Plenary

Cardiovascular Biomechanics

Cardiovascular

Podium

[Hemodynamics and Atherosclerosis: Arteries To Cells, and Back Again](#)

Giddens, Don P

General Biomechanics

General

Podium

[The Novel Aerodynamics of Insect Flight: Applications To Micro Air Vehicles](#)

Ellington, Charles

Muscle & Musculoskeletal

Muscle

Podium

[Single Molecule Mechanics and the Myosin Family of Molecular Motors](#)

Spudich, James A; Shih, William; Murphy, Coleen; Mehta, Amit;

Rock, Ron; Rice, Sarah; Purcell, Tom; Rief, Matthias

Orthopeadics

Orthopeadics

Podium

[Functional Adaptation and Remodeling of Biological Soft Tissues](#)

Hayashi, Kozaburo

Tissue Engineering

Cellular/Molecular

Podium

[Cell Structure and Function: Plenty of Room for Biomechanics](#)

Meister, Jean-Jacques

Invited

Cardiovascular Biomechanics

Cardiovascular

Podium

The Engineering of Vascular Substitutes

Nerem, Robert M

Feature of Arterial Blood Flow Associated with the Biological Functions

Tanishita, Kazuo

Application of Models To Understand the Integration of Coronary Vascular Control Mechanisms

Spaan, Jos AE

Effect of Viscous Fluid Stresses on Cells and Bio-Artificial Capsules

Barthès-Biesel, Dominique

Infrastructure for the lups Physiome Project

Hunter, Peter

Mechanisms Of Mechanotransduction In Cell Processes And Microvilli

Weinbaum, Sheldon

General Biomechanics

General

Podium

Skiing with Carved Skis: Challenges on Performance and Safety

Müller, Erich; Schwameder, Hermann; Schiefermüller, Christian

Has Computer Simulation of Locomotion Delivered All Its Promise in the Past 20 Years?

Vaughan, Christopher L

Biomechanics in Oceanography

Pedley, T J

Injuries in Sport: Reduction Through a Biomechanical Intervention

Elliott, Bruce

Tendon Excursion and Gliding Mechanism

An, K-N; Zhao, C F; Zobitz, M E; Amadio, P C

Critical Issues in the Behavior of Human Skeletal Muscle During Ssc Activities

Komi, Paavo V

Muscle & Musculoskeletal

Muscle

Podium

New Approaches To Integrating Muscle Function And Design From Molecular Biophysics To Whole-Animal

Rome, Lawrence

How Do Biological Motors Work?

Katayama, Eisaku; Uyeda, TQP; Iwane, AH; Ikebe, Mitsuo; Yanagida, Toshio

Orthopeadics

Orthopeadics

Podium

Mechanical Adaptation of Bone Mass and Architecture: Towards a Unified Theory

Huiskes, Rik; Ruimerman, Ronald

Structure Properties of Bone: the Influence of Mechanical and Biologic Stimuli

Goldstein, Steven A

The Small Proteoglycan in Tendon

Vogel, Kathryn G

Biomechanics of Very Soft Tissues

Bilston, Lynne

Cartilage Nanomechanics, Mechanotransduction, And Tissue Engineering

Grodzinsky, Alan; Ortiz, Christine; Seog, Joonil; Dean, Delphine; Ng, Laurel; Jin, Moonsoo;
Kisiday, John; Frank, Eliot

Tissue Engineering

Cellular/Molecular

Podium

The Convergence of Cardiovascular Genomics and Endothelial Biomechanics

Davies, Peter F; Helmke, Brian P; Depaola, Natacha; Shi, Congzhu; Rosen, Amy B;
Polacek, Denise

Molecular Basis of Cellular Responses To Mechanical Forces

Chien, Shu

Mechanical Stimuli and Endothelial Cell Mechanics

Sato, Masaaki

What Can We Learn From Looking At Biological Processes, One Molecule At A Time

Chu, Steven

Cells, Gels And The Engines Of Life: A Fresh Approach To Biological Motion

Pollack, Gerald

Tissue

Podium

Exploring Structure/Function Relationships in Articular Cartilage Using Novel Experimental Approaches

Broom, Neil

Cartilage Mechanics, Diagnostics And Repair

Buschmann, Michael

Award

Podium

Muscle Force Not Work Defines Muscle Contributions To Forward Progression

Neptune, R R; Kautz, SA; Zajac, FE

Mechanical and Metabolic Requirements of Lateral Stabilization in Human Walking

Donelan, J Maxwell; Shipman, David W; Kuo, AD

Is Sensory Control of the Locomotor System Crucial Or Not?

Yakovenko, Sergiy; Prochazka, Arthur

Residual Stress and Strain in the Lamellar Unit of the Aorta: Experiment and Analysis

Matsumoto, Takeo; Goto, Taisuke; Sato, Masaaki

Effects of Stretching and Shortening on Isometric Forces on the Descending Limb of the Force-Length Relationship in Cat Soleus Muscle

Schachar, Rachel; Herzog, Walter; Leonard, Tim

Muscle Synergies Controlling Ground Reaction Forces During Balance

Ting, Lena H; Macpherson, Jane

Force Depression Following Muscle Shortening of Electrically Stimulated and Voluntarily Activated Human Adductor Pollicis

Lee, Hae-Dong; Herzog, Walter; Won, Young-Doo

Thermal Finite Element Analysis of Osteocyte Kill Zones Achieved with a Cryo-Insult Probe

Reed, Karen L; Brown, Thomas D; Conzemijs, Michael G

Smelling With Hairy Little Noses: The Physical Design Of Olfactory Antennae

Koehl, Mimi AR

Experimental Validation of a Computational Model of the Patellofemoral Joint

Elias, John J; Wilson, David R; Adamson, Robert; MacIntyre, Norma J; Cosgarea, Andrew J

Anterior-Cruciate Ligament Forces in the Intact Knee During Normal Gait

Shelburne, Kevin B; Pandy, Marcus; Anderson, Frank; Torry, Mike

The Loading Response Phase of the Gait Cycle is Important To Knee Osteoarthritis

Astephen, JL; Deluzio, KJ; Wyss, UP

Computational Modeling of Flow and Mass Transport in a Microfabricated Array Bioreactor for Perfused 3-D Liver Culture

Kaazempur-Mofrad, MR; Sivaraman, A; Upadhyaya, A; Domansky, K; Powers, MJ; Kamm, RD; Griffith, LG

A Computational Model of Postoperative Knee Kinematics

Chen, Elvis C; Ellis, Randy R; Rudan, John; Bryant, J Tim

Modulation of Anabolic and Catabolic Mechanical Signals in Bone: From Mechanics to Genetics

Judex, Stefan

Symposium

Cardiovascular Biomechanics

Cardiovascular/Respiratory

Podium

Finite Reynolds Number Flows in Three-Dimensional Collapsible Tubes

Hazel, Andrew L; Heil, Matthias

Bioengineering of An Experimental Bioartificial Heart Muscle.

Brackhan, Joseph; Banes, Albert; Cascio, Wayne E

Dynamic Particle/Liquid-Lining Interactions in Peripheral Lung Airways

Weekley, SJ; Rosenzweig, J; King, JR; Waters, SL; Jensen, Oliver

Time-Domain Representation of Ventricular-Arterial Coupling as a Windkessel and Wave System

Tyberg, John; Wang, Jiun-Jr; Shrive, Nigel G; Parker, Kim H

A Novel Age-Related Index of Cardiovascular Function

Niki, Kiyomi; Sugawara, Motoaki; Dehua, Chang; Okada, Takashi; Harada, Akimitsu

Wave Intensity in the Carotid Artery is a New Index of Left Ventricular Systolic and Early Diastolic Performance

Ohte, Nobuyuki; Narita, Hitomi; Niki, Kiyomi; Okada, Takashi; Harada, Akimitsu; Sugawara, Motoaki; Kimura, Genjiro

Non-Invasive Measurement of Wave Intensity - Reproducibility and Effect of Gtn

Jones, Christopher J H; Nicolaides, Eleftherios; Boden, Lucy; Fraser, Alan; Frenneaux, Michael

Shear Stress-Induced Atp Release and Calcium Signaling in Endothelial Cells

Ando, Joji; Yamamoto, Kimiko; Kamiya, Akira

Identification of Genes Regulated by Mechanical Forces Using Microarray Technology in Human Endothelial Cells

McIntire, Larry V; Butcher, ED

The Role of Integrin in Mechanotransduction in Endothelial Cells

Shyy, John Y-J

Stressing Integrins Alters Gene Expression

Wang, Ning

The Free Volume Theory of Mechanochemical Transduction

Frangos, John

Changes of Caveolin-1 in Human Endothelial Cells Exposed To Shear Stress

Sun, Ruijuan; Wang, Xiong; Dong, Xi; Muller, Sylvaine; Stoltz, Jean-Francois

Laminar Shear Stress Induces Vasodilator-Stimulated Phosphoprotein Change in Cultured Human Endothelial Cells

Wei, Lei; Ouyang, JingPing; Muller, Sylvaine; Stoltz, Jean-François; Wang, Xiong

Prediction of Three-Dimensional Orientation of Stress Fibers in Cultured Endothelial Cells Under Cyclic Deformation

Yamada, Hiroshi; Takemasa, Tohru; Yamaguchi, Takami

Studies on the Single Binding Force of LFA-1 and ICAM-1

Zhuang, Fengyuan; Zhao, Hong; Dong, Xi; Li, Xiufeng

Numerical Simulation of the Cardiovascular System : a Multiscale Approach

Formaggia, L; Nobile, F; Quarteroni, A

Wave Propagation in Blood Vessels Using Velocity Profiles Based on Boundary Layer Theory

van de Vosse, Frans N

Influence of Coronary Vascular Bed Compliance on the Shape of Pressure-Flow Waves

Einav, Shmuel; Shalman, Evgeny

Blood Flow Simulations From Phase Contrast MRI Data for the Measurement of Large Gradient Arterial Wall Shear Stresses

Karolyi, Daniel R; Oshinski, John; Giddens, Don P

Hemodynamic Modeling in Stented Arteries

Moore Jr., James; Frank, Andreas O; He, Yong; Walsh, Peter W

Fluid Dynamics and Wall Mechanics in Peripheral Bypass Anastomoses

Perktold, Karl; Berk, Thomas; Leuprecht, Armin; Prosi, Martin; Brandl, Tanja; Cerny, Martin;

Trubel, Wolfgang; Schima, Heinrich

Characterisation and Simulation of In-Vivo Perhiperal Distal Bypass Grafts

Sherwin, S J; Giordana, S; Peiró, J; Papaharilaou, Y; Doorly, D J; Caro, CG; Jackson, M;

Bicknell, C; Zervas, V; Cheshire, NJW

Effective Hemodynamic Diameter: a Parameter with Predictive Value for Patency

Loth, Francis; Meyerson, Shari L; Skelly, Christopher L; Curi, Michael A; Schwartz, Lewis

Wall Shear Stress and Albumin Permeability At the Porcine Aortic Trifurcation

Friedman, Morton H; Grzybowski, Deborah M; Hazel, Andrew L; Himburg, Heather A; LaMack,

Image Based Systematic Modeling of Large Arteries for Clinical Cardiovascular Medicine

Yamaguchi, Takami; Mori, Daisuke; Hayasaka, Tomoaki

Numerical Study of Human Aortic Blood Flow: a Comparison Between Healthy and Disturbed Flow Distal To Artificial Heart Valves

Leuprecht, Armin; Perktold, Karl; Kozerke, Sebastian; Boesiger, Peter

Effects of Vessel Motion on Right Coronary Artery Hemodynamics

Zeng, D; Ding, Z; Friedman, M H; Ethier, C R

Computed Blood Flow Dynamics in An Anatomically Realistic Cerebral Aneurysm

Steinman, David A; Milner, Jaques S; Norley, Chris J; Lownie, Stephen P; Holdsworth, David W

Self-Assembling Peptide Scaffold Promotes Differentiation and Network Formation in Three-Dimensional Culture of Human Microvascular Endothelial Cells

Narmoneva, Daria; Lee, Richard T; Gertler, Jonathan G; Kamm, RD

Comparison of Scaffold Designs for Tissue-Engineered Small-Diameter Graft Applications

Ratcliffe, A; Landeen, L; Sotoudeh, M; Alexander, H G; DalPonte, D; Garcia, A; Kleinert, L; Kern, A;

Ong, S; Jahed, A; Calzo, R; Chien, S; Fung, Y-C; Williams, SK

Tissue Engineered Blood Vessels (Tebv) : the Future is Now

Auger, François A

Scaffolds in Cardiovascular Tissue Engineering - Ultra Thin Layer by Layer

Teoh, Swee-Hin

Mechanical Properties of Elastin-Hybrid Tissue Engineered Vascular Constructs

Berglund, Joseph D; Sambanis, Athanassios; Nerem, Robert M

Mechanical Forces and Engineered Vessels

Niklason, Laura; Solan, Amy

Engineered Arterial Reconstruction: Integration of Biomechanical, Genetic, and Stem Cell Engineering

Matsuda, Takehisa

Pre-Clinical Testing of Mechanical Heart Valves for Potential To Cause Thrombosis: a Milk-Based Procedure as An Adjunct Or Alternative To Animal Trials

Christy, JRE; Martin, A

Understanding the Mechanisms of Mechanical Heart Valve Cavitation

Manning, Keefe B; Fontaine, Arnold A; Deutsch, Steven; Johansen, Peter; Nygaard, Hans;

Tarbell, John M

Mixed-Element Ale Method for Simulation of Mechanical Heart Valve Function

Lai, Yong G; Chandran, KB

High-Frequency Pressure Fluctuations Measured in Heart Valve Patients

Nygaard, Hans; Andersen, Tina S; Hasenkam, J Michael; Paulsen, Peter K

Evaluation of Bileaflet Mechanical Heart Valve Induced Blood Damage During Leakage Flow Using Laser Doppler Velocimetry and Indicators of Platelet Activation

Travis, Brandon; Ellis, Jeff; Hwa-liang, Leo; Fallon, Anna; Marzec, Ulla;

Hanson, Steven; Yoganathan,

Stretch-And-Fold Fractal-Like Aerosol Bolus Spreading in the Rhythmically Expanding Alveolated Duct

Tsuda, Akira; Butler, James; Henry, Frank S

Augmented Longitudinal Diffusion In Oscillatory Flow Along A Lateral Grooved Tube Imitated Of Trachea With Uneven Inner Surface By Cartilage

Shimizu, Akihiro; Miyahara, Kosuke; Shimizu, Masashi; Ryumae, Saburo

Modeling the Intersubject Variability of Ozone Uptake Into Human Airways

Zugates, Gregory; Ultman, James

Anatomically Based Models of Gas Flow and Gas Exchange in the Human Lung

Tawhai, Merryn; Hunter, Peter

A Model of Ventricular Anatomy Based on Structural Measurements From Pig Hearts.

Stevens, Carey; Legrice, Ian; Smaill, Bruce; Hunter, Peter

Studying Electromechanical Behavior in Vivo with MRI Tagging and Epicardial Electrical Mapping

McVeigh, Elliot; Faris, Owen; Ennis, Dan; Evans, Frank

Principal Component Analysis of Cardiac Function

Augenstein, Kevin f; Young, Alistair A

Modeling Electrical and Mechanical Activation Times in the Normal Heart

Kerckhoffs, Roy; Bovendeerd, Peter; Prinzen, Frits; Kotte, Jiska; Smits, Karel; Arts, Theo

Asynchronous Electrical Activation in a Three-Dimensional Model of Cardiac Electromechanics

Usyk, Taras P; McCulloch, Andrew D

Cycle-Induced Flow and Transport in An Alveolus for Partial Liquid Ventilation

Wei, Hsien-Hung; Grothberg, James B

Covariance Amongst Response Terms Will Magnify the Experimental Error That is Inherent in Mechanical Tests on Myocardium

Criscione, John

Effects of Sarcomere Length, Ca²⁺ and Stimulation Rate on Force Generation of Mouse Cardiac Muscle

Stuyvers, Bruno D; McCulloch, Andrew; Guo, Jiqing; Duff, Hank J; ter Keurs, Henk EDJ

Candidate Mechanical Stimuli for Hypertrophy During Early Volume Overload

Guterl, Kathryn A; Holmes, Jeffrey

Shear Properties of Ventricular Myocardium

Legrice, Ian; Dokos, Socrates; Smaill, Bruce; Young, Alistair

Cytoskeletal Defects Alter Myocardial Mechanics Before the Heart Fails

Lorenzen-Schmidt, Ilka; McCulloch, Andrew D; Omens, Jeffrey

Mechanical Effects on Cardiac Myocyte Electrophysiology

Kohl, Peter

Post-Translation Modification of Titin and Effects on Passive Tension in Cardiac Myocytes.

Wu, Yiming; Yamasaki, Robert; McNabb, Mark; Labeit, Siegfried; Granzier, Henk

Analysis of 3-Dimensional Culture of Cardiac Myocytes and Fibroblasts That Simulate Mechanical Conditions in Vivo

Borg, Thomas K; McFadden, Alexander; McNeal, Anna; McCulloch, Andrew; Goldsmith, Edie

Force and Sarcomere Shortening Velocity in Rat Heart

ter Keurs, Henk EDJ; Deis, Nathan; Zhang, Mei L; Landesberg, Amir

Engineered Tissues as Model Systems for Studying Myocardial Biomechanics

Lee, Eun Jung; Knezevic, Vedran; Holmes, Jeffrey; Costa, Kevin D

Wave Intensity in the Pulmonary Circulation

O'Brien, Aoife B; Parker, Kim H

Finite Element Implementation of a Structural Model for Aortic Valve Tissue

Einstein, DR; Reinhall, P; Nicosia, M; Kunzelman, KS; Cochran, RP

Tensile Vs. Compressive Glycosaminoglycan Profiles in Normal and Myxomatous Mitral Valves

Grande-Allen, K Jane; Vesely, Ivan

In Vitro Exploration of Synergies Between Fatigue Damage and Proteolysis in Bovine Pericardial Bioprosthetic Materials

Lee, J Michael; Margueratt, Sean D; Khanna, Rajesh A

Rationale for Biomechanical Mimicry in the Design of Artificial Heart Valves

Kasyanov, Vladimir A; Schoepfoerster, Richard T

Modelling the Nonlinear Anisotropic Porcine Heart Valves

Li, Jue; Luo, XiaoYu

Biofluid Effects of Therapeutic Ultrasound on Biological Tissues

Kimmel, Eitan; Krasovitski, Boris

Numerical Simulation of Cerebrospinal Fluid Motion Within a Healthy and Diseased Spinal Canal

Kalata, Wojciech; Lee, Seung E; Alperin, Noam; Fischer, Paul F; Loth, Francis

Degradation of Drug Tablets and Mixing in the Stomach Using Computer Simulation with the Lattice-Boltzmann Algorithm

Brasseur, James G; Pal, Anupam; Abrahamsson, Bertil

Aqueous Humor Flow and Passive Iris Deformation

Heys, Jeffrey J; Huang, Eric C; Barocas, Victor H

Uterine Biofluid Dynamics

Eytan, Osnat; Yaniv, Sarit; Jaffa, Ariel J; Elad, David

Simulation Based Medical Planning for Cardiovascular Surgery: Recent Developments

Taylor, Charles A

Arterial Blood Filtration for the Prevention of Ischemic Stroke

Lieber, Baruch B; Grad, Ygael; Nishri, Boaz; Tanne, David; Einav, Shmuel; Yodfat, Ofer

Analysis of Total Cavopulmonary Connection Fluid Dynamics: Experimental Studies

Frakes, David H; Lucas, Carol; Ensley, Ann E; Healy, Timothy M; Sharma, Shiva; Yoganathan, Ajit

Laser Doppler Anemometry in the Evaluation of Mechanical Heart Valves' Hemodynamics

Grigioni, Mauro; Daniele, Carla; D'Avenio, Giuseppe; Barbaro, Vincenzo

Platelet Activation in Flow Through a Stenosis Model: Comparison Between CFD and Cdpiv Results

Raz, Sagi; Einav, Shmuel; Alemu, Yared; Bluestein, Danny

Flow Patterns and Preferred Sites of Intimal Thickening in End-To-End and End-To-Side Anastomosed Arteries

Karino, Takeshi; Ishibashi, Hiroyuki; Sunamura, Makoto

Dissociation of Pecan-1/Gq with Temporal Gradients in Shear Stress

Loufrani, Laurent; White, Charles; Jiang, Guang-Liang; Frangos, John

A Role for Molecular Dynamics of Endothelial Cell Lipids in Mechanotransduction

Butler, Peter J; Bowen, Benjamin P; Woodbury, Neal

Changes in the Properties of the Endothelial Glycocalyx Affect the Distribution of Shear Stress and Shear Rate on Endothelial Cells

Wang, Wen

Measuring Spring Constants of the P-Selectin/Psgl-1 Molecular Complexes by Afm

Marshall, Bryan; McEver, Rodger; Zhu, Cheng

Leukocyte Tethering Under Flow: Model for Interfacial Compression, Viscoelastic Tether Extension, and Cytoskeletal Unbinding

King, Michael R; Heinrich, Volkmar; Evans, Evan; Hammer, Daniel A

Rheological Properties of the Blood and Local Haemodynamics Modulating Leukocyte Attachment To Selectin-Coated Surfaces

Nash, GB; Abbitt, KB; Skilbeck, CA; Westwood, SM; Walker, PG; David, T

Divalent Ion Induced Adhesion of Neutrophils To ICAM-1 and Vcam-1 Coated Surfaces

Waugh, Richard; Lomakina, Elena; Spillmann, Christopher; Knauf, Philip

The Nature of Mechanical Forces Regulating Shear-Induced Platelet Activation

Neelamegham, Sriram; Shankaran, Harish

Of Mice and Pigs: the Coronary Microvasculature

Kassab, Ghassan

Morphology of Endothelial Cells Under Flow Alteration in Vivo

Masuda, Hirotake; Kawamura, Koichi; Nanjo, Hiroshi; Komatsu, Masayo; Sugiyama, Tatsuo;

Sho, Eiketsu; Sugita, Akihiro; Asari, Yasushi; Kobayashi, Mikio; Ebina, Toshihito; Hoshi, Naoto;

Singh, Tej M; Xu, Chengpei; Zarins, Christopher K

Coronary Microvascular Resistance as Derived From Intracoronary Pressure and Velocity Measurements in Humans

Siebes, Maria

Rescue by Transplanted Endothelial Cells for Ischemic Renal Failure Visualization of Peritubular Capillaries Using Intravital Videomicroscopy

Yamamoto, Tokunori; Noiri, Eisei; Tada, Tetsuhiro; Hashimoto, Reiji; Brodsky, Sergey V; Kajiya, Fumihiko; Goligorsky, Michael S

Inhibitors of Nitric Oxide Synthase in Relation To Disturbance of Coronary Subendocardial Microvessels

Yada, Toyotaka; Kajiya, Fumihiko

The Effect of Pulsatile Bubble Motion on Surfactant Distribution During Airway Reopening

Gaver, Donald; Zimmer, M; Halpern, D; Williams, HAR

Biophysical and Biological Research in Lung Surfactant Drug Development

Egan, Edmund A; Notter, Robert H

3D Airway Reopening: the Steady Propagation of An Air Finger Into a Strongly Collapsed Elastic Tube

Heil, Matthias; Hazel, Andrew L

Structural and Functional Aspects of Alveolar and Airway Surfactant

Schürch, Samuel; Geiser, Marianne; Gehr, Peter

Dynamics of Wound Healing in Airway Epithelial Cells: Gfp-Actin Remodeling

Waters, Christopher M; Desai, Leena; Aryal, Ashish; West, A Nico; Fischer, David

Cell-Immersed Microbeads Used as Probes of Cytoskeleton Mechanical Properties

Laurent, Valérie M; Hénon, Sylvie; Planus, Emmanuelle; Fodil, Redouane; Balland, Martial; Gallet, François; Isabey, Daniel

The Effect of Prestress on Mechanical Properties of Adherent Contractile Cells

Stamenovi, Dimitrije; Liang, Zhuangli; Wang, Ning

Microrheology of the Living Cell: are We Built of Glass?

