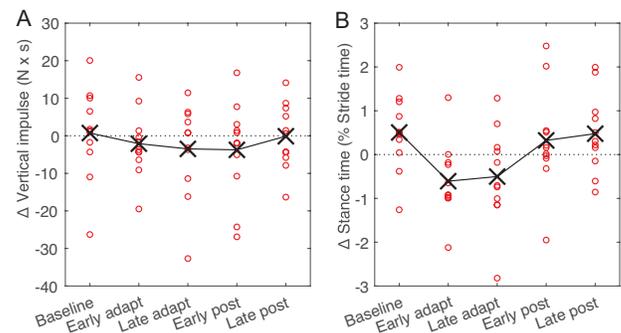

To calculate the vertical impulse, ground reaction forces (GRF) were low-pass filtered (15 Hz, 3<sup>rd</sup> order Butterworth) and normalized to body weight. The integral of GRF were calculated for each stance phase. Stance times were normalized to stride time. The difference ( $\Delta$ ) between legs (low leg – high leg) was calculated for the vertical impulse and normalized stance times to quantify symmetry and then these were averaged across first 50 strides for baseline, first 50 and last 50 strides for adaptation and post-adaptation. To examine between-condition differences, we

used a repeated-measures ANOVA with a Bonferroni post-hoc test.

### Results and Discussion

In general, participants did not alter vertical impulse symmetry, but altered stance time symmetry with asymmetrical shoe heights (Fig. 1).  $\Delta$  Vertical impulse was not different between conditions ( $F(4,40) = 0.73$ ,  $p = 0.580$ ), but  $\Delta$  Stance time was different between conditions ( $F(4,40) = 14.19$ ,  $p < 0.001$ ).  $\Delta$  Stance time during early and late adaptation was lower compared to baseline ( $p = 0.005$ , Mean difference (MD) = -1.1%;  $p = 0.001$ , MD = 1.0%), early post-adaptation ( $p = 0.031$ , MD = -0.9%;  $p = 0.021$ , MD = -0.8%), and late post-adaptation ( $p = 0.009$ , MD = -1.1%;  $p = 0.025$ , MD = -1.0%; Fig. 2).

We were surprised to find that stance time symmetry but not vertical impulse symmetry was significantly different during adaptation compared to baseline. This may suggest that humans prioritize force symmetry and alter stance symmetry to accommodate different shoe height. The immediate change in and nonsignificant difference in baseline and early-post stance symmetry (i.e. little to no aftereffect) suggests that healthy humans may employ reactive strategies to accommodate the change in footwear height.

**Figure 2:** Group mean for vertical force impulse (A) and stance time symmetry (B). Red o's indicate data from each participant. Dotted line at 0 indicates perfect symmetry.

### Significance

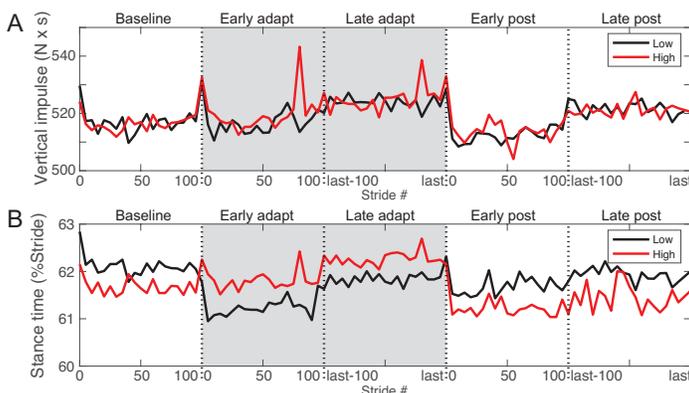

Asymmetrical footwear may alter temporal gait mechanics, but may not induce long-term neuroplastic changes. However, based on the variability we observed, more studies should be done on long term exposure to different asymmetrical footwear.

# Movement Variability During Dynamic Tasks In Individuals After Anterior Cruciate Ligament Reconstruction

Xenia Demenchuk, Jennifer Perry, Robert A. Siston, Laura C. Schmitt  
 The Ohio State University, Columbus, OH, USA  
 Email: [demenchuk.1@osu.edu](mailto:demenchuk.1@osu.edu)

## Introduction

Individuals who undergo anterior cruciate ligament reconstruction (ACLR) often experience suboptimal post-operative outcomes<sup>1</sup> such as high risk of reinjury<sup>5</sup>, low levels of returning to former level of sport<sup>1</sup> and increased risk of developing knee osteoarthritis<sup>2</sup>. Abnormal knee motion and movement patterns<sup>3,8</sup> have been observed following ACLR and rehabilitation which may be the cause for these suboptimal results<sup>3</sup> and is not currently considered in return to sport criteria<sup>7</sup>. The dynamic movement theory<sup>3</sup> proposed that there is a preferred range for movement variability; variability that is too high can lead to instability and reduced adaptability to environmental demands while variability that is too low is accompanied by lower ranges of motion. This theory into dynamic movements has been used in gait studies post-ACLR<sup>3,4</sup> but has not yet been used to analyze more demanding dynamic tasks, such as jumping and landing, that are commonly performed by the young, active cohort with ACL injuries. Further understanding of movement variability after ACLR during demanding tasks could provide additional insight into the suboptimal outcomes of this patient population. Therefore, the purpose of this study was to compare lower extremity movement variability during a single leg drop test between young individuals who have undergone ACLR (ACLR group) and a Control group. We hypothesized that both limbs of the ACLR group would show increased movement variability compared to Controls, and that within the ACLR group, the involved limb would have increased movement variability compared to the uninvolved limb.

## Methods

As secondary analysis of an ongoing, prospective study<sup>8</sup>, data from a total of 100 participants after primary, unilateral ACLR (ACLR group) (M/F 30/70; 17.65±2.7 y; 168.1±10.4 cm; 66.9±14.8 kg) and 55 uninjured participants (Control group) (M/F 15/40; 17.1±2.3 y; 166.4±8.9 cm; 61.5±12.1 kg) were analyzed. All participants, or parents/guardians, provided written informed consent. The ACLR group participated within 4 weeks after medical clearance for return to sports. Three-dimensional motion analysis was used to collect lower extremity kinematic data during the single leg drop test; three trials were collected per leg. A 10-camera motion analysis system (240 Hz cameras; Motion Analysis Corp., Santa Rosa, CA, USA) was used to track 37 retroreflective markers on the upper and lower extremities and trunk of each participant. The landing phase, defined as initial contact to lowest position of the center of gravity, was examined. A vector coding technique<sup>3</sup> was used to calculate coupling angles between two adjacent joints to form an angle-angle curve of angular displacements of the proximal and distal joints (Table 1) for each trial. The overall root mean square of the resulting circular standard deviation at each time point across the three trials was computed to represent the within-subject and within-limb variability. A paired Wilcoxon signed-rank test was used to compare the involved/uninvolved sides of the ACL group and a Mann-Whitney U test was used to compare both of the involved and uninvolved sides to the dominant side of Controls.

## Results and Discussion

Increased coordination variability was found in both limbs in the ACLR group when compared with Controls which supports our first hypothesis (Table 1). These findings support Devis et al<sup>3</sup> which found increased movement variability in HR/KR, HA/KR and HR/KA for the involved limb during walking and in HA/KR, HR/KR and HR/KA in the uninvolved limb when compared to healthy controls. In this study, more joint couplings showed variability during the single leg drop which suggests that the more demanding movement leads to higher instability and reduced adaptability<sup>3</sup>. We reject our second hypothesis, as there was not a significant difference between the injured limb when compared to the uninjured limb, which only showed an increase in variability in one joint coupling.

**Table 1:** Difference in Joint Coordination Variability

Symbols indicate statistical difference in: IC – injured leg vs. control; UC – uninjured leg vs. control; IU – injured leg vs. uninjured leg

Coupling	Variability (Mean ± STD of RMS)			p-Value < 0.05
	Injured	Uninjured	Control	
Hip Abduction-Adduction/Knee Abduction-Adduction (HA/KA)	0.835±0.252	0.823±0.273	0.691±0.234	IC, UC
Hip Abduction-Adduction/Knee Rotation (HA/KR)	0.855±0.247	0.835±0.26	0.69±0.248	IC, UC
Hip Flexion-Extension/Knee Abduction-Adduction (HF/KA)	0.821±0.237	0.749±0.251	0.739±0.222	IC, IU
Hip Flexion-Extension/Knee Flexion-Extension (HF/KF)	0.662±0.233	0.607±0.25	0.525±0.228	IC, UC
Hip Rotation/Knee Abduction-Adduction (HR/KA)	0.972±0.227	0.955±0.269	0.863±0.26	IC, UC
Hip Rotation/Knee Rotation (HR/KR)	0.928±0.234	0.918±0.25	0.782±0.262	IC, UC
Knee Abduction-Adduction/Knee Flexion/Extension (KA/KF)	0.704±0.234	0.652±0.222	0.575±0.207	IC, UC
Knee Abduction-Adduction/Knee Rotation (KA/KR)	0.947±0.23	0.913±0.256	0.831±0.247	IC, UC
Knee Flexion-Extension/Ankle Flexion-Extension (KF/AF)	0.598±0.239	0.558±0.246	0.437±0.189	IC, UC

## Significance

The increased bilateral movement variability observed may be an indicator for the risk of injury in more dynamic tasks and could contribute to the suboptimal outcomes seen in the ACLR population. Further research needs to be done on the impact that changes in coordinative strategies play on ACLR patients' outcome, which may inform new rehabilitation practices and return to sport criteria

## Introduction

Musculoskeletal injuries due to repetitive stress and falls remain a pervasive threat to soldier readiness<sup>1</sup>. A proposed culprit, load carriage, is a common encumbrance to military occupational tasks. Soldiers are often required to traverse large distances utilizing a forced march (FM) locomotion pattern, walking at a velocity exceeding their gait transition velocity (GTV), in conjunction with load carriage. A lack of motor variability and gait complexity while executing steady state ambulation may reduce the ability to disperse forces across multiple supportive structures. Moreover, suboptimal organization of the locomotor system components and limited movement solutions impedes adaptability/stability to perturbations. However, there is a paucity of information regarding load carriage and motor control. The purpose of this study was to determine the interactive effect of load magnitude and locomotion pattern on motor variability, stride regulation and gait complexity in recruit-aged females. It was hypothesized that increases in load and FM would reduce motor variability and gait complexity but yield stricter stride regulation.

## Methods

Eleven healthy recreationally active females (24.8±2.2 years) participated in this IRB-approved study. Biomechanical data was collected via twelve infrared cameras (Vicon Motion Systems Ltd., Oxford, UK) and an instrumented dual-belt treadmill (Bertec, OH, USA) at 100Hz and 1000Hz respectively. Participants wore standard issue military combat boots and an evenly distributed anterior/posterior weight vest. One minute of running and forced marching (FM) was performed at a velocity 10% above GTV for three load conditions; unloaded (BW), +25% and +45% of their bodyweight. Strides were considered heel strike (50N threshold) to ipsilateral heel strike. Stride length (SL) and stride time (ST) were calculated for a minimum of 120 consecutive strides. Motor variability and stride regulation were assessed with goal equivalent manifold (GEM) decomposition<sup>2</sup>. GEM generates tangential ( $\delta_T$ ) [good] and perpendicular ( $\delta_P$ ) [bad] coordinates of stride variations on a goal manifold based on combinations of observed SL and ST. Relative variability is then calculated as  $\sigma\delta_T/\sigma\delta_P$ ;  $\sigma$  represents standard deviation. Stride regulation was assessed with detrended fluctuation analysis (DFA) of  $\delta_T$  and  $\delta_P$  time series, which yields a scaling exponent ( $\alpha$ ). Gait complexity was assessed with DFA of SL and ST time-series. Suboptimal complexity is  $\alpha < .75$  and  $\alpha > 1.3$ , while  $\alpha = .75-1.3$  represents optimal. Two-way RMANOVA (load x locomotion) was conducted for relative variability and SL/ST scaling exponents. Three-way RMANOVA was (load x locomotion x direction) conducted on  $\delta_T/\delta_P$ . Post hoc Bonferroni corrected pairwise comparisons were performed for load. Estimated marginal means reported for effects of locomotion and direction (tangential vs perpendicular).

## Results and Discussion

*Motor Variability:* For relative variability, there was a main effect of load ( $p=.01$ ), with +45% (1.28±.05) having less ( $p=.02$ ) relative variability than BW (1.55±.07). Additionally, there was a main effect of locomotion ( $p=.01$ ) with FM (1.53±.08) having more relative variability than running (1.27±.04). Reductions in relative variability indicate an increase in stride fluctuations that impede successful task execution. Further, lower relative variability exhibits a limited movement solution capacity. Alternatively, higher relative variability could represent a task learning behaviour of a novel movement in the form of state-space exploration.

*Stride Regulation:* There was a main effect of load ( $p=.002$ ), with BW (.6±.08) exhibiting looser control than +45% (.04±.11). There was a main effect of locomotion ( $p=.02$ ) with FM (.19±.08) exhibiting stricter control than running (.46±.07). There was also a main effect of direction ( $p<.001$ ) with perpendicular (bad) variability (.18±.07) being controlled more tightly than tangential (good) variability (.47±.06). During the steady-state task at greater load magnitudes stride to stride fluctuations were regulated more tightly or overcorrected quickly each stride, evidenced by  $\alpha < .5$  which represents statistical anti-persistence.

*Gait Complexity:* For SL and ST there was a main effect of load ( $p=.002$ ,  $p=.007$ ) with complexity at BW (.69±.08) being greater ( $p=.02$ ,  $p=.03$ ) than +45% (.00±.17). There was a main effect of locomotion ( $p=.02$ ,  $p<.001$ ) with complexity for running (.68±.09) being greater than FM (.11±.14). During running at BW optimal locomotor system output was exhibited ( $\alpha=.96$ ). However, FM+45% constrained the system, resulting in less complexity that could result in a negative outcome (fall/injury) with additional perturbations. Therefore, individuals with +45% load may be unable to accommodate a varying terrain or minor injury sustained during mission due to compromised locomotor system component organization (reduced system redundancy).

## Significance

There were no significant interactive effects, but load magnitude and locomotion pattern did independently alter motor variability, stride regulation and gait complexity. A load magnitude of +45% diminishes motor variability which may predispose individuals to repetitive stress injuries through a lack of energy dispersion across supportive structures. FM compared to running had increased relative variability but less gait complexity indicating a potential lack of movement stability. A +25% load magnitude failed to illicit significant changes in gait motor variability and complexity. Future research should utilize heavier loads and longer trials to investigate role of fatigue.

Email: mcaminit@umd.edu

## Introduction

Understanding the motor synergies developed between two independent central nervous systems (CNS) could provide critical insight into the underlying mechanisms behind many of our interpersonal interactions and inform the mechanisms for future physical human-robot collaborations (PHRCs). Previous research regarding motor synergies focuses almost exclusively on interlimb synergies or the synergies formed within a single CNS [1,2,3]. The motor behaviors elicited when two individuals work together to complete a motor task without any direct neurological connection is unknown. Additionally, the role of sensory information exchanged between co-workers also remains unknown. Therefore, the purpose of the current study is to examine the synergistic performance of a motor task by co-working partners involving handling a heavy object at both the interpersonal and interlimb levels under two conditions: with visual feedback between co-workers and without visual feedback between co-workers. We hypothesize that both interpersonal and interlimb motor synergies exist during this motor task and removal of visual feedback between co-working partners decreases synergistic performance.

## Methods

Twenty-six healthy young adults ( $23.7 \pm 3.7$  yrs) participated in the study comprised of 13 gender and height-matched pairs. The pairs performed a motor task which involved working together to lift, move, hold, and place a heavy, table-like object (Fig. 1). The object was instrumented with four 6-dimensional force/torque sensors (ATI Industrial Automation, Apex, NC) to record the forces and moments of force applied to the apparatus by the individual hands of each participant during task performance. The task was performed under two conditions: a) with visual feedback, where partners were able to see each other, and b) without visual feedback, where a screen occluded vision between partners. The analysis presented is limited to the vertical component of forces during the moving phase of the task.

**Figure 1:** a) Snapshot of co-working partners performing the motor task and b) biomechanical model of the task performance.

## Results and Discussion

Examination of the moving phase of the task reveals interlimb motor synergy is present between the hands of individual person. As described in our previous work [4], negative covariance (Table 1b) indicates the presence of a force-stabilizing synergy at

the interlimb level between hands. Although a significant synergy exists at the interlimb level in both task conditions, there is no significant difference in the magnitude of the synergy with or without visual feedback between co-workers. At the interpersonal level, the positive covariance (Table 1a) suggests synergy between co-workers to maintain rotational stability of the object during the moving phase of the task. The magnitude of the covariance between the two visual conditions is also not significantly different.

**Table 1.** Mean  $\pm$  SD for Covariance: a) between co-working partners (P1 and P2, interpersonal level), and b) between the right (RH) and left (LH) hand of each individual partner (interlimb level).

(a) Interpersonal Level Covariance			
	Visual Feedback	No Visual Feedback	$p$
P1 vs. P2	19.3 $\pm$ 18.41	15.44 $\pm$ 12.30	0.531
(b) Interlimb Level Covariance			
	Visual Feedback	No Visual Feedback	$p$
P1: LH vs. RH	-64.0 $\pm$ 32.9	-66.0 $\pm$ 42.6	0.895
P2: LH vs. RH	-50.9 $\pm$ 36.8	-61.4 $\pm$ 27.7	0.421

On both the interlimb and interpersonal level these findings support our hypothesis that synergies exist at both levels. However, the findings do not support our hypothesis regarding changes in synergistic performance due to the removal of visual feedback between co-working partners. The findings suggest that perhaps the haptic connection between partners moving an object is in fact more critical to successful task completion than the ability to see one another during the moving phase of task at both task levels. Moreover, the lack of a significant difference between visual conditions is fitting on the interlimb level, as one CNS is controlling both hands, and may not need to rely on visual information. At the interpersonal level the formation of a synergy suggests a favoring of moment stabilization and synchronous performance for successful task completion.

## Significance

The findings of this study can have far reaching impact in the fields of human movement science, robotics, and engineering. The demand for PHRCs is increasing rapidly in society, and more so today with the current need for social distancing. Understanding how two human partners work together holds the key to suggesting safer, more intuitive, and efficient mechanisms for future human-robot collaborations.

E-mail: c.hasson@northeastern.edu

## Introduction

In current practice, the manipulative forces generated by rehabilitation robots are governed by mathematical equations. On the other hand, forces from the hands of a human trainer are regulated by a relatively noisy biological control system, which introduces significant variability into manipulative forces. Self-generated (intrinsic) variability can promote exploration of novel motor actions that can drive learning<sup>1</sup>. Could this also hold for variability injected from an external source, i.e., from a human trainer to a patient? In other words, could the variability from a human trainer be beneficial for patient learning?

Any beneficial aspects of trainer manipulative variability could be masked by trainer fatigue or other sensorimotor encumbrances associated with hands-on manual locomotor training. We address this with a novel approach that robotically augments human trainers, allowing them to physically assist patients with minimal effort, called *Cyberphysical Rehabilitation* (CR). In this approach, a trainer holds onto a small robotic manipulandum that shadows the motion of a locomoting patient (Fig. 1). When the trainer applies a force to the manipulandum, the force is amplified and transferred to the patient with a magnetically-attached robotic arm. We performed a feasibility study that used CR to test the hypothesis that manipulative variability from human trainers promotes patient learning.

## Methods

Six patients with prior strokes (P1-P6) undertook a six-day locomotor training program; the goal was to increase the affected leg's step length by 25%. Each patient received CR from one or two robotically-augmented human trainers (separately). The CR system amplified trainer forces by a factor of 18.75 at the maximum transmitted output force of 30 N. An experienced CR trainer (Trainer T1) assisted P1-P3 on all training days except the fifth day, on which a different experienced trainer (Trainer T2) assisted (Trainer T1 was unable to participate). Trainer T2 provided assistance using the CR system for all six sessions for patients P4-P6. Both trainers were familiar with the CR system operation but were not rehabilitation professionals.

Figure 1. Robotically augmented human trainer.

## Results and Discussion

The magnitude of the assistance force provided by the robotically augmented human trainers was variable between patients, trainers, and days (Fig. 2), in agreement with early work using non-augmented human trainers<sup>2</sup>. On the other hand, the step-to-step variability of trainer forces was, on a relative basis, largely consistent between patients, trainers, and

days. This could be a function of the CR system. The human trainers only needed to modulate their force by a small amount to produce large changes in the applied force, e.g., only 1.6 N was required to transmit 30 N to the patient. Thus, trainer forces spanned a small range of their force capability, which constrains variability since human sensorimotor noise scales with motor command magnitude<sup>3</sup>. The relatively low step-to-step variability of trainer manipulative forces makes it difficult to relate this variability to patient learning outcomes at the present time.

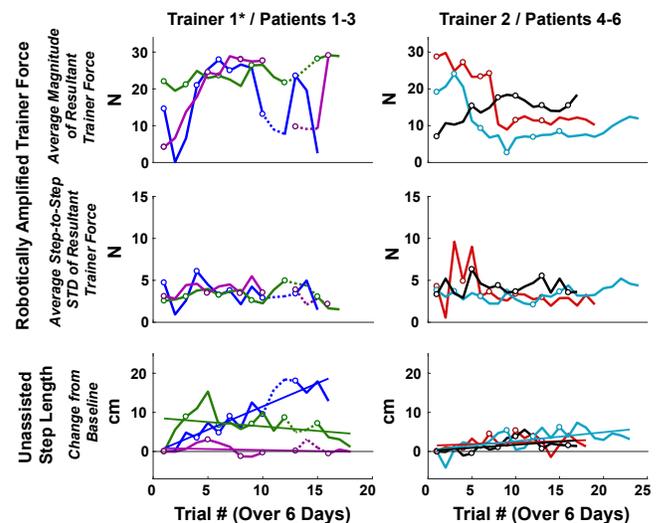

Figure 2. Changes in trainer assistive force magnitude (top row), step-to-step force variability (middle row) and unassisted patient step length (bottom row) across six training days for six individuals who survived strokes. Patients 1-3 (left) were assisted by Trainer 1 (\*except on Day 5 Trainer 2 gave assistance to Patients 1-3, indicated by dashed lines). Patients 4-6 (right) were assisted by Trainer 2. Forces shown are amplified 18.75 times at 30N. (Day 5 data excluded for Patient 3 [purple] because resistance was applied instead of assistance). Step length is relative to Day 1 baseline. Circles = first trial of each day.

## Significance

This new approach, called *Cyberphysical Rehabilitation* (CR), allows robotically augmented human trainers to manipulate a patient's body in real-time during treadmill locomotion. Future work could use CR to modify further how therapist forces are transmitted to patients, with the aim of providing a larger variability bandwidth from which to test the hypothesis that human trainer manipulative variability promotes patient learning.

# Exoskeleton Hip Assistance during Walking: Assisting Flexion or Extension?

Xianlian Zhou\*, Neethan Ratnakumar

Department of Biomedical Engineering, New Jersey Institute of Technology

\*Email: alexzhou@njit.edu

## Introduction

The use of robotic exoskeletons to assist human motion has become one of the most promising approaches to augment human performance or rehabilitate gait disorders. Assistance to lower body joints such as hip, knee, and ankle has been investigated by many researchers. Hip muscles consume the greatest percentage of the total human muscle energy expenditure [1] and thus torque assistance to the hip joint is expected to reduce the metabolic cost of human walking to a great degree.

Hip muscles generate substantial torques for both flexion and extension with similar magnitudes during walking. Exoskeletons have been designed to assist hip in either the flexion [2] or extension direction [3] considering that assisting only one direction can greatly simplify the design and actuation of the exoskeleton. However, there is no clear or conclusive evidence on which assistance direction is better. This study investigates and compares the effects of hip assistance in these two directions through a modelling and optimization approach and aims to provide clues on which one is more efficient in reducing metabolic cost of transport (COT).

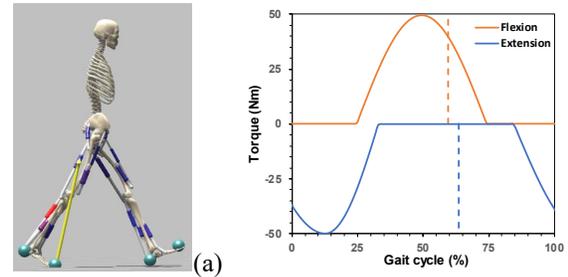

## Methods

To study human walking, we employed a subject musculoskeletal model that was actuated by sixteen Hill-type muscle tendon units, as shown in Fig. 1(a). The muscle excitations were generated through muscle reflex control whose parameters were optimized with a Covariance Matrix Adaptation Evolutionary Strategy (CMA-ES) method. The optimization was conducted with the SCONE software [4], which used OpenSim[5] to execute single shoot forward dynamics simulations of walking within each optimization iteration. The objective function of this optimization was a weighted combination of multiple motion characteristics, including metabolic COT calculated from a muscle energetics model [6], walking speed range, and penalties for falling, injury, and joint limit violations.

An optimization was first performed to generate a normal walking motion with Self Selected Speed (SSS). Then parameterized hip joint torques (flexion/extension) were directly added to the hip joint for assistance simulations. The assistance torque profile was assumed to take the form of a raise-peak-fall curve [7] and the parameters include the offset time, raise time, fall time, and the peak torque. For flexion assistance, the reference starting time ( $t=0$ ) for offset is at the middle stance phase whereas for extension the reference time is at the beginning of the swing phase. The peak torque limit was set to be 50 N/m. During optimizations, these assistance parameters were optimized together with the muscle reflex control parameters such that adaptations of muscle reflex and gait were expected.

## Results and Discussion

Table 1 compares gait characteristics of normal walking with those of assisted walking, for which the predicted optimal torque profiles are shown in Fig. 1(b). With assistance, the SSS increased by 16.7% and 9.7% for flexion and extension, respectively. Flexion assistance changed the stride length ( $L$ )

**Figure 1:** (a) The human subject musculoskeletal model; (b) Predicted optimal hip flexion and extension torque profiles. The gait cycle starts from the heel strike and dashed lines indicate the start of swing phases.

minimally but shortened the stride duration ( $D$ ) (i.e. increased step frequency) whereas extension assistance increased step frequency further but decreased the stride length. Flexion assistance increased the maximum hip flexion angle by  $10.7^\circ$  and reduced the extension angle by  $2.4^\circ$ . The extension assistance also increased the hip flexion angle slightly (by  $1.6^\circ$ ) and decreased the extension angle by  $4.5^\circ$ . In the latter case, the decrease in hip extension angle is likely caused by faster walking with a short stride and the absence of extension assistance during the late stance phase. For both assistances, the COT decreased considerably, by 19.1% for flexion and 11.7% for extension.

In summary, we demonstrated a computational approach to evaluate the effectiveness of hip assistance to human walking and predicted gait adaptation and change of energetics. We found that the hip flexion assistance performed better than hip extension assistance in terms of COT reduction and caused less changes of gait patterns (stride length and duration).

**Table 1:** Comparison of gait characteristics for normal and assisted walking. The unit for COT is  $J/(kg \cdot m)$ ; ( $\theta^\circ$ ) is the hip angle range.

	SSS (m/s)	$L$ (m)	$D$ (s)	( $\theta^\circ$ )	COT
Normal	1.194	1.683	1.41	(-24.2, 41.5)	3.263
Flexion	1.393	1.686	1.21	(-21.8, 52.2)	2.639
Extension	1.310	1.402	1.07	(-19.7, 43.1)	2.881

## Significance

Designing wearable exoskeletons is often a trade-off process considering various factors such as power, actuation, cost, weight, and wearability. Knowing how and when to apply assistance to a joint is critical for designing wearable exoskeletons. Our study can provide guidelines for optimal hip actuation (e.g. timing and profiles) and help designers make informed decisions. The method can also be extended to study assistance to other joints.

# A comparison of kicking kinematics among college students with and without Autism Spectrum Disorder

Kathy Reyes, BS<sup>1</sup>, Teri A. Todd, PhD<sup>1</sup>, Melissa A. Mache, PhD<sup>2</sup>, and Danielle N. Jarvis, PhD, ATC<sup>1</sup>

<sup>1</sup>Department of Kinesiology, California State University, Northridge

<sup>2</sup>Department of Kinesiology, California State University, Chico

Email: [danielle.jarvis@csun.edu](mailto:danielle.jarvis@csun.edu)

## Introduction

Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder affecting social communication and interaction skills.<sup>1</sup> Compared to typically developing children, individuals with ASD exhibit poor motor skills at a young age.<sup>2-3</sup> These motor skill deficits in children may contribute to lower levels of physical activity in persons with ASD, leading to a sedentary lifestyle and obesity. However, it is unknown if the motor skill deficits seen in children carry over into adulthood.

Kicking is one gross motor skill commonly performed by children. A proficient kick requires sequential movements of the kicking leg.<sup>4</sup> Forward motion is initiated by rotating the pelvis around the supporting leg and by bringing the thigh of the kicking leg forward while the knee continues to flex backward.<sup>4</sup> Proficient kicking is an essential element of several sports and play activities, such as kickball and soccer. The purpose of this study is to compare the kicking kinematics of college students with and without ASD. It was hypothesized that college students with ASD would exhibit a less proficient kick, demonstrated by decreased peak hip extension in the wind-up, and decreased peak hip flexion and knee extension velocities during the acceleration phase.

## Methods

Ten college students with ASD and ten college students without ASD participated in this study (Table 1).

**Table 1:** Demographic characteristics of participants

	With ASD	Without ASD
Sex (male:female)	8:2	8:2
Age (years)	23.3 ± 3.83	21.70 ± 2.50
Height (cm)	173.10 ± 12.45	171.90 ± 7.75
Body weight (kg)	101.29 ± 23.61	75.82 ± 18.10
BMI	33.88 ± 7.86	25.76 ± 6.08

*Note.* Values presented as mean ± standard deviation, except for sex which is presented as frequency.

A computer-aided 12-camera video motion analysis system and force plates were used to assess movement patterns. Following a demonstration of the kick, participants were asked to complete five kicking trials where they kicked a ball hard into a net. Hip, knee, and ankle kinematics were calculated. Stance leg peak hip flexion, knee flexion, and ankle dorsiflexion, and kicking leg peak hip extension, knee flexion, hip flexion velocity, and knee extension velocity were extracted and compared between groups using independent t-tests. Alpha level was set at ≤ 0.05.

## Results and Discussion

There were no statistically significant differences between groups in stance leg peak hip flexion, knee flexion, or ankle dorsiflexion (Table 2). There were no statistically significant differences in kicking leg peak hip extension or knee flexion during the preparation, or in peak hip extension velocity or knee extension velocity during the kick (Table 3). For all variables, the ASD

group had a higher standard deviation than the control group, indicating they may perform kicking with greater variability.

**Table 2:** Stance leg peak lower extremity joint angles.

Variable	With ASD	Without ASD	p value
Hip Angle	39.18±12.46	39.25±11.17	0.989
Knee Angle	55.06±11.00	54.56±8.23	0.908
Ankle Angle	8.28±8.45	7.68±7.00	0.864

*Note.* Angles reported in degrees, with positive values indicating hip flexion, knee flexion, and ankle dorsiflexion.

**Table 3:** Kicking leg peak lower extremity kinematics.

Variable	With ASD	Without ASD	p value
Hip Extension	10.05±8.45	14.56±7.37	0.219
Knee Flexion	83.36±13.96	85.84±11.85	0.9674
Hip Extension Velocity	496.9±178.8	442.1±92.5	0.401
Knee Extension Velocity	788.7±259.6	935.7±220.5	0.189

*Note.* Angles reported in degrees and velocities reported in degrees/second. Values presented as mean ± standard deviation.

## Significance

There were no statistically significant differences in kicking kinematics between college students with and without ASD. After noting the high kicking leg standard deviations, visual inspection of the data revealed that participants may have approached the kick differently, with some relying more on the hip to drive the kick while others relied more on the knee. It may be possible to break these participants into subgroups for a more detailed analysis to determine if there are differences between groups that were not identified using the present approach. In the future, we also plan to examine the coordination patterns and timing of movements during kicking to determine if differences between groups exist. A detailed analysis of variability may also reveal differences between groups in terms of motor control. While the dependent variables selected for the present analysis did not reveal differences between groups, further work to identify deficits in kicking can contribute to the development of interventions to improve kicking mechanics in individuals with ASD. Improving kicking skills in this population could help with balance and coordination and promote greater participation in physical activity.

### Introduction

Muscle synergy analysis has been broadly used to quantify motor coordination during movement, particularly among individuals with neuromuscular disorders. In cerebral palsy (CP), individuals commonly exhibit reduced coordination complexity compared with typically developing peers [1]. It has been hypothesized that this reduction reflects a simplified control architecture stemming from the primary neurologic injury. However, individuals with CP also commonly adopt altered gait patterns (e.g. equinus, crouch gait). Previous studies have suggested that the biomechanical constraints of these gait patterns may limit the feasible solution space for muscle activity, resulting in the reduced complexity observed [2].

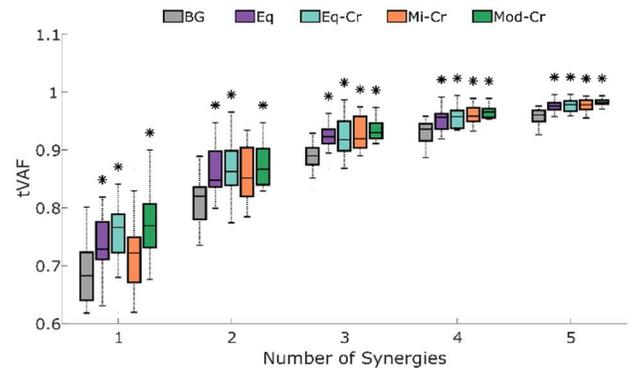

Studying the isolated effects of neurologic injury and gait pathology on coordination may elucidate their relative impacts and inform treatment. Prior work has demonstrated that typically developing individuals can replicate common CP gait patterns, but impact of these patterns on motor coordination has not been studied [3-5]. Investigating changes in synergies while unimpaired individuals emulate CP gait patterns provides a unique means of uncoupling the biomechanical constraints from the neurologic injury. We hypothesize that if reduced coordination complexity in CP is primarily neurogenic, then altered mechanical constraints during unimpaired emulation will have minimal impact on synergy complexity.

### Methods

Fourteen typically developed participants (7M/7F; 24.1 ± 4.7 yrs) were enrolled. Participants walked at a self-selected speed on a split-belt instrumented treadmill for all trials. Participants performed one, three-minute baseline gait trial (BG) along with three, three-minute emulation trials for the following CP gait patterns: equinus (Eq), equinus-crouch (Eq-Cr), mild crouch (Mi-Cr), and moderate crouch (Mod-Cr). Mi-Cr and Mod-Cr trials were defined as 20° and 30° knee flexion set with a goniometer during standing, respectively [6], and reinforced using a visual aid in-trial. Verbal instruction and researcher demonstration were provided for Eq trials. For Eq-Cr trials, participants adopted the same equinus posture as for Eq trials and knee flexion was set at 20°; a visual aid was again used to reinforce knee flexion.

Kinematic data were collected from a full-body marker set. Electromyography data were collected for a bilateral, eight muscle set spanning the hip, knee, and ankle joints. To reduce learning or fatigue effects, all analyses were performed for 43 strides taken from the middle of one trial for each participant. Muscle synergy decomposition was performed on the concatenated EMG data and total variance accounted for (tVAF) was used to evaluate synergy complexity.

Multiple paired t-tests with Bonferroni correction ( $\alpha_{\text{adjusted}}=0.0125$ ) were used to evaluate differences in synergy complexity between BG and each of the emulated gait patterns.

**Figure 1:** The tVAF during baseline and emulated gait for 1-5 synergies. Larger tVAF for any synergy solution indicates reduced coordination complexity. \*Denotes significant difference from BG.

### Results and Discussion

Synergy complexity was significantly reduced compared to BG in Eq, Eq-Cr, and Mod-Cr patterns across all synergy solutions ( $p < 0.01$ ). Mi-Cr resulted in significantly reduced complexity for  $N > 2$  synergies ( $p < 0.002$ ). Participants demonstrated significant deviations from BG in the joint angles targeted by each emulation pattern; the observed trends were qualitatively similar to CP gait. [3-5].

These data suggest that gait pathology may contribute to reduced synergy complexity seen in CP. However, prior research has shown that changes in kinematics in CP are not associated with changes in synergies [7], suggesting reduced synergy complexity is not entirely biomechanically driven. As such, further work is needed comparing the changes in coordination complexity in these TD emulated gait patterns to a kinematically-matched CP cohort to understand the relative impacts of altered biomechanics and neurology on coordination.

### Significance

Our results suggest that, at least among TD participants, biomechanical constraints reduce synergy complexity. While more work is needed to extend these results to a CP population, this study improves understanding of the factors that impact coordination complexity and may help instigate further research into therapy or other coordination-targeting interventions to improve gait for people with CP.

## Introduction

Gait adaptation has shown improved symmetry in hemiparetic stroke survivors. Existing methods typically use expensive equipment such as split-belt treadmills or robotic devices, which may make a translation to the clinic less feasible. Using a unilateral leg weight overground may be a more feasible solution.

We hypothesize that adding a weight to either the paretic or nonparetic side may alter spatiotemporal gait symmetry in subjects with stroke and tested both conditions in short-term experiments.

## Methods

Five participants with chronic stroke (2 females; 61.4±2.5 years; 93.3±16.1 kg; 171.8±12.5 cm tall) with unilateral hemiparesis were recruited. They walked over ground without a weight, after adding a weight of 3% body weight on participant's ankle, and after the weight (2.67±0.43 kg) was removed (**Figure 1**; BL: Baseline, EA: Early Adaptation, LA: Late Adaptation, ED: Early Deadaptation, LD: Late Deadaptation). During all conditions, participants were instructed to walk at a comfortable speed with their arms free. For safety, the participant wore a gait belt and a researcher walked close and behind the participant.

The participants were assessed over two visits with at least one week between them. Before visit 1's BL, participants walked on a gait mat to find the leg with the shorter step. The weight was placed on this leg in visit 1 and on the contralateral leg in visit 2. Kinematic data were recorded at 120Hz using VICON.

Step length (SL) and step time (ST) for each leg were calculated using a custom Matlab code. The symmetry index (SI) for a variable  $X$  is  $SI = (X_{\text{nonparetic}} - X_{\text{paretic}}) / (X_{\text{nonparetic}} + X_{\text{paretic}})$ . An SI of zero means perfect symmetry. A repeated-measures ANOVA was performed using SPSS. We considered the repeated measures of the testing periods and paretic-perturbed (PP) versus nonparetic-perturbed (NPP). The interaction was assessed in the model.

## Results and Discussion

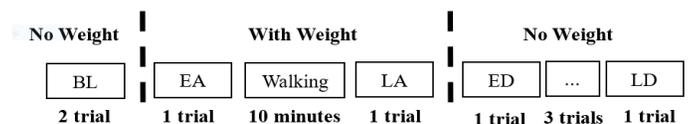

For step-length SI, ANOVA with repeated measures of testing periods and PP-NPP revealed no significant main effect or interaction effect. Therefore, the PP-NPP groups were merged (**Figure 2**, upper panel). An ANOVA with repeated measure of the testing periods revealed no significant effect.

For step-time SI, ANOVA with repeated measures of testing periods and PP-NPP revealed no significant main effects, but a significant interaction ( $p=0.044$ ). A post-hoc analysis revealed no significant difference between PP and NPP at each testing period. However under NPP only, the BL was significantly different from LA, ED, and LD ( $p=0.008, 0.033, 0.029$ , respectively) (**Figure 2**, lower panel).

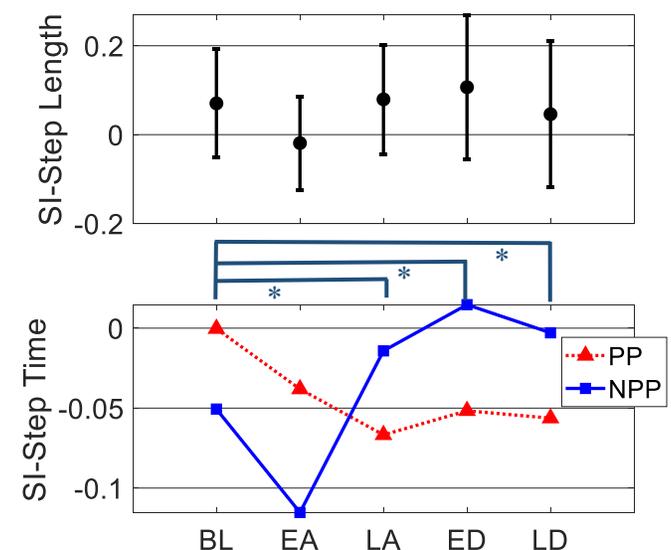

Taken together, the results suggest that a leg weight does not alter the spatial symmetry of hemiparetic gait, however, it does alter the temporal symmetry when the weight is added to the nonparetic leg. This is a positive outcome since the step time

starts asymmetrical in BL (**Figure 2**) and converges to symmetry at the end (LD).

Our results are in line with a study (Khanna et al., 2010) that also reported no change of temporal SI (for % stance duration) when loading on the paretic leg and walking overground. They differ from previous findings on a treadmill with leg swing resistance of 1.25% body weight (Savin, Tseng, Whittall, & Morton, 2013), where step-length SI was altered. This may be due to the different context of a treadmill, the weight perturbation during swing only, or perturbing the leg with the shorter step regardless of being the paretic or nonparetic. These alternative hypotheses need testing in a systematic manner.

**Figure 1:** Testing periods. BL=Baseline, EA=Early Adaptation, LA=Late Adaptation, ED=Early Deadaptation, LD=Late Deadaptation.

**Figure 2:** Symmetry index (SI) of step length and time. PP: Paretic Perturbed, NPP: Nonparetic Perturbed. The significant values (denoted by \*,  $p<0.05$ ) are for step-time SI in NPP.

## Significance

This study extends the scope of investigating effects of adaptation on overground gait symmetry by testing the effect of perturbing the paretic versus nonparetic sides in individuals after chronic stroke.

<sup>2</sup>Movement Control Rehabilitation (MOCORE) Laboratory, Email: ssanford@stevens.edu

### Introduction

Neuromuscular pathologies can reduce functional capabilities of body extremities. Rehabilitation with the assistance of a myoelectric device is a time-intensive process. We aim to accelerate the rehabilitation process by providing multi-sensory feedback for training of muscle activity [Sigrist 2013]. More consistent muscle activation patterns lead to more effective device control [Huang 2016]. **Our objective** is to develop a rehabilitation platform that applies multi-sensory feedback to optimize myoelectric control after neuromuscular trauma.

### Methods

Motion capture system included nine infrared cameras (Prime 17W, Optitrack) to track user head position. Wireless EMG sensors (Trigno, Delsys) were used for measuring muscle activation patterns on up to 14 upper-body muscles spanning the forearm, upper arm, and trunk/shoulder. Machine learning (ML) classification of subject isometric EMG activity will control the subject virtual arm position. Matlab® was used to train and evaluate the ML techniques. The virtual reality environment was created in Unity®. **Multi-sensory Feedback:** *Visual:* Subject and target positions provided with the goal to minimize error between the two. *Haptic:* Vibrotactile feedback to induce more distinct EMG activity for device control.

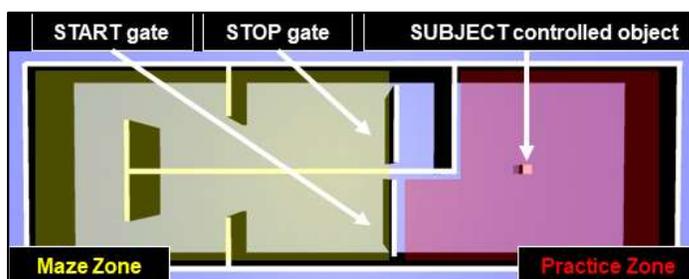

**Figure 1:** Experimental protocol of a multi-sensory feedback rehabilitation paradigm. Visual and haptic feedback are provided for optimizing myoelectric control of a virtual reality task.

### Results and Discussion

Preliminary studies identified 1. The optimal visual feedback (VF) display and 2. The effects of imitated amputee populations on task performance. First, we determined the most effective VF for a multi-segmented movement is presented with body-discernible features. Other VF paradigms presented as abstract cues, or as a single degree of freedom, were less effective for training consistent movement and EMG activity. Therefore, in our rehabilitation paradigm, **Figure 1**, the VF target position was represented as a multi-segmented prosthetic arm. Next, we aimed to identify the effects of reduced muscle sets on myoelectric

control by imitating amputee populations. We represented transhumeral and transradial clinical populations by reducing the number of EMG sensors as real-time inputs into the ML classifier. Subjects completed a virtual maze task (**Figure 2**) with EMG input from all 14 muscles, 10 muscles (no forearm, imitated transradial), or 8 muscles (no forearm or upperarm, imitated transhumeral). Two ML methods were evaluated for real-time performance, linear discriminant analysis (LDA) and support vector machine (SVM). For LDA, the set of all 14 muscles had the highest functional task performance measured as completion time and wall collision count (**Table 1**). For SVM, highest performance was found for the 10 muscle set. We concluded that amputees, or participants with reduced muscle capacity, may have high precision myoelectric control in our virtual environment.

**Figure 2:** Virtual reality maze task during preliminary study.

Table 1. Results of virtual reality maze task		
Completion time (sec)		
(n=5)	LDA	SVM
14 muscles	9.2 ± 3.6	15.0 ± 18.0
10 muscles	10.9 ± 4.1	7.5 ± 3.0
8 muscles	14.9 ± 14.4	26.4 ± 14.2
Number of collisions with maze walls (#)		
	LDA	SVM
14 muscles	2.0 ± 4.6	4.3 ± 1.0
10 muscles	3.3 ± 8.9	1.5 ± 1.7
8 muscles	10.4 ± 34.7	6.2 ± 3.2

### Significance

Current rehabilitation programs lack feedback elements informing the subject of task performance beyond verbal cues from clinicians and visual cues from mirrors. Initially, our system will employ motion capture, electromyography, and virtual reality for providing motion and muscle activity performance of a functional task. This can be applied to clinical populations for enhancing current modalities of rehabilitation and training myoelectric device control. Eventually, this system will be commercialized for at-home usage to promote the development of intrinsic mechanisms, such as muscle memory, for greater independent function.

# Functional connectivity analysis during direct EMG prosthesis control

Wentao Liu<sup>1\*</sup>, Aaron Fleming<sup>1</sup>, and He (Helen) Huang<sup>1</sup>

<sup>1</sup> Joint Department of Biomedical Engineering, NC State University and UNC-Chapel Hill

Email : \*wliu29@ncsu.edu

## Introduction

The study aims to explore the feasibility of functional connectivity analysis to indicate the influence of direct EMG control of robotic prosthetic ankle on neuromuscular control in individuals with lower limb amputations. Powered lower limb prostheses with direct neural control<sup>[1]</sup> allows amputees to generate control signals using residual muscles and thus partially restore their biomechanics function. How amputee's neuromuscular control mechanism changes under this condition remains unknown. In this study, we assessed and compared multi-muscle function and coordination by performing functional connectivity analysis on surface EMG from an able-bodied person (AB) and a transtibial amputee (TT) during postural sway task. The results might inform a unique way to unveil the potential shift of neuromechanics caused by direct neural control of prosthetic limb, and demonstrate mechanism of neuro control behind it.

## Methods

One AB and TT participant were involved in the experiment with IRB approval. All participants was instructed to do forward-backward postural sways following a 0.5 Hz metronome. We collected EMG signals from bilateral tibialis anterior (TA), gastrocnemius (GM), rectus femoris (RF), vastus lateralis (VL), biceps femoris (BF), soleus (SOL), and gluteus medius (GMED). For TT, EMG of SOL on the residual limb was missing.

We applied functional connectivity analysis on EMG data by calculating pair-wise intermuscular coherence for all EMG envelopes. To assess muscle coherence under distinct frequency ranges, we decomposed coherence between all muscle pairs by using Non-Negative Matrix Factorization (NNMF)<sup>[2]</sup>. Basic components and their corresponding factor loadings yield spectral signatures and functional connectivity strength between all muscle pairs.

## Results and Discussion

Three major components derived from AB and TT subject (as shown in Fig. 1) indicated different functional connectivity patterns, among which low frequency components are strongly shaped by kinematics of musculoskeletal system, and the influence of motor neural system are expected to be pronounced on the middle and high frequency components.

We observed similarities exist in 'low' frequency component between two subjects, suggesting TT wearing direct neural control prostheses can produce similar kinematics during postural sway task as AB subject. The 'middle' frequency component for TT shifted to a relatively higher frequency range compared to able-bodied person. The pattern of middle and high components are different, and it's obvious that the middle frequency's energy shifted to a higher band area. Raethjen et al's study found corticomuscular transmission of the oscillation between 6-15 Hz to the limbs<sup>[3]</sup>. The majority of energy in the middle frequency component found in TT's EMG activity concentrates in this band, thus it might reflect active recruitment of supraspinal area during postural sway.

Under each component we pulled out top three pairs of muscles with highest loading, which means these pairs have strongest connection under corresponding component. Based on the topological representation of muscles, they were classified into intra-limb pair or inter-limb pair. The total number of muscle pairs fall under each category is listed in Table 1.

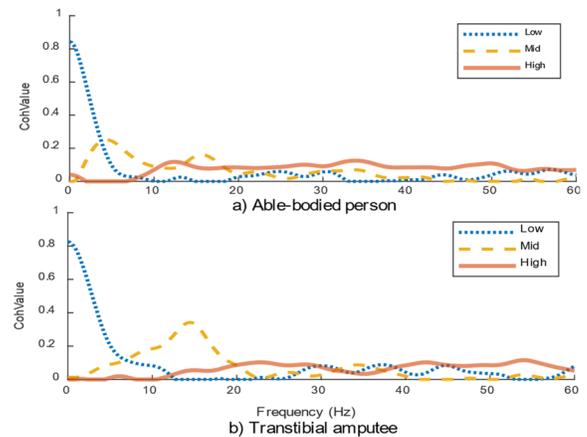

Figure 1: Frequency spectra of three components.

Table 2: Different kinds of intermuscular connectivity observed in AB and TT

	Intra-limb	Inter-limb
Able-bodied person	4	5
Transtibial amputee	7	2

We found AB and TT used different neural control strategy. AB's muscle connection showed more evenly distribute between intra and inter limb, and in contrast TT focused more on intra-limb. The fact that AB has more bilateral connectivity indicated that the functional links are more balanced. However, for TT we found a very strong inter-limb TA-TA connection similar to AB. Perhaps, the motor control system in the CNS has begun to restore the original neural pathway for TA-TA recruitment.

## Significance

We demonstrate that functional connectivity analysis for multi-muscle analysis can potentially unveil the neuroplasticity in postural control of lower limb amputees. It will benefit many researches in understanding the neuromechanics of lower limb amputee. Our future study building upon this feasibility study may be used to study the effects of novel prosthetic technology on human neuromuscular control.

# Psychological Readiness is Evident in Motor Unit Action Potentials with ACL Injury

Nathan D. Schilaty<sup>1</sup>, April L. McPherson<sup>1</sup>, Takashi Nagai<sup>1</sup>, Nathaniel A. Bates<sup>1</sup>

<sup>1</sup>Mayo Clinic Biomechanics Laboratories & Sports Medicine Center, Rochester & Minneapolis, MN, USA

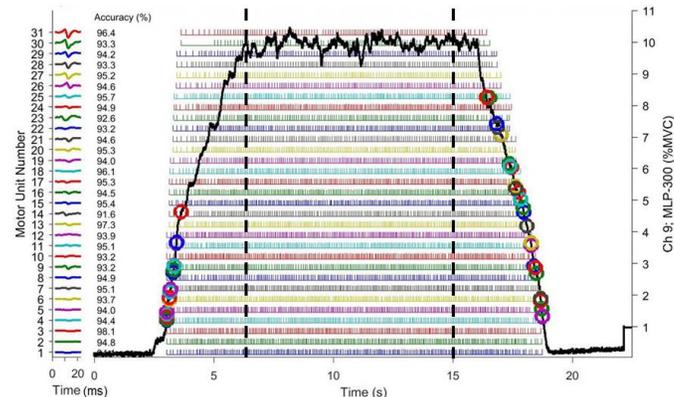

Email: schilaty.nathan@mayo.edu

## Introduction

Following ACL injury, reconstruction (ACLR), and rehabilitation, only 33-44% of athletes return to their same level of play. [1]. Other psychological responses include: lack of self-confidence, kinesiophobia, depression, and anxiety. Psychological readiness to return to sport is commonly assessed with the ACL-RSI. As psychological readiness can have an affect on motor control, potentially with induction of neuroplasticity [2-3], it is important to understand the motor control deficits related to these psychological responses. This study was designed to assess the effect of psychological readiness on motor control output. Objective demonstration of neural deficits that associate with psychological responses may improve both physical and emotional health outcomes.[4]

## Methods

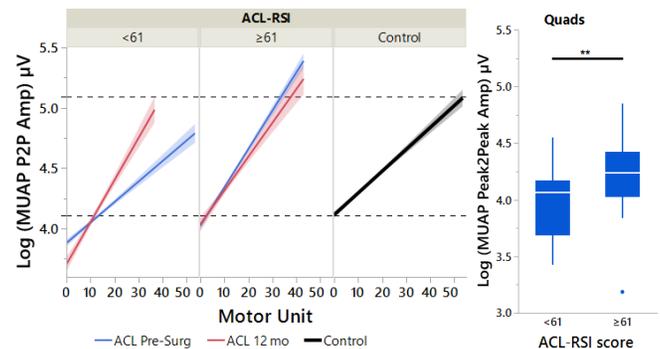

Decomposed electromyography (dEMG) was acquired with a five-pin array sensor (Delsys *Bagnoli*; Natick, MA) placed on four major thigh muscles from 56 subjects [Female (n=32); Control (n=25)]. ACL subjects were longitudinally assessed at Pre-ACLR, 6-mo post-ACLR, and/or 12-mo post-ACLR. Data was acquired at 20 kHz from isometric contractions (quads, hams) with force measured by a custom load cell apparatus. Acquired dEMG data (band-pass filtered 20–1750 Hz) was analyzed with *dEMG Analysis* software to extract average firing rate (AvgFR), inter-pulse interval, recruitment thresholds [% maximal voluntary isometric contraction (%MVIC)], and MU action potential (MUAP) from detected MUs ( $\geq 90\%$  accuracy, **Fig. 1**). ANOVA and linear regressions were performed with *JMP Pro 14*. To ensure parametric data for assessment, a *Log* transformation was selected for MUAP. For psychological readiness categorization, an ACL-RSI cutoff value of  $\geq 61$  was utilized.[5]

**Figure 1: Isometric Waveform and MU Identification.** With each contraction, the subject followed a trapezoidal waveform with a 3 sec ramp-up, 10 sec hold, and 3 sec ramp-down. The output force is shown (black line). This trial (10% MVC) identified 31 MUs. MU (de)recruitment are denoted by colored circles while firing pattern is demonstrated by color-matched spikes. Data for this analysis was specifically windowed during the ‘plateau phase’ of contraction (7–15 sec; dashed lines).

## Results and Discussion

Linear regressions of MUAP peak-to-peak amplitude (MUAP P2P) demonstrated that the ACL-RSI score  $< 61$  group had lower amplitudes with earlier recruited MUs than Controls and  $\geq 61$  group. Further, the ACL-RSA  $< 61$  group did not achieve MUAP P2P values similar to controls with later recruited units (**Fig. 2**). The ACL  $\geq 61$  group demonstrated higher MUAP P2P than controls with later recruited MUs. ANOVA between the ACL-RSI groups demonstrated significantly higher MUAP P2P for quadriceps musculature for the  $\geq 61$  group compared to  $< 61$  group ( $p=0.010$ ; **Fig. 2**). Similarly, for the hamstrings, the  $\geq 61$  group demonstrated significantly higher MUAP P2P compared to  $< 61$  group ( $p=0.012$ ).

**Figure 2: MUAP Peak-to-Peak Amplitude by Recruited MU.** Linear regression demonstrates the lower MUAPs utilized by those with lower psychological readiness. Dashed lines represent Control values. The box plot demonstrates the differences of MUAP between ACL-RSI groups for quadriceps.

The MUAP P2P value is a surrogate of MU size.[6] The ability to recruit larger MUs will provide additional control to the musculature. This data demonstrates that those that have lower psychological readiness express MU inhibition across the spectrum of rehabilitation. Those that score higher appear to compensate by recruiting larger MUs.

## Significance

This data demonstrates objective results of motor control associated with psychological readiness. These results are important to provide personalized rehabilitation to athletes. Further, it can provide an objective measure to demonstrate effectiveness of psychological counselling to athletes.