Fredberg, Jeffrey; Fabry, Ben; Butler, James

A Model of Non-Uniform Lung Parenchyma Distortion

Denny, E; Schroter, R C

Adaptive Responses of Endothelial Cells To Cyclic Pressure

Shin, Hainsworth Y; Smith, Michael L; Toy, Karen J; Williams, Mickey P; Gerritsen, Mary E; Bizios,

Biomechanical Aspects of Tumor Microcirculation: with Special Emphasis on Leukocyte-Endothelium Interactions

Ohshima, Norio; Miyoshi, Chika; Suzuki, Toshishige; Yanagi, Kennichi

Simultaneous Measurement of Red Cell Velocity and Pressure in Microvessels Revealed Advancement in Phase of Flow Pulse Relative To the Pressure Pulse by P/4

Seki, Junji; Satomura, Yasuhiko; Ooi, Yasuhiro

Implications of a Thick Endothelial Cell Glycocalyx for Microvascular Function in Mice

Vink, Hans; den Berg, Bernard van; Constantinescu, Alina; Spaan, Jos

Exclusion of Neutral and Polyanionic Plasma Tracers by the Capillary Glycocalyx in Equilibrium and Deformed Configurations Predicts Mechano-Electrochemical Properties in VIVO

Damiano, Edward R; Stace, Thomas M; Vink, Hans

Reconstitution of GpIb-Mediated Platelet Behavior in Microcirculation

Suematsu, Makoto; Katayama, Tomihiro; Nishiya, Takako; Kashiwagi, Satoshi; Murata, Mitsuru; Handa, Makoto; Ikeda, Yasuo

Modulation of Cytochrome P450 (Cyp) 1a1 and 1b1 and Ctgf Expression by Shear Stress

Eskin, S G; Turner, N A; McIntire, L

Shear Stress-Induced Strain Focusing in the Endothelial Cytoskeleton

Helmke, Brian P; Rosen, Amy B; Davies, Peter F

Control Mechanisms of the Fluid Shear Response in Circulating Leukocytes

Fukuda, Shunichi; Marschel, Peter; Schmid-Schönbein, Geert W

Differential Modulation of Focal Adhesion Dynamics by Shear Stress and Serum During Endothelial Cell Migration

Li, Song; Chien, Shu

Hydrodynamic Shear and Tethering on E-Selectin Signals Adhesion of Human Neutrophils

Simon, Scott; McDonough, Daniel; McIntosh, Fiona; Goldsmith, Harry

Flow Regulation of Gap Junctional Communication and the Functional Compartmentalization of Vascular Endothelium

Depaola, Natacha; Florez, Lucio; Essien, Eno; Polacek, Denise; Kim, Sanghee

Fluid-Structure Interaction And Collagen Remodeling In The Aortic Heart Valve

Baaijens, FPT; Boerboom, Ralf; Bouten, VC Carlijn; Driessen, Niels; Gawlitta, Debbie; Hart, Jurgen de; Peters, Gerrit; Huyghe, Jacques

Developing A Composite, Tissue-Engineered Aortic Valve

Vesely, Ivan; Shi, Yaling; Ramamurthi, Anand

Fabrication And Characterization Of Fibrin-Based Tissue-Equivalent Valves

Neidert, Michael; Oegema, Theodore; Tranquillo, Robert

The Role Of Dynamic Stresses During Incubation In Increasing Tissue Strength

Sacks, Michael S; Gulesarian, Kristine; Martin, David; Mayer, John

Biomechanics & Hydrodynamics Of Decellularised Porcine Aortic Heart Valves

Korossis, Sotiris; Booth, Cath; Wilcox, Helen; Watterson, Kevin; Kearney, John; Ingham, Eileen; Fisher, John

Fluid Shear Stress Affects Vascular Smooth Muscle Cell Function

Tarbell, John M; Tada, Shigeru; Garanich, Jeff; Ainslie, Kristy; Civelek, Mete

Poster

Inspiratory Flow in Bronchial Airway Models: Bifurcation Plane Rotation

Caro, CG; Schroter, Robert; Watkins, N; Sherwin, SJ; Sauret, Veronique

Increasing Number of Interconnected Elements in Tensegrity Models Induces a Structural Softening Consistent with Cortical Cytoskeleton Function

Wendling, Sylvie; Cañadas, Patrick; Laurent, Valérie M; Planus, Emmanuelle; Fodil, Redouane; Chabrand, Patrick; Isabey, Daniel

Assessment of Structural Viscoelasticity of Cytoskeleton by Tensegrity Model

Cañadas, Patrick; Laurent, Valérie M; Fodil, Redouane; Planus, Emmanuelle; Wendling, Sylvie; Isabey, Daniel

Effect of Ventilation on Instilled Liquid Transport in the Pulmonary Airways of Rats

Anderson, Joseph C; Dawson, Christopher A; Molthen, Robert C; Haworth, Steven T; Glucksberg, Matthew R; Grotberg, James B

Limitation of Expiratory Flow in Liquid Ventilation

Bull, Joseph L; Reikert, Craig A; Komori, E; Tredici, S; Grotberg, JB; Hirschl, RB

Anatomically Based Models of Blood Flow in the Human Pulmonary Microcirculation

Burrowes, Kelly; Tawhai, Merryn; Hunter, Peter

A Multi-Segmental Model of the Coupling of Inspiratory Flow with the Compliant Nose Structure Assessed in Vivo.

Fodil, Redouane; Brugel, Lydia; Isabey, Daniel; Harf, Alain; Louis, Bruno

Steady Flow and Particle Deposition in Non-Planar Airway Bifurcation Model

Fujioka, Hideki; Schroter, Robert C

Effect of Tissue Viscoelasticity and Lung Surfactant on Eustachian Tube Mechanics

Ghadiali, Samir N; Swarts, J Douglas; Federspiel, William J

The Influence of Cell Topography on Epithelial Cell Stresses During Airway Reopening

Jacob, Anne Marie; Gaver, D P

Use of Computational Fluid Dynamics To Study Inhaled Gas and Particle Transport in the Nasal Passages

Kimbell, Julia S; Segal, Rebecca A; Asgharian, Bahman

Predicting the Mixing of Ultra-Fine Particles in a Model Lung Acinus

Leeming, Angus; Schroter, Robert C

Pulmonary Epithelial Cell-Matrix Signalling Via Alpha-6/Beta-4 Integrin

Margulies, Susan; Hawk, Michele; Weaver, Valerie

Finite Element Geometric Models of the Human Lung and Diaphragm

Mithraratne, Premakumar; Carden, Geoff; Tawhai, Merryn; Hunter, Peter

Computational Analysis of Inspiratory Heat and Water Vapor Fluxes in the Human Nose

Naftali, Sara; Rosenfeld, Moshe; Wolf, Michael; Elad, David

An Asymptotic Model of Unsteady Airway Reopening

Naire, S; Horsburgh, MK; Jensen, Oliver

Alveolar Transport During Total Liquid Ventilation

Patterson, Ryan C; Wei, Hsien-Hung; Suresh, Vinod A; Grotberg, James B

A Realistic Mechanical Model of the Human Chest Wall

Ratnovsky, Anat; Zaretsky, Uri; Elad, David

Effects of Boundary Conditions on Particle Deposition Predictions in Human Nasal Passages

Segal, Rebecca A; Kimbell, Julia S

Gravity Effects on Liquid Plug Transport and Distributions in Airway Models

Suresh, Vinod; Grotberg, James B

Three-Dimensional Airway Closure: Surface-Tension-Driven Non-Axisymmetric Instabilities Of Liquid-Lined Elastic Tubes

White, Joseph P; Heil, Matthias

General Biomechanics

Biomechanics, Biotechnology and Bioengineering

Podium

Determining Patterns of Motor Unit Recruitment During Animal Locomotion

Wakeling, James; Herzog, Walter; Syme, Doug

Failure Analysis of the Lower Limb in Axial Impact Loading

Hopcroft, R; Hynd, D; Willis, C; Manning, P; Roberts, A; Lowne, R; Wallace, W A

Head Restraint Position Affects Occupant Response in Rear-End Collisions

Chimich, Dennis D; Heinrichs, Bradley E; Brault, John; Demarco, Alyssa L; Siegmund, Gunter P

Computational Modeling and Experimental Validation of Human Eye Interaction with High-Speed Foam Particles

Stitzel, Joel; Power, Erik D; Cormier, Joseph M; Hurst, William J; Herring, Ian P; Duma, Stefan M

The High Frequency Material Properties of Brain Tissue as Determined by Ultrasound

Naesborg, Henrik; Hye-Knudsen, Christian T; Skotte, Jorgen

A New Method for Quantifying Fibre Bundle Orientation Within Intact Intervertebral Discs Using 3-D Scanning Acoustic Microscopy.

Johnson, Scott; Jones, Mike; Halliwell, Mike; McNally, Donal

Effect of a Dual Cage on the Mechanical Behaviour of the Lumbar Spine

Rohlmann, Antonius; Zander, Thomas; Fehrmann, Michael; Bergmann, G

Effect of a Laminectomy on the Mechanical Behavior of the Lumbar Spine

Zander, Thomas; Rohlmann, Antonius; Bergmann, G

Discoligamentous Structures of the Lower Cervical Spine Get Injured in In Vitro Low-Speed Side Collisions

Wilke, Hans-Joachim; Kettler, Annette; Schultheiß, Markus; Kinzl, Lothar; Claes, Lutz; Hartwig,

Lumbar Spine Motion Analysis Via Automatic Segmentation

Zheng, Yalin; Allen, Robert; Nixon, Mark S

Evaluation of a Magnetic Tracking Device for Estimating Cumulative Low Back Compression.

Agnew, Michael J; Andrews, DM; Callaghan, JP; Potvin, JR

Effects of Mechanical Compression on Anabolic and Catabolic Gene Expression in a Rat Tail Model

Lee, CR; MacLean, JJ; Grad, S; Ito, K; Alini, M; Iatridis, JC

Cyclic Tensile Stretch Decreases Proteoglycan Production by Anulus Fibrosus Cells Through Production of Nitrite Oxide

Rannou, Francois; Corvol, Maite; Revel, Michel; Shyy, John Y-J; Poiraudau, Serge

A Non-Invasive Approach for Measuring Sagittal Balance of the Spine

Stanford, Chriss; Marks, Michelle; Newton, Peter O

Electrical Conductivity of Lumbar Annulus Fibrosis

Justiz, MA; Yao, H; Vega, A; Gu, Wy

Effect of Swelling Pressure on Dynamic Compressive Stiffness of Lumbar Annulus Fibrosis

Yao, H; Justiz, MA; Flagler, D; Gu, Wy

A Preliminary Evaluation of a Limb-Segment Model for Lifting Tasks

Cheng, Pei Lai; Tate, Angela J; Périé, Delphine; Dumas, GA

An Annular Strain Energy Function with a Physiologic Basis

Wagner, Diane R; Lotz, Jeffrey

Quantifying the Contribution of Individual Muscles To Lumbar Spine Stability

Kavcic, Natasa S; McGill, Stuart M

Analysis of Sagittal Balance of the Spine During Various Standing Positions and Gait

Marks, Michelle; Stanford, Chriss; Mahar, Andrew; Newton, Peter O

Tissue Engineering

Cardiovascular/Blood

Poster

Effect of Co-Cultured Vascular Smooth Muscle Cells on Pdgf-B Mrna Expression of Endothelial Cells Under Shear Stress

Jiang, Zonglai; Li, Yuquan; Zhang, Yan; Wang, Dong

Biomechanics & Hydrodynamics of Decellularised Porcine Aortic Heart Valves

Korossis, Sotiris; Booth, Cath; Wilcox, Helen; Watterson, Kevin; Kearney, John; Ingham, Eileen; Fisher, John

Liver/Pancreas

Poster

Bile Canaliculi Reformed by Rat Small Hepatocytes, and Its Dynamic Movement

Sudo, Ryo; Kohara, Hiroshi; Mitaka, Toshihiro; Ikeda, Mariko; Tanishita, Kazuo

Skin/Musculoskeletal

Poster

Viscoelastic Characterization of Collagen Gel Constructs

Krishnan, Laxminarayanan; Weiss, Jeffrey; Wessman, Michael D; Hoying, James B; Das, Rosalina

Apoptosis in Ligament After a Sub-Failure Stretch

Provenzano, Paolo P; Muir, Peter; Hao, Zhengling; Vanderby Jr., Ray

Nutrient Diffusion and Flow-Induced Nutrient Transport in 3-D Cell-Scaffold Composites

Botchwey, Edward; Laurencin, Cato T; Levine, Elliot M; Pollack, Solomon R

Chondrocytes and Fibrochondrocytes Respond Differently To Oscillatory Tension

Vanderploeg, EJ; Collier, KR; Imler, SM; Levenston, ME

The Effect of a Cyclic Compressive Strain on the Differentiation of Osteoblast-Like Cell (Mc3t3-E1) in 3-Dimensional Scaffolds

Choi, K; Kim, JK; Park, YS; Bae, EH; Chun, KJ; Lee, TS

Lipoatrophia Semicircularis: a Biomechanical Approach

Goossens, Richard HM; Snijders, Chris J

Novel Alginate-Chitosan Hybrid Fibers as a Scaffold for Tendon Or Ligament Tissue Engineering

Funakoshi, Tadanao; Majima, Tokifumi; Iwasaki, Norimasa; Harada, Kazuo; Nonaka, Sachiko

Chitosan-Based Hyaluronan Hybrid Polymer for Scaffold in Ligament Tissue Engineering

Majima, Tokifumi; Funakosshi, Tadanao; Iwasaki, Norimasa; Harada, Kazuo; Nonaka, Sachiko

Cyclic Strain and Fluid Flow Induce Different Responses in Human Bone Cells

Mullender, M; Haj, AJ El; Yang, Y; Magnay, J; Duin, MA van; Klein-Nulend, J

Effects of Matrix Properties on Intracellular Signaling

Lai, Jeng-Yu; Basford, Jeffery R; Pittelkow, Mark R; Zobitz, Mark E

Fingertip Pulp Mechanics During Voluntary Tapping

Jindrich, Devin L; Becker, Theodore; Dennerlein, Jack Tigh

BILATERAL DEFICIT IN MAXIMUM ISOMETRIC FORCE, NEURAL DRIVE AND RATE OF FORCE DEVELOPMENT.

Jaap H. van Dieën; Arnold de Haan

Institute for Fundamental and Clinical Human Movement Sciences, Faculty of Human Movement Sciences, 'Vrije Universiteit', Amsterdam, The Netherlands

INTRODUCTION

It has been reported that activity of the motor cortex in one hemisphere reduces the excitability of homologous parts of the opposite hemisphere (Oda and Moritani, 1996). This has been suggested to result in a bilateral deficit in neural drive and force production (e.g. Secher, et al., 1988). However, the existence of such a bilateral deficit has been subject of debate (Herbert and Gandevia, 1996). Three experiments were performed to test the existence of a bilateral deficit in finger flexor and knee extensors muscles.

METHODS

Ten healthy young subjects performed maximum isometric finger flexions bilaterally and unilaterally. In all trials force output and agonist electromyographical activity (EMG) were recorded.

The same protocol was used to test for a bilateral deficit in the knee extensor muscles in 12 subjects. EMG was recorded from the vastus lateralis (VL) and rectus femoris (RF) muscles. In addition, superimposed tetanic stimulation (300 Hz, 80 ms) was used to assess neural drive of the knee extensors. The extra force produced during the tetanic stimulation superimposed on the maximum voluntary effort was divided by the force during a control tetanus prior to the voluntary contraction. The ratio of the superimposed tetanus force and the control tetanus force was used as an estimate of voluntary activation.

In the third experiment, the same 12 subjects performed unilateral and bilateral knee extensions with the instruction to generate force as fast as possible. The peak rate of force development was determined.

RESULTS

In bilateral finger flexions, force output was 22% less than in unilateral exertions ($p = 0.001$). Agonist EMG amplitudes were reduced by similar amounts as force output ($p = 0.015$).

In bilateral knee extension, force output, VL and RF EMG amplitudes were also significantly lower, as compared to unilateral extension by 5%, 8%, and 15% respectively. The voluntary activation as assessed by superimposed stimulation was 4% lower in bilateral contractions ($p = 0.003$).

When subjects were instructed to build up force as fast as possible, the peak rate of force development was 13% lower in

the bilateral contraction ($p = 0.002$) as compared to the unilateral contraction.

DISCUSSION

The present study consistently showed a bilateral deficit, albeit with large differences in magnitude between muscle groups and subjects. The deficit values found are within the wide range reported in the literature. It was considered important to show the presence of a deficit in a small muscle group (finger flexors), since Herbert and Gandevia (1996) have argued that the deficit is mainly found in large muscles as a consequence of the difficulties subjects would experience in maintaining their posture during bilateral contractions of large muscle groups. Furthermore, the study confirmed both by EMG data and superimposed stimulation that the bilateral deficit could be attributed to a reduced neural drive.

The deficit in the rate of force rise was on average larger than the deficit in force. This probably reflects the fact that rapidly building up force requires higher activation, than producing the maximum isometric force (de Haan, 1998). This was supported by our EMG data, which showed higher values during force development.

The reductions in voluntary muscle activation, and the consequent reductions in force and rate of force rise in bilateral contractions are of a sufficient magnitude, to substantially affect performance. Since specific training may obviate the bilateral deficit (Howard and Enoka, 1991), this - limiting factor for performance should be taken into account in training for bilateral exertions.

SELF-ORGANIZING MAPS AND THE REPRESENTATION OF EMG SIGNALS IN TERMS OF MUSCULAR SYNERGIES

Jason J. Kutch and Thomas S. Buchanan¹

Center for Biomedical Engineering Research, University of Delaware, Newark, Delaware USA

¹buchanan@udel.edu

INTRODUCTION

In order to correctly activate the muscles of a neurologically impaired individual who has lost muscular control, it is necessary to understand what information the CNS normally uses to plan and control movement. We have previously shown that the CNS may control cyclic flexion/extension of the elbow by using the joint moment and a measure of total muscular activity (Kutch & Buchanan, 2001). This previous paper used the linear method of principal components analysis (PCA) to represent the EMG from eight elbow muscles in terms of only two parameters. In this present paper, we would like to generalize our results to consider muscular synergies that are nonlinear.

METHODS

EMG data from eight elbow muscles were collected from three subjects during cyclic flexion/extension using fine-wire EMG electrodes. EMG data were rectified, filtered, and normalized to maximum effort. The elbow joint moment was simultaneously recorded.

A self-organizing map (SOM) is a type of neural network for pattern classification. A description and the SOM algorithm may be found in Haykin (1999). Suppose that we have a cloud of data in an n -dimensional space and we would like to represent that data in a two-dimensional space with minimum information loss. Whereas the PCA algorithm can at best fit a hyperplane to the data, a two-dimensional SOM will represent the data with a optimal nonlinear hypersurface.

Each trial consisted of isometric flexion followed by immediate isometric extension at various flexion angles. 10×10 SOM grids were trained on individual trials using only EMG (no moment data).

RESULTS AND DISCUSSION

It has been previously reported that EMG data from multiple muscles can be adequately represented with fewer parameters than an EMG signal from each muscle (Weijis, 1999). For our tasks consisting only of elbow flexion and extension, the EMG from the eight elbow muscles studied could be adequately represented in two dimensions. After a SOM has been trained on the EMG data, the two parameters necessary to define the EMG data are the horizontal and vertical position on the SOM grid. Let z_1 denote the horizontal position and z_2 denote the vertical position. We used these two parameters alone to reconstruct the EMG signal for all eight muscles. Figure 1

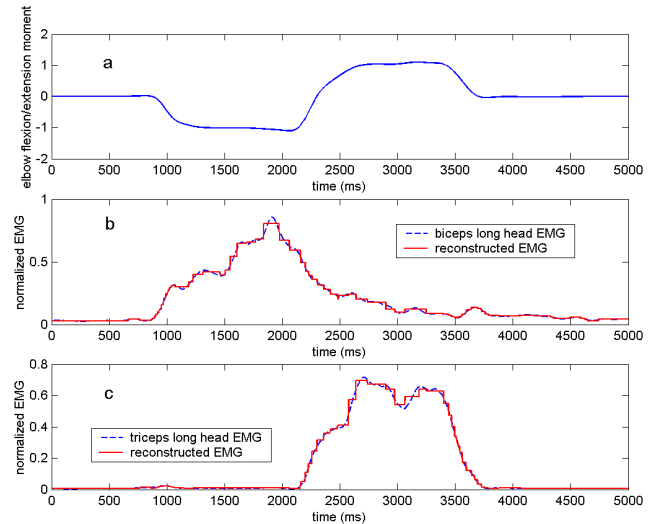

FIGURE 1: *a) The elbow flexion/extension moment in arbitrary units. b) The original and reconstructed biceps long head EMG from this trial. c) The original and reconstructed for the triceps long head EMG.*

shows the results from a sample trial.

We found that even by using a relatively low resolution SOM, better than 96% of the EMG data from the eight muscles controlling this task could be found on a two-dimensional nonlinear surface.

SUMMARY

Eight-dimensional EMG data from the human elbow during flexion and extension can be represented by only two parameters, z_1 and z_2 , which specify a position on a two-dimensional SOM. These results suggest that the CNS need only know two parameters to control the activation of the eight muscles involved in this task.

BIOMECHANICAL MODELING OF INDENTATION TESTING AND APPLICATION IN PLANTAR PRESSURE PREDICTION OF DIABETIC FOOT

Dequan Zou¹, Michael J. Mueller¹, Kirk Smith², Mary Hastings¹ and Joseph W. Klaesner¹

¹Program in Physical Therapy, Washington University School of Medicine, St. Louis, MO, USA, Email: zoud@msnotes.wustl.edu

²Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, MO, USA

INTRODUCTION

Accurate modeling of soft tissue behavior on the plantar surface of the foot is essential for the prevention and treatment of many foot disorders, such as foot ulcerations in the patients with diabetes. In the present study, a mathematical model of soft tissue mechanical properties was used to model indentation testing on the plantar surface of the foot. The modeling of in vivo indentation testing provides the mechanical properties needed in the finite element analysis (FEA) of the foot.

METHODS

The indenter device combines a load cell, a three-dimensional (3-D) measurement device and a cylindrical stylus with a diameter of 7.9 mm (Klaesner, et al., 2001). The force, displacement measurement from indenter device and timing are collected at 40Hz on a notebook computer via analog-to-digital converter (ADC) and communication ports. The structure and geometry of the bones and soft tissues were measured using three-dimensional spiral x-ray computed tomography (SXCT) imaging method. A two-term Mooney-Rivlin model was used to describe the in vivo biomechanical characteristics of the plantar soft tissue. The strain energy (W) is expressed as a function of principal stretches (λ):

$$W = C_1(\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) + C_2\left(\frac{1}{\lambda_1^2} + \frac{1}{\lambda_2^2} + \frac{1}{\lambda_3^2} - 3\right)$$

For the indentation test, the uniaxial stress per unit undeformed area (p) is given as:

$$p = 2\left(\lambda^2 - \frac{1}{\lambda}\right)\left(C_1 + \frac{C_2}{\lambda}\right)$$

The stress-strain data from the indentation testing on the plantar soft tissue of foot was used to solve for the constants (C_1 and C_2) in the Mooney-Rivlin model. The above material model was used in the FEA to predict the pressure and deformation on the plantar surface of the foot. Three diabetic patients with a history of ulcers on the plantar surface of the foot and three control subjects that were matched for age, gender and body mass index (BMI) (Table 1) were modeled. The geometry data points defining the skin surface and bony contours were extracted from the SXCT images and used to create the models in the ALGOR FEA software (Algor Inc., Pittsburgh, PA). A nonlinear analysis was performed to model the in vivo behavior of the tissue and the contact interaction between the foot and the floor. Peak plantar pressures were collected using the F-Scan system (Software v.4.21, Tekscan, Boston, MA). Tissue and bone structure data from the SXCT

measurement provided boundary conditions for the FEA modeling.

Table 1: Age, gender and BMI for subjects

Subject #	Group	Age	Gender	BMI
15	DP	40	M	25.3
30	Control	43	M	24.8
17	DP	80	F	36.6
27	Control	66	F	35.5
36	DP	58	M	38.9
35	Control	44	M	32.3

RESULTS AND DISCUSSION

The stress-strain relation from the indentation measurement was applied in nonlinear 2-dimensional FEA modeling to predict the contact pressure on the plantar surface of foot. Table 2 shows the calculated peak contact pressure and measured peak contact pressure under the second metatarsal head. Good agreements have been observed between the predicted and measured pressure distribution on the plantar surface of the foot.

Table 2: Calculated and measured peak pressure

Subject #	Pressure (kPa) (measured)	Pressure (kPa) (FEA)	Error (%)
15	200.0	218.9	9.5
30	227.0	221.0	2.6
17	303.4	299.4	1.2
27	229.5	251.7	9.7
36	193.1	185.6	3.9
35	206.9	199.3	3.7

SUMMARY

The plantar surface contact pressure prediction results show that the in vivo biomechanical characteristics of the soft tissue from the indentation test may be applied to the FEA modeling of the plantar soft tissue of foot with reasonable accuracy (max. error <10% and avg. error = 5.1%).