# Use-dependent learning, not error-based learning, occurs during perturbed recumbent stepping

Seyed Yahya Shirazi<sup>1\*</sup>, and Helen J Huang<sup>1,2</sup>

<sup>1</sup>Mechanical and Aerospace Engineering Department, University of Central Florida, Orlando, FL, USA

<sup>2</sup>Disability, Aging, and Technology Cluster, University of Central Florida, Orlando, FL, USA

Email: [shirazi@ieee.org](mailto:shirazi@ieee.org)

## Introduction

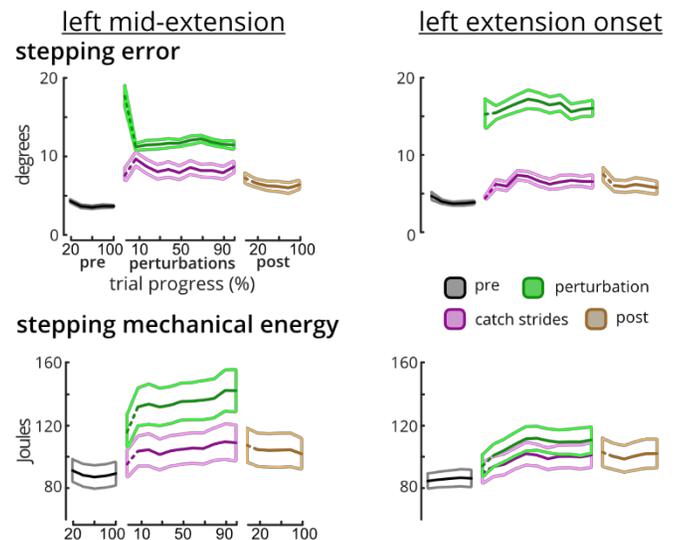

Locomotor adaptation is usually an error-based learning experience in which humans modify walking behavior to reduce motor errors in response to perturbations. This adapted behavior often washes out soon after the perturbations are removed [1]. Subjects also initially increase energy cost to respond to the perturbations and then decrease energy cost with adaptation [2]. In seated locomotor tasks (e.g., recumbent stepping), the stakes of an error are lower as the subjects do not need to maintain their balance. Perturbations during seated locomotor tasks, however, likely still engage similar adaptation processes as perturbed walking, which could be beneficial for gait rehabilitation. The purpose of this study was to quantify the motor and mechanical energy responses to brief perturbations during recumbent stepping. We hypothesized that similar to perturbed walking, both stepping error and mechanical energy cost would decrease as subjects adapt to perturbations during recumbent stepping.

## Methods

Subjects (n=17) completed four 10-minute trials on a motorized recumbent stepper. Each trial included six minutes of perturbed recumbent stepping as well as two minutes of unperturbed stepping at the beginning and the end of the trials. Subject experienced perturbations at either mid-extension or extension-onset of the left or right leg as a brief 200 ms increase in stepping resistance. A random no perturbation “catch” stride occurred in every five perturbed strides. We provided a visual pacing cue at one step per second and instructed subjects to step smoothly while matching the pace of the visual pacing cue. We defined stepping error as the maximum difference of the stepping profile from the average unperturbed stepping profile and quantified the stepping mechanical energy cost using the limb forces and stepper speed. We acquired forces from the force sensors in the handles and pedals and the speed from the stepper servomotor.

## Results and Discussion

Firstly, subjects were successful at maintaining a stepping pace within ~50 ms of pacing cue during perturbed strides, except for the very first mid-extension perturbed stride. Stepping error decreased significantly during the first perturbed strides of the mid-extension perturbations, indicating fast adaptation to those perturbations and supports our hypothesis (Fig. 1). In contrast, stepping error did not change from early to late during extension-onset trials, indicating that subjects did not adapt and does not support our hypothesis. Interestingly, post-perturbation stepping errors did not wash out and were consistently higher than the pre-perturbation errors for all perturbations. Unlike perturbed walking, stepping mechanical energy cost continuously increased during the perturbations for all trials, which also does not support our hypothesis (Fig. 1). Post-perturbation mechanical energy costs were also higher than the pre-perturbations. During the catch strides, subjects stepped ~200 ms faster than the pacing cue, suggesting they were anticipating a perturbation. Catch strides also had less stepping error than the perturbed strides but did not adapt from early to late perturbation.

**Figure 1:** Stepping error and mechanical energy cost of the left mid-extension and extension-onset trials. The light borders indicate standard error. Right-side trials had similar errors and energy costs.

The continuous increase in mechanical energy cost, non-adapting errors, and sustained post-perturbation errors are in line with the use-dependent learning paradigm [3]. When perturbations do not hinder the task goal (here stepping in time), the learning process does not necessarily lead to error reduction. Instead, motor error builds upon the previous instances of the motor behavior and will sustain longer after removing perturbations. The increasing catch stride errors also support this notion of use-dependent learning.

## Significance

Brief mechanical perturbations during recumbent stepping enhanced use-dependent learning instead of error-based learning, which resulted in sustained changes during post-perturbation stepping. This aligns with a recent walking study that also reported use-dependent learning and sustained post-perturbation by adding small (and even imperceptible) accelerating perturbations during push-off [4], which is similar to the timing of extension-onset perturbations during recumbent stepping. The sustained motor changes can be particularly beneficial for improving motor impairments and restoring “normal” movement patterns, but further study is needed to determine whether increased energy cost is beneficial or detrimental in rehabilitation.

## OPTIMAL-Based Virtual Reality Feedback to Reduce Dual-Task Balance Cost

Ashley Williams, Samantha Kendall, Jennifer Hogg, Colton Jenkins, Gary B. Wilkerson, and Shellie Acocello  
Email: yyb151@mocs.utc.edu

### Introduction

Approximately 23-25% of anterior cruciate ligament reconstructed (ACL-R) patients will re-tear the previously injured ACL or contralateral ACL.<sup>1</sup> It is suggested that current ACL rehabilitation practices do not adequately address the demands of real-time competition, resulting in high re-injury rates. Recent evidence indicates that neuromuscular control of the affected limb does not occur in isolation, but is likely governed by central integrative processes of vision, cognition, proprioception, and motor control. The Optimizing Performance through Intrinsic Motivation and Attention for Learning theory (OPTIMAL),<sup>2</sup> a recently developed motor learning framework, shows promise for improving retention of clinical rehabilitation to real-world competition, during which athletes must attend to multiple stimuli simultaneously. Therefore, the purpose of this study was to determine the effectiveness of a motor learning intervention to improve the dual-task cost of adding a cognitive load to a single-leg balance task. We hypothesized that an OPTIMAL-based virtual reality delivered intervention would decrease cognitive-balance task cost immediately after the intervention and at a 24-hour retention test.

### Methods

Researchers recruited 21 male and 24 female participants, who were between the ages of 18 and 30 years, and free of concussion, vertigo, lower extremity surgery, and lower extremity injuries within the past 6 months. Participants attended 2 sessions, separated by approximately 24 hours. Participants were randomly assigned to 1 of 3 groups (group 1: control, group 2: autonomy support (AS), group 3: enhanced expectancies (EE)). On force plates sampled at 1000 Hertz, participants completed a single-task balance (20 s) followed by a cognitive-balance task before and after the motor learning intervention on day 1, and for a retention test the following day. The intervention consisted of 5 x 8 single-leg squats on each leg, with adequate rest. Participants wore Virtual Reality (VR) goggles on which was displayed an avatar (control). AS group chose the color of their avatar, and EE group was instructed to keep positive feedback placed on their avatar lit through the duration of each set performed. EE group was instructed to move within pre-determined kinematic thresholds (15° knees valgus and 20° pelvic drop) and received visual feedback via the avatar thresholds.

Dependent variables: Center of pressure(CoP) average velocity cost, Medial lateral(ML) center of pressure standard deviation(SD) cost, Anterior posterior(AP) CoP SD cost, ML Average Velocity Cost, AP Average Velocity Cost. Independent variable was group allocation.

Repeated measures analysis determined change in dual-task cost following intervention and retention. Alpha level was set at .10.

### Results and Discussion

On the left side, participants differed over time for CoPAvgVelCost ( $p=.05$ ,  $\eta_g^2=.06$ ), APCoPSDCost ( $p=.02$ ,  $\eta_g^2=.08$ ) and APVelAvgCost ( $p=.08$ ,  $\eta_g^2=.04$ ) and differed between groups for CoPAvgVelCost ( $p=.01$ ,  $\eta_g^2=.04$ ) and APCoPSDCost ( $p=.10$ ,  $\eta_g^2=.05$ ). On the right side, participants differed over time for APVelAvgCost( $p=.04$ ,  $\eta_g^2=.03$ ) and MLVelAvgCost( $p=.09$ ,  $\eta_g^2=.02$ ). The EE group's average COP velocity decreased by .18 m/s after intervention and remained lower than baseline at retention.

Visual feedback improved postural control and the addition of a cognitive load during stance did not affect the EE group as much. This suggests a favorable central nervous system adaptation, and allowed the participants to maintain a more stable center of pressure.

### Significance

Lower extremity/ACL reinjury is a major risk in the athletic/clinical community. An OPTIMAL-based motor learning intervention using visual feedback to improve cognitive-balance control shows promise for reducing dual task cost and improving re-injury outcomes. As this is a pilot study, future work is needed to validate these findings in larger, clinical, and injured cohorts. This work is promising for optimizing ACL rehabilitation and improving transfer of safe motor patterns to real-world sport.

# Sensory-Motor Assessment of the Lower Extremity in Tibial Rotation: Towards Knee Osteoarthritis Rehabilitation

Ahmed Ramadan\*, Raziye Baghi, and Li-Qun Zhang

University of Maryland, School of Medicine, Department of Physical Therapy and Rehabilitation Science, Baltimore, MD, USA

Email: \*[ramadana@som.umaryland.edu](mailto:ramadana@som.umaryland.edu)

## Introduction

Knee osteoarthritis (OA) is the most common cause for disability in older adults [1]. The objective of this preliminary study is to examine lower-limb sensory-motor properties in tibial rotation (stiffness, ROM, and proprioception) and build new insights for a rehabilitation program on a modified elliptical machine [2], [3].

## Methods

Four healthy participants (1 male (S2); 28-42 years old) participated in this study. Each subject had their right knee flexed at 90° and the foot mounted onto a footplate of a modified elliptical machine [2], [3]. The footplate rotated horizontally about the long axis of the tibia using a servomotor. The assembly included a 6-axis force/moment sensor whose vertical axis was aligned with the tibial rotation axis.

During the ROM and stiffness test, an ankle brace was used to reduce ankle rotation. Participants were instructed to relax while the footplate rotated at a constant speed 3°/s until a terminal angle (45°) or a peak moment (5Nm except for subject1's 3Nm) was reached for 5 cycles. The most anomalous cycle (by visual inspection) was removed in Matlab. The remaining 4 cycles were divided into descending limbs and ascending limbs, where a 5<sup>th</sup> order polynomial was fitted to each limb. Polynomial derivatives yielded the rotational stiffness.

For the proprioception test, subjects (S2-S4) closed eyes and the footplate rotated at 0.8°/s in randomized directions until the subject pressed a hand-held switch when motion was detected. Proprioception acuity was measured 4 times in each direction.

## Results and Discussion

The female subjects had a less steep hysteresis curves (Figure 1 and 2) compared to the male subject, which agrees with previous study [4]. Each stiffness curve (Figure 2) has an approximate flat region or subtle ramp in the middle. Since this area contains minimum stiffness, we refer to it as the resting stiffness region.

The resting stiffness may reflect the subjects's preference of toe-in, toe-out, or straight-toe during sitting. For example, S1's resting stiffness is approximately from -25° to 5° suggesting this subject prefers toe-out during sitting. Table 1 summarizes these results and the self-reported preferences.

Some knee OA rehabilitation programs target minimizing external knee adduction moment (EKAM) [2], which can be achieved by the foot progression angle (toe in or out). The current test can potentially give rehabilitation programs a proactive subject-specific strategy (what direction of foot progression angle) to reduce EKAM. However, this should be investigated further because of limitations including: this test is done in a sitting position while EKAM is computed during stepping. The different context (sitting versus standing) may affect the suggested proactive strategy.

The proprioception acuity (Table 2) for female subjects is less than that reported in [3] (3.5°), which may be due to the different context (sitting versus standing with measurements on the weight-bearing side). Improving proprioception acuity through training is an expected outcome as in [3].

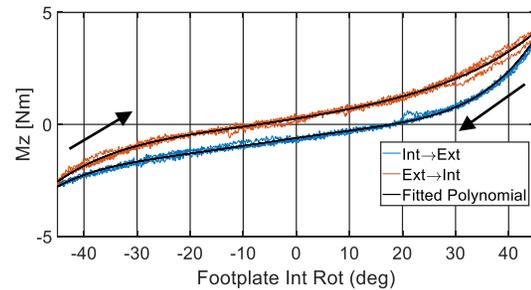

Figure 1: A typical hysteresis curve (for subject#3)

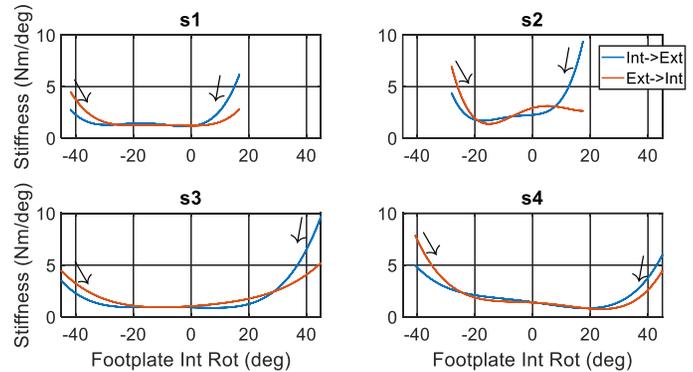

Figure 2: The stiffness curves for each subject

Table 1: Subjects' preference during sitting

	S1	S2	S3	S4
Self-reported	Toe-out	Toe-out	Toe-out	Toe-in
Resting stiffness	Toe-out	Toe-out	Toe-out	Toe-in

Table 2: Subjects' proprioception acuity as mean(SD) in degrees

	S1	S2	S3	S4
External rotate	-	4.35(1.58)	0.94(0.14)	1.64(0.10)
Internal rotate	-	2.75(1.14)	1.20(0.33)	1.64(0.33)

## Significance

We suggest a new proactive subject-specific strategy to reduce EKAM via a resting-stiffness principle driven from a sensory-motor assessment of the lower extremity in tibial rotation.

## Acknowledgments

L. Zhang has equity positions in Rehabtek LLC, which received federal grants in developing the robotic device used in this study.

# Evaluating activation patterns of the hand and wrist during dynamic tasks using a similarity index

Sarah Agnew<sup>1</sup>, Grace Han<sup>1</sup>, Yonatan Eshetu<sup>1</sup>, and Brad J. Farrell<sup>1</sup>

<sup>1</sup>Georgia State University, Atlanta, GA

Email: jhan39@student.gsu.edu

## Introduction

Hand and arm function are vital to recovery following neurological injuries such as those sustained following a brain or spinal cord injury. Inpatient and outpatient rehabilitation provided by Physical Therapists improves motor function acutely, but after discharge from therapeutic care patients often revert to utilizing the uninvolved limb to accomplish tasks. Underutilization of the affected limb results in diminished overall function and patient independence. One way to improve at home care is to utilize the muscle activation patterns to monitor compliance and efficacy of muscle recruitment. The purpose of this study was to determine if the muscle activation patterns can be used reliably to identify the intended movement pattern during dynamic tasks. We hypothesized that a similarity index could reliably identify each dynamic hand and wrist biomechanical movement when prompted by an on-screen video.

## Methods

Twenty, non-injured subjects were recruited via a convenience sample. Each subject performed static wrist flexion and extension, radial and ulnar deviation, and hand closing and opening, while electromyography (EMG) data was collected from a low-cost armband around the forearm. Each subject was then asked to perform the tasks in a dynamic fashion, such as repeating wrist flexion and extension, repeating opening and closing of the hand, and a global dynamic pattern task where each movement was prompted by a video in a random order. During each task, EMG data was acquired and streamed via Bluetooth to an Android tablet using a custom software app to quantify and identify the intended movement pattern.

Static and dynamic EMG patterns were compared using a vector similarity index (SI), which ranged from 0 to 1, to evaluate the movements. For the dynamic tasks, a 50 ms moving window was utilized to compare the EMG observed during the dynamic tasks to each static task for identification. A one-way ANOVA was used to evaluate statistical significance.

## Results/Discussion

For the non-injured group, similarity index analysis could discriminate between various movements, yielding reproducible and reliable results across subjects (Fig 1). Of the 3 antagonistic movements, wrist flexion and extension and wrist radial and ulnar deviation showed significant differences in SI. However,

closing and opening the hand elicited a less reliable SI compared to the others especially wrist extension. For the dynamic tasks, wrist flexion, wrist extension, ulnar deviation, and hand closing were most reliably identified (> 85% time). However, the transition phases between movements or tasks required a thresholding procedure, as no similarity index was appreciably high during this period.

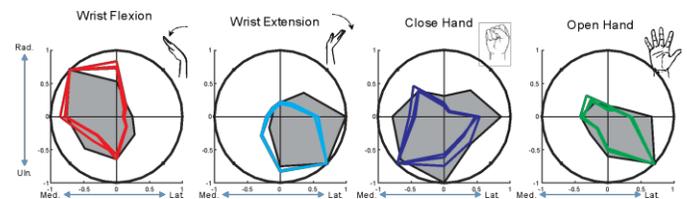

Figure 1: Average patterns (gray) from the 8-sensor EMG armband during specific movements and 3-trials from a representative subject. Note the similarity index for each movement was > 0.95.

## Significance

Our hypothesis that muscle activation patterns may be used to differentiate movement patterns was generally maintained. Therefore, we propose that this similarity index calculation can be integrated into a mobile software app to help delineate dynamic movements during training or natural behavior. Perhaps these movement patterns can also be incorporated as feedback to the participant in an effort to facilitate proper patterning during wrist and hand movements, especially following neurological injury. However, as always, more analysis is needed to fully develop this method.

### Introduction

Mid-portion tendinopathy is the most common pathologic condition of the Achilles tendon in adults. In addition to symptoms of pain, Achilles tendinopathy has been shown to significantly alter gait function [1], resulting in lower levels of physical activity and detriments to overall health and well-being [2]. Although full symptomatic recovery is evident after exercise treatments, this does not ensure full functional recovery [3]. Further, it is unknown if changes in patient-reported outcomes of Achilles tendinopathy treatment are related to adaptations in lower limb gait. Thus, the purposes of this study were to (1) evaluate changes in pain, patient-reported outcomes, and gait 24 weeks after initiation of Achilles tendon-loading exercise treatment, and (2) determine relationships between patient-reported outcomes and gait prior to and 24 weeks after initiation of treatment in patients with mid-portion Achilles tendinopathy.

### Methods

Twenty-five (11 M, 14 F, 51.2 ± 11.6 yrs) participants with clinically confirmed mid-portion Achilles tendinopathy underwent an effective exercise-based treatment program [3]. Pain, patient-reported outcomes, and gait data were collected at baseline and 8-, 16-, and 24-week follow up visits.

Pain was objectively assessed via pain pressure threshold (PPT). Algometer-applied (SBmedic, Solna, Sweden) pressure (kPa) at the Achilles tendon was recorded for 3 trials. Patient-reported outcomes of pain, symptoms, quality of life, and physical activity/sport function were assessed with two validated questionnaires: Victorian Institute of Sport Assessment-Achilles (VISA-A), Foot and Ankle Outcome Score Quality of Life (FAOS-QOL) and Sport and Recreation Function (FAOS-SP) subscales. A MuscleLab IMU system (Ergotest Innovations, Oslo, Norway) was used to collect gait data during a 10-m walk at a self-selected pace. The percentage of time spent in stance, mid-stance, and swing phases over 3 gait trials were calculated.

Average PPT, questionnaire score, and average gait outcomes for the most symptomatic limb were quantified for analysis. Repeated measures ANOVAs were used to test the main effect of time (baseline, week 8, week 16, week 24). Bonferroni corrections were used for post-hoc analysis of significant effects. Pearson's correlations were used to determine relationships between patient-reported outcomes and gait at baseline, and changes over the 24-week period. Alpha was  $p < 0.05$ .

### Results and Discussion

Twenty-four weeks after initiation of Achilles tendon exercise treatment, participants displayed significant clinical and functional improvements in their most symptomatic limb (**Table 1**). PPT increased at 16 and 24 weeks compared to baseline ( $p=0.011$ ;  $p=0.001$ ). Patient-reported outcomes of pain and symptoms measured by the VISA-A ( $p<0.001$ ) improved, while quality of life and physical activity/sport function measured by

the FAOS-QOL ( $p<0.001$ ), FAOS-SP ( $p<0.001$ ) increased throughout treatment compared to baseline. VISA-A and FAOS-QOL scores exceeded the minimum clinically important difference/change values [4-5]. Percentage of gait in stance phase decreased ( $p=0.039$ ) and swing phase increased ( $p=0.044$ ) from baseline to week 24 of treatment. After correcting for type I error, there was no effect of time on the mid-stance phase of gait ( $p>0.05$ ).

**Table 1:** Mean (SD) of outcome measures at baseline and 24 weeks.

	Baseline	Week 24
PPT*	170.9 (67.6)	220.5 (85.5)
VISA-A*	47.2 (20.9)	69.6 (20.9)
FAOS-QOL*	43.0 (18.3)	69.3 (23.3)
FAOS-SP*	58.0 (20.6)	79.4 (17.6)
Stance*	64.5 (2.5)	63.1 (2.8)
Mid-Stance	27.7 (5.2)	26.7 (5.4)
Swing*	35.6 (2.5)	36.9 (2.8)

\*significant effect of time ( $p<0.05$ )

Gait function displayed a moderate ( $\pm 0.3 < r < \pm 0.7$ ) correlation to patient-reported outcomes at baseline and improvements following the treatment period (**Table 2**). Of clinical relevance, at baseline, lower FAOS-QOL and FAOS-SP scores were correlated to an increased percentage of gait spent in mid-stance ( $p<0.01$ ). Twenty-four weeks after initiation of treatment, higher FAOS-SP scores were correlated to a decreased percentage of gait spent in mid-stance ( $p=0.001$ ).

**Table 2:** Correlation (r) of changes in patient-reported outcome and gait measures from baseline to 24 weeks.

	VISA-A	FAOS-QOL	FAOS-SP
Stance	0.096	-0.192	-0.031
Mid-Stance	-0.326	-0.116	-0.629*
Swing	-0.088	0.190	-0.036

\*significant at  $p<0.01$

Improvements in PPT, patient-reported outcome measures, and gait function were observed in patients with mid-portion Achilles tendinopathy. Patient-reported outcomes and gait were moderately correlated at baseline and 24 weeks after initiation of exercise treatment.

### Significance

In patients with midportion Achilles tendinopathy, clinical improvements may be related to functional gait measures during mid-stance 24 weeks after initiation of an Achilles tendon exercise program.

**Introduction**

Ultrasound shear wave elastography (SWE) has been used as a non-invasive method to estimate muscle tissue elasticity [1–3], and may be useful for quantitatively assessing changes in elasticity following acute muscle strain injury. Most studies investigating tissue elasticity with SWE do not report the reliability of their measures [4]. When reliability measures are reported, conflicting evidence exists with larger muscles of the lower extremity, such as the hamstrings, especially in repeat imaging sessions [4,5]. The purpose of this study was to determine the test-retest reliability of shear wave speed (SWS) measures in different regions of the hamstring muscles.

**Methods**

Ten participants were recruited (18-35 years of age, self-reported regular exercise, no history of lower extremity surgery or hamstring injury) and provided written informed consent.

Participants were asked not to exercise for >3 hours prior to image acquisition. Participants were positioned in prone with their hips and knees in a neutral position, fully supported, and with no active muscular contraction. Locations corresponding to 33, 50, and 67% of the thigh length (proximal, mid-belly, and distal, respectively) from the ischial tuberosity to the midline between femoral condyles were marked bilaterally.

SWS measures were obtained for each hamstring muscle (semimembranosus: SM; semitendinosus: ST; biceps femoris long head: BF<sub>lh</sub>) at each location along the thigh by an experienced sonographer (5+ years) using the same US system (Aixplorer, Supersonic Imagine). Gel was applied along the length of the thigh and the transducer (SuperLinear, SL 10-2, 38 mm aperture) was applied with minimal pressure. A single image (5 cm depth) was captured at each location and the mean of 3 SWS measurements within the mid-thickness of the muscle (Q-box with 5.0 mm diameter) was calculated. Repeat images were captured bilaterally with 60 s of seated rest between trials.

Intraclass correlation coefficients (ICC(3,1)), standard error of measurement (SEM), minimal detectable change (MDC), and coefficients of variation (CV) were calculated. Reliability

was defined as poor (ICC<0.5), moderate (0.5 ≤ ICC < 0.75), good (0.75 ≤ ICC < 0.9), or excellent (ICC ≥ 0.9).

**Results and Discussion**

Participants (6 females:4 males) had mean ± standard deviation (SD): age 22.7 ± 1.8 years and BMI 22.6 ± 2.2 kg/m<sup>2</sup>. Test-retest reliability for most locations across all muscles was moderate to good (Table 1), except at the distal BF<sub>lh</sub>. SEM ranged from 0.11 – 0.17 (mean: 0.13 m/s) with MDC ranging from 0.31 – 0.48 m/s (mean: 0.35 m/s). The CV across all locations and muscles was less than 9% (range: 4.1 – 8.9%).

Poor reliability at the distal BF<sub>lh</sub> may be explained by its morphology as it begins to taper and become more tendinous as it joins with the BF short head. This study adds to the current understanding of SWE reliability, as most studies have only imaged at a single location in the muscle [2,5]. Previous studies have reported SWE CV values [kPa] in excess of 15% [5] whereas we found CV values less than 9% across all locations.

**Significance**

This study indicates SWS measures can be reliable in the hamstring muscles, but care should be taken in extrapolating repeatability measures at a single location (e.g. mid-belly locations reported in many studies) across the whole muscle.

# Development and Validation of a Finite Element Model of the Cervical Spine

Shadman Tahmid<sup>1</sup> and James Yang<sup>1\*</sup>

<sup>1</sup>Human-Centric Design Research Lab, Department of Mechanical Engineering, Texas Tech University

Email: james.yang@ttu.edu

## Introduction

The cervical spine protects the spinal cord along with nerve roots, provides structural support and flexibility of movement of the head and neck complex. Injuries to the cervical spine can be fatal [1]. Finite element (FE) model can help understand the injury mechanism and dysfunction in the head and neck complex [2,5]. With the advancement of powerful computational capabilities, FE models are now being widely used as a tool for biomedical applications. There have been a lot of work in modeling cervical spine using finite element technique in the past few decades [2,3,6,7]. Unfortunately, most of these models are not publicly available hence there is a need for building our own model. Verification and validation against experimental study is required for an FE model to be applicable. This study aims to develop a detailed finite element model of the cervical spine and validate the model against existing literature.

## Methods

The geometries of the cervical spine finite element model were developed based on CT scan data provided by Texas Back Institute. The three-dimensional model consists of six cervical spine vertebrae (C2 to C7). The vertebral bodies of the model have the cortical bone, the cancellous bone and the posterior bony structure. The spaces between two vertebrae are filled with intervertebral discs. An endplate of approximately 0.1mm thickness is integrated between each disc and vertebra. Each disc is constructed with annulus fibrosus and nucleus pulposus. Five major ligaments (anterior longitudinal ligament (ALL), posterior longitudinal ligament (PLL), ligamentum flavum (LF), interspinous ligament (ISL) and capsular ligament (CL)) are modeled between the vertebrae and discs as shown in Figure 1.

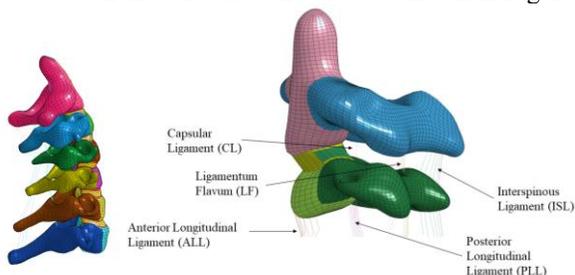

Figure 1. Meshed cervical spine model from C2 to C7 along with the ligaments.

The three-dimensional surfaces of the vertebrae went through a smoothing process using Blender (Blender Foundation, Amsterdam, Netherlands). This procedure removed all spikes and unwanted holes on the surface of the vertebral geometry. Meshing was performed in IA-FEMesh (University of Iowa, Iowa City, IA, USA) using multiblock technique. The intervertebral discs were modeled with concentric layers of elements where the nucleus remains centered. The nucleus is around 40% of the entire disc volume. Nonlinear stress-strain curves were used for the material properties of the ligaments.

## Results and Discussion

The complete model was simulated in LS-DYNA. Pure moment (2, 1.5, 1, 0.5 Nm) applied to the C2 vertebrae about x-axis

created flexion (+) / extension (-) while all the nodes of the bottom surface of C7 vertebrae were constrained in all degrees of freedom. The model was tested in flexion-extension against experimental data published by Wheeldon et al. [4] and Nightingale et al. [5], and finite element simulation results by Erbulut et al. [6] and Panzer et al. [7]. The range of motion (ROM) of each spinal unit in flexion-extension is in the range of the specified literature as shown in Figure 2. The ROM mostly follows experimental corridor in the literature though a slight stiffness can be noticed in the flexion of C2-C3 spinal unit. For all other spinal units, the result is closer to the studies conducted by Panzer et al. Overall results show an asymmetry in the flexion and extension direction.

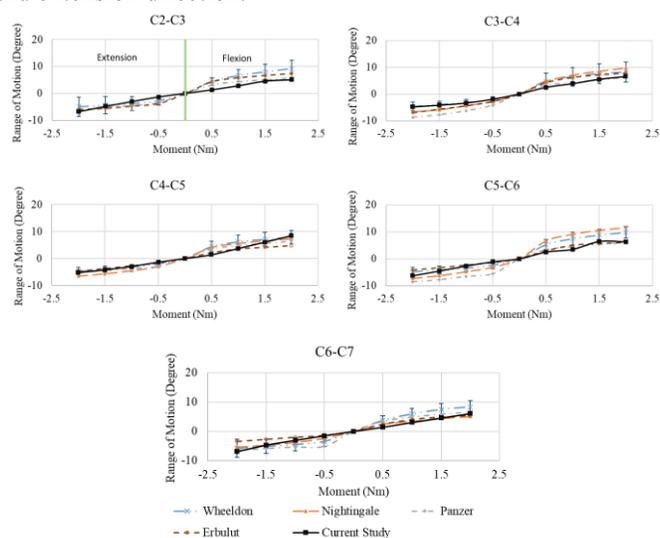

Figure 2. Range of motion during flexion-extension compared with specified literature for different spinal units.

## Significance

Finite element models can be applied in medical science to study and simulate real-life situations. Whiplash in car accidents, disc degenerative disease or high-g acceleration during flight maneuvers can injure the cervical spine. These conditions can be studied in detail using this validated finite element model.

# Quadriceps Muscle Morphology Predicts Vertical Ground Reaction Forces Following ACL Injury

Kazandra M. Rodriguez<sup>1</sup>, Steven A. Garcia<sup>1</sup>, and Riann Palmieri-Smith<sup>1,2</sup>

<sup>1</sup>School of Kinesiology, University of Michigan-Ann Arbor

<sup>2</sup>Department of Orthopaedic Surgery, University of Michigan Medicine

Email: [kazandra@umich.edu](mailto:kazandra@umich.edu)

## Introduction

Quadriceps weakness is a ubiquitous consequence following ACL injury and reconstruction. Alterations in muscle morphology is one factor theorized to contribute to quadriceps weakness. [1] Features such as muscle cross-sectional area (CSA) and fascicle length determine the force production of muscle. Although greater quadriceps strength is linked to lower peak ground reaction forces, [2] it is unclear whether muscle morphology can predict ground reaction forces. Given that alterations in muscle morphology are associated with deficits in quadriceps force, [3] it is plausible that features such as cross-sectional area and fascicle length may contribute to ground reaction forces during gait. Muscle morphology is a factor that can be modified through interventions such as eccentric exercise [4], thus investigating the relationship between muscle morphology and loading during gait may provide valuable insight into targeting abnormal loading after ACL injury.

Therefore, the primary purpose of this study was to examine the contributions of vastus lateralis (VL) cross-sectional area and fascicle length to vertical ground reaction forces in individuals with ACL injury.

## Methods

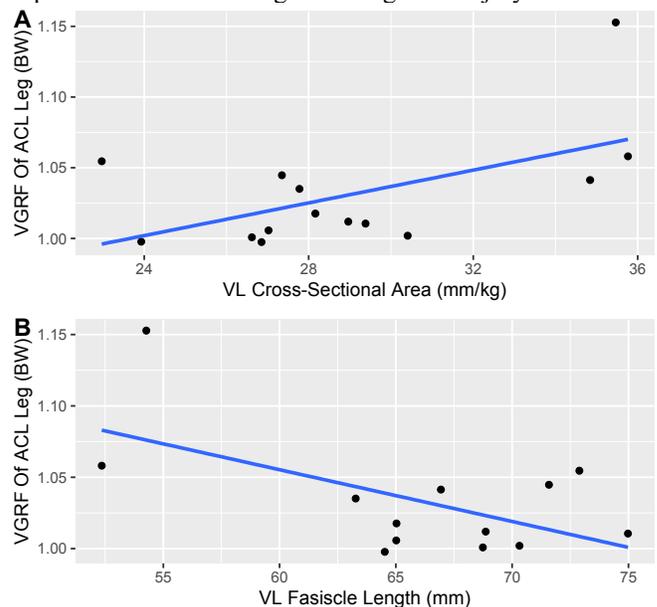

Fourteen individuals participated in this study (X M/X F; age = Y; time since injury = ZZ). Eligibility criteria included 1) aged 14-45 years of age and 2) an acute ACL rupture. Prior to surgery, 3-D joint kinematics and kinetics were collected during overground walking at 1 m/s using a 10-camera motion capture system (Qualisys; 12 Hz) and two fixed force plates (AMTI; 2000 Hz). Peak vertical ground reaction forces of the ACL-injured leg were extracted from the first half of stance and averaged over 3 trials. Static CSA and fascicle length of the VL were collected using ultrasonography (GE Logiq; 12 MHz, gain 15 dB). Images were assessed using ImageJ and averaged for 3 trials. Cross-sectional area was normalized to body mass (mm/kg) and ground reaction forces were normalized to units of body weight (GRF in N/body mass in N). Linear regressions assessed the contribution of CSA and fascicle length of the VL to peak vertical ground reaction forces. Statistical analyses were performed using R (Version 3.6.1) and level of significance set *a priori* at  $p < 0.05$ .

## Results and Discussion

CSA and fascicle length of the VL significantly predicted peak vertical ground reaction forces of the ACL-injured leg (Adj-R<sup>2</sup><sub>CSA</sub> = 0.25; Adj-R<sup>2</sup><sub>FASCICLE-LENGTH</sub> = 0.27). Greater VLCSA and shorter fascicle lengths were predictive of higher vertical ground reaction forces ( $p = 0.04$ ).

Although the relationship between quadriceps morphology and joint loading after ACL injury has not been studied to date, the current findings are consistent with muscle morphology and its relationship to force production. Pennate muscles like the VL have fascicles oriented at an angle relative to the muscle line of action [5] and result in shorter fascicle lengths. [6] The shorter fascicle lengths allow a greater number of sarcomeres in parallel and greater fascicle rotation, which increases the force production

of the muscle. Concurrently, greater CSA would increase the number of sarcomeres in parallel and increase force production further. [7] Thus, individuals with greater GRFs during walking may demonstrate greater quadriceps muscle forces due to larger CSA, shorter fascicle lengths, and greater changes in fascicle rotation. Considering quadriceps strength contributes to tibiofemoral loading during gait, [8] the current findings suggest muscle morphology may present a modifiable parameter to improve abnormal loading following ACL injury.

**Figure 1:** Correlations between A) VL CSA of the injured leg and VGRF of the injured leg and B) VL fascicle length of the injured leg and VGRF of the injured leg. The line represents the best linear fit.

## Significance

Static quadriceps muscle morphology is predictive of joint loading of the ACL-injured leg during gait. However additional research is needed to directly examine the contribution of quadriceps muscle morphology to joint loading during locomotion. Future studies examining joint loading and dynamic muscle morphology during locomotion may provide further insight.

## Introduction

Anterior cervical discectomy and fusion (ACDF) is performed approximately 150,000 times per year in the US [1]. However, 14-32% of ACDF patients are symptomatic again within 10 years of the initial surgery [2]. It is unclear whether the new pathology is related to the surgical procedure, which may affect adjacent segment loading and lead to degeneration, or if the new pathology is part of the natural history [3]. Intervertebral range of motion (ROM) is typically used to evaluate adjacent segment kinematics following ACDF, but ROM only provides information regarding the quantity of motion rather than the quality of motion (*i.e.* how the motion occurs). The instant center of rotation (ICR), which incorporates the combined translation and rotation that occurs during movement, has been proposed to evaluate motion quality [4]. The aim of this study was to evaluate (1) the effect of pathology on the ICR, as well as (2) the effect of ACDF on the ICR. We hypothesized that both pathology and fusion affect the ICR.

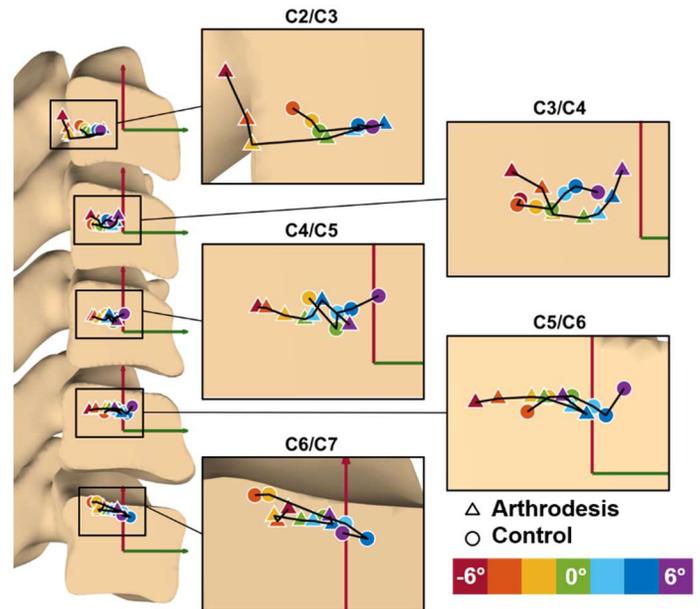

## Methods

This analysis included 30 middle aged controls (10M, average age 46.3±6.7yrs.) and 45 arthrodesis patients (22M, average age 48.4±7.2yrs.) set to receive either single or double level ACDF at either the C4/C5, C5/C6, or C6/C7 motion segments. All participants consented to participate in these IRB-approved studies. Synchronized biplane radiographs were collected at 30 images/second for 3 seconds as participants moved through three trials of full flexion/extension ROM. Radiographs of the arthrodesis patients were collected before (PRE) and 1 year after (POST) surgery. Six degree-of-freedom kinematics were determined using a validated registration process that matched subject-specific CT-based bone models to the biplane radiographs with sub-millimeter accuracy [5]. The ICR was then calculated using the finite helical axis method, as previously described [6,7]. ICR location was evaluated at every 2° increment of intervertebral flexion/extension from -6° (extension) to +6° (flexion) at each subaxial motion segment. Additionally, changes from before to after surgery in ICR location were analyzed in the arthrodesis patients at the motion segments superior and inferior to the fusion. A Student's t-test was used to identify differences between groups at corresponding motion segments and within the fusion group from PRE to POST with significance set at  $p < 0.05$  and a Bonferroni correction applied to account for multiple comparisons ( $n = 7$ ).

## Results and Discussion

Eight arthrodesis patients received ACDF at the C4/C5 segment, 37 received ACDF at the C5/C6 segment, and 25 received ACDF at the C6/C7 segment. There were no differences found in either the AP or SI location of the ICR between the controls and PRE arthrodesis patients at the asymptomatic C2/C3 or C3/C4 motion segments (all  $p > 0.1$ ) or the symptomatic C4/C5 or C6/C7 motion segments (all  $p > 0.35$ , Figure 1). The ICR at the symptomatic C5/C6 was more anterior in the arthrodesis group than the controls at 6° of flexion (purple circle vs triangle,  $p <$

0.038, Figure 1). Generally, it does not appear that pathology alters the quality of the intervertebral motion compared to age-matched controls.

**Figure 1.** ICR locations from 6° of intervertebral extension (dark red) to 6° of intervertebral flexion (purple) in the arthrodesis (triangles) and control (circles) at each intervertebral level.

There were no changes observed in either the AP or SI location of the ICR at the superior or inferior adjacent segments from PRE to POST (all  $p > 0.2$ ) nor were there differences in the change of ICR location at the adjacent levels following either single or double level fusion (all  $p > 0.07$ ). We found no evidence to suggest that ACDF alters the quality of adjacent segment intervertebral motion at 1 year after surgery.

## Significance

Neither pathology nor ACDF surgery appear to alter how motion occurs at the symptomatic or adjacent segments during cervical spine flexion/extension. This finding fails to support the belief that pathology or ACDF surgery alter adjacent segment kinematics.

## Acknowledgments

This work was supported by NIH Grant R01 AR069543.

## Introduction

Head injury risk secondary to unsafe head accelerations is a growing concern for athletic populations as new discoveries of adverse effects from even sub-concussive impacts have been made. In order to investigate the potential effects of neck strength on head-acceleration injury risk, previous efforts have used static strength tests and dynamic impact simulations to identify factors that may have injury-prevention implications. While neck strength and muscle size have been shown to have a protective effect in laboratories, their relationships have shown mixed results when used to predict on-field injury rates, stressing the need for a clearer understanding of the muscle size-strength relationship and how it might vary across different conditions and population groups.

Therefore, the purpose of this study was to elucidate the neck muscle size-strength relationships and explore the effects of gender and neck posture on the relationships.

## Methods

Thirty healthy adult subjects (13 males, 17 females) underwent neck strength testing and MR imaging of the neck region. In strength testing, the subjects wore a helmet, were strapped into a seat within a custom-built test frame, and performed maximal voluntary exertions (MVEs) by pressing via a helmet-mounted interface against a tri-axial load cell in three different configurations: A) flexion in a neutral posture, B) flexion in a 40° extended posture, and C) extension in a 40° flexed posture. The analysis of MR images (3T clinical scanner, PD-TSE, 3.0mm slice thickness, no gap) involved manual segmentation in MIMICS 20.0 of the following muscles: sternocleidomastoid (SCM), infrahyoids (IH), anterior scalene (AS), longus capitis and colli (LONGUS), semispinalis cervicis and multifidus (DEEP), splenius capitis and cervicis (SPL), longissimus capitis and cervicis (LONGISS), semispinalis capitis (SSC), levator scapula (LS), and trapezius (TRAP).

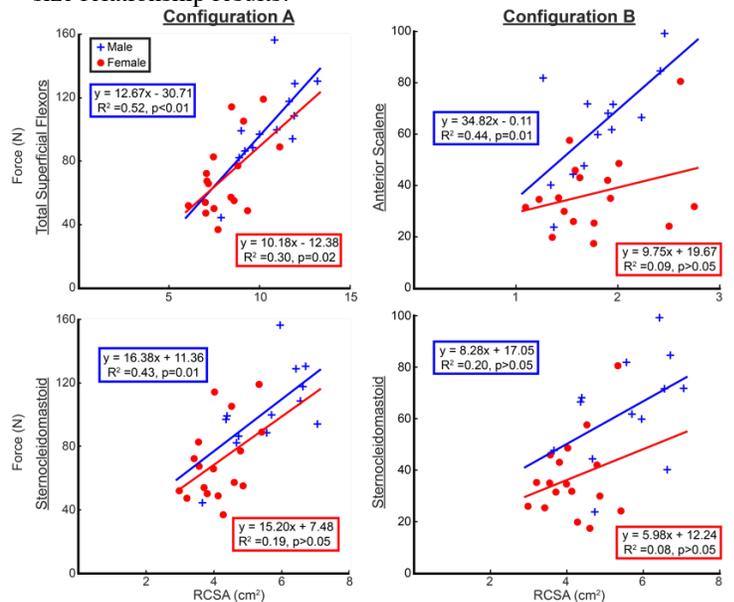

The following muscle size measures were defined and calculated for each muscle: anatomical cross-sectional area (ACSA) was defined as the single largest cross-sectional area for a given muscle; muscle volume (MV) was calculated by multiplying the sum of segmented areas from all MRI slices by slice thickness; reconstruction-based cross-sectional area (RCSA) was a novel measure of physiologic cross-sectional area calculated by dividing MV by muscle length (ML)—estimated by re-slicing the 3D point cloud reconstruction of a segmented muscle into 3mm axial sections and finding the length of the cubic polynomial fit to the sections' centroids.

Student's t-tests were used to compare anthropometric, strength, and muscle size measures between genders. Linear regression and ANCOVA were used to analyze muscle size-strength relationships and test for gender differences.

## Results and Discussion

Males had significantly greater neck strengths than females in all configurations while there were no statistical differences in age,

weight, or BMI between the two genders. Female neck strengths showed significant inter-configuration correlations while male strengths did not. ANCOVA models found total superficial flexor (TSF = SCM+AS+IH) and SCM sizes to have significant correlations with flexion strength in the neutral posture, with no gender difference; for males, the SCM was a strong predictor of neck flexion strength in the neutral posture, while the AS muscle was evidently more involved in the extended posture—none of these however held true for females (Fig. 1). Less strength variability was explained by muscle size alone in females than in males. All muscle size metrics yielded nearly identical strength-size relationship results.

**Figure 1:** Sample muscle strength-size relationships where statistical significance ( $\alpha = 0.05$ ) was identified for TSF and SCM in config A and for AS but not SCM in config B, for at least one gender.

## Significance

Males and females exhibited distinct strength and muscle correlations, highlighting the importance of gender-specific strength data analyses and applications. Such applications may include musculoskeletal modeling, strength prediction for injury prevention, and job design. Muscle strength testing results in the most commonly adopted neutral posture are not good predictors for strengths in deviated neck postures, which may be more relevant to practical or clinical applications. Lastly, there is no readily apparent advantage of one muscle size metric over another when analyzing neck muscle size-strength relationships.

## Introduction

Sports-related concussion (SRC) negatively affects players' neurocognitive function as measured by a simple clinical cognitive test (i.e. the ruler-drop test) [1]. Quicker neck muscle reaction time (RT) against neck perturbations and the rate of muscle force development (RFD) have shown to play a critical role in increasing neck stiffness and reducing potential impacts and severity of SRC [2,3]. In an attempt to examine one's ability to generate neck muscle force in response to specific directions via visual cues, we built a custom neck strength measurement device to measure neck force output (peak force: PF and RFD) [4] in addition to the capability to provide and calculate visual cues with RT. Multidirectional neck muscular characteristics in response to visual cues have not been investigated. Therefore, the purpose of the study was to establish test-retest reliability of an individual's visual-neck muscle RT, PF, and RFD.

## Methods

Fifteen subjects (10 females/5 males, Age: 24.5±2.1yrs, HT: 168.1±7.4cm, WT: 70.6±11.3kg) with no history of neck pain/issues participated in the study. Testing was in a research laboratory two times, one week apart. Data was collected with a custom neck strength testing device at 1000 Hz. RT, PF, and RFD were measured for cervical flexion, extension, and lateral flexion. For RT, subjects pushed as hard and quick as they could in response to a black arrow which appeared on a computer screen. The arrow also directed the specific direction of "push" (flexion, extension, right, or left lateral flexion). The trigger time (for the arrow to display) was variable (3-10sec) and the direction of the arrow was randomized. After several practice trials, the average of three trials for each direction were recorded and analysed. RT was the time between the trigger and >5 N at the initiation of responses (in milliseconds:ms). Subjects were verbally encouraged to keep pushing as hard as they could for at least 3 seconds. PF was the highest force output reported during each trial (in Newtons:N). RFD was calculated by dividing the change in neck force over the change in time (in N/sec) from the initiation of responses (~5N) to various points based on the time to pass individual's PF (50% and 90%) and based on actual times (50ms, 100ms, 150ms, and 200ms). Descriptive statistics, test-retest intraclass correlation coefficient (ICC) model (3,1) and standard error of measurements (SEM) were used for statistical analyses.

## Results and Discussion

Average RT ranged from 478ms to 533ms. Neck extension PF was higher (187 N) than other directions (115-135 N). Highest RFD was observed at 50%PF and at 100ms (**Table 1**). *Good to excellent* ICCs (ICC=0.536-0.957) were reported except for lateral flexion RT and RFD at 90% (**Table 2**). More subjects

and refinement of the protocol will likely improve ICC and SEM by minimizing potential outliers due to missed/delayed responses to visual cues and pushed wrong directions.

	RT (ms)	PF (N)	RFD50%	RFD90%

**Table 2. Reliability and Precision: ICC (SEM).**

## Significance

The current findings confirm that most variables related to neck neuromuscular characteristics and multidirectional visual-neck RT can be reliably assessed using the custom-made neck device. Clinical significance of slower RT or lower RFD in individuals with different musculoskeletal conditions such as SRC, neck pain, and whiplash should be examined in future investigations.

## Acknowledgments

The neck strength device was built with the financial support by the Mayo Clinic Ice Hockey Research Group.

# Biomechanical Effect of Valgus/Varus Knee Joint Alignment on ACL Reconstruction Surgery

Byeongchan Cho<sup>1</sup>, Tae Soo Bae<sup>1</sup>

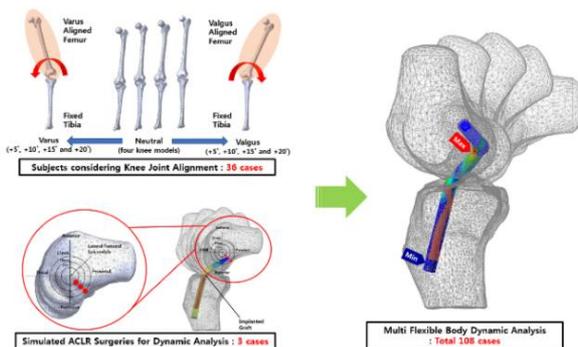

<sup>1</sup> Department of Biomedical Engineering, Jungwon University, Goesan-gun, Korea, Republic of Email: \*[ktroy@wpi.edu](mailto:ktroy@wpi.edu) \*include just the corresponding author email

## Introduction

In case of the excessive varus and valgus deformities of the knee joints, they can cause damages to articular cartilage or secondary injuries to peripheral tissue of the knee joint [1]. To maintain the functional balance of the knee joint, the joint alignment should be considered when anterior cruciate ligament reconstruction (ACLR) is performed. However, there were few studies on the varus and valgus deformities of the knee joint in ACLR surgery. Therefore, the aim of this study was to analyze the biomechanical effects of implanted graft in ACLR surgery by calculating the stress which in each surgical site according to the varus and valgus alignment of the knee joint.

## Methods

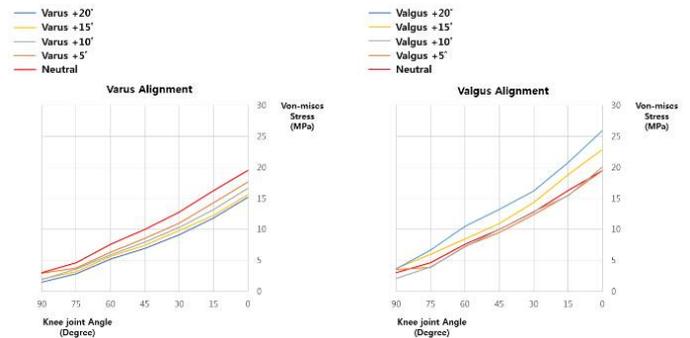

The images of the femur and tibia were obtained through computed tomography of the left knees of four males who have no orthopedic diseases in the musculoskeletal system. Each three-dimensional knee joint model was reconstructed by using an image processing program (Mimics 20.0, Materialize, Belgium). Through multi-flexible body dynamics (MFBD) analyses, von-mises stresses on the implanted graft were calculated during continuous knee flexion and extension motions. In order to apply the continuous knee motion, the knee angle was set by coordinates the movements of the several landmarks on the femur at intervals of 15 degrees. The MFBD analyses were performed for a total of 108 cases were calculated to simulate neutral, varus and valgus deformities (Neutral, +5, +10, +15 and +20 degrees) at three recommended surgical sites (Posteroproximal areas of 5, 10 and 15mm radii on the femoral epicondyle)[2] and then the calculated stresses of implanted graft were compared among them (Figure 1).

**Figure 1:** Process of making a 3D varus/valgus knee joint models and recommended surgical sites during MFBD analysis.

## Results and Discussion

In the varus and valgus alignment knee joints, the stresses of implanted graft were increased as the knee joint angle decreased. Compared to the stress values (19.53 MPa) of the neutral alignment knee joints at the knee bending angle of 0 degrees, the stress of the the 20-degrees varus alignment knee joints lower by 23% on average. On the other hand, the stress of the 20-degrees valgus alignment knee joints was higher by 32% on average.

**Figure 2:** Von-mises stress on implanted graft considering varus and valgus knee joint alignments as knee joint angle.

In the varus alignment knee joints, the stresses of implanted graft were decreased as the alignment angle increased. In the knee joints of 15-degrees and 20-degrees valgus, the stresses of the implanted graft were 22.9MPa and 25.93MPa, which increased slightly (Figure 2).

## Significance

Based on the results of this study, we propose that the ACLR surgery for severe valgus deformity knee joint (more than valgus deformity of 15-degrees) was implemented after varus alignment of knee joint considering the stress of implanted graft. However, varus and valgus alignments were performed for normal knee models in this study. In the future, we will conduct additional researches for patients' knee models with severe varus and valgus deformities. Furthermore, we will also evaluate the surgical technique that performs ACLR and high tibial osteotomy together.

# Evaluation of Texture Features from Micro-Computed Tomography of Osteogenesis Imperfecta Bone Specimens

Andrea H. Rossman, Katarina Radmanovic, Gerald F. Harris, Carolyn I. Albert, Peter A. Smith, and Jessica M. Fritz  
Medical College of Wisconsin, 8701 W. Watertown Plank Rd., Milwaukee, WI 53226, USA

## Introduction

Osteogenesis imperfecta (OI) is a genetic, heritable disorder resulting in defective collagen network formation necessary for proper bone formation. Consequently, people born with OI are prone to frequent long bone fractures. There exists a need to better characterize OI bone properties to improve fracture mitigation as well as activity and rehabilitation prescriptions. Volumetric bone mineral density (vBMD) is commonly used to describe bone quality in OI patients [1,2]. However, this density measure does not account for structural differences within the bone. Previous imaging studies have evaluated 3D texture parameters to assess variations in bone texture in OI populations [1,3]. While texture has been studied previously, the use of higher order texture statistics has yet to be investigated. These texture features are used to classify tumors in the field of radiomics [4,5]. We hypothesize that second order texture features (contrast, correlation, energy and homogeneity) derived from micro-computed tomography (CT) images will have higher correlation to mechanical properties than previously used porosity and vBMD values.

## Methods

Cortical bone samples taken from two children with OI type III were each machined into eight miniature beams cut in both the transverse and longitudinal directions. There were four beams in each group. The beams were then imaged via micro-CT at a resolution of 10  $\mu\text{m}$  and underwent flexural testing in three-point bending [6]. Porosity and vBMD were calculated using the scanner's SCANCO voxel-counting algorithm. Each beam's modulus of elasticity (E) was calculated from the stress-strain curves of the flexural testing.

A customMATLAB algorithm automatically selected regions of interest (ROIs) from each micro-CT bone scan and calculated four texture variables (Figure 1). For each beam, three ROIs from different levels within the scan were taken. The values from each slice were averaged for use in the analysis.

**Figure 1:** This ROI clearly demonstrates heterogeneous texture throughout its area.

Second order texture statistics (contrast, correlation, energy and homogeneity) derived from the gray-level co-occurrence matrix (GLCM) were calculated to evaluate the bone texture [7]. The GLCM compares the value of pixels to their neighbors, thus encoding spatial information into its derived variables; contrast, correlation, energy, and homogeneity.

The Pearson's Correlation Coefficient was calculated to compare each of the six imaging variables to E for each beam. The longitudinal and transverse beams were analyzed separately.

## Results and Discussion

The GLCM-derived variables had higher correlation coefficients than porosity and vBMD for the longitudinal beams (Table 1). However, the E of the transverse beams was most highly

correlated to porosity and vBMD. These results indicate that measuring GLCM texture features would be able to more accurately describe longitudinal bone properties. The small sample sizes of each group and the heterogeneity within each bone sample represent a limitation to the current preliminary study. Continued sample collection and data extraction will increase the power of the analysis.

**Table 1:** Pearson's correlation coefficients (r) for modulus of elasticity (E) vs. imaging variables, for longitudinal and transverse bone beams.

Variable	r, Longitudinal	r, Transverse
Porosity	-0.43	-0.81
vBMD	0.43	0.73
Contrast	0.63	0.58
Correlation	0.62	0.34*
Energy	-0.71	-0.58
Homogeneity	-0.63	-0.58

\* This value based on three samples, as one correlation value was found to be not a number (NaN), and thus was excluded

## Significance

The texture parameters show a stronger correlation to E than vBMD and porosity for the longitudinal beams. This demonstrates potential evidence to use additional texture variables other than porosity and vBMD in estimations of mechanical properties from clinical imaging. Highly correlated imaging and mechanical property variables are needed to better inform patient-specific predictive models for OI fracture risk [8]. Clinical decisions in OI for rehabilitation, surgical options, and lifestyle modifications are made based on the presumed fracture risk; therefore, more accurate, patient specific models would allow for personalized medical care to maximize the patients' quality of life.

## Auxetic Behavior of Achilles Tendons while Loading to Failure

Alexander W Hooke<sup>1</sup>, Christopher V Nagelli<sup>1</sup>, Sebastian A Mueller<sup>1,2</sup>, Christopher H Evans<sup>1</sup>

<sup>1</sup>Mayo Clinic, Rochester, MN, USA; <sup>2</sup>University of Basel, Switzerland

Email: hooke.alexander@mayo.edu

### Introduction

The Achilles tendon is the largest and strongest tendon in the human body. Scientific understanding of the mechanical and/or biological functions contributing to this exceptional strength remains poorly understood.<sup>3</sup> Previous studies investigated the material properties of the tendon via *ex vivo* testing, but conclusions from these investigations are limited because *in vivo* behavior was not well replicated and the anisotropic stresses and strains along the Achilles' unique geometry were unaccounted for.<sup>1-3</sup> Our team tested Achilles tendons to failure using an anatomically correct fixation and positioning system while measuring the 3D deformations of the entire posterior surface of the tendon using digital image correlation (DIC).