MATHEMATICALLY MODELING GROWTH AND REMODELING OF SOFT TISSUES AND MECHANOCYTES

J.D. Humphrey

Department of Biomedical Engineering, Texas A&M University, College Station TX

INTRODUCTION

Diverse research over the past two decades has revealed the ubiquitous role of mechanical factors in controlling structure and function in many types of cells, which are collectively referred to as mechanocytes. Although specific mechanisms of mechanotransduction remain known, it is clear that changes in mechanical stimuli change cell orientation and cytoskeletal structure, cell spreading, migration, contraction, differentiation, proliferation, hypertrophy, and apoptosis, as well as cellular production of many molecules, including surface receptors, adhesion molecules, cytokines, growth factors, proteinases, and vasoactive molecules. Hence, mechanosensitive changes in cellular activity regulate the extracellular matrix, and thus tissue-level responses such as development, tissue maintenance, wound healing, and pathogenesis.

Many different approaches have been suggested for quantifying tissue and cell level mechanics, including growth and remodeling (see Taber, 1995; Cowin and Humphrey, 2000; Zhu et al, 2000; Humphrey, 2002). Herein, it is suggested that a new continuum approach may apply to both cytoskeletal (CSK) and extracellular (ECM) growth and remodeling (G&R) and offer some advantages over other methods.

MATHEMATICAL FRAMEWORK

Connective tissues and cytoskeleton consist of a multitude of important constituents, including primary structural elements such as type I collagen, muscle and elastin or intermediate filaments, actin and microtubules as well as supporting water, proteoglycans, and accessory proteins such as actinin. Because the interactions between solid constituents have yet to be quantified, it may be sufficient under many circumstances to model the ECM or CSK as a solid-fluid mixture wherein the solid is further modeled as a constrained mixture of the structurally dominant solid constituents. For simplicity here, however, let us consider cases where solid-fluid interactions are secondary. Following Humphrey and Rajagopal (2002), let the total (mixture) Cauchy stress \mathbf{t} be

$$\mathbf{t} = -p\mathbf{I} + \phi^f 2\mu\mathbf{D} + \frac{1}{\rho} \sum \frac{1}{\det \mathbf{F}_\kappa^j} \int_{-\infty}^t m_\alpha^j S^j(\tau) \mathbf{f}_\kappa^j(\mathbf{F}_\kappa) \det \mathbf{F}_\kappa^j d\tau$$

where p enforces incompressible behavior, ϕ^j denotes mass fractions for each constituent j , \mathbf{D} and \mathbf{F} are the stretching and deformation gradient tensors, respectively, $\kappa \equiv \kappa_n$ denotes the natural configuration, which may evolve with G&R, and \mathbf{f}^j is the stress response for each j . Finally, m_α is a mass production rate (to be determined via full mixture equations for mass balance) and S^j is a survival function that defines the life-span

of each constituent that is produced over time. Finally, note that superscripts f denote fluid, u a constituent that does not turnover rapidly (e.g., elastin, intermediate filaments), and $j=1,2$ represents constituents that do turnover, such as collagen and muscle or microtubules or actin for the ECM and CSK. Full details are in Humphrey and Rajagopal. The take-home message is that by using a rule-of-mixtures relation for the stress in the solid constituents, we can account for time varying natural configurations and material symmetry while avoiding complex issues with regard to partial tractions on the boundaries (i.e., standard linear momentum applies). Fundamental to implementing this approach, however, are kinetic equations for the mass production and survival as well as how the natural configurations change for each constituent – each nontrivial to find. One role of theory, however, is to identify quantities that must be measured.

CONCLUSIONS

Despite an extensive literature, and copious *observations* of diverse cell responses to a wide variety of applied loads (e.g., via atomic force microscopy, cell poking, magnetic bead cytometry, micropipet aspiration, cell stretching, imposed fluid-induced shear stresses), there is clearly a need for new theoretical frameworks to motivate the design of stringent *experiments* to test competing hypotheses and theories.

A STUDY OF PASSIVE REPEATEDLY PLYOMETRIC METHOD FOR TRAINING UPPER ARM'S STRENGTH AND POWER

Wei-Hua Ho¹, Hong-Chang Ho², Tzyy-Yuang Shiang², Chuan-Show Chen³

¹Tzu-Chi University, Hualien, Taiwan, afa@mail.tcu.edu.tw

²National College of Physical Education and Sport, Taoyuang, Taiwan

³National Taiwan College of Physical Education, Taichung, Taiwan

INTRODUCTION

Strength and power are important factors in sport competition, and various training methods have been proved to be helpful for athletes (Poprawski, B. 1987). But sport scientists and coaches are still looking for the most efficient method of training strength and power. In order to train muscle power, the function of reflex stretch and phenomenon of stretch-shortening-cycle in neuromuscular system (Komi, P.V. 1984). Furthermore, we were used to design Passive Repeated Plyometric training machine. The purpose of this study was to compare the strength and power trained by traditional weight training and Passive Repeatedly Plyometric (PRP) training method.

METHODS

There were 12 health male subjects divided into 2 groups randomly. The mean age, height and body mass of subjects were 20(\pm 2.2)years, 173.2(\pm 4.7)cm and 71.2(\pm 5.3)kg, respectively. The experimental group was trained by the Passive Repeated Plyometric training machine. The control group used the traditional isotonic weight training method. The training period was 6 weeks, and the training effects were compared by testing bench press and shot-put throwing pre-training and post-training. Average values were considered significantly different at $P < 0.05$.

RESULTS AND DISCUSSION

The pre-training and post-training maximum muscle strength were 85.00(\pm 7.07) kg and 102.50(\pm 12.14) kg for experimental group. The pre-training and post-training muscle power (shot-put throwing) were 4.85(\pm 0.62) m and 5.51(\pm 0.71) m for experimental group. The training effect on maximum strength muscle improved the percentage of experimental group and control group were 20.39(\pm 7.19)% and 15.71(\pm 7.95)%. The training effect on muscle power improved the percentage of were 13.59 (\pm 4.79)% and 6.12 (\pm 6.34)% for experimental group and control group. The statistical results were analyzed by repeated measurement t-test and summarized as followed. The maximum muscle strength were significantly improved

after 6 weeks training for both experimental group and control group. But only the experimental group improved the muscle power significantly. By comparing the training effect between experimental and control groups, the muscle power training effect of experimental group is significantly better than control group.

Figure: To compare with the strength and power by traditional (control group) and PRP (experiment group) training method during 6 weeks.

SUMMARY

The results suggested that a good training method should be used to enhance the training effect. PRP training method is not only a good approach to train muscle strength, but also a great method to train muscle power. Further attention should be focus on the EMG analysis to thoroughly understand the mechanism of this training method, and compare with other training approaches.

ACCURACY AND RELIABILITY OF Q ANGLE MEASUREMENT METHODS

Ian C. Cooper¹, Michael J. Agnew¹, Shannon M. Mahar², and Lori A. Livingston^{1,2}

¹Dept. of Kinesiology and Physical Education, Wilfrid Laurier University, Waterloo, Ontario, Canada

²School of Health and Human Performance, Dalhousie University, Halifax, Nova Scotia, Canada, Lori.Livingston@Dal.ca

INTRODUCTION

The reliability and accuracy of measurement methods must be known if they are to be used in clinical decision-making (Batterham et al., 2000; Brosseau et al., 2001; George et al., 2000). Manual goniometric methods yield reliable (e.g., Byl et al., 2000; Lathinghouse et al., 2000) but not necessarily accurate (France et al., 2001) estimates of the frontal plane Q angle. The purpose of this investigation was to assess the accuracy and reliability of two video-based techniques to identify an improved Q angle measurement method that is both cost- and time-effective.

METHODS

A calibration jig was constructed by attaching a full circle goniometer with 1° increments to two rigid bars. Markers (flat circular adhesive or spherical reflective, 1.25 cm diameter) were affixed to the jig to represent the bony landmarks of the Q angle (Figure 1). One investigator captured video images of ten Q angles of known magnitude for each type of marker. Two other investigators (Testers 1, 2) measured the Q angles by (1) applying a universal goniometer to single-frame hard copy video printouts of the adhesive markers on the jig, and (2) using a PEAK Motus© software/computer system.

Figure 1. Diagram of the calibration jig showing the embedded goniometer and the three markers used to define the Q angle.

The two types of markers were then affixed by Testers 1 and 2, during separate sessions, to the right ASIS, MP, and MT of 27 young adults. Images were captured on videotape and Q angles were determined using the methods previously described. Before leaving the lab, Q angles for each individual were also measured using manual goniometric techniques.

Two-way ANOVA procedures determined where significant differences, if any, in measured Q angles existed between testers and methods, while intraclass correlation coefficients (ICC[2,1]) were used to assess the accuracy and intertester reliability of the video-based measurement methods.

RESULTS AND DISCUSSION

The ICC[2,1] values (Table 1) indicate that the measurement accuracy of the video goniometry and PEAK Motus© measurement methods is excellent, while intertester reliabilities range from good (0.68) to excellent (>0.75) (Fleiss, 1986).

Table 1: ICC[2,1] for measurement accuracy and intertester reliability.

	Manual Goniometry	Video Goniometry	PEAK Motus©
Accuracy			
Tester 1 vs Jig		0.96	0.79
Tester 2 vs Jig		0.92	0.92
Reliability (Tester 1 vs 2)			
Jig		0.98	0.88
Young adults	0.81	0.79	0.68

Depending upon the method of measurement utilized, mean Q angle values derived from the young adult sample ranged from 9.0°±8.7 to 12.6°±7.2 for Tester 1 to 11.7°±8.4 to 13.0°±6.9 for Tester 2. In both instances, video goniometry yielded the lowest values while manual goniometry yielded the highest values. For both testers, the mean values obtained via the video goniometric and PEAK Motus© methods varied by about 1°. Statistically significant differences in values between testers or methods, or interaction effects, were not observed.

SUMMARY

The video goniometry method of Q angle measurement is both accurate and reliable. Although more expensive than manual goniometry, it provides a time- and cost-effective method of measurement with known accuracy and reliability characteristics that rival more sophisticated computer-based measurement systems.

IS ACTIVE FORCE PRODUCTION OF SKELETAL MUSCLES ALTERED BY COLLAGEN CONTENT?

Mark E.T. Willems, G. Roger Miller and William T. Stauber
Department of Physiology & Pharmacology, West Virginia University,
Morgantown, WV, USA, mwillems@hsc.wvu.edu

INTRODUCTION

Connective tissue of contracting skeletal muscle-tendon complex is involved in lateral (Huijing et al, 1998) and longitudinal force transmission (Patel and Lieber, 1997). Collagen content of skeletal muscles can be altered by exercise training and aging (Kovanen et al, 1987). In this study, we used a rat model of repeated muscle strains that does not lead to increases in muscle mass (Wong and Booth, 1990) to examine the effect of altered collagen content on active muscle force.

METHODS

Female Sprague Dawley rats (4-5 mo) were exposed to repeated stretch-shorten contractions (5x10 repetitions, 5 d/wk for 6 wk) by manually applied ankle rotations between about 140° and 40° with subcutaneous electrical stimulation (70 Hz, 20-40 V, 0.2 ms pulse duration). Functional testing was performed with tibial nerve stimulation (supramaximal voltage, 0.2 ms pulse duration) with frequencies between 5 and 120 Hz. Force of the plantar flexor muscles was recorded as a reaction force under the sole of the foot with knee and ankle held at 90° (Cutlip et al, 1997). For plantar flexor muscles and Achilles tendon, we examined collagen content (hydroxyproline) and collagen cross-links (pyridinoline) using high performance liquid chromatography. Data were analyzed with Student's t test (two-tailed, $P < 0.05$) and presented as mean \pm sem.

RESULTS AND DISCUSSION

Weights of plantar flexor muscles remained unaltered [repeated muscle strains: 2114 ± 36 mg ($n = 15$); control: 2182 ± 28 mg ($n = 17$)]. Significant increases in collagen content were found in gastrocnemius medialis (30.9%) ($P = 0.019$, $n = 7$), plantaris (32.3%) ($P = 0.006$, $n = 7$), soleus (27.6%) ($P = 0.039$, $n = 7$), and Achilles tendon (3.3%) ($P = 0.014$, $n = 7$). No changes were observed for collagen cross-links. Six weeks of muscle strains increased the isometric force only at high stimulation frequencies [at 80 Hz by 21% ($n = 10$, $P = 0.046$), at 100 Hz by 23% ($n = 10$, $P = 0.030$) and at 120 Hz by 22% ($n = 10$, $P = 0.032$)] (Fig. 1). An increase in isometric force in the absence of a change in muscle mass could be due to the following factors: 1) an increased number of cross-bridges (i.e. greater forces) per cross-sectional area or 2) a shift in fiber type from low force generating slow-twitch muscle fibers to high force generating fast-twitch muscle fibers. Any of these factors would have resulted in force increases at all stimulation

frequencies which was not the case. Increased maximal isometric force resulting from an increase in collagen content of individual plantar flexor muscles and Achilles tendon has not been reported. The mechanism of altered active force production by increased collagen content only at high stimulation frequencies remains undetermined.

Figure 1: Force-frequency relationship of rat plantar flexor muscle-tendon complex with normal and increased collagen content.

SUMMARY

Repeated muscle strains for a period of 6 weeks which increased the collagen content of skeletal muscles and Achilles tendon of rats was associated with an increase in isometric force production only at high stimulation frequencies.

COMPENSATORY IMPULSE GENERATION BY INDIVIDUALS WITH A UNILATERAL BELOW-KNEE AMPUTATION DURING GAIT INITIATION

Craig D. Tokuno¹, David J. Sanderson², J. Timothy Inglis³

UBC Biomechanics Laboratory, University of British Columbia, Vancouver, British Columbia, Canada

¹tokuno@interchange.ubc.ca; ²david.sanderson@ubc.ca; ³tinglis@interchange.ubc.ca

INTRODUCTION

Gait initiation, the transition from quiet stance to steady state gait, requires the unequal generation of forward propulsion from the two lower limbs. The initial stepping, or *lead*, limb generates a peak force of 7% of body weight (BW), while the non-stepping, or *trail*, limb, produces two slightly greater bursts, first in the magnitude of 14% BW, followed by another of 22% BW (Nissan and Whittle, 1990).

For individuals with a unilateral below-knee amputation (BKA), this asymmetrical requirement can be a concern as there are known propulsion deficiencies with the prosthetic limb (Sanderson and Martin, 1997). Because the magnitude of this effect will differ depending upon the role of each limb, it was hypothesized that individuals with a unilateral BK amputation would require distinct movement compensations depending upon the choice of leading limb.

METHODS

Eleven individuals (8 males, 3 females; mean age=44±14) with a unilateral BKA, and 11 age and gender matched controls (8 males, 3 females; mean age=45±12) were recruited for this study. Subjects began each trial by standing with each foot on a separate force platform (Bertec model 4060). After the presentation of a visual stimulus, they were required to initiate gait at their preferred step length. The choice of stepping limb was randomly established by the visual cue. Fourteen trials were completed by each subject, with half of the trials starting with the right leg, the other half leading with the left.

Horizontal impulse values were calculated from the leading and trailing limbs. The starting frame was the start of sway (>4 mm shift from the baseline center of pressure), and the ending frame was the initial toe-off for each particular limb. The two impulses (e.g. impulse from a left lead plus that from a right trail) were then summed to determine the total impulse applied for each trial.

RESULTS AND DISCUSSION

It was found that amputees were concerned with the duration of force application, as they took a significantly longer time to reach the initial toe-off phase ($p<0.001$) (Figure 1A and 1B). The magnitude of peak force was not modulated by the intact limb, as it did not show a significant increase compared to the control conditions. The prosthetic limb did however apply a significantly smaller amount of peak force due to the loss of ankle musculature ($p<0.007$) (Figure 1A and 1B).

To make up for the smaller impulse generated by the prosthetic limb, it was found that regardless of whether it was used as the leading or trailing leg, the intact limb had compensated by significantly increasing its magnitude of impulse generation ($p<0.003$) (Figure 1C). The extent of this compensation was sufficient such that the summed (intact + prosthetic) impulse became comparable to the control conditions.

SUMMARY

Individuals with a unilateral BKA compensated for the limitations of the prosthetic limb by increasing the amount of impulse applied by the intact leg. This was accomplished by altering the duration of force application, without changing the peak force. This strategy was used during gait initiation as the task did require immediate movement. Whether this same strategy is used during perturbations that require immediate stepping deserves further investigation.

INTRODUCTION

Study of Blood flow in the vicinity of moving boundaries is widely applicable to various problems in biofluid dynamic. In the present investigation a two-dimensional numerical model of a pneumatic driven VAD is generated, introducing a computational approach for modeling the interaction between moving diaphragm and fluid flow.

NUMERICAL MODELING

The proposed VAD design was made available by the T. Giken Co. In the present study heart valves effect is ignored. The diaphragm thickness is considered infinitesimal and its surface is assumed smooth, uniform and differentiable. Large displacement of the diaphragm results in arising non-linear terms in the equation of motion. The diaphragm is assumed homogen and hyperelastic. Consequently, Hamilton's principle is introduced as governing equation of motion and FEM is used for solving the resulting set of equations.

Blood flow is considered Newtonian, turbulence appearance is ignored and air is considered incompressible. Set of unsteady Navier-Stokes equations governs the behavior of fluid flow, which is solved employing consistent penalty method. Two-dimensional fluid dynamic in a stenosed channel is numerically investigated during physiological pulsation to validate the generated code.

In order to model the interaction between diaphragm and fluid flow at each physical time step, the pressure of the fluid elements, located in the vicinity of the diaphragm, is applied to the diaphragm to determine the diaphragm movement at the subsequent physical time step. The movement of the diaphragm is also imposed to the computational fluid domain as moving boundary condition to compute the behavior of the blood and air flow fields (figure 1).

RESULTS

Performance characteristics of the numerical model of VAD are carried out, which show satisfactory agreement with the obtained results from similar experimental studies and improve the reliability of the computational model (Figure 2). Numerical experiences show that the blood flow regime is usually laminar due to its pulsating nature. Furthermore, during systole phase the shear rate of blood flow is high enough to make the blood behave as a Newtonian fluid whereas during diastole phase some regions with low shear rates are observed in which the blood flow is non-Newtonian.

Figure 1: Numerical modeling of interaction between fluid flow and diaphragm movement.

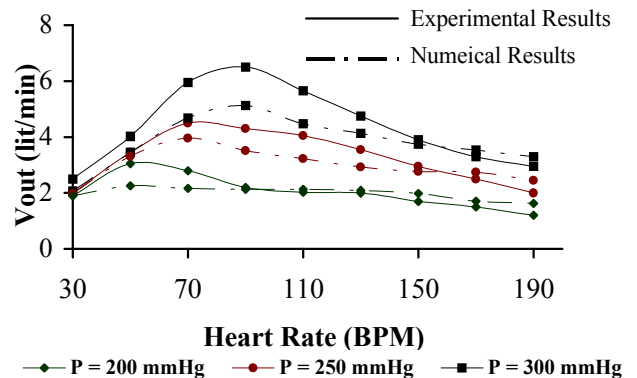

Figure 2: Functional characteristics of numerical model of VAD in comparison with experimental investigation results.

SUMMARY

In this investigation, the interaction of a pulsating blood flow and a moving boundary is well defined and validated, which can be widely applicable to many problems in hemodynamics, such as modeling the blood flow through the arteries, natural heart and any VAD or TAH containing moving boundaries. Furthermore, the computational model of VAD can be easily extended to a 3-D model for more exact results.

RELATIONS BETWEEN BONE ADAPTATION AND LOADING FORCES ASSOCIATED WITH A NOVEL OSTEOPOROSIS INTERVENTION PROGRAM

Man-Ying Wang and George J. Salem

INTRODUCTION

Bone responds to mechanical loadings that are dynamic, of a high magnitude, of a high loading rate, and exhibit an unusual strain distribution in nature (Chilibeck, 1995). To investigate the relations between external loading characteristics and bone adaptation in humans, we developed an upper extremity dynamic impact-loading model (Wang, 2001). The model is an attempt to provide a practical and accessible osteoporosis prevention program, Dynamic Impact Loading Exercise (DILE), while allowing investigators to characterize potential osteogenic loading stimuli. This paper reports the relations between upper extremity reaction forces and bone adaptations after performing DILE for 6 months.

METHODS

Twenty-four healthy adults (mean age = 29 ± 6 yrs) performed DILE 36 cycles a day, 3 days a week, for a total of 24 weeks. The exercised arm was allocated randomly to either the dominant side or the non-dominant side. In addition, subjects were randomly assigned into either damped loading or non-damped loading treatment arms in order to examine the effects of different loading histories on forearm bone mass. In the damped loading group, subjects performed the DILE on the wall covered with a foam pad. Bone mineral density (BMD), bone mineral content (BMC) and bone cross-sectional area (CSA) at the distal third radius (DR), ultra-distal radius (UD), the area between DR and UD (MID), and total distal 1/3 of radius (Total) were measured on each subject using dual-energy X-ray absorptiometry (DEXA, Hologic QDR1500, Waltham, MA, USA) at the baseline and after 6 months. Subjects were also required to perform 3 loading trials to obtain reaction forces associated with the exercise at the baseline and after 6 months. Reaction forces perpendicular to the wall, including peak loads, peak loading rates, and loading impulse (area under the load/time curve; AUC), were collected by a wall mounted force platform (AMTI, Watertown, MA). Data processing software including Vicon Reporter (Oxford Metrics, Oxford, UK) and Peak Fit (SPSS Inc., Chicago, IL, USA) were used to analyze the reaction forces. Two-tailed Pearson's correlation analyses were employed to investigate the relations between the changes in radial bone mass after 6-month intervention and reaction forces including peak loads, peak loading rates, and AUC.

RESULTS AND DISCUSSION

Table 1 shows the loading forces associated with DILE in the damped and non-damped conditions. Peak loads ($p = 0.28$) and peak loading rates ($p = 0.40$) did not significantly differ between groups because of the large variation among subjects. Statistically significant correlations were not observed between the loading parameters and bone measurements in the *damped* loading group except for a modest correlation between changes in UDBMC and peak loads ($r = .65$, $p < .05$). In the *non-damped* loading group, peak loads during DILE were positively correlated to BMD changes at DR ($r = .73$, $p < .05$), MID ($r = .75$, $p < .05$), and Total ($r = .82$, $p < .01$); and negatively correlated to Total CSA ($r = -.68$, $p < .05$). Moreover, there were positive correlations between the energy absorbed by the radius (AUC) and DRBMC ($r = .65$, $p < .05$), MIDBMD ($r = .76$, $p < .05$), and Total BMD ($r = .75$, $p < .05$), but a negative relation between AUC and UDBMC ($r = -.80$, $p < .01$). No correlations between peak loading *rates* and bone changes were found. These results suggest that the relations between the loading forces and bone changes differed between the two distinct loading programs. In general, bone mass changes in the non-damped loading group were correlated to the peak loads and AUC; whereas, bone mass changes in the damped loading group were independent of loading magnitude. Nevertheless, because the relations varied among the different bone measurement sites, further examination is required to determine the longer-term effects of DILE on bone mass changes and to define the threshold for DILE induced osteogenesis.

SUMMARY

Investigations examining the relations between mechanical loading events and bone adaptation have traditionally used animal models. The upper extremity DILE model was developed to help bridge the gap between the animal and human studies. We found that loading forces associated with the DILE were highly correlated with the bone changes in the non-damped condition. Further analysis is required to identify the optimal mechanical loading factors for osteogenesis.

BIOMECHANICAL DIRECTIONS FOR THE POST-SURGICAL RECOVERY OF THE ACL

Dario Santos and Gabriel Fabrica

Facultad de Ciencias, Universidad de la República, Montevideo, Uruguay. biomec@fcien.edu.uy

INTRODUCTION

The anterior cruciate ligament (ACL) is one of the features of the knee that is most frequently injured (Insall, 1995). One element to take into account during the post-surgical recovery is the tone of the quadriceps muscle. The action of this muscular group is risky for the ACL, as one component of the muscular force tends to move the tibia forwards in regard to the femur, yielding stress on the ACL (Kapandji, 1987). The aim of this paper is to develop a tool that permits to control stress on the ACL during the isometric exercises of the quadriceps for any knee angle.

METHODS

The sample was composed by eight male individuals, which ages ranged from 18 to 35 years. Height, body mass and leg length was recorded for each individual. Strictly profiled X-ray were taken at different knee angles. On each X ray picture, an axis system and the line of action of the patellar ligament were drawn, to determine the lever arm of the quadriceps (F_q). Such moment is given by $T = F_q (d_2 \text{ sen } \phi)$, where ϕ is the angle of action of the patellar ligament.

To determine the stress of the ACL, a system in static condition was considered, composed by leg, foot and added mass. A free body diagram was drawn (Figure 1), considering two external forces, F_q and weight (W). The masses of the segments were determined after regression equations (Zatsiorsky, 1998). Through inverted dynamics, it was determined the place on the leg where a mass should be added to achieve a preset stress on the ACL. Data obtained were processed using Matlab 5.3 and ANCOVA analysis was performed.

RESULTS AND DISCUSSION

Stress on the ACL was controlled by equalising the moment arm of the weight of the system (d_1) with the moment arm of the weight of the system, $F_q (R/\text{Sen}\phi)$.

Significant differences were found in the value of ϕ at different knee angles in individuals of similar anthropometric features. Those differences are associated to the form and position of the patella in regard to the femoral condyles.

Therefore, it is concluded that ϕ is a fundamental variable to choose the place and modulus of the added mass during the quadriceps isometric exercises to control stress on the ACL.

Free body diagram

Figure 1

SUMMARY

In this paper, a biomechanical model is proposed, that optimises the rehabilitation of the knee's anterior cruciate ligament. (ACL). By using a simple model, an equation was obtained, that allows to establish the point where a determined mass has to be put to make the ACL to withstand a pre-set stress at any angle. This constitutes a fundamental tool during the recovery, as the model includes anthropometric features of the patient as well as physical elements. The considered system includes leg, foot and an added mass. Two external forces, the one exerted by the cuadriceps (F_q) and the weight (W). The analysis was carried out in two dimensions. The origin of the axis system was set on a point on the articular surfaces of the inner femoral condyle, in such a way that the model's X axis corresponds with the geometrical axis of the tibia at any angle of knee flexion. To calculate the mass of the body segments regression equations were used. The variables were obtained through direct measurements on strictly profiled X-ray photographs. The obtained data was used for calculations from the ecuations derived from the model. The conclusions drawn give new and more accurate criteria for the first recovery stages.

ON THE ROLE OF INTRAMURAL STRESS AND STRAIN IN THE RESTENOSIS OF FEMORAL ARTERY BYPASS GRAFTS

Reena Cole¹, Mark Davies¹ and Pierce Grace²

¹Stokes Research Institute, Mechanical and Aeronautical Engineering Department,
University of Limerick, Limerick, Ireland; reena.cole@ul.ie

²Vascular Surgery Department, Mid Western Regional Hospital, Limerick, Ireland

INTRODUCTION

The cause of stenoses in bypass grafts is as yet unknown, but smooth muscle proliferation and intimal thickening appear to play a major role in the failure of vascular reconstructions. In synthetic grafts significant intimal thickening develops at the anastomosis or just beyond in the distal vessels and usually appears within 2 years of reconstruction [Echave *et al.* (1979), LoGerfo *et al.* (1983)]. The seriousness of this problem is reflected in the very poor patency rates reported for infrapopliteal reconstructions using synthetic grafts: 14% vs. 67% for autologous vein at 5 years (Whittmore, 1995).

Most research into the mechanism of intimal thickening comes from animal and cell culture studies and various biological factors – such as vasoactive, pro-thrombotic and growth factors from platelets – have been identified as important in promoting endothelial cell growth and smooth muscle proliferation [Jawien and Clowes (1991), Malek and Izumo (1995)]. Perktold and Resch (1990) and Friedman (1993) state that atherosclerosis appears to show predilection for more complex regions of the vasculature such as branch regions, which leads to the conclusion that when an artificial branch or bifurcation is introduced, by the addition of a graft bypass, that there will also be a tendency for restenosis. Factors which have been cited as possible reasons for restenosis include: surgical injury, anastomotic angle, material mismatch, wall shear stresses, suture line stresses, and more recently intramural stresses.

There has been much investigation into the effects of fluid dynamics on restenosis, most specifically the effect of wall shear stress. However there are conflicting theories in the literature as to whether it is high [Fry (1968), Caro *et al.* (1969)] or low [Ku *et al.* (1985), LoGerfo *et al.* (1981)] wall shear stress that is to blame. A more recent hypothesis (Nazemi *et al.*, 1990), suggests that low wall shear stress contributes to the onset of atherosclerotic plaque formation, with high wall shear stress encouraging plaque growth. Due to the contradictory nature of the wall shear stress theories, other possible factors are being investigated, with one area of interest being the role of mechanical stress and strain in atherogenesis.

Thubrikar and Robicsek (1995, 1997) among others [Thubrikar *et al.* (1990), Perktold and Rappitsch (1995), Salzar *et al.* (1995) and Moore *et al.* (2001)] contend that it is blood pressure induced arterial wall stress that is the principal factor in the localisation of the atherosclerosis in naturally occurring bifurcations in the arterial system. Indeed Roberts

(1975) reported that a reduction in mean blood pressure leads to a reduction in mortality.

RESULTS AND DISCUSSION

Initial *in vitro* experiments were made using a model femoral artery and bypass graft, inflated to match a peak systolic pressure of 150mmHg. Images were taken, using a CCD camera, and this allowed strain to be measured.

Using thick shell theory the circumferential stress (σ_H) and longitudinal stress (σ_L) were calculated to be 4.90×10^4 and $1.45 \times 10^4 \text{ Nm}^{-2}$ respectively. These values are of a magnitude 10,000 greater than the mean wall shear stress in an adult male, found to be $1.3 \pm 0.3 \text{ Nm}^{-2}$ by Samijo *et al.* (1997).

These results show that the intramural stress and strain are also an important factor in the restenosis of femoral artery bypass grafts. Further work will involve the measurement of intramural strain *in vivo* using video extensometry and duplex ultrasound.

LONG-TERM SIMULATOR WEAR STUDY OF SURFACE ENGINEERED MOM HIP PROSTHESES

John Fisher¹, Xiao Q Hu¹, Sophie Williams¹, Joanne L Tipper¹, Eileen Ingham¹, Martin H Stone¹, Peter Hatto², Graham Berry³, Cath Hardaker⁴ and Graham Isaac⁴

¹School of Mechanical Engineering, University of Leeds, Leeds LS2 9JT, UK, j.fisher@leeds.ac.uk;

INTRODUCTION

Polyethylene wear debris-induced osteolysis has led to the re-emergence of clinical interest in metal-on-metal (MOM) hip prostheses. Despite the low wear rates of MOM prostheses, the release and toxicity of metal wear particles and metal ions from corrosion and wear remains a concern. In this study, thick (8-12 μm) surface coatings were investigated with the aim of improving the wear resistance and producing fewer and less toxic wear particles in MOM hip prostheses.

METHODS AND MATERIALS

Twenty eight millimetre diameter MOM hip prostheses were coated (IonBond Ltd., UK) in this study. Four different articulations of heads and inserts, which included CrN v. CrN, CrCN v. CrCN, CrN v. TiN (fully coated) and CrN v. high carbon (HC) CoCrMo (half coated), were tested for 5 million cycles in 25% (v/v) new born bovine serum using a physiological anatomical hip joint simulator (Barbour *et al.* 1999, Firkins *et al.* 2001) and compared to a clinically used MOM bearing couple. Three to five pairs of each bearing couple were studied. Heads and inserts were polished after coating to a surface finish $R_a < 0.03 \mu\text{m}$. The average volume loss and wear rate was determined gravimetrically from both components for each type of prosthesis.

Metal ion levels in the serum lubricants after the first 0.33 million cycles of the wear test were analysed by atomic absorption spectrometry (AAS, Varian Inc., Surrey, UK). Prior to measurement, the samples were centrifuged at 2000 g for 1 hour to remove the wear debris, and the clear supernatant was used for analysis. Ion levels were determined by the mean of three measurements.

Wear particles were characterised from the serum collected during hip simulator testing at 0.33, 1 and 2 million cycles by transmission electron microscopy (TEM) as described by Tipper *et al.* (1999). The cytotoxicity of CoCrMo, CrN, CrCN and TiN wear debris produced in a simple geometry model in water was assessed by co-culture with U937 macrophages and L929 fibroblast cells. The effect of the wear debris on cell viability was measured. Data was analysed using one way analysis of variance (ANOVA) and the minimum significant difference between means determined using the T-method.

RESULTS AND DISCUSSION

For the MOM couple (Fig. 1), a high bedding-in wear rate was observed in the first million cycles. The coated combinations, however, experienced no bedding-in period and the wear rates remained constantly low throughout five million cycles. After 5 million cycles testing, the wear of the

Figure 1: Wear rates from different stages over 5 million cycles.

Figure 2: Metal ion levels in the serum lubricants from different prosthesis combinations. *titanium < 1 p.p.m.

three fully coated combinations (CrN v. CrN, CrCN v. CrCN and CrN v. TiN) were at least 38-fold lower compared to the MOM prostheses. The wear of the half coated combination, CrN v. HC, was also at least 13-fold lower. The differences between the wear rates of the surface engineered bearings and MOM prostheses were highly significant (one-way ANOVA and Tukey test, $P < 0.01$). The wear particles produced by all combinations were generally less than 30 nm in size, similar in size to the wear debris from MOM prostheses. The metal ion concentrations in the serum lubricants from the three surface engineered systems were at least 6-fold lower than the MOM controls (Fig 2). The cell-culture studies showed that the wear particles from the fully coated surface engineered bearings were at least 10-fold less toxic than the wear particles produced by MOM bearings. These initial findings support the further development and clinical application of surface engineered MOM bearings.

EFFECT OF BONE GRAFT POSITION ON LOADING OF PEDICLE SCREWS

Antonius Rohlmann, Thomas Zander, Georg Bergmann

Biomechanics Laboratory, University Hospital Benjamin Franklin, Free University of Berlin, Germany, rohlmann@biomechanik.de

INTRODUCTION

After stabilizing a lumbar spine with an internal spinal fixation device pedicle-screw breakage is a common complication. Rohlmann et al [1994] modified the internal spinal fixator after Dick and measured the loads on the implant during many activities. In one of the patients with the telemeterized internal spinal fixation device a pedicle screw broke three months after implantation. The aim of this study was to analyze analytically this unexpected case of pedicle screw breakage.

MATERIAL AND METHODS

Situation that led to a broken pedicle screw

Telemeterized internal spinal fixation devices were implanted in a patient with degenerative instability and a narrow spinal canal in order to measure the fixator loads during daily activities. To realign the lumbar curvature because of wedge-shaped disc space, the motion segments L3-L5 were distracted about 5 mm on the right side. Anterior interbody fusion using bone grafts from the iliac crest was performed three weeks later. The second operation was performed by a minimally invasive microsurgical approach. It involved removing the intervertebral discs L3/4 and L4/5, slightly milling their adjacent vertebral end-plates and inserting the precisely fitted grafts in a ventral position. On removal of the implants three months later, a fatigue fracture was found in the upper right pedicle screw. Unexpectedly, the crack started on the caudal side of the cross-sectional area and progressed cranially [Rohlmann et al. 1998].

Finite element model

Figure 1: Outer mesh of the finite element model of the lumbar spine with internal fixators and two bone grafts in ventral position.

A three-dimensional, nonlinear finite element model of the human lumbar spine with internal fixators and bone grafts was created to simulate the above described situation (Fig. 1). The element mesh of the vertebrae is based on the model used by Smit [1996]. The nucleus pulposus was simulated by an incompressible fluid-filled cavity and the annulus fibrosus by volume elements with superimposed spring elements representing the fibers. The facet joints could only transmit compressive forces. The capsule of the facet joints and the six ligaments of the lumbar spine were included. The material properties of all tissues were taken from the literature. The internal spinal fixators were simulated by beam elements and the bone grafts by volume elements. Both, ventral and dorsal graft positions were

successively simulated. The lower end-plate of the L5 vertebra was fixed and the model was loaded with the body weight and muscle forces representing standing. The finite element model is described in detail elsewhere [Zander et al. 2001].

RESULTS

Figure 2 shows the bending moment in the upper right pedicle screw for standing. When in the finite element model the bone graft position was moved from ventral to dorsal, maximum bending moment within the screw thread (between 17 mm and 52 mm in Fig. 2) changed the sign. Due to the stress concentration factor and a smaller diameter in the threaded part compared to the cylinder-shaped part, the highest stresses are in the threaded part of the Schanz' screw close to the non-threaded part.

Figure 2: Bending moment in the upper right pedicle screw

DISCUSSION

In the finite element model the highest stresses in the screw were calculated exactly where the screw broke *in vivo*. The model also predicted the highest stresses in the threaded part on the caudal side of the cross-sectional area when the graft is in a ventral position. This means, the upper right pedicle screw was loaded as during three point bending [Rohlmann et al. 1998]. A graft placed in the center of the end-plate minimizes the stresses in the pedicle screw and thus the risk of breakage.

ON THE EXISTENCE OF AN OPTIMUM END-TO-SIDE GRAFT/ARTERY JUNCTION GEOMETRY TO INCREASE THE PATENCY RATES OF BYPASS SURGERY

Michael Walsh¹, Tim McGloughlin¹ and Pierce Grace²

¹ Biomedical Engineering Research Centre, M&AE Dept., University of Limerick, Ireland (tim.mcgoughlin@ul.ie)

² Regional Hospital, Dooradoyle, Limerick, Ireland

INTRODUCTION

Hemodynamic flow patterns in distal end-to-side anastomoses are widely implicated in the initiation of the disease formation process, Giddens et al., 1993. The flow patterns created by these graft/artery junctions exert abnormal wall shear stress (WSS) distributions on the endothelial cells (EC) on the bed of the junction, Xiao et al., 1997. The role of WSS in intimal thickening has been the subject of much debate with high WSS, low WSS, WSS gradient, and oscillating WSS theories all being proposed as aetiological factors for anastomotic intimal thickening. All of these theories can be supported by experimental findings and it is possible that each theory has a role to play in the restenosis process. Several surgical techniques exist, including the Taylor Patch and Miller cuff techniques, that use vein cuffs or patches to alter the junction geometry, attempting to improve patency rates of bypass procedures. The flow patterns associated with these surgical approaches can be represented by the angle between the impinging flow and the junction bed, i.e. the Taylor patch creates a lower impinging flow-junction bed angle than the Miller cuff.

MATERIALS AND METHODS

Two idealised geometries, models 1 & 2, were developed to produce different impinging flow-junction bed angles, having angles of 45° and 22.5° respectively. Numerical simulations, using Fluent, a commercially available computational fluid dynamics package, used a non-Newtonian fluid model and time-dependent in-flow boundary conditions. Rigid walls and zero flow in the proximal outflow segment were assumed. The results are presented as distributions of the local gradient in WSS on the junction bed, as described below in equation 1.

$$\tau_g = \left[\frac{d\tau_z}{dz} \right] \frac{\tau_{za}}{r_a} \quad \text{Eq 1}$$

where τ_g = normalised spatial WSS gradient, τ_z = WSS, τ_{za} = average WSS on the bed centreline in the host artery and r_a = average radius of the model.

RESULTS AND DISCUSSION

The normalised WSSG distribution for model 1 can be seen as the navy line in figure 1. The profile of this distribution is significant in that in a healthy idealised artery, the local spatial WSSG is zero. Therefore the deviation from zero of the normalised WSSG distribution in figure 1 represents the areas in the junction bed where the EC experience abnormal WSSGs which could be the initiating factors for the disease formation processes. The red line in figure 2 represents the normalised WSSG distribution for the reduced graft/artery angle of model 2. It can be seen that reducing the graft/artery angle reduces

the peak values of the normalised WSSG distribution and a consequence of this is the increasing of the bed area over which the abnormal WSSG are experienced.

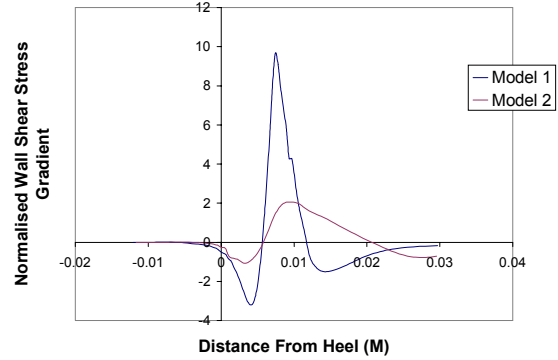

Figure 1 - Normalised WSSG distributions

As a result optimising the graft/artery junction geometry reduces to the simple choice of reducing the peak values in the normalised WSSG distribution or reducing the area over which the normalised WSSG distribution has a non-zero value. Thus, the graft/artery junction can be designed resulting in “optimised” geometries which have characteristics of either a Taylor Patch or Miller Cuff anastomosis. Reported patency rates for the Taylor Patch and Miller cuff techniques include 35% at 3 years, Eagleton et al., 1999, and 38% at 3 years, Kreienberg et al., 2000, respectively. This suggests that the results for each of these techniques are similar to those for conventional bypass grafts, 43% at 3 years, Fichelle et al., 1995. Since both surgical techniques have moderate patency rates it is concluded that an optimum end-to side graft/artery junction geometry, which would significantly increase the patency rates of peripheral bypass surgery, may not exist.

INCIDENCE OF VALVE PROSTHESIS INCLINE ON LEFT VENTRICULAR FLOW DYNAMICS.

INTRODUCTION

Diastolic normal flow in the ventricle is characterised by a large vortex that occupies almost the whole cavity. This vortex turns anticlockwise, from the posterior wall along the apex to the interventricular septum and can be clinically observed with color Doppler in apical four-chamber view. When implanting heart valve prosthesis, studies have shown that there is a favourable orientation of the valve with respect to the natural valve leaflets; but no study has paid attention on the incline of the heart valve with regard to the mitral annulus plane. Indeed, clinical observations have put into light an inversion of the rotating sense of the vortex when the prosthesis is veered towards the septum.

METHODS

Using a Dual Activation Simulator of the left heart, flow past heart valve prosthesis in mitral position was studied with Particle Image Velocimetry. A Medtronic-Hall valve was used to reproduce a similar diastolic flow structure than past a natural valve and a Carpentier-Edwards bioprosthesis was successively implanted in "apex directed" position (CEAD) and in "septum directed" position (CESD).

RESULTS AND DISCUSSION

For the CESD, in early diastole, a central jet induces two contrarotatives vortices whose cores move with jet propagation. During deceleration, the jet weakens and is deviated by the apical vortex. The aortic vortex, little fed, is absorbed. In systole, still stronger than the aortic eddy, the apical eddy goes up along the posterior wall then along mitral valve towards the aortic valve. For the CEAD, in early diastole, an important jet follows the posterior wall and a vortex develops in the whole ventricle. During diastasis, due to the absence of flow from the mitral valve, the main vortex develops; an apical contrarotative eddy develops also but stays weak. In systole, the ejection is mainly along the septal wall, the core of the eddy moves below the mitral valve.

The flow past Medtronic-Hall and CEAD present both an anticlockwise vortex and a favourite ejection in systole along the septum through the left ventricular outflow tract. The flow past the CESD presents a clockwise pattern and ejection is principally along mitral valve, opposite to the septum.

When comparing the two inclines, it can be noticed that the flows through the ventricle are different. We can observe a changing in rotating direction when changing the incline of the valve. In the septum inclined case, the interaction of the flow from the mitral valve and the vortex in diastole can create a

resistance to ventricle filling. During systole, the ejection is completely asymmetric and could create hemolysis locally.

Figure 1: Flow (velocity magnitude) in the ventricle downstream mitral CESD (left) and CEAD (right) in early diastole (top), during diastasis (middle) and in systole (bottom)

CONCLUSION

This study highlights the influence of the valve incline in relation with mitral annulus on the flow in the ventricle. This incline induces an inversion of the rotating motion, a risk of increased valvular resistance during ventricular filling and a risk of hemolysis and endothelial damage. What are the consequences on ventricular function, at short and long term? This inversion could affect left ventricular function recovery. From this study we recommend whenever it's possible that surgeons implant preferably the prosthesis "apex directed"

HYDRODYNAMICS OF MITRAL PROSTHETIC HEART VALVES: COMPARISON OF NORMAL CONDITIONS WITH ATRIAL FIBRILLATION VARYING THE HEART RATE

Frederic Mouret, Vincent Garitey and Regis Rieu

INTRODUCTION

Artificial valve substitutes are used to replace incompetent natural heart valves. Due to the inertia of mobile elements and to the functional float of mechanical parts, heart valve prostheses regurgitate. The regurgitant volume is defined as the volume of fluid which flows backwards through a valve during the cardiac cycle. It is represented by the sum of the closing volume (linked to the closing dynamics of the valve) and the leakage volume. Trials are often run in simulated conditions encountered in a healthy young man. However, heart valve implantation is often associated with other pathologies, such as atrial fibrillation. Our aim is to draw close to actual operating conditions of valve prosthesis in vivo, through in vitro trials and to assess the hydrodynamic behavior of artificial valves in normal and pathological conditions.

METHODS

Trials have been achieved on a Dual activation simulator. This test bench has been fully described in Mouret (2000). Both atrial and ventricular contractions are controlled independently allowing the reproduction of physiological signals through a left heart model. Four valves have been tested. The prosthesis is implanted in mitral position. The orientation is similar to usual clinical implantation in vivo. The fluid used to mimic blood has a viscosity analog to blood. The heart rate is set at 50, 70, 90 and 110 bpm successively, mean cardiac output is 5 L/min. These conditions are repeated in normal conditions (E wave magnitude is twice the A wave) and in atrial fibrillation (no A wave, regular heart rhythm).

Figure 1: Mean closing volume for all type of valves in normal conditions when varying the heart rate

RESULTS AND DISCUSSION

The different valves have been voluntarily named A, B, C and D to respect the confidentiality in this abstract.

In normal conditions (figure 1), it can be said that the valve B has a significant lower closing volume than the other valves, valves A and C can be considered as similar. In atrial fibrillation (figure 2), valve D has the lower closing volume whatever is the heart rate. Once more valves A and C have a behavior hard to separate the one from the other.

The behavior of valve D in atrial fibrillation could be explained by a greater lift force of the mobile element(s) which induces a position very close to the closed position at the end of diastole.

Figure 2: Mean closing volume for all type of valves in atrial fibrillation when varying the heart rate

CONCLUSION

As described by Dellsperger (1983), the closing volume does not vary a lot when changing the heart rate. Nevertheless, a small decrease is observed in some valves at rapid heart rate, probably due to timing in vortex shedding behind leaflets. From these tests, valve B appears to be the best compromise for all flow conditions. It has to be kept in mind that they only concern the regurgitant characteristics of the valves. No conclusion has to be extrapolated to other hydrodynamics parameters. These tests offer important data when considering trials for certification and reinforces the need to test heart valve prostheses in real simulated conditions.

CO-ACTIVATION OF KNEE FLEXORS IN ISOMETRIC EXTENSION EFFORTS

Idsart Kingma and Jaap H. van Dieën

Institute for Fundamental and Clinical Human Movement Sciences, Faculty of Human Movement Science
Vrije Universiteit, Amsterdam, Netherlands

INTRODUCTION

Co-activation of knee flexors is known to occur in dynamic as well as static knee extension tasks. Simulation studies suggest that hamstrings activation would, except near full extension, aid in reducing forward tibial shear forces (Imran and O'Connor, 1998) thereby reducing the strain on the anterior cruciate ligament (ACL). If an active protection mechanism through hamstrings co-activation would normally be present, hamstrings activation should depend on shear force challenges to the joint. The aim of this study was to test the effect of changes in joint angle, load level and external shear forces on knee flexor co-activation in extension efforts.

METHODS

Ten healthy subjects performed isometric knee extension efforts at 10 knee joint angles (ranging from 5 to 50 degrees of flexion). For each joint angle, external moments of 20, 50 and 80 Nm were applied using a load that was applied perpendicular to the long axis of the shank. All three moments were applied at three distances from the knee joint axis (95, 212 and 307 mm), resulting in three levels of external backward shear force for each moment. The subjects were required to hold the knee joint at each target angle during 5 seconds. An opto-electronic movement registration system (Optotrak) was used to provide a target angle and real-time feedback of the knee joint angle to the subjects. Surface EMG was measured on the Rectus Femoris (RF), Vastus Medialis (VM), Vastus Lateralis (VL), Biceps Femoris (BF), Semitendinosus (ST), Gastrocnemius Lateralis (GL) and Gastrocnemius Medialis (GM) muscles. Rectified EMG signals were averaged over 3 seconds, and a measure of co-activation (EMG/mom) was obtained by dividing EMG by the actual knee extension moment (the externally applied moment plus the moment due to shank mass). For all muscles, ANOVA's were applied with subject, joint angle, external load level and load position as independent variables.