### Methods

11 fresh frozen, Achilles tendons were tested. Each specimen's calcaneus was potted in bone cement with the Achilles insertion above the cement and visible. The muscle-tendon junction was fixed with a cryo-clamp. The tendon's posterior surface was coated with a black and white speckling pattern to enable the DIC system (GOM, Braunschweig, Germany) to record, calculate, and analyze the 3D deformation response. Specimens were mounted to a servo-hydraulic testing machine, oriented to simulate the anatomic position of a plantigrade foot in a neutral position. Tendons were pre-conditioned for 10 cycles then loaded to failure at 5 mm/s.

### Results and Discussion

The distribution of the major strain (Fig 1A) was non-uniform and varied by ~20% at the moment before failure. The greatest

strain occurs away from the site of failure (Fig 1A,C,D) with a localized strain peak at the failure site occurring only just prior to rupture. The direction of the major strain in a majority of the tissue is not parallel to the loading direction (Fig 1B). Independent examinations of the transverse (Fig 1C) and longitudinal strain (Fig 1D) indicate that the tissue exhibits a negative Poisson ratio, a quality known as auxetic behavior, meaning it becomes wider when stretched. Auxetic materials are recognized for their ability to absorb energy and resist fracture. Previous research on Achilles auxetic behavior shows similar behavior patterns to those identified here, but were limited to a smaller region of the tendon at sub-failure loading.<sup>4,5</sup>

### Significance

The strain distribution and extreme degree of auxetic behavior measured in the present study have not been observed before and provide novel insights into the material properties and mechanical behavior of the human Achilles tendon.

## Introduction

Professional athletes are commonly diagnosed with concussive injuries due to head trauma sustained through collisions or falls. Recently, evidence of the permanent psychiatric consequences of these injuries has motivated the development of novel technology for concussion prevention [1]. Studying biological injury mitigation mechanisms utilized by animals that experience routine head-impacts may inspire the design of effective head protection systems.

Male bighorn sheep participate in seasonal bouts of intraspecific combat involving high impact head-butting. A lack of symptomatic brain injuries suggests these animals have evolved biological mechanisms for injury mitigation. Computational studies have shown that the bony horncore of bighorn sheep horns plays a key role in absorbing energy during ramming which has clear implications for injury mitigation [2]. Studies of bone tissues from other species have demonstrated that bone has an exceptional ability to adapt its composition and microstructure to provide specialized mechanical functionality [3]. Thus, it was hypothesized that bighorn sheep horncore cortical bone has a reduced mineral content compared to cortical bone from other mammalian species that provides increased energy absorption during loading.

## Methods

Cortical bone was extracted from the horncore of 6 bighorn sheep rams that died of natural causes and spanned a wide range of horn size. Three-point bend samples were milled into beams with dimensions of 30 x 3.5 x 2 mm (length x width x depth) and tested to failure with a cross-head speed of 1 mm/s at room temperature under physiological hydration. Engineering beam theory was used to determine the elastic modulus (E), bending strength (BS), and fracture energy (W) of each sample. One half of each fractured specimen was ashed to determine the bone mineral content (BMC) similar to previous studies [4]. Histological sections were stained with toluidine blue and assessed for porosity. Analysis of variance compared the measured parameters to those of cortical bone from black bear tibias [4] and red deer antler [5,6]. Correlations between outcome variables and horn curl length were assessed via regression. Stepwise regression was used to assess the contribution of porosity and BMC to the mechanical properties.

## Results and Discussion

The bighorn sheep cortical bone mechanical properties demonstrated positive correlations with curl length, suggesting the older and larger rams have bone with greater mechanical properties. The mechanical properties of horncore cortical bone are all lower than those from black bear tibias and red deer

antler (Table 1). The ram horncore and red deer antler have similar BMC, which is lower than black bear tibia BMC. Lower BMC in antler is believed to promote high energy absorption by increasing ductility in these structures that experience impact during combat [3]. Therefore, it was surprising the fracture energy was lower in ram horncore than in red deer antler despite similar BMC levels. However, horncore cortical bone may demonstrate improved energy absorption at the strain rates experienced during ramming, which are several orders of magnitude higher than what was used for this testing [2].

The low fracture energy may also be attributed to the high porosity of horncore bone. Stepwise regression of ram and bear bone indicated that porosity alone was the best predictor of fracture energy. Porosity explained nearly 60% of the variation in fracture energy and demonstrated a negative correlation. Including BMC did not improve the model. It is not clear why ram bone has higher porosity than bear bone, but the porosity of bighorn sheep samples is mainly due to large resorption cavities. One possibility is extreme levels of microdamage develop in ram bone during headbutting and damage-induced targeted bone remodeling leads to high porosity.

Most of the volume inside the keratin horn of bighorn sheep is filled by a porous bone material with a very unique architecture [2]. Previous finite element modeling showed that this porous bone significantly reduces brain cavity accelerations [2]. Therefore, it is possible the horncore cortical bone serves primarily to interface the keratin horn with the high energy absorbing porous bone.

## Significance

The energy absorbing mechanisms of bighorn sheep horn and horncore bone have only begun to be elucidated. The mechanical properties measured in this study can be used in future computational models to investigate the role of the porous bone architecture in brain injury mitigation during combat. Additionally, high strain rate testing on cortical and porous horncore bone will further increase our understanding of these unique materials. Ultimately, the mechanical properties and architecture of bighorn sheep horncore bone could influence novel bioinspired designs for injury mitigation devices in humans. [2].

## Padding on the support table affects spinal posterior-to-anterior stiffness measurements

<sup>1</sup>Sid Williams Center for Chiropractic Research, Life University, Marietta, GA

<sup>2</sup>Kennesaw State University, Marietta, GA

Email: Edward.owens@life.edu

### Introduction

Manual therapists use posterior-to-anterior spinal stiffness (PAS) testing as part of routine diagnostic evaluation for low back pain patients. The PAS measurement involves a measure of the bulk displacement of the spine in a prone person lying on a supporting structure subjected to forces directed posterior-to-anterior onto the spine.

While therapists generally use manual palpation in practice, measurements with instruments are considered more objective. Researchers have developed several PAS measurement systems and identified several variables that can affect stiffness measures.[1] Still, the phenomenon itself is poorly understood.

For example, we noticed very different stiffness measures reported in 2 studies of similar patient populations using similar measurement equipment (11 N/mm[2] versus 6 N/mm [3]). One notable difference in the testing apparatus was the presence of padding on the supporting surface of one study and no padding on the other. In the present study we sought to test the hypothesis that table padding could have influenced the stiffness measures.

### Methods

We used a custom testing apparatus for this study, which consists of a super-structure supporting a displacement transducer and weights over the prone subject. Forces were directed onto the spinous process of the 3<sup>rd</sup> lumbar vertebra of subject's spine through a shaft with a load cell affixed to its end. We manually raised and lowered the weights in a series of 10 cycles while recording displacement and applied force.

We used a mannequin as the subject of the study which ensured that there would be no artifacts due to breathing or muscle contraction and no complaints about a long testing session. Moreover, it would not change between readings as a human subject might. We performed the PAS test with the mannequin resting directly on the hard surface of the table, and with two different layers of foam padding. One padding was 3 inches of firm upholstery foam. The other was 2.5" of softer foam.

We calculated stiffness as the slope of the force displacement curve for each cycle in the force range from 55-75 N using linear regression, omitting the 1<sup>st</sup> and last cycle of each 10 to avoid stopping and starting artifacts. We also omitted outliers in the analysis.

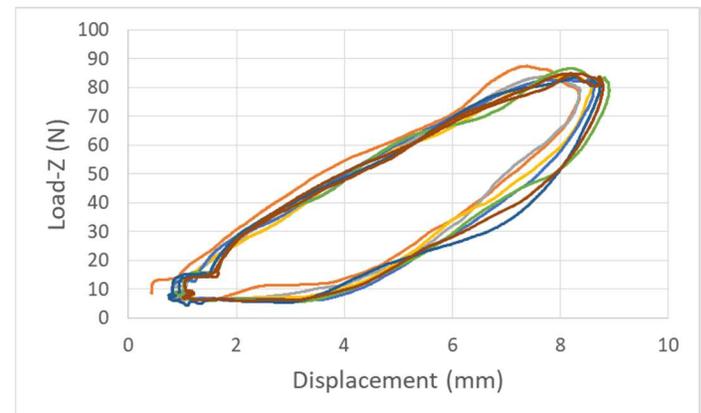

### Results and Discussion

Plots of force versus displacement show a non-linear relationship with significant hysteresis on unloading (Figure 1). Six runs of 10 pressure cycles each were performed for each of the 3 levels of support conditions. This produced 44 usable data sets yielding the stiffness characteristics shown in Table 1.

We found distinct differences between the stiffness measured when the mannequin was supported on a soft-foam covered table and when there was no foam or stiff foam. Both types of foam would be expected to compress somewhat when the mannequin

rests on it. A force plate under the table section supporting the mannequin alone registered 204N. The addition of another 90 newtons during the testing compressed the soft foam further, contributing to the displacement measurement and resulting in apparent lowered stiffness. However, the dense foam did not undergo enough compression during the test to affect results.

**Figure 1:** A typical plot of load versus displacement for the mannequin.

**Table 1.** Calculated stiffness factors and standard deviation based on 2 trials of 10 loading cycles at each of 3 different support conditions. \* Statistically different p < 0.0001

	N	Mean Stiffness (N/mm)
No foam	15	12.1 (2.17)
Soft Foam	16	8.8 (1.58)*
Firm Foam	13	13.2 (2.36)

### Significance

Foam padding on the patient support structure could have contributed to the differences in PAS reported in the literature on human testing. This suggests that it is important for future researchers to report on the support surface conditions of the testing apparatus used. This is rarely seen in the literature.

# The Effects of Triceps Surae Muscle Stimulation on Localized Achilles Subtendon Tissue Displacements

Nathan L. Lehr<sup>1</sup>, William H. Clark<sup>1</sup>, Michael D. Lewek<sup>2</sup>, Jason R. Franz<sup>1</sup>

<sup>1</sup>Joint Department of Biomedical Engineering, UNC Chapel Hill & NC State University, Chapel Hill, NC, USA

<sup>2</sup>Division of Physical Therapy, UNC Chapel Hill, Chapel Hill, NC, USA

Email: jrfranz@email.unc.edu

## Introduction

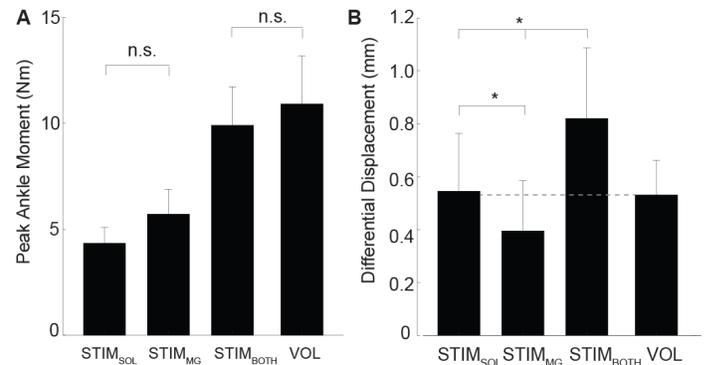

A substantial portion of the mechanical power needed to walk is generated by the triceps surae muscles (*i.e.*, medial gastrocnemius [MG], lateral gastrocnemius [LG], and soleus [SOL]) [1]. That power is generated by muscle forces transmitted via interaction with the Achilles tendon (AT), which itself is comprised of distinct subtendons originating from each muscle [2, 3]. During maximal voluntary isometric contractions (MVIC), differences in the magnitude of shortening between the MG and SOL positively correlate with differences in displacement in their associated subtendons of the Achilles. However, complex inter-muscular patterns of volitional activation may confound our interpretation of emergent subtendon tissue displacements. The goal of this study was to leverage electrical muscle stimulation to quantify the effects of activation to individual triceps surae muscles on localized Achilles subtendon tissue displacements at controlled magnitudes of force transmission. We hypothesized that electrical stimulation of individual triceps surae muscles would elicit larger displacements in their associated subtendon.

## Methods

We report data for 11 healthy young subjects (age: 22.5±2.9 years, 7 females). Subjects first walked for 6 minutes on a treadmill (Bertec Corp.) at 1.2 m/s to precondition their Achilles tendon [4]. Subjects then sat in a dynamometer (Biodex Medical Systems) and performed MVICs with their knee flexed to 20° and ankle extended to 20° to establish a baseline ankle moment prescribed for all conditions described below. Subjects twice completed 4 separate experimental conditions at each of 3 fixed ankle joint angles (-20°, 0°, 20°): MG stimulation (Stim<sub>MG</sub>), SOL stimulation (Stim<sub>SOL</sub>), combined stimulation (Stim<sub>BOTH</sub>), and a volitional contraction (VOL). We determined stimulation intensities for Stim<sub>SOL</sub> and Stim<sub>MG</sub> to individually produce 7.5% of subjects' MVIC ankle moment. Stim<sub>Both</sub> was designed to produce 15% MVIC ankle moment while preserving the voltage ratio from Stim<sub>MG</sub> and Stim<sub>SOL</sub>. Finally, for VOL contractions, subjects used real-time biofeedback to match the same 15% MVIC ankle moment. We applied stimulation (Grass Instruments S48 Square Pulse Stimulator) using 11 300 μs pulses at 33 Hz according to published recommendations [5]. In all conditions, we recorded raw radiofrequency ultrasound data from the Achilles free tendon and used 2D cross-correlation to estimate longitudinal displacements of tendon tissue arising from the MG and SOL muscles [6]. We have thus far analysed data for the neutral (0°) and dorsiflexed (-20°) joint postures. A repeated measures ANOVA tested for main effects of condition, while one sample t-tests determined whether differential tissue displacements (*i.e.*, SOL-MG) differed from zero ( $\alpha=0.05$ ).

## Results and Discussion

Consistent with our intended experimental design, we found no significant difference in the elicited peak ankle moment between Stim<sub>SOL</sub> and Stim<sub>MG</sub>, nor between Stim<sub>Both</sub> and the VOL contraction (**Fig. 1A**). At both of the analysed ankle joint angles,

**Figure 1.** Group average (SE) peak (A) ankle moment and (B) subtendon differential displacements (SOL-MG) for each stimulation condition at the neutral ankle posture. Asterisks (\*) indicate  $p < 0.05$ .

differential displacement (*i.e.*, SOL subtendon displacement – MG subtendon displacement) was positive for all stimulus conditions ( $p$ -values  $\leq 0.05$ ), implying larger SOL subtendon tissue displacements than GAS subtendon tissue displacements, independent of individual muscle stimulation (**Fig. 1B**). At the dorsiflexed ankle posture, we found no main effects of stimulus condition for two likely reasons: (i) the much lower force transmission measured at this posture and/or (ii) that subtendon tissue was less receptive to displacements elicited by stimulation in the presence of high levels of baseline passive tension. However, in support of our hypothesis and scientific premise, peak differential displacement (*i.e.*, the relative difference between SOL and GAS subtendon tissue displacement) at the neutral ankle posture was much larger in the presence of SOL stimulation compared to GAS stimulation ( $p < 0.05$ ) despite no difference in tendon force transmission (**Fig. 1**). Here also, Stim<sub>Both</sub> differential displacement was significantly larger than individual muscle stimulation ( $p$ -values  $\leq 0.05$ ), but no different from VOL.

## Significance

Our results suggest that localized tissue displacements within the architecturally complex Achilles tendon respond in anatomically consistent ways to different patterns of triceps surae muscle activation. Accordingly, this *in vivo* evidence points to at least some neuromechanical independence in actuation between the human triceps surae muscle-tendon units.

## Regional Differences in Shear Wave Velocity in the Short and Long Head of Biceps Brachii

<sup>4</sup>Physical Medicine and Rehabilitation, , Northwestern University, <sup>4</sup>Shirley Ryan AbilityLab, Chicago, IL

Email: s-lee@northwestern.edu

### Introduction

Shear wave velocity (SWV) has been shown to be sensitive to changes in the net material properties of the muscle [1] and has also been associated with the net stress in some materials [2]. However, there are regional variations in the material composition, architecture, strain, and stresses within a muscle. [3,4] and it is unclear if SWV is sensitive to these variations. The biceps brachii muscle is of particular interest as it is comprised of long and short head muscles and has different proximal and distal musculotendinous structures. The distal tendon includes a distal internal aponeurosis that spans approximately one third of the length whereas the proximal tendons form external aponeuroses. Thus, our goal was to determine if SWV varies in different regions of the biceps brachii (proximal, belly, and distal), as well as between the short and long head.

### Methods

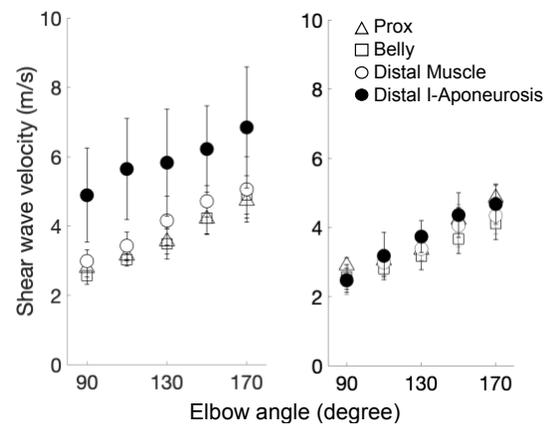

Six healthy young adults (2 males and 4 females; mean  $\pm$  std, age:  $25.17 \pm 2.23$  yrs; mass:  $59.5 \pm 14.98$  kg; height:  $1.62 \pm 0.09$  m) participated in this study. Participants were instructed to sit upright in a custom chair with their upper arm resting on a plastic support that was secured to a six-degree-of freedom load cell. Ultrasound data (Aixplorer V9 SuperSonic Imagine) was captured of the biceps brachii (short and long head) at three different locations (proximal, belly, and distal) at a range of elbow flexion angles ( $90^\circ$ ,  $110^\circ$ ,  $130^\circ$ ,  $150^\circ$ ,  $170^\circ$ ). All measurements were obtained under passive conditions. Surface electromyography was placed on the belly of the short and long head of the biceps brachii to verify there was no activation at the time the ultrasound data was captured. For the proximal and distal locations, the region of interest (2cm by 1cm) was placed such that it bordered the musculotendon junction so that the SWV in most proximal and distal regions of the muscle, respectively, could be measured. For the belly location, the region of interest (2cm by 1cm) was placed in the thickest part of the muscle. To provide context of the size of the region of interest relative to the overall muscle lengths, optimal muscle length of the short and long head of the biceps brachii has been reported to be 23.4 and 21.6 cm, respectively [5]. Post-processing included cropping the region of interest to only include muscle or the distal internal aponeurosis. This primarily affected the superficial to deep direction, not the proximal-distal direction. The average SWV of the cropped region was calculated.

### Results and Discussion

We observed that SWV increased as elbow angle was increased for all regions in the short and long heads (Fig 1). Shear wave velocity values of the belly region are comparable to previous studies [6]. Shear wave velocity was significantly higher in the short head compared to the long head at the distal location for both the muscle and distal internal aponeurosis (all  $p < 0.001$ ), as well as the belly ( $p = 0.005$ ). For the short head, SWV in the distal region was significantly greater than the proximal and belly

region ( $p = 0.008$  and  $p = 0.04$ , respectively). Shear wave velocity in the distal internal aponeurosis was 46-63% higher than the muscle at all locations (all  $p < 0.001$ ). For the long head, there were no significant differences across the three regions.

These results indicate that SWV is not constant throughout the biceps brachii. Rather, it differs between the short and long head, in particular in the belly and distal regions. This suggests that SWV may be sensitive to heterogeneity of mechanical properties and or force throughout muscle under passive conditions.

**Figure 1:** Mean shear wave velocity and standard deviation across elbow angle for short head (left) and long head (right) of the biceps brachii at different locations (prox = proximal, belly, distal muscle, and distal I-aponeurosis = distal internal aponeurosis).

### Significance

Our results show that SWV varies depending on region and specific head of the biceps brachii under passive conditions at different lengths. Our results indicate that SWV is sensitive to location. Given that mechanical properties and force vary throughout muscle, shear wave ultrasound elastography is a potential technique for assessing the heterogeneity of such properties and force for which *in vivo* assessment is currently challenging. These findings have implications for muscle models that assume homogeneity and clinically, to better understand how and where musculotendinous injuries occur.

## Preliminary Evaluation of Articular-Sided Supraspinatus Surface Strain for Varying Infrapinatus Loads

<sup>2</sup>Center for Advanced Orthopaedic Studies, Carl J. Shapiro Department of Orthopaedic Surgery, Beth Israel Deaconess Medical Center, Boston, MA

Email: anazaria@bidmc.harvard.edu

### Introduction

Rotator cuff (RC) tears are the most common cause of shoulder disability, representing one of the highest days-away-from-work rates compared to other work-related injuries. (1) Articular-sided rotator cuff tears are common in overhead athletes for whom conservative treatment is strongly recommended, (2) though worse clinical outcomes for articular-sided tears have been reported (3) and return to previous level of play is diminished. (4) Classically, Nakajima *et al* reported that the articular side of the tendon is more vulnerable to tensile load than the bursal side, (3,5) which may be related to the random orientation of collagen fibers in this region.(4) However, no evidence exists to determine which articular-sided tears are stable and which may progress. (6)

Andarawis-Puri *et al.* showed that the supraspinatus and infrapinatus tendons interact mechanically, but the effect of different loads on the infrapinatus tendon were not evaluated. (7) *Our goal was to assess the effect of different infrapinatus loads on the strain of the articular side of the supraspinatus tendon. We hypothesized that increased infrapinatus load would increase the strain on the supraspinatus tendon.*

### Methods

A cadaveric, left shoulder specimen (56 y/o; Male) was dissected free of all tissue, leaving the supraspinatus and infrapinatus tendons. The humeral head was resected to allow visual access to the articular-side of the supraspinatus tendon. A 5×3 grid of surface markers (Aluminum beads, 1/32" dia.) was attached to the articular side of the tendon using surgical glue (VetBond, 3M, MN) **Figure 1A**. Three dimensional geometry of the humerus, tendon, and markers were obtained using a computed tomography (CT) machine (XtremeCT, Scanco Medical, Switzerland). A soft-tissue scanning protocol (126mAs, 60 kVp, 0.246 mm slice thickness) was used to visualize the tendon. The specimen was then mounted in the

material testing machine (Instron, Norwood, MA) in a custom jig to allow for axial load of the supraspinatus tendon. The supraspinatus tendon was preloaded 5-50N for 10 cycles. (8) The infrapinatus was loaded statically to a series of loads: 1, 2, 3, 4, and 5lbs. Images of the tendon were recorded at 1 Hz using a CMOS camera (PL-B686CU, PixeLINK, CN).

A 3D model of the supraspinatus-infrapinatus complex and markers (MIMICS, 3-Matic) was made using the CT data **Figure 1B**, and imported into the FE Solver (ABAQUS, Dassault Systemes, France). Strain of the supraspinatus tendon was estimated using the FE solver by applying the displacements recorded in the cadaveric setting to the beads. (8)

### Results and Discussion

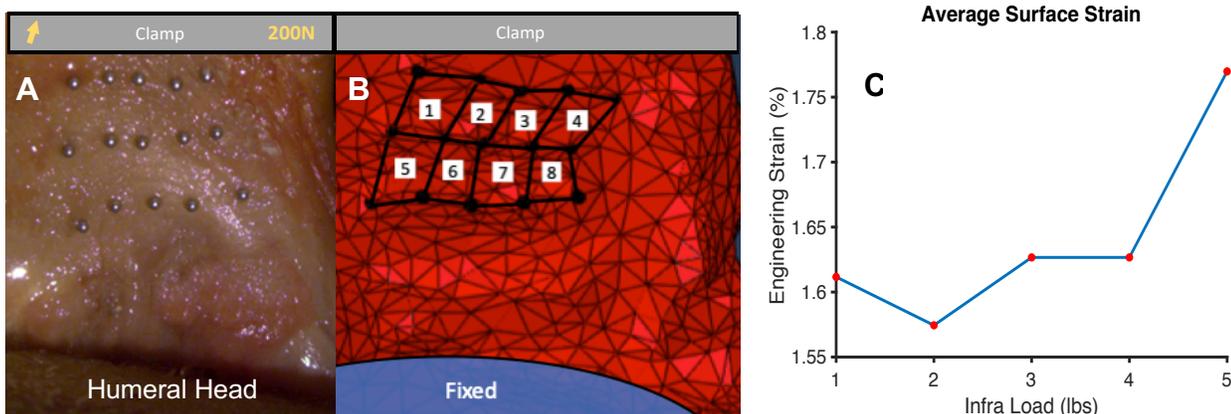

The articular supraspinatus tendon strain increased with increasing infrapinatus load, **Figure 1C**; however, the magnitude of the applied strain to this region is small. This may be due to the condition of the insertion of the tendon in this specimen, which will be evaluated with further samples. Increasing the load on the infrapinatus will allow for evaluation of critical infrapinatus loads.

### Significance

This preliminary analysis establishes a method for analyzing articular surface supraspinatus strain, which may prove to be affected by infrapinatus load magnitude.

## Chronic Neck Pain: *In Vivo* Cervical Spine Kinematics

Craig C. Kage<sup>1</sup>, Matthew M. MacEwen<sup>1</sup>, Bryan Ladd<sup>1</sup>, and Arin M. Ellingson<sup>1</sup>

<sup>1</sup>University of Minnesota, Minneapolis, USA

Email: [ellin224@umn.edu](mailto:ellin224@umn.edu)

### Introduction

Neck pain is the 4<sup>th</sup> leading cause of years lived with disability [1] and along with low back pain, is the highest US healthcare expense with over \$134 billion spent annually [2]. Typical diagnostic imaging techniques are limited to static and/or 2D acquisitions and are unable to capture the dynamic, 3D motion of the cervical spine. Biplane radiography (BR) is able to accurately capture the underlying bony kinematics and provide a quantitative assessment of cervical spine motion [3, 4]. Presently, there is a limited understanding of the underlying, bony-level kinematics for those with chronic mechanical neck pain (MNP). **The purpose of this work was to quantify the underlying bony kinematics of a healthy cohort (CTRL) compared to a cohort with MNP for a flexion/extension task.**

### Methods

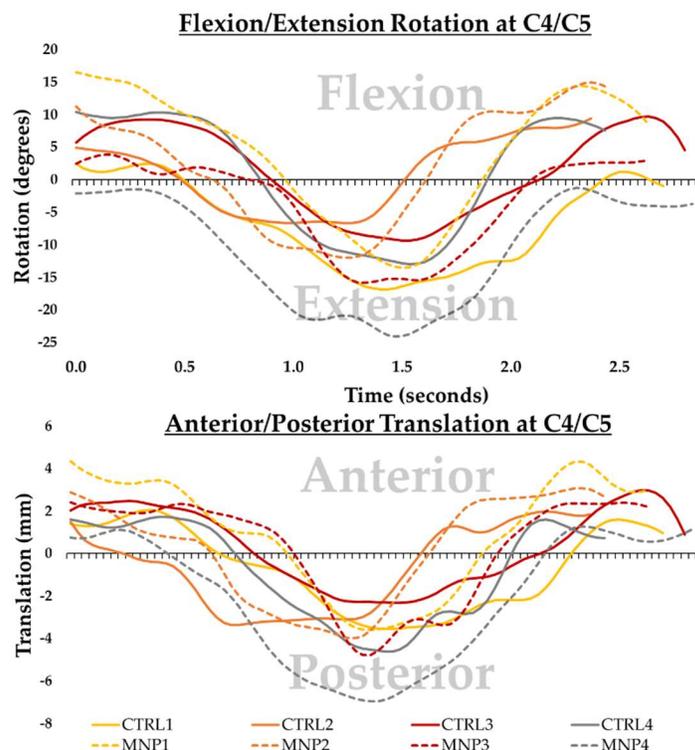

Eight participants provided informed consent (recruitment ongoing); four without neck pain (27.8±3.8 years | 2M,2F) and four with a history of neck pain >12 weeks (22.0±1.8 years | 1M,3F). Underlying bony anatomy was obtained via CT (100kVp; 0.2×0.2×0.6mm; 1.6mSv, Siemens Biograph, USA). Participants completed three trials of flexion/extension/flexion during BR (160mA, 70-74kV, 3.5ms, 55° IBA, 174cm SID, 30Hz; 0.16mSv/trial). Motions were completed with a metronome (50bpm) for pacing. CT acquisitions were reconstructed (MIMICS Materialise, USA) for levels C3-C6 and anatomic coordinate systems were identified for each vertebrae [4]. Calibration, undistortion, anatomic coordinate identification, and shape-matching were completed in DSX Suite (C-Motion, USA). The final (third) trial was analyzed. Kinematic data were filtered in DSX with a 3.0Hz spline filter and relative kinematics were computed in MATLAB (MathWorks, USA). T-tests were completed in R (R Core Team, Austria).

### Results and Discussion

Kinematic variables are presented in Table 1, separated by group, spinal level, and in-plane rotations and translations (flexion/extension (FE) and anterior/posterior (AP)). Kinematics of C4 relative to C5 are displayed for all participants in Figure 1. Those with MNP had significantly greater AP translation at C4/C5 and significantly greater total C3-C6 AP translation. Although not statistically significant, those with MNP demonstrated, on average, greater segmental FE and AP motion components, greater global FE ROM, and lower FE:AP ratio. The trend of the MNP group towards a lower FE:AP ratio implies a greater proportion of AP translation with FE motion (despite a greater FE ROM), which may provide insight into contributions to pain and/or degeneration in those with chronic MNP.

**Table 1: Kinematics of controls versus those with chronic MNP**

	Flexion/Extension ROM			Anterior/Posterior ROM			Total ROM	Total C3-C6 ROM		Total FE:AP Ratio		
	C3/C4	C4/C5	C5/C6	C3/C4	C4/C5	C5/C6	Vicon	FE(deg)	AP(mm)	C3/C4	C4/C5	C5/C6
CTRL	18.7±4.7	19.4±3.0	20.5±2.0	5.7±1.8	5.6±0.5	5.3±0.3	112.4±15.9	58.6±7.9	16.7±2.5	3.5±0.6	3.4±0.3	3.9±0.5
MNP	22.3±5.8	24.9±4.5	22.6±5.0	7.3±1.2	7.6±0.6	7.1±2.2	130.95±20.8	69.7±9.2	22.0±2.5	3.0±0.3	3.3±0.6	3.3±0.3
p-value	0.37	0.10	0.49	0.20	<0.01*	0.21	0.21	0.12	0.02*	0.37	0.67	0.08

**Figure 1:** Kinematics of C4 relative to C5 for flexion/extension rotation and anterior/posterior translation components of a FE task.

### Significance

Despite the small sample size, we were able to detect significant differences in the kinematics (in particular AP translation) during a FE task in those with chronic MNP compared to a control group. Recruitment efforts are ongoing to achieve sufficient power and additional exploration into multiplanar tasks is underway to better understand the underlying kinematic and coupled differences that may exist in those with chronic MNP.

## Introduction

Duchene muscular dystrophy (DMD) is a fatal muscle wasting disease, with no cure or effective treatment to date. Respiratory insufficiency is a leading cause of death in DMD patients, resulting due to dysfunction of the diaphragm muscle<sup>1</sup>. An increase in muscle stiffness occurs with buildup of fibrotic tissue, characterized by excessive accumulation of extracellular matrix (ECM) components such as collagen. Previous studies focus on the impact of increased collagen amount in DMD, but the role of collagen amount on stiffness is unresolved to date<sup>2,3</sup>. Therefore, we are interested in how complex collagen organization is affected in DMD, its impact on passive force production, and how this may lead to respiratory insufficiency. We used scanning electron microscopy (SEM) to capture collagen organization and quantified collagen direction relative to muscle fiber direction as well as collagen straightness parameter. We hypothesized a difference in collagen direction and straightness with the progression of DMD in diseased mice, as well as relative to age matched healthy mice.

## Methods

Four samples of diaphragm muscle were collected from each group: 3 (N=2), 6 (N=3), and 12-month (N=2) diseased (*mdx*) and 3 (N=3), 6 (N=4), and 12-month (N=4) healthy (C57BL6) mice. Samples were placed in solution to maintain a relaxed state and collagen structure was isolated by digesting muscle fibers in 10% sodium hydroxide solution<sup>4</sup>. For each sample, an SEM image was taken of collagen fibers (1kX) and fibrils (50kX) in the epimysial layer of the ECM. An image processing algorithm was developed using the Radon transform to measure collagen orientation in local windows for each image in MATLAB. Mean orientation, quantified in degrees relative to muscle fiber orientation, was used to measure collagen fiber (1kX) or fibril (50kX) preferred direction. Collagen straightness parameter (Ps) was determined for collagen fibers (1kX) by measuring the length of a collagen fiber (Lf) and a straight line connecting the ends of the measured fiber (L0) in ImageJ. Collagen straightness parameter ( $Ps=L0/Lf$ ) was then calculated for three fibers representative of the fibers in each image and averaged. Significance was measured with ANOVA and t test.

## Results and Discussion

Differences between diseased and healthy groups were seen, with increased fibril level disorganization at 12 months (Fig 1B). Collagen fibers were straighter in older healthy and all diseased groups: The collagen straightness parameter, measured at fiber level, was significantly different between diseased and healthy groups at 3 and 6-months, as well as between 3 and 12-month healthy and 6 and 12-month healthy groups ( $p<0.05$ ) (Fig 1C). Collagen preferred direction was approximately perpendicular to muscle fiber direction and maintained between fiber and fibril levels. While there was a significant difference between diseased and healthy groups at 3-months at fiber level ( $p<0.05$ ) (Fig 1D), there was no significant difference in diseased groups between ages, with preferred direction ranging from 68-83 degrees at fiber level. Taken together, our results suggest that collagen maintains its orientation relative to the muscle fiber direction, but the waviness seen in young healthy mice is decreased in 12-month healthy mice, and in all ages of diseased mice.

## Significance

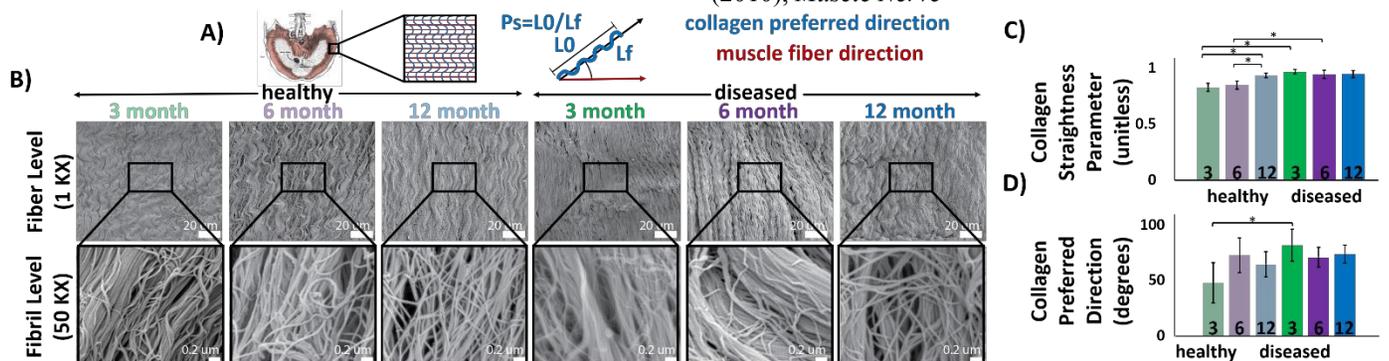

As collagen fibers lose their waviness, they can take up less strain before being stretched in tension. This results in a shorter toe region on the passive stress-strain curve, with higher stress experienced at lower strains in the elastic region. Therefore, we propose that collagen limits cross-fiber stretch in diaphragm muscle of *mdx* mice. Impairment in respiratory function and fibrosis is reported in *mdx* mice starting at 3 months and reduction in strength and elasticity is reported at 12-18 months<sup>5,6</sup>. Our findings implicate changes in collagen organization on diaphragm function and we will continue to explore the role of cross-fiber stretch on respiratory insufficiency in DMD.

## Acknowledgments

Thank you to the National Institutes of Health for funding this project (Grant # U01AR06393).

# Changes in Active and Passive Mechanics of the Diaphragm During the Progression of Duchenne Muscular Dystrophy

C. Hunter Wallace<sup>1</sup>, Laura Caggiano<sup>1</sup>, and Silvia S. Blemker<sup>1</sup>  
<sup>1</sup>Department of Biomedical Engineering, University of Virginia  
 Email: chw3gr@virginia.edu

## Introduction

Duchenne muscular dystrophy (DMD) is a progressive muscle wasting disease that ultimately results in morbidity in the mid-twenties, commonly due to respiratory failure associated with diaphragm muscle degeneration and associated dysfunction<sup>[1]</sup>. Current assessment of diaphragm function relies on either measuring the changes in the along-fiber properties of individual strips of diaphragm tissue in isolation or imaging movement of the diaphragm as a whole<sup>[2,3]</sup>. However, the effects of along and cross-fiber changes on *in vivo* diaphragm mechanics and breathing ability are not well understood. In order to address this critical gap, the goals of this study are to (i) design a method of measuring *in vivo* tissue strains both in the muscle fiber direction and transverse to the fiber direction and (ii) use this method to investigate the mechanics of diaphragm function in healthy and dystrophic mice and (iii) relate the measured *in vivo* mechanics to *ex vivo* passive testing.

## Methods

Six 6-month-old and 12-month-old healthy (C57Bl6) mice and eight 6-month-old and 12-month old *mdx* mice, a model for DMD, were used in this study. A pair of ultrasound crystals was glued to the muscle in the along-fiber direction and a second pair in the cross-fiber direction and displacement measurements were taken over several continuous breaths (Fig1A). Strains were calculated from the measured displacements and compared between age groups and disease state. Dots were marked on the tissue with dye where the ultrasound crystals were. Following *in vivo* measurements, the mid-costal region of the diaphragm used for sonomicrometry was explanted for biaxial passive testing. Each sample was stretched to 20 percent strain at a strain rate of 1% per second. Starting lengths for passive testing were defined as the point at which passive resistance began and deemed optimum fiber length. Stresses were calculated from the measured forces and areas and compared between age groups and disease state. Finally, to relate *ex vivo* passive measurements to the *in vivo* testing, we

divided the *in vivo* resting length by optimum fiber length to determine the resting fiber stretch.

## Results and Discussion

We found a decreasing trend in along-fiber strains and a significant decrease in the cross-fiber strains with age in healthy mice. Dystrophic mice had significantly lower strains in both directions compared to healthy mice at 6mo but not at 12mo and no significant changes with age. Strains in young dystrophic mice are indistinguishable from healthy and dystrophic aged mice suggesting a rapid and early degeneration (Fig 1B).

There was a significant increase in along and cross-fiber stresses at all age groups with disease state. No significant changes with aging were found for healthy or dystrophic mice (Fig 1C).

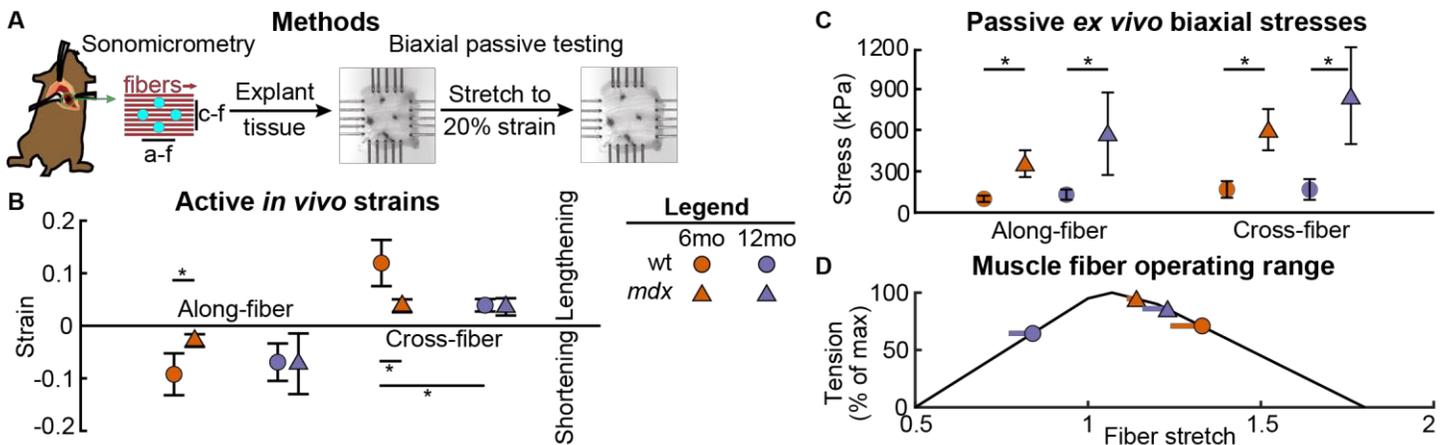

Finally, relating the *in vivo* to *ex vivo* testing, we found a significant change in the aged healthy mice where all other groups are above optimum fiber length while the aged healthy mice are significantly lower (Fig 1D). This shift down the ascending limb of the force-length curve could explain the decrease in *in vivo* strains with age in the healthy mice.

## Significance

We have developed a method to measure both along-fiber and cross-fiber strains of the diaphragm *in vivo*. Our results are supported by previous studies<sup>[2,3]</sup> that found a decrease in diaphragm movement with age and disease. We are now able to connect these findings to alterations in the *in vivo* fiber behavior and the passive mechanics. Future steps include using our measurements as the basis for a computational model to further investigate the mechanical changes occurring in dystrophic muscle and identify potential targets for therapies.

# Biomechanical Assessment of Bone Staples: Effect of Declining Bone Mechanical Properties

Tanetta L. Curenton<sup>1</sup>, Brian L. Davis<sup>1</sup>, and Josiah S. Owusu-Danquah<sup>1</sup>

<sup>1</sup>Cleveland State University, Cleveland, OH, USA

Email: [j.owusudanquah@csuohio.edu](mailto:j.owusudanquah@csuohio.edu)

## Introduction

Bone quality changes can occur as a result of aging, inadequate nutrition, and bone diseases. The weakening of bone leads to higher risks of fractures, and poses a greater challenge for fixation due to the declining mechanical strength of bone. Stable internal fixation leading to a quicker return to full weight-bearing activities and adequate bone holding and healing is vital to a patient's quality of life [1].

Internal fixation of bone with diminishing quality can be difficult, with a failure rate ranging from 10% to 25% in osteoporotic bone [2]. Employing an appropriate contact force and contact area to stabilize the bone and prevent malunion or nonunion could lead to higher success rates and better quality of life outcomes. The purpose of this study was to investigate the effects of deteriorating bone mechanical properties on the contact force and contact area of stainless steel and superelastic nitinol staples. A finite element simulation approach was used to vary the Young's Modulus of bone.

## Methods

A fracture fixation model consisting of a simple staple surrounding a segment of bone was evaluated using Abaqus 2017 (Dassault Systèmes Simulia, Johnston, RI, USA). The bridge and legs of the staple were 20mm. The staple cross-section was 2mm x 2mm. To simulate post-deployment of the staples, the legs of the stainless steel staple were designed straight while the legs of the superelastic nitinol staple were tilted in by 1mm. (A few data points for nitinol staple legs tilted in by 2mm were also collected). The bone segment was modeled as an 18mm x 16mm block, with the base of the block being 16.50mm. Young's Modulus and Poisson's ratio was set to 205GPa and 0.275, respectively, for the stainless steel staple. The nitinol staple was modeled using a nonlinear user-defined material model [3]. The Young's Modulus of bone varied from 21GPa to 11GPa to indicate the change in the mechanical properties of bone from a healthy state to a diseased state. The simulation procedure involved two loading steps. In the first step, pressure was applied to the staple legs to simulate the opening of the staple before deployment at the fractured site. In the second step, pressure was removed, allowing the staple to establish and maintain contact with the bone.

## Results and Discussion

As bone mechanical properties declined, the maximum contact force in steel staples and superelastic nitinol staples decreased (Fig. 1). A 0.02036N decrease occurred in steel staples from the highest elastic modulus to the lowest elastic modulus of bone. A 0.36374N decrease occurred in the nitinol staples tilted in 1mm. A 7.6961N decrease occurred in the nitinol staples tilted in 2mm. The superelastic properties of nitinol and ability to recover more strain play a role in the higher contact forces. Higher contact forces may correlate to improved stabilization of the bone. The greater overall contact force and greater decrease in the contact force for nitinol staples during declining bone mechanical properties could better accommodate bone with diminishing quality. The contact area gradually decreased for steel staples with bone degradation and gradually increased for nitinol staples

(Table 1). Larger contact area may reduce stress and contribute to better holding of the fractured bone, which is important in bone with diminishing mechanical properties. Nitinol staples tilted in 2mm had a greater amount of increase in contact area and decrease in contact force compared to the other staples as bone mechanical properties declined. In a study using solid polyurethane foam foot models with the same mechanical properties, Aiyer et al. also reported that nitinol staples have larger contact forces and contact areas and suggested that nitinol staples may be capable of adjusting to gapping and resorption [4]. This study showed that the adjustment of a bone staple, such as pre-deployment opening and post-deployment closure, can impact contact force and area which may be considered to start full weight-bearing sooner and may reduce failure rates in degrading bone if a particular contact force and area may better correlate with particular bone qualities. Material, thickness, curvature, and other properties of fixation devices could be optimized to accommodate cases of diminished bone quality. However, further studies are needed.

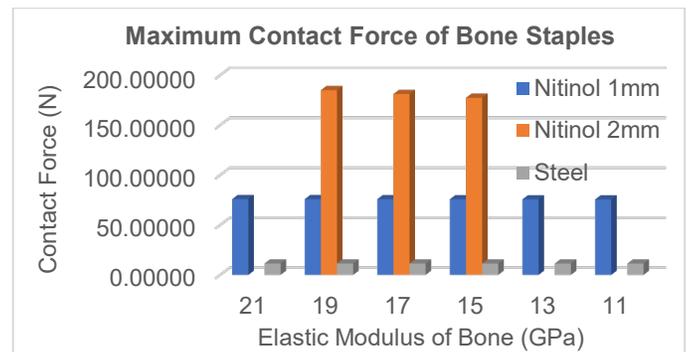

Figure 1: Maximum contact force is highest in nitinol staples.

Table 1: Contact area decreases in steel and increases in nitinol staples with declining bone mechanical properties.

Bone E (GPa)	Steel (mm <sup>2</sup> )	NiTi 1mm (mm <sup>2</sup> )	NiTi 2mm (mm <sup>2</sup> )
19	0.170275	0.942223	0.092224
17	0.170261	0.942224	0.092750
15	0.170244	0.942226	0.093556

## Significance

Bone diseases and aging can cause bone properties to decline over time. New fixation device designs optimizing for contact forces and contact areas that accommodate bones of varying quality may improve the short and long-term benefits of fixation in patients with declining bone quality. More regard given to bone quality could be vital for clinical outcomes, particularly if fixation methods could be optimized for a more personalized approach to address diminishing bone mechanical properties.

# The OpenArm Project: Exploring Deformation as a Measure of Muscle Force

Laura A. Hallock and Ruzena Bajcsy

Department of Electrical Engineering and Computer Sciences, University of California, Berkeley

Email: [lhallock@eecs.berkeley.edu](mailto:lhallock@eecs.berkeley.edu)

## Introduction

While many musculoskeletal simulation frameworks rely on estimates of muscle force [1], there exists no noninvasive, in vivo method of measuring the force exerted by individual muscles. Instead, forces are estimated based on motion-specific assumptions and/or noisy measures of neural activation. A direct, accurate measure of muscle force would enable improved understanding of dexterity, better quantification of pathology, and safer, more expressive assistive device control. We propose measuring muscle force via *muscle deformation*, a signal that is intrinsically coupled to force production: as muscles shorten and widen during the cross-bridge cycle, tendons lengthen and force increases. In this work, we present *a*) evidence that this deformation is observable during voluntary exertion and (when correctly parameterized) is correlated with joint torque; *b*) preliminary findings on useful signals for force inference; and *c*) the OpenArm project,<sup>1</sup> an open-source collection of data and analysis code to enable study of the force–deformation relationship by the wider research community.

## Methods

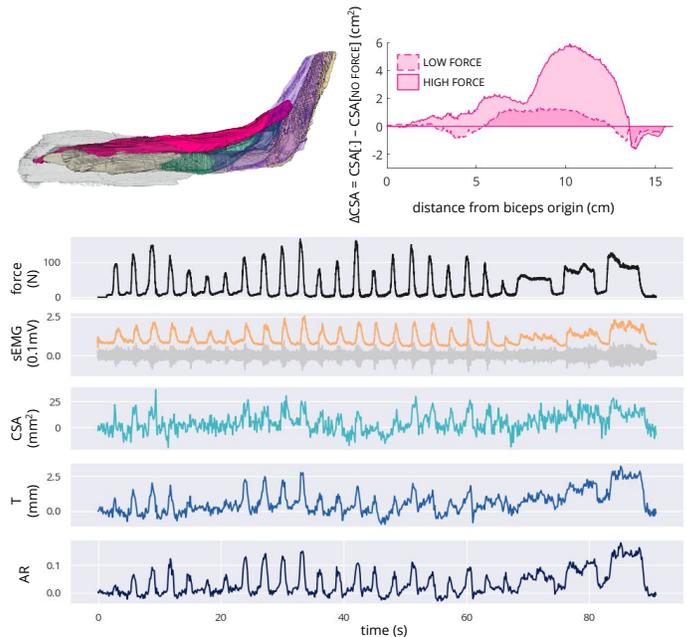

While deformation is readily observable via 2D ultrasound in the movement of each muscle’s surrounding fascia, the observed signal changes substantially based on an individual’s morphology, the geometry induced by their joints’ kinematic configuration, contact dynamics with other tissue, and sensor location. To enable analysis under this complexity, we developed two exploratory data sets: first, a set of full 3D reconstructions of elbow flexor muscle volumes under varied (static) loading conditions [2, 4], and second, time series data of 2D brachioradialis deformation under isometric time-varying loads and alongside sEMG values [3]. Both sets were collected using ultrasound under multiple elbow angles and for multiple subjects. These data were then analyzed geometrically to establish the relationship between elbow force and various parameterizations of the deformation signal.

## Results and Discussion

Example data is shown in Fig. 1. As reflected in the 3D exemplar, the overall shape of the elbow flexors is irregular; however, when cross-sectional area (CSA) is measured from a certain range of locations along the biceps brachii, this CSA value reliably increases with force exertion, a relationship that generalizes across elbow angles (but varies in magnitude) [2]. These observations confirm the feasibility of measuring force-associated deformation signals and affirm the importance of considering both kinematic configuration and sensor location during their analysis.

Similarly, the exemplar time series data in Fig. 1 — collected from a location along the arm informed by our 3D analyses — show that this static correlation between joint force and muscle CSA (and two other deformation measures) extends to dynamic isometric contractions [3]. While these correlations are reliably strong across subjects and most elbow angles, the measure that is most correlated — and even the sign of that correlation — varies by subject. These results confirm that the force-associated defor-

mation studied in our static analyses can be observed (and tracked [3]) over time from a single ultrasound scan; they also highlight the importance of accounting for individuals’ morphological variation.

**Figure 1:** *Top:* Example 3D reconstruction of the elbow flexors (*left*) alongside biceps cross-sectional area (CSA) changes under force loading (*right*) [2]. *Bottom:* Time series force and sEMG data alongside three measures of brachioradialis deformation (CSA, thickness  $T$ , and aspect ratio  $AR$ ) during pulsed and sustained isometric contractions [3].

## Significance

Our results constitute quantitative evidence that deformation signals are both observable and correlated with joint force under isometric conditions; ultimately, we aim to expand this predictive power to individual muscle forces during natural movement. Identifying good signals for such models will require extensive exploratory data analysis, but will open up new avenues of research in biomechanics, neuroscience, robotics, ergonomics, and even animation. Our system identification efforts use the SimTK OpenArm platform, which contains all data and analyses described here and which we hope will inspire novel collaboration across these domains.

### Introduction

Adult degenerative scoliosis (ADS) is a common musculoskeletal problem in older adults affecting up to 68% of the individuals older than 70 years old [1]. ADS causes low back pain and mobility issues. Surgical interventions to restore the original disk spacing remains as one of the treatments for ADS. However, tracking the gait improvements in ADS patients is challenging due to the high inter-subject variations such as affected side, number of the affected disks, and the position of the deformity.

Our prior research extracted a set of *muscle synergies* to explain the walking behavior of ADS patients before and after surgery [2]. Muscle synergies can be thought of as lower-dimensional building blocks of the Central Nervous System (CNS) in controlling motor tasks, where a lower number of required synergies is often associated with less complexity and quality of the motor task [3]. Although our study showed an increase in the number of walking synergies after surgery in ADS patients (i.e. higher complexity), we argue that both the quantity and quality of synergies can reveal gait improvements. Quality of muscle synergies can be examined using the concept of entropy. Higher entropy is associated with more chaotic control while a lower entropy presents more deterministic control (Fig. 1).

We intend to track the walking improvements in ADS patients following surgical procedures by measuring the entropy on their walking muscle synergies. We hypothesize that the entropy of synergies will decrease, indicating a more deterministic control, after surgery.

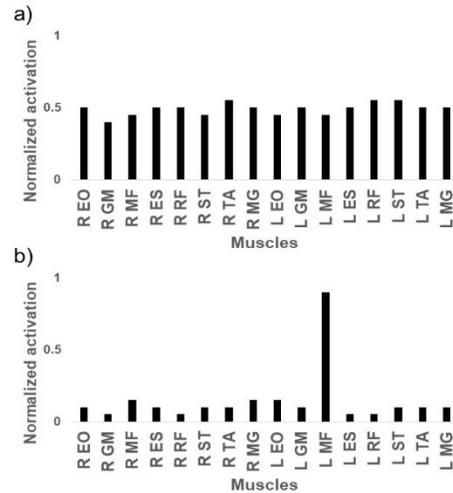

### Methods

Thirteen ADS patients participated in this IRB-approved study. To ensure a comparable severity of their ADS condition, subjects were excluded in case of a Cobb angle greater than 50 degrees. Subjects were asked to walk at their comfortable speed before and 3 months after their surgical interventions. Surface EMG was collected from the following muscles, bilaterally: External Oblique (EO), Gluteus Maximus (GM), Multifidus (MF), Erector Spinae (ES), Rectus Femoris (RF), Semitendinosus (ST), Tibialis Anterior (TA), Medial Gastrocnemius (MG). EMG was collected and processed as described in [2], then fed into a non-negative matrix factorizer to extract seven synergies and their activation.

The summation of all activations in a synergy was then normalized to 1, to enforce each synergy to resemble a probability density function. The entropy of an individual's synergy was defined as:

$$H(W_i) = - \sum_{j=1}^n P(j) \log_2 P(j)$$

where  $H$  is the entropy,  $W_i$  is  $i^{\text{th}}$  synergy, and  $P(j)$  is the normalized activation of a muscle in a synergy. A paired t-test with a significance of 0.05 was performed to find significant differences in entropies pre- and post-surgery.

**Figure 1:** Examples of a high entropy (a) and low entropy (b) muscle synergy. Please note the deterministic control in (b).

### Results and Discussion

The entropy values for each individual's synergy was calculated ( $13 \times 7 = 91$  values), where minimum, maximum, average, and standard deviations were 2.40, 3.76, 3.19, and 0.26, respectively. All seven muscle synergies indicated a significant decrease in their entropy following surgery with  $p$ -values  $< 0.001$ .

The higher entropy may indicate a more random and chaotic control of the muscles. This shows that surgery is helping ADS patients to have more complex control while walking. In other words, lower entropy may indicate that the CNS is more likely to deliberately choose to activate a muscle to reach a certain kinematic or kinetic goal (Fig. 1). Consistently, researchers claimed that a lower entropy in quiet standing indicated a more deterministic control of the COM to maintain balance [4].

### Significance

Using muscle synergies are generally advantageous to kinematic analysis due to its robustness to different conditions. However, synergies can be challenging to interpret due to its numerous dimensions. Specifically, in ADS patients, individuals show improvements on different sides and different muscles due to the nature of the disease. Our introduced method can help track the possible improvements despite the high variation of scenarios in different patients and can be a novel method of assessment.

### Introduction

Approximately 14 million tendon and ligament injuries are reported each year in the U.S., costing \$254 billion<sup>1</sup>. Injured tendons are mechanically inferior, compromising function and increasing the risk of tendon rupture. Dry needling (DN) is a conservative treatment used to alleviate pain and improve tendon healing. However, it is invasive with mixed success rates<sup>2</sup> due to high inter-practitioner variability. High-intensity focused ultrasound (HIFU) is an emerging therapeutic ultrasound modality that can induce bioeffects in a well-defined focal volume, with the potential to non-invasively enhance tendon healing. The objective of this study is to compare the effect of DN and HIFU treatments on the mechanical properties of *ex vivo* rat Achilles tendons and develop a finite-element model to evaluate their effect on tendon strain pattern.