RESULTS

With increasing knee flexion, a strong and non-linear decrease was found for the EMG and EMG/mom (figure 1) of all muscles except GM. EMG of all muscles increased with applied moment ($p < 0.001$), suggesting an increase of co-activation with load level. However, this increase was less than proportional, since EMG/mom decreased for all flexor and extensor muscles with increasing load level ($p < 0.001$; figure 1 left). The load position affected only the medial knee flexors (ST and GM) and the RF (all $p < 0.01$). EMG/mom decreased in the GM (27%) and the ST (12 %) but increased in the RF (9%) at the load position closest to the joint.

Figure 1: EMG divided by moment against knee angle, for 3 selected muscles, averaged over 10 subjects and over 3 load positions (left) or 3 moment levels (right).

DISCUSSION

The load position closest to the joint causes the largest (externally applied) backward shear force, acting to reduce quadriceps-induced forward tibial shear (Pandy and Shelburne, 1997), and thereby reducing the need for co-contraction. The reduction of medial flexor EMG that we found with loads close to the joint indeed suggests a reduced protective co-activation response. The increase in co-activation near full extension suggests a response to a reduced effectiveness of knee flexors in counteracting shear forces. A reduced level of co-contraction (indicated by EMG/mom) with higher moment levels may be related to the cost of co-contraction (requiring also additional extensor activation).

ELECTROMYOGRAPHY OF KNEE-JOINT MUSCLES IN UNILATERAL BELOW-KNEE AMPUTEES DURING WALKING AND RUNNING

David J. Sanderson and Craig D. Tokuno

School of Human Kinetics, University of British Columbia, Vancouver, BC, Canada
david.sanderson@ubc.ca, tokuno@interchange.ubc.ca

INTRODUCTION

In previous work, Sanderson and Martin (1996;1997) argued that while persons with a below-knee amputation walk symmetrically they do so with dramatically different joint moment patterns at the knee and hip joints. They reported a significant reduction in the prosthetic leg knee-extensor moment for both walking and running, for a group of persons with a unilateral below-knee amputation. It is reasonable to suggest, therefore, that if the joint-moment patterns were different on the prosthetic leg there should be some variation in the activation of the knee-joint musculature. For example, the reported reduced knee extensor moment could have arisen because of increased activation in hamstrings to provide more stability or, conversely a down regulation of vastus lateralis to reduce knee-joint loading. The objective of this project was to provide an analysis of the knee-joint muscular activity during walking and running for a group of unilateral below-knee amputees and an age-matched control group as a means to examine the relationship between the knee-joint moment and muscle activation. It was hypothesized that the activity of vastus lateralis would be reduced in order to maintain knee-joint stability.

METHODS

Data were acquired as the participants passed over a flush-mounted force platform in the centre of a measurement area of approximately 4 meters in length as part of a 20-meter runway. As the participants passed through the area the six-camera video recording system recorded their movements continuously. Simultaneously, the force platform recorded the loading patterns as the participant passed over the device and the electromyographic system recorded the activity of the vastus lateralis and semitendinosus muscles. Data were collected for three trials at each of two walking speeds (1.2 m/s & 1.6 m/s) and two running speeds (2.7 m/s & 3.5 m/s). A successful trial was one where there was no obvious targeting of the force platform and the average speed remained within $\pm 3\%$ of the target speed. The sequence for each leg was presented randomly to the participants. Data were recorded from the left and right legs of the non-amputee group and from both the intact and the prosthetic leg of the amputee group providing three limbs for comparison. The EMG data were amplitude normalized to the maximum peak at the slow walk speed and a score of relative activity was computed as:

$$\Delta EMG = \int_{\text{heelstrike}}^{50\% \text{ stance}} EMG dt_{VL} - \int_{\text{heelstrike}}^{50\% \text{ stance}} EMG dt_{HAMS}$$

RESULTS AND DISCUSSION

Kinematic and kinetic data recorded from these groups were consistent with earlier publications (e.g. Sanderson and Martin, 1996; 1997) showing that the persons with a unilateral below-knee amputation walked with kinematic symmetry but did so with altered hip and knee joint moments. For example, in early stance the knee extensor moment was reduced by 50% compared to the intact and control limbs.

The EMG data, summarized in the table below showed that the ΔEMG values for the prosthetic leg were reduced compared to the other leg conditions for both walking and running conditions. It was concluded that across conditions the activity of the vastus muscle was being down regulated in the prosthetic leg.

	Non Amputee	Slow Walk	Fast Walk	Slow Run	Fast Run
Vastus lateralis		7024	9849	16890	18791
Semitendinosus		4067	4672	5190	6406
•EMG		2957	5178	11700	12385
Intact					
Vastus lateralis		5758	10512	14297	19983
Semitendinosus		5029	6322	7504	9954
•EMG		729	4190	6792	10029
Prosthetic					
Vastus lateralis		5244	6180	9410	10048

•EMG		-179	-562	3087	3654

Table 1. Mean Integrated EMG for the initial 50% of stance.

SUMMARY

This reduced knee-extensor moment arose because of the shift in the degree of activation of the vastus lateralis. These data support the original hypothesis that there is some re-organisation. The goal for the individual appears to be one to provide increased stability to the knee joint during the initial portion of stance, the period when the weight of the body is being taken up by the legs, by reducing the contribution of vastus lateralis and reducing the knee-joint extensor moment.

INVESTIGATION OF THE DIFFERENCES BETWEEN INERTIAL AND CADENCE EFFECTS ON NEUROMUSCULAR COORDINATION DURING CYCLING

Brian Baum and Li Li

Motor Behavior Laboratory, Louisiana State University, Baton Rouge, LA, USA, LLI3@LSU.EDU

INTRODUCTION

Muscular activity and coordination may be influenced by movement speed and the inertial properties of the limbs. Observed changes in pedal forces, joint moments, and muscular activities have been attributed to inertia, especially at greater pedaling speeds during cycling (i.e. Kautz & Hull, 1983; Li, 1999; Neptune & Herzog, 1999). In these investigations, movement speed and inertia were coupled. Therefore, the purpose of this study was to investigate the effects of cadence and inertial influences on lower extremity neuromuscular coordination during cycling.

METHODS

Sixteen male subjects [mean (SD) age: 23 (5) years, height: 1.8 (0.2) m, mass: 85 (10) kg] cycled at different cadences and with different loads attached to the distal ends of their thighs. Electromyographic (EMG) data were collected from seven muscles of the left lower extremity (see Figure 1). Subjects cycled at 250 W across three pedaling cadences (60, 80, and 100 rpm) and five loads (0, 0.5, 1.0, 1.5, and 2.0 kg) in a random order. Onset, offset, duration, peak magnitude, and peak timing values from the EMG linear envelopes were calculated. Cross-correlation coefficients and phase differences were determined as in Li & Caldwell (1999). Repeated measures ANOVA were used to test statistical significance. Statistical significance of all tests was set at $\alpha = 0.05$.

RESULTS AND DISCUSSION

Neuromuscular coordination and muscular activity patterns displayed differential reactions to cadence and load, as in the muscular responses (exemplar data shown in Figure 1). Timing and magnitudes changed with both greater loads and cadences, but more profound pattern and coordination changes were observed with cadence changes. Results from the cross-correlation technique suggested that coordination changes occurred between mono- and bi-articular antagonists due to cadence but not due to load manipulation. Because of this discrepancy, and that the cross-correlation technique is magnitude insensitive, it is proposed that inertial influences may be more relevant to event magnitudes rather than timing.

SUMMARY

This study aimed to distinguish between inertial and cadence effects on neuromuscular coordination during cycling. Subjects cycled at different cadences and with loads attached to the distal ends of their thighs, and EMG data were collected and analyzed. The results led to the conclusion that movement speed effects have a greater influence on the lower extremity muscles during cycling but the inertial effects were apparent.

BIOMECHANICS OF PERIVASCULAR FLOW IN SYRINGOMYELIA

Lynne Bilston¹ and David F. Fletcher²

¹ Prince of Wales Medical Research Institute
Barker St, Randwick, NSW 2031, Australia, l.bilston@unsw.edu.au

²Department of Chemical Engineering,
University of Sydney, NSW 2006, Australia.

INTRODUCTION

Syringomyelia is a neurological condition in which syringes (fluid-filled cysts) form in the spinal cord. If these syringes are large, they can cause neurological deficits. To date, the exact biomechanical mechanism by which cerebrospinal fluid (CSF) from the subarachnoid space enters the spinal cord to form a syrinx is unknown. One hypothesis suggests that the fluid is pushed into the central canal of the spinal cord from the fourth ventricle in patients with chiari malformations. Alternatively, Stoodley et al (1999) have shown that CSF enters a syrinx through the perivascular spaces in an animal model of syringomyelia, and that this flow is abolished in the absence of arterial pulsations. The aim of this study was to develop a computational fluid dynamic model of flow in the spinal perivascular spaces in order to determine whether arterial pulsations could cause perivascular fluid flow.

METHODS

A 250 μm long segment of a “typical” spinal artery was modelled, with a diameter of 100 microns. The perivascular space was modelled as a 25 μm thick annulus surrounding the artery (Thron, 1988). The outer boundary of the perivascular space has been assumed not to deform. The exact amount of arterial wall deformation in the spinal cord is unknown, however in other tissues, small arteries expand by 5-10% during systole (Hoeks et al, 1999). Arterial expansion was modelled as a periodic travelling sinusoidal wave of wall deformation in the outer wall of the artery, at 10% of the artery radius (5 μm), with a frequency of 1 Hz. Cerebrospinal fluid was modelled as a Newtonian fluid with viscosity of 1.0×10^{-3} Pa.s (Bloomfield et al, 1998).

The flow field was solved using CFX4 (CFX, 2000). This code solves the Navier-Stokes equations using an implicit finite volume method, using a collocated mesh that can be deformed in time to model transient effects. No slip boundary conditions were applied at all walls with the inlet and outlet set as mass flow boundaries. A simulation was run until a quasi-steady-state was reached in which the flux and velocities in the middle of the flow domain had reached a quasi-steady-state.

RESULTS AND DISCUSSION

The simulations showed that the pulsations drive fluid flow in the perivascular space along the same direction that the pulsations travel. Net flow rate was 2.7×10^{-7} kg/s. Figure 1 shows the fluid velocity distribution in the perivascular space at equilibrium. There is a net pressure drop generated of 560 Pa as a result of the wall motion.

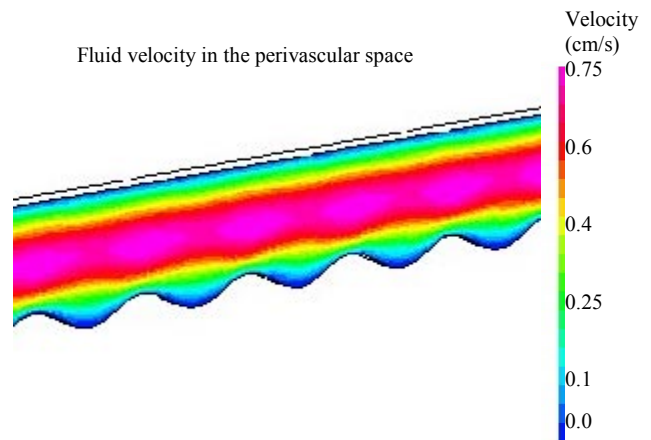

Figure 1: Fluid velocity in the perivascular space model.

SUMMARY

This model demonstrates that fluid can be caused to flow along perivascular spaces as a result of arterial pulsations. This flow may play a role in the development of syringomyelia when there is a disturbance to the outflow or absorption of CSF from within the spinal cord.

THE EFFECT OF TRABECULAR BONE MICROSTRUCTURE ON STRESS DISTRIBUTION OF A DENTAL IMPLANT

INTRODUCTION

Many previous studies assumed that the mandibular trabecular bones are homogeneous. Moon *et al.* (1997) introduced homogenization method for stress analysis in a dental implant system. They regarded trabecular bone as a structure of unit cell. However, they have the limited accuracy and applicability due to the high degree of material heterogeneity in the trabecular bone structure of mandible. In the present study, a microstructure model for stress analysis in a dental implant system is suggested and the results of the present model and previous models are compared using finite element analysis.

METHODS

A mandibular specimen with a premolar was obtained from a cadaver. The microstructure of the specimen was scanned with micro-CT and captured by BIONIX (CANTiBio Co.). A Micro-FE model in Fig. 1(b) was reconstructed from micro-CT images at mid-sagittal plane of the tooth. Fig. 1 shows the modeling process of this study. A vertical (100N) and horizontal (100N) load was applied to the top surface of the implant system and stress distribution was calculated along the implant surface (Figs. 1,2). For the comparison purpose, the fixed boundary condition in Fig. 1 is applied to the bottom of the mandible. To compare the results of models generated by the previous methods with those of the microstructure model, a homogeneous model of Fig. 1(c) and a D1 bone model with only cortical bone in Fig. 1(d) were also generated and analyzed using commercial finite element software (MSC NASTRAN). In the microstructure model and the D1 bone model, the same material properties (a Young's modulus of 12Gpa, a Poisson's ratio of 0.3) were assigned to elements of cortical bone and trabecular bone. However, in the homogeneous model, a Young's modulus of 345Mpa was used in those of the trabecular bone.

RESULTS AND DISCUSSION

The stress curve across the implant surface is given in Fig.2. The highest tension stresses for all models were on 'A' (Figs. 1,2). The second greatest stresses were on 'C' in both homogeneous model and D1 model, but in microstructure model, they were between 'A' and 'B'. This result indicates that the microstructure of trabecular bone in a mandible needs to be considered in FEA studies to produce reasonable results and thus implant system with high success rate. Since this study is a preliminary investigation, more in-depth studies on the implant system with mandibular trabecular bone need to be followed.

Figure 1: Modeling process: (a) Micro-CT reconstruction, (b) Microstructure model, (c) Homogeneous model, (d) D1 bone model.

Figure 2: Stress curve along the implant surface.

SUMMARY

Because of the complex geometry in the mandibular trabecular bone, many previous researchers assumed that the mandibular trabecular bones are homogeneous and isotropic. Therefore, the accuracy of the previous models is limited. In this study, a micro-FE model of implant system with mandibular trabecular bone is generated and analyzed. The stress curve along a dental implant surface is compared with that of the previous models. This study shows that microstructure model needs to be considered in FEA studies to produce reasonable results and thus implant system with high success rate.

DYNAMICS RATHER THAN EQUILIBRIUM POINT IS CONTROLLED IN HUMAN MOVEMENTS

Mark R. Hinder and Theodore E. Milner*

School of Kinesiology, Simon Fraser University, Burnaby, B.C., V5A 1S6, Canada

* Corresponding author tmilner@sfu.ca tel: 604 291 3398, fax: 604 291 3040

INTRODUCTION

The equilibrium point hypothesis (EPH) was conceived as means whereby the central nervous system could control limb movements by a relatively simple shift in equilibrium position without the need to explicitly compensate for task dynamics. Many recent studies have questioned this view with results that point to the formation of an internal model of the task dynamics (Shadmehr & Mussa-Ivaldi, 1994; Thoroughman & Shadmehr, 2000), while proponents of the EPH still argue for its virtues (Feldman et al, 1998). In this study, we have tested one of the fundamental predictions of the EPH, namely, equifinality.

METHODS

Subjects learned to perform goal-directed wrist flexion movements without visual feedback. A torque motor provided assistance in proportion to the instantaneous velocity, which resulted in underdamped oscillation of the wrist about the final position. Subjects were instructed to produce a single movement and not to react voluntarily to any changes in the assisting torque.

The assisting torque was unexpectedly reduced on random trials by 0%, 25%, 50%, 75% or 100%. These perturbed trials comprised 10% of the total number. Kinematic data and surface EMG of all major wrist muscles was recorded.

Error in the final position was quantified by calculating the difference in final position between perturbed trials and trials immediately preceding the perturbed trials.

Cumulative EMG was analysed to investigate whether motor commands remained invariant between the perturbed trials and preceding trials. Changes in stretch reflex gain and threshold were estimated for flexor muscles by comparing the level of EMG activity during the half cycles of the oscillations corresponding to flexor stretch.

RESULTS AND DISCUSSION

Subjects stopped short of the target on the trials where the magnitude of the assistance was randomly decreased, compared to the preceding control trials ($F=14.782$, $p=0.003$), i.e., equifinality was not achieved. This is contrary to the EPH, which predicts that final position should not be affected by external loads that depend purely on velocity. However, such effects are entirely consistent with predictions based on the formation of an internal model of the task dynamics.

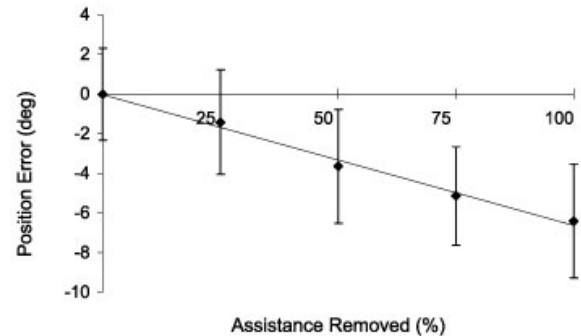

Figure 1 Linear fit of the error in the final position

Cumulative EMG revealed that the motor command remained invariant across all conditions, suggesting that an internal model was formed during learning that was robust to random changes in the assisting torque level.

Analysis of flexor EMG during the oscillations about the target revealed that the level of assisting load did not affect the stretch reflex gain and threshold. Therefore, according to the EPH, the error in final position could not be explained by a reduction in stretch reflex contribution to the motor command, strengthening the case for the formation of an internal model.

SUMMARY

We have shown that one of the fundamental predictions of the EPH, equifinality, does not hold. We conclude that learning leads to the formation of an internal model of the load torque dynamics by the central nervous system which is used for feedforward control of motor commands to muscles.

A VERTEBRAL BODY REPLACEMENT FOR *IN VIVO* LOAD MEASUREMENT

Antonius Rohlmann, Udo Gabel, Friedmar Graichen, Georg Bergmann

Biomechanics Laboratory, University Hospital Benjamin Franklin, Free University of Berlin, Germany, rohlmann@biomechanik.de

INTRODUCTION

In cases involving considerable burst fractures of a vertebral body, post-traumatic kyphosis or tumors of a vertebral body an implant for replacement of a vertebral body is often indicated for restoring normal load-bearing in the anterior spine. Several different implants for this purpose are clinically used. After positioning, the anterior implant is mostly distracted *in situ* by a thread or an expansion mechanism. This provides best contact with adjacent end-plates and three-dimensional stability, thus minimizing the possibility of correction loss or secondary dislocation. If desired, bone cement or bone grafts can be added to the implants. After insertion of a vertebral body replacement the implant takes over the load normally transferred by the anterior column of the spine. The anterior implants are mostly supplemented by a stabilizing implant, e.g. an internal spinal fixation device. The load is then shared at least by the anterior and the posterior implants.

The aim of this paper is to introduce a telemeterized implant for the replacement of a vertebral body which allows the measurement of three force and three moment components.

IMPLANT DESIGN

Synex (STRATEC Medical, Oberdorf, Switzerland) is an implant for vertebral body replacement that meets the above mentioned requirements. It consists of an inner and an outer part both made out of titanium, and a supporting ring. Synex is hollow, smaller than the anterior defect when initially fitted in an undistracted state, and can be distracted *in situ* to the desired height with a special distractor after precise placement in the spinal lesion [Knop et al, 2000]. A self-blocking ratchet mechanism prevents a telescopic shortening of the vertebral body replacement under load.

Figure 1: Schematic sketch of the instrumented vertebral-body-replacement implant

DESIGN OF THE TELEMETERIZED IMPLANT

For the instrumentation the original implant was modified. The lateral window of the inner part of the implant was omitted. This necessitated a new anti-twist mechanism. We chose the tongue and groove principle. On the outer side of the cylinder two grooves 0.85 mm deep and 1 mm wide were milled.

To allow the measurement of six load components, six semiconductor strain gauges are glued around the circumference of the inner wall at a distance up to 5 mm from the end-plate (Fig. 1). Two each are glued at $+30^\circ$, 0° , and -30° to the long axis of the inner part. The telemetry circuit is the same as used for the internal fixator [Graichen et al, 1996]. The telemetric unit was placed in a cylinder made out of a material of high permeability (Megaperm 40L, VAC). The secondary coil for the inductive power supply used this cylinder as a core. Megaperm increases the inductivity of the coil reeled on the cylinder, and it shields the circuit against the magnetic field needed to supply the telemetry.

The cylinder-shaped hollow part is hermetically closed by a 1 mm thick titanium seal plate using electron beam welding. In the seal plate an electrical feedthrough used in pacemakers is laser beam welded. The inner side of the niobium wire is connected to the electric circuit of the telemetry unit and the outer side to a niobium wire (diameter 0.5 mm) which serves as a transmitter antenna. A polyethylene cap which is mechanically fixed to the implant protects the wire-antenna against deformation.

In order to adjust to the different heights of the vertebral bodies, two different lengths of the outer part of the implant were manufactured. One combination covers a range from 38 mm to 48 mm, the other from 45.5 mm to 58 mm. Two tongues 5 mm long and 1 mm wide are fixed at opposite sides in order to prevent relative turning between inner and outer part.

Prior to implantation, the modified implants are mechanically tested, and calibrated by applying defined forces and moments.

The external telemetry system is the same as for the internal fixators [Graichen et al, 1996; Rohlmann et al, 1994]. For the measurements an induction coil will be placed around the body at the level of the implant. A small loop antenna with an integrated amplifier will be placed on the patient's back near the implant to receive the pulse-interval-modulated signals of the 8-channel telemetry. The patient will be videotaped and the load-dependent signals will be stored on the same videotape. From the signals the forces and moments will be calculated in a PC and the loading curves will be shown online on a monitor.

FATIGUE AND MUSCLE COORDINATION IN SUBJECTS WITH PATELLOFEMORAL PAIN SYNDROME

Gertjan Ettema¹, Trine Tegdan² and Karin Roeleveld¹

¹Human Movement Science Section, Sport Sciences Programme, NTNU, Trondheim, Norway. email: gertjan.ettema@svt.ntnu.no

INTRODUCTION

The patellofemoral pain syndrome (PFPS) is a common knee problem, especially in adolescents and physically active young adults. Abnormal muscle activation of compartments of the Quadriceps Femoris (QF) in PFPS (Callaghan et al., 2001) may disturb the dynamics of the patellofemoral joint, thereby leading to PFPS. In this study intermuscular coordination aspects of the QF under demanding conditions, in this case fatigue, were examined.

METHODS

Twelve subjects with PFPS (3 males, 9 females) and 14 pain free control subjects (4 males, 10 females) volunteered. The groups did not differ for age, height or weight. The average duration of PFPS, as diagnosed by an orthopedic surgeon, was 19,9 ($\pm 13,3$) months. The subjects were asked to stand on one leg in a semi-squatted position (120 degrees knee flexion) for as long as possible. Position maintenance was checked using digital kinematic recordings (ProReflex). Bipolar surface EMG (sample rate 2000Hz, bandpass-filtered at 10-500Hz) was recorded of oblique vastus medialis (VM_o), vastus lateralis (VL) and rectus femoris (RF). Mean power frequency (MPF) and amplitude (A) were calculated for the start period of the exercise and at exhaustion. The change of MPF (ΔF) and normalised A ($\Delta A\%$) during the exercise were used to compare groups.

RESULTS AND DISCUSSION

PFPS subjects demonstrated a shorter time ($90.1 \pm 48.5s$) to exhaustion than the controls ($215.7 \pm 111.7s$) (t-test: $p < 0.001$). ΔF and $\Delta A\%$ results are summarized in Table 1. Both groups, although reporting full exhaustion showed no significant changes in A or MPF. However, a two-factor ANOVA for repeated measures (taking account for individual differences) revealed significant effects of muscle on ΔF . Within a single group, the same effect was found for the controls but not for the PFPS group. A striking finding was that the ΔF values tended to correlate high between muscles in the patient group,

but not in the control (Fig. 1). Also a larger proportion of patients than controls showed significant correlations (r considered significant at $p < 0.01$) for MPF between muscles during the entire exercise (20 measurement points taken during performance) (group difference by Chi Squared test, $p = 0.011$). These group differences were not found for amplitude.

Figure 1: ΔF values VL against VM_o . PFPS correlation is significant ($p < 0.001$), when excluding gray data point (as outlier) r reduces to 0.73 ($p = 0.01$).

These results indicate that, regarding the EMG frequency spectrum, PFPS subjects show a more monotone change during fatigue among three QF muscle compared to controls. The physiological basis for the current findings are unclear. However, change in frequency content is a good indicator for fatigue (e.g. Gerdle et al, 2000). Thus, it is suggested that PFPS patients demonstrate a lesser ability to independently adjust certain muscle activation aspects in different muscles (or compartments), which may lead to or may be the result of PFPS. We speculate that PFPS patients show a reduced number of degrees of freedom in QF coordination, and therefore fatigue their QF in a more monotone manner.

EVALUATION OF A MATHEMATICAL MODEL OF MUSCLE ENERGETICS

Han Houdijk

Institute for Fundamental and Clinical Human Movement Sciences, Faculty of Human Movement Sciences, Vrije Universiteit Amsterdam, The Netherlands. H_Houdijk @ fbw.vu.nl

INTRODUCTION

To simulate submaximal cyclic movements, a model is required that captures both muscle mechanics and energetics. Models that capture muscle mechanics have been described and validated abundantly in the literature. Models that capture muscle energetics are, however, rather scarce and the existing models have not yet been validated adequately. In this study, a model of muscle energetics was evaluated using experimental data of muscle energetics that were obtained from literature.

METHODS

Muscle mechanics were modeled using a Hill-type muscle model as described by Van Soest and Bobbert (1993). Muscle energetics were modeled using a model previously described by Hatze and Buys (1977). This model calculates energy cost as the sum of heat and work produced by a Hill type muscle. Heat production is divided in three components: the cross bridge independent 'activation heat' (a function of stimulation frequency), the cross bridge dependent 'maintenance heat' (a function of active state and contractile element (CE) length), and the 'shortening heat' (a function of CE shortening velocity).

The muscle model was used to simulate a muscle fiber experiment that was performed by Barclay et al. (1993). In this experiment, fiber bundles of mouse slow-twitch m. soleus (SOL) and fast-twitch m. extensor digitorum (EDL) performed iso-velocity contractions at different velocities. Heat and work were measured.

The muscle specific parameters for the mechanical submodel were derived from the experimental data of Barclay et al. (1993). The parameters for the energetics submodel were taken from Hatze and Buys (1977), who had derived these from various animal species under various experimental conditions.

The rate of energy cost (heat + work) and muscle efficiency (work / (heat + work)) were compared between experiment and simulation.

RESULTS

Close agreement existed between the isometric heat production in the experiment and simulation for both SOL and EDL. The rate of energy cost of isometric contraction for SOL was 26.8 vs. 23.8 mW/g for the experiment and simulation respectively. For EDL this amounted to 134.2 vs. 144.0 mW/g.

In accordance with the experimental results, the rate of energy cost for the dynamic contractions of SOL increased almost five-fold between zero and maximal shortening velocity. The

model predicted a three-fold increase in energy cost for EDL. This was twice as high as the increase seen in the experimental data. However, the overestimation of the energy cost in the simulation was the result of both an overestimation of the work rate and shortening heat rate. This might be the result of an inaccuracy in the Hill constants provided by Barclay et al. (1993).

The model quite well predicted the relation between shortening velocity and muscle efficiency for both SOL and EDL (fig. 1). Muscle efficiency was overestimated a little for both muscles, but as in the experiment, maximal efficiency was equal between muscles, and the fast-twitch EDL was more efficient at higher relative contraction velocities than SOL.

Figure 1: muscle efficiency versus relative CE shortening velocity for SOL and EDL in the **experiment** and **simulation**.

CONCLUSION

It can be concluded that the model for muscle energetics and its parameters, used in this study, can adequately reproduce muscle efficiency of mammalian muscles during discrete iso-velocity contractions. Our next step in the validation of this model will be to test it for more natural, cyclic stretch-shortening contractions.

DEFORMATION OF A BIOARTIFICIAL CAPSULE IN PLANE HYPERBOLIC FLOW

INTRODUCTION

Cells and vesicles are commonly modelled as capsules, e.g. droplets enclosed in a thin membrane. Capsules are also met in numerous biomedical or pharmaceutical applications. We present a numerical model of the motion and deformation of an initially spherical (radius a) liquid filled capsule freely suspended in a linear shear flow. Both internal and external fluids are Newtonian, have the same dynamic viscosity μ , and obey the Stokes equations, since the particle Reynolds number is very small. The membrane is infinitely thin and hyperelastic with surface shear modulus G_s . We focus on the influence of the membrane rheology on the capsule motion.

METHODS

In an unbounded flow field of velocity \mathbf{v}^∞ , the velocity $\mathbf{v}(\mathbf{x})$ of a point on the membrane M , is given by the integral equation (Pozrikidis, 1992):

$$\mathbf{v}_i(\mathbf{x}) = \mathbf{v}_i^\infty(\mathbf{x}) - \frac{1}{8\pi\mu} \int_M \mathbf{J}_{ij}(\mathbf{x}, \mathbf{y}) \Delta f_j(\mathbf{y}) dS(\mathbf{y}),$$

where $\Delta \mathbf{f}$ represents the viscous stress jump across the interface and the kernel \mathbf{J} is a free-space Green's function. For an infinitely thin membrane, $\Delta \mathbf{f}$ is equal to load exerted on the elastic interface and is thus related to the elastic tensions tensor \mathbf{T} through the membrane equilibrium equation :

$$\nabla_s \cdot \mathbf{T} + \Delta \mathbf{f} = \mathbf{0}.$$

The constitutive law of the membrane material relates the tensions to the deformations of the surface. We confront a neo-Hookean law (NH), commonly used for elastomers, and the Skalak et al. (1973) law (SK) where the shear modulus G_s and the area dilatation modulus $(1+2C)G_s$ are of the same order. The undisturbed velocity field \mathbf{v}^∞ corresponds to a plane hyperbolic flow of intensity $\dot{\gamma}$, with components:

$$v_1^\infty = \dot{\gamma} x_1 \quad v_2^\infty = -\dot{\gamma} x_2 \quad v_3^\infty = 0$$

An important parameter is the capillary number $\varepsilon = \mu a \dot{\gamma} / G_s$ that measures the ratio of viscous to elastic forces.

The interface is described with general Lagrangian coordinates by means of bi-cubic B-splines, so that very large deformations can be reached with good accuracy. Once their velocity is calculated, the membrane material points \mathbf{x} are convected by means of the differential equation $\dot{\mathbf{x}} = \mathbf{v}(\mathbf{x})$.

RESULTS

The hyperbolic flow is created experimentally in the centre of a cell with four contra-rotating cylinders. This device was used by Chang & Olbricht (1993) to measure the deformation of capsules with a nylon membrane. The steady deformation in the extension plane (x_1, x_2) is measured by the Taylor parameter $D_{12} = (L_1 - L_2) / (L_1 + L_2)$, where L_1 and L_2

denote the particle lengths along axes 1 and 2. As shown on Figure 1, up to a deformation of 10%, the membrane law has no influence and the numerical results match the asymptotic predictions of Barthès-Biesel & Rallison (1981). For larger deformations, the SK law with $C=1$ captures the strain hardening behaviour of the nylon capsules. The SK law with $C=10$ is too strain-hardening. Figure 2 shows a comparison between the model (SK, $C=1$) and experimental profiles.

For large deformations, corresponding to values of ε that depend on the membrane rheology, the membrane tends to buckle and the model fails. The bending rigidity of the membrane should then be taken into account.

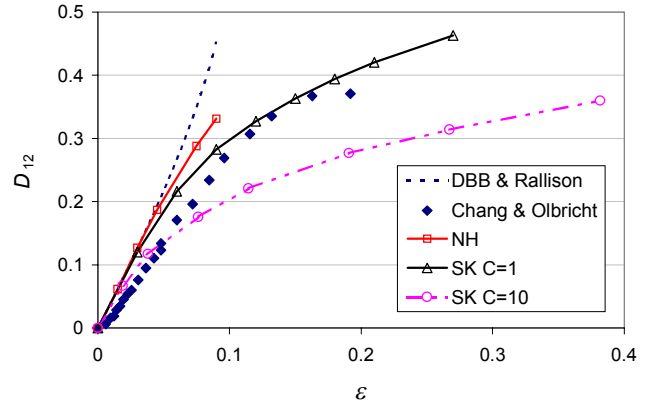

Figure 1 : Deformation vs. capillary number ε for a capsule placed in a hyperbolic flow.

Figure 2 : Comparison between numerical (SK, $C=1$) and experimental capsule profiles in hyperbolic flow ($\varepsilon = 0.132$).

MUSCLE ACTIVITY IN THE LOWER EXTREMITY DAMPS THE SOFT-TISSUE VIBRATIONS WHICH OCCUR IN RESPONSE TO IMPACT FORCES

James M. Wakeling, Antra I. Rozitis and Benno M. Nigg

Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

Impact shocks are delivered to the body during heel-strike in walking and running. It has been proposed that muscle activity in the lower extremity is tuned in order to minimize the soft-tissue vibrations that would occur after such impacts (Nigg, 1997). Evidence shows that muscle activity is altered in response to heel-strike impacts with different frequency contents (Wakeling et al. 2001), however there is currently no direct evidence linking the frequency of the impact force, the muscle activity and the vibration properties of the soft-tissues. The purpose of this study was to test the hypothesis that there are increases in the damping and natural frequency of the soft-tissues when the frequency of an impact force matched the natural frequency of that tissue.

METHODS

Soft-tissue vibrations were measured using skin mounted accelerometers, and muscle activity using surface EMG sampling at 2400 Hz whilst 20 subjects stood on a vibrating platform. Measurements were made from the soft-tissue groups of the quadriceps, hamstrings, tibialis anterior and triceps surae. Bursts of continuous vibration and bursts of isolated impacts were delivered in a 8x5 randomized, repeated block manner. Input frequencies were varied between 10 and 65 Hz. The power dissipated by soft-tissue, and intensity of muscle activity were determined for each trial. The resonance spectra for the soft-tissues were determined whilst subjects stood on the platform with white-noise displacements.

RESULTS AND DISCUSSION

Tuning responses were categorized when there was a test frequency which resulted in elevated muscle activity or power dissipation. Responses occurred for both the continuous vibration trials and the pulsed impact trials for all four soft-tissues tested, and occurred when the test frequency matched the natural frequency of the soft-tissue (Fig. 1).

The results supported the hypothesis that there are increases in muscle activity and vibration damping when the frequency content of the impacts match the natural frequencies of the soft-tissue. However, there was no evidence to support the hypothesis that if the impact frequency matched the natural frequency of the tissue that there would be an increase in the natural frequency.

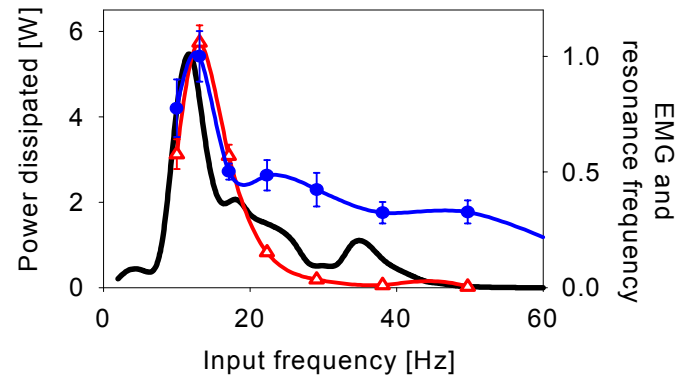

Figure 1. EMG intensity (blue circles), power dissipation (red triangles) and resonance spectra (black line) for the triceps surae whilst subjects were exposed to bursts of continuous vibration. Data (mean \pm SEM) are shown for all cases where a response occurred ($N=18$).

The frequency of the impact forces can be modified by the material hardness of a shoe (eg. Frederick et al. 1984; Lafortune et al. 1996). These results thus indicate a mechanism by which the muscle activities in the lower extremity can be altered by changing the material properties of a shoe.

SUMMARY

Muscle activity is used in the soft-tissues to damp the vibrations from impact forces when the frequency of the impact matches the natural frequency of the tissue.

DETERMINING PATTERNS OF MOTOR UNIT RECRUITMENT DURING ANIMAL LOCOMOTION

James M. Wakeling¹, Walter Herzog¹ and Doug Syme²

¹Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada

²Department of Biological Sciences, University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

Fast and slow muscle fibres have different electrical properties and conductances. It should be expected that the motor unit action potentials which travel along the fast and slow muscle fibres produce different myoelectric signals, and therefore these may be used to distinguish their activity. The mean EMG frequency is greater for persons with a higher proportion of fast muscle (Sadoyama et al. 1988), and for stimulated contractions with a greater proportion of fast- motor units (Solomonow et al. 1990). However, the myoelectric frequency spectra from distinct fast and slow muscle has not yet been determined. The purpose of this study was to test the hypothesis that fast muscle fibres have higher myoelectric frequency bands than slow muscle fibres.

METHODS

Fine wire EMG was recorded from the medial gastrocnemius of six rats *in situ*, whilst the muscle was stimulated through a tripolar electrode on its nerve. A combination of blocking and innervating stimuli generated isometric contractions with either just slow motor units or a combination of fast- and slow (Solomonow et al. 1990). EMG was also recorded from the white and red myotomal muscle of 16 rainbow trout *Oncorhynchus mykiss*, and the medial gastrocnemius and soleus muscles from four cats during *in vivo* locomotion. The intensity of the myoelectric signals was resolved into its components in time-frequency space using wavelet techniques (von Tscherner, 2000). Myoelectric intensity spectra were determined for rat muscle during slow and fast+slow fibre contractions, during various locomotor activities including slow swimming and fast-starts in the fish, and slow walking and rapid paw-shakes in the cat.

RESULTS AND DISCUSSION

EMG intensity spectra were determined when just the slow motor units were activated, and when both fast- and slow-motor units were active in the rat gastrocnemius. Subtraction of these spectra yields the spectra for just the fast- motor units. The fast- and slow- motor units resulted in high and low frequency bands, respectively (Fig. 1).

The fast and slow muscle fibres are anatomically separated in fish, allowing direct recording from these muscle types. The fast and slow fibres generated high and low frequency bands in their intensity spectra in a similar manner to the rat (Fig. 1).

In mammals the fast- and slow-muscle fibres can be mixed within each muscle, making it difficult to determine when each fibre type is active *in vivo*. The cat paw-shake is a predominantly fast-fibre activity (Smith et al. 1980) whereas a larger proportion of slow fibres are active during slow walking. Subtracting the EMG intensity spectra for the paw-shake (fast fibres, blue dashed line, Fig. 1) from that for slow-walking thus results in an estimate of the intensity spectra for the slow fibres in the gastrocnemius (Fig. 1). The estimated intensity spectra for the slow motor units from the medial gastrocnemius was similar to that measured for the soleus muscle which contains predominantly slow fibres (Fig. 1).

Figure 1. EMG intensity spectra for fast (blue) and slow (red) motor units from the myotomal muscle of the rainbow trout (solid lines), medial gastrocnemius and soleus muscles of the cat (dashed lines), and medial gastrocnemius muscle of the rat (dotted lines).

SUMMARY

The myoelectric frequency spectra from fast- and slow muscle fibres can be characterized by high and low frequency bands, respectively. These bands can be distinguished even during *in vivo* activities. Therefore, these methods may be used to determine the pattern of motor unit recruitment during locomotion.

BIOMECHANICAL EFFECTS OF INTERMEDIATE SCREWS IN SHORT AND LONG ANTERIOR CERVICAL FUSION CONSTRUCTS

Raghu N. Natarajan, Nelson Oi, Luck Curylo, Gunnar B.J. Andersson and Howard An

Department of Orthopedic Surgery

Rush-Presbyterian-St.Luke's Medical Center, Chicago, Illinois. E-mail : rnataraj@rush.edu

INTRODUCTION

Anterior cervical plating has been accepted as an effective adjunctive procedure to anterior cervical discectomy and fusion (ACDF), particularly in multi-level cases to improve the fusion rate and to provide proper cervical alignment. ACDF with plating can be performed with screws at each end vertebral bodies or segmentally at each end and intermediate vertebral bodies. The purpose of this study is to compare motion and stresses between ACDF constructs with intermediate screws (IS) or without intermediate screws (NIS) in both two and three fused motion segments using a validated finite-element-model (FEM).

METHODS

A three dimensional non-linear finite element model of an intact C3-T1 cervical spine segment was developed using CT scans of 38 year old female normal subject. From this intact model, four different models were developed to include various constructs of anterior plating with interbody fusion models. Anterior plating was 18 mm wide and varied in length depending on the length of the fusion modeled. The screw was of 4.35 mm in diameter. The graft was placed in between appropriate vertebrae so that it occupied about 65% to 75% of the adjacent endplate areas. To simulate the laxity between the screw and the plate, elastic modulus of the plate was assumed as one thousands of the elastic modulus of CoCr. The screw was assumed to be rigidly connected to the bone. The rotation of all the vertebra in the sagittal plane, von Mises stress in the cancellous bone near the screw and the movement of screw with respect to the surrounding bone were extracted from the finite element model results.

RESULTS

As expected, in both 3 level and 4 level platings, intermediate screws (IS) provided lesser total motion as compared to terminal screws (NIS) under flexion/extension moment load (Table 1). Also, 4 level plating produced less total motion as compared to 3 level plating and was more prominent under extension than in flexion. Intermediate screws provided greater rigidity for both short and long plating constructs under flexion and extension.

The von Mises stress in the bone near the screws was higher in the long construct for both IS and NIS cases: 3.0 MPa under flexion and 4.5 MPa under extension. In the shorter construct, maximum stress occurred at the superior vertebra at 1.9 MPa both under flexion and extension. The long construct induced localized (posterior edge of the screw) tensile strain (anterior-posterior direction) in the superior vertebra under flexion

moment in both IS and NIS cases while the tensile strain was distributed over 50% of the cross-section in the inferior vertebra under extension moment in NIS case. Flexion produced localized maximum tensile strain of 0.4% (same for both IS and NIS cases) while extension moment produced a distributed tensile strain of 0.3% in NIS and localized strain of 0.2% in IS case. In the shorter construct as well, a similar behavior was observed. Flexion produced a localized strain of 0.3% in both IS and NIS cases while extension induced a distributed strain of 0.2% in the inferior vertebra. Compressive stress in the graft was of higher magnitude in NIS for both short and long plating as compared to IS constructs. Flexion produced maximum graft stress of 4.0 MPa while the graft stress was much higher under extension (13.0 MPa).

CONCLUSION

The most rigid ACDF construct is predicted in the shorter construct with intermediate screws, and the intermediate screws were effective in reducing motion in flexion and extension. The intermediate screws also enhance the construct stability in the long construct greater in flexion than in extension. The results of tensile strain distributed over the cross-section (rather than localized) in the inferior vertebra with terminal screw construct show that chances of screw pullout are greatest in the long constructs. The presence of higher von Mises stresses of the bone around the screw at the inferior vertebrae of the long constructs further enhances the chance of screw pull-out. Graft collapse may be possible in both long and short constructs without intermediate screws, especially under extension moment load. These FEM predictions favor the use of intermediate screws in ACDF and plating cases but should be further validated with experimental studies.

	Total Motion		Motion at Fusion Level	
	3 Level Plating	4 Level Plating	3 Level Plating	4 Level Plating
NIS	9.2 (23.9)	6.9 (15.5)	1.6 (3.9)	3.8 (9.2)
IS	8.7 (23.0)	6.0 (13.7)	1.0 (3.2)	1.8 (7.3)

Table 1: Effect of intermediate screws in both short and long fusion constructs under flexion and extension (values given in bracket) moment loads. The values are given as a ratio : motion due to the external moment for a specific fusion construct / motion in an intact motion segment under same external moment.

DIFFERENT GAIT PATTERNS CAN BE CLASSIFIED BY USING MUSCULAR ACTIVITY PATTERNS

Li Li, Ph.D.

Department of Kinesiology, Louisiana State University, Baton Rouge, Louisiana, USA, LLI3@LSU.EDU

INTRODUCTION

Classification of human locomotion often based on the unique characteristics presented in the kinematic patterns of different modes of locomotion. For example, double or single stance phase are the differences between walking and running. Based on central pattern generator (CPG) theory, Golubisky et al. (1999) suggested four primary gait patterns for bipedal locomotion based on their control mechanisms. There are two different ways to control each leg and the two legs can be in synch or out-of-phase. The theory predicts two primary gaits when the legs are out-of-phase, i.e., walk and run. Theory also predicts two different primary gaits when the legs are in phase, two different hops, i.e., slow and fast hops. The control in each leg should be similar comparing slow hop and running and the control in each leg should be similar comparing fast hop and walking. The purpose of this study was to examine the abovementioned theory using muscular activity patterns during the four proposed gait patterns. Muscular activity patterns were represented by the linear envelopes of surface electromyography (EMG).

METHODS

Eight college students recruited as participants of the study. Informed consent forms were signed after the experiment protocol discussed in detail. There were four testing conditions in the experiment: walking at 1.55 m/s and running at 3.1 m/s on a Kistler Gateway treadmill; as well as slow and fast hopping on an AMTI force platform. Vertical ground reaction forces were collected to identify gait cycles. One gait cycle was defined as the time between the initiations of two consecutive ground contacts. EMG data were collected from gluteus maximus (GM), rectus femoris (RF), biceps femoris (BF), vastus lateralis (VL), tibialis anterior (TA),

gastrocnemius (GS), and soleus (SL) of both legs. EMG and ground reaction forces were collected in a synchronized fashion at 960 Hz.

Raw EMG data were processed (bias removal, full wave rectification, low pass digital filter – zero lag fourth order ButterWorth with cut off frequency of 6 Hz) to produce their linear envelopes. The patterns of the EMG profiles were evaluated by using their temporal parameters (onset, offset, and duration). ANOVA with repeated measures were employed for the statistics analysis.

RESULTS AND DISCUSSION

The frequency of the fast hops was at approximately 5 Hz where the frequency of the slow hops was close to 1 Hz. The EMG patterns of walking and running were comparable with literature (Figure 1). Within each leg, greater amounts of cocontraction were observed in slow hopping, where less cocontraction observed with fast hopping. These observations were more pronounced when focused on the patterns of TA in comparison to GS and SL (see exemplar data in Figure 1). There are four different patterns of locomotion can be defined according to the different muscular activity patterns of lower extremity: 1). alternating muscle activity with limbs out-of-phase: walk; 2). cocontraction muscle activity with limbs out-of-phase: run; 3). alternating muscle activity with in-phase limbs: fast hop; and 4). cocontraction muscle activity with in-phase limb motion: slow hop. These observations agree with the predictions of Golubisky et al., (1999).

BIOMECHANICAL COMPARISON OF THE LUQUE-GALVESTON AND COLORADO II METHODS FOR SACROPELVIC FIXATION

Andrew Mahar¹, Richard Oka¹, Sean Early², Peter Newton¹

¹ Department of Orthopedics, Children's Hospital, San Diego, CA

² Department of Orthopedics, Children's Hospital, Los Angeles, CA

INTRODUCTION

The Luque rod system with Galveston pelvic fixation has become standard for treating childhood and adolescent neuromuscular scoliosis. The Galveston method provides reasonable lumbar-pelvic fixation with a relatively simple method of insertion. Clinical reviews of sagittal plane stability in neuromuscular patients with Galveston fixation performed at our institution have led to concerns regarding the technique's ability to maintain proper lumbar lordosis. Other instrumentation constructs may improve lumbosacral alignment while also preventing recurrence of pelvic obliquity. A biomechanical study evaluated lumbosacral stability of two sacropelvic fixation methods: the standard Luque-Galveston method and the Colorado II sacropelvic fixation method using the Chopin plate-screw block. Construct rigidity was also compared between two proximal fixation methods; one utilizing proximal pedicle screws and the other with proximal sublaminar wires.

METHODS

Eight fresh frozen human cadavers were dissected from L1 to the sacrum. The anterior and posterior longitudinal ligaments and the discs were left intact. The interspinous ligaments and ligamentum flavum were removed to allow passage of 18 gauge sub-laminar wires at L2, L3, L4, and L5. At L1, bilateral 6.5 mm poly-axial pedicle screws were placed. All segmental instrumentation was secured to two 5.5 mm rods contoured for appropriate lumbar lordosis. The proximal pedicle screws were tested in both locked and unlocked conditions. The unlocked condition simulated L1 sub-laminar fixation.

The end of the sacrum was potted in two-part epoxy resin and rigidly bolted to the load cell. The proximal spine was also potted in epoxy resin and attached, with screws, to either a cantilever apparatus for applying bending moments or an axially aligned fixture for torque testing. Intact specimens were tested in an MTS 858 servohydraulic machine, followed by sequential testing of the Galveston and Colorado systems. Proximal fixation was randomized across tests. Torsional testing involved axial rotation performed at 1° per second with torque limits of ± 2 Nm. Angular displacement and torque data were collected at 20 Hz over 20 cycles. The upper mount of the spine was changed to a cantilever bending apparatus for the flexion/extension bending test. The cantilever allowed application of bending moments of 5 Nm in flexion and extension. Flexion and extension tests were performed for 20 cycles while collecting displacement and force data at 20Hz. Load tests were randomized between spines and constructs.