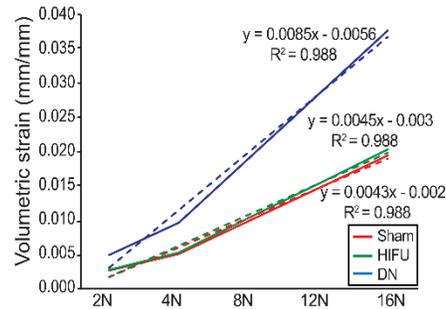

### Methods

Tendons from adult Sprague Dawley rats were randomly assigned to DN, HIFU, or sham, with 5 tendons/group. For DN, a fine-gauge (25G) needle was inserted and quickly removed from central portion of the tendon 5 times over 12 s. For HIFU, the central portion of the tendon was exposed to 10 ms pulses repeated 60 times at 1 Hz with peak +ve pressure >80 MPa and peak -ve pressure >20 MPa. Following DN, HIFU, or sham exposure, mechanical testing was performed using an MTS 858 Mini Bionix (MTS Systems Corp., Eden Prairie, MN) mechanical testing system, using an established testing protocol<sup>3</sup>. Tendon mechanical properties including elastic modulus, stiffness, and percent relaxation were determined. A finite-element model was developed in COMSOL (v.5.4, COMSOL Inc., Burlington, MA) using manual segmentation of magnetic resonance images from a rat. The muscle-tendon unit was modeled as a transversely isotropic material with experimentally measured mean mechanical properties used as model parameters. Loads equivalent to 0.5x (2N), 1x (4N), 2x (8N), 3x (12N), and 4x (16N) mean body weight were applied along the muscle-tendon unit's long-axis. Fifteen computational simulations were performed to predict strain at the tendon-bone interface. Statistical analysis was performed using a one-way ANOVA in SAS software (SAS Institute, Inc., Cary, NC, v9.4) for the comparison of group mean mechanical properties, with  $p < 0.05$  considered significant. Linear regression analysis was used to determine the trend of maximum strain across various applied loads.

### Results and Discussion

**Figure 1:** (A) Elastic modulus; (B) stiffness, and (C) percent relaxation of rat Achilles tendons exposed to sham, DN, and HIFU.

**Figure 2:** Volumetric strain patterns of sham, DN, and HIFU models for applied loads of 0.5x (2N), 1x (4N), 2x (8N), 3x (12N), and 4x (16N) mean body weight.

Elastic moduli of tendons in the DN (127.7±28.0MPa) group were significantly lower than sham (248.8±56.9MPa;  $p=0.0003$ ) and HIFU (237.9±15.2MPa;  $p=0.0006$ ) (Fig.1A); there was no difference in elastic moduli between the HIFU and sham groups ( $p=0.6573$ ). Stiffness of tendons exposed to DN (116.3±78.9N/mm;  $p=0.0025$ ) and HIFU (142.9±41.5N/mm;  $p=0.0091$ ) was significantly lower than sham (260.3±53.5N/mm) (Fig.1B). There was no difference in percent relaxation of tendons exposed to DN (16.07±12.7%;  $p=0.1981$ ) or HIFU (8.42±5.8%;  $p=0.9617$ ) compared to sham (8.69±5.2%) (Fig.1C). Predicted maximum strain from the DN model (avg. 19.7e-3mm/mm) was greater than HIFU (avg. 10.5e-3mm/mm) and sham (avg. 10.1e-3mm/mm) models (Fig.2). A linear increase (avg.  $R^2=0.988$ ) in predicted maximum strain with increased applied load was seen in all models. However, the DN model showed a larger increase (32.9e-3mm/mm) in strain across loading conditions (0.5x body weight to 4x body weight) compared to HIFU (17.7e-3mm/mm) and sham (16.9e-3mm/mm) models.

Results from mechanical tests suggest HIFU has the potential to preserve mechanical properties of tendon better than DN. Modeling results show that strain levels in the DN model were higher near the tendon-bone interface compared to the HIFU model. This suggests that tendons treated with HIFU experience less strain for similar applied forces than DN, making those tendons less susceptible to injury.

### Significance

The location of maximum strain from these analyses could inform predictions of location-specific initiation and progression of tendon injuries. This information also could aid in calculating risk of injury and provide insight into injury prevention. Further studies are needed to evaluate the effects of HIFU in animal models to understand if HIFU may be an alternative, non-invasive treatment for tendon injuries.

## Introduction

Low back pain (LBP) is a leading cause of disability in the world<sup>1</sup>. In particular, pain associated with the sacroiliac joint (SIJ) results in a very low quality of life and contributes to 15-30% of low back pain cases<sup>2,3</sup>. This pain is both intra-articular and peri-articular<sup>4,5</sup>. During abnormal or excessive motion, it is theorized the complementary grooves and ridges of the articular surface no longer conform. Therefore, it is clinically important to understand the arthrokinematics of the SIJ during dynamic activities. **The objective of this study is to quantify the intra-articular distances during induced nutation\counternutation.**

## Methods

Two osteoligamentous cadaveric specimens (49F;60F) were obtained and four 1mm tantalum beads were embedded into the sacrum and each ilium to co-register the motion data to the bone models. The pelvises then underwent a CT scan to determine bead location and construct 3D models of the ilium and sacrum (MIMICS Materialise). The L4 vertebral body and the right ischium were potted and loaded into a 6-DOF Spine Tester (MTS 858 Mini Bionix, MTS). Pure moments of up to 7.5 Nm were applied in nutation\counternutation and kinematics were recorded via 4-camera optical motion capture system (Vicon). Bead location was digitized prior to biomechanical testing. SIJ rotations and translations were calculated with the following anatomical coordinate system: x-lateral bending, y-axial rotation, and z-nutation\counternutation<sup>6</sup>. The minimum distances between the joint surfaces were calculated dynamically. The mean and minimum distances were measured along with the percent differences from the initial neutral position.

## Results and Discussion

The results of induced nutation\counternutation are shown below in Table 1 and Figure 1. The ROM for the primary axis of rotation

for each specimen was shown to be comparable at 3.00° and 2.75°, consistent with literature<sup>7</sup>. The proximity of the surfaces shown in Figure 1b indicates the percent difference of the proximity compared to its initial position. There is a greater shift within the first specimen's conformity of surfaces (represented with varying ranges), possibly attributed to the amount of translatory motion in Specimen 1.

The proximity maps help pinpoint regions impacted by the morphological shift of the surfaces. There is a greater change in conformity within the anterior regions of both specimens during counternutation and the inferior concave region during nutation – highlighting regions of potential articular surface contact. Both specimens minimize percent difference in the neutral position during dynamic motion indicating the efficacy this metric to measure conformity changes. Analysis is on going to achieve sufficient power and analyse additional motions and introduce a destabilized experimental condition.

## Significance

The results provide insight into the arthrokinematics of the SIJ during macroscale motions. This can ultimately aid in better understanding the SIJ's role in LBP.

## Acknowledgements

We would like to thank Excelen for their generous cooperation in obtaining the cadaveric specimens.

## Knee Valgus Angle: MRI versus Motion Capture

Christopher Weathers<sup>1</sup>, Taylor Oldfather<sup>1</sup>, Michael Zabala<sup>1</sup>  
<sup>1</sup>Mechanical Engineering, Auburn University, Auburn, AL, US  
 Email: zabalme@auburn.edu

### Introduction

Precise mathematical methods have been developed to quantify lower limb kinematics in anatomically meaningful ways. In both imaging (particularly magnetic resonance imaging, MRI) and movement analysis, the knee valgus angle (KVA) is commonly measured to determine ACL injury risk and to measure chronic conditions such as knee osteoarthritis [1]. MRI angles are also used for surgery in ACL reconstruction and knee replacement to facilitate normal kinematic functioning of the knee. Knowing how knee angles measured using MRI relate to angles measured during gait, using motion analysis, may help customize knee alignment in total knee replacement surgeries or other repairs. The purpose of this study is to test the hypothesis that multiple knee angles measured with motion capture are related to similar angles measured via MRI.

### Methods

A 10-camera Vicon motion capture system (Vicon, Vantage V5 Wide Optics), along with 79 retro-reflective markers placed based on the Point Cluster Technique, was used to collect the biomechanics of nine female student soccer athletes from Auburn University (height = 171.2 +/- 8.9 cm, weight = 66.3 +/- 8.6, kg age = 19.8 +/- 1.9 yr) [2]. The athletes were not excluded based on prior injuries or surgeries. The subjects walked 25 feet at a self-selected pace. The marker data was filtered using a 15 Hz lowpass butterworth filter, and Visual 3D was used to analyze the data. Frontal plane knee angles were measured at maximum knee flexion (KF) during the stance phase of gait. Knee abduction angle (KA) was calculated using the Grood and Suntay joint coordinate system [3]. In addition, KVA was calculated as the angle between the shank and global vertical axis [4]. Secondly, a 7-Tesla MRI machine was used to image both right and left knees using a true fast imaging (TRUFI) sequence. The subjects were placed in the scanner in a comfortable, supine position. The MRI images were segmented in Amira (Thermo Fisher Scientific) to generate 3D point clouds of the distal femur and proximal tibia. Blender software was used to generate local reference frames of both bones with a method based upon that described by Miranda et. al. [5]. The MRI KA and KF were calculated using the Grood and Suntay joint coordinate system [3]. The angles from MRI and motion capture were then compared using a two-tailed Pearson Correlation test with a 95% confidence interval.

### Results

Table 1: Mean and standard deviation (SD) of the KF, KA, and KVA measured during walking; and KF and KA measured from the MRI scan.

Activity	Angle	Mean	SD
Walking	KF	1.099507	2.492473
	KA	14.4554	6.379568
	KVA	0.085509	0.037876
MRI	KF	3.085956	6.02223
	KA	0.322674	1.979525

Table 2: The correlation between walking KA, KVA, and MRI KF and corresponding significance level.

Walking Angle	MRI KF	
	r	P
KA	0.700	0.036
KVA	0.767	0.016

### Discussion

The results of this study support the hypothesis that knee angles measured from MRI are related to angles measured using motion capture data. More specifically, the results show a correlation between the resting KF angle measured with MRI with KVA at maximum KF measured from motion capture during the gait cycle. Therefore, KF angle in MRI gives insight to KVA and KA measured with motion capture. This may allow physicians to better understand how surgical alignment of the knee will impact subsequent gait kinematics. The fact that the MRI KF is highly correlated with KVA from motion capture shows that using static measurements for reconstruction alignment is beneficial for the dynamic functions of the knee

Figure 1: A 3D rendering of the femur and tibia from

### Future Work

Further correlation between MRI and motion capture angles could be found by using additional subjects and scan types, such as x-ray or functional MRI. Comparing angles at different points in the gait cycle could also be beneficial. It would also be valuable to compare the MRI KA with the motion capture KA at points throughout the gait cycle where KF is equal to the subject's KF from MRI. Additionally, controlling for the amount of knee flexion in the MRI could lead to additional correlations in other angles. Finding a combination of MRI angles and motion capture angles that correlate to one other using these methods has the potential to give more insight to how individuals' knees can be aligned during surgery to result in more natural kinematics during gait.

\*Corresponding author email: d.morrissey@qmul.ac.uk

## Introduction

Musculoskeletal foot and ankle pain is common and typically aggravated by weight-bearing activity. Examination is usually based on a patient's symptom description, physical examination and imaging findings with severity graded subjectively in the clinical setting using patient reported outcome measures (PROMs). Objective severity grading is challenging to obtain. Therefore, a novel graded loading challenge (GLC) test was devised to grade foot pain severity with an objective measure of potential use in the clinical setting. This study aimed to assess GLC intra-tester reliability and validity, both with respect to patient reported severity and task progression.

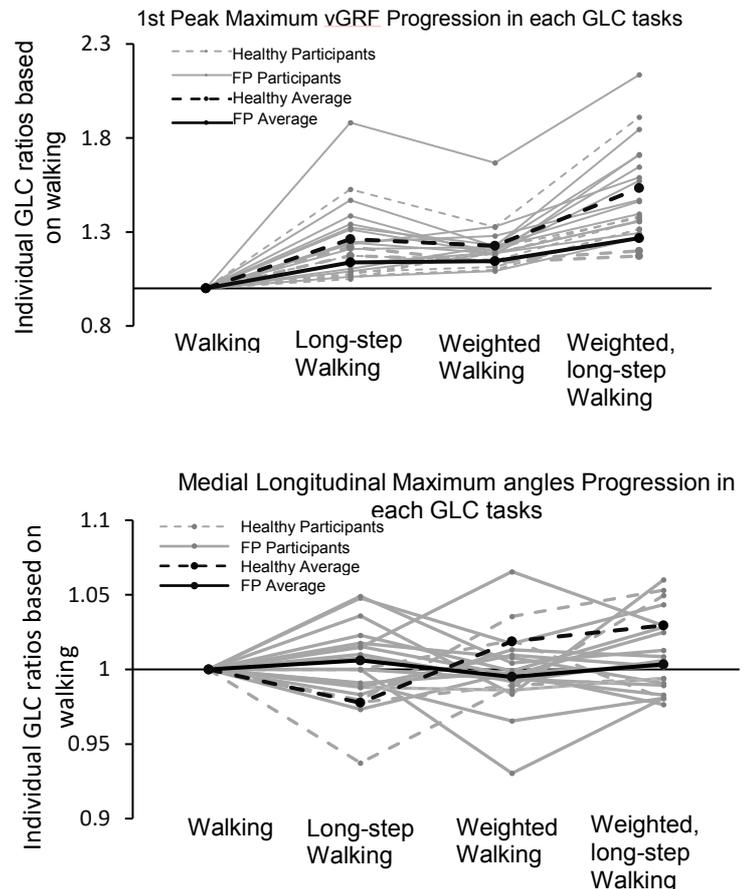

## Methods

People with foot pain of various kinds (♀=9, ♂=8) and healthy (♀=4, ♂=3) controls were recruited. Prior to performing the tests, all patients completed the Foot Health Status Questionnaires (FHSQ) to severity status. Kinetic and kinematic motion capture were performed during the GLC utilising in-floor force plates (500Hz; 9281CA, Kistler) and an infrared motion analysis system (100Hz; CX-1), respectively. The GLC consisted of four different difficulty levels: 1) normal walking with self-selected speed and step length, 2) walking with a 25% longer step length of participants' original step, 3) normal walking while carrying a load of 25% of body mass (BM), and 4) walking with the 25% longer step length plus the extra 25% load, which is a combination of tasks two and three. There were 10 repetitions of each task. The peak vertical ground reaction force (vGRF) at loading response (first peak), terminal stance (second peak) and rate of peak force development (RFD); Medial longitudinal arch (MLA) and first metatarsophalangeal joint (MTPJ1) angles were calculated at 50% stance and toe off, respectively. A numeric pain rating scale (NRS) was ascertained after each task. GLC score is calculated via the sum of pain values which are multiplying with grade of each task (1,2,3,4) for all levels were then correlated with the participant's score in the FHSQ pain subscale. A two tailed spearman's rank-order correlation test was used for results. Reliability was evaluated with repeated measures of 9 participants on separate days.

## Results and Discussion

Each test showed moderate to excellent reliability for intra-rater assessment (ICC: 0.60-0.92 with %95 CI) except for the MLA within the walking with weight task. First and Second Peak Maximum vGRF are significant with linear trend from polynomial contrast, (F1.4, 11.1=30.8; P<0.001) (Figure 1), (F3, 24=8.3; P=0.001) respectively. While, MTPJ1 Maximum angles (F2.3, 18.8=0.40; P=0.703) and MLA Maximum angles (F2.1, 17.1=2.8; P=0.087) (Figure 1), both are non-significant across the four tasks. Correlations were found between the total GLC score and FHSQ as  $r=0.410$ ,  $p=0.065$ . The biomechanical measures were repeated and demonstrated similar reliability to published work for kinetics. Kinematic re-test reliability was not as comparable necessitating particular care with marker placement. Results showed that GLC increases in maximum and second peak of GRFs with no progressive change in kinematics. However, the most important parameter of pain provocation during the tasks was seemed to be accumulated effect of the four tasks is suggested to increase the likelihood of achieving a pain

response for each patient. The correlation between FHSQ and GLC is supporting the assumption that the GLC can evaluate and quantify the symptoms of patients with foot pain.

## Significance

Specific clinical tests for assessing patients with foot pain facilitate the clinician's understanding of the patient's status, response to intervention, which provide determining of the best treatment option. In this study, easily applied functional tests elicited the patient's relevant foot pain, thus ascertaining a valid clinical assessment. Considering that mechanical overload is thought to be a causal reason for foot pain, and instrumented gait analysis the gold standard, we attempted to construct a graded loading challenge based on previous work to progressively challenge the load-bearing capacity of the plantar fascia by manipulating stride length and carried load. If compressive or tensile load are the biggest aggravating factors for foot pain<sup>1</sup>, our results suggest the graded loaded challenge tasks may be a useful indicator of severity, particularly as the kinetic values show a graduated increase with task. The ability of these tests to evaluate changes in the patient's status over time or after therapeutic intervention needs further evaluation.

# The Utilization of Porcine Ligament Properties as a Substitute for Human Ligaments in a Spinal Finite Element Model

Michael Polanco<sup>1</sup>, Sebastian Y. Bawab<sup>1</sup>, Stacie I. Ringleb<sup>1</sup>, Michel Audette, Carl St. Remy, James Bennett

<sup>1</sup>Department of Mechanical and Aerospace Engineering, Old Dominion University, Norfolk, VA USA

Email: [mpola002@odu.edu](mailto:mpola002@odu.edu)

## Introduction

Finite element modeling can be used to non-invasively assist in answering pre-surgical questions pertaining to surgical outcomes, which are best answered through input of patient-specific geometric data. However, it is nearly impossible to obtain in-vivo ligament properties and can be difficult to acquire human cadavers for in-vitro experiments. Porcine ligaments are similar in morphology and mechanics when compared with humans [1]. However, porcine spines can behave mechanically different depending on the spinal region of interest [2]. The purpose of this study is to compare the mechanical behavior of a functional unit within the human lumbar spine using porcine ligament stiffness properties with human ligaments.

## Methods

Quasi-static analyses were conducted in LS-DYNA (Livermore Software Technology Corporation, Livermore, CA) using an L4-L5 functional spinal unit finite element model (Figure 1). Vertebral and intervertebral disc geometry was obtained from CG Hero (CG Hero Ltd., Manchester, UK) and constructed using HyperMesh (Altair Engineering, Troy, MI). Human material properties for the intervertebral disc and vertebrae were characterized as hyperelastic and linear elastic respectively [3]. Ligaments were characterized as nonlinear tension-only springs. In-vitro porcine ligament data were collected in our lab [4] and human ligament data [5, 6] as well as capsular ligament properties [6] were obtained from the literature. Capsular ligament properties were the same for human and porcine ligament data sets. A pure moment of  $\pm 10$  N-m was applied in flexion and extension over a rigid body element distributed to the superior endplate and facet processes of L4, while the inferior endplate and facet processes of L5 were fixed. Functional Spinal Unit (FSU) kinematics were assessed with all ligaments intact and then serially removed beginning with spinous ligament removal, followed by facet joint removal, and ending with ligamentum flavum removal in flexion. Only intact and facet joint removal configurations were analyzed in extension. These reflect sequential steps for spinal flexibility gain in a posterior spinal fusion conducted by a surgeon.

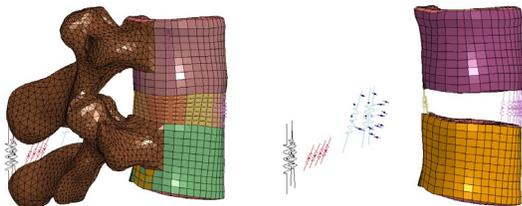

Figure 1. Finite element model of L4-L5 FSU

## Results and Discussion

The model showed that the functional unit with porcine ligaments intact matched the in-vitro data [7] more closely than human ligaments (Figure 2), which aligns with similar kinematic assessments [3]. The greatest differences in flexion exist in both cases when the ligamentum flavum is removed from the

configuration, because it was stiffer than the other ligaments. In extension, the human and porcine ligament sets guide the FSU to similar behavior while matching in-vitro data with prescribed moments under 5 N-m. Little differences can be found between both sets of kinematics due to the toe stiffness regions of the Anterior Longitudinal Ligament being similar between the porcine and human subjects utilized.

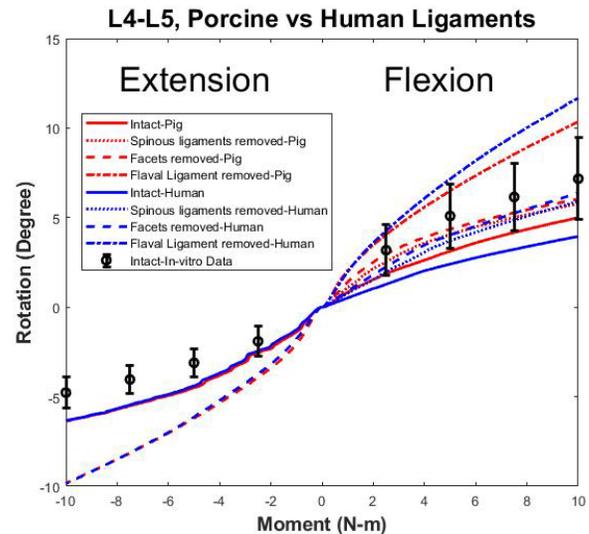

Figure 2. Flexion and Extension-Porcine vs Human

The results only reflect ligament stiffness data for one pig specimen and one FSU from the lumbar region. Future work should incorporate ligament stiffness data from multiple pig subjects while exploring various regions of the spine and human ligament properties.

## Significance

As porcine specimens continue to be used as practical alternatives to human subjects because of anatomical similarity and availability, animal ligaments may be sufficient sources for material properties needed for computational modeling. As shown by sagittal kinematics, qualitative behaviour of porcine ligaments in tension may justify their future use as a surrogate for human ligament properties.

## Acknowledgments

This work was funded by the SMART Scholarship received by M. Polanco and the Children's Research Foundation. Stephanie Anderson, Matthew Cribb, Cyndal Martell, Robert Martin, and Steve Parasidis collected in-vitro porcine ligament data.

# INVESTIGATING ENERGY TRANSFER DUE TO THE WINDLASS MECHANISM: A PILOT STUDY

Lauren R. Williams<sup>1</sup>, Dustin A. Bruening<sup>1</sup>  
Brigham Young University, Provo, UT, USA  
Email: lauren.williams523@gmail.com

## Introduction

Metatarsophalangeal joint (MTP) extension exerts tension on the plantar fascia, pulling the midtarsal (MT) joint into plantarflexion and raising the arch<sup>1</sup>. This windlass mechanism has been suggested to redistribute some of the energy absorbed by MTP extension<sup>2</sup>, as power generation at the MT joint occurs concurrently with power absorption at the MTP joint.<sup>3-5</sup> However, further investigation is necessary to determine the extent of the power transfer between the MT and MTP joints.

The purposes of this study were twofold: 1. To investigate the relationship between motion at the MTP and MT joints and arch stiffness during three conditions: A) passive MTP extension, B) normal heel raises (Normal), and C) heel raises where MTP extension was altered (ToeFlexed) and 2. To compare MT joint work, as well as distal-to-hindfoot work (DTH; the net contributions of MT and MTP joints and any deformable structures distal to the hindfoot)<sup>5</sup> during both heel raises. We hypothesized that higher arch stiffness would result in more motion at the MTP and MT joints. We also hypothesized that during heel raises, the ToeFlexed condition would result in decreased positive work at the MT joint while DTH work would remain the same.

## Methods

Arch stiffness was measured using the arch-height-index measurement system.<sup>6</sup> To measure MT motion during passive MTP extension, the participant's leg rested on a platform while the researcher extended the toes. This was performed 10 times to a metronome (45 bpm). To determine the relationship between motion at the MT and MTP joints, the slope of these two data sets was calculated for each subject and then compared to the subject's arch stiffness.

5 healthy males (age: 29±9.5 years, mass: 86.8±11.0 kg, height: 1.85±0.04 m) participated in this pilot study. The participant's right lower limb was outfitted with a multi-segment foot marker set.<sup>7</sup> In conjunction with a motion analysis system (Qualisys), a force plate (AMTI) was used to collect data during two heel raise conditions. For both conditions, participants performed 2 sets of 10 heel raises to a metronome (45 bpm). Participants were instructed to achieve a maximum height during the heel raise. In Normal, the participant's entire foot was on the force plate. In ToeFlexed, the foot was placed so that the hallux was off the force plate and curled over the edge. ROM at the ankle and MT joints, as well as the work done at the MT joint and DTH work, were calculated for the upward phase of the heel raise (start to peak heel raise). Paired t-tests ( $\alpha = 0.05$ ) were used to identify differences between conditions for each metric.

## Results and Discussion

The relationship between MTP and MT motion followed a linear trend with a slope of 14.2±3.9 degrees (i.e. for every 14.2 degrees of MTP extension there is one degree of MT plantarflexion). For 4 out of the 5 subjects, the relationship between this slope and arch stiffness were inversely related. These preliminary results suggest that in individuals with stiffer

arches the windlass mechanism is more effective at pulling the MT joint into plantarflexion.

The ROM at the ankle joint was not statistically different between Normal and ToeFlexed ( $p=0.33$ ), verifying that the subjects achieved the same heel raise height. However, the ROM at the MT joint was greater during Normal compared to ToeFlexed ( $p=0.02$ ; 21.7±6.5 degrees vs. 18.9±7.5 degrees, respectively), suggesting that the windlass mechanism was more engaged during Normal compared to ToeFlexed.

The relationship between MTP and MT motion followed a linear trend for both heel raise conditions with a slope of 1.8±0.5 degrees for Normal and 1.7±0.6 degrees for ToeFlexed ( $p=0.18$ ). The slopes for both Normal and ToeFlexed were both substantially lower than passive MTP extension ( $p<.01$ ), suggesting that much of the motion at the MT joint during heel raises is likely due to active muscle contractions with the windlass mechanism playing a secondary role, but further investigation is necessary to confirm this.

As hypothesized, the work done at the MT joint decreased during ToeFlexed compared to Normal (0.13±0.05 vs. 0.16±0.05;  $p<0.001$ ), while DTH work was not statistically different between conditions (0.21±0.09 vs. 0.21±0.08;  $p=0.99$ ). However, DTH work was higher for both conditions than the work done just at the MT joint. Due to the negative work typically performed by the MTP joint during push-off of walking<sup>5,7</sup> we expected DTH work to be less than MT work. Heel raises may have reduced MTP negative work since the center of pressure does not move as anterior as it does in walking and additional positive work may be performed at joints distal to the MT joint (e.g. Lisfranc joint complex).

## Significance

During heel raises, work production and motion at the MT joint are decreased when MTP extension is altered. These results further support previous findings of an energetic interplay between the MTP and MT joints through the windlass mechanism.<sup>2</sup> Further work is needed to fully understand the elevated DTH work relative to gait studies.

### Introduction

Spinal ligaments play a role in stabilizing the spine and preventing excessive motion. Thus their mechanical properties are useful for computational models of the spine [1] frequently used for pre-surgical spinal planning and treatment. However, while human spinal ligaments have been previously tested [2], in-vitro ligament test datasets from literature are limited. Because porcine and human ligaments bear structural and morphological similarities with one another [3], porcine ligaments may be comparable to human ligaments. Additionally, when developing an experimental protocol, a pig is easier to obtain. The purpose of this study is to develop a repeatable method for performing ligament testing and to obtain ligament mechanical properties from a porcine specimen.

### Methods

The spine of a 151 lb adult pig was harvested and four vertebral pairs dissected: one lower thoracic (T12-T13) and three lumbar (L1-L2, L3-L4, L5-L6). From each vertebral pair, five bone-ligament-bone (BLB) specimens were isolated, totaling 20, including the anterior and posterior longitudinal ligaments (ALL, PLL), ligamentum flavum (LF), intertransverse (IT), and the interspinous/supraspinous ligament complex (ISL/SSL). The bone ends were potted in a two-part epoxy using a 3D printed clamshell-popsicle potting design that provided adaptability to the various bone geometries. The potted BLB specimens were inserted into a fixation apparatus that adapted to a 10ST tensile testing machine (Tinius-Olsen, Horsham, PA). Specimens were frozen between preparation and epoxy curing stages averaging 10 hours of ambient exposure. All ligaments were preconditioned prior to static loading to failure at 0.01 mm/s from which stiffness data was obtained.

### Results and Discussion

Force-deflection curves (Fig. 1) generally reveal characteristics of a ligament loaded in tension, including toe and linear regions up to failure [4]. 15 datasets were included for analysis. Excluding ITL, small standard deviation for each ligament type relative to the mean indicates similar results, regardless of the location in the spine. The ALL registered the highest failure load, followed by LF and PLL. The ISL/SSL ligament complex registered a lower failure load. These patterns are qualitatively consistent with observations made from in-vitro human lumbar

ligament experiments. The porcine ligament failure loads were higher than observed in human ALL and flaval ligament specimens with standard deviations of 36.6 Newtons and 40.1 Newtons respectively, while the ISL/SSL complex registered a failure load lower than observed with a standard deviation of 5 Newtons. The PLL failure loads exhibited a standard deviation of 34.2 Newtons; however, the mean was in range of reported failure load values [2]. The differences in failure loads could be attributed to the amount of connective tissue removed from each BLB specimen, which was difficult to distinguish during dissection. Among specimens considered, the ITL failure loads exhibited a standard deviation of approximately 4.3 Newtons due to difficulty in aligning the ligament fibers with the axial load direction, leading to premature lateral tearing. Existing in-vitro ligament testing literature often do not identify testing setup limitations and lack specificity on ligaments isolation. To further refine the experimental protocol and establish statistical significance of the datasets provided, future work includes testing and collecting data from multiple pig spines.

### Significance

Porcine ligament specimen testing is a practical alternative to testing human spines for developing robust spinal ligament experimental methods. This is enabled by relatively similar anatomy between porcine and human spine. Therefore, a robust method developed from porcine testing can translate directly to human testing with minor modifications. Furthermore, literature identifies that porcine spinal ligaments have similar qualitative mechanical properties to a human's [5], which could be applicable to human computational studies.

### Acknowledgments

The project was funded by the Children's Research Foundation.

# Relative Contribution of Material and Morphological Properties to Altered Achilles Tendon Stiffness in Aging

Jordyn N. Schroeder<sup>1</sup>, Lindsey Trejo<sup>1</sup>, Owen N. Beck<sup>1,2</sup>, and Gregory S. Sawicki<sup>1,2</sup>

<sup>1</sup>George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, USA

<sup>2</sup>School of Biological Sciences, Georgia Institute of Technology, Atlanta, GA, USA

Email: [jschroeder9@gatech.edu](mailto:jschroeder9@gatech.edu)

## Introduction

Both material properties (*e.g.* Young's Modulus ( $E$ )) and morphological properties (*e.g.* cross sectional area (CSA) and slack length ( $l_{\text{slack}}$ )) affect tendon stiffness ( $k_t$ ). While previous studies have observed reduced Achilles tendon (AT)  $k_t$  in older adults versus young adults<sup>1,2</sup>, the mechanisms for this reduced stiffness are unclear. Some findings suggest decreased  $E$  and increased local CSA<sup>1</sup>. Others suggest that increased collagen crosslinking in aging decreases  $E$  but increased mechanical stiffness<sup>3</sup>. Differences in methodological approaches across laboratories make it difficult to come to consensus about age-related changes in tendon structure-function. The objective of this study was to take comprehensive, functionally relevant measures of AT material and morphological properties to assess the relative contributions leading to decreased  $k_t$  in older adults. We hypothesized that changes in morphology (*i.e.*, lower CSA, longer  $l_{\text{slack}}$ ) would counteract increased  $E$  and explain age-related decreases in AT  $k_t$ .

## Methods

In this preliminary study, we recruited three young adults (YA: 25.3 +/- 3.2 yrs) and one older adult (OA: 77 yrs). Tendon stiffness ( $k_t$ ) was measured during isometric contractions of the right leg with the knee fully extended and the ankle fixed at 0°, 15° and 30° plantarflexion. Subjects were instrumented with an ultrasound probe over the medial gastrocnemius (MG) - AT junction, electromyography electrodes over the skin superficial to the tibialis anterior (TA), lateral gastrocnemius (LG), and soleus (SOL) muscles, and 3D motion capture markers on the medial knee, medial malleolus, and head of the 1<sup>st</sup> metatarsal. Measurements of  $k_t$  were taken as the slope of the AT force-displacement relationship at a matched absolute force across age groups. AT  $l_{\text{slack}}$  was measured from the most proximal point of the AT-calcaneus junction to the MG-AT junction at 0 degree angle. CSA was measured along the length of the AT, in 10% AT length increments by taking manual measurements from ultrasound images in ImageJ.  $E$  for the AT was calculated using the relationship  $k_t = E \cdot \text{CSA} / l_{\text{slack}}$  using the CSA from the most distal measurement location.

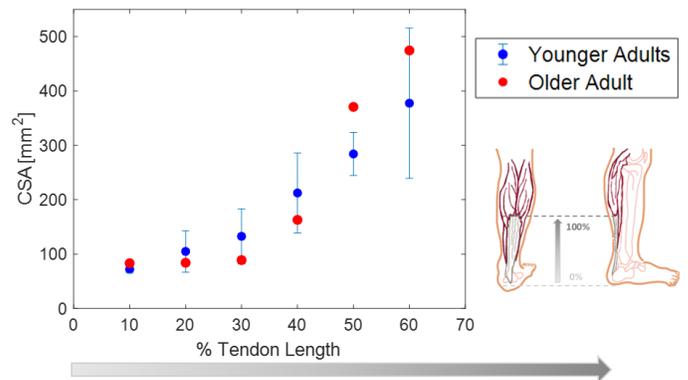

## Results and Discussion

As expected, the older adult had reduced AT  $k_t$  versus the younger adults (Table 1). These preliminary results suggest that in both age groups, CSA increased as you move proximally up the AT. However, differences in older adult vs. younger adults CSA varied depending on the AT location. The older adult had larger CSA near the AT-MG junction but smaller CSA distally.

In partial support of our hypothesis, our results suggest that age-related decreases in  $k_t$  may be driven by changes in morphology rather than material properties of the AT. Though our participant sample size is limited, we found that large

increases in  $l_{\text{slack}}$  overshadowed smaller changes in CSA and  $E$  to yield a more compliant older AT.

The goal of this study was to understand how age-related trade-offs in AT CSA,  $l_{\text{slack}}$ , and  $E$  contribute to changes in AT  $k_t$  in older adults. As we collect more participants, we will apply linear regression models to evaluate the impact of CSA,  $l_{\text{slack}}$ , and  $E$  on AT  $k_t$ .

**Figure 1:** Cross-sectional area (CSA) along the free length of the Achilles tendon (AT). Error bars indicate SD.

	$k_t$ [kN/m]	$E$ [GPa]	CSA [mm <sup>2</sup> ]	$l_{\text{slack}}$ [mm]
<b>Younger Adults</b>	136.3 ± 25.2	35.0 ± 8.7	71.9 ± 6.5	18.3 ± 1.7
<b>Older Adult</b>	115.9	32.3	83.2	23.2

**Table 2:** Achilles tendon (AT) material and morphological properties across age.

## Significance

Here, we lay the groundwork to address the key factors that impact AT structure-function across the lifespan. Understanding how changes in morphological and material properties of tendon trade-off in aging is important because therapeutic approaches to alter tendon mechanics, (*e.g.*, drugs, exercise, exoskeletons) often target specific tendon properties.

## Introduction

Some musculoskeletal pathologies, such as rotator cuff tear, tendon rupture, and limb amputation, are associated with detachment of muscle-tendons from bone. Reattaching the biological muscle-tendons may not be possible if the tendon is damaged or missing. One group recently developed a synthetic tendon that is intended to replace a damaged or missing biological tendon [1]. The synthetic tendon is composed of a polyester suture that is coated in medical-grade silicon. Previous studies tested the synthetic tendon *in vivo* in a goat model [1] but did not quantify the effect of the synthetic tendon on locomotor function.

We are developing a New Zealand White rabbit model to assess locomotor function after replacing the biological Achilles tendon with a synthetic tendon. In the previous *in vivo* study [1], the synthetic tendon was anchored to bone using a sturdy metallic plate. Alternatively, in a previous surgery, we anchored the synthetic tendon to the calcaneus using a 2.2mm-diameter Arthrex suture anchor (AR-1318FT-40) and a strand of size 4-0 Fiberwire suture. Two weeks after the surgery, we observed that the 4-0 Fiberwire failed, releasing the synthetic tendon. The objective of this preliminary study was to quantify the mechanical strength of our tendon-anchoring system with the previous (4-0 Fiberwire) and two next-larger sizes of Fiberwire suture that are compatible with our anchoring system. We hypothesized that the strength of the 4-0 Fiberwire would be less than the estimated maximum force of the triceps surae muscles during rabbit hopping, while the strength of the larger sutures would exceed the maximum muscle force.

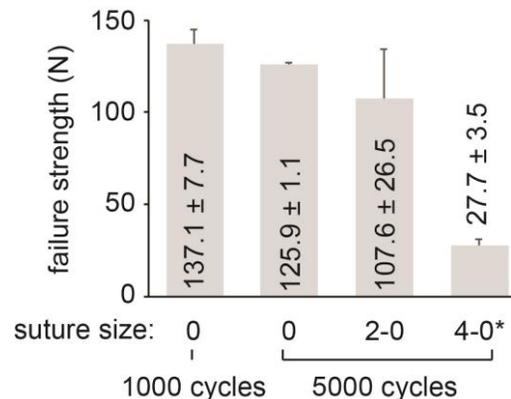

## Methods

We use three different sizes of Fiberwire suture: four of size 0, three of size 2-0, and two of size 4-0. Custom-fabricated synthetic tendons were tied, using the Fiberwire sutures, to 2.7mm-diameter Arthrex suture anchors (AR-1319FT), since the 2.2mm anchors are too small for the size 0 Fiberwire suture; the 2.7mm anchors are compatible with our rabbit model. We clamped the suture anchor and proximal end of the synthetic tendon to an Instron tensile tester.

From a biomechanical model of the rabbit hindlimb [2], we estimated the maximum forces generated by the medial gastrocnemius ( $32.0 \pm 8.8$  N), lateral gastrocnemius ( $15.5 \pm 2.0$  N), and soleus ( $10.2 \pm 0.6$  N) muscles during an average gait cycle. We summed the means of the three maximum muscle forces (and rounded up) to approximate the maximum triceps surae force during an average gait cycle as 60 N. We programmed the Instron tensile tester to apply a cyclic (1 Hz, approximate gait cycle duration) 60 N tensile force to the synthetic tendon and suture anchor assembly. In an initial test, we ran two of the size 0 sutures for 1000 cycles; thereafter, we ran all remaining samples for up to 5000 cycles. After the cyclic loading, we applied an increasing pull-out force to the assembly until it failed.

## Results and Discussion

All of the size 0 and 2-0 sutures remained intact after 5000 cycles, indicating that the size 0 and 2-0 sutures could withstand the

**Figure 1:** Failure strength of the Fiberwire suture. Values over bars are mean  $\pm$  standard deviation. \*The size 4-0 suture failed during the first load cycle.

average maximum force of the triceps surae muscles for at least 5000 gait cycles. In contrast, the size 4-0 suture broke during the first cycle of each test, which explains why it failed *in vivo* soon after our first surgery. All assemblies failed at the Fiberwire suture linking the tendon and anchor, just adjacent to where the suture was knotted near the loop in the synthetic tendon.

The mean failure strength of the size 0 suture was only 18.27 N more than that of the smaller size 2-0 suture, whose failure strength was 47.66 N (or 79%) more than the 60 N maximum muscle force. Therefore, we expect that both the size 0 and 2-0 sutures are suitable for our *in vivo* locomotor function tests. We plan to use the size 0 and size 2-0 sutures with the 2.7mm and 2.2mm suture anchors, respectively, in future surgeries.

For the size 0 suture, the failure strength was 11.22N lower after 5000 cycles than after 1000 cycles (Figure 1), indicating that there is some effect of cycle number on failure strength. If the failure strength trend continued linearly, then the size 0 suture could withstand approximately 26,500 cycles of the 60 N load. We will conduct additional cyclical loading tests to measure the maximum number of cycles that the size 0 and 2-0 sutures can withstand.

## Significance

In this study we evaluated the failure strength of the suture connecting the synthetic tendon to the suture anchor. The data shows that the size 4-0 suture is too weak for our rabbit model, and that size 0 or 2-0 sutures should be used in future surgeries. Our data provides critical support for future biomechanical studies of synthetic tendon, a potentially valuable medical device for tendon repair and replacement.

### Introduction

Limb-salvage surgery without reconstruction of the pelvis is a promising treatment for type-II pelvic sarcoma. Patients improve in their ability to walk over time despite resection of the native hip joint, loss of surrounding musculature, and significant limb shortening. The exact mechanism for these improvements has not been explained and if determined could lead to optimized treatment planning. The psoas muscle is the only hip flexor preserved after internal hemipelvectomy and likely influences transient gait function. It can undergo atrophy prior to surgery as well as significant shortening after surgery with periods of understretch. Strengthening of the psoas muscle after surgery may explain the improved ambulatory function over time. Since muscle strengthening is indicated by increased muscle size, magnetic resonance (MR) images were retrospectively reviewed for maximum cross-sectional area (CSA) and volume changes at two post-operative time points. The patients with psoas hypertrophy were hypothesized to have improved ambulatory function. Other factors such as superior migration of the femoral head on ipsilateral side of the sarcoma are also thought to affect the ambulatory functions.

### Methods

Retrospective imaging and clinical data of 12 patients (10 male, 2 female; mean age at the time of surgery, 28.5 years; range, 13 – 64 years) who underwent internal hemipelvectomy without reconstruction for type-II pelvic sarcoma at the same institution at approximately three months after surgery (patient walking with assistance) and during the patients' most recent clinical visit (patient walking without assistance) were reviewed.

Sectional volume and maximum CSA of each patient's psoas on ipsilateral and contralateral sides of the sarcoma were measured on reconstructed surface geometries built from their T-1 weighted axial MR images. Superior migration of femoral head was measured on MR images and normalized by each patient's height at the time of the visit. The ambulatory function of a patient was indicated by the results of Timed Up and Go (TUG) test and gait speed test during their physical therapy examination and performed within one month of their MR imaging.

Paired t-test of the volume and maximum CSA changes between the ipsilateral and contralateral sides and single t-tests on volume and maximum CSA changes on both sides, normalized migration at 3 months and at latest visit, follow-up time between the two time points, and weight gain ( $\alpha=0.05$ ) were computed. The coefficients of determination were calculated to measure the linear correlation between each of the different variables and functional measurement improvement. A step-wise linear regression of all variables was computed for each ambulatory function.

### Results and Discussion

All 12 patients spent less time to complete the TUG test and walked faster in their gait speed test at the most recent follow-up compared to their 3 month follow-up. The volume of psoas

muscle on the ipsilateral side and contralateral side of each patient increased on average by 29% (SD: 47%) and 38% (SD: 43%) respectively; the maximum CSA increased on average by 21% (SD=38%) and 37% (SD=37%) respectively. Paired t-test showed no significance difference of the volume ( $p=0.46$ ) or maximum CSA change ( $p=0.24$ ) between the two sides. The single t-tests showed a significant increase of all variables from zero except for ipsilateral side muscle size changes.

**Table 1:** Single t-test results and correlation coefficients between variables and ambulatory function scores

	p	R with TUG	R with Gait
Ipsilateral side volume change (%)	0.06	0.38	0.72
Ipsilateral side max CSA change (%)	0.08	0.44	0.78
Contralateral side volume change (%)	0.01	0.25	0.38
Contralateral side max CSA change (%)	0.01	0.28	0.39
Normalized migration at 3 months (%)	0.00	-0.66	-0.35
Normalized migration at latest visit (%)	0.00	-0.31	-0.22
Follow-up time (number of months)	-	0.43	0.24
Weight gain (%)	0.02	0.17	0.26

On the ipsilateral side, psoas volume change and maximum CSA were moderately correlated with gait speed improvement and weakly correlated with TUG test improvement. On the contralateral side, psoas volume change and maximum CSA were weakly correlated with both the TUG test improvement and gait speed improvement.

Step-wise linear regression showed that TUG score improvement ( $R^2=0.59$ ) and gait speed improvement ( $R^2=0.72$ ) were most sensitive to normalized migration at 3 months, psoas muscle maximum CSA change on the ipsilateral side, and follow-up time. This suggested that greater ambulatory function improvement was correlated to longer follow-up time, greater psoas muscle strength on ipsilateral side, and less superior migration of the femoral head.

### Significance

This study explored whether ambulatory function improvement is correlated to psoas muscle size growth and other factors after limb-salvage surgery for pelvic sarcoma without pelvic reconstruction. Understanding the correlation could lead to optimal treatment planning.

## Introduction

Spinal Cord Injuries (SCI) affect 28-55 million people in the United States [1]. Immediately following a SCI, there is rapid muscle atrophy. This loss of muscle can lead to decreased metabolic rate and increased fat storage as well as increased risk of obesity-related injuries, such as cardiovascular disease [2]. Robotic exoskeletons are becoming increasingly available in clinical settings for SCIs. Robotic exoskeletons use motors at the hip and knee, controlled by a computerized control system, to allow for assisted walking and rehabilitation [3]. Exoskeleton assisted gait training is used to deliver controlled repetitive training and reduce physical burden on physical therapists [4]. However, it is unclear whether the passive motion and weightbearing that are associated with exoskeleton-assisted walking in non-ambulatory individuals Here we validated methods to measure changes in muscle density and volume over time using quantitative CT data collected during a clinical trial. We hypothesized that exoskeleton-assisted walking would increase both muscle density and volume in the legs.

## Methods

Twenty-four adults with AIS A-C (non-ambulatory) spinal cord injury were enrolled in a 12 month clinical trial (NCT02533713; age:  $33.7 \pm 8.8$  years, height:  $177.8 \pm 10.2$  cm, mass:  $74.8 \pm 14.1$  kg.) Participants were randomized to either Immediate Gait Training (months 0 to 6) or Delayed Gait Training (months 6-12), with the other 6-month period being observation only/usual activities. Gait training lasted for 1 hour, 3 days a week. Each subject received a CT scan of a 30 cm length surrounding the knees at month 0 (baseline), 6 (midpoint) and 12 (final). The present analysis examined only pre/post gait training data.

Muscle volume and density pre- and post gait training was measured within a 15% limb length region above and below each knee using Mimics v. 18.0 (Materialise, Leuven, Belgium). Density, expressed in Hounsfield units (HU), is an indirect measure of intramuscular adiposity/muscle quality: fat has HU values around -50, water: 0 HU, and muscle/soft tissue up to 200 HU. Using a fixed threshold of -49 to 169 HU, our density and volume measures have %CV of 1.3 and 1.4%, respectively.

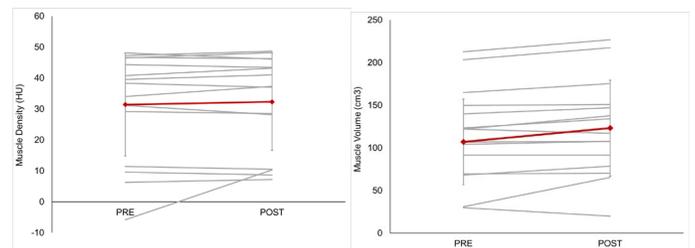

**Figure 1:** (left) Cross-section of the calf, with muscle highlighted. (right) sagittal plane section of the thigh, with muscle highlighted.

Paired t-tests were used to compare pre/post measures of muscle volume, density, and a composite measure of volume\*density for each participant. Pearson correlations were calculated for demographics and baseline values of muscle volume and density.

## Results and Discussion

Baseline muscle volume was significantly correlated with body size (mass and height,  $r > 0.44$ ,  $p < 0.04$ ). Overall, gait training was associated with significant increases in muscle density\*volume (mean change:  $102 \text{ HU} \cdot \text{cm}^3$ ;  $p \leq 0.035$ ). This came from increases to volume, with no change in density (Figure 2).

**Figure 2** Pre/post changes in muscle density (left) and volume (right). Average muscle density did not change during gait training, but muscle volume increased significantly by 15% ( $p = 0.02$ ). Red bars show the group average at each timepoint (error bars are SD).

Although this exoskeleton-assisted walking intervention did not include any direct stimulation of the muscles, it was associated with significant increases in muscle mass. Exoskeleton walking may benefit leg muscles by placing the individual in a standing position and through passive motion, which can both stretch the muscles and increase circulation.

## Significance

Currently, little is known about the musculokeletal benefits of using an exoskeleton. This research demonstrates that even passive motion generated during exoskeleton-assisted walking may improve muscle quantity in individuals with SCI. This is significant because muscle mass contributes to overall and cardiovascular fitness. These results can be used to develop and evaluate improved rehabilitation interventions for individuals with SCI and other impairments that result in muscle loss.

## Introduction

Deficits in voluntary quadriceps activation are considered critical in the biomechanical cascade underlying high rates of osteoarthritis (OA) in individuals with anterior cruciate ligament reconstruction (ACLR) and other knee pathologies [1]. During walking, diminished peak knee extensor moments (pKEM), potentially arising from quadriceps dysfunction [2], may improperly distribute loads accommodated by the articular cartilage in locations and with magnitudes unprotected by prior loading experience [3]. However, little empirical data exist to elucidate the association between changes in pKEM and articular cartilage loading during walking. Our purpose was to leverage novel real-time inverse dynamics in a biofeedback paradigm capable of prescribing systematic changes in pKEM in combination with musculoskeletal simulations to estimate cause-effect changes in knee joint outcomes relevant to the onset of OA.

## Methods

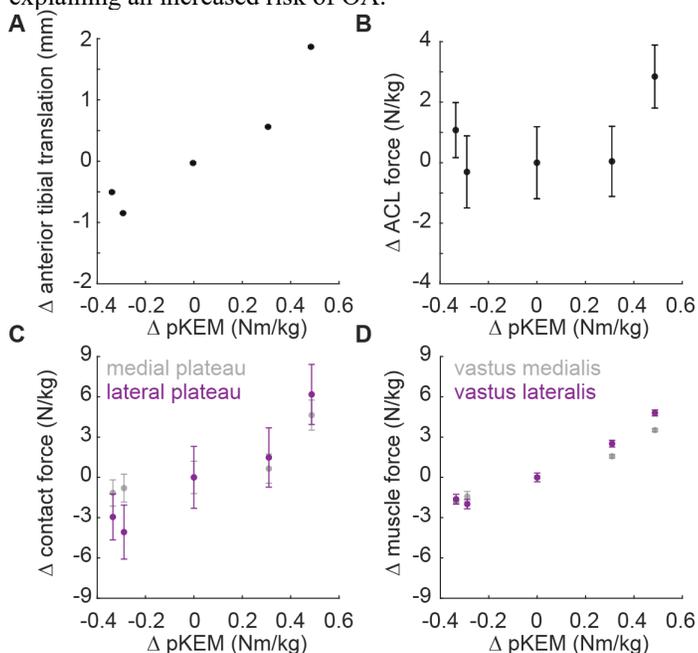

**Experimental Measurements.** Twelve uninjured participants (23.6±2.6 yrs; 6M/6F) completed five treadmill walking trials at their preferred speed. Subjects first walked normally without biofeedback. We immediately analyzed this trial using a real-time surrogate model of the lower limb to extract pKEM targets for use in our biofeedback paradigm. Four biofeedback trials visually cued participants to walk with ±20% and ±40% of normal values. We recorded ground reaction forces (GRFs), 3D motion capture data, and the activity of seven muscles spanning the knee.

**Model Predictions.** We have completed simulations on one male participant to date (22 yrs, 1.68 m, BMI 22.1). We used measured GRFs and marker trajectories from a representative stride to drive a scaled whole-body musculoskeletal model embedded with a validated 12 degree-of-freedom model of the knee joint that included representations of 12 ligaments [4]. A concurrent simulation algorithm (i.e., COMAK) predicted secondary knee joint kinematics and muscle, ligament, and articular contact forces necessary to generate the measured motion [4]. Monte carlo simulations accounted for ±30% and ±2% in ligament stiffness and reference strain, respectively, and we report model-predicted variance about the mean. Model outcomes included anterior tibial translation, ACL force, contact force on the medial and lateral tibial plateaus, and vasti (medial and lateral) muscle forces, and all were reported as change relative to usual walking.

## Results and Discussion

Biofeedback prescribed pKEM values that ranged from 0.22 to 1.05 Nm/kg. Targeting larger than normal pKEM elicited greater anterior tibial translation and higher ACL force, consistent with quadriceps' classification as ACL antagonists (Fig. 1A) [5]. Conversely, ACL force also increased when targeted 40% smaller than normal pKEM (Fig. 1B), likely due to other secondary knee kinematics and/or diminished mechanical advantage of the hamstrings with increased knee joint extension (not shown). Articular contact forces (Fig. 1C) and the quadriceps muscle forces most responsible for them (Fig. 1D) increased

when targeting larger than normal pKEM. However, lateral forces (muscle and contact) were more sensitive to volitional changes in pKEM than medial forces – an outcome consistent with the larger physiological cross-sectional area of the vastus lateralis versus medialis. Targeting smaller than normal pKEM (in this subject by up to 60%), yielded 15% smaller total articular contact forces. This prediction provides convincing evidence that readily-observed gait changes in individuals with ACLR may lower articular contact forces to values below normal physiological loading. Ultimately, these gait changes may disrupt the balance between cartilage breakdown and repair, thereby explaining an increased risk of OA.

**Figure 1.** Changes in model-predicted outcomes as a function of those in measured stance phase pKEM prescribed via real-time biofeedback. Zero (0) in all cases represents values during normal walking.

## Significance

We demonstrate that changes in pKEM during walking, common to individuals with ACLR and other knee joint pathologies, are accompanied by changes in ACL force, tibia anterior translation, and medial and lateral articular contact forces relevant to the development and progression of osteoarthritis.

# Spatial gait characteristics are related to impaired hip abductor strength in women with hip osteoarthritis

Burcu Aydemir and Kharma C. Foucher

Department of Kinesiology and Nutrition, University of Illinois at Chicago, IL, USA

Email: [baydem2@uic.edu](mailto:baydem2@uic.edu)

## Introduction

Hip Osteoarthritis (OA) is a common condition affecting up to 25% of older adults over a lifetime [1] with a higher prevalence in women. Walking is essential for independent living and it is an exercise that is commonly recommended to people with OA. To be performed safely, walking gait requires sufficient flexibility and stability by the musculoskeletal system. The hip abductor muscles are crucial for stabilization within the frontal plane during single-limb support while the swing leg advances forward to the next step. People with hip OA demonstrate significant hip abductor strength deficits, primarily on the affected side [2]. Any degree of impairment could potentially modulate laterally and anteriorly directed steps consequential to the weakness and instability surrounding the affected hip. Individuals with hip OA also demonstrate altered spatiotemporal gait characteristics compared to adults without OA [3]. However, it remains unclear whether these alterations are related to hip abductor impairment. Our goal was to investigate how impaired hip abductor strength in women with hip OA may be related to commonly reported altered spatiotemporal gait characteristics. We hypothesized that lower hip abductor strength would be significantly associated with a 1) shorter step length on the affected side, 2) wider step width, and 3) slower gait speed in women with unilateral hip osteoarthritis.

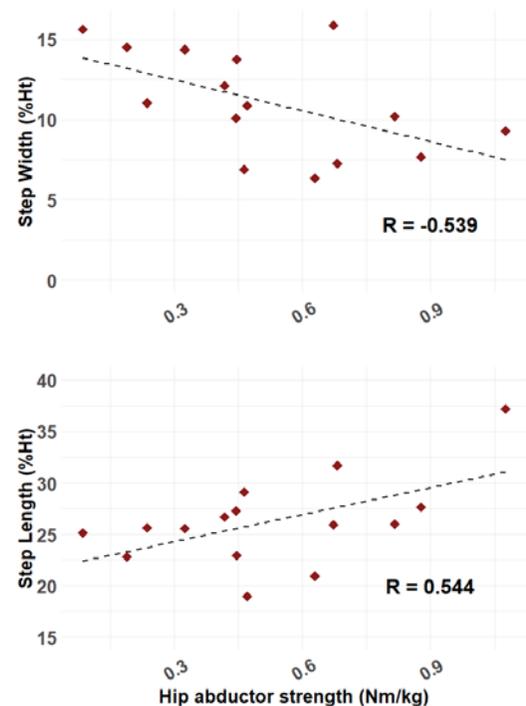

## Methods

Fifteen women (age  $56.2 \pm 6.3$  years; BMI  $30.2 \pm 6.5$  kg/m<sup>2</sup>) with self-reported unilateral hip OA consented to participate in this cross-sectional study. Hip abductor strength of the affected side was tested in a side-lying position, using an isokinetic dynamometer [Biodex System 4 Pro, Biodex Medical Systems, Inc., Shirley, NY]. Peak isometric torque was measured from three 5 s bouts alternated with 30 s rest and normalized to body mass (Nm/kg). Three-dimensional gait analysis data were collected via an 8-camera motion analysis system (Motion Analysis Co., Santa Rosa, CA) operating at 120 Hz. Subjects were given a 3 min acclimation period to find their preferred walking speed on a split-belt treadmill, followed by a 2.5 min walking trial. Passive markers were placed bilaterally over selected bony landmarks using standard methods. Step length and step width, normalized to body height (%), were defined as the anterior-posterior and mediolateral distances between the heel markers at heel contact, respectively. The average peaks over 10 consecutive steps were processed and extracted using a custom MATLAB algorithm (MATLAB, Natick, MA). The relationships between hip abductor strength, step width, step length, and self-selected gait speed were evaluated using Pearson correlation coefficient ( $r$ ). Alpha was set at  $p \leq 0.05$  for all analyses.