Stiffness was calculated from the linear portion of the load-displacement curve for each test. Data for construct stiffness were analyzed using a two-way analysis of variance ($p < 0.05$) with the dependent variables being type of sacropelvic fixation and use of rigid L1 pedicle screws. Tukey *post-hoc* testing was done when significant differences were found to perform multiple comparisons as indicated.

RESULTS AND DISCUSSION

For flexion/extension and torsion testing, significant differences were found when comparing locked conditions to unlocked conditions (Tables 1 and 2). When examining only those constructs that were locked or unlocked (eg. C-U and G-U), there were no statistical differences.

Table 1: Flexion-extension stiffness

	C-U	C-L	G-U	G-L
Mean	0.933	1.384	0.878	1.453
C-U		0.025	0.983	0.008
C-L	0.025		0.010	0.967
G-U	0.983	0.010		0.003
G-L	0.008	0.967	0.003	
interaction term = 0.563				

Table 2: Torsion stiffness

	C-U	C-L	G-U	G-L
Mean	1.150	2.034	1.445	2.482
C-U		0.001	0.466	0.000
C-L	0.001		0.030	0.135
G-U	0.466	0.030		0.000
G-L	0.000	0.135	0.000	
interaction term = 0.588				

SUMMARY

The Colorado II and Luque-Galveston methods of sacropelvic fixation demonstrated similar construct stiffness under flexion-extension and torsional loads. Since locking superior instrumentation (pedicle screws) increased the stiffness of the system, rigid fixation at L1 may increase the chances of lumbopelvic fusion. Greater understanding of failure mode differences between systems from retrospective clinical review will influence subsequent biomechanical studies and alterations to the system design.

BIOMECHANICAL STABILITY BETWEEN TWO TYPES OF PERIACETABULAR OSTEOTOMIES FOR SURGICAL CORRECTION OF DEVELOPMENTAL DEFORMITIES OF THE HIP

Andrew Mahar¹, Wally Yassir², Afshin Aminian³, Dennis Wenger¹, Peter Newton¹

¹ Department of Orthopedics, Children's Hospital, San Diego, CA

² Department of Orthopedics, Tufts University Hospital, Boston, MA

³ The Orthopedic Center, Cedar Knolls, NJ

INTRODUCTION

Periacetabular osteotomies are performed for improvement of femoral head coverage in a variety of clinical scenarios. These differ in surgical technique, amount of coverage attainable, and biomechanical strength. The modified triple innominate osteotomy (Tonnis) frees the acetabular fragment from its attachments to the pelvic floor ligaments allowing increased mobility of the osteotomized fragment. The Ganz procedure allows rotation of the acetabular fragment via bone resection and preserves a portion of the posterior ischial column. It is theorized that this allows minimal intraoperative fixation and early postoperative weight bearing. This osteotomy violates the triradiate cartilage, however, and cannot be performed in skeletally immature individuals, making the triple innominate osteotomy a necessary surgical alternative. The purpose of this study was to compare fragment stability following each type of osteotomy.

METHODS

Eight fresh-frozen male cadavers (mean age 39 years \pm 4.3 years) were dissected to expose the regions from L1 to the mid-shaft of each femur keeping an intact hip joint capsule and sacrospinous and sacrotuberous ligaments. Each specimen underwent both types of osteotomies, with random assignment to either the right or left side. The acetabular fragments were fixed with AO 4.5 mm cortical screws in three different screw constructs (Figure 1). In addition, the Tonnis osteotomies were fixed with wire across the pubic osteotomy.

A triad of 4 mm retro-reflective markers was placed on each sacrum at the center sacral line to establish a pelvic coordinate system. Additional marker triads were placed on each acetabular osteotomy fragment and femur. The x, y, and z axes corresponded to the anterior-posterior, medial-lateral, and superior-inferior directions, respectively. The local coordinate system for each fragment was matched to the pelvic coordinate system, establishing a baseline orientation for each fragment relative to the pelvic coordinate system. Each specimen was placed into the testing rig with femurs pointing cephalad and iliac wings pointing caudad. The rig base held each specimen in 8 degrees of anterior pelvic tilt. Loads were applied directly to the superior iliac wings with an MTS 858

machine. Each specimen was cyclically loaded in axial compression from 0 to 450 Newtons for 10 cycles for each screw construct. The loading profile was that of full weight bearing for a 50kg 12-year-old boy, approximating partial weight bearing in an adult. Each specimen underwent loading with the 2, 2W, 3A, 3AW, 3B, and 3BW screw constructs. The order of fixations was randomized to prevent bias from increased osteotomy fragment motion in the later trials. Motion data were sampled at 20Hz for the duration of 10 trials for each screw construct for each cadaver. The maximum and minimum displacements and angular rotations were collected from the final four loading cycles and then averaged. Four 2 (Ganz vs. Tonnis) X 6 (2, 2W, 3A, 3AW, 3B, 3BW) ANOVA's using SPSS statistical analysis software were performed to compare mean displacements and angular rotations among osteotomy type and screw constructs. Post hoc analyses included one independent samples t-test to examine a trend within a particular screw construct and one ANOVA to examine a trend across screw constructs within the Tonnis osteotomy. The Bonferroni corrected significance level was set at $p = 0.008$.

RESULTS

No statistically significant difference in displacement could be found between the Ganz and Tonnis osteotomies ($p = 0.37$). Very little displacement was encountered during loading for all screw constructs, with a range of 0.6 to 1.3 mm on average. Post hoc analysis of the 2W trial (2 screws in Ganz osteotomy vs. 2 screws in Tonnis with pubic wire) approached statistical significance, with the Tonnis osteotomy showing less displacement in this construct ($p = 0.05$). For 3 screw constructs, the addition of a pubic wire adds little to the stability. There were no significant differences in angular motion for any comparison.

CONCLUSION

Small amounts of displacement and angular rotation were noted when comparing the two osteotomies across fixation methods. For partial weight bearing in adult and full weight bearing in pediatric populations, it appears that while 2 antegrade screws provide adequate clinical stability, greater fixation is achieved with 3 screws.

MUSCLE SYNERGIES CONTROLLING GROUND REACTION FORCES DURING BALANCE

Lena H. Ting and Jane M. Macpherson

Neurological Sciences Institute, Oregon Health & Science University, Beaverton, OR, 97006 USA
Email: tingl@ohsu.edu

INTRODUCTION

A limited set of functional muscle groupings for controlling ground reaction forces components during balance have been proposed in the standing cat (Jacobs and Macpherson 1996). These groupings are based on correlation analysis of muscle activity and force magnitude and direction associated with automatic postural responses. The current study uses a muscle synergy extraction scheme to determine whether muscle activation patterns observed experimentally can indeed be characterized by additive combinations of a small set of muscle synergies.

METHODS

Cats standing quietly were subjected to translations of the support surface in 16 evenly spaced directions in the horizontal plane (5 cm at 15 cm/s). EMG activity in hindlimb muscles and 3D ground reaction forces at each limb were collected (see Macpherson 1988a, 1988b). Automatic postural responses are typically elicited 60 ms after perturbation onset. Mean EMG levels 60-135 ms after perturbation onset were averaged in each cat for use in the synergy analysis. Corresponding ground reaction forces were taken at 120-195 ms after perturbation onset.

An additive muscle synergy extraction scheme similar to one developed by Tresch, et al. (1999) was used to analyze the 16 different patterns of EMG activity observed across all perturbation directions. Each muscle synergy is a vector with elements constrained to be between 0 and 1. Each element represents the level of activity of one muscle in the synergy. For a given synergy set, a least-squares fit was used to determine the best reconstruction of the experimental data using the muscle synergies and non-negative weighting functions. A gradient search algorithm was used to find muscle synergies that provided the best fit to the experimental data. Random initial synergy values, and different numbers of synergies were used in several searches.

RESULTS AND DISCUSSION

Three muscle synergies were necessary to consistently reproduce >95% of the EMG activity. Synergies were highly repeatable regardless of initial conditions. The first two synergies could be characterized as extensor or flexor muscle groups (Fig. 1A,B). The third (Fig. 1C) was similar to a primarily biarticular group responsible for horizontal plane forces proposed by Jacobs and Macpherson (1996). However, note that muscles are not limited to a single synergy, and muscles do not group simply by anatomical classification.

The synergy weighting functions indicate the level at which each synergy is activated in response to a particular

perturbation direction. They tend to vary with the stabilizing forces produced by the limb (Fig. 1).

Figure 1: Muscle synergies and weighting functions that reconstruct 98% of experimental data. Synergy A varies with increased loading of the leg, B with unloading, and C with increased horizontal ground reaction force.

SUMMARY

While only EMG information is used in the muscle synergy extraction, the synergy weighting functions that indicate when the synergy is activated bear remarkable resemblance to the Cartesian components of the ground reaction forces produced by the leg. This demonstrates that complex muscle activation patterns observed during automatic postural responses can be reproduced by additive linear combinations of just three muscle synergies. The nervous system may use these synergies to simplify the control of force production in the leg.

INTRODUCTION

Fluid mechanical factors have been linked to both the initiation and progression of atherosclerotic plaques; however, the exact mechanisms are not clearly understood. Currently, our laboratory is undertaking a study in which we are attempting to correlate plaque progression at the carotid bifurcation with computed fluid mechanical indices. Using black blood magnetic resonance (MR) imaging, arterial geometry and plaque distributions are measured annually in human subjects over a number of years. From each annual MR scan, finite-element meshes of the lumen geometry are generated and patterns of fluid mechanical indices are derived from computational fluid dynamic (CFD) simulations. Creating such finite element meshes requires substantial user effort, and the resulting models can exhibit variability caused by subjective modeling decisions made by the operator. In this abstract we propose a technique to minimize this by using the manually generated “baseline” finite element meshes as a template to be automatically deformed to match “follow-up” MR image data.

METHODS

The initial tetrahedral finite element mesh (e.g., Figure 1a) is first generated from the “baseline” serial MR images using the procedure previously described by Steinman et al. (2002). Briefly, a 2-D discrete dynamic contour (DDC) is used to semi-automatically extract the lumen boundary from each serial MR image. These lumen contours are then used as masks to create a binary 3-D image dataset, within which a 3-D DDC (Ladak et al., 2000) is inflated to provide the 3-D lumen boundary for subsequent octree-based generation of the tetrahedral finite element volume mesh. The deformation procedure begins by manually orienting the initial mesh within the “follow-up” MR image data. An image-based force field is calculated from the 3-D image (Ladak et al., 2000), and then used to drive the vertices of the “baseline” FE mesh to the “follow-up” lumen boundary. To keep the model smooth in the presence of noise and to maintain the quality of the finite elements for subsequent CFD simulation, at each iteration Laplacian smoothing is applied to the deformed surface triangulation and then, with the surface triangles fixed, to the volume tetrahedral elements.

RESULTS AND DISCUSSION

To test this algorithm a “follow up” dataset was created by manually deforming the lumen boundaries of the “baseline”

binary 3-D image data to simulate the growth of small plaques (maximum height of 3 and 6 pixels normal to the original wall) at the internal carotid artery just distal to the bifurcation. As illustrated in Figure 1b, automated deformation and smoothing of the mesh was able to capture even a 6-pixel change in the lumen geometry. Element quality, as measured via the radii-ratio metric (Pebay et al., 2001), was found to be comparable to that of the “baseline” mesh.

Figure 1: (a) “Baseline” finite element surface mesh; (b) Deformed and smoothed mesh after introduction of the 6 pixel high mild plaque (indicated by arrow).

SUMMARY

Our tests demonstrate that the proposed method can deform the “baseline” finite element mesh to match the corresponding “follow-up” image while maintaining mesh quality. Future work will focus on optimizing the algorithm, via selection of appropriate Gaussian kernel and iteration parameters, to allow for the capture of larger and more complex deformations.

MODELING OF BIOMECHANICS OF TACTILE SENSATION ON FINGERTIPS

John Z. Wu¹, Ren G. Dong, Aaron W. Schopper, and W. Paul Smutz

National Institute for Occupational Safety and Health, Morgantown, WV, USA. ¹E-mail: jwu@cdc.gov

INTRODUCTION

Tactile perception threshold measurement has been widely used to diagnose the severity of peripheral neuropathy, for example, hand-arm vibration syndrome. The study of biomechanics of the fingertips is vital to enhance an understanding of mechanism of tactile sensation and sensory thresholds. The reported fingertip models (e.g., Phillip and Johnson, 1981; Srinivasan and Dandekar, 1996) do not incorporate the nonlinear and time-dependent effects associated with the anatomical substructures and tissue material properties. The purpose of the present research was to develop a finite element model to simulate the mechanics of tactile sensation of a fingertip.

Figure 1: Finite Element Model. (a): Multi-layered fingertip model. (b): Two-point discrimination (2PT) test

METHODS

The biomechanics of tactile sensation of a fingertip were analyzed using a multi-layered two-dimensional finite element model, as shown in Fig.1a. The fingertip was assumed to be composed of a skin layer, subcutaneous tissue, bone, and nail. The fingertip dimensions were assumed to be representative of index finger of a male subject. The skin tissue, including epidermis and dermis, was assumed to be hyperelastic and linearly viscoelastic. The subcutaneous tissue was assumed to be a biphasic material composed of a fluid phase and a hyperelastic solid phase. The nail and the bone were considered as linearly elastic. Numerical tests were performed to study the mechanics of tactile sensation of the fingertip in two-point (2PT) discrimination tests (Fig.1b). The fingertip was fixed on the center of nail surface, while two indentors (each with a circular contact surface and thickness of 1 mm) were used to deform the skin surface of the fingertip by 1 mm within a ramping period of 1 s. Four numerical tests with different spacing between the indentors ($d = 1.5, 2.0, 3.0$, and 4.0 mm) were performed. The analyses were performed to compute the displacement, stress, and strain fields within the soft tissue at the state of maximum depression. The mechanical states (stress/strain) of the tissue at a depth of 0.75 mm from the undeformed skin surface, where the Merkel cell receptors are located, were analyzed in the study.

RESULTS AND DISCUSSION

The simulation results reveal that differences in horizontal and vertical strains (E11 and E22, respectively) and strain energy

density (SED) developed in the skin at the contact points and at the geometric center of the fingertip vary only slightly with a decrease in the indenter spacing from 4.0 to 3.0 mm (Fig. 2). These differences, however, decrease considerably with a further decrease in the indenter spacing from 3.0 to 2.0 mm. The corresponding differences in the vertical displacement (U2) and shear strain (E12), however, decreased almost linearly with a decrease in the indenter spacing from 4.0 to 1.5 mm.

Figure 2: Normalized variations of horizontal (E11), vertical (E22) and shear strains (E12), vertical displacement (U2), and strain energy density (SED) as a function of 2PT spacing. The

normalized variations were evaluated by $[f(\text{contact point of indenter}) - f(\text{geometry center})] / f(\text{contact point of indenter})$.

SUMMARY

The present analysis suggest that, assuming mechanoreceptors in the dermis sense the stimuli associated with normal strains (E11 and E22) and strain energy density (SED) rather than those associated with shear strain (E12), the threshold of 2PT discrimination test for the fingertip may lie between 2.0 and 3.0 mm. This analysis is consistent with the experimental observations by Perez et al. (2000) who reported an average 2PT discrimination distance of 2.1 mm in tactile sensation threshold tests of the index finger.

GLIDING RESISTANCE VERSUS WORK OF FLEXION—TWO METHODS TO ASSESS FLEXOR TENDON REPAIR

Tatsuro Tanaka, Peter C. Amadio, Chunfeng Zhao, Mark E. Zobitz, Kai-Nan An
Biomechanics Laboratory, Department of Orthopedics, Mayo Clinic/Mayo Foundation
200 First Street SW, Rochester, MN 55905, e-mail: pamadio@mayo.edu

INTRODUCTION

Two methods for measuring the ability of the flexor tendon to glide following repair are commonly cited in the literature: gliding resistance [1] and work of flexion (WOF) [2]. While the gliding resistance measures the friction force at the tendon-pulley interface, the work of flexion characterizes whole finger function during flexion. The purpose of this study was to compare work of flexion and gliding resistance, in assessing the mechanical outcome of flexor tendon repair.

METHODS

48 mongrel dogs were used. One randomly selected second or fifth flexor digitorum profundus (FDP) tendon was exposed in the paw between the proximal and distal pulleys. A complete laceration was created 5 mm from the distal edge of the proximal pulley on the FDP tendon with the digit in full extension. The tendon was repaired with a modified Kessler technique using 4-0 Supramid loop suture and an epitendon running suture using 6-0 Nylon. Postoperatively, the operated paw was immobilized in a cast. Dogs were sacrificed of 1, 3, 5 or 7 days after surgery.

WOF Measurement: The testing device was composed of a testing frame, an actuator, linear potentiometer, and two load transducers. The distal end of the FDP tendon was exposed and attached to a small load transducer (F_d) which was fixed to the distal phalanx. A K-wire was inserted through the metacarpophalangeal joint with this joint extended to support the specimen in the testing frame. A 0.49 N weight was attached to the proximal end of the extensor tendon. The proximal end of the FDP tendon was connected to a second transducer (F_p), an actuator and a linear potentiometer. The actuator pulled the FDP tendon proximally (2mm/s) to flex the finger against the weight until the full flexion position was reached. Proximal (F_p) and distal (F_d) forces were recorded and plotted against the tendon excursion. Total work of flexion (TWOF) is the area under the F_p curve. The area between the F_p and F_d curves represents the energy expended due to the tendon pulley interaction and is termed internal work of flexion (IWOFF).

Gliding Resistance: The same specimens were used to assess the gliding characteristics of repaired tendon after measuring TWOF and IWOFF. The proximal pulley, the parietal membrane at the proximal pulley, the visceral membrane of the FDP tendon, the FDS tendon and its insertion were preserved. The vincula of the FDP tendon were cut. A K-wire was inserted through the proximal phalanx to support the specimen in the testing jig. Load transducer, F_2 , was attached between the mechanical actuator and proximal FDP tendon. The distal transducer, F_1 , was connected to a 4.9N weight. The tendon was pulled proximally by the actuator against the

weight at a rate of 2mm/s. The differences between F_1 and F_2 were averaged to represent the gliding resistance (GR).

RESULTS

Average values of work and gliding resistance at each time point are shown in Figure 1. GR was not different significantly at any time point. On the other hand TWOF and IWOFF decreased within 5 days after surgery, but there were significant increases at 7 days. Relationships between TWOF and IWOFF versus GR for all specimens are shown in Figure 2 and for each sacrifice day in Table 1. Overall, IWOFF showed a strong correlation to gliding resistance ($r=0.76$), while there was little correlation between TWOF and gliding resistance.

Figure 1: Work and Resistance

Figure 2: Correlations Between WOF and Gliding Resistance

Table 1: Correlation coefficients		
Sacrifice Day	GR vs. TWOF	GR vs. IWOFF
1 day	$r=0.53$	$r=0.80$
3 days	$r=0.52$	$r=0.86$
5 days	$r=0.45$	$r=0.92$
7 days	$r=-0.03$	$r=0.65$

DISCUSSION

Since measurement of TWOF includes external resistance such as joint stiffness, soft tissue resistance, mass of digits, resistance of antagonist muscles and internal resistance, a weak correlation with gliding resistance is not surprising. Meanwhile, IWOFF includes variables such as bulk friction, GR, and incremental resistance resulting from adhesions, a strong correlation between gliding resistance and IWOFF suggests that the measurement of gliding resistance could be used easily for the assessment of IWOFF. Namely, if the correlation between GR and IWOFF is strong, it suggests that little adhesion formation may occur. The reduced correlation between GR and IWOFF at 7 days post-operative suggests that variations perhaps due to minor adhesion formation may occur at 7 days.

MAXIMUM NET TANGENTIAL FORCE AND MUSCULAR ACTIVITY DURING INDUSTRIAL HANDWHEEL ACTUATION

Tyler Amell¹, Shrawan Kumar¹, Yogesh Narayan¹, and Ambikaipakan Senthilselvan²

¹Ergonomics Research Laboratory, University of Alberta, Edmonton, Alberta, Canada, T6G 2G4

²Department of Public Health Sciences, University of Alberta, Edmonton, Alberta, Canada

INTRODUCTION

Large handwheels are used in numerous industries as control devices employed to regulate process and production. Industries such as the petroleum, chemical, waste treatment and power generation commonly use these devices. The task of industrial handwheel actuation requires the exertion of large tangential forces about the control device. These forces are typically generated manually, and have been associated with increased risk of musculoskeletal injury in operators (Amell and Kumar, 2001). The purpose of this study was to determine the maximum two-handed net tangential handwheel force and electromyographic activity of the primary muscles contributing to the task during actuation at various heights, pitch angles, contours of foot support and distances of foot support.

METHODS

Participants were required to exert upon a custom-built handwheel fixed to a force measuring device. All exertions were counter-clockwise in direction. The maximal static two-handed net tangential forces as well as electromyographic (EMG) activity of 20 healthy male participants were recorded with respect to 24 experimental conditions. Four independent variables were examined: 2 handwheel pitch angles (90° and 0° to the horizontal); 2 contours of foot support (flat and convex); 2 distances of foot support (19 cm and 58 cm); and 3 handwheel heights (35, 93 and 168 cm from the grade). Flexor carpi radialis, biceps brachii, anterior deltoid and erector spinae muscle activity at the L4 vertebral level was recorded bilaterally using surface electrodes.

RESULTS AND DISCUSSION

Figure 1 illustrates the mean maximum tangential force for each experimental condition while the mean maximum EMG for each muscle sorted by distance of foot support is depicted in figure 2. Mean maximum tangential forces ranged from 585 N to 760 N. Less force was generated at the 19 cm distance of foot support compared to the 58 cm distance ($p = 0.007$). No statistically significant ($p > 0.05$) main effects were obtained for the pitch angle, contour of foot support or the handwheel height. EMG analysis revealed the flexor carpi radialis and the erector spine to be very active in this task. The mean maximum normalized activity in these muscles was 330% and 230% respectively. The results reveal that handwheel design has an effect upon both maximal tangential force and muscular activity.

Figure 1: Mean maximum net tangential force sorted by experimental condition for 20 healthy male participants.

Figure 2: Normalized EMG activity for each muscle studied sorted by distance of foot support for 20 healthy male participants.

SUMMARY

The design of these control devices must consider the strength capabilities as well as the anthropometrics of the operator in order to optimize safety in industrial handwheel operation.

BICYCLE SEAT DESIGNS AND THEIR EFFECT ON PELVIC ANGLE, TRUNK ANGLE, AND COMFORT IN FEMALES DURING CYCLING

Eadric Bressel¹, Cherianne Mecham¹, and Megan E. Bressel²

¹Biomechanics Laboratory, Utah State University, Logan, UT, USA, ebressel@coe.usu.edu

²Mountain West Physical Therapy, Logan, UT, USA

INTRODUCTION

As a cyclist leans forward onto the handlebars of a bicycle, undesirable pressure is often applied to the anterior perineum. The pressure applied to the perineum may prevent the pelvis and trunk from moving into an anterior tilt position, which increases the load placed on the seat and lumbar region of the spine (de Vey Mestdagh, 1998; Salai et al., 1999). Newly designed bicycle seats constructed with either no or minimal filling at the anterior-medial region may improve perineal comfort and allow the pelvis and trunk to move into a greater anterior tilt position, however, these latter theories have not been tested. The purpose of this study was to examine if bicycle seats with anterior-medial cutouts influence pelvic angle, trunk angle, and comfort in females during cycling.

METHODS

Ten experienced ($M_{age} = 27.14 \pm 5.15$ yrs) and 10 novice ($M_{age} = 21.00 \pm 1.41$ yrs) female cyclists volunteered as subjects. Subjects pedaled a stationary bicycle with their hands on the tops and drops of the handlebars under three different saddle conditions illustrated in Figure 1.

Figure 1: A top view of the three saddle designs and their physical dimensions.

Subjects pedaled for 7 min at each saddle condition while pelvic angle was measured using an inclinometer technique based on the procedures of Walker et al. (1985). Trunk angle was quantified from two-dimensional coordinate data taken from the digitization of reflective markers using a motion analysis system. Kinematic data were calculated with respect to an absolute horizontal reference such that greater angles indicated an anterior tilt of the pelvis and trunk. Comfort level was assessed by having participants subjectively rank the saddles from most to least comfortable. Mean differences were assessed using a repeated-measures analysis of variance with experience level as a between subjects factor. Probability of Type I error was set at .05.