## Results and Discussion

The mean self-selected walking speed was  $0.67 \pm 0.24$  m/s. In support of our first and second hypothesis, we found that lower hip abductor strength was associated with a shorter step length of the affected side ( $p = 0.036$ ), and wider step width ( $p = 0.038$ ) (Figure 1). Previous studies similarly reported that people with

hip OA tend to walk with shorter [3] and wider steps [4]. Our findings add to the current literature by suggesting hip abductor strength may be a contributor to these altered gait characteristics. These observed stepping strategies could be protective bracing mechanisms adopted due to the weakened hip musculature to place the affected limb in a position that is most stable and reduces loading at the affected hip joint. Contrary to our third hypothesis, hip abductor strength was not significantly associated with gait speed ( $r = 0.511$ ,  $p = 0.052$ ). However, this association may be significant with a larger sample size.

**Figure 1:** Lower hip abductor strength is associated with higher step width (top) and lower step length of affected side (bottom).

## Significance

A better understanding of how hip abductor strength impairments may impact spatiotemporal gait characteristics can lead to effective combined interventions of gait and strength training. Combined therapies aimed at increasing strength and stability in people with lower limb OA may help aid in promoting participation in exercises, such as walking.

### Introduction

Osteoarthritis (OA) of the thumb Carpometacarpal (CMC) joint is a complex disease of bone and cartilage with highly individualized rates of progression. Radiographic assessment of CMC OA in 2D is hindered by the complex geometry and bony overlap in basal thumb x-rays, and at best delivers a coarse categorical metric.

With advancements in the ability to quantify osteophytes (OPs) from CT images<sup>1</sup>, an objective variable of disease state can be calculated. In this study, the magnitudes and rates of OP volume change over a six-year period were combined into a single classifier, with the goal of stratifying CMC OA patients into stable and advanced OA categories. Once categorized, differences in OP volume and dorsal subluxation were evaluated between OA groups and a healthy population over time.

### Methods

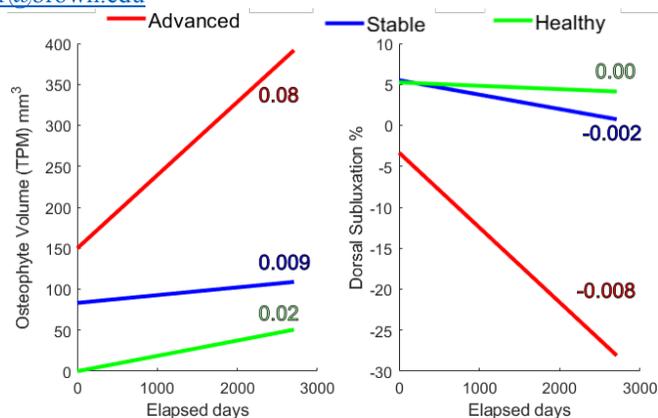

Following IRB approval, 86 patients with early thumb CMC OA (self-reported pain and radiographic Eaton 0/1 grading) and 22 age-matched asymptomatic healthy volunteers were recruited into an NIH-funded thumb CMC OA biomechanics study.

At enrollment (day 0) and four time points spaced at 1.5-year intervals, data were collected for each OA patient; healthy volunteers returned for only a 6-year follow-up visit. At each visit, CT scans of the affected (patient) or dominant (healthy) wrists were acquired in 11 range-of-motion and task-related positions<sup>2</sup>. At each follow-up visit, the elapsed day count from each subject's day 0 was recorded to measure longitudinal change ( $\Delta$ /day).

Digital surface models of the trapeziae (TPM) and first metacarpals (MC1) were segmented from CT data. For each day 0 model, coordinate systems (CS) were calculated from manually delineated TMC articular facets<sup>3</sup>.

OP volumes were calculated via subtraction of a best-fit bone model<sup>1</sup> from each patient's 1.5, 3, 4.5 and 6-year bone models and via Boolean subtraction of the day 0 models from the 6-year follow-up models in the healthy cohort. The rate of OP growth ( $\text{mm}^3/\text{day}$ ) for each participant was determined using linear regression of OP volumes over time. Subluxation was defined as the MC1 CS origin position resolved in the TPM coordinate space in dorsal(-)-volar(+) and radial(+)-ulnar(-)<sup>3</sup> directions for each subject, visit, and CT position. Values were reported as percentage of subject TPM facet area (more negative reflecting greater dorsal subluxation).

Participants were categorized as stable or advanced OA based on thresholds for both magnitude and rate of OP volume growth. The threshold values were defined as the population median of each metric ( $\alpha=150\text{mm}^3$  OP volume;  $\beta=0.04\text{mm}^3/\text{day}$  OP growth). Patients were classified as advanced OA if any visit OP volume exceeded  $\alpha$  or the subject's rate of OP growth exceed  $\beta$ . Linear mixed models with random intercept and slope were created for the three-way comparison of stable OA, advanced OA, and healthy cohort; evaluating differences in rate of OP growth and rate of subluxation % change.

**Figure 1:** OP volume and subluxation % change over elapsed days from initial visit by TMC OA patient groups: Advanced (49/86) (red), Stable (37/86) (blue) and Healthy subjects (green). Annotated slope values for each group measured in units of  $\text{mm}^3/\text{day}$  (OP volume) and  $\%/\text{day}$  (Subluxation).

### Results and Discussion

The rate of OP growth over time was significantly greater in patients with advanced OA than in patients with stable OA ( $p<0.0001$ ) or healthy subjects ( $p<0.0001$ ) (Fig. 1, left). Group differences in subluxation were greatest in thumb flexion. In flexion, the advanced patients' rate of dorsal subluxation was significantly more negative than that of the stable ( $p=0.0009$ ) and healthy subjects ( $p=0.0004$ ), which were alike ( $p=0.99$ ) (Fig. 1, right). Similar trends in subluxation were found for all positions, with a subset (6/11; grasp, grasp-loaded, pinch-loaded, abduction, adduction) also revealing significant differences between stable and advanced OA groups. This indicates that pathological dorsal subluxation may be kinematically coupled, being provoked in some thumb positions more than others.

Patients were successfully grouped into stable or advanced OA by OP volume, allowing group differences in subluxation values to be analysed. In a large longitudinal dataset of patients with suspected disease state heterogeneity, having a robust and objective metric for group differentiation is incredibly valuable. This metric can be improved via sensitivity analysis of  $\alpha$  and  $\beta$  threshold modifications on grouping success statistics.

### Significance

The ability to differentiate stable patients from within a progressive disease cohort holds promise for the development of predictive tools of thumb CMC OA disease progression.

## Introduction

The accuracy of cartilage material models is determined by realistic material properties of articular cartilage. However, material properties in conventional confined or unconfined compression tests of a cartilage plug have been shown to be inaccurate in describing *in vivo* cartilage deformations. In this study, we aimed to estimate articular cartilage material properties in porcine hips by comparing cartilage deformation patterns in finite element (FE) analysis with the deformation patterns from CT (computerized tomography) images.

## Methods

### Loading experiments

Four cadaveric porcine hips were tested. We developed a custom plastic axial loading device. A joint sample was potted in the normal standing position of porcine hips. The direction of joint resultant forces was aligned with the loading axis of the compression device. The joint sample was completely submerged in a PBS solution to avoid dehydration of cartilage tissue. Positions of femoral and acetabular bones were recorded by acquiring CT images (matrix: 512 × 512, FOV: 150 mm, slice thickness: 1 mm) of a joint sample in every 3 min while a 650 N of compressive loading was continuously applied for 15 min.

**Figure 1:** (a) boundary & loading conditions of compression test (b) deformation of compression test (c) FE results with measured material properties (d) FE results with optimized material properties

### Finite element modelling with image-based optimization

Cartilage and bone models in femoral and acetabular compartments of the joint sample were created from CT images. An isotropic biphasic poroelastic material model with strain-dependent permeability was used for articular cartilage while the bones are completely rigid. We used C3D8P elements and the femoral bone was subjected to a distributed axial load and the upper surface of acetabular bone was fully fixed (Figure 1.(a)). Fluid flow across an interface was not conceded. We simulated the loading experiment in FE analysis and tried to find optimum material properties (Young's modulus, Poisson's ratio, intrinsic permeability, and permeability constant) to match the cartilage

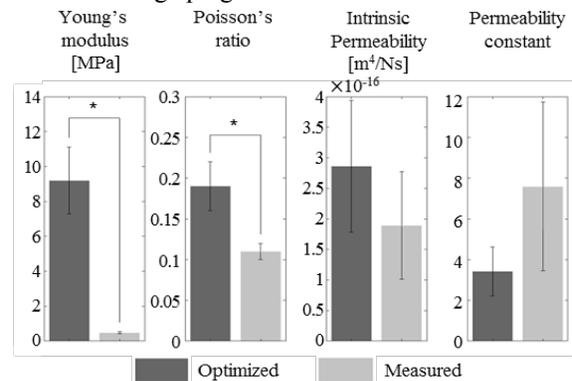

deformation patterns in the FE simulation with the cartilage surface profile in CT images (Figure 1.(b)(c)(d)). This optimization was done by non-linear simulated annealing(SA) algorithm.

### Unconfined compression tests of cartilage plugs

We collected multiple cartilage plugs from the joint samples after the loading experiments. Conventional unconfined compression tests were used to measure the material properties of cartilage plugs, which were finally compared with the material property values from image-based optimization process.

## Results and Discussion

Articular cartilage material properties for the poroelastic material model in the image-based optimization and unconfined compression tests are shown in Figure 2. image-based optimization estimated significantly greater Young's modulus ( $P < 0.05$ , student t-test) and Poisson's ratio ( $P < 0.05$ ) than the values in unconfined compression tests. However, we did not find differences in intrinsic permeability and permeability constant valued between both measurements. Fluid flow in *in vivo* articular cartilage is limited by the opposing joint structures and adjacent cartilage tissues. Thus, cartilage deformations in *in vivo* joints would be significantly reduced than the deformations measured in cartilage plug tests.

**Figure 2:** Results for the material properties

### Significance

Our results showed that articular cartilage material models with material properties from conventional plug tests may result in greater cartilage deformations than the deformation in *in vivo* articular cartilages. Our image-based optimization technique would be useful to produce accurate articular cartilage material models which describe realistic deformational behaviours in various *in vivo* joints.

## Introduction

Osteophyte formation is a critical part of the degeneration of a joint with osteoarthritis (OA). While often qualitatively described, few studies have succeeded in quantifying osteophyte growth over time. A detailed understanding of osteophyte formation is limited in part by the ability to quantify bone pathology. Osteophytes can be quantified relative to pre-osteoarthritic bone, or to the contralateral bone if it is healthy; however, in many cases neither are available as references.

We present a method for computing three-dimensional osteophyte models with a library of healthy control bones with a dissimilarity-excluding Procrustes registration technique (DEP).<sup>1</sup>

We applied DEP to a computed-tomography (CT) image dataset from a longitudinal, observational study of thumb carpometacarpal (CMC) OA. Our aim was to describe osteophyte growth by quantifying location-specific changes in peri-articular bone volume on the first metacarpal (MC1) and trapezium (TPM) over a three-year period in men and women with early OA.<sup>2</sup>

## Methods

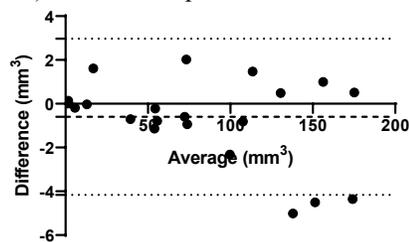

Our analysis was performed using an existing dataset containing the computed tomography scans of 90 patients with early thumb CMC OA.<sup>2</sup> A corresponding dataset of 46 healthy subjects formed the reference library from which best-fit bones were calculated.<sup>1</sup> Our method best-fit a healthy bone to an OA subject's bone using a dissimilarity-excluding Procrustes registration technique (DEP) that minimized the influence of dissimilar features (i.e., osteophytes).<sup>1</sup> Osteophyte models were then computed via Boolean subtraction of the reference bone models from the OA bone models.

DEP reference bones conformed significantly better to the OA bones ( $p < 0.0001$ ) than finite difference iterative closest point registration (RMS distances  $0.33\text{mm} \pm 0.05\text{mm}$  and  $0.41\text{mm} \pm 0.16\text{mm}$ , respectively). The effect of library size on dissimilarity measure was investigated by leave-k-out cross-validation randomly reducing k from 46 to 1. A library of  $n \geq 31$  resulted in less than 10% difference from the theoretical minimum value. To quantify the accuracy and the limitations of the method, a series of artificial osteophytes were generated by extruding the surfaces of healthy control trapezia at different locations around the CMC articular facet and by different heights. Bland-Altman plots were used to evaluate the agreement between the ground truth and computed osteophyte volumes (Figure 1).

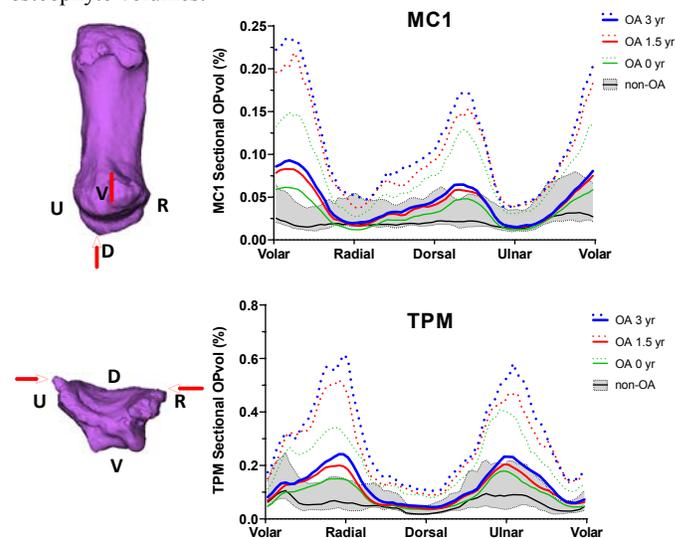

The DEP method was applied to study osteophyte formation and progression in 90 patients with early thumb CMC OA (pain, with Eaton 0/1 radiographic changes).<sup>2</sup> All study participants were recruited after IRB approval. Patients with early thumb OA were assessed at enrolment (year 0), 1.5, and 3 years with CT imaging. Osteophyte volume and location on the MC1 and TPM were computed for each patient at each follow-up time point.

Mixed models were used to evaluate differences in osteophyte volume by time and sex. Curves of normalized osteophyte volume (as a percent of total bone volume) were plotted as a function of location about the joint circumference and

reported with descriptive statistics (median, 25th percentile, and 75th percentile) at each time point.

**Figure 1:** Bland-Altman analysis of the DEP method for computing osteophyte volumes.

**Figure 2:** Osteophyte formation occurred at specific non-opposing locations (red arrows) on the MC1 and TPM.

## Results and Discussion

We developed an accurate method to compute osteophyte volume and location and to quantify osteophyte progression of patients with OA, whose volume increased significantly over the 3-year follow-up. After normalizing for size, we did not find a statistically significant difference between women and men. Notably, osteophyte formation started and grew fastest at specific locations on the MC1 and the TPM that did not oppose each other (Figure 2).

## Significance

Understanding the mechanism behind osteophyte formation that occurred at specific locations may shed insight into OA progression.

## The effect of toe-in and toe-out gait on hip moments in people with medial knee osteoarthritis

### Introduction

Individuals with knee osteoarthritis (OA) have a 25% lifetime risk of developing hip OA<sup>1</sup>, likely due to mechanical and biological effects of secondary risk factors. Compressive joint loading is related to OA progression<sup>2</sup>, but it cannot be directly measured in the native joint. External moments, such as the knee adduction moment, are used as surrogate measures of joint loading<sup>3</sup>. Gait modifications, such as modifying the foot progression angle, aim to decrease the knee adduction moment in order to slow the progression of OA in the medial compartment of the knee<sup>4</sup>. Similarly, the external hip moment can act as a surrogate measure for hip contact force<sup>5</sup>. People with knee OA who adopt an altered foot progression angle often benefit from a reduction in the knee adduction moment, but it is unknown whether this intervention increases external hip moments, thereby altering the loading environment at the hip and placing it at increased risk of OA initiation or progression<sup>6</sup>. The purpose of this study was to determine how altering foot progression angle affects hip moments in individuals with medial compartment knee OA.

### Methods

Fifty-four individuals with medial compartment knee OA (grade 1-3 on the Kellgren-Lawrence scale and pain of >3 on the 11-point numeric rating scale) walked on an instrumented treadmill. Participants performed a baseline walking trial followed by 2 foot progression angle modification trials where they were given biofeedback to either toe-in or toe-out by 10° relative to their baseline foot progression angle. The final 20 steps from each trial, from which the participant's foot angle was within 2.5° of their target angle, were analyzed.

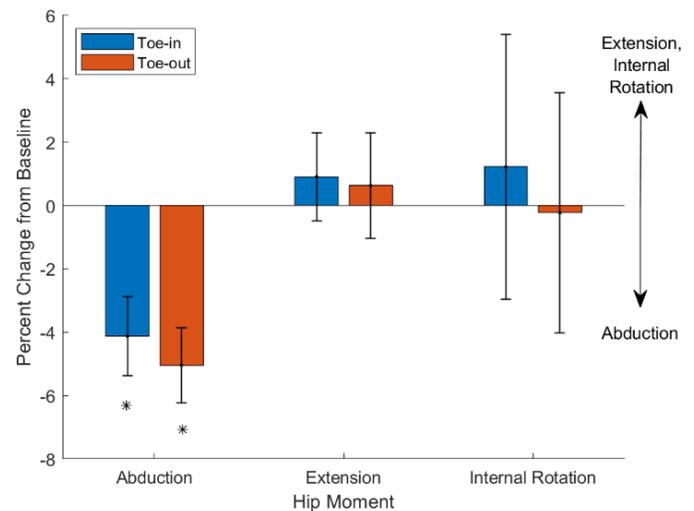

Hip joint moments from baseline, toe-in and toe-out gait were estimated using OpenSim 4.0. A generic musculoskeletal model<sup>7,8</sup> was scaled to incorporate subject-specific frontal-plane mechanical alignment from a leg-length radiograph and to match marker positions from a standing static calibration pose. We then performed inverse kinematics and inverse dynamics to estimate the hip abduction, extension, and internal rotation moments.

The average moment during 15-20% of stance phase, the typical time of first peak hip contact force<sup>5</sup>, was calculated for each step and averaged across all steps in each walking condition. The hip abduction, extension, and internal rotation moments during toe-in and toe-out gait were compared to baseline gait using a Wilcoxon signed-rank test ( $\alpha=0.05$ ) with a Bonferroni correction for multiple comparisons. Average values are reported as mean  $\pm$  standard error.

### Results and Discussion

The hip abduction moment was reduced by  $4.1 \pm 1.3\%$  ( $p=0.025$ ) during 10° toe-in gait compared to baseline (Figure 1). Similarly, the hip abduction moment was reduced by  $5.0 \pm 1.2\%$  ( $p=0.003$ ) during 10° toe-out gait. There were no significant changes in hip extension or internal rotation moments compared to baseline. These results demonstrate that foot progression angle

modifications that reduce the frontal-plane knee moment have similar effects on the frontal-plane hip moment but do not systematically change sagittal or transverse-plane hip moments.

**Figure 1:** Participants reduced their average hip abduction moment during 15-20% of stance by  $4.1 \pm 1.3\%$  ( $p = 0.025$ ) with toe-in gait and  $5.0 \pm 1.2\%$  ( $p = 0.003$ ) with toe-out gait compared to baseline.

### Significance

Modifying foot progression angle may slow the progression of medial compartment knee OA by decreasing the peak knee adduction moment. Importantly, this gait modification does not statistically increase external hip moments as compared to baseline gait in patients with knee OA. These results suggest that on average, 10° toe-in and 10° toe-out gait modifications may not increase loading in the hip joint. Future work could estimate the effects of foot progression angle modifications on hip contact force estimated from a validated musculoskeletal model.

## Total Ankle Replacement Wear Testing: ISO 22622 vs. Previous Wear Testing

Nathan Webb MS<sup>1</sup>, Jesse Fleming<sup>1</sup>, Emmanuel Lim BS<sup>1</sup>, Doug Linton<sup>1</sup>, Jon Moseley PhD<sup>1</sup>

<sup>1</sup>Wright Medical Technology, Memphis, TN

Email: \*Nathan.webb@wright.com

### Introduction

Early Total Hip Arthroplasties (THAs) suffered from buildup of ultra-high molecular weight polyethylene (UHMWPE) wear particles in the joint capsule, and caused reduced bone quality in the area around the implant, leading to loosening. Cross-linking the UHMWPE substantially reduced wear and showed a clinical reduction in the amount of aseptic loosening. Compared to THAs, Total Ankle Replacements (TARs) are geometrically more complex, and move in more degrees of freedom.

Joint simulator studies allow TARs to be evaluated for wear, and approximate the kinematics of a normal walking gait. A set of kinematics representing normal walking gait was adopted from the University of Leeds [1] by most device manufacturers in the United States for previous wear testing. In 2019, however, the International Organization for Standardization (ISO) published a standard for wear testing of TARs, ISO 22622 [2], which differed from the University of Leeds kinematics.

### Methods

Two groups of kinematics - the 2007 Leeds version ("Legacy"), and the new ISO 22622 Displacement-controlled version ("ISO") - were applied to a commercially available Total Ankle Replacement device (Inbone, Wright Medical).

Two types of ultra-high molecular weight polyethylene (UHMWPE) inserts were used: Conventional UHMWPE (CPE) and prototype UHMWPE cross-linked with 65 kGy gamma radiation (XLPE). Both kinematic profiles were used on each type of UHMWPE, for a total of four test groups. N=3 inserts for each group were tested in vitro (30% calf serum) in a six-station simulator (Shore Western, Monrovia, CA). The Legacy kinematics were run for 3 million cycles (Mc), while the ISO kinematics were run for 5 Mc.

For command of the wear simulator channels, as based on Legacy kinematics: Flexion and extension were set from -15° to 15°, axial load from -170N to -2800N, anterior to posterior translation from -1.5mm to 1.5mm, while medial to lateral and rotation in varus and valgus were allowed to float freely. The internal/external rotation was set from -2° to 8°, where the toes move towards the midline of the body.

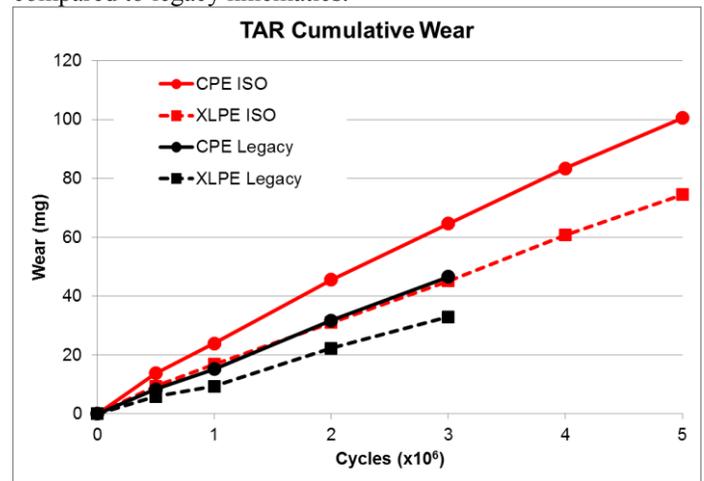

ISO Kinematics used the same endpoints (except for load) but with a different curve shape for each motion. Load in the ISO kinematics ranged from -194N to -2366N.

Lubricant was exchanged every 0.5 Mc; mass loss measurements, dimensional change (by CMM), and wear scar analyses (determination of the modes of wear) were performed every 1Mc.

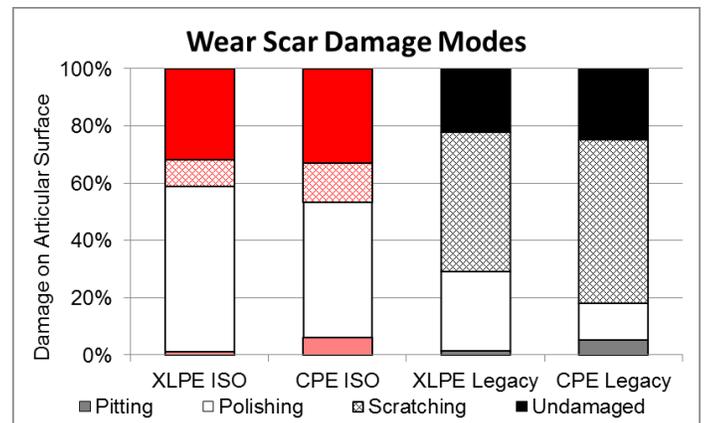

### Results and Discussion

Figure 1 shows a plot of the wear for both sets of kinematics on both materials. With both kinematic profiles, the XLPE material showed a lower wear rate than CPE. Surprisingly, the new ISO 22622 kinematics increased the wear rate by about 30% for both CPE and XLPE. These changes were statistically significant ( $p = 0.03$  XLPE,  $p = 0.01$  CPE, two-sample t-test).

Wear scar analysis (Figure 2) showed that the ISO standard had lower amounts of wear scarring on the surface of the UHMWPE than the legacy kinematics (32% XLPE, 33% CPE vs 22% XLPE, and 25% CPE, respectively). Although the mass lost during wear was higher for the ISO standard group, the wear was distributed over a smaller area of the articular surface. ISO kinematic wear samples also had significantly less amounts of scratching and greater amounts of polishing (burnishing) when compared to legacy kinematics.

**Figure 1:** Mass loss vs number of cycles for CPE and XLPE materials. Solid lines are conventional UHMWPE (CPE); dashed lines are XLPE.

**Figure 2:** Wear scar analysis graph for XLPE and CPE materials.

### Significance

As seen in the gravimetric test results, knowing the kinematics of the ankle joint between the tibia and talus is necessary to properly evaluate a TAR device for use in patients. Minor changes in the motions of the kinematic inputs of the wear test created large changes in the amount and mode of wear scarring observed on the articular surface.

# Changes in the Plantarflexion Moment Arm of the Achilles Tendon following Total Ankle Arthroplasty

Francesca E. Wade<sup>1</sup>, Gregory Lewis<sup>2</sup>, Andrea Horne<sup>2</sup>, Lauren Hickox<sup>1</sup>,  
Michael Aynardi<sup>2</sup>, Paul Juliano<sup>2</sup>, Umur Aydogan<sup>2</sup>, and Stephen Piazza<sup>1</sup>  
<sup>1</sup>Biomechanics Laboratory, The Pennsylvania State University, State College, PA  
<sup>2</sup>Penn State Milton S. Hershey Medical Center, Hershey, PA  
Email: few2@psu.edu

## Introduction

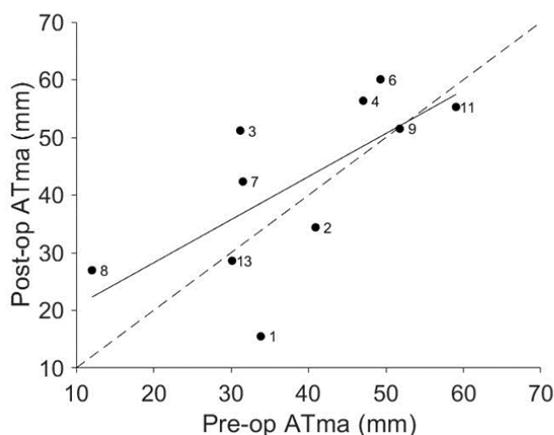

Following total ankle arthroplasty (TAA), patients have been found to exhibit normal gait kinematics, but deficits persist in gait kinetics [1]. Lack of plantarflexor moment and power in these patients may occur as a result of alterations to joint structure following from TAA. One key structural parameter potentially influenced by TAA is the plantarflexion moment arm of the Achilles tendon (ATma). ATma determines the leverage of the plantarflexor muscles that insert on the Achilles, and therefore is a critical determinant of push-off mechanics during gait [2]. No study to date has quantified how ATma are affected by TAA.

The purpose of this study was to quantify ATma one month prior to TAA and six months post-op in the same patients. We hypothesized that no differences in ATma would be evident between the two timepoints.

## Methods

Ten TAA patients (age:  $62.86 \pm 9.72$  y; height:  $1.72 \pm 0.08$  m; body mass:  $97.81 \pm 20.89$  kg; 4 female) underwent our data collection protocol approximately one month pre-op and six months post-op. All procedures were approved by the Penn State Hershey Medical Center Institutional Review Board. ATma was quantified while patients were seated with the knee extended, using a previously published method combining ultrasound imaging of the Achilles tendon with 3D motion tracking of the foot, shank, and ultrasound probe [3].

Sagittal-plane weightbearing radiographs were obtained pre- and post-operatively, and we determined the anterior-posterior distance from the center of the talar dome to the posterior margin of the calcaneus normalized to calcaneus length ( $d_R$ ). The absolute magnitude of differences in both ATma and  $d_R$  were tested to see if they differed from zero using a one-sample t-test. Pre- and post-TAA ATma and  $d_R$  were also compared using linear regression. Significance was set at the level of  $\alpha = 0.05$ .

**Figure 1:** Post-op and pre-op Achilles tendon moment arms were found to be moderately correlated ( $r^2 = 0.461$ ,  $p = 0.031$ ). Participant numbers are beside each marker, and the dashed line indicates  $y = x$ .

## Results and Discussion

The magnitudes of the differences in both ATma and  $d_R$  were both found to be significantly different from zero. For ATma the mean difference was  $9.6 \pm 6.8$  mm ( $p = 0.001$ ) and for  $d_R$  the mean difference was  $4.6 \pm 3.0\%$  of calcaneus length ( $p = 0.001$ ). We therefore rejected our hypothesis that post-op ATma would approximate pre-op values, although on average these values were similar. We found a moderate correlation between pre- and post-op ATma ( $r^2 = 0.46$ ,  $p = 0.03$ , Figure 1), and between pre- and post-TAA  $d_R$  ( $r^2 = 0.41$ ,  $p = 0.046$ ). At the individual level, however, some participants exhibited large and differently-signed changes in ATma. For example, the ATma of Participant 1 was reduced by 54.2% following TAA, whilst the ATma of Participants 3 & 8 were 64.1% and 124.0% greater, respectively, following surgery (Figure 1). When we examined the correlation between change in ATma and change in  $d_R$ , 49.7% of the change in ATma was explained by the corresponding change in  $d_R$  ( $p = 0.023$ ).

These results suggest that TAA does appear to alter ATma in individual patients, and that the magnitude of this change is related in substantial part to pre-post changes in the anterior-posterior position of the talar dome.

## Significance

One implication of our finding that ATma changes following TAA is that ATma some patients may experience benefits related to altered ATma in terms of locomotor function. Longer ATma may augment ankle plantarflexor strength and in this manner permit higher walking velocity. Future work should consider the relationship between the change in ATma following TAA and the corresponding change in gait speed and other measures of mobility. Additionally, a change in ATma may alter the function of the plantarflexor muscles, by changing where they operate on their force-length, and force-velocity curves [4] and may alter the capacity for plantarflexor work and elastic energy storage in the Achilles tendon. Future studies should also consider the extent to which muscles will adapt to altered ATma, especially at follow-up times greater than six months.

<sup>2</sup>Penn State Milton S. Hershey Medical Center, Hershey, PA

Email: few2@psu.edu

### Introduction

Outcomes following total ankle arthroplasty (TAA) are largely positive, with high levels of patient satisfaction, and a return to normal walking kinematics within two years [1]. However, performance on functional clinical assessments has received little attention in TAA patients, and residual pain after the surgery has been identified in up to 60% of cases [2]. While associations between implant kinematics and pain following TAA have been found during walking [3], to date there have been no studies of pain and function during more challenging locomotor tasks.

The purpose of this study was to determine how changes in function experienced by patients receiving TAA are related to pain. We hypothesized that following TAA, improvements in function would be correlated with reductions in pain.

### Methods

Complete data sets were obtained for 11 TAA patients (age:  $64.04 \pm 9.26$  y; height:  $1.71 \pm 0.07$  m, body mass:  $98.55 \pm 20.07$  kg; 3 implant designs). All procedures involving human subjects were approved by the Penn State Hershey Medical Center Institutional Review Board. All tasks were performed one month prior to and 6 months following TAA in a motion laboratory. Participants completed the RAND 36-Item Health Survey 1.0 (SF-36), whose global pain score was used in our analysis. Each participant performed three functional tasks: 1) single leg balance task on the involved limb (SLBT), where participants stood with eyes open to a ceiling time of 1 minute or the elevated foot touched the ground; 2) a Timed Up-and-Go test (TUG), where participants stood up from a standardized chair, walked 3m to a cone, pivoted and returned to a seated position; 3) a six-minute walk (6MW) where participants walked in a level hallway, turning every 30 m. From the distance walked, both velocity and a velocity normalized by height were computed. Linear regression analysis was performed to investigate how change in performance on these tasks was dependent on the patients' pre-to-post change in pain ( $\Delta$ pain) and their BMI.

### Results and Discussion

Performance on the SLBT improved significantly post-TAA (mean difference: 6.17 s,  $p = 0.048$ ), but no significant improvements were found for TUG (mean difference: 1.04 s,  $p = 0.270$ ), 6MW velocity (mean difference: 0.11 m/s,  $p = 0.072$ ), and normalized 6MW velocity (mean difference: 0.07 statures/s,  $p = 0.079$ ). Whilst the mean reduction in TUG time we observed

(1.04 s) was not significant, a mean reduction of 0.9 – 1.40 s has been identified as clinically important [4].

Linear regression did not predict change in function from  $\Delta$ pain alone, but when BMI and its interaction with  $\Delta$ pain was included, moderate to good fits were obtained (Table 1). Improvements in pain levels (when accounting for BMI) accounted for the majority of improvement in average walking velocity (Adj.  $R^2 = 0.79$ ,  $p = 0.003$ ), and might explain up to half of the variation in improvement of TUG, although this was not significant at the level of  $\alpha = 0.05$  (Adj.  $R^2 = 0.48$ ,  $p = 0.06$ ).

These results suggested that patients with larger BMI were unable to take advantage of reduced pain, whilst those participants with lower BMI were able to walk faster with reduced pain. The relationship might be weaker for TUG because it is task shorter in duration and thus less affected by pain. Neither  $\Delta$ pain, nor BMI, nor their interaction predicted performance on the SLBT; it is likely that other factors not considered here have more of an influence on balance tasks following TAA.

### Significance

To our knowledge, this is the first study relating changes in locomotor function to changes in pain following TAA. Contrary to our hypothesis, we found that changes in pain, as assessed by the SF-36, did not explain variation in observed improvements in function. However, including the interaction between pain and BMI in our regression models, nearly 80% of the changes in 6MW velocity were explained, and approximately 50% of TUG performance change was explained. Despite this, pain and BMI leave substantial variance unaccounted for and other factors, such as changes to the joint structure, might explain some of this unaccounted variance. In conducting investigations of function following TAA, the pain levels and BMI of participants should be taken into account.

## Introduction

Ankle osteoarthritis (A-OA) has been associated with severe pain and disability and the etiology is post-traumatic in most cases. A-OA has been shown to significantly impact gait mechanics [1, 2] and result in a side-to-side difference in gait mechanics [3]. Asymmetry severity in A-OA patients has not been reported previously. Previous studies have reported an asymmetry of <10% in various gait parameters in healthy adults [4]. The purpose of this study was to determine the degree of gait asymmetry present in A-OA patients and to determine if asymmetry in A-OA patients is significantly different than an age & gender-matched healthy participants.

## Methods

Thirty-seven unilateral A-OA [Age  $60.16 \pm 10.4$  years, BMI  $25.41 \pm 3.5$ , 9 males, 28 females] patients from a previously collected prospective database were age, gender and BMI matched to thirty-seven healthy participants [Age  $59.92 \pm 11.7$  years, BMI  $24.69 \pm 3.3$ , 9 males, 28 females]. Each participant completed between four and seven walking trials at a self-selected pace while walking speed and motion capture data were collected. Walking speed was measured using timing gates placed 5 meters apart. Motion capture data for A-OA gait mechanics was captured using an eight-camera motion capture system (Motion Analysis Corporation, Santa Rosa, CA; 120 Hz) while the healthy participant group data was captured with a ten-camera motion capture system (Qualisys, Sweden; 120 Hz). The same modified Helen-Hayes marker set was used during all of the testing. The ground reaction forces (GRF) were captured with four AMTI force plates (AMTI, Watertown, MA, 1200 Hz).

Average walking speed and five symmetry variables were compared between the A-OA group and the healthy controls to determine the effects of A-OA on gait symmetry. Gait symmetry was calculated using the Normalized Symmetry Index (NSI) [3]. NSI ranges between -100% to 100% where 0% indicates full symmetry [3]. A-OA and healthy participant data was processed as intact/OA side and dominant/non-dominant respectively. All NSI symmetry measures were calculated using a custom MATLAB script and included knee flexion, hip extension, ankle plantar flexion (PF), knee range of motion (ROM), hip ROM, weight acceptance (early-stage GRF), and propulsion (late-stage GRF).

To compare symmetry measures between the A-OA and healthy participants while accounting for the significant difference in walking speed ( $p=0.0001$ ), an analysis of covariance (ANCOVA) was performed. The statistical analysis was completed using SPSS with an alpha level of 0.05.

## Results and Discussion

Participants affected by A-OA had slower average walking speed ( $0.88 \pm 0.29$  m/s) compared to healthy control participants ( $1.32 \pm 0.20$  m/s) indicating gait is significantly affected by A-OA. Hip extension symmetry, weight acceptance symmetry and propulsion symmetry showed a difference between A-OA and healthy participants (Table 1). A reduction in GRF caused a

statistical difference in GRF symmetry consistent with previously published findings [4].

**Table 1:** NSI measures in A-OA and healthy participants. A-OA vs Healthy Older Adults

NSI	A-OA vs Healthy Older Adults				p-value
	A-OA Mean	A-OA SD	Healthy Mean	Healthy SD	
Knee Flexion (%)	2.29	10.88	1.51	11.34	0.678
Hip Extension (%)	15.94	33.14	-6.03	15.57	0.003 *
Ankle PF (%)	11.63	43.52	-10.69	24.25	0.064
Knee ROM (%)	-1.21	15.67	0.36	10.92	0.716
Hip ROM (%)	-5.45	15.03	0.85	5.27	0.107
Weight Acceptance (%)	-0.891	6.302	0.67	7.91	0.026 *
Propulsion (%)	-1.83	4.66	1.08	6.63	0.031 *

\* p-value < 0.05

These results demonstrate that the presence of A-OA affects gait mechanics as reported by Schmitt et al., as well as gait asymmetry when compared with healthy control participants. Similar to Schmitt et al., the A-OA participants used greater hip extension to compensate for limitations in ankle motion which most likely resulted in the increase in hip extension asymmetry. The large standard deviation (SD) in ankle motion present in the current study could impact study results and indicates the need for a larger sample to account for this increase in variability between participants. A limitation of this study is that data was collected at two different locations using two different motion capture systems. While this should not impact study outcomes, the differences in marker placement between testing sites could have impacted the study outcomes. Future studies should assess the restoration of symmetry following surgical intervention and develop targeted rehabilitation programs to improve symmetry.

## Significance

This study demonstrates that the presence of A-OA increased gait asymmetry compared to a healthy participants. Knowing that hip extension symmetry is effected by A-OA, targeted therapies can be developed to treat patients with A-OA and prevent further injury.

## Acknowledgments

A-OA data was initially collected at Duke University. All healthy control data as well as data processing and analysis were completed at Virginia Tech. We would like to acknowledge Laura Dickerson for her help with the collection of the healthy participant data.

## Introduction

Knee extensor (KE) function is important for locomotion, joint stability, and load attenuation during such tasks as walking and stair climbing [1]. KE weakness is commonly exhibited in individuals with knee osteoarthritis (KOA) [2] and may contribute to increased disability in this population. Pain, a primary symptom in KOA, has been suggested as a key contributor to KE dysfunction. However, evidence of the impact of pain and fluctuations in pain on KE function is limited. Previous research has shown that while habitual exercise has a beneficial effect on KOA pain [3], individual bouts of exercise can result in acute pain exacerbations [4]. A better understanding of the impact of exercise-induced pain on KE function is needed to determine the role of pain on mobility limitations in those with KOA. Therefore, the purpose of this study was to investigate the impact of exercise-induced pain on KE function in individuals with KOA. We hypothesized that the peak KE torque and rate of torque development (RTD) would decrease post exercise and be related to the change in pain.

## Methods

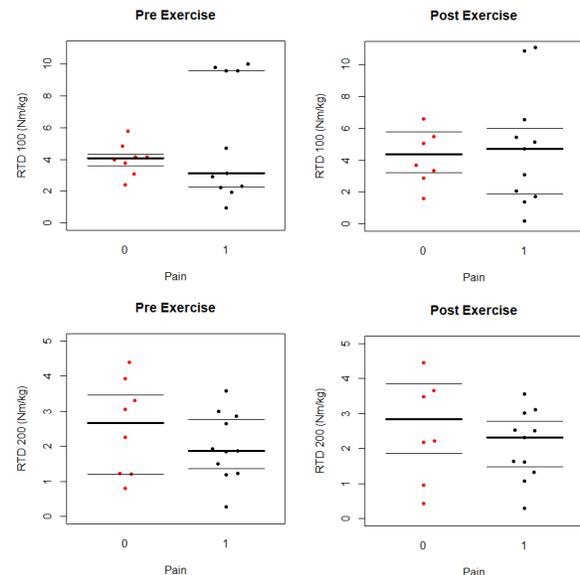

Eighteen adults with symptomatic KOA (Age: 65.9±5.1 years, BMI: 25.1±3.5 kg/m<sup>2</sup>, KOOS pain: 71.2±20.6) participated in this study after completing informed consent approved by the University's IRB. Participants completed three maximal isometric KE contractions on an isokinetic dynamometer (Biodex System 4 Pro, Shirley, NY) set at 60° of knee flexion before and after a 20min treadmill walk (20MTW) previously shown to increase pain in KOA [5]. Early (0-100 ms) and late (100-200 ms) rate of torque development (RTD100, RTD200), and peak torque were extracted and normalized to body mass (kg). Perceived pain was evaluated on an 11-point verbal numeric rating scale (vNRS) every two minutes throughout the 20MTW. The pain scores in the first and final 2 min of the 20MTW were used to evaluate change in pain in response to exercise.

Paired samples t-tests were used to compare torque, RTD and pain variables between pre and post 20MTW ( $\alpha = .05$ ). Participants were also subgrouped into those with and without exercise-induced pain ( $\geq 1$ pt on vNRS) to further probe the impact of pain on KE function changes using independent t-tests. Pearson's correlation was used to determine the relationship between baseline strength and the change in pain post exercise ( $\alpha = 0.05$ ).

## Results and Discussion

There was not a significant difference pre to post 20MTW in peak torque in all participants but there was significant decrease in both RTD100 ( $t(18) = -4.95$ ;  $p < .001$ ) and RTD200 ( $t(18) = -7.43$ ;  $p < .001$ ) post 20MTW. Similar to prior research [5], close to half ( $n=8$ ) of participants experienced a significant increase in pain ( $\Delta\text{pain} = 2.2 \pm 0.5$ ,  $p < .001$ ) while the remaining participants did not experience a pain change. Baseline peak torque was not correlated to the change in pain ( $p > 0.05$ ). The change in peak torque, RTD 100 and RTD 200 pre to post 20MTW did not differ between those with and without pain ( $p > .05$ ). These results

suggest that exercise to a greater degree than perceived pain may be a sufficient stimulus to induce changes in neural activation of the KE in individuals with KOA. The lower RTD100 in individuals with KOA post exercise may be indicative of lower motor unit recruitment and firing rate [6]. The lower RTD200 post exercise may suggest a change in recruitment pattern and greater recruitment of type I fibers in early contraction [7].

**Figure 1.** Pre to Post RTD 100 (Top row) and RTD 200 (bottom row). Dark horizontal lines indicate group mean, grey horizontal lines indicate 25<sup>th</sup> and 75<sup>th</sup> quartiles, (0=pain, 1=no pain).

## Significance

The study findings suggest that RTD rather than peak torque may be a useful screening tool to assess KE dysfunction in individuals with KOA. The RTD changes with exercise may be a result of changes in muscle recruitment pattern and thus may contribute to acute impairments in mobility in this population. The changes in RTD following exercise may also contribute to altered loading of the knee [8] and thus to clinical or structural progression of KOA. The consequences of changes in RTD for mobility and KOA progression should be investigated in future work.

## Introduction

The number of total knee replacement (TKR) is expected to increase 3.5 million by 2030 [2]. It is rather common to have a second joint replacement after the primary TKR procedure. Limited gait biomechanics research has shown that bilateral TKR patients showed reduced knee ROM and ground reaction force (GRF) [1, 3], and reduced knee extension moment (KEM) [4], compared to healthy controls. To our knowledge, no studies have examined differences of knee biomechanics in gait between the 1<sup>st</sup> and 2<sup>nd</sup> replaced TKR limbs in literature. It is unknown if patients with bilateral and unilateral TKRs would have similar knee kinematics and kinetics.

Therefore, the purpose of this study was to examine differences in knee joint biomechanics in both limbs of bilateral TKR patients and replaced and non-replaced limbs of unilateral TKR patients during level walking. It was hypothesized that bilateral TKR patients would have similar peak KEM, KAbM and ROM between the 1<sup>st</sup> and 2<sup>nd</sup> replaced limbs, and similar peak KEM and KAbM compared to unilateral TKR patients.

## Methods

Fifteen bilateral TKR patients (69.4±5.0 yrs, 1.7±0.10 m, 95.6±15.2 kg) and 15 unilateral TKR patients (68.7±6.2 yrs, 1.7±0.1 m, 87.7±15.7 kg) were recruited. Patients performed 3-5 trials of level walking at their self-selected speed. Kinematic (240 Hz, Vicon) and GRF (1200 Hz, AMTI) data were collected. A 2×2 (Group×Limb) ANOVA was performed to determine differences between groups and limbs. Post-hoc comparisons were performed on significant interactions with the alpha level adjusted using a stepwise Holm adjustment.

## Results and Discussion

The bilateral and unilateral TKR patients had similar walking speed: 1.1 vs 1.2 m/s, respectively. There were no differences in knee extension and abduction range of motion (ROM) between the patient groups and limbs. During the push-off, peak vertical GRF showed decreased vertical GRFs in bilateral TKR

patients ( $p = 0.016$ , Table 1). A group×limb interaction ( $p = 0.024$ ) was found for peak loading-response (LR) KEM. Post hoc comparisons showed the 1<sup>st</sup> replaced limb of bilateral patients had a significantly higher LR peak knee extension moment compared to 2<sup>nd</sup> replaced limb ( $p = 0.024$ ). The 1<sup>st</sup> replaced ( $p = 0.010$ ) and 2<sup>nd</sup> replaced ( $p < 0.001$ ) limbs of bilateral patients were significantly lower than non-replaced limbs of unilateral patients. Furthermore, KEM for the 2<sup>nd</sup> replaced limb was lower than unilateral replaced limbs ( $p = 0.001$ ). A group main effect difference was identified for the peak LR KAbM ( $p = 0.033$ ) showing that it was lower for the bilateral patients than the unilateral patients. Finally, no differences were found in the range of motion for knee extension and abduction between the 1<sup>st</sup> and 2<sup>nd</sup> replaced limbs and between bilateral and unilateral patients.

Our results supported our hypothesis between 1<sup>st</sup> and 2<sup>nd</sup> replaced limbs, but not the hypothesis between bilateral and unilateral TKR patients. These results suggest that the bilateral TKR patients still showed greater deficits in the peak KEM and KAbM during level walking even though they had similar knee kinematics and walking speed, and much longer recovery times (71.9 month) compared to the unilateral patients (27.9 month).

## Significance

These results indicate that bilateral TKR patients may have produced neuromuscular adaptations that are different compared to unilateral patients, showing similar knee kinematics but deficits in knee joint kinetics. In future studies of TKR gait, bilateral TKR patients should not be combined with unilateral TRK patients.

Email: [dyocum@albion.edu](mailto:dyocum@albion.edu)

## Introduction

The high number of current and increased future need for total knee replacements (TKR), as well as a high risk for contralateral TKR following initial TKR, is well established [1,2]. Many researchers have used stair negotiation to investigate the gait of TKR patients. Compared to healthy controls during stair negotiation, unilateral TKR patients have exhibited reduced peak knee internal extension moment (KEM), which may be a sign of a quadriceps avoidance gait [3].

One study found no biomechanical differences at the knee joint between unilateral and bilateral TKR [4]. One study examined bilateral TKR patients with different implants in each knee, and found no differences [5]. To our knowledge, no studies have examined biomechanical differences between 1<sup>st</sup> and 2<sup>nd</sup> replaced limbs of bilateral patients during stair negotiation.

This study compared the 1<sup>st</sup> and 2<sup>nd</sup> replaced limbs of bilateral patients, and replaced and non-replaced limbs of unilateral patients. We hypothesized that peak KEM and internal knee abduction moment (KAbM) would not be different between limbs of bilateral patients. We also hypothesized KEM and KAbM in bilateral patients would be different than the non-replaced limb of unilateral TKR patients.

## Methods

Fifteen bilateral TKR patients (69.40±5.04 years, 1.73±0.09 m, 95.56±15.24 kg) and fifteen unilateral TKR patients (64.93±5.11 years, 1.75±0.09 m, 89.18±17.55 kg) were recruited. Patients performed 3-5 trials of stair ascent and descent. A 2×2 (group x limb) ANOVA was performed to determine differences between limbs and groups.

## Results and Discussion

Bilateral patients had similar KEM and KAbM between 1<sup>st</sup> and 2<sup>nd</sup> replaced limbs in both ascent and descent, supporting our first hypothesis (Table 1). This shows that both replaced limbs have similar functional capacity and recovery following

TKR surgery. Average time since surgery for 1<sup>st</sup> replaced limbs was approximately 6.33 years, 5.46 years since 2<sup>nd</sup> replacement, an average of 3.2 years longer than unilateral patients. Given the longer time that bilateral patients have had replacements, any differences in acute adaptations between 1<sup>st</sup> and 2<sup>nd</sup> replaced limbs may no longer be present.

During ascent, peak LR KEM of 2<sup>nd</sup> replaced limbs of bilateral patients was lower than non-replaced limbs of unilateral patients (Table 1). KEM of replaced limbs of unilateral patients was lower than their non-replaced limbs, which was found previously [4].

During descent peak LR KEM moments were lower in 1<sup>st</sup> and 2<sup>nd</sup> replaced limbs of bilateral patients, compared to replaced and non-replaced limbs of unilateral patients. PO KEM was lower in both 1<sup>st</sup> and 2<sup>nd</sup> replaced limbs of bilateral patients, compared to non-replaced limbs of unilateral patients (Table 1). Significant group differences in KEM may indicate a quadriceps avoidance, seen previously in unilateral patients, which may be more prevalent in bilateral patients. In the frontal plane, no kinetic differences were found during either ascent or descent.

## Significance

Implications for this study are that bilateral patients may have functional adaptations that are different than those of unilateral patients. This can be seen in lower KEM in bilateral patients which may be due to decreased muscular strength, and kinesiophobia. Our bilateral patients reported an average 5.47±2.42 days per week of stair usage. Alterations in joint moments in the bilateral group does not inhibit them from using stairs.

### Introduction

Joint acoustic emission (AE) sensing has been used to non-invasively quantify knee joint health. This technique employs wide-band, low noise accelerometers placed on the skin above the joint to sense the surface vibrations generated by the dynamic interactions of the underlying anatomy during articulation [1,2]. In this work, we adapt our previously validated knee AE sensing system into one capable of performing measurements around another commonly injured and diseased joint - the wrist.

### Methods

For this study, 7 healthy subjects (three male/four female,  $24.9 \pm 3.5$  years,  $65.3 \pm 8.4$  kg, and  $168.0 \pm 10.1$  cm) with no history of major wrist injury or joint disease were recruited. They performed flexion-extension and rotation exercises while wrist AEs were recorded using highly sensitive uniaxial accelerometers (Series 3225f7, Dytran Instruments, Inc., Chatsworth, CA) placed on the skin at 8 locations around the wrist (Figure 1). An inertial measurement unit (BNO055, Adafruit Industries, New York, NY) placed within a custom grip synchronously recorded motion. The accelerometer signal was filtered using a Kaiser-window bandpass filter (150Hz – 20kHz). The signal was separated into individual cycles of motion (~2 sec) and windowed (400ms windows with 50% overlap). Nine previously validated signal features were extracted from each window, and the mean, median, and standard deviation were calculated for each cycle to best quantify the AEs from the wrist. Similarity and repeatability of the AE recordings in healthy subjects are indicative of high recording quality [3] and were assessed using the intraclass correlation coefficient (ICC) and the Jensen-Shannon (JS) divergence of the nine features. Finally, windows of characteristic joint AE clicks and motion artifact were extracted from each recording to calculate signal-to-artifact ratio (SAR) in order to quantify the strength of AE signal in each recording.

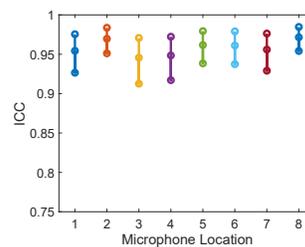

**Figure 1:** Palmar and Dorsal View of the wrist and marked locations where uniaxial accelerometers were placed to record the AEs excited during wrist flexion-extension and rotation exercises

### Results and Discussion

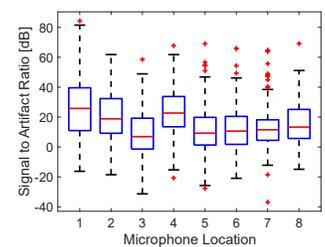

First, a qualitative analysis of the recordings was performed to ensure the system was properly recording AEs. This included visual inspection of the time-series data and listening to the recordings from both exercises at all 8 locations. This perfunctory analysis ensured us that key characteristics of AEs (e.g. signal clicks and grinding sounds) were successfully captured [1-3].

A more thorough quantitative analysis was then performed. Flexion-extension exercises demonstrated high levels of repeatability, with an average ICC of 0.967 (UB/LB at 0.975/0.975,  $p = 0.05$ ). Rotation exercises showed slightly higher repeatability, with average ICC of 0.972 (UB/LB at 0.979/0.964,  $p = 0.05$ ). Both exercises also demonstrated high correlation via JS divergence, indicating that these exercises consistently excite AEs from the wrist joint. With the exercises validated, the optimal location of placement needed to be analyzed.

The location analysis found the signal to be repeatable regardless of location, as repeatability scores via ICC (Figure 2) and JS divergence between each location ranged from an ICC score of 0.972 (UB/LB at 0.985/0.954,  $p = 0.05$ ) at location 8, to 0.946 (UB/LB at 0.971/0.913,  $p = 0.05$ ) at location 3. The SAR was calculated (Figure 3) to assess the impact that motion artifacts have on each location. The high SARs at locations 1, 2, and 4 demonstrate that the wrist joint AE signals are less affected by the motion artifacts than other locations, which indicates that accelerometer placement proximal to the end of the radius is better at minimizing motion artifacts within the signal than accelerometer placement distal to or at the end of the radius.

**Figure 2:** ICC values, upper bounds, and lower bounds with  $p$ -value = 0.05 for each of the 8 locations around the wrist

**Figure 3:** Box-and-Whisker plot of all Signal-to-Artifact Ratios for the 8 locations around the wrist

### Significance

High AE signal repeatability as determined with ICC and JS divergence as well as a high SAR demonstrates that it is possible to record high quality and repeatable AEs from the joint. This work supports our hypothesis that flexion-extension and rotation will reliably elicit AEs from the wrist. These AEs have previously been used to noninvasively grade the health of the knee in previous studies. 3 locations proximal to the end of the radius provide the highest repeatability scores in recording AEs while minimizing motion artifacts. This work lays a foundation for future work in using wrist AEs as a biomarker of musculoskeletal pathologies and injury.

## Introduction

Osteoarthritis (OA) is a common joint disease that can typically occur in the knee. At the end stage of OA, total knee arthroplasty (TKA) can deliver pain relief, restore mobility and function and provide quality long-term results. A recent study has shown that subjective measures of function based on patient reported outcome measures (PROMs), directly reflect objective biomechanical measures in TKA patients (1).

The purpose of this study is to investigate how patient perceived measures of pain and ability to perform standard activities are related to biomechanical measures. Previous studies have shown that PROMs could potentially be an indicator of biomechanical function (2). The connection between these measures could help improve the lack of standardization in measuring both patient-perceived function and gait biomechanics following surgery (1). We hypothesize that patient perceived function is not related to biomechanical function.

## Methods

The study included 39 subjects with confirmed OA (M/F: 21/16, age: 65±6 years, BMI: 31±4 kg/m<sup>2</sup>) who received TKA with posterior stabilized implants. The protocol for the study was approved by an institutional board and all subjects gave written informed consent. All 39 subjects completed PROMs and biomechanical testing before surgery and 19 patients returned to complete both measures six-months post-op.

The PROMs used for this study were pain with level walking (PW) and pain with standard activities of daily living (SA) (The 2011 Knee Society Scoring System). A lower score for PW and a higher score for SA indicates a better subjective measure. Range of motion (ROM) of the knee (flexion-extension) was measured manually using a goniometer. The static and dynamic balance (SB, DB) were tested using the Biodex Balance System. The Timed Up and Go test (TUG) measures the time the subject takes to rise from a chair, walk three meters, turn around, walk back to the chair, and sit down. The averages of three trials were used for SB, DB and TUG. Lastly, one trial of the 10 Time Sit-to-Stand test was performed. A lower value for TUG, S2S, SB and MB and a higher value for ROM indicate a better objective functional measure. Bivariate Pearson correlation tests and paired t-tests were performed using SPSS with an alpha set to 0.05.

**Table I:** Mean±SD for measures of subjective (PW, SA) and objective (TUG, S2S, ROM, SB and DB) function, \* p<0.05 pre-op vs. post-op.

Measures of Function	Pre-Op n=39	Pre-Op n=15	Post-Op n=15
Pain with Level Walking (PW)	5±3	6±3	2±3*
Knee Function with Standard Activities (SA)	13±4	12±5	23±6*
Timed Up and Go (TUG) (s)	11±3.6	11±3.1	11±7.3
10-time St to Stand (S2S) (s)	33.6±10.2	33.6±9.1	27.5±8*
Range of Motion (ROM) (deg)	118±14	122±10	128±7
Static Balance Test (SB)	1.6±1.5	1.9±1.2	1±0.8*
Dynamic Balance Test (DB)	1.6±0.9	1.8±0.8	1.3±0.7

## Results and Discussion

Both subjective measures (PW and SA) and two of the objective measures (S2S and SB) were significantly improved following TKA at 6-month post-op (Table I). There were no significant changes for TUG, ROM and DB following TKA at 6-month post-op. Pearson correlation coefficients between subjective and objective measures of function for pre-op, post-op and changes following TKA at 6-month post-op (post-pre) were listed in Table II. For pre-op, both PW and SA were significantly related to SB. SA was also significantly related to TUG. For post-op, there were no significant correlations between subjective and objective measures of function. For changes following TKA at 6-month post-op, both PW and SA were significantly related to ROM and PW was also significantly related to DB.

**Table II:** Pearson correlation values for measures of subjective (PW, SA) and objective function (TUG, S2S, ROM, SB, MB), \* p<0.05.

		TUG(s)	S2S(s)	ROM(deg)	SB	DB
Pre	PW	.285	-.005	-.037	.317*	.136
	SA	-.323*	-.045	.032	-.394*	-.299
Post	PW	.108	.263	-.111	.082	.186
	SA	-.217	-.119	-.369	-.096	-.169
Post-Pre	PW	-.047	-.127	-.609*	-.037	.466*
	SA	-.226	-.117	.613*	-.179	-.254

ROM improvement following TKA is probably a better objective measure than those measured at pre-op and post-op. Relative less change of DB following TKA may be linked to functional deficit when performing more demanding motor tasks. No significant correlations between subjective and objective measures at the 6-month post-op may be linked to small sample size. Small sample size may also contribute to no significant changes following TKA at 6-month post-op for some objective measures. More subjects will be tested in future to improve the sample size. Findings of this study indicate that both subjective and objective measures are important when assessing functional improvement of subjects who undergo TKA. Both pain level with walking and knee function with standard activities contributed to the results of biomechanical measures of function. For some objective measures, changes following TKA are better measures and they should be recorded at both pre-op and post-op.

## Significance

A patient's perceived level of pain and function performing standard activities may be used as an indicator for their functional deficits. Objective functional tests are important measures to discover functional deficits.

### Introduction

The position of the glenohumeral joint center (GHJC) relative to the scapula is directly linked to the scapulohumeral (SH) muscle moment arms and the kinetics and kinematics of the glenohumeral (GH) joint [1]. The GHJC is often represented by the humeral head center (HHC), considering the congruency of the humeral head and the glenoid cavity curvatures [2], and is used for pre-operative planning and shoulder arthroplasty to regulate the resting tension and the functional capacity of the SH muscles [3]. The GHJC and the HHC location may vary between people based on bony specific characteristics and require advanced imaging and/or mathematical estimates based on scapular/humeral anatomic landmarks. A number of techniques and/or modalities have been used with inherent limitations in terms of accuracy, invasiveness, practicality, and cost.

The aim of the present study was to compare the 3D location of the HHC and the glenoid fossa center (GLF) using CT to ultrasound imaging (US) combined with 3-D motion capture, as well as, the GHJC generated from predictive regression and a functional method.

### Methods

Ten (10) right-handed adult males (25.9 ±4.7 years) with no shoulder impairment/pathology participated in this project. The HHC, the GLF and the GHJC position were localized using computed tomography (CT), ultrasound (US) and motion capture (17 reflective marker-set including 3-marker humeral and acromial clusters), via a 10-camera motion capture system. Subjects were supine for the CT scan and seated upright for the US and motion capture sessions with the palm facing medially and thumb anterior. Eight (8) independent great arc US images were taken of the humeral head (2 horizontal & 2 vertical on the anterior and posterior-lateral surface aspects) using a 4-marker cluster equipped US linear probe. Twenty CT points on the humeral head and the glenoid fossa, and forty US humeral head points were least-squares sphere fitted to localize the center of the respective structures. Two additional widely used robust methods, predictive regression (REG) and functional (FNC) were also implemented in determining the GHJC [4,5]. The CT and the probe digitized coracoid process (CP), acromial angle (AA), trigonum spinae (TS), and inferior angle (IA) relative to the acromial cluster, were used to localize the HHC, GLF and

GHJC in the ISB scapula coordinate system [6]. One-way repeated measures ANOVA was used to determine between methods differences ( $\alpha < 0.05$ ).

### Results and Discussion

Mean and standard deviation values for three orthogonal offsets for all methods are shown on Table 1. There were significant differences between methods for the respective centers in the inferior and anterior direction relative to AA-TS-IA scapula reference frame. Specifically, the FNC-GHJC was the most inferior on the plane of the scapula from AA and it was significantly further from the REG-GHJC. The REG-GHJC was significantly more anterior in the normal to scapula plane direction, than all other methods, while the CT-HHC was the least anterior and significantly farther from the CT-GLF and US-HHC. The CT-GLF sphere fitting radius of the GLF was significantly longer (32.38 ±3.29) than the humeral head radii determined by sphere fitting (24.99 ±1.31 & 22.62 ±2.55) for the HHC obtained by CT and US, respectively [2]. While the values, represented in mm, are comparable to those reported in literature, normalized data will be presented to account for size differences between people [7,8].

### Significance

Findings support the utilization of US imaging to localize the HHC as a viable, cost-effective, non-invasive, subject-specific method. The impact of the differences between methods in the GHJC on 3D dynamic GH joint motion will be discussed.

### Introduction

Post-traumatic osteoarthritis (PTOA) is characterized by a chronic state of joint inflammation and cartilage degeneration and remains a significant clinical and socioeconomic challenge. Failure to traffic pro-inflammatory cytokines following traumatic joint injury can propagate chronic inflammation and cartilage catabolism. Joint clearance is regulated via multiple mechanisms, including through blood flow, microvascular permeability, and lymphatic drainage (1). Exercise, the only clinically proven treatment to provide PTOA symptomatic relief, is thought to facilitate joint clearance through increases in blood and lymph flow (2), though if and how this exercise-induced joint clearance occurs remains largely unknown. Understanding the effect of exercise on joint clearance kinetics may provide insight into targeted physical approaches that may be able to restore homeostasis following joint trauma. The goals of these studies were to determine the role of exercise in joint clearance and in treating a preclinical model of PTOA. We hypothesized that exercise will slow PTOA progression by decreasing cartilage degradation and improving joint function in part by expediting joint clearance via venous and lymphatic mechanisms.

### Methods

#### *Exercise as a treatment for PTOA*

Male Lewis rats received either a sham (medial collateral ligament transection only) or medial meniscus transection (MMT) surgery, with or without exercise (N=6/group). Exercised animals began treadmill walking (10 m/min) 21 d post-surgery, after mild PTOA has developed, and exercised 5 d/wk for up to 30 mins. Gait was measured at 3 and 6 weeks post-surgery. Cartilage and osteophyte morphology and cartilage attenuation (inversely proportional to sGAG content) in the medial tibia were quantified using EPIC- $\mu$ CT.

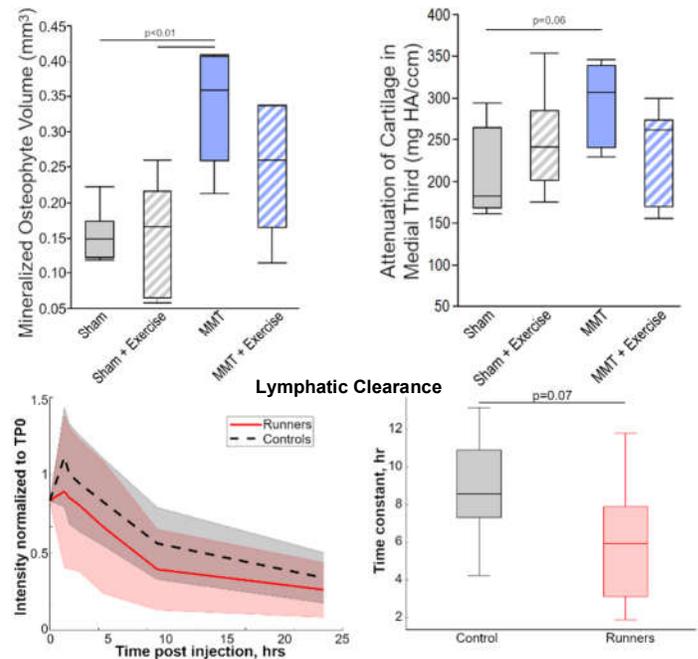

#### *Role of exercise in joint clearance rates*

Naïve male Lewis rats were acclimated to the treadmill prior to two experiments. On the morning of each experiment, both knees of eight rats received intra-articular injections of a carboxylate modified IRDye800CW and IRDye680RD with 40 kDa polyethylene glycol. The mechanisms of clearance are size-dependent, with the 40 kDa PEG-NIR and free dye clearing via lymphatic and venous systems, respectively (3). NIR images were collected immediately and out to 24 hours after injections. Four rats remained within their cages throughout both experiments. The other four rats underwent treadmill walking (10 m/min for 30 mins) either immediately before or after injection.

### Results and Discussion

#### *Exercise as a treatment for PTOA*

MMT caused a significant increase in cartilage volume ( $p=0.05$ ) and attenuation ( $p=0.01$ ) in the medial third of the medial tibia plateau at 6 weeks. MMT also caused significant increase in cartilage surface roughness ( $p=0.01$ ) and mineralized osteophyte volume ( $p<0.05$ ). Exercise did not alter any morphological outcomes in sham animals. Exercised MMT animals showed no significant differences in cartilage volume, attenuation, surface roughness, or mineralized osteophyte

**Figure 1:** Top: MMT caused an increase in osteophyte volume and attenuation (~loss of proteoglycan) that was not observed in exercised MMT animals. Bottom: NIR clearance and time constants for lymphatic clearance, which was expedited when running after injection.

volume compared to sham animals. Exercise also increased step frequency, decreased step length, and increased duty factor in all animals, regardless of surgery, suggesting a functional modification in these animals. These results suggest that the exercise treatment was largely successful in attenuating PTOA.

#### *Role of exercise in joint clearance rates*

Exercise immediately prior to NIR injection, which we hypothesized would prime the lymphatic and venous system, had no effect on clearance rates via either mechanism (not shown). Exercise immediately following injection, however, reduced lymphatic clearance time by ~50% ( $p=0.07$ ), with no observed differences in venous clearance (exercise:  $2.5 \pm 0.4$  hrs, none:  $2.6 \pm 0.7$  hrs,  $p=0.42$ ). Notably, both the collagenase sub-group of MMPs and fragmented aggrecan fall into the size range cleared by lymphatics. In the naïve animal, exercise alone can modulate the lymphatic clearance of the knee joint. While it is unknown if exercise can resolve osteoarthritic dysfunction in clearance, the observations here may provide one potential mechanism by which exercise can effectively modulate disease progression.

### Significance

Our results suggest that mild exercise can slow PTOA, potentially by enhancing lymphatic clearance of the knee.

# A Comparison of Modular Control of the Lower Limbs during Gait Following Total Knee Arthroplasty

Rebecca M. Weiss, Rebekah R. Koehn, Laura C. Schmitt, Ajit M.W. Chaudhari, and Robert A. Siston  
The Ohio State University, Columbus, OH, USA  
Email: Weiss.506@osu.edu

## Introduction

Total knee arthroplasty (TKA) is the end-stage treatment for knee osteoarthritis (OA), but one in five patients report poor post-operative function.<sup>1</sup> Recent literature has suggested that altered neuromuscular control patterns may provide insight into functional deficits following TKA.<sup>2</sup> Muscle activations have been found to be symmetric between limbs in healthy individuals<sup>3</sup> and abnormal muscle activation patterns have been observed bilaterally in subjects with knee OA<sup>4</sup> and following TKA.<sup>5</sup> Conversely, asymmetric muscle activations have been observed in subjects with hip OA,<sup>6</sup> suggesting that separate neural circuits might control the limbs independently.<sup>7</sup> However, it is difficult to gain insight into an overall strategy of both limbs with individual muscle activations alone. A recent study<sup>8</sup> found that differences in motor control in a TKA-involved limb, characterized by a higher number of motor modules<sup>9</sup> (or synergistic muscle activations), were related to better patient-reported outcomes. However, it remains unknown whether asymmetric motor control patterns exist bilaterally following TKA and whether the existence of asymmetric motor control is related to patient function.

Therefore, the purpose of this study was to determine if differences in bilateral motor control strategies exist in a cohort of patients 6-months after unilateral TKA and if a relationship exists between functional outcomes and modular control of the operated and non-operated limbs. We hypothesized that (i) asymmetric modular control would be present in a majority of individuals with TKA and (ii) modular asymmetry would be related to poor post-operative function.

## Methods

17 participants (M/F 7/10; 59.8±6.6 y; 97.2±20.5 kg; 1.7±0.1 m) provided written informed consent prior to receiving a unilateral posterior-stabilizing TKA. Subjects were tested 6-months post-TKA and completed multiple over-ground walking trials at a self-selected speed. We collected surface electromyography (EMG) data from eight lower extremity muscles, bilaterally: rectus femoris, vastus lateralis and medialis, semitendinosus, biceps femoris, medial and lateral (LG) gastrocnemii, and soleus. We processed the EMGs<sup>10</sup>, extracted modules<sup>11</sup>, and selected a representative gait cycle for each leg. Patient function was measured using the 6 Minute Walk (6MW) test<sup>12</sup> and was categorized as high- or low- functioning relative to the median.

We compared modular complexity (i.e. number of modules) between limbs. For subjects demonstrating 3 modules in both limbs, we compared muscle weights bilaterally using paired t-tests or Wilcoxon sign-rank tests. We performed a Chi-Square test to examine whether symmetric modular complexity was related to 6MW performance level.

## Results and Discussion

We found that 52.9% of subjects had symmetric modular complexity and 47.1% had asymmetric modular complexity. For the operated limb, 2 subjects demonstrated 2 modules, 13 subjects demonstrated 3 modules, and 2 subjects demonstrated 4

modules. For the non-operated limb, we found that 1 subject demonstrated 2 modules, 9 subjects demonstrated 3 modules, and 7 subjects demonstrated 4 modules. Of the 9 subjects with symmetric modular complexity, 1 demonstrated 2 modules 7 demonstrated 3 modules, and 1 demonstrated 4 modules. Of the 7 participants demonstrating 3 modules bilaterally, the only muscle with weighting differences which approached significance was the LG in the plantar flexor-dominated module ( $p = 0.076$ ) and the hamstrings-dominated module ( $p = 0.053$ ). Although there were no significant differences in the other muscle weights (all  $p \geq 0.214$ ), nearly half of the participants demonstrated asymmetric modular complexity, only previously seen in subjects following incomplete spinal cord injury.<sup>7</sup>

Our results did not support our hypothesis that asymmetric modular complexity would be associated with poor function ( $p = 0.457$ ) as measured by the 6MW (Table 1). Our results may be limited by the small sample size and selected measure of function. Future work will investigate modular symmetry before and 2-years following surgery and will examine additional functional measures.

**Table 1:** Number of participants demonstrating symmetric or asymmetric modular complexity with high or low 6MW performance.

Chi-square:  
 $p = 0.457$ .

	High 6MW	Low 6MW
Symmetric	4	5
Asymmetric	5	3

## Significance

Although our results suggest that the symmetry of modular complexity is not related to patient function 6-months after TKA, the asymmetry of modular complexity demonstrated by nearly half of the participants is a novel finding for a cohort following orthopaedic surgery. Such a finding suggests a need for further investigation into whether those results are present in a larger population over multiple gait cycles. Our work has the potential to inform rehabilitation clinicians on whether or not symmetric muscle coordination during gait is desirable in order to improve patient function after a TKA.

## Does osteoarthritis impact gait and balance abilities in people with Parkinson's Disease?

Abigail C. Schmitt, Justin N. Daniels, Sidney T. Baudendistel, Chris J. Hass  
Department of Applied Physiology and Kinesiology, University of Florida, Gainesville, FL, USA  
Email: [a.schmitt@ufl.edu](mailto:a.schmitt@ufl.edu)

### Introduction

Parkinson's disease (PD) is a degenerative neurological disorder that affects over ten million people worldwide<sup>1</sup>. The cardinal signs of PD are motor related, and many patients report gait dysfunction as the most debilitating symptom<sup>2</sup>. These gait impairments include decreased gait velocity, step length, and time spent in single support<sup>3</sup>. Impairments in gait and balance are largely attributed to faulty dopaminergic circuitry. As a result, current therapies often aim towards improving mobility impairments through these mechanisms. Perhaps surprisingly, these interventions remain relatively ineffective in ameliorating gait and balance dysfunction. Underlying comorbidities, that are not being addressed by dopamine targeting therapies, may contribute to the resiliency of gait dysfunction.

Osteoarthritis (OA) is one of the most prevalent comorbidities in individuals with PD, affecting approximately 50% of patients<sup>4</sup>. Knee OA, an inflammatory condition characterized by pain and joint deterioration, is associated with gait alternations such as decreased gait speed, step length, and time spent in single support. Further, individuals with OA exhibit mobility limitations associated with stiff joints, slowness, and inflexibility. Both OA severity and mobility impairments progress over time. These symptoms, limitations, and progression are similar to those reported in PD.

Unfortunately, the extant literature has failed to consider the compound influence that co-occurring OA may have on gait and balance performance in individuals with PD. Understanding this impact, of OA on PD symptomology, is critical to determine the extra burden that OA may contribute to mobility impairment in individuals with PD. Thus, we sought to understand to what extent the presence of OA impacts gait and balance performance in these patients.

### Methods

Gait and balance performance was evaluated in 30 individuals with idiopathic PD (23M, 7F, age:  $70 \pm 5$  yrs, Hoehn & Yahr score:  $2.0 \pm 0.5$ ) using a 12-camera 3D motion capture system (Vicon Motion Systems) and 3 embedded force plates (Bertec Corp). Participants received bilateral knee X-rays to determine the presence/severity of knee OA using the Kellgren-Lawrence (KL) classification system.

Overground gait was assessed while participants walked at their typical, comfortable pace and spatiotemporal metrics were analyzed. Quiet stance was measured during: 1) Rigid Surface Eyes Open (RSEO), 2) Rigid Surface Eyes Closed (RSEC), 3) Compliant Surface Eyes Open (CSEO), and 4) Compliant Surface Eyes Closed (CSEC). Ground reaction forces were collected for 30 sec and center of pressure based measures were used to quantify postural steadiness.

Two MANOVAs were used to separately compare the spatiotemporal gait data and the balance data between the PD and PDOA groups ( $\alpha=.05$ ). Cohen's *d* was used for effect size, with 0.2, 0.5, and 0.8 denoting small, medium, and large effect sizes respectively.

### Results and Discussion

Sixteen of the 30 participants showed radiographic evidence of OA (i.e., KL scores  $>1$ ) in at least one knee. We observed no significant differences between groups for gait measures ( $\Lambda=.802$ ,  $F=1.543$ ,  $p=.220$ ), but moderate to large effect sizes suggest meaningful differences exist in gait velocity (Cohen's  $d=.642$ ), step time (Cohen's  $d=.529$ ), and time spent in single support (Cohen's  $d=.844$ ). Specifically, those with PD and OA walk slower, with shorter step times and spend less time in single support on the affected limb (Fig. 1).

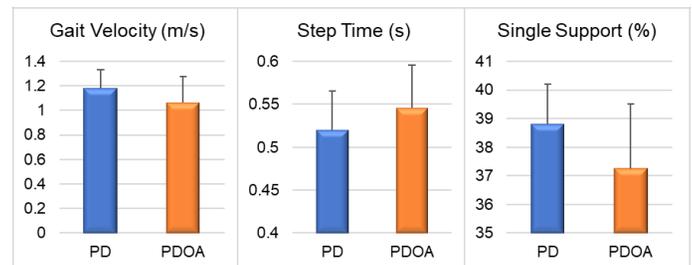

Figure 1: Spatiotemporal metrics between the PD and PDOA groups.

Although there were no significant differences between groups across balance conditions ( $\Lambda=.755$ ,  $F=1.425$ ,  $p=.254$ ), a significant vision\*surface interaction was observed as expected ( $\Lambda=.201$ ,  $F=17.467$ ,  $p<.001$ ). Regardless of group, all participants decreased postural control as balance conditions became more difficult (Fig. 2).

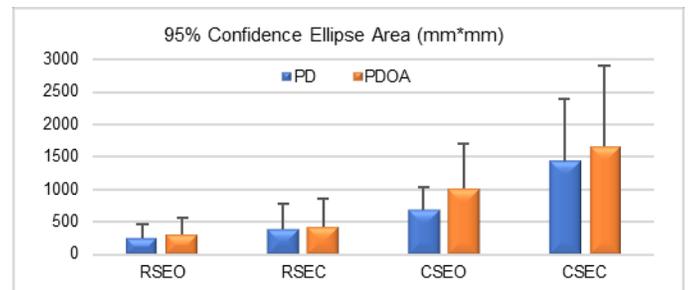

Figure 2: 95% Confidence Ellipse Area across quiet standing conditions.

### Significance

Individuals with PD and co-occurring OA appear to have similar balance performance as those with PD alone. The presence of OA is, however, associated with meaningful, but not significant, decrements in gait measures in those with PD.

## AP laxity after TKA does not predict long-term quadriceps strength

### Introduction

Studies have observed reduction in quadriceps activation and weakness in both the knee osteoarthritis (KOA) and post-total knee arthroplasty (TKA) populations as compared to healthy controls, and the mechanism and biomechanical mediators of this loss in function are areas of ongoing study. [1,2] In a set of patients with KOA awaiting TKA, we have shown that perceived instability is predicted by strength, but not varus-valgus laxity of the diseased knee measured intraoperatively [4], supporting previous work [5]. We have also shown that varus-valgus laxity is associated with weaker knee extension strength [6]. Two years post-TKA, these same patients' knee extension strength and stair climbing time both improve [3]. However, the relationship between anterior-posterior (AP) laxity and knee extension strength in either the KOA population or post-TKA remains unknown and has not been studied. Understanding this relationship could provide guidance on both surgical technique, i.e. whether a specific amount of AP laxity should be targeted, and on post-operative rehabilitation.

Therefore, in this study, our purpose was to test the hypothesis that intraoperatively measured knee AP laxity would be negatively associated with normalized quadriceps strength after two years.

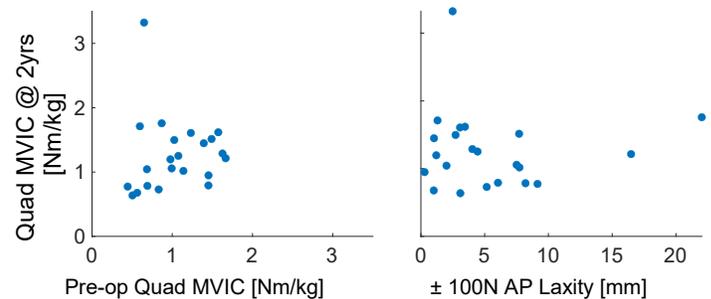

### Methods

Twenty-one IRB-consented patients (8 male, age  $62.6 \pm 8.5$  years) diagnosed with predominantly medial compartment osteoarthritis and varus knee deformity participated. Potential participants were excluded for revision TKA, BMI > 45, or for requiring an assistive device for ambulation. One patient with bilateral involvement had each knee assessed separately, for a total of 22 knees.

Intraoperatively, a custom navigation system was used by the orthopaedic surgeon to track femoral translation during passive flexion after cruciate ligament excision and implantation of posteriorly-stabilized components (LPS Flex, Zimmer Biomet) [7]. Using the device's optical tracking markers and load cells, AP knee laxity data were collected after cementing in the prosthesis. With the knee straightened, anterior-posterior laxity was collected at  $\pm 100\text{N}$ .

Within 30 days prior to their TKA ( $21.9 \pm 24.8$  days), subjects underwent evaluation of their involved limb quadriceps strength using a stationary dynamometer (Biodex, Shirley, USA). Subjects' maximum voluntary isometric contractions (MVIC) were recorded with the patient seated, their knees flexed at 60 degrees over 5 seconds with verbal encouragement throughout the task, then normalized by mass. The subjects returned 24 months post-op ( $787.4 \pm 59.6$  days) for the same quadriceps strength evaluation.

Forward stepwise regression was used to determine significant predictors of normalized 24-month post-operative quadriceps MVIC, considering normalized pre-operative quadriceps MVIC and  $\pm 100\text{N}$  AP knee laxity measured intraoperatively.

**Figure 1:** Subjects' pre-operative quadriceps MVIC and  $\pm 100\text{N}$  AP knee laxity plotted against two-year quadriceps MVIC.

### Results and Discussion

Forward stepwise regression analysis selected neither pre-operative quadriceps normalized MVIC, nor  $\pm 100\text{N}$  AP knee laxity as significant predictors of 24-month post-operative quadriceps normalized MVIC ( $p = .817, .987$ , respectively).

This result differs from the ACL-deficient knee, where AP knee laxity has previously been implicated in quadriceps strength loss [8]. That relationship does not appear to exist in this population even though wide variation in AP laxity was observed (Figure 1). The data suggest the strength improvements observed in our previous study [3] are not driven by anterior-posterior laxity with the leg in extension. Potential limitations to this study include the lack of standardized rehabilitation prescribed to the subjects, the difference between knee flexion angles at which AP laxity and knee extension torque were measured, and small sample size. Further study will examine other aspects of intraoperative knee kinematics and their potential role in knee extension strength, in the context of perceived instability.

### Significance

Though previous studies have shown long-term quadriceps strength increases among patients following TKA, AP laxity measured intraoperatively is not associated with quadriceps torque after two years.

## Introduction

The Sit-to-Stand (STS) transfer is a biomechanically challenging task commonly used to evaluate how individuals after total knee arthroplasty (TKA) rise from a chair<sup>1,2</sup>. Individuals after TKA perform this task more slowly, are more likely to fall, and demonstrate altered kinematics, kinetics, muscle strength and activations compared to healthy older adults<sup>3-6</sup>. Inter-limb differences (asymmetry) in STS kinematics, kinetics, and muscle activations between involved (INV) and uninvolved (UNINV) limbs in individuals with TKA have also been found<sup>1,3</sup>, and our previous simulation work indicates that asymmetries in muscles forces and contributions to the acceleration of the body's center of mass (COM) are observed in young healthy individuals, as well<sup>7</sup>. Thus, it is important to investigate both how these variables differ between limbs and how these differences relate to patient function in individuals after TKA. As a result, this study's purposes were to 1) compare muscle forces and contributions to acceleration between limbs in individuals after TKA during a STS transfer and 2) relate chair-rise time, as an indicator of function, to asymmetries in muscle forces and contributions to COM acceleration.

## Methods

Nine participants (7F/2M, 80.7±9 kg, 1.6±0.1 m, 60.5±8 y) completed a 5-times STS transfer six months after TKA (210±80 days). We collected motion capture, ground reaction, and electromyography data using methods previously described<sup>7</sup>.

We used OpenSim<sup>8</sup> to simulate one chair-rise using similar methods to our previous study<sup>7</sup>. We scaled an updated<sup>9</sup> Caruthers Full Body Model<sup>7</sup> with unconstrained knee rotations and strengthened hip and back muscles to match anthropometric data and determined kinematics and kinetics using an inverse dynamics approach. We used Static Optimization to estimate muscle forces by minimizing the sum of activations squared and ran an Induced Acceleration Analysis to calculate each muscle's contributions to horizontal and vertical COM accelerations<sup>7</sup>.

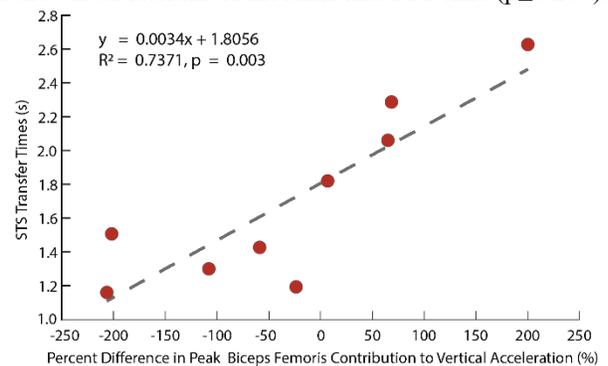

For ten muscles, we used separate three-way repeated measures ANOVAs and post hoc Tukey t-tests to examine differences in peak forces (normalized by body weight, xBW) and contributions to acceleration between INV and UNINV limbs across STS phases: flexion-momentum (P1), momentum transfer (P2), and extension (P3)<sup>7,10</sup>. We then used Pearson correlation or Spearman rank tests to determine associations between chair-rise time (STS time) and asymmetries in both peak forces and peak contributions to acceleration (as defined by the percent difference and the absolute value of the percent difference<sup>3</sup>) ( $\alpha=0.05$ ).

## Results and Discussion

Larger peak forces were observed in UNINV limbs than in INV limbs for the vastus lateralis (76±96% larger), vastus medialis (40±33% larger), semimembranosus (79±127% larger, P1 only), tibialis anterior (977±1750% larger, P2 only), and psoas (992±1830% larger, P3 only) ( $p\leq 0.048$ ). Similarly, the UNINV limb had larger peak negative contributions to horizontal acceleration (decelerating the body's COM) in the vastus medialis

(21±28% larger, P3 only) and tibialis anterior (318±1990% larger, P2 only) ( $p\leq 0.038$ ) and larger peak contributions to vertical acceleration in the vastus lateralis (90±106% larger) and medialis (57±50% larger) ( $p\leq 0.009$ ).

While some asymmetries were associated with slower STS times, others were associated with faster times. Slower STS times were associated with relatively greater tibialis anterior peak forces in the INV limb and greater relative tibialis anterior peak contributions to vertical acceleration ( $p\leq 0.025$ ) in the UNINV limb in P1. Conversely, faster STS times were associated with greater relative peak contributions to vertical acceleration from the biceps femoris (long head) in the INV limb in P3 (Fig. 1,  $p=0.003$ ), and greater symmetry in semimembranosus peak forces and contributions to horizontal acceleration ( $p\leq 0.045$ ) between limbs in P1. Even though the vasti had significant inter-limb asymmetries and are a common focus of TKA rehabilitation, there were no significant associations between asymmetries in either the vastus lateralis or medialis and STS time ( $p\geq 0.286$ ).

**Figure 1:** STS transfer time vs percent difference of biceps femoris (long head) peak contributions to vertical acceleration during P3. Negative values indicate that the INV limb was greater than the UNINV limb.

## Significance

Understanding asymmetries in muscle forces, contributions to acceleration, and their associations with chair rise times can help inform how physical therapists may tailor rehabilitation protocols in order to help individuals after TKA more efficiently and safely perform activities of daily living, such as rising from a chair.

## Introduction

Knee osteoarthritis (OA) is a leading cause of pain and disability associated with diminished quality of life and significant burden to healthcare systems. Laterally wedged footwear insoles have been explored as low cost, conservative interventions having the potential to provide pain relieve and slow disease progression. Clinical evidence for treatment effectiveness has been mixed, and this has motivated studies of biomechanical effects to elucidate treatment mechanisms with a view to optimizing effect. A previous report [1] explored the effect of lateral wedging on the frontal plane moment arm ( $MA_{GRF}$ ), also known as the lever arm, of the ground reaction force (GRF) vector about the knee joint center. The GRF vector usually passes medially to the knee center during the stance phase of walking gait; this is associated with a knee adduction moment which may overload the medial compartment. Lateral wedging lateralizes the center of pressure at ground contact and may thereby reduce this adduction moment. Here we report the effects of three levels of wedging on  $MA_{GRF}$  as measured in people with symptomatic knee OA.

## Methods

We report results from 11 participants (7M, 4F,  $59 \pm 9.5$  years). Research procedures were approved by the Kessler Foundation Institutional Review Board. Participants had symptomatic, predominantly medial knee osteoarthritis confirmed by physical examination and a standing frontal radiograph. Exclusions included advanced knee OA, more than minimal radiographic signs of lateral OA, and lower extremity joint replacement or recent surgery or viscosupplementation. One knee was assigned as the index knee based on clinical and radiological OA severity, and results are reported for this knee. All participants were tested while walking in standardized walking shoes (New Balance MW577) with lateral wedging of 3°, 6°, and 9°, as well as a neutral ('N') insole. Insoles were prepared by a professional pedorthist; the base insole was constructed of 5/16" thick neoprene, and lateral wedging of 3°, 6°, and 9° was added using cork layers applied to the full width tapering to zero thickness medially. Lengthwise, wedging was applied from the heel to the metatarsal heads.

Data were collected at two walking speeds; here we present data collected at a pace selected by each participant as typical for leisure walking. Testing order within walking speeds was randomized (N/3°/6°/9°). Standard motion analysis (Motion Analysis Corp., CA) and ground reaction force (GRF - Bertec Corp., OH) data collection and reduction methods were used. Walking trials were candidates for analysis if (1) speed was within  $\pm 5\%$  of the initially established speed; (2) kinetic data were recorded for the complete stance phase. The peak knee adduction moment at the instant of the first peak of this moment was calculated for all trials, and a standard method for outlier removal was used before averaging across trials to generate final measures. The  $MA_{GRF}$  measure was calculated at the same instant using custom developed code to (1) compute the vector from the knee joint center to the closest point on the ground reaction force

vector, and (2) compute the norm of the medial/laterally and superior/inferiorly directed components in the laboratory reference frame. Positive  $MA_{GRF}$  was computed when the GRF passed medial to the knee. Data were analyzed statistically using a repeated measures ANOVA with lateral wedge level as a repeated factor.

## Results and Discussion

While ANOVA testing yielded no significant linear effect of wedge angle on  $MA_{GRF}$  ( $p=0.220$ ), a significant quadratic effect ( $p=0.016$ ) was found. The quadratic effect represented

initial reduction in  $MA_{GRF}$ , followed by a weakening and reversal at higher wedging angles (Fig. 1). Paired t-tests showed  $MA_{GRF}$  to be significantly lower for the 3° condition than neutral, whereas the 6° wedge trended lower. Also, an ANOVA test across only the N/3°/6° conditions indicated a trend toward a linear main effect ( $p=0.077$ ), representing reducing  $MA_{GRF}$  in this range.

## Significance

The finding of reduced  $MA_{GRF}$  with lateral wedging in the range of 3° to 6° is consistent with prior reports on 5° lateral wedging [1]. These results suggest a limitation and potential reversal of effect of wedge level on reduction of  $MA_{GRF}$  as the level increases beyond this range. Overall, therefore, the results support a proposition that treatment efficacy across a group may be optimized in the 3° to 6° range. Ongoing work is examining the data for individual-specific responses that may contribute to variability of results in pooled analysis. It is important to recognize that individual patients may benefit most from specifically prescribed lateral wedging levels.

## Introduction

High knee adduction moment (KAM) and dynamic varus angle (VA) have been linked to both severity<sup>1</sup> and progression<sup>2,6</sup> of medial knee osteoarthritis (OA). Following total knee arthroplasty (TKA), increased KAM and VA may increase the risk of implant failure<sup>7,8</sup>. However, inconsistent data processing methodologies of previous research evaluating post-TKA changes in KAM and VA has contributed to the inconclusive and often conflicting results. The purpose of the current study was to determine how KAM and VA change over time by processing method. KAM and VA were compared between Nexus and Visual 3D (V3D). Within V3D, KAM was determined by joint coordinate system (JCS) or segment resolution coordinate systems: thigh (TRCS) and shank (SRCS).

## Methods

Nine participants (under 85 and able to walking without an aid) were diagnosed with knee OA and scheduled for unilateral or bilateral TKA by one orthopedic surgeon. Walking gait was assessed pre-TKA and post-TKA at six weeks, three months, six months, and one year. Kinematics (240Hz) of three walking trials were collected with 27 retroreflective markers placed in accordance with a Plug-in Gait model and time synchronized with kinetics (480Hz) collected from a force plate embedded flush with the floor. First peak KAM and VA were determined from Nexus and V3D. A Helen-Hayes model was created in V3D.

Repeated measures ANOVA was performed to compare main effects over time for each processing method. Pairwise comparisons between the factor level means were made using the Fisher's least significant different (LSD) method for multiple comparisons. Paired sample t-tests were used to determine mean differences between the processing methods at the same timepoints. Significance level was set at  $p < 0.05$ .

## Results and Discussion

The trend in KAM following TKA was significantly different between Nexus and varying coordinate systems within V3D (Table 1). The trend in VA was also significantly different between Nexus and V3D (Table 2). Of significant clinical importance, changes in KAM and VA appear to be dependent upon the software and coordinate system in which they are derived. Data processed in Nexus yields outcomes indicating an increase in KAM at one year post-TKA and a worsening of VA at six months and one year post-TKA, consistent with previous research<sup>9,10</sup>. Conversely, data processed with TRCS, SRCS, and JCS, suggest an improvement in KAM and VA post-TKA, consistent with previous research<sup>11,13</sup>. SRCS and JCS methods yielded similar results ( $p > 0.05$ ) at each timepoint.

## Significance

The current study demonstrates that KAM and VA values calculated on the same subjects produced significant processing related differences. These markers of TKA outcomes are clinically important; however, variability in outcomes may be due to processing methodology, versus actual changes. Further research is needed to clarify which method is preferred.

## Introduction

Knee adduction moment (KAM) is an indicator of the progression of medial knee osteoarthritis (OA). Higher occurrence of the medial compartment knee OA is attributed to excessive medial compartment compressive overloading, which is closely related to KAM. Therefore, in rehabilitation of patients with medial knee OA, reduction of KAM should be considered. Reduction in KAM could be achieved through a change in foot progression angle (FPA) [1]. However, this modification affects other knee moment components. In this pilot study, we investigate the effects of a change in FPA on total knee moment components while stepping, using a custom-designed elliptical trainer that produces less vertical loading on the knee in comparison to that of over ground walking. Also, the question as to whether the same patterns of KAM reduction repeats in different evaluation sessions days apart is evaluated.

## Methods

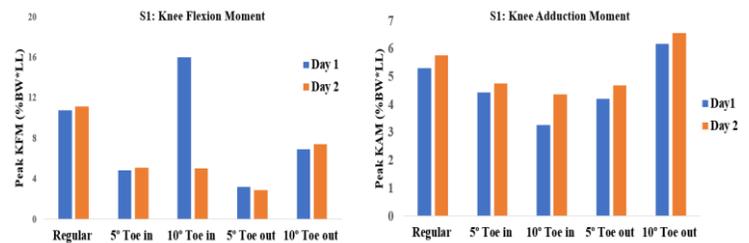

A customized elliptical trainer with a 6-DOF ankle goniometer was used for the knee moment estimation while stepping on the elliptical trainer. A 6-axis force/torque sensor was mounted underneath each footplate to measure forces and moments in each direction. Footplates of this customized elliptical trainer are modified and can rotate in transverse plane. Five healthy subjects (female; 28-42 years old) with no history of lower limb injury participated in this study. They were asked to perform stepping on the elliptical trainer with their self-selected constant speed in the following order of FPA: neutral position, 5° toe-in, 10° toe-in, 5° toe-out, and 10° toe-out. Each condition lasted 1.5 minutes. Also, the same evaluation was conducted on a second day to examine the repeatability of the FPA that induces minimum KAM in each subject.

## Results and Discussion

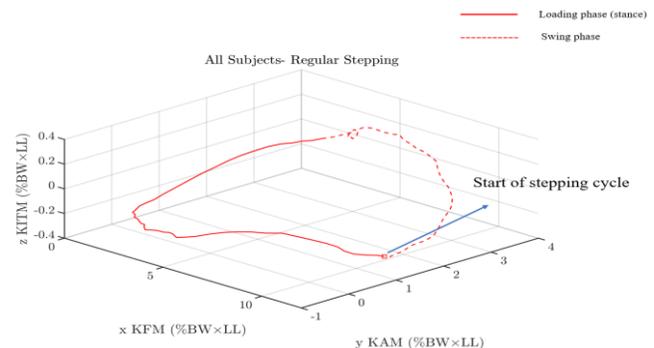

Results of this study showed a significant difference in KAM, knee flexion moment (KFM), and knee internal rotation moment (KITM) between different stepping conditions across subjects ( $P < 0.05$ ), which is in line with another study [1] (Table.1). Although, all subjects showed reduction in KAM and KFM during multiple stepping conditions, the FPA that demonstrated the greatest decrease in KAM was subject-specific. The only study that evaluated the effect of different degrees of toe-in and toe-out on reduction in KAM for healthy subjects, reported the greatest reduction did not happen in the same position for all subjects [1]. Furthermore, peak KAM and peak KFM values during stepping with different FPAs almost had consistent patterns between two days. Also, the FPA that induced the minimum KAM was different from the condition that induced minimum KFM in each subject (Fig.1). This observation can be explained by 3-D view of knee moment components (Fig.2). In other words, a decrease in one knee moment component is compensated by an increase in another knee moment component which induces a circular shape of 3-D knee moment components.

**Table 1:** Mean (SD) values of the knee moment components during stepping with different FPA. Knee moments normalized to the product of body weight (BW) and leg length (LL).

Knee moment component (%BW*LL)	Peak KFM	Peak KAM	Peak KITM	Peak KTM
Regular	13.43 (2.13)	5.17 (3.84)	0.50 (0.32)	8.76 (1.20)

**Figure 1:** Between-day comparison of the peak KAM and peak KFM during stepping with different FPA in a subject.

**Figure 2:** Tracking of three knee moment components among all subjects during regular stepping.

## Significance

Our findings suggest the applicability of this modified elliptical trainer in design of a subject-specific rehabilitation program for individuals with medial knee OA.

# Countermovement Jump Phase-Specific Differences Between Fast and Slow Jumpers in Division 1 Collegiate Male Basketball Players

John Krzyszkowski<sup>1</sup>, Luke D. Chowning<sup>1</sup>, John R. Harry<sup>1</sup>

<sup>1</sup>Department of Kinesiology & Sport Management, Texas Tech University, Lubbock, TX, USA

Email: [john.krzyszkowski@ttu.edu](mailto:john.krzyszkowski@ttu.edu)

## Introduction

Countermovement jump (CMJ) time (i.e., time to take off [TTT]) is a variable extracted from the CMJ force-time series to quantify the quickness of the CMJ (2, 3). In addition, TTT and has been used in conjunction with jump height to compute a reactive strength score, referred to as the modified reactive strength index (RSI<sub>mod</sub>) (2). It was suggested that the downward portion of the CMJ be deconstructed into phases that reflect the center of mass (COM) movement effects while also including the predominant muscle action across the involved muscles driving changes in COM movement where appropriate (1). However, phase-specific variables explaining TTT are not well understood in trained populations. This study determined whether quick jumpers, defined by TTT, display superior performance in CMJ phase-specific (a) temporal, (b) yank (i.e., rate of force development), and (c) force production variables.

## Methods:

Twenty-two collegiate male basketball players (height: 1.99±0.06m; mass: 93.8±7.5kg; age: 20±2 years) performed 3 CMJs while ground reaction force (GRF) data were obtained (1000 Hz) with two 3D force platforms (OPT464508, Advanced Mechanical Technology, Inc., Watertown, MA, USA). The raw GRF data was exported to Matlab (r2019a; The MathWorks, Inc., Natick, MA, USA) and then smoothed using a fourth-order, dual-pass, low pass Butterworth filter using a cutoff frequency of 50Hz with the order and cutoff before the two passes. Vertical center of mass (COM) acceleration was calculated using Newton's law of acceleration ( $a = \Sigma F/mass$ ), where mass was calculated by dividing body weight (i.e., the average vertical GRF during the first 500 data points of quiet standing before the start of the CMJ trial) by the absolute value of gravitational acceleration (9.81 m/s/s). The vertical COM velocity was obtained by calculating the time-integral of vertical COM acceleration using the trapezoidal rule. The CMJ was deconstructed into unloading, eccentric yielding, eccentric braking, and concentric phases (1). The start of the unloading phase was defined as the instant when the vertical GRF decreased below a threshold equal to 2.5% calculated bodyweight value. The end of the unloading phase and the start of the yielding phase was defined as the local minimum vertical GRF succeeding the start of the unloading phase. The end of the yielding phase and the beginning of the braking phase was identified as the instant of peak negative COM velocity. The end of the braking phase and the beginning of the concentric phase was identified as the instant when vertical COM velocity

was greater than 0 m/s after the start of braking phase. The end of the concentric phase was identified as the instant when vertical GRF decreased below 20N after the start of the concentric phase. Phase-specific RFD and force variables were normalized to body mass and calculated as the average RFD (i.e., force at the start and end of each phase divided by the duration of each phase) and discrete force magnitudes within the CMJ phases. The COM depth was calculated as the change in vertical position from the start of the unloading phase to the end of the braking phase. Independent samples t-tests ( $\alpha=0.05$ ) and Cohen's *d* effect sizes (large≥0.8) were used to compare performance between the fast and slow TTT groups.

## Results and Discussion

RSI<sub>mod</sub> ( $p<0.001$ ,  $d=1.34$ ), unloading time ( $p=0.008$ ,  $d=1.25$ ), unloading RFD ( $p<0.001$ ,  $d=2.32$ ), and unloading force ( $p<0.001$ ,  $d=1.66$ ), were significantly greater in the fast TTT group when compared to the slow TTT group. (Table 1). The COM depth was not significant ( $p=0.812$ ,  $d=0.54$ ) among groups. Since center of mass depth has been shown to influence TTT (4), the differences in TTT and phase durations cannot be attributed to individuals decreasing the depth of their countermovement, which in turn would shorten the duration of each phase and of the jump.

Table 1: Performance, temporal, force, and RFD parameters for the high and low TTT groups.						
Variable	Low TTT Group		High TTT Group		<i>p</i>	<i>d</i>
	Mean ± SD	95% CI	Mean ± SD	95% CI		
Jump Height (m)	0.46±0.07	[0.41,0.51]	0.45±0.04	[0.42,0.48]	0.752	0.16
RSI <sub>mod</sub> * (m/s)	0.66±0.13	[0.57,0.75]	0.52±0.07	[0.47,0.57]	0.005	1.34
COM Depth (m)	-0.26±0.06	[-0.30,-0.22]	-0.29±0.05	[-0.32,-0.26]	0.812	0.54
TTT* (s)	0.70±0.07	[0.65,0.75]	0.88±0.07	[0.83,0.93]	<0.001	2.57
Unload Time* (s)	0.16±0.07	[0.11,0.21]	0.29±0.13	[0.20,0.38]	0.008	1.25
Unload RFD* (N/kg/s)	-50.9±14.7	[-60.8,-41.0]	-21.7±10.1	[-28.5,-14.9]	<0.001	2.32
Unload GRF* (N/kg)	2.40±1.13	[1.64,3.16]	4.22±1.06	[3.51,4.93]	<0.001	1.66

**Note:** Data are presented as mean ± standard deviation, 95% confidence interval in brackets. Abbreviations: RSI<sub>mod</sub>, modified reactive strength index; TTT, time to takeoff; COM depth, center of mass depth; RFD, rate of force development; *d*, Cohen's *d* effect size.

## Significance

Quick jumpers appear to demonstrate superior (i.e., quicker and more forceful) unloading strategies that slower jumpers in a population of collegiate male basketball players.

## Introduction

One of the primary biomechanical variables analyzed in the sport of weightlifting is the trajectory of the bar, in part because it captures key aspects related to weightlifting technique and performance [1, 3]. Bivariate functional principal components analysis (*bfPCA*) is a statistical technique that has been used to investigate differences in the shapes of two simultaneously varying time series data [2, 4]. Application of *bfPCA* to barbell trajectory pattern would enable weightlifters, coaches, and sports biomechanists to quantify the shape of, or patterns in, the trajectory throughout the entire snatch and provide a way to analyse these patterns in relation other biomechanical variables related to either weightlifting performance, technique, etc. The purpose of this study was to use *bfPCA* to quantify the patterns of barbell trajectories during the snatch and to correlate these patterns with biomechanical variables related to weightlifting performance.

## Methods

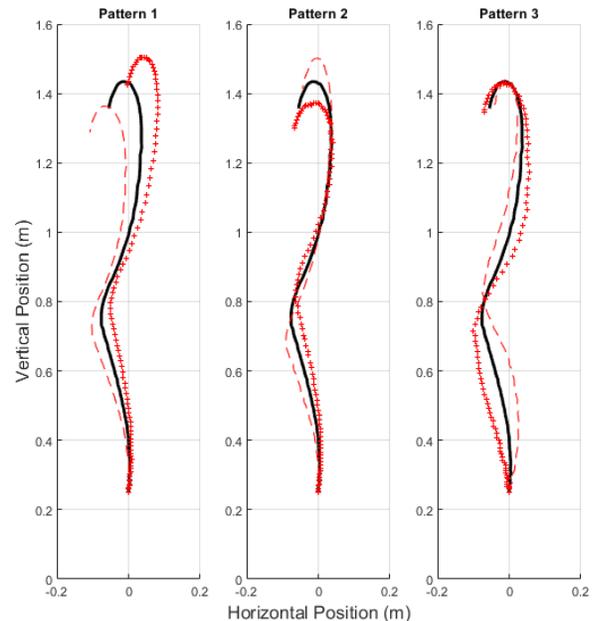

The participants of this study consisted of six competitive weightlifters (body-mass: 97.6 kg). Data were collected during the snatch session of a competition with a six-camera motion analysis system at 250 Hz. All three attempts (90-105 kg) from each of the six weightlifters were recorded. The horizontal and vertical position of markers attached to the bar were extracted and smoothed with a 4<sup>th</sup> order low-pass Butterworth filter at a cut-off frequency of 6 Hz, determined through residual analysis. Peak vertical bar velocities during the second pull were calculated and extracted. Time-normalised horizontal and vertical position data from each lift were centered, concatenated, and pooled into a single matrix and used as input for the *bfPCA* [2, 4]. Correlations between *bfPC* scores and body-mass normalised barbell mass and peak vertical barbell velocity were analysed with Spearman's rho correlations. Bootstrap resampling was performed 100 times to establish 90% confidence intervals for each correlation. The significance level was set to 0.05, and only correlation coefficients where the bootstrapped 90% confidence interval did not cross zero were interpreted as significant.

## Results and Discussion

The *bfPCA* extracted bar trajectory patterns related to forward/backward shifts (pattern 1), peak height (pattern 2), and crossing of the vertical reference line (i.e., "0" on the x-axis) (pattern 3). Non-parametric correlation analysis showed that bar mass (normalised to body-mass) of each lift was correlated with pattern 1 ( $\rho = -0.736$ ) and 3 ( $\rho = 0.751$ ), whereas peak vertical bar velocity was only correlated with pattern 1 ( $\rho = 0.580$ ).

Pattern 1 captured a general forward/backward shift in bar trajectory during the entire lift phase. The variation explained by this pattern captured bar path trajectories typically classified as A or B type trajectories (both exhibit initial backward motion, but only A type trajectories cross the vertical reference line) [4]. The results suggest that B type trajectories were associated with better

lift performance (i.e., greater bar mass), whereas A type trajectories were associated with greater peak bar velocities.

**Figure 1:** Variations in bar trajectories captured by the three *bfPC*s (i.e., patterns 1-3). Ensemble average bar trajectories are given by the black line, whereas the effect of positive and negative *bfPC* scores on bar trajectories are given by the + and - symbols, respectively.

Pattern 3 captured variation related to the crossing of the vertical reference line in bar trajectories during the first and second pull phases. More specifically, the variation explained by this pattern captured bar path trajectories typically classified as either an A or C type (where A type trajectories exhibit an initial backward motion and C type trajectories exhibit an initial forward motion that crosses the vertical reference line) [4]. The results suggest that in the current sample, better performance (i.e., lifted greater barbell mass) was associated with A type rather than C type trajectories.

## Significance

Better weightlifting performance in the snatch was associated with bar trajectories that exhibited an initial backward motion and did not cross the vertical reference line during the second pull. In addition, these trajectories were associated with smaller peak velocities, which may imply a more efficient technique.

# The Effects of Isokinetic Testing Speed on Ham:Quad Ratios and Asymmetry Indexes

Ben W. Meyer  
Shippensburg University, Shippensburg, PA, USA  
Email: [bwmeyer@ship.edu](mailto:bwmeyer@ship.edu)

## Introduction

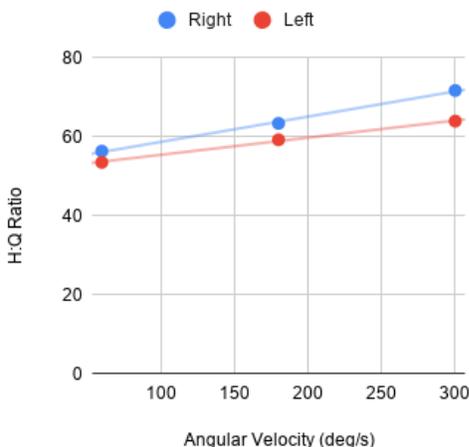

The purpose of this project was to examine the ratio between the hamstrings and quadriceps (H:Q ratio) and strength asymmetry index (AI) between right and left legs in isokinetic knee torque testing. Previous literature has examined the effects of training methods on the H:Q ratio and found an increase in the ratio as testing speed increased [1]. A study of intercollegiate athletes showed the same trend in a variety of sporting populations [2]. In male distance runners, the magnitude of the AI increased with increasing speed for flexion, but the magnitude of the AI decreased with increasing speed for extension [3]. It was hypothesized that in a sample of healthy college students, the H:Q ratio would increase and the magnitude of the AI would increase as isokinetic testing speed increased.

## Methods

Twelve males and seven females (age =  $21 \pm 1$  yrs; mass =  $83 \pm 18$  kg; height =  $1.74 \pm 0.11$  m) participated in the study. Each participant performed isokinetic knee extensions and flexions on both right and left legs using a Biodex Isokinetic Dynamometer. Three speeds were tested on the dynamometer: 60, 180, and 300 degrees per second. The dynamometer recorded peak extension and flexion torques for both right and left limbs at each speed. Hamstring:quadriceps ratio and strength asymmetry index were computed using standard procedures. A two-way 3 x 2 mixed ANOVA was used to check for the presence of differences. Statistical significance was set at  $\alpha = 0.05$ .

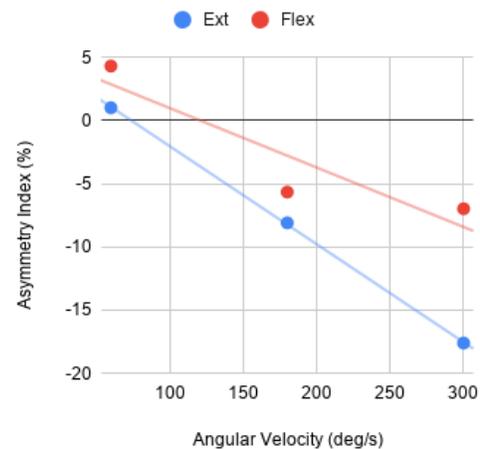

## Results and Discussion

Figure 1 shows the H:Q ratios for right and left legs across the tested velocities. No significant interaction was found for H:Q ratio for velocity  $F(2,48) = 0.10$ ,  $p > 0.05$ . The main effect of leg was not significant  $F(1,48) = 1.18$ , nor was the main effect of testing velocity  $F(2,48) = 1.79$ ,  $p > 0.05$ . Although no significant differences were found, a modest increase in the H:Q ratio was noted as testing velocity increased.

**Figure 1:** Hamstring:quadriceps ratios for right and left legs across angular velocities of 60, 180, and 300 degrees per second.

Figure 2 shows the AI values across the tested velocities. No significant interaction was found for H:Q ratio for velocity  $F(2,48) = 0.19$ ,  $p > 0.05$ . The main effect of leg was not significant  $F(1,48) = 0.82$  nor was the main effect of testing velocity  $F(2,48) = 1.27$ ,  $p > 0.05$ . Although no significant differences were found, the AI values were positive at 60 degrees per second but negative at larger angular velocities. In addition, as the testing velocity increased, the magnitude of the AI values also increased.

**Figure 2:** Strength asymmetry indexes for extension and flexion across angular velocities of 60, 180, and 300 degrees per second.

## Significance

The H:Q ratios and AI values found in this study fall within the ranges provided in previous literature. The H:Q ratio may be used as a baseline to assess imbalances and those who might be at risk for knee injury [1]. In addition, the changes in AI values across testing speeds, while not significant, do suggest that the symmetry between right and left legs varies with different testing speeds. The functional impact of AI values may vary by sport, and the effects of AI values in excess of 10% on performance need to be examined further [3]. Future research should address the changes in H:Q ratio and AI across testing speeds in larger samples and across broader varieties of participants.

# Shoulder, hip, and trunk sagittal plane kinematics during stand up paddle boarding

Corina Kaufman and Jamie E Hibbert

Department of Kinesiology, California State University San Marcos, San Marcos, CA, USA

Email: jhibbert@csusm.edu

## Introduction

Stand up paddle boarding (SUP) is a growing sport with an increasing number of recreational participants. SUP has been shown to be a good exercise modality to improve cardiovascular fitness [1,2]. Due to the relative simplicity of SUP most recreational participants are self-taught and are not aware of specific techniques that may be helpful for optimizing performance and avoiding injury. There are studies that have been published outlining common injuries sustained by SUP participants [3,4]. Currently, there is only a single study that has been published examining any biomechanical parameters of SUP. This study focused on differences in the SUP stroke between experienced and inexperienced SUP participants [5]. There is still a need to establish kinematic characteristics of SUP technique adopted by injury-free recreational participants.

The purpose of the current study was to analyse sagittal plane kinematics during both standing and kneeling postures commonly adopted by recreational SUP participants. It is also unknown whether there are differences in kinematics between sexes. We hypothesized that there would be greater sagittal plane joint excursion at the trunk and hip while standing, and greater sagittal plane joint excursion at the shoulder while kneeling. We also hypothesized that there would be greater sagittal plane joint excursion at the shoulder in male participants, and greater sagittal plane joint excursion at the trunk and hip in female participants.

## Methods

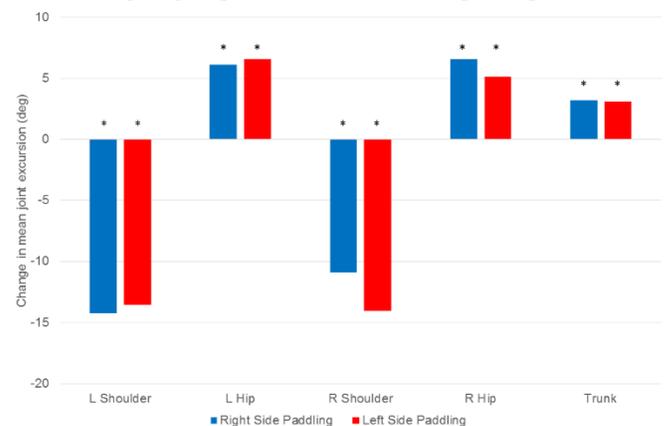

18 self-identified recreational stand up paddle boarders, 7 males and 11 females ( $22.6 \pm 2.15$  years), were recruited from the community. All study related procedures were approved by the CSUSM IRB. Informed consent was obtained prior to participation. Participants were fitted with a standard 32 marker set for 3D motion capture (Qualisys, Goenborg, Sweden). Participants performed six paddling trials in both kneeling and standing postures using a stand up paddle board ergometer (SUP ergometer, KayakPro, Miami, FL). Kinematic data were evaluated for differences in shoulder, hip, and trunk excursion in the sagittal plane. The data were also evaluated to determine any sex differences in shoulder, hip, and trunk sagittal plane kinematics. An a priori alpha level was set at  $\alpha=0.05$ . All statistical analyses were conducted using paired t-tests (Excel, Microsoft, Redmond, WA).

## Results and Discussion

There were significant positive differences in mean joint excursion for both left and right side paddling at the left hip ( $p=0.005$ ;  $p=0.007$ ), right hip ( $p=0.001$ ;  $p=0.002$ ), and trunk ( $p=0.008$ ;  $p=0.01$ ) (Figure 1). There were significant negative differences in mean joint excursion for both left and right side paddling at the left ( $p=0.0004$ ;  $p=0.001$ ) and right shoulders ( $p=0.0002$ ;  $p=0.0006$ ) (Figure 1).

There were no significant differences noted between sexes in mean joint excursion at the shoulders, hips, or trunk regardless of posture or paddling side.

These data support our hypothesis that sagittal plane joint excursion would be greater at the trunk and hip while standing and greater at the shoulder while kneeling. Our hypothesis that there would be significant differences in sagittal plane kinematics with sex, was not supported by these data. Data collection is ongoing to determine whether any sex-related difference emerge with more equal groups of male and female participants.

**Figure 1:** Mean differences in sagittal plane joint excursion between kneeling and standing postures. A negative value indicates greater excursion kneeling. A positive value indicates greater excursion standing. \* indicates significance at  $\alpha=0.05$ .

## Significance

The purpose of this study was to examine the sagittal plane kinematics of stand up paddle boarding in two commonly adopted postures; standing and kneeling. There has not been any previous reporting on kinematics for recreational stand up paddle boarders. These data collected from healthy, pain-free participants may be used in the future to examine differences between healthy and pathological participants to explain the common injuries noted in previous studies [3,4].

These data may also be helpful for developing coaching material for use by self-taught stand up paddle boarders.

Email: [\\*gcrowder@highpoint.edu](mailto:*gcrowder@highpoint.edu)

## Introduction

The analysis of kinetic data recorded via force platforms and their associated software is becoming increasingly common in the sport performance and injury literature, as portable systems allow for greater opportunity to screen athletes on a massive scale. However, understanding the validity of such systems is necessary prior to their widespread use. Therefore, the purpose of this study was to validate the use of a portable dual-force platform against the current gold standard. We hypothesized that the portable system would be a valid measurement tool.

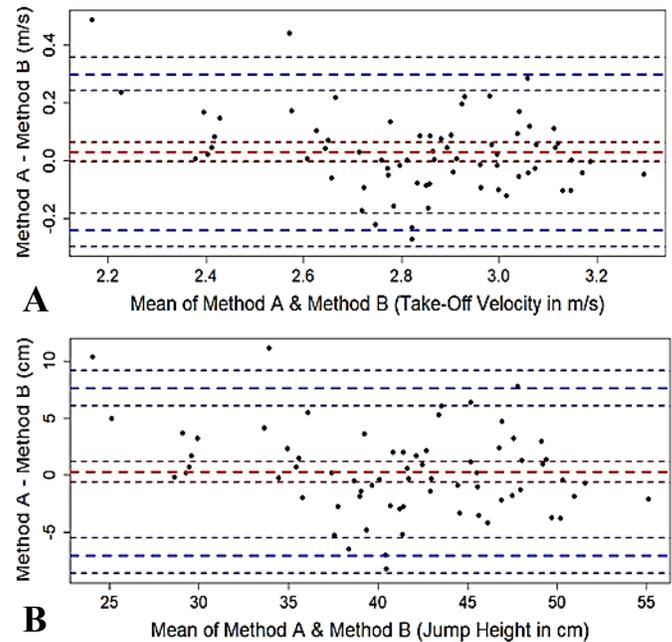

## Methods

As part of their pre-season screening, 69 NCAA Division-I athletes ( $19.5 \pm 1.3$  yr,  $1.8 \pm 0.1$  m,  $79.0 \pm 9.1$  kg) performed three maximal-effort countermovement jumps (CMJ) on two separate force-plate systems. System #1 (Method A; gold standard) consisted of two laboratory grade in-ground force plates (AMTI, Watertown, MA) sampling at 1200 Hz, whereas system #2 (Method B) consisted of a portable dual-force plate system (Hawkin Dynamics, ME) sampling at 1000 Hz. Both systems were integrated with their respective manufacturer-provided software for data collection and reduction. Athletes were allowed to swing their arms, and were instructed to jump with maximal effort. Three-trial averages were calculated for each athlete's velocity at takeoff and vertical jump height. Validity was assessed via Pearson's correlation coefficients between the two methods. Bland-Altman plots and 95% limits of agreement (LOA) analysis were then used to assess absolute measurement consistency between the two methods.<sup>1,2</sup>

## Results and Discussion

Pearson's correlation coefficients indicated strong positive associations between methods for both take-off velocity ( $r = 0.862$ ,  $r^2 = 0.743$ ;  $p < .001$ ) and jump height ( $r = 0.863$ ,  $r^2 = 0.745$ ;  $p < .001$ ). Bland-Altman plots displaying the mean difference between methods for take-off velocity and jump height are shown in Figure 1A and 1B. LOA analyses (absolute measurement error) revealed good agreement between methods with mean differences (Method A – Method B) of 0.03 m/s (95%LOA: 0.24, 0.30 m/s) and 0.26 cm (95%LOA: -7.10, 7.63 cm) for take-off velocity and jump height, respectively. In 95% of the cases, jump height recorded using the portable system (Method B) could be expected to range anywhere from 7.10 cm lower to 7.63 cm higher than that measured by the gold standard (Method A; Figure 1B). In support of our hypothesis, and in agreement with prior work<sup>3</sup>, these results indicate that the portable dual-force plate system examined is a valid method for evaluating CMJ performance. Figure 1A,B shows that mean differences are reduced as take-off velocities and jump heights increase, suggesting that the current findings may have been

influenced by within-subject factors such as individual effort or level of experience. Allowing athletes to swing their arms during CMJ trials may have also been a factor.

**Figure 1.** Bland-Altman plot displaying the mean difference and 95% limits of agreement for vertical velocity at takeoff [A] and maximal vertical jump height [B].

## Significance

Portable force plates allow for more cost-effective options to screen athletes outside of the laboratory. Although jump mats and other inexpensive pieces of equipment can also be used to assess vertical jump height, a portable dual-force system can provide researchers and practitioners with force-derived metrics in addition to information regarding asymmetrical loading, countermovement depth, rate of force development, etc.; and can thus serve a variety of applications. More on-site athlete screenings may help improve performance techniques and reduce injury risk.

# The effects of fatigue on knee mechanics during a landing and cutting task in healthy females: a statistical parametric mapping approach

Shelby A. Peel<sup>1</sup>, Jake A. Melaro<sup>1</sup>, Joshua T. Weinhandl<sup>1</sup>

<sup>1</sup>The University of Tennessee, Knoxville, Knoxville, TN, U.S.A.

Email: [speel@vols.utk.edu](mailto:speel@vols.utk.edu)

## Introduction

Muscular fatigue is a controversial lower extremity injury risk factor, in part due to its complexity. It is thought that when an individual becomes fatigued, the musculature's ability to absorb energy is reduced, leading to decreases in neuromuscular control and altered lower extremity mechanics [1,2]. Few studies have observed the effects of fatigue on lower extremity mechanics in healthy females, which as led to conflicting results. Because fatigue in athletics is unavoidable, a better understanding of its influence on lower extremity mechanics is warranted.

Therefore, the purpose of this study was to determine the effects of muscular fatigue on lower extremity kinematics and kinetics in healthy females using a laboratory-based fatigue protocol. We hypothesized that lower extremity kinematics and kinetics would be different pre- to post-fatigue.

## Methods

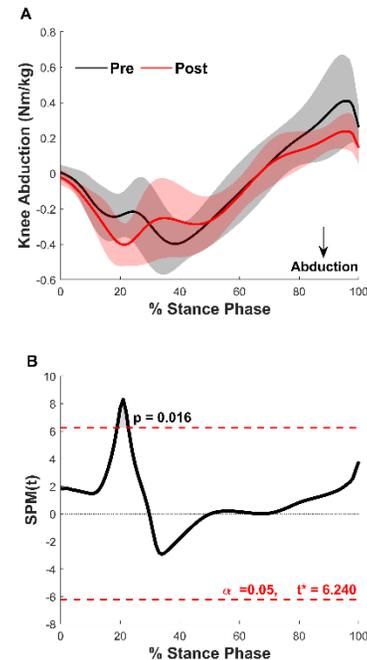

Six healthy, recreationally active females ( $23.0 \pm 2.7$  yrs,  $68.2 \pm 7.0$  kg;  $1.65 \pm 0.6$  m) volunteered to participate in this study. Participants first completed a 5-minute self-selected warm-up, followed by five box land-and-cut trials from a 30 cm box placed  $\frac{1}{2}$  their height from the force plates. The box land-and-cut task required participants to jump off the box with their left foot, land on the force plate with their right foot and make a  $45^\circ$  cut to the left. They then completed a laboratory-based fatigue protocol, before returning to the laboratory to perform five additional box land-and-cut trials. Briefly, the fatigue protocol consisted running to 4 different exercise stations and performing various types of body weight exercises. Participants were asked to complete as many rounds as possible, and the protocol stopped when participant maximal jump and reach height decreased 25% during two consecutive jumps.

A 12-camera motion capture system (200Hz, Vicon) and a force platform (2000Hz, AMTI) were used to collect marker coordinate and GRF data, respectively. Visual3D (C-Motion) was used to process and analyze all data. Marker coordinate and GRF data were filtered using fourth-order Butterworth low-pass filters with cut-off frequency of 12 Hz. 3D knee joint kinematics were calculated using a joint coordinate system approach. 3D internal knee joint moments were expressed in the joint coordinate system and normalized to body mass. Pre- and post-fatigue knee kinematics and kinetics were compared across the landing phase with one-dimensional statistical parametric mapping t-tests (SPM{t}; ( $\alpha=0.05$ ).

## Results and Discussion

Participants completed  $9 \pm 5$  rounds of the fatigue protocol (end heart rate:  $187.1 \pm 7.2$  bpm; end RPE:  $18.3 \pm 1.5$ ) with a decrease in jump height of approximately 14% from pre- to post-fatigue. SPM{t} showed that internal knee abduction moment post-fatigue was significantly greater (mean difference: 0.12 Nm/kg) from 19% to 23% of stance phase compared to pre-fatigue (Figure 1). No statistically significant

differences were found between knee flexion, abduction, and rotation angles as well as knee extension and rotation moments pre- and post-fatigue during stance phase of the anticipated box-land-and-cut task.

**Figure 1:** Results from the SPM{t} analysis of knee abduction moment pre- and post-fatigue. A) Black line: pre-fatigue time series, Red line: post-fatigue time series. B) Grey shaded region: supra-threshold cluster representing statistically significant difference.

## Significance

Our results indicate that muscular fatigue may play a role in influencing knee kinetics (i.e. knee abduction moment), but not knee kinematics in healthy females. Even more interestingly, by observing the pre- and post-fatigue time series (Figure 1), it appears that fatigue also influences the timing of peak knee abduction moment. During pre-fatigue, peak knee abduction moment occurred at approximately 40% of the stance phase, while post-fatigue peak knee abduction moment transpired at approximately 20% of stance phase. It is plausible that the anticipatory nature of the box-land-and-cut task caused the body's predetermined motor program to adjust muscle mechanics during the stance phase after fatigue [3,4]. Previous research also indicates the body changes optimal movement strategy to perform tasks pre- and post-fatigue [5]. As such, future research is needed to understand this phenomenon.

## Cutting Down on Cutting Injuries: Knee Flexion and ACL Injury Risk at Different Levels of Competitive Women's Ultimate Frisbee

Paul R. Slaughter, Peter G. Adamczyk

Department of Mechanical Engineering, University of Wisconsin, Madison, WI, USA

Email: pslaughter@wisc.edu

### Summary:

Ultimate frisbee players have a high rate of ACL injuries. We studied high-risk cutting maneuvers in women's Ultimate across 3 different leagues using lower body wearable motion sensors. More advanced players showed less knee flexion during cut deceleration, suggesting higher ACL strain. This comparison, along with forces and impulses, will reveal at risk populations among different Ultimate leagues.

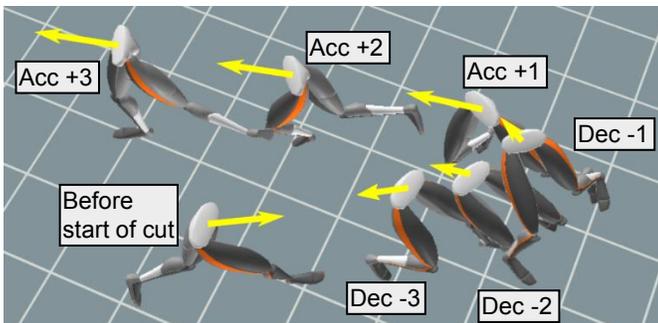

### Introduction:

Injuries in Ultimate, such as anterior cruciate ligament (ACL) tears, are common [1] and occur at higher rates than in other collegiate club sports [2]. In these leagues, women get hurt twice as often as male Ultimate players and are at a greater risk of ACL tears [2]. Despite these high injury risks, Ultimate has rarely been studied in clinical or biomechanical research.

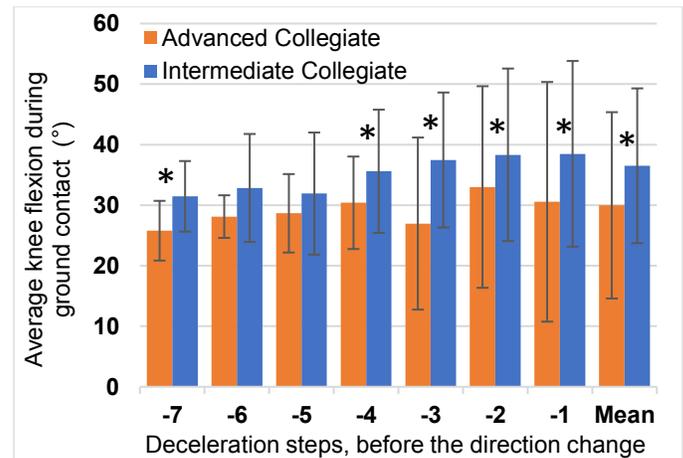

To better evaluate ACL injury risk in Ultimate, we tracked the cutting maneuvers of female players during competition, and then examined their knee kinematics. Cutting was examined because of its high injury risk. Knee flexion angle was used to examine quadriceps dominance, a prominent mechanism of ACL injury: greater quadriceps dominance leads to less knee flexion, causing greater ACL strain [3]. Thus, differences in knee flexion may quantify the relative ACL injury risk experienced by players in different leagues.

### Methods:

11 female Ultimate players played in 16 tournament games in three different leagues (intermediate collegiate, advanced collegiate, club) while wearing motion tracking sensors, including a lower body XSens MVN Awinda inertial sensor system (7 segments) and a VX Sport GPS sensor. Movement was reconstructed using the XSens lower-body model, including spatial displacement and bilateral limb pose. For each foot contact gathered during game play, pelvis acceleration and knee rotations were calculated. Cuts were defined as movements beginning from at least 2 m/s running speed, followed by a sequence of 2-7 deceleration (Dec) steps, a 60° or greater change in direction, and 2-7 acceleration (Acc) steps, and finally ending at a running speed above 2 m/s again (see Fig 1 for an example).

**Figure 1:** Footfall impulses throughout a cut. This cut features 3 deceleration steps and 3 acceleration steps.

**Figure 2:** The average knee flexion for the players on the advanced and intermediate collegiate teams. Asterisks represent statistical difference between teams.

Forces and impulses were estimated during cutting maneuvers using pelvis acceleration as an estimate of whole-body center of mass acceleration. To examine quadricep dominance, the average knee flexion during ground contact for each cut deceleration step was calculated.

### Results and Discussion:

79 points of play were recorded, lasting a mean of 2.4 minutes and containing a mean of 3.4 cuts. Fig 1 shows an example cut with the impulse for each footfall overlaid on the XSens kinematic model showing mid-stance body configuration on each step of the cut. Fig 2 shows that players on the advanced collegiate team exhibited less knee flexion than players on the intermediate teams. This suggests that advanced players exhibit greater quadriceps dominance, potentially putting them at a higher risk of ACL injury. This straighter leg among more advanced players correlates with greater deceleration during cutting ( $1.66 \text{ m/s}^2$ ) than in intermediate players ( $1.07 \text{ m/s}^2$ ).

### Significance:

This study is important to the field of sport biomechanics because measuring natural movements during competitive games is more realistic and representative than controlled movements in a laboratory. Additionally, results regarding quadricep dominance, along with impulse data, will help build the foundation for understanding cutting maneuvers in real Ultimate games. Knowing more about the mechanics of cutting in Ultimate will help to develop a preventative training program; such programs have been successful in other sports at reducing ACL injuries [3]. Knowing which leagues are most at risk of ACL injury will help to effectively disseminate this new knowledge.

## Relationships Between Vertical Stiffness and Jump Performance in NCAA Division-I Athletes

Meghan E. Haser<sup>1\*</sup>, Brittany M. Warren<sup>1</sup>, Kevin R. Ford<sup>2</sup>, Brett S. Pexa<sup>3</sup>, and Justin P. Waxman<sup>1</sup>

<sup>2</sup>Department of Physical Therapy, High Point University, High Point, NC

<sup>3</sup>Department of Athletic Training, High Point University, High Point, NC

Email: \* [mhaser@highpoint.edu](mailto:mhaser@highpoint.edu)

### Introduction

It is well accepted that some level of lower-extremity stiffness is necessary to safely stabilize the joints during dynamic activity, with higher stiffness levels generally regarded as being beneficial for athletic performance.<sup>1</sup> To this end, greater stiffness is reported to be associated with greater running economy, running speed, and peak propulsive power, among others.<sup>2</sup> However, this evidence is limited by small sample sizes and a lack of stratified research designs, making it difficult to tease out the true extent to which such measures are related. Therefore, the purpose of this study was to evaluate the extent to which vertical stiffness ( $K_{\text{Vert}}$ ) is related to maximal vertical jump height and peak propulsive power measured during maximal countermovement jumps.

### Methods

Ninety-one NCAA Division-I athletes (Baseball = 34, Men's Soccer = 27, Women's Soccer = 30;  $19.35 \pm 1.24$  years,  $1.76 \pm 0.09$  m,  $75.87 \pm 10.83$  kg) performed a series of three maximal-effort countermovement jumps (CMJ) and the  $K_{\text{Vert}}$  assessment atop a portable dual-force plate system. For the CMJ, athletes were permitted to swing their arms. Maximum vertical jump height (cm) and peak propulsive power (W) were then extracted from each of the CMJ trials and averaged prior to analysis.  $K_{\text{Vert}}$  was assessed via stationary, double leg, barefoot hopping at a set target frequency of 2.2 Hz. For each hop, initial contact and toe-off were defined as the instants at which the vertical ground reaction force (vGRF) became greater than and less than 10 N, respectively.  $K_{\text{Vert}}$  was then calculated as the ratio between peak vGRF and maximum center-of-mass displacement (kN/m).<sup>3</sup> As both propulsive power and  $K_{\text{Vert}}$  are associated with body size, these variables were also expressed, and statistically analyzed, relative to body mass (W/kg and kN/m/kg). Differences in demographics and all other variables of interest were evaluated via a preliminary one-way ANOVA. Relationships between  $K_{\text{Vert}}$  and CMJ performance were examined via simple regression. All analyses were performed with an a-priori alpha level of  $\leq 0.05$ .

### Results and Discussion

Significant differences in body mass, peak vGRF, absolute and normalized  $K_{\text{Vert}}$ , jump height, and absolute and normalized peak power were identified across sport ( $p < .05$ ). Men's baseball and soccer athletes were taller, had greater body mass, and displayed higher peak vGRFs, absolute  $K_{\text{Vert}}$ , jump height, and both absolute and normalized peak power compared to women's soccer ( $p < .05$ ; Table 1). Additionally, men's baseball displayed higher jump heights and absolute peak power compared to men's soccer ( $p < .05$ ); however, the difference in peak power was not statistically significant following normalization to body mass ( $p = .110$ ; Table 1). Men's soccer displayed greater normalized  $K_{\text{Vert}}$  than men's baseball and women's soccer ( $p < .05$ ); however, there was no difference in normalized  $K_{\text{Vert}}$  between men's

baseball and women's soccer athletes ( $p = .546$ ; Table 1). Regression analyses revealed absolute  $K_{\text{Vert}}$  to be weakly related to jump height ( $R^2 = .179$ ,  $p < .001$ ) and absolute peak power ( $R^2 = .310$ ,  $p < .001$ ) when all athletes were pooled together; however, the relationship between absolute  $K_{\text{Vert}}$  and absolute power only remained significant in women's soccer ( $R^2 = .165$ ,  $p = .026$ ) when evaluated by sport. Following normalization,  $K_{\text{Vert}}$  was not found to be related to jump height or peak power for any of the groupings analyzed ( $R^2$  range =  $.008 - .092$ ,  $p > .05$ ).

**Table 1.** Descriptive statistics (mean  $\pm$  SD) by sport.

Notes. <sup>a</sup> different from men's soccer and baseball; <sup>b</sup> different from men's soccer ( $p < .05$ ).

### Significance

Vertical stiffness, as measured via stationary, barefoot, vertical hopping, does not appear to be associated with measures of athletic performance as assessed during a countermovement jump. These findings contradict the results of previous work,<sup>2</sup> and suggest that additional studies focused on better understanding the various types information that can be gained from the vertical stiffness assessment, as it relates to other characteristics of athletic performance, appear warranted. The findings of the current study are significant in that they should cause researchers and clinicians to question some of the previous evidence supporting a theoretical relationship between vertical stiffness and measures of athletic performance.

### Introduction

Evidence suggests that an optimal amount of lower-extremity stiffness is required for successful athletic performance, with too much or too little stiffness increasing injury risk; however, this “optimal range” remains elusive.<sup>1</sup> This may be in part due to the large variability in stiffness values displayed by relatively homogenous groups of athletes.<sup>2</sup> Identifying differences in stiffness as a function of sex and sport represents an important first step towards establishing normative ranges to better understand stiffness values and the potential clinical utility of vertical stiffness assessments. Therefore, the purpose of this study was to examine the effects of sex and sport on bilateral and unilateral measures of vertical stiffness ( $K_{\text{Vert}}$ ).

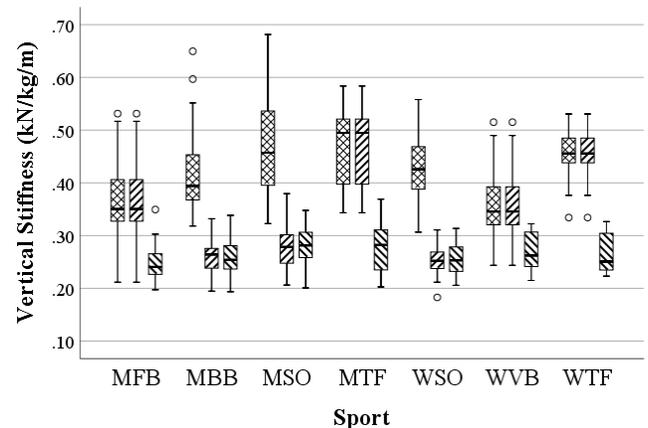

### Methods

As part of a larger pre-season screening, vertical stiffness ( $K_{\text{Vert}}$ ) was assessed on a total of 181 athletes from men’s high-school football (MFB:  $n = 47$ ,  $15.05 \pm 1.41$  yrs,  $1.74 \pm 0.09$  m,  $80.33 \pm 21.88$  kg), men’s NCAA Division-I baseball (MBB:  $n = 34$ ,  $19.33 \pm 1.29$  yrs,  $1.82 \pm 0.06$  m,  $84.86 \pm 6.77$  kg), soccer (MSO:  $n = 27$ ,  $19.63 \pm 1.31$  yrs,  $1.80 \pm 0.06$  m,  $74.98 \pm 6.72$  kg), and track and field (MTF:  $n = 13$ ,  $19.07 \pm 1.04$  yrs,  $1.78 \pm 0.04$  m,  $72.46 \pm 25.37$  kg), and women’s NCAA Division-I volleyball (WVB:  $n = 18$ ,  $19.28 \pm 1.27$  yrs,  $1.75 \pm 0.08$  m,  $74.96 \pm 10.32$  kg), soccer (WSO:  $n = 30$ ,  $19.13 \pm 1.12$  yrs,  $1.66 \pm 0.06$  m,  $63.90 \pm 6.60$  kg), and track and field (WTF:  $n = 11$ ,  $18.86 \pm 1.86$  yrs,  $1.67 \pm 0.06$  m,  $57.73 \pm 7.63$  kg). Standing barefoot atop a force platform, athletes were instructed to hop (hands on hips) to the beat of a metronome set at 2.2 Hz under bilateral and unilateral (left leg, right leg) conditions. Two trials of 20 hops were recorded for each condition. For each hop, initial contact and toe-off were defined as the instants at which the vertical ground reaction force (vGRF) became greater than and less than 10 N.  $K_{\text{Vert}}$  was then calculated as the ratio of peak vGRF to maximum center-of-mass displacement.<sup>3</sup> Only trials in which the hops fell within 5% of 2.2 Hz were statistically analyzed. Because  $K_{\text{Vert}}$  is associated with body size, stiffness was also normalized to body mass. Between-sex differences in absolute and normalized  $K_{\text{Vert}}$  were evaluated via one-way ANOVA. Separate one-way ANOVAs were used to evaluate differences in  $K_{\text{Vert}}$  across sport.

### Results and Discussion

Between-sex comparisons revealed that men displayed greater absolute  $K_{\text{Vert}}$  compared to female athletes across all hopping conditions (double:  $31.57 \pm 7.84$  vs.  $26.50 \pm 4.98$  kN/m,  $p < .001$ ; left:  $19.89 \pm 4.02$  vs.  $16.75 \pm 2.68$  kN/m,  $p < .001$ ; right:  $19.94 \pm 4.02$  vs.  $16.79 \pm 2.54$  kN/m,  $p < .001$ ); however, this sex effect disappeared when  $K_{\text{Vert}}$  values were normalized to body mass (double:  $0.41 \pm 0.09$  vs.  $0.41 \pm 0.07$  kN/kg,  $p = .928$ ; left:  $0.33 \pm 0.09$  vs.  $0.32 \pm 0.09$  kN/kg,  $p = .736$ ; right:  $0.26 \pm 0.04$  vs.  $0.26 \pm 0.03$  kN/kg,  $p = .828$ ). As such, all sport comparisons were conducted using normalized  $K_{\text{Vert}}$  values. The sport main effect was statistically significant across all hopping conditions ( $p \leq$

.002). Follow-up pairwise comparisons (Bonferroni) revealed that MFB displayed significantly less double-leg  $K_{\text{Vert}}$  compared to MSO, WSO, and MTF ( $p < .05$ , Figure 1). Additionally, WVB displayed less double-leg  $K_{\text{Vert}}$  compared to MSO, MTF, and WTF ( $p < .05$ , Figure 1). On the left leg, statistically significant differences in  $K_{\text{Vert}}$  were observed for all sport comparisons except when comparing AFB to WVB, MBB to MSO and WSO, MSO to WSO, and MTF to WTF (Figure 1). Finally, on the right leg, the only significant finding was that MFB displayed lower  $K_{\text{Vert}}$  compared to MSO ( $p < .001$ , Figure 1).

**Figure 1.** Boxplot displaying normalized vertical stiffness values by sport. Woven pattern = Double Leg; Slant Left = Left Leg; Slant Right = Right Leg.

### Significance

To our knowledge, this is the first study to evaluate differences in vertical stiffness ( $K_{\text{Vert}}$ ) as a function of sex and sport using a large and diverse sample of athletes. Our finding that sex differences in stiffness were eliminated after normalization to body mass suggests that between-sex differences in  $K_{\text{Vert}}$  are primarily due to differences in body size; hence, future studies using between-subject designs are encouraged to use normalized values. Additionally, our findings of significant differences in normalized stiffness among levels of sport suggests that future studies interested in how stiffness relates to injury risk and athletic performance should incorporate sport-stratified analyses.

# Effects of Box Height on Instantaneous Lower Extremity Joint Stiffness during Drop Vertical Jump

Youngmin Chun<sup>1</sup>, Joshua P. Bailey<sup>1</sup>

<sup>1</sup>Department of Movement Sciences, University of Idaho, Moscow, ID

Email : \*[yechun@uidaho.edu](mailto:yechun@uidaho.edu)

## Introduction

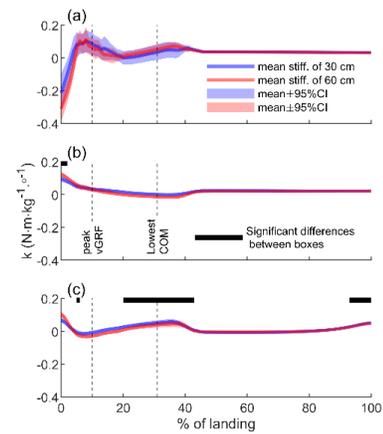

Joint stiffness is used to represent the ability of a joint to resist deformation or compliance in response to loads. Traditionally, joint stiffness has been modelled by applying a simple linear model to the moment-angle graph [1,2], but it is unclear that a simple linear model adequately represents the data throughout the whole stance phase. Our lab has proposed that using a quadratic model of best fit is more appropriate to represent this relationship. Thus, the purpose of this study was to investigate the lower extremity joint stiffness changes in subdivided landing phases and due to box height using a quadratic model of best fit.

## Methods

Thirty healthy college students participated in this study (15 males: age = 25.8 ± 6.6 yrs, ht = 1.82 ± 0.04 m, mass = 82.4 ± 12.1 kg; 15 females: age = 25.2 ± 9.2 yrs, ht = 1.71 ± 0.09 m, mass = 64.5 ± 11.2 kg). Fifteen drop vertical jumps from each 30 cm and 60 cm of box were collected using 3D motion capture system (Vicon, 250 Hz) synchronized with two force platforms (AMTI, 1000 Hz). The obtained data of preferred limb (kicking limb) were exported to Visual 3D software and lowpass filtered at 15 Hz with 4<sup>th</sup> order Butterworth filter. The initial contact (IC) was identified if the vGRF of the preferred limb was greater than 20 N. The descending phase (IC to lowest vertical COM position) was divided into loading (IC - peak vGRF) and absorption (peak vGRF to lowest COM vertical position) phases [3]. The phase following absorption phase to TO was defined as propulsion phase. The quadratic regression model was used to calculate the estimates of  $x^2$  for each phase. The instantaneous joint stiffnesses were calculated by the slope of tangent lines using a derivative of the quadratic regression model [  $f'(x) = ax + b$  ] (Figure 1). Two-way repeated measures ANOVAs (box × phase) for each joint were performed to examine changes in estimates of  $x^2$  with .05  $\alpha$ -level. Post-hoc analyses were performed if significant effects were found. Also, ensemble curves were created with mean stiffness ± 95% CI to identify differences of changes in joint stiffness between boxes.

## Results and Discussion

Significant phase main effects were observed in estimates of  $x^2$  of all joints (hip:  $F_{(2,174)} = 9.911, p < .001$ ; knee:  $F_{(2,174)} = 13.902, p < .001$ ; ankle:  $F_{(2,174)} = 30.430, p < .001$ ). *Post-hoc* analyses are shown in Table 1. Knee stiffness of 60 cm box was significantly greater than 30 cm box at the beginning of the loading phase (0 – 2%), and ankle stiffness of 30 cm box was significantly greater than 60 cm at 5 - 6, 20 – 43, and 93 – 100% (Figure 1).

**Figure 1.** Ensemble curves of instantaneous joint stiffness with mean ± 95% CI. (a) Hip, (b) knee, and (c) ankle joint stiffness of 30 and 60 cm boxes.

## Significance

Although there were no box differences when comparing the  $x^2$  coefficients across box heights, the ankle joint demonstrated the greatest change in stiffness between box heights. Ankle joint increased compliance during approximately 30% of the cycle, indicating a potential preferred ankle strategy during the box drop jumps.

## Fabrication of a Hand Brace for a Collegiate Basketball Player Following Surgery: Identification of Hand Forces during Dribbling and Passing

Nicole Arnold<sup>1</sup>, Nick Richey<sup>1</sup>, Joshua Drost<sup>1</sup>, Amber Vocelle<sup>1</sup>, Justin Scott<sup>1</sup>  
and Tamara Reid Bush<sup>1</sup>, PhD

Email: reidtama@msu.edu

### Introduction

Eighty-five percent of all hand fractures that occur in sports happen while playing ball related activities and about two thirds of these hand fractures are in the metacarpals [1]. Many athletes may return to play using a hand brace as long as the fracture is immobilized and protected, even following surgery. Designing proper protection requires an understanding of the forces that will be placed on that body region during play.

In this case study, a college basketball athlete sustained a left 4th metacarpal hairline fracture, which was surgically repaired with fixation using a pin. The athletic trainer asked our engineering team to design a brace that would permit play after surgery and allow the individual to participate in the 2019 Big10 tournament and March Madness. Published data with regard to the forces transmitted into the hand while handling a basketball were not available in the literature. Therefore, the goal of this work was to estimate the loads experienced by the hand during dribbling, an aggressive two-handed single bounce (generally occurring prior to a shot, called a power dribble), a crossover dribble and while receiving a chest pass. These data were then used to assist with brace design and material selection.

### Methods

Two male college basketball players, one with the injury and another with similar abilities, served as the participants for this work. Two sets of force data were collected. The first set consisted of data collected during three dribbling styles: normal dribble, crossover, and power dribble. The force plate (Bertec, Columbus, OH) was positioned on the ground, collected forces generated by the ball. The second data set was collected from a chest pass. We placed the force plate on a nearly vertical section of a sports prep table that was mounted to the wall and recalibrated the plate. Basic camera video was also recorded in each trial. A 3D scanner (Sense 3D Scanner, Rock Hill, South Carolina) was used to obtain a scan of the physical features of the injured player's hand, which were used to produce a 3D printed model. The hand was scanned with the thumb side up and hypothenar side resting on the table. Four different hand positions were scanned which included a posture to mimic when the hand was gripping the basketball, a semi-flexed, relaxed hand and the hand in full extension.

### Results and Discussion

The maximum force of the ball transmitted into the force plate was used to calculate the maximum pressure experienced by the hand. The maximum force values for a dribble, two-handed dribble, power dribble and chest pass ranged from 1260N-1653N, 1188N-1480N, 1721N-2489N and 540N-1024N, respectively. Based on video evidence, we estimated that the 2<sup>nd</sup> through 5<sup>th</sup> proximal and middle phalanges, the 1<sup>st</sup> distal phalange, the metacarpals, and the distal palm would initially contact the ball. Using the force data and the estimated contact area, the overall pressures were calculated. These data yielded pressure ranges of 11-140kPa.

There are several limitations to this work. These include the estimate of the hand contact area which was based on basic video evidence. Ideally, a high frequency pressure sensing glove would be used to obtain actual contact area and pressure data. Also, we used the force as measured by the force plate which is an overestimation of the force into the hand as it does not account for the force reduction as it moves upwards against gravity. However, when compared to a study of peak hand pressures experienced by softball catchers (269kPa) our peak pressures were less than those by 48-78% [2].

A CAD (computer aided design) file was created from the hand scans and a 3D printer was used to print a full-scale model of the athlete's hand (Figure 1, left). This model was used as a form to mold two composite plates (Figure 1, right). The composite brace was developed from carbon fiber and epoxy which is lightweight, thin and durable. Thus, it was selected as the best material to protect the hand based on our initial load estimates. The brace consisted of two plates each

Figure 1: 3D printed model of injured athlete's hand (left) and composite dorsal and palmar plates developed from carbon fiber and epoxy which is lightweight, thin and durable (right).

on the palmar and dorsal sections of the hand. The athlete wore this brace, covered with thin foam padding and played in the tournaments. These force data fill a gap in existing literature. Further, by using the 3D hand scans, a brace was personalized for this player.

### Significance

This approach may lead to advances in sports braces with additional customization for the player and injury. This method also allows us to examine and treat those with unusual or specific need cases. Designing a customized brace in this fashion addressed an unmet need of helping athletes who are not able to use an "off-the-shelf" brace system. Also, this work received a tremendous amount of media coverage - linking engineering and athletics is exciting for the K-12, college students and the general public and may be an avenue for exposure of biomechanics to many individuals.

### Acknowledgements

Email: bdecoux@bridgew.edu

### Introduction

An athlete's performance and musculoskeletal health hinges on their ability to exploit the abundant degrees of freedom in the body and adapt their movement patterns when faced with changes in environmental constraints. Some of the environmental constraints imposed are derived from physical properties of the playing surface, such as firmness and traction. However, research has yet to offer a thorough understanding of the biomechanical response of athletes to synthetic and turf surfaces and whether coordination variability is adjusted as a result [1]. Therefore, the purpose of this study was to investigate lower extremity inter-segmental coordination variability in athletes during two fundamental sport-related tasks, hopping and running, on four turf surfaces—three different synthetic turf surfaces and one natural turf surface.

### Methods

Seventeen healthy male recreational athletes (age:  $23.1 \pm 2.9$  years; height:  $1.81 \pm 0.06$  m; mass:  $77.8 \pm 9.9$  kg) were recruited from the surrounding community to participate in this study. All participants indicated their voluntary involvement by signing an informed consent document approved by the Institutional Review Board prior to participation.

To minimize potential variations induced by differences in cleat models across participants, each individual wore one of two provided models, both of which had the same upper, heel, and shoe plate construction, and stud configuration. Eight wireless inertial measurement unit (IMU) sensors (MTw, Xsens Technologies B.V., Enschede, the Netherlands) were affixed bilaterally to the feet, lower legs, and thighs as well as to the pelvis and trunk. With this inertial motion capture system, kinematic data were obtained at 100 Hz during three hopping trials and three running trials on each of the four surfaces (Xsens MVN Analyze, Version 2019.0, Enschede, the Netherlands). For the single leg hopping trials, participants were instructed to hop in place ten times at a steady, self-selected frequency, on their dominant limb with their hands resting on their hips. For the running trials, the participants were instructed to run 35 m at a steady, submaximal, self-selected frequency.

Data were imported in Visual3D (C-Motion, Germantown, Maryland, USA) for reduction to only the braking and propulsion sub-phases of the hopping and running trials. Braking and propulsion data were then imported into MATLAB® (R2016a, Mathworks, Inc., Natick, MA) in order to compute continuous relative phase (CRP) variability for the following segment couplings of interest: pelvis-thigh, thigh-shank, thigh-foot, and shank-foot sagittal plane couplings and pelvis-thigh and thigh-foot frontal plane couplings

### Results and Discussion

Only one significant difference in CRP variability between turf surfaces was found for any of the segment couplings during hopping and running. The single significant finding was observed during the braking sub-phase of hopping ( $\chi^2(3) =$

$8.365$   $p = .037$ ), which is when the body is tasked with resisting downward acceleration of the center of mass. Specifically, the sagittal plane pelvis-thigh coupling demonstrated significantly less CRP variability on synthetic turf 1, which was the firmest of the surfaces, compared to natural turf which was the least firm of the surfaces ( $55.3^\circ \pm 16.8^\circ$  vs.  $67.1^\circ \pm 17.2^\circ$ ,  $p = .03$ ,  $W = .16$ ).

Movement patterns that allow for greater but not excessive variability between segments are widely considered to be a healthier, more flexible display of adaptive coordination than movement patterns with less variability [2]. Observations of a reduction in variability may place that system at greater risk of injury due to repetitive stress being applied to the same tissues [3]. Evidence of reduced coordination variability in the pelvis-thigh sagittal plane coupling was found in a study comparing CRP measures in people with and without chronic low back pain during free-speed walking [4]. Though not directly observed as a symptom of chronic low back pain and not the cause, the author suggested that a less variable coordination pattern may be indicative of a reduced ability to absorb shock and may lead to further injury [4,5]. Given that low back pain is commonly reported in athletes after playing on synthetic turf [6,7], the reduced coordination variability in the pelvis-thigh sagittal coupling observed on the firmest of the synthetic turfs tested in this study, warrants attention and should be investigated further. Future research should consider the different alignments employed between the trunk, pelvis, and thigh to ascertain whether the altered postures place a greater demand on the trunk extensors.

### Significance

This study demonstrated that coordination variability between relative segments, in the dominant limb, is largely unaffected by different turf surfaces. However, the significant reduction in variability observed between the pelvis and thigh may indicate an adverse alternative movement pattern during the braking sub-phase of hopping and warrants further attention.

# SIMULATED EXERCISE DEVICE VIBRATION ISOLATION SYSTEM FOR SPACEFLIGHT APPLICATIONS

Blocker, A<sup>1</sup>, Lostroscio, K<sup>2</sup>, Carey, SL<sup>1\*</sup>

<sup>1</sup>University of South Florida, Tampa, FL, <sup>2</sup>Johnson Space Center, Houston, TX

\*scarey3@usf.edu

## Introduction

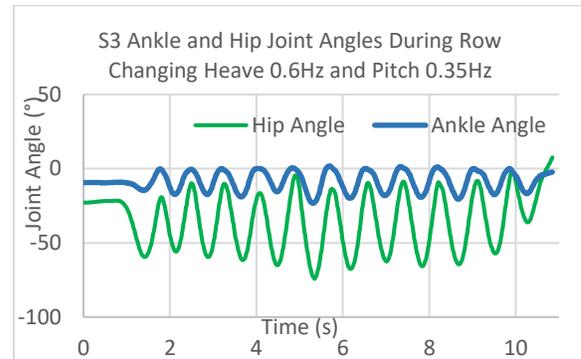

With future NASA goals including long-duration spaceflight missions, proper countermeasures must be taken to facilitate human health in microgravity environments. Exercise is a vital countermeasure used to prevent bone and muscle loss, among other health interests. An important factor in integrating exercise devices with spacecraft is the vibration isolation component, which allows for exercise to occur on spacecraft without creating unwanted vibrations. This human factor study tested the viability of a vibration isolation system (VIS) by having subjects perform exercise in a simulated VIS environment.

## Methods

This study used the Computer Assisted Rehabilitation Environment (CAREN) system to simulate a VIS system. The CAREN (Motek) is a 6-DOF platform with treadmill and force plate capabilities. A Vicon motion capture system, incorporated with the CAREN system, was also used to analyze human kinematics. The VIS System was simulated by applying sine wave inputs to the platform in the heave direction at frequencies of 0.1, 0.35, and 0.6 Hz, as well as a subject-determined baseline frequency. Pitch amplitude was also altered for eight trials, up to 6°, and simultaneous pitch and heave movement was implemented for three trials. Three females and one male were tested from ages 18-44. Height and weight were within range of historical astronaut measurements.

## Results and Discussion

Biomechanical analysis of results show that knee, ankle, and hip joint angles are maintained during exercise on the moving platform. Peak joint angles for the knee during the squat exercise center around 95°, indicating that proper squat form was being reached in the knee.<sup>2</sup> Peak hip angle centered around 90° and peak ankle angle centered around 30°, seen in **Figure 1**. These angles are within normal exercise range for the squat exercise.<sup>2</sup> Synchronization with hip and ankle joints with the platform motion indicate that in trials where multiple motion was occurring (i.e. pitch and heave moving at differing frequencies) caused subjects to have difficulty synchronizing to platform motion. This does not indicate that proper exercise form was not being followed, but it may be considered in order to promote astronaut safety and comfort while using the device.

**Figure 1** demonstrates how subjects were able to continue exercise and achieve desired peak joint angles even when pitch and heave moved with different frequencies. Pitch amplitude was  $\pm 2^\circ$  and heave amplitude was  $\pm 0.04$  m.

## Significance

The results from this study indicate that further testing may be safely performed using this program and future algorithms to understand the effect of passive and active VIS designs on human exercise. This information will then impact the design and implementation of exercise devices aboard spacecraft, because if a subject is not able to perform exercise completely or get the proper joint loading with the existing design, then the purpose of exercising as a countermeasure to bone and muscle loss will be lost. Future studies will focus on testing human subjects on the additional simulations and analyzing kinetic and kinematic data. Other studies of interest include using motion capture data, joint angles, and/or force data to determine the progression of a squat and move the platform accordingly, as a true VIS might do.

# Use of Inertial Measurement Units to Quantify Performance in Alpine Skiing

Sarah A. Wilson<sup>1</sup>, Scott Tashman<sup>1</sup>

<sup>1</sup>Steadman Philippon Research Institute, Vail, CO

Email: swilson@sprivail.org

## Introduction

Inertial Measurement Units (IMUs) offer a promising technique to evaluate athlete biomechanics in sporting environments outside of laboratory constraints. IMU kinematics have been well-validated against video-motion capture in the laboratory [1]; however, use of IMUs in the field remains limited until validated against sport-specific measures that align with coaches' and athletic trainers' "clinical" observations.

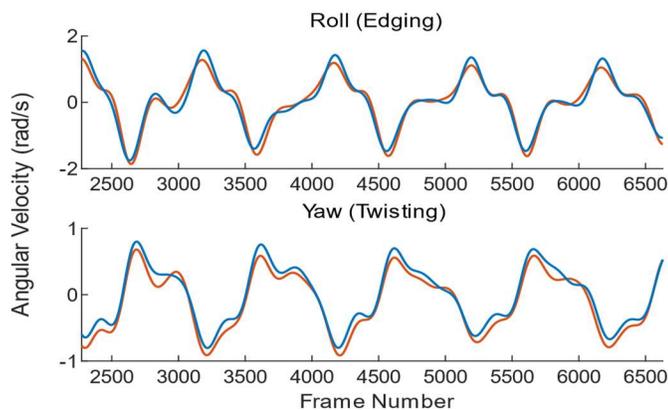

Alpine skiing cannot be reproduced in a laboratory, and there have been several attempts to quantify skiing movement with IMUs. Martínez et. al. developed and validated an algorithm using IMU gyroscopes to determine the transition point between turns [2]. This algorithm is based off timing of edge transition, but similar concepts can be applied to additional axes of the gyroscope to quantify skiing performance.

High performance skiing is characterized by simultaneous edge release; equal tipping of the skis; and turning the feet, legs, and skis "gradually and progressively" throughout the turn [3]. This study demonstrates that IMU gyroscope data can quantify these technical characteristics of ski performance, supporting the viability of IMUs as a tool for measuring skiing movements.

## Methods

Thirteen intermediate- to expert-level skiers provided informed consent to participate in this IRB- approved research study. Each skier was outfitted with standard ski equipment (Nordica SportMachine boots, Rossignol Experience-84 skis) and IMUs (APDM Opal2, Portland, OR; 128Hz sample rate). Participants skied a twelve-turn giant-slamol style course on moderate terrain twice using a skidded-parallel turn. Skier ability level was assessed on a 9-point scale by three independent, professionally-certified instructors/coaches and was averaged.

IMUs were mounted to the top of both boots between the toe and instep buckles with a rubber backing to reduce vibration. The triaxial gyroscope data were filtered using a 4<sup>th</sup>-order bidirectional 0.5hz Butterworth filter (Figure 1). The left and right foot roll-axis signals were averaged, and the extrema of the resulting signal were used as the Edge Transition times (ET) [2]. Rotational Transition times (RT) were determined from the zero-crossings of the yaw-axis. The first and last turns were omitted, resulting in five turns each direction per run.

**Figure 1:** Left (red) and right (blue) filtered gyroscope data from a portion of one run.

Five measures of skier performance were extracted by comparing the edging (roll-axis) and twisting (yaw-axis) gyroscope signals of both feet for each turn cycle, and were averaged. These measures are described briefly in Table 1.

## Results and Discussion

Agreement between raters of skier ability level was fair (ICC=0.64). Raters varied with an average range of 1.3 points between the highest and lowest ability score for each skier, with no consistent offset between raters, underscoring the need to identify quantifiable, objective measures of technical skiing ability. Despite this, most of the metrics extracted from the IMU were significantly correlated with skier ability (see Table 1).

**Table 1:** Correlation of gyroscope metrics with skier ability level

Performance Parameter	R-value	P-value
Edge Synchronicity (ES) $\Delta T =  ET_L - ET_R $	0.64	*0.017
Rotational Velocity at ET (RV <sub>ET</sub> )	0.74	*0.004
Max Rotational Velocity (L-R avg) RV <sub>Max Avg</sub>	0.58	*0.039
Rotational Velocity Symmetry RV <sub>Sym</sub> = (RV <sub>MaxR</sub> - RV <sub>MaxL</sub> )/RV <sub>MaxAvg</sub>	0.51	0.073
ET-RT	0.75	*0.003

In a stepwise multiple-regression analysis, no combination of performance parameters outperformed any individual metric. The best regression, Ability = 7.67(RV<sub>Max Avg</sub>) - 8.19(RV<sub>ET</sub>), resulted in an R of 0.75 (p=0.007). This regression considered a change in angular velocity in the ski rotation between ET and maximum, and an acceleration-like parameter could feasibly characterize the "progressive and gradual twisting of the ski throughout the turn." However, this was not better than RV<sub>ET</sub> or ET-RT, which were each able to account for approximately 56% of the variability between subjects; thus, an additional type of metric or data stream may be necessary to more fully characterize skier performance.

## Significance

The ability of IMU metrics to quantify skier ability level supports their use as a functional training and movement measurement tool in skiing. IMUs characterized the simultaneity of edge release and the rate of rotation of the feet throughout the turn to a much higher level of precision than visual observation. These metrics have potential for evaluating the efficacy of interventions for improving skier performance.

# Assessing the Generalizability of Dual-Task Effects across Different Movements

Patrick D. Fischer<sup>1</sup>, Keith A. Hutchison<sup>2</sup>, James N. Becker<sup>3</sup>, and Scott M. Monfort<sup>1</sup>

<sup>1</sup>Department of Mechanical and Industrial Engineering, <sup>2</sup>Department of Psychology, <sup>3</sup>Department of Health and Human Performance  
Montana State University, Bozeman, MT, USA

Email: patrick.fischer2@student.montana.edu

## Introduction

Although jump-landing and sidestep cutting tasks are both sport-specific movements that are associated with non-contact anterior cruciate ligament (ACL) injury<sup>1</sup>, they load the knee differently during single-task performance<sup>2</sup>. Cognitive function has been associated with non-contact ACL injury risk<sup>3</sup> as well as high-risk biomechanics during dual-task jump-landing<sup>4</sup> and sidestep tasks<sup>5</sup>. However, it is unknown if dual-task effects are generalizable across these movements. Expanding the understanding of how cognitive-motor function ability transfers between injury-relevant movements would guide injury screening and prevention programs.

The purpose of this study was to investigate the generalizability of athletes' cognitive-motor function across jump-landings and running sidesteps. We hypothesized that dual-task costs (DTC) from cognitive distractions during a jump-landing would positively correlate with DTC from analogous cognitive distractions during a running sidestep.

## Methods

Twenty-eight female soccer athletes participated in this study (20±3yrs, 63.5±8.9kg, 1.68±0.05m). On separate, non-consecutive days, participants completed jump-landing tasks<sup>4</sup> and running 45° sidestep tasks off their non-dominant limb. The jumping tasks included a baseline, a working memory task that required participants to memorize and recall the location of six letters on a TV screen (WM\_J), that same working memory test with an added challenge of identifying a single stimulus letter during the jump-landing (WM+VA\_J), and the WM+VA\_J task while reacting to a directional cue (WM+VA+UA\_J). The sidestep tasks included a baseline, the working memory task as described above (WM\_S), the working memory test with an added letter-identification task (WM+VA\_S), and the working memory task while reacting to a directional cue (WM+UA\_S).

Motion capture and force plate data were recorded at 250 Hz and 1000 Hz, respectively. Recorded data were filtered using a 4<sup>th</sup> order, lowpass Butterworth filter at 15 Hz in Visual3D. Peak knee flexion angle (pKFA) and abduction angle (pKAbA) of the non-dominant limb were calculated. Externally defined peak knee abduction moments (pKAbM) were normalized to participant height and weight. Peak values were identified within a 50ms window of participants impacting the force plate<sup>6</sup>. DTC for pKFA, pKAbA, and pKAbM<sup>1</sup> were calculated as the percent change between the multitasking condition and the movement-specific baseline. Spearman's rho correlations tested for relationships between jump-landing DTC and sidestep DTC for analogous cognitive tasks. Significance was set at p<0.05 without correcting for the nine comparisons.

## Results and Discussion

There was a significant negative correlation in pKFA DTC between WM+VA+UA\_J and WM+UA\_S ( $\rho=-0.51$ ,  $p=0.01$ ); greater decreases in knee flexion in WM+VA+UA\_J were associated with greater increases in knee flexion in WM+UA\_S (**Table 1**). No other comparisons were significant (all  $p \geq 0.17$ ).

**Table 1. Spearman correlations for each DTC between jump landing and sidestepping when performed with a similar cognitive task. Values are: rho (p-value). \*indicates (p<0.05)**

	pKFA DTC	pKAbA DTC	pKAbM DTC
WM_J vs. WM_S	-0.06 (0.77)	-0.08 (0.71)	0.15 (0.49)
WM+VA_J vs WM+VA_S	-0.01 (0.98)	<0.01 (0.99)	-0.27 (0.17)
WM+VA+UA_J vs. WM+UA_S	<b>-0.51 (0.01)*</b>	0.04 (0.86)	0.04 (0.84)

The only relationship to reach significance suggested that similar cognitive challenges had opposite effects on neuromuscular control during different movements. This, in combination with the lack of relationships for any other comparisons, suggest that the dual-task conditions cause different neuromuscular responses between the jump-landing and sidestep tasks. Both movements are relevant to injury prevention research<sup>1</sup>, but the current findings do not support the idea that dual-task effects are generalizable across injury-relevant movements. Caution should be taken when comparing the effects of similar distractions on different injury-relevant movements. Further research is needed to provide insight into mechanisms that cause task-dependent cognitive-motor relationships.

## Significance

Jump landing and sidestep cutting movements are commonly investigated for ACL injury prevention research. The results of this work suggest against generalizing individuals' cognitive-motor function across movement types. They also motivate the need for more comprehensive assessments into the spectrum of cognitive-motor function across cognitive and movement tasks.

# DYNAMIC SIMULATION ANALYSIS AND OPTIMIZATION OF A STANDING POWER THROW

Beau Kewley<sup>1</sup>, Manoj Srinivasan<sup>2</sup>, Gregory Freisinger<sup>1</sup>

<sup>1</sup>United States Military Academy – West Point, <sup>2</sup>The Ohio State University

Email: gregory.freisinger@westpoint.edu

## Introduction

With the United States Army’s implementation of the Army Combat Fitness Test (ACFT), many different factors are being analysed for their impact on performance in the various events. It is hypothesized that the height of an individual will have a positive correlation to the distance they are able to throw a 10 lb medicine ball during an overhead Standing Power Throw (SPT). This study aims to investigate the effect of limb length on the distance a ball can be thrown, as the multi-link dynamics may provide additional insight compared to strictly looking for relationships to an individual’s height.

A dynamic simulation modelling the upper and lower arm as a two-link pendulum was developed and optimized to maximize throw distance. This simulation allows for a controlled way to adjust link length while keeping other factors such as applied torque and release position constant. The results of this work may provide insight into ways to potentially normalize results of Soldier performance based on anthropometric differences.

## Methods

A dynamic simulation of simplified human motion utilizing MATLAB [Natick, MA] allowed for optimization based on specified criteria<sup>1</sup>. Optimization was conducted using the *fmincon* function, which takes in multiple subfunctions to provide the constraints and objective function. This was used alongside the equations of motion for a two-link pendulum with a fixed origin representing the shoulder and point masses representing the weight of the upper arm and forearm, hand, and ball, respectively. Joint torque was modelled at the fixed shoulder and elbow joint. Two-link pendulum differential equations were solved using *ode45*. The constraint function set the boundary conditions to only allow motion similar to a human arm during optimization. In this case, the objective was set to maximize the distance a ball can be thrown by a two-link pendulum releasing at an angle of  $\pi/3$  radians. MATLAB’s *fmincon* iterates from a supplied initial condition until it reaches the set of conditions that meet the objective function within supplied constraints.

We completed optimizations at varied link lengths, where each link was set to either 0.1, 0.5, 1.0, or 2.0 meters (Figure 1). The maximum allowable torques at the elbow and shoulder (75 N-m for each) and point mass of the upper-arm (1 kg) and forearm, hand, and ball (3 kg) remained constant. It is important to note that the chosen values were based on convenience and not

an extensive search of the literature. Our main objective was to analyse differences between simulation results, not the accuracy of predicting human performance. Therefore, these values were simplified to ease convergence to an optimal solution.

## Results and Discussion

After iterating the 0.1, 0.5, 1.0, and 2.0 lengths, a negative relationship was evident between link length and distance the ball was able to be thrown as shown in Figure 1. These results are contrary to our initial intuition that longer link lengths would increase the throwing distance. However, with the constant torque and mass constraints, it appears that shorter link lengths reduce the system mass moment of inertia therefore increasing the initial velocity of the ball at release. The only exception to this was at length 0.1, where it did not continue to increase the distance thrown. A more extensive parameter analysis would also serve beneficial to further understand how the limb lengths, torque maximums, constraints, and possible other factors each impact the maximum throwing distance.

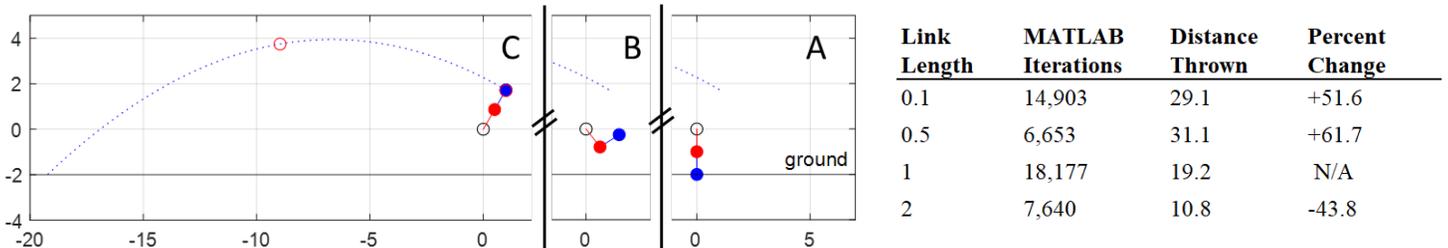

While these were not the results anticipated, it is possible that with additional links to represent the lower body and torso contribution to a SPT, the linkage lengths may still positively impact the distance thrown. The dynamics of a four-link pendulum provide significantly more operating space for the MATLAB optimization, and the potential for the stronger lower-body joints to create a “whip-like” action at release, which is intuitively our expectation based on observation of human technique.

## Significance

This study identified optimal local maximums for a two-link pendulum model of an overhead SPT with varied linkage lengths. Limitations of this model include that it is only a two-link pendulum, and therefore does not fully account for lower limb or torso contribution to an overhead SPT. Future work includes comparing the results of dynamic simulations to the results of the diagnostic tests being conducted by the United States Army. This would serve as an avenue to validate any inferences obtained by this dynamic simulation study.

# Elucidating the Spectrum of Cognitive-Motor Relationships during a Sidestep Cut

Patrick D. Fischer<sup>1</sup>, Keith A. Hutchison,<sup>2</sup> James N. Becker,<sup>3</sup> and Scott M. Monfort<sup>1</sup>

<sup>1</sup>Department of Mechanical and Industrial Engineering, <sup>2</sup>Department of Psychology, <sup>3</sup>Department of Health and Human Development  
Montana State University, Bozeman, MT, USA

Email: patrick.fischer2@student.montana.edu

## Introduction

Movement during competitive sport is often done with cognitive distractions, and differences in cognitive ability influence athletes' non-contact anterior cruciate ligament injury risk<sup>1</sup>. Research into the effects of cognitive dual-task challenges during sport-relevant movement is needed to more completely understand musculoskeletal injury risk factors.

The purpose of this study was to quantify the effects of working memory and visual attention tasks on neuromuscular control during a sidestep cut. We hypothesized that introducing cognitive load from various types of stimuli would result in increases in peak knee abduction angles (pKAbA) and moments (pKAbM) and decreases in peak knee flexion angles (pKFA)<sup>2</sup>.

## Methods

Thirty female recreational soccer athletes (20.5±3yrs, 62.7±9.1kg, 1.68±0.06m) completed running 45° sidesteps off their non-dominant limb under a single-task baseline (BL) and six dual-task conditions. The dual-task conditions were: while dribbling a soccer-ball (BH), reacting to a directional cue instructing them to cut or run straight ahead (UA), with a working memory task of memorizing and recalling letters (WM)<sup>3</sup>, the WM task while also dribbling (WM+BH), the WM task with the visual directional cue for unanticipated change of direction (WM+UA), and the WM task with an added visual task of identifying a stimulus letter during the sidestep movement (WM+VA). Approach speed was controlled to participant-specific maximal effort while dribbling a soccer ball. Three good trials of each condition were assessed.

Marker (modified Plug-in Gait) and force data were collected at 250 Hz and 1000 Hz, respectively. Recorded data were filtered using a 4<sup>th</sup> order, lowpass Butterworth filter at 15 Hz in Visual3D. pKAbA, pKAbM, and pKFA of the plant limb were calculated within 50ms<sup>4</sup> from IC (1<sup>st</sup> frame of data where the force plate reading exceeded 10N). Externally defined knee joint moments were normalized to subject weight and height.

Linear mixed models were used to test for fixed effects of trial condition on pKAbA, pKAbM, and pKFA, with 'Participant' as a random effect. Post-hoc pairwise comparisons were tested using Tukey tests. Significance was set at  $p < 0.05$ .

## Results and Discussion

There was a significant effect of trial condition on pKAbA ( $F=2.68$ ,  $p=0.016$ ). An effect of trial condition on pKFA trended towards significance ( $F=1.84$ ,  $p=0.054$ ). There was no significant effect of trial condition on pKAbM ( $F=0.88$ ,

$p=0.51$ ). (Table 1). Post-hoc analysis found that participants experienced greater pKAbA during the UA task compared to the baseline ( $p=0.046$ ) and the WM+VA task ( $p=0.017$ ). No other comparisons reached statistical significance.

Only the comparisons between the UA and baseline and between the UA and WM+VA conditions reached statistical significance, leaving our hypothesis only partially supported. This is in line with previous studies that found similar effects of unanticipated conditions on sidestep cut performance.<sup>5</sup> However, our findings offered no evidence to suggest that the other cognitive challenges were difficult enough to induce detectable effects on neuromuscular control during the sidestep cut. Notably, we previously observed an effect of BH in male competitive soccer players on pKAbA.<sup>6</sup> Additional work is needed to understand the nuances of how factors such as sex, experience level, and cognitive task difficulty influence neuromuscular control during dual task sidestep cutting.

We previously reported that dual-task conditions with divided visual attention (UA, WM+VA, WM+VA+ UA) led to decreased pKFA during a jump-landing task<sup>7</sup> when compared to baseline. We used analogous cognitive challenges during the sidestep study, however we found no such relationship here. This may be because the jump-landing and sidestep tasks load the knee differently, and so the effects observed during one sport-specific movement may not be generalizable to another.

## Significance

Cognitive multitasking during dynamic movements is an emerging area of research. Understanding the spectrum of effects of cognitive load on injury-relevant biomechanics during sport-specific movements will help improve the efficacy of injury prevention programs.

## Introduction

Golf is a widely played sport with participants ranging across all skills levels. For these golfers, strength, flexibility, and balance are all considered important attributes to successful performance, and these attributes have been studied for direct effect on performance<sup>1-2</sup>. Indeed, many of these skills contribute to increased club head speed or increased driving distance. In addition to single shot improvements, a golfer's ability to consistently replicate the same swing to produce the same output is highly important<sup>3</sup>.

While strength, flexibility, and balance have been studied together, balance has yet to be studied in isolation from other training methods. Additionally, few studies have investigated consistency across multiple swings for elite golfers. The purpose of this study was to determine the effects of a golf specific balance training intervention on golf swing consistency. We hypothesized that higher levels of balance would correlate to increased swing consistency measured by decreases in the kinematic range and decreased kinematic variance.

## Methods

Eight National Collegiate Athletic Association Division I golfers were assessed for postural stability and golf swing kinematics before and after completing a balance training program. Golfers completed the golf specific balance training program three times a week for eight weeks.

A modified Balance Error Scoring System (BESS)<sup>4</sup> and a 3-axis force plate (AccuSway, AMTI, Watertown, MA) were used to evaluate standing postural stability. Each golfer completed a series of double and single leg stances, with eyes open and closed, while standing on a force plate, and an investigator counted errors according to the BESS scale for each stance. Swing kinematics were assessed using an eight-camera 3D motion capture system (Qualisys AB, Gothenburg, Sweden). A Trackman<sup>®</sup> launch monitor (Trackman, Scottsdale, AZ) was used to measure swing and ball flight data. Testing was completed before and after competition of the eight week balance training program.

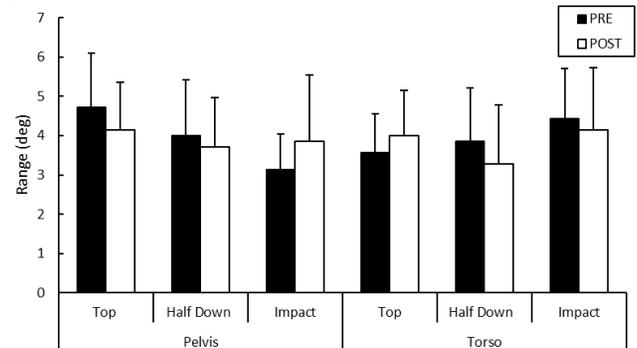

Postural stability was evaluated as deviation in center-of-pressure (COP) measured by the 95% ellipse area of the COP movement during the test period. Modified BESS scores were determined for each stance position. Swing data was analyzed for all 10 swings, and data from 8 swings was included in analysis. Average values, variance, and range for club head speed (CHS), face angle (FA), club path (CP), and pelvis and torso position were determined for each golfer.

## Results and Discussion

Postural stability improved for all golfers following the balance training. Significant decreases in BESS scores were noted for both legs for the single leg, eyes closed stance conditions. Changes in COP deviation as measured by the 95% ellipse area were not significant for any stance conditions, but all stance conditions trended towards decreased COP deviation.

CHS, FA, and CP were all unaffected by the balance training. Maximum variance for CHS spanned from a decrease of 4.52 to an increase of 5.43 post-training within the group of golfers. However, average range for the cohort decreased from  $9.14 \pm 3.53$  km/hr to  $8.43 \pm 1.27$  km/hr post-training. Average range decreased slightly for FA ( $4.67 \pm 1.12$  to  $4.17 \pm 1.62$ ) and stayed the same for CP ( $2.11 \pm 0.54$  to  $2.11 \pm 0.61$ ). There were no significant changes for pelvis or torso body segment position consistency for any swing location (Figure 1). Range for the top and half down position for the pelvis and for the half down and impact positions for the torso decreased following the balance training.

Pearson's correlations indicated no relationship between postural stability levels and variance in swing kinematics. Correlations were determined using the 95% ellipse area for the single leg, eyes closed stance position as a representative stance.

**Figure 1:** The range of body segment positions (as an angle position) across 8 swings for specific locations in the golf swing were determined each golfer.

## Significance

Golf performance has been shown to be affected not only by standard skills practice, but also by dedicated strength and conditioning training. Elite collegiate athletes are limited by time constraints, thus understanding the outcomes of dedicated training programs is highly important. The results of this study indicate that isolated balance training *does* improve balance, but *does not* affect golf swing consistency for elite collegiate golfers.

## Acknowledgments

Funding for the study was provided by the Robert H. Brooks Sports Science Institute (RBSSI). The authors would like to acknowledge Thomas Evans for his assistance with developing the balance intervention.

## Introduction

Basketball shooting is a technical skill that requires regulation of ball velocity at release. Due to the strategy and demands of the game, shots are taken at various distances from the hoop. Differences in max angular velocity<sup>1</sup> and timing of max upper extremity joint angular velocities relative to ball release<sup>2,3</sup> across distances has been observed; however, little is known how individuals control their upper extremity in relation to their center of mass (CM) trajectory during the shooting motion. Our aim was to characterize how individual players coordinated their upper body segment shooting motions in relation to their CM trajectory during shots and determine if players use common strategies to regulate ball velocity at release when increasing shot distance. Shot initiation by the upper extremity was hypothesized to occur closer in time to the maximum CM vertical velocity with increases in shot distance.

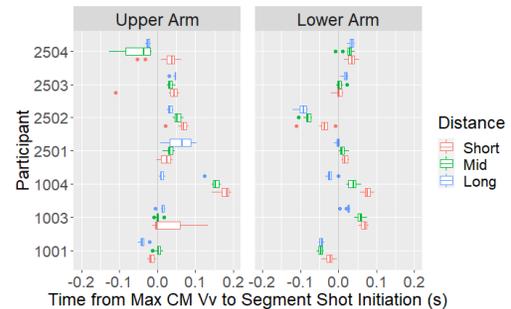

## Methods

Seven male and female basketball players (>10 years of experience, current players in university club and recreational leagues) provided informed consent and volunteered to participate. A minimum of 10 shots were taken from short (<2.5m), mid (4.57m, free throw line), and long (6.02m, high school three-point line) distances. Participants received a chest pass from underneath the hoop and were asked to perform a shot “as if they were in a game.” Competition regulation sized balls were used (male: 29.5; female: 28.5).

Two portable force plates (1200Hz, Kistler) measured reaction forces by each leg. Inertial measurement unit sensors (120Hz, APDM) measured arm segment angular velocities in the sagittal plane. Ball trajectories were video recorded (120Hz, Panasonic) and ball kinematics were measured using custom Python code. CM vertical velocity during the shooting motion was calculated using reaction forces and measured body weight. The last positive-minimum value of arm angular velocity (flexion of shoulder joint) and initial instant of negative lower arm angular velocity (extension of elbow joint) defined shot initiation. The angle of the ball CM velocity at release was determined relative to the horizontal (ball release angle). Multiple comparisons using medians on difference scores tested for differences within-participant amongst the timing of upper and lower arm shot initiation between shot distances. p-values were adjusted using the Benjamini-Hochberg method<sup>4</sup>.

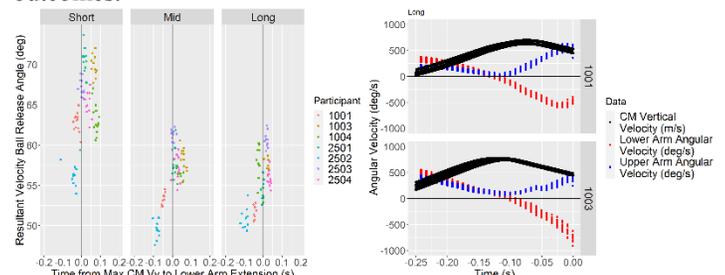

## Results and Discussion

Regulation of ball velocity at release to accommodate for increases shot distance varied across players. Only 14 of 26 shot adjustments involved shot initiation closer to the time of maximum CM vertical velocity during the shooting motion. Upper arm rotation occurred significantly closer to max CM vertical velocity (short-mid: 2/2; short-long: 3/4; mid-long: 2/5; Figure 1) in 7 of 11 significant comparisons. Lower arm rotation occurred significantly closer to max CM velocity (short-mid: 1/3; short-long: 3/6; mid-long: 3/6; Figure 1) in 7 of 15 significant comparisons.

**Figure 1:** Shot adjustments in upper and lower arm rotation relative to the CM vertical velocity made with progressive increases in shot distance (short, mid, long) made by each participant.

Changes in the timing of lower arm rotation in relation to CM trajectory to accommodate for increases in shot distances were associated with differences in ball release angles. In general, initiating the lower arm shooting motion closer to the max CM vertical velocity was associated with an increase in ball CM vertical velocity and a greater ball release angle (Figure 2). The two players that initiated lower arm shooting motion earliest before max CM vertical velocity had the lowest ball release angles during the mid and long shots. This suggests timing of the upper body shooting motion relative to whole body motion may affect ball release angle, subsequently affecting performance outcomes.

**Figure 2:** Left: Relationship between ball release angle and coordination between lower arm shot initiation and CM vertical velocity trajectory. Right: Example of how differences in coordination strategies affect ball release angle (top: mean 51.8°; bottom: mean 57.3°).

## Significance

Determining how an individual utilizes their capabilities to achieve the mechanical objectives of tasks under progressively more challenging conditions provides meaningful insights as to control priorities as well as modifiable factors that affect task performance.

## Reliability of muscle activity during adaptive rowing: A pilot study

Elizabeth Euler, MS<sup>1</sup>, Margaret Finley, PT, PhD<sup>1</sup>

<sup>1</sup>Drexel University, Health and Rehabilitation Sciences, Philadelphia, PA

Email: [ede29@drexel.edu](mailto:ede29@drexel.edu)

### Introduction

More than 2.7 million people use a manual wheelchair (MWC) for mobility in the United States.<sup>1</sup> MWC users are highly dependent on their upper extremities for activities of daily living and mobility. A secondary injury affecting the upper extremity can negatively impact function, independence, and perceived quality of life.<sup>2,3</sup> Evidence shows that rowing offers several benefits for MWC users including decreased shoulder pain, improved cardiovascular fitness, increased resistance to muscular fatigue, increased muscle strength and lean body mass, as well as providing opportunity for social engagement, participation, recreation and competition, and perceived increase in quality of life.<sup>4,5,6,7</sup>

The purpose of this study was to determine the reliability of upper extremity electromyography (EMG) in MWC users during adaptive rowing. We hypothesized that upper extremity muscle activity would be reliable across multiple trials of submaximal ergometer rowing, regardless of rowing experience.

### Methods

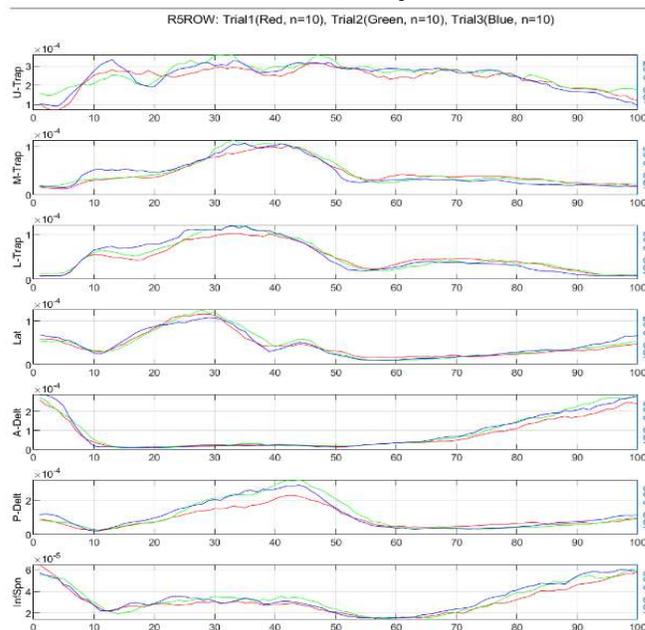

Data were collected on 10 individuals (male n=7, female n=3) who use a MWC for at least 50% of community mobility. Participants had a range of rowing experience from no experience to competitive racing. Health conditions of participants included spinal cord injury (n=8), cerebral palsy (n=1), and congenital amputation (n=1). EMG determined muscle activation of seven muscles [upper trapezius (UT), middle trapezius (MT), lower trapezius (LT), latissimus dorsi (LAT), anterior deltoid (AD), posterior deltoid (PD), infraspinatus (IN)] of the dominant upper extremity during the rowing stroke. Following a warm-up and familiarization period, participants completed a 10-stroke maximum effort test for normalization between participants. Next, three submaximal rowing trials (30-35% maximum watts as determined from the 10-stroke maximum) of 20-strokes were completed. The middle 10 strokes of each trial were time normalized (0-100% of the stroke cycle) and mean RMS during of 10% cycle bins determined. Interclass correlation coefficient (ICC) determined intra-person reliability across the three trials.

### Results and Discussion

Figure 1 depicts the EMG recording of a full stroke cycle for each of the seven muscles recorded from one representative participant. The stroke is represented from 0 to 100%, where the cycle starts and ends at the catch phase of the stroke (arms fully extended).

As hypothesized, individuals were able to maintain consistent activation patterns across trials regardless of rowing experience. The average reliability across the full stroke cycle was moderate to excellent for each of the seven muscles examined.<sup>8</sup> The UT (ICC=0.90), PD (ICC=0.95), and the IN (ICC=0.90) had excellent reliability, the MT (ICC=0.79), LT (ICC=0.86), and AD (ICC=0.85) had good reliability, and the LAT (ICC=0.67) had moderate reliability. Moderate reliability for the LAT can likely attributed to the EMG sensor coming into contact with the back of the adapted seat during the rowing stroke creating excess

noise and inconsistency in the recording. As such, we are investigating alternative methods to collect EMG data of the LAT to reduce this source of error/variability.

**Figure 1:** Stroke cycle for one participant, three trials. Interclass Correlation Coefficient (ICC) two-way random effects model, consistency, single rater/measurement. ICC interpretation: <0.5 = poor, 0.5-0.75= moderate, 0.75-0.9= good, >0.9 = excellent.<sup>8</sup>

### Significance

Rowing offers the unique benefit of repetitive activation of posterior shoulder muscles which are not primary muscles used during MWC propulsion.<sup>5,9</sup> Although reduced shoulder pain has been reported by MWC users who participated in various rowing-type interventions,<sup>4,5,7</sup> the underlying mechanisms for reduced impairment has not been determined. This pilot data is the first step in a comprehensive look at the biomechanics of the adapted rowing stroke in MWC users. We plan to build a better understanding of the mechanism by which rowing could help to reduce the frequency and intensity of shoulder pain in MWC users, along with other benefits of participation.

# Blood Flow Restriction Exercise Limb Occlusion Pressure in Hypertensive and Normotensive Participants

Matt J. Wagner<sup>1</sup>, Colin W. Bond<sup>1</sup>, Sean J. Mahoney<sup>1</sup>, Heather A. Evin<sup>1</sup>, Benjamin C. Noonan<sup>1</sup>, Lisa MacFadden<sup>1</sup>

<sup>1</sup>Sanford Orthopedics and Sports Medicine, Sanford Health, Sioux Falls, SD

## Introduction

Low-load blood flow restricted (BFR) exercise has demonstrated the ability to increase muscle size and strength.<sup>1,2</sup> Due to mechanical stress placed on the musculoskeletal system with high-load resistance training, certain clinical populations, such as those post-acute injury, post-operative, or with debilitating chronic conditions, must perform low-load exercise. These populations may benefit from augmenting their low-load exercise with BFR, though they may have other comorbidities such as hypertension. One factor that is presumed to be related to the tourniquet pressure required to occlude the flow of blood is the individual's blood pressure.<sup>1,2,3</sup> In this regard, some clinicians and researchers have prescribed tourniquet pressure relative to the individual's blood pressure (e.g. 1.3 x systolic blood pressure (SBP)).<sup>2,3</sup> One emerging method to determine tourniquet pressure is to identify the individual's limb occlusion pressure (LOP)<sup>1,2</sup> which is defined as the minimum pressure required with a specific type of tourniquet to occlude arterial blood flow into the limb distal to the tourniquet in a specific individual.<sup>2,3</sup> The effects of hypertension on individualized tourniquet pressure has yet to be described. Consequently, the purpose of the present study was to compare LOP, as measured by a commercially available BFR device, between normotensive and hypertensive groups. It was hypothesized that LOP will be similar between hypertensive and normotensive groups.

## Methods

The present study was approved by the Sanford Health Institutional Review Board. Thirty nine subjects participated in this study. Twenty-four of the subjects were male and fifteen were female ( $26 \pm 5.2$  years,  $1.76 \pm 0.09$  m,  $78.9 \pm 14.9$  kg). After five minutes of rest, participants had their brachial artery blood pressure measured manually on the right arm while they laid in the supine position. Blood pressure was taken in duplicate to ensure accuracy. Participants were then stratified into normotensive ( $n = 22$ ) and hypertensive ( $n = 17$ ) groups using a 120 mm Hg systolic blood pressure threshold. After obtaining each participants' blood pressure, a PTS ii portable tourniquet system designed specifically for BFR and a corresponding tapered, limb circumference specific Easy-Fit Tourniquet (Personalized Tourniquet System for Blood Flow Restriction & Easy-Fit Tourniquet, Delphi Medical, Vancouver, BC, Canada) were used to determine the participant's LOP. The participants laid in the supine position during the LOP assessment. The BFR device progressively increased tourniquet pressure by approximately 10 mm Hg and identified the tourniquet pressure required to eliminate the pressure pulsations in the tourniquet's bladder caused by the underlying arterial flow of blood. LOP was determined on the right leg. Data was analyzed using SPSS (IBM SPSS Statistics v. 26). In order to assess the effect of group on LOP, an independent t-test was performed. Significance was set a priori to  $p < .05$ .

## Results and Discussion

The independent t-test indicated that there was no evidence of a difference ( $t(37) = .054$ ,  $p = .957$ ) in LOP between the normotensive ( $184.1 \pm 23.4$  mm Hg) and hypertensive ( $184.5 \pm 19.4$  mm Hg) groups. Furthermore, systolic blood pressure and LOP were found to have an insignificant positive correlation ( $r(39) = .20$ ,  $p = .22$ ). Based on the results of the present study, hypertensive populations do not have a greater LOP than normotensive populations and systolic blood pressure is not associated with LOP. Thus, despite previous assumptions of the significance of blood pressure in determining LOP, the current results indicate that there exists no strong relationship between them. In fact, systolic blood pressure explains just 4.8% of the variance in LOP.

Concerns regarding the limitations of the study may offer a window for further analysis. The present study only included 39 participants, of which only 5 were clinically hypertensive (SBP > 130). Additionally, the hypertensive group was stratified without thorough investigation into their etiology, which may include idiopathic, secondary, or white coat syndrome. Not identifying the cause of elevated blood pressure amongst these participants may have, in part, lead to the lack of the evidence of a difference in LOP between hypertensive and normotensive individuals and association of systolic blood pressure with LOP. The results of this study are important to clinicians. Hypertensive patients will not be exposed to high tourniquet pressures based on their blood pressure alone. Excessively high tourniquet pressures may be dangerous and could lead to disruption of the soft tissues beneath the tourniquet application site.

## Significance

Previous BFR literature has not described the effects of hypertension on LOP. The current study provides insight for clinicians using BFR who may work with populations where hypertension is prevalent. The results of this study conclude that there is no significant difference in LOP between hypertensive and normotensive populations. Thus, there is no particular advisement on determining LOP in hypertensive populations compared to normotensive populations.

## Mass Distribution and Jump Performance

John H Challis<sup>1</sup>, and Zachary Domire<sup>2</sup>

<sup>1</sup>Biomechanics Laboratory, The Pennsylvania State University, University Park, PA 16802

<sup>2</sup>Department of Kinesiology, East Carolina University

Email: [jhc10@psu.edu](mailto:jhc10@psu.edu)

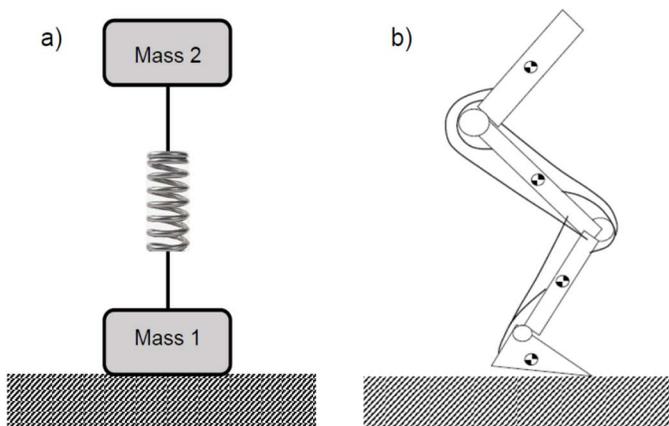

### Introduction

Analysis of maximum vertical jumping with arm swing identifies two mechanisms via which jump height is increased due to the arm swing. One mechanism is that arm swing produces additional vertical energy, and the other is that arm swing slows hip extension which may permit muscles to work on a more favourable region of the force-velocity curve (Domire and Challis, 2010). The second mechanism suggests that a heavier upper body could confer some advantage in maximum vertical jumping compared with jumps with a lighter upper body. Perez-Castilla et al. (2020) examined jump heights with added masses, and while jump height did decrease the decrease with increasing added mass was modest for the lower masses added.

The purpose of this study was to examine the influence of upper body mass on maximum vertical jump performance.

### Methods

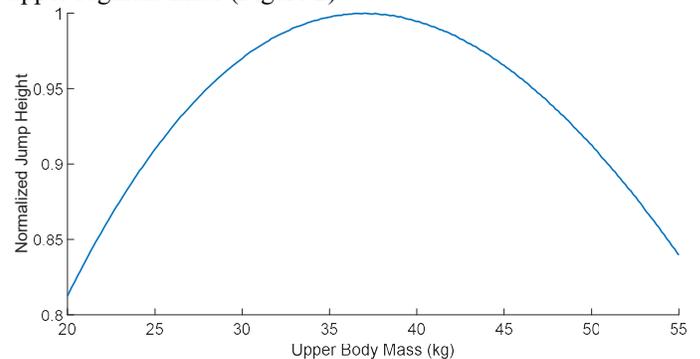

Two simulation models were used to examine vertical jumping. The first was a simple model comprised of two masses separated by a spring (Figure 1a). With this model the spring was compressed and then released and the model jumped. The mass of the upper body was systematically varied and the jump height for each mass determined. The second model was a previously validated muscle model driven direct dynamics model (Domire and Challis, 2007; Figure 1b). This model comprised four segments and was actuated by eight muscles, each comprised of a series elastic component and a Hill-type muscle model. With this model the lower limb inertial properties were constant but the properties of the upper body (head, arms, and trunk) were systematically varied. The model was an optimal control model where for each set of inertial properties the muscle activations were determined which maximized center of mass height and velocity at the instant of take-off.

**Figure 1:** The two models of jumping a) the simple mass-spring-mass, and the b) the direct dynamics optimal control model.

### Results and Discussion

For the simple model the same energy was stored in the spring for simulations with a range of masses for the upper segment (Mass 2). Jump height was normalized to maximum jump height. There was a mass which produced optimal jump height, but decreases in upper segment mass decreased jump height at a greater rate than the decrease in jump height with increasing upper segment mass (Figure 2).

**Figure 2:** The normalized jump height for the simple model as upper segment model mass is increased.

Simulations were performed with the complex model with variations in the inertial properties of the upper body systematically varied. Similarly to the results from the simple model as upper body inertial properties were either decreased or increased there were corresponding decreases in jump height. When the upper body inertial properties were negligible jump height was approximately 9% lower than the jump height with the original model inertial properties. These results can be explained as with lower upper body inertial properties the body is rapidly accelerated resulted in shorter times to generate jump impulse, in the simulations with a higher upper body inertial properties the jumps take longer allowing the muscles longer time to generate greater force thus obviating some of the constraints due to the greater inertial properties.

### Significance

Olympic high jumpers are noted for their gracile physiques (e.g., Khosla and Broom, 1985), these results suggest that simply having a smaller upper body does not necessarily result in increases in jump height.

# An investigation into the release factors of the hammer throw

Suzanne M. Konz  
Marshall University, Huntington WV, USA  
Email: [konz@marshall.edu](mailto:konz@marshall.edu)

## Introduction

The ability of a hammer thrower to achieve the distance thrown is based upon the positions the thrower utilizes. Traditionally, the furthest distances are obtained through the optimal use of projectile-based release factors. Release factors include release velocity, release angle, and release height. The importance of release factors has been cited in sports science literature.[2-5] The distance thrown is affected by athlete strength, athlete anthropometrics, and technique.

This study investigated 1) the differences in release variables of American hammer throwers between throw distance groups and sex; and 2) the differences (changes) in release variables over time of American hammer throwers.

## Methods

The video from 94 hammer throws (52 female throws and 42 male throws) were analyzed. The footage was captured at the 2016-2019 USA Track and Field Olympic Trials and USA Track and Field National Championships. Two high-speed cameras capturing at 59.94 fps were used to record every throw. Trimmed video was digitized using twenty-four anatomical landmarks on the subject. Bivariate correlation and 1-way ANOVAs analyzed the data. Significance was set at the .05 level. Throw distance groupings (TDG) were delineated as follows: 75m & above, 70-74.99m, 65-69.99m, and below 65m.

## Results and Discussion

Correlation analysis indicated relationships among variables exist; however, the correlations were at the moderate to low end of the scale.

One-way ANOVA determined that resultant release velocity ( $F_{1,3} = 9.832, p < .001$ ), vertical release velocity ( $F_{1,3} = 2.957, p = .011$ ), and lateral release velocity ( $F_{1,3} = 3.964, p < .001$ ) differed among the TDG. Tukey post-hoc indicated that resultant release velocity for throws for the 75m plus distance ( $29.02 \pm 1.59^\circ/\text{sec}$ ) were faster than throws at the 70-74.99m ( $27.31 \pm 2.02^\circ/\text{sec}, p = .005$ ), 65-69.99m ( $26.51 \pm 1.65^\circ/\text{sec}, p < .001$ ), and below 65m ( $25.99 \pm 0.64^\circ/\text{sec}, p = .001$ ) distances. Tukey post-hoc determined that vertical release velocity for throws at the 75m plus ( $-5.86 \pm 6.61^\circ/\text{sec}$ ) was significantly different than the 65-69.99m ( $0.63 \pm 7.66^\circ/\text{sec}, p < .001$ ). Tukey post-hoc indicated that lateral release velocity for throws at the 75m plus ( $18.52 \pm 1.86^\circ/\text{sec}$ ) was significantly higher than the 65-69.99m ( $16.32 \pm 2.23^\circ/\text{sec}, p < .001$ ).

One-way ANOVA determined that horizontal release velocity ( $F_{1,3} = 4.206, p < .001$ ), vertical release velocity ( $F_{1,3} = 15.262, p < .001$ ), lateral release velocity ( $F_{1,3} = 7.65, p < .001$ ), release angle ( $F_{1,3} = 16.104, p < .001$ ), and release height ( $F_{1,3} = 6.749, p = .000$ ) significantly differed for the year thrown. Tukey post-hoc testing determined that the horizontal release velocity in 2017 ( $21.35 \pm 1.75\text{m}/\text{sec}$ ) was significantly faster than the

horizontal release velocity in 2019 ( $20.83 \pm 1.57\text{m}/\text{sec}, p = .034$ ) and 2018 ( $20.15 \pm 2.44\text{m}/\text{sec}, p = .005$ ); that the vertical release velocity in 2019 ( $18.16 \pm 1.24\text{m}/\text{sec}$ ) was significantly faster than in 2017 ( $15.79 \pm 1.91\text{m}/\text{sec}, p < .001$ ) and 2016 ( $15.02 \pm 3.03\text{m}/\text{sec}, p < .001$ ) and that the vertical release velocity in 2018 ( $18.10 \pm 1.83\text{m}/\text{sec}$ ) was significantly faster than in 2017 ( $15.79 \pm 1.91\text{m}/\text{sec}, p = .002$ ) and 2016 ( $15.02 \pm 3.03\text{m}/\text{sec}, p < .001$ ); that 2017 ( $5.08 \pm 14.67\text{m}/\text{sec}$ ) throws were significantly further to the left of the center of the sector than 2018 ( $-5.31 \pm 7.00\text{m}/\text{sec}, p < .001$ ) and 2019 ( $-3.90 \pm 4.50\text{m}/\text{sec}, p < .001$ ); that throw release angle in 2016 ( $33.69 \pm 6.53^\circ$ ) was lower than during 2019 ( $41.10 \pm 2.05^\circ, p = .000$ ), 2018 ( $42.06 \pm 5.35^\circ, p < .001$ ), and 2017 ( $36.54 \pm 4.65^\circ, p = .000$ ); and that throw release height was higher in 2016 ( $1.38 \pm 0.34\text{m}$ ) than in 2017 ( $0.99 \pm 0.38\text{m}, p = .002$ ), 2018 ( $1.10 \pm 0.29\text{m}, p = .012$ ), and 2019 ( $1.08 \pm 0.15\text{m}, p = .002$ ).

One-way ANOVA determined that the vertical release velocity ( $F_{1,1} = 3.924, p = .05$ ), horizontal release velocity ( $F_{1,1} = 11.241, p = .001$ ), release angle ( $F_{1,1} = 10.513, p = .002$ ) lateral release velocity ( $F_{1,1} = 14.675, p = .001$ ) were significantly different between females and males. Females had lower vertical release velocity, greater horizontal release velocity, lower release angles, and a lateral release velocity that placed the hammer further to the right.

Release factor changes indicate that athletes are adopting more strength and power-related strategies to achieve throw distance, forsaking the optimal use of physics principals. Another explanation could be related to the balance of the system as the throw progresses to completion. An athlete who is part of an unbalanced hammer-thrower system will employ countermeasures to keep the throw progressing and legal.

## Significance

Hammer throw technique appears to be changing. Athletes are using less than optimal release characteristics.[1] The changes may be the result of athlete strength or the athlete attempting to maintain an unbalanced system until throw release. The hammer throw athlete is unable to affect influence on the implement once released. A suggestion for optimizing the release factors is made to improve throw distance.

## Introduction

An estimated 600,000 youth athletes participate in ice hockey in the United States each year, with rising popularity [1]. Ice hockey has a high incidence of injury; estimated rates of concussion in ice hockey are similar to those of American football [2,3]. Recent increased interest in sports-related concussion has motivated research to better understand the incidence of injury and sport-specific injury mechanisms. While the majority of hockey athletes compete at the youth level, injury studies of pediatric populations are limited [3-6]. This study quantified peak head kinematics and impact, adding to existing knowledge of hockey head impact exposure. The introduction should provide basic information about the field, and additional background with more detail. Include background/context needed to support your hypotheses. Clearly state the general problem that you are addressing with this particular study. If you have hypotheses, state them here. It's ok to use first person.

## Methods

This study enrolled male athletes (ages 12-14) participating in a local 14U hockey team for this study. Athletes were fit with a custom instrumented mouthguard to wear for the duration of the season. Each mouthguard features a tri-axial accelerometer and gyroscope embedded within a rigid retainer material bonded to a soft elastomer overlay. Acquisition was triggered when a mouthguard received an impact greater than 5g and a total of 60 ms of data were recorded. This data was paired with time-synchronized video of each corresponding session to identify the contact scenarios associated with the mouthpiece recorded event. Impacts were defined as mouthpiece-recorded events that occurred concurrently with a visually-verified contact scenario involving the instrumented athlete. Analysis of the field data follows the methodology detailed by Rich et al. (2019) [7]. Following data transformation, resultant time histories and summary statistics associated with peak resultant values for linear acceleration, rotational velocity, and rotational acceleration were calculated and compared by contact scenario.

## Results and Discussion

A total of 682 contact scenarios were observed from video across all athletes. The three most common contact scenarios observed from video were ice checks (n = 255), board checks (n = 211), and falls (n = 179). Unintentional collisions with the boards (n = 15), punches (n= 9), and other head impacts (n= 13), accounted for the remaining 5.4% of video-verified contact scenarios.

Impact rates were calculated per athlete exposure (AE) for each athlete based on the number of video-verified contact scenarios observed and the number of sessions each athlete attended, with session attendance ranging from 34 total sessions to 49 total sessions (45.14 ± 4.8). Impact rates varied between games and practices (2.93 ± 0.6 and 1.20 ± 0.8 respectively). Of the 682 contact

scenarios observed across the complete season, 465 (68%) were classified as “true positive impacts”. Board checks (n = 113), falls (n = 152), and ice checks (n = 165) represented 92% of all true positive impacts. Table 1 depicts the median [95<sup>th</sup> percentile] peak kinematics for the three most common impact types by head contact.

**Table 1: Median [95<sup>th</sup> percentile] linear acceleration (LA), rotational velocity (RV), and rotational acceleration (RA) of the three most common impact types.**

	Board Check (n=113)	Fall (n=152)	Ice Check (n=165)
LA (g)	7.01 [27.7]	6.53 [33.2]	7.92 [47.1]
RV (rad/s)	7.75 [18.8]	5.02 [15.3]	8.03 [18.0]
RA (rad/s <sup>2</sup> )	544.7 [2613]	391.6 [2798]	606.9 [4243]

## Significance

Across 58 total sessions during one 25-week season of play, our instrumented mouthpiece collected 465 video-verified impacts from 682 contact scenarios across seven athletes. The median [95<sup>th</sup> percentile] linear acceleration, rotational velocity, and rotational acceleration was 7.04 [33.4] g, 6.72 [17.7] rad/s, and 505.5 [3155] rad/s<sup>2</sup> respectively. Overall impact rates ranged from 1.38 to 2.94 impacts per session per athlete and were higher in games than in practices, likely reflecting the role competition plays in athletes' willingness to check. This data represents the first youth study to the authors' knowledge to collect kinematic data using an instrumented mouthpiece, which is associated with improved skull coupling as compared to other wearable head impact sensors [8].

## Acknowledgments

The authors thank the Childress Institute for Pediatric Trauma for funding this study and extend their gratitude to the Triad Alliance Hockey Association for participation in this study. Special thanks Konstantina Strates for her efforts in project management and study coordination.

### Introduction

Treadmill tests have been commonly used in both clinical and research settings for gait analysis. Prior to data collection, participants are often given ample time to familiarize with the treadmill condition and achieve a stable and consistent gait pattern. Familiarization time is thus defined as a state that no significant kinematic or kinetic differences are observed across strides. [1] Meanwhile, different types of running shoes may have a discernible influence on the running biomechanics. Therefore, it is important to ensure that the participant is familiar with the test footwear condition so that errors to the outcomes are avoided. However, due to the lack of evidence, there is no consensus on a suggested treadmill familiarization time when experimenting with a treadmill running condition with different types of running shoes. This study investigated the change in the lower limb kinematics in a group of regular treadmill runners when running in two novel shoe conditions vs. their usual shoes. We aimed to provide evidence suggesting a sufficient treadmill familiarization time for different shoe models. We hypothesized that different treadmill familiarization time would be required when running with different types of running shoes.

### Methods

Eleven young adults (age: 26.1±4.1 years) with regular running experience completed three 10-minute running trials at their preferred running speed (8.36±6.36 km/h) on an instrumented treadmill (AMTI, Watertown, MA, USA). Three different types of shoes were used in a randomized order, including their usual running shoes, one pair of minimalist shoes (Brand), which is characterized as minimal amount of foot arch support and low heel-toe drop, and one pair of maximalist shoes (Brand), which provides extra cushioning than usual shoes.

Joint kinematic data from the dominant leg was sampled at 200 Hz using an inertial measurement unit (IMU) based motion-capture system (Noraxon, Arizona, USA) and filtered at 12 Hz [2]. The IMUs were placed on bilateral feet, shanks and thighs, and the pelvic girdle. Synchronized ground reaction force (GRF) was sampled at 1,000 Hz and filtered at 50 Hz.

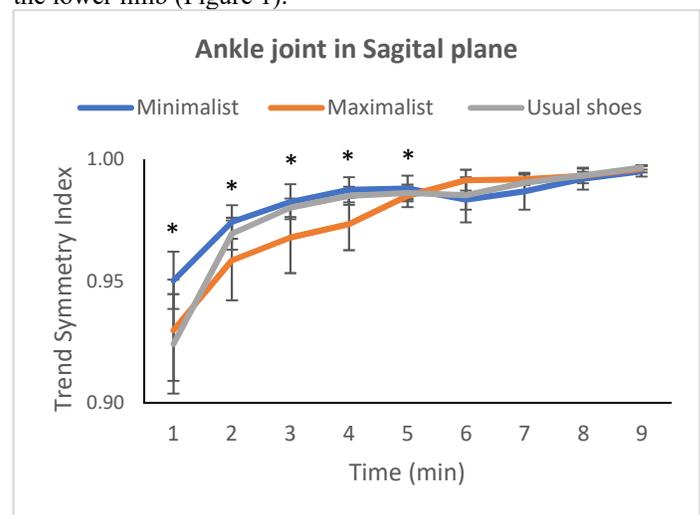

Time of initial foot-ground contact was defined as the time the vertical GRF exceeded 50 N. [3] Ankle, knee and hip joint angles in the sagittal plane were segmented and time-normalized to each gait cycle, and the first ten gait cycles in every minute running were extracted for further analysis. [2]

We compared the time-normalized ankle, knee, and hip joint angle curve between every two consecutive strides in a given minute by calculating trend symmetry (TS). [4] TS is a quantitative measure of pattern similarity between entire gait cycles, which offers a comprehensive comparison of the kinematic curves between conditions. A value of zero indicates perfect asymmetry, and one indicates perfect symmetry. TS ≥ 0.95 indicates highly symmetrical gait cycles. [2]

Differences in symmetry values for the ankle, knee, and hip were compared using two-way repeated-measures ANOVA [running shoes (3 levels) x time (10 levels)], respectively. If indicated, post-hoc paired t-tests with Bonferroni adjustment were conducted between consecutive minutes. A significance level was set as  $p \leq 0.05$ .

### Results and Discussion

There was no significant interaction effect of running shoes × time, nor the main effect in shoes. A significant main time effect was observed in the ankle, knee, and hip, which suggested that individuals needed time to familiarize the treadmill running regardless of the footwear condition. A paired t-test showed that at least 6 minutes were required to achieve stable kinematics in the lower limb (Figure 1).

**Figure 1:** Trend symmetry index of ankle kinematics in the sagittal plane for three running shoes. \* indicates significance from paired t-test with Bonferroni adjustment were conducted between consecutive minutes ( $p < 0.05$ ).

### Significance

Our preliminary results showed that there was no difference in the familiarization period required for different types of running shoes when running a treadmill. At least a 6-minute familiarization time is required for treadmill running regardless of the type of running shoes. Future analysis of changes in 3-dimensional kinematics with larger sample size is warranted.

## Lower-Extremity Inter-segment Coordination during Ice Hockey Skating Starts

### Introduction

Quality forward skating starts are essential to ice hockey in order to ultimately out-pace opponents. Skating starts require a distinctive pattern of locomotion in order for skaters to produce sufficient ground reaction forces despite low ice surface friction. It has been established that kinematic differences exist between high-caliber male and female hockey players during skating starts, particularly during the fourth step [1]. Despite the complexity of skating movements, inter-segment coordination during skating tasks is not well established though it may hold implications for more efficient and effective movement patterns.

The objective of this study was to compare lower extremity inter-segment coordination between male and female high-caliber ice hockey players during forward skating starts. It was hypothesized that differences would exist in coordination between males and females, with male players likely more out-of-phase.

### Methods

Ten high-calibre female and nine high-calibre male hockey players were recruited. An 18-camera Vicon motion capture system was used to collect forward skating data on an indoor ice surface. Participants began on the blue line and were instructed to perform a forward start, skating with maximal effort to the next blue line (15.3 m). Data were sampled at 240Hz and 30 passive retro-reflective markers were used.

Continuous Relative Phase (CRP) was calculated for the fourth step of each trial, regardless of limb, for shank-sagittal/thigh-sagittal and shank-sagittal/thigh-frontal segments by determining the absolute difference in phase angles of the segments. Phase angles were computed using the Hilbert transform approach with values closer to 180° considered more out-of-phase and values closer to 0° more in-phase. Principal component analysis (PCA) extracted important characteristics from the CRP waveforms called principle components and individual waveforms were scored against these principal components (*PC-scores*). Hierarchical linear model investigated relationships between *PC-scores* and sex after controlling for speed, with individual trial level data entered into the model and clustered within participants to allow for variability to be partitioned both within and between participants.

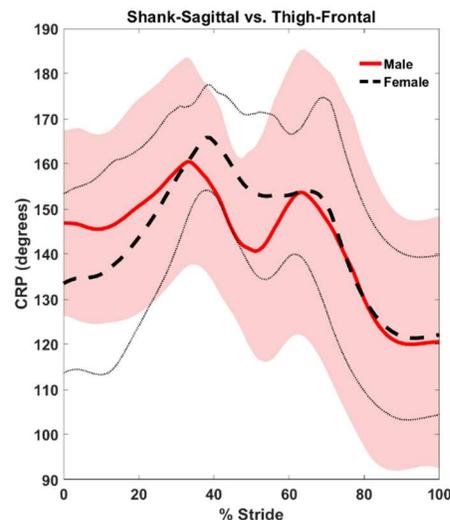

### Results and Discussion

For shank-sagittal/thigh-sagittal *PC1-scores*, adding sex significantly improved the model ( $p=0.00$ ). Males were associated with higher *PC1-scores* which indicated a higher CRP (more out-of-phase) throughout the entire stride.

For shank-sagittal/thigh-frontal *PC3-scores*, the model was significantly improved by adding sex ( $p=0.019$ ). *PC3* represents the difference in CRP from late stance to recovery. Males had lower *PC3-scores*, indicating that they were more in-phase during late stance.

These results support the hypothesis that differences exist between male and female inter-segment coordination. However,

the mode of coordination (more in-phase or out-of-phase) seems to depend on the direction. Males have previously demonstrated significantly wider step widths during step four; a more in-phase mode of coordination of shank-sagittal/thigh-frontal segments may contribute to this by providing increased stability. Previous studies have suggested that females may have less coordination variability [2] which is reinforced by smaller changes in CRP in late stance/early recovery phases. Males also demonstrated more out-of-phase coordination of shank-sagittal/thigh-sagittal segments. More out-of-phase coordination is considered more variable and may allow players to more readily adapt to and account for changes in ground reaction force and friction as the player pushes against the ice. The findings of this study can help improve understanding of how males are able to generate greater forward acceleration during their initial skating steps.

**Figure 1:** Group means for CRP of shank-sagittal/thigh-frontal segments during step 4 of a forward skating start for male (red, solid lines) and female (black, dashed lines) groups. The pink shaded area represents one standard deviation for the male group, dotted lines represent one standard deviation for the female group.

### Significance

With women's ice hockey steadily growing in popularity, a better understanding of kinematic differences between male and female players is warranted. Training programs better tailored to the needs of these athletes can help to improve skill and raise overall level of play as well as potentially decrease risk of injury, as female hockey players have a higher incidence of injury [3]. Establishing patterns of inter-segment coordination in forward skating will contribute to the overall understanding of human locomotion.

## Introduction

The front kick in martial arts is a kick executed by lifting the knee straight forward while keeping the foot and shin either hanging freely or pulled to the hip, and then straightening the leg in front of the practitioner and striking the target area [1]. It is desirable to retract the leg immediately after delivering the kick, to avoid the opponent trying to grapple the leg and (unless a combination is in the process) to return to a stable fighting stance. In Taekwondo, the front kick bears the name Ap Chagi. It is distinct from the push kick (Mireo Chagi) in that the power should be delivered instantaneously [2], [3]. The main goal of this study was to evaluate whether there were differences in the front kicking kinematics of lower limb joints (hip, knee, and ankle) executed by professional Kyorugi Taekwondo players.

## Methods

Fifteen Taekwondo black belt (M ± SD: age 26.0±3.1 years, mass 69.9±8.7 kg, height 173.6±5.8 cm) executed front kick (Ap Chagi) with their dominant legs [4]. The kinematics and kinetics data were recorded using eight high-speed cameras (VICON, Oxford, UK, 120 Hz). Thirty-nine reflective markers were attached to bony landmarks according to plug-in gait model markers. In order to facilitate the analysis, the time of trials normalized to the percentage. Inverse kinematics was used to evaluate the lower limb kinematics during the front kick. Mean and standard deviation were used to represent the lower limb kinematics during the front kick cycles.

**Figure 1:** The average of ankle, knee, and hip joint angles during Taekwondo front kick (Ap Chagi). The shaded areas represent one standard deviation.

## Results and Discussion

Figure 1 represents lower extremity kinematics variables during the Taekwondo front kick (Ap Chagi). Hip abduction-adduction and hip extension-flexion were observed with one apex at 39% while knee extension-flexion observed with two apexes

at 24% and 61% of trial time. Results present maximum hip flexion ( $87.65^{\circ} \pm 7.1^{\circ}$ ) happened at minimum knee extension ( $3.1^{\circ} \pm 2.2^{\circ}$ ) at 39% of front kick normalized time. These results show professional Taekwondo players follow certain kinematics patterns to executed effective and correct techniques. Based on our results, the kinematics relationship between hip and knee can reveal the various characteristics of athletics. In addition, the kinematics characteristics of professional athletics. These patterns can be used as patterns where coaches and physiologists evaluate the amateur and injured athletics, respectively.

## Significance

According to our results, kinematics executions strategies for certain movements (front kick) can change motor control and kicking efficacy. Analyzing this kind of research and understanding of motor control patterns can improve the knowledge of athletics and coaches to better performance in training and learning strategies. The recognition of kinematic patterns and coordination between joints can reveal athletics levels of injuries. In addition, this type of study of training strategy and motor control knowledge can reduce sports injuries during matches or training. This study presents the motor control and joint kinematics pattern during Taekwondo front kick (Ap Chagi).

## 2D kinematics of skating on a slide board versus skating on a treadmill

Tatiane Piucco<sup>1</sup>, Maria Rodriguez<sup>1</sup>

<sup>1</sup>Health and Physical Education Department, Mount Royal University, Calgary, AB T3E 6K6, Canada.

Email: [tatipiucco@gmail.com](mailto:tatipiucco@gmail.com)

### Introduction

Skating-related exercises have a very specific technique, neuromuscular and physiological responses. The low crouched position during skating and long phase of isometric contraction results in high intramuscular forces and reduced blood perfusion in the working limbs [Foster, 1999]. Despite the importance of this fact, the number of studies investigating skating-specific performance are still limited. The lack of studies could be related to difficulties in reproducing the skating movement in the laboratory, or to control test conditions and measurements on an ice track [Foster et al, 1993]. To overcome this limitation, the use of a slide board to simulate skating movement is a feasible alternative as maximal and submaximal physiological responses on a slide board are similar to real skating [Piucco et al. 2018, 2017a, 2017b]. However, comparison between the skating technique simulated on a slide board and real skating still remains to be established. Therefore, this study aimed to investigate the 2D kinematics of skating on the slide board compared to skating on a treadmill at three different intensities.

### Methods

Eleven well-trained speed skaters ( $17.6 \pm 0.7$  years,  $61.6 \pm 6.4$  kg) performed a skating incremental test to exhaustion on a slide board and on a treadmill. The first and second ventilatory thresholds (VT1 and VT2) and maximal skating intensities (Max) were determined for each athlete. Two video cameras were positioned in the frontal and sagittal views. The athletes skated for 3 minutes at each intensity while 1-minute video was recorded at 120 frames per second. The relative knee flexion (KNE), absolute trunk and hip flexion (TRK and HIP), and the absolute abduction angle of the hip (ABD) for each intensity were analysed using the software Kinovea 0.8.15 (Figure 1).

**Figure 1:** Knee, trunk and hip angles measured during skating on a treadmill (panel A) and on a slide board (panel B). Values were measured at beginning of gliding phase for 3 strides.

### Results and Discussion

Mean values at each intensity are presented in Table 1.

**Table 1:** Knee (KNE), hip (HIP), trunk (TRK) flexion and hip abduction (ABD) angles for thresholds (VT1 and VT2) and maximal intensities

	Slide Board			Treadmill		
	VT1	VT2	Max	VT1	VT2	Max
KNE	136.4±5	131.1±6*	130.3±7*	131.5±7	123.8±7	118.7±9
HIP	60.5±4	57.3±4*	56.7±5*	59.5±5	53.0±4	47.8±4
TRK	40.0±14	28.9±8	27.4±6	44.7±15	37.6±13	35.2±9*
ABD	48.8±2*	51.0±1*	51.9±1*	35.8±4	42.1±5	46.6±5

\* significantly higher values (ES >0.8).

High correlations ( $r \geq 0.7$ ) between slide board and treadmill were found for TRK at VT1 and ABD at VT2.

Postural adjustment at each intensity was similar between slide board and treadmill skating as the KNE, HIP and TRK angles decreased and ABD angle increased with increase in workload for both treadmill and slide board skating.

### Significance

The results of this work showed that the 2D kinematics of skating on a slide board is similar to real skating at different intensities. These findings support the use of a slide board as an ergometer to evaluate skating-related exercise, such as speed skating, hockey, skate skiing and figure skating, as it mimics the technique and physiological responses of real skating.

This is particularly important for training prescription as physiological and neuromuscular adaptations are specific to the activity itself, and exercise prescription from cycling or running tests results are not suitable for skaters.

Some limitations to this study include the lack of information related to rotational movement, as well as other kinematics parameter such as angular and linear velocities. The muscle recruitment strategy during skating on a slide board versus skating on a treadmill should also be considered in future investigations.