RESULTS AND DISCUSSION

Mean pelvic angles for the partial and complete cutout saddles were 16% and 25% greater respectively, than values for the standard saddle condition in the top handlebar position (Table 1). In the drop handlebar position, pelvic angle data exhibited a similar trend.

Table 1: Mean (\pm SD) angle data for all subjects on tops

Variable	Pelvic Angle (deg)	Trunk Angle (deg)
Standard	14.18 (7.23)	140.25 (5.30)
Partial Cutout	16.48 (6.44) ^a	139.74 (3.68)
Complete Cutout	17.68 (6.93) ^a	141.62 (3.64)

^a $p < .05$. Significantly greater than standard saddle condition

Trunk angle data were not different between saddle conditions (Table 1). Fifty percent of the subjects ranked the partial cutout saddle as the most comfortable and 25% ranked the standard saddle as the most comfortable. Angle and comfort data were not different between experienced and novice subjects ($p > .05$).

Our findings indicating a greater anterior pelvic tilt may be appealing because of the potential for reduced stress on the lumbar spine during cycling (Salai et al., 1999), however, a complete anterior cutout design may not be practical during real cycling conditions that rely on the anterior region of the saddle for stability and steering (de Vey Mestdagh, 1998). The partial cutout design may be a good compromise as it maintains stabilizing features of the standard saddle, increases anterior pelvic tilt, and may improve comfort. Comfort and pelvic angle data of this study supports this latter contention.

SUMMARY

These data indicate that complete and partial cutout saddle designs may enhance an anterior pelvic tilt under select cycling conditions and that partial cutout designs may be more comfortable than a standard or complete cutout saddle.

THE CORRECTION OF INERTIAL GROUND REACTION FORCES DUE TO A MOVING BASE OF SUPPORT

Richard Preuss and Joyce Fung

Jewish Rehabilitation Hospital Research Centre, McGill University, Montreal, Québec, Canada, (joyce.fung@mcgill.ca)

INTRODUCTION

The study of postural reactions triggered by surface perturbations often involves the analysis of ground reaction forces (GRF) from a force plate (FP) mounted on a moveable surface. One limitation, however, is that the recorded signal will contain force and moment-of-force components resulting from the inertia of the FP (Force Plate Inertial Components - FPIC). The purpose of this work was to validate a method for calculating the FPIC from the kinematics of the moving platform, so that the FPIC can be subtracted from the recorded signal.

METHODS

Three reflective markers were firmly mounted on the surface of a six-degree-of-freedom motion base (MB) (Fung and Johnstone, 1998). The empty MB (no subject) was subjected to eight different perturbations in the pitch (x) and roll (y) planes, at 45° angles to one another (about the yaw (z) axis). The perturbation stimulus consisted of a ramp signal with a duration of 400ms and a magnitude of 10°. A 6-camera Vicon 512 motion analysis system was used to record the kinematic data (sampling frequency 120Hz) for the MB, while forces were collected from an AMTI (OR6-7) force plate (sampling frequency 1080Hz, digitally re-sampled at 120Hz) firmly mounted on an aluminum plate within the MB. A 2s long trial was collected for each MB perturbation.

The frequency content of the force plate data from the eight perturbation trials was analyzed using a power spectral density function (PSDF), in order to determine an appropriate cutoff frequency for filtering. The filtered signal (filtered using a 4th-order, zero-phase-lag, digital Butterworth filter, cutoff frequency 10Hz) was taken to represent the actual FPIC for each trial.

The kinematic data from the MB perturbations was analyzed using an Euler rotation-matrix algorithm in order to determine the orientation, velocity and acceleration of the MB, as well as the orientation of the gravity vector relative to the MB, for each trial. Using the inertial properties of the force plate, an estimate of the FPIC was calculated from the kinematic data. The calculated FPIC were low-pass filtered (as above) with a cutoff frequency of 6Hz. This filtered, calculated FPIC was then subtracted from the raw force plate data, and the resulting signal was low pass filtered with a cutoff frequency of 10Hz. This result was taken to represent the residual FPIC.

The residual and actual FPIC were then integrated over time as a means to compare the magnitude of the two signals.

RESULTS AND DISCUSSION

The integrated residual FPIC was found to be smaller than the integrated actual FPIC in all components of force and moment (that contained an actual signal), for all MB perturbations. The mean decrease in the integrated signal was 85.5% for F_x , 86.0% for F_y , 45.1% for F_z , 76.9% for M_x , and 74.0% for M_y (no yaw (M_z) component was present). An example of the actual and residual FPIC is given in figure 1.

Figure 1: Actual (blue line) and residual (red line) FPIC for a 10° rotation, ramp duration 400ms, about the negative y-axis

Based on these results, when data are collected from a force plate mounted on a moving platform, it is possible to greatly reduce the component of a force plate signal that results from the inertial characteristics of the force plate through analysis of the platform kinematics. The residual FPIC resulting from this technique is due mainly to high frequency noise in the kinematic and force plate data, as well as some noise introduced by the subtraction process itself.

SUMMARY

When a force plate is mounted on a moving platform, a component of the recorded data will result from the inertial characteristics of the force plate (FPIC). An estimate of the FPIC can be calculated from the kinematics of the platform and the inertial characteristics of the force plate, and subtracted from the recorded force plate data, in order to correct the GRF of the subject balancing on the surface.

RADIOGRAPHIC ANALYSIS OF THE WRIST WHILE GRIPPING A KAYAK PADDLE

Brad J. Larson¹ and Eadric Bressel²

¹Alpine Orthopaedic Specialists, Logan, UT, USA

²Biomechanics Laboratory, Utah State University, Logan, UT, USA, ebressel@coe.usu.edu

INTRODUCTION

It has recently been reported that 61% of the injuries occurring during whitewater kayaking influence the upper extremity and that 21% of the injuries were tendonitis related (Fiore & Houston, 2001). Werner et al. (1997) have argued that the shape of a hand tool, such as a kayak paddle, is directly related to the stress on the upper extremity. For example, repeated physical exertion with the wrist deviated from neutral may cause cumulative trauma that leads to tendonitis (Kroemer, 1992). While the kayaks themselves have undergone many new innovations to improve their performance and comfort, the general shape of the kayak paddle shaft has remained relatively unchanged. It was hypothesized that the wrist exhibits a high degree of radial deviation during kayaking. As this hypothesis has not been previously tested it was the purpose of this study to analyze wrist radial deviation while gripping a kayak paddle.

METHODS

Twenty novice kayakers who were physically active males between the ages of 18-24 years volunteered for this investigation. Wrist deviations were quantified from radiographic images taken in the frontal plane as subjects held a straight shaft kayak paddle (3 cm diameter) according to the illustration shown in Figure 1.

Figure 1: An illustration of the upper extremity position held by subjects while radiographic images were taken of the wrist.

Hands were in pronation, elbows were flexed to 90 deg, and the shoulders were in the anatomical position. This upper extremity position was chosen to reflect a paddle position associated with peak propulsive forces of the pulling arm (Mann & Kearney, 1980). The angle formed between the longitudinal axis of the radius and third metacarpal of the left wrist represented wrist deviation in this study (Figure 2). Descriptive statistics were then applied to angular data.

RESULTS AND DISCUSSION

The results indicated that subjects exhibited a mean radial deviation of $12.45 (\pm 1.85)$ deg when gripping a kayak paddle according to Figure 1. Representative data for one subject is shown in Figure 2.

Figure 2: A radiographic image of the left wrist. Lines represent the longitudinal axes used to calculate wrist deviation in the frontal view.

This study was limited to a two-dimensional static analysis under a controlled laboratory condition yet, provides important new information on the potential radial wrist deviations that may occur during kayaking. The mean deviation reported in this study (i.e., 12.45°) approximates population norms for peak ranges reported by Kroemer et al. (1997; $14-22^\circ$). Since extreme wrist deviations compromise muscle strength and increase the risk for cumulative trauma (Kroemer, 1992), an ergonomically correct kayak paddle shaft that encourages a neutral wrist position may be warranted.

SUMMARY

The results of this study indicate that kayakers may exhibit approximately 12.45 deg of radial deviation during paddling. Excessive radial deviation may contribute to tendonitis reported in kayakers.

STRENGTH AND EMG OF CERVICAL MUSCLES IN DIRECTIONAL MAXIMAL VOLUNTARY CONTRACTIONS

Shrawan Kumar, Yogesh Narayan and Tyler Amell

Ergonomics Research Laboratory, University of Alberta
Edmonton, AB T6G 2G4 Canada

INTRODUCTION

Cervical pain and dysfunction due to whiplash-associated disorders has become a significant health and economic burden to our society (Spitzer, et al. 1995). One of the primary reasons disputes relates to loss of function of affected patients. However, there are no data published in the literature to which the functional capacities of those affected can be compared. Therefore, a study was designed to measure the force generated by superficial cervical muscles (sternocleidomastoids, upper trapezius and splenius capitis) and their pattern of EMG in isometric contraction in sagittal, coronal and intermediate planes.

METHODS

Forty normal young adults (21 male and 19 female) were tested on a specially designed and fabricated cervical strength tester (CST). A load cell (I-250) was inserted below the pivot point at right angles to the arm which would be rotated when pushed by the head due to cervical muscle contraction. The load cell signals were input into the force monitor. Silver, silver chloride surface electrodes of 1 cm diameter were placed with an inter-electrode distance of 2 cm on upper trapezius, sternocleidomastoids and splenius capitis bilaterally. The electrodes were connected to a fully isolated low noise and low non-linearity amplifier system by short cables and tip plugs. The amplification system was run off an internal charged battery and had a CMRR of 130 dB. The strength was measured in N and EMG was measured in μ V. The subjects exerted for a 5 s period in a maximal contraction against the upholstered headpiece in 8 direction. After each test the subjects were allowed a minimum of 2-minute rest before starting the next randomized condition. Smoothed EMG tracks were normalized. Torque and EMG were correlated and regression analyses were done to determine predictability of torque from EMG.

RESULTS AND DISCUSSION

The force and EMG (Figure 1) were significantly different between the directions of effort ($p < 0.01$). There was a modest correlation between EMG and force ($r = 0.15$ to 0.76 ; $p < 0.01$). EMG output was approximately 66% higher in flexion than in extension while force output was 30% less in flexion than extension. All regressions were significant

Figure 1: Calibrated force and EMG output of all investigated muscle in left anterolateral flexion at 10% force levels in female sample.

($p < 0.01$). The intermediate positions (anterolateral and posterolateral) revealed ratios of force to EMG that were intermediate in relation to force/EMG ratios of pure flexion and extension. The cervical muscle strength and EMG were found directionally dependent. This direction dependence supports the contention that the mode and site of injury to cervical region in automobile accidents may be dependent on direction.

SUMMARY

The cervical muscle strength was found to be highest in extension and lowest in flexion. The strength progressively declined as one moved from posterior to anterior direction. The EMG output in flexion was significantly higher in flexion (66%) than in extension whereas the force was 30% less. The direction dependence of the strength and EMG of the cervical muscles indicate directional dependence of mode and site of injury to cervical region in motor vehicle accidents.

LIPID TRANSPORT IN THE REGIONS OF DISTURBED FLOW: ITS IMPLICATION IN THE DEVELOPMENT OF ARTERIAL STENOSES

Xiaoyan Deng

The State Key Laboratory of Structural Analysis for Industrial Equipment, Department of Engineering Mechanics, Dalian University of Technology, Dalian, China, dengxy@dlut.edu.cn

INTRODUCTION

The early event leading to the genesis of atherosclerosis is the accumulation of cholesterol and other lipids within the intima. These lipid deposits are believed to be derived primarily from plasma lipoproteins particularly low-density lipoproteins (LDL). Because the endothelium of the artery displays low permeability to plasma proteins, the filtration flow across the artery wall may cause a *concentration polarization* of lipids, a well-known mass transport phenomenon, at the blood/wall interface, with an increased lipid concentration from the bulk value towards the interface. Our hypothesis is that the concentration of atherogenic lipids at the luminal surface may vary according to its location in the circulation, even if the bulk concentration remains constant. In areas of disturbed blood flow (flow separation and recirculation) with a low wall shear rate, the luminal surface lipid concentration may be elevated, leading to a greater lipid infiltration and the onset of atherosclerosis in these areas (Deng et al., 1995). The present numerical study is to test this hypothesis.

METHODS

The geometric domain consisted of an axisymmetric tube with a local constriction that served as an arterial stenosis. Numerical simulations were carried out assuming a flow rate of 275 ml/min that is the flow rate for the human common carotid artery. The Reynolds number was 250 at this flow rate and the filtration rate was set at 4.0×10^{-6} cm/sec. The Schmidt number used in the computations was between 1.6×10^5 and 6.6×10^5 , corresponding to a lipid diffusion coefficient in the range of 2.0×10^{-7} to 5.0×10^{-8} cm²/sec. The Navier-Stokes equations, in the form of stream-function and vorticity, and a convective-diffusive mass transfer equation were solved numerically using the second upwind finite-difference method. A non-uniform grid was used to minimize the number of nodes while maintaining a sufficient degree of accuracy in the solution.

RESULTS

The numerical results showed that the maximum value of the luminal surface LDL concentration occurred immediately distal to the summit of each stenosis. In the stenosis with a 30% cross-sectional area reduction, the C_w/C_0 distribution curves were rather smooth, compared to those in the more severe stenoses (Fig. 1). Considering that no flow separation occurred distal to the 30% stenosis at Re=250, the sharp peaks recorded by other curves for more severe stenoses were mainly attributed

to the flow separation distal to the stenosis. These peaks were in fact located at the exact location corresponding to the flow separation points where the wall shear rate was zero. It was noted that the peak value first increased when the stenosis severity increased from 30 to 40%, then decreased when the severity increased further. The results also showed that the larger the Schmidt number (i.e., the larger the lipids), the higher the peak value of the luminal surface lipid concentration.

Figure 1: Plots of C_w/C_0 as a function of the distance from the constriction of the stenosis for three different Schmidt numbers. The letters S and R indicate the locations of the flow separation point and the reattachment point, respectively. (A) 30% stenosis (no flow separation). (B) 40% stenosis.

CONCLUSION

In the present of a filtration flow across the arterial wall, lipids accumulated at the arterial wall with the highest concentration occurring at the flow separation point. The results obtained suggest that the fluid layer with highly concentrated lipids in the area of flow separation point may be responsible for the formation and development of the arterial stenosis.

RECOVERY STRATEGY FROM PERTURBATION OF THE UPPER BODY DURING STANDING USING MECHANICAL ENERGY ANALYSIS

Wu Ming, Ji Linhong, Jin Dewen, Wang Rencheng and Zhang Jichuan

Dept. of Precision Instrument and Mechanology, Tsinghua University, Beijing 100084, China.
Rehabilitation Engineering Research Center, wum@post.pim.tsinghua.edu.cn

INTRODUCTION

Human body employs multi-joints to recovery from perturbation during standing (Runge, 1999, Tony, 1998). However, little is known about the relationship between balance mode and the intensity of disturbance. Besides, the contribution of each joint, especially the metatarsophalangeal (MP) joint, to balance recovery still needs to be evaluated quantitatively.

METHODS

A 4-degree-of-freedom dynamic model of standing human body, which includes the MP joints, was derived using Kane method. Experiments were performed on 4 healthy adult volunteers, who gave informed consent. Mechanical energy generation and absorption at each joint during the recovery process, was analyzed to identify the balance recovery strategies.

RESULTS AND DISCUSSION

The results show distinct multi-joints coordination in the recovery process. All joints contribute to balance recovery. However, MP joints and hip joints dominate the contributions to balance recovery from the perturbation of upper body during standing. The ankle and knee joints have less

contribution. Balance recovery mode changes with the intensity of disturbance and it is observed that each joint's contribution changes with different balance mode. However, MP joints and hip joints still do dominate contributions to the overall disturbance form upper body. Besides, it is shown that there is a close relationship between the rotation momentum of body relative to MP joint and stability after perturbation of upper body. The stability of human body after perturbation of upper body deteriorates with the increase of the magnitude of rotation momentum of the body.

INTRODUCTION

Microseparation of the femoral head and acetabular component can occur following total hip replacement surgery (Dennis *et al.* 2001). Previous studies (Nevelos *et al.*, 1999) have shown stripe wear on explanted alumina ceramic on ceramic (COC) bearings. However, COC bearings tested in a standard hip simulator had very low wear rates (0.1mm³ per million cycles) and no stripe was observed. When swing phase microseparation was introduced into the normal gait cycle, results were more clinically relevant; the wear volume increased (1.7 mm³ per million cycles) and stripe wear on the femoral head was observed (Stewart *et al.* 2001).

This study aimed to assess and compare the effect of swing phase microseparation on COC, meal on metal (MOM) and ceramic on polyethylene (COP) total hip replacements. Wear rates produced by standard and microseparation conditions were compared.

METHODS

A physiological hip simulator was used to test 28mm femoral heads and acetabular cups. Five pairs of each material combination were tested under each condition. Ceramic components were BioloX Forte HIPed alumina and metal components were cobalt chrome alloy. Components were mounted anatomically, heads underwent flexion/extension -15° to +30° and the acetabular component internal/external rotation ±10°. Loading was applied vertically to approximate *in vivo* conditions. Testing was conducted at 1 Hertz for 5 million cycles in 25% new-born calf serum. Measurements were taken every million cycles. Wear of ceramic and metal components was determined gravimetrically, wear of polyethylene cups was measured geometrically.

Microseparation was achieved by inferior displacement of the head (about 0.8mm) during swing phase which caused the head to contact the inferior rim of the acetabular component. On heel strike, the displaced head contacted the superior rim of the cup; this caused a stress concentration on the head and attributed to the formation of a wear stripe. The head then relocated into the normal articulating position.

RESULTS AND DISCUSSION

Wear rates for different bearing combinations under standard and microseparation conditions are shown in Figure 1.

Figure 1: Wear rates (mean ± 95% CL)

Hard bearings (COC and MOM) had lower wear in comparison to COP couples. Hard bearings demonstrated increased wear under swing phase microseparation compared to standard conditions. Some insert rim damage and head stripe wear was observed on all components. Stripe wear on metal heads has not been observed *in vivo*, it is postulated that this is masked by a self polishing mechanism.

COP bearings showed about four times less wear under swing phase microseparation, compared to standard conditions. Evidence suggests that this was due to the entrapment of the lubricant during microseparation resulting in a reduction in wear via a squeeze film mechanism. Microseparation led to the head contacting the superior rim at heel strike causing creep deformation and permanent rim damage. The ceramic head showed no increase in roughness against polyethylene.

CONCLUSION

Swing phase microseparation increased wear of hard on hard bearings (COC and MOM); however, wear remained less in comparison to COP couples. Swing phase microseparation reduced polyethylene wear; indicating that small, controlled amounts of microseparation could be advantageous in these prostheses.

SHOULDER BIOMECHANICS IN VOLLEYBALL SPIKING: IMPLICATIONS FOR INJURIES

Gary A. Christopher¹ and Mark D. Ricard²

¹Doctoral Student, Oregon State University, Corvallis, OR, garyalan@byu.net
²Director, Human Performance Research Center, Brigham Young University, Provo, UT

INTRODUCTION

The potential for overuse injuries in volleyball has been linked to impact magnitude, impact frequency, rate of loading, and number of years of competition.

The purpose of this study was to determine the reaction forces and torques at the shoulder during the volleyball spike and to investigate the relationship between shoulder biomechanics and the potential for injury.

METHODS

Shoulder biomechanics of 11 collegiate volleyball players (6 female, 5 male) were determined using 120 Hz video analysis. Subjects performed at least 10 maximum effort spiking trials toward a region 6 to 9 meters from the center of a regulation height volleyball net.

Retroreflective markers were affixed to the subjects at anatomical landmarks and to the ball. A motion analysis system (Motion Analysis Corporation, Santa Rosa, CA) was used to collect digital images of the volleyball spike. Cameras were positioned to allow image capture from all sides and EVA 6.0.3 software (Motion Analysis Corporation) was used to capture and digitize the spiking trials.

Two trials from each subject were digitized; a DLT algorithm was incorporated to determine the 3D coordinates of the markers. Raw positional data were exported to a custom program for analysis.

RESULTS AND DISCUSSION

Mean maximum ball velocity compared favorably to similarly skilled athletes (Chung, 1988; Chung et al., 1990). A strong positive correlation was found between maximum ball velocity and maximum shoulder compressive force ($r = 0.872$, $p < 0.001$).

While the impact magnitudes (~46-94% BW) and loading rates (~5-15 BW/s) reported herein are relatively small when compared to activities such as running or jumping, the ability of the shoulder to handle impact loading is limited. The dynamic stability of the shoulder complex is generally sufficient for most activities, but any situation that compromises the health of the shoulder musculature can increase the potential for overuse injuries (Norkin and Levangie, 1992).

Cumulative fatigue in the rotator cuff muscles, associated with repetitive overhead motions and/or technique errors, may impair their ability to stabilize the humerus, resulting in superior translation and entrapment of soft tissues, leading to

or exacerbating tendinitis and/or impingement. Accumulated microtrauma to the rotator cuff muscles and soft tissues of the shoulder may result in increased symptoms and may limit participation (Briner & Kacmar, 1997; Schaeffle, 1993; Watkins, 1994).

SUMMARY

The magnitude and rate of impact loading during volleyball spiking constitute considerable potential for shoulder overuse injuries among volleyball hitters. They are especially prone to biceps tendinitis and impingement syndrome (Briner & Kacmar, 1997; Schaeffle, 1993; Watkins, 1994).

CLASSIFICATION OF TRABECULAR SURFACES FOR USE IN TISSUE-LEVEL BONE ADAPTATION MODELS

Michal Be'ery and Amit Gefen

Department of Biomedical Engineering, Faculty of Engineering, Tel Aviv University, Tel Aviv 69978, Israel, gefen@eng.tau.ac.il

INTRODUCTION

Trabecular bone is a complex structure composed of interconnected mineralized struts and plates (Odgaard, 2001). It is generally accepted that both its micro-architecture and tissue material properties are dependent upon the applied mechanical stress stimuli. Significant changes in the stress stimuli will affect trabecular morphology, by mechanisms of apposition or resorption of minerals at the trabecular surfaces. In recent years, computational models have been developed to predict alterations in trabecular density and respective elastic properties in response to changes in the stress stimuli (Gefen, 2001). Several two-dimensional models of trabecular lattices could also predict the “tissue-level” changes in surface geometry of individual struts (Mullender et al., 1998; Huiskes et al., 2001). In order to expand the potential of these simulations, parametric representation of trabecular surfaces is needed. In this study, mathematical formulation of typical trabecular surfaces and volumes was developed for their geometric classification, based on optical microscopy.

METHODS

6 specimens were transversally cut from the epiphyseal parts of 5 ovine femurs, using electrically-powered saw, after drying the bones in 85°C for 4.5 hours. The samples were kept at -18°C and defrosted to room temperature before measurements. Geometrical dimensions including base thickness (t_{max}), minimal thickness (t_{min}) and length (L) were recorded for 201 randomly selected trabecular profiles (Fig.1), using optical microscopy (Axiolab A, ZEISS) at a spatial resolution of 0.8 μm . For the purpose of parametric representation, it was assumed that trabecular profiles are symmetric around the x and y axes, and thereby, they could be fitted to the expression

$$y = \pm \left\{ \cos \left(2x/L \cos^{-1} \left(\frac{1}{2} (2 + t_{min} - t_{max}) \right) \right) - (1 + t_{min} / 2) \right\} \quad (1)$$

Eq. (1) was shown to represent well the trabecular profiles: cross-correlations of real versus fitted geometry yielded average correlation coefficients of 0.87 for the shape overlapping, and 0.97-0.99 and 0.99 for the symmetries around the x and y axes, respectively ($n=40$). Accordingly, statistical analyses were used to parameterize this relation in order to apply it for classification of human trabeculae.

RESULTS AND DISCUSSION

Linear correlation was found between base and minimal thickness values ($R^2=0.71$), and thus, the base thickness could be expressed as $t_{max}=\alpha t_{min}+\beta$, with the constants $\alpha=1.3736$ and $\beta=40.932$ μm (Fig. 1). Eq.(1) then becomes

$$y = \pm \left\{ \cos \left[\frac{2x}{L} \cos^{-1} \left(1 - \frac{\beta}{2} + \frac{(1-\alpha)(2t-\beta)}{2(1+\alpha)} \right) \right] - \left[1 + \frac{(2t-\beta)}{2(1+\alpha)} \right] \right\} \quad (2)$$

where t averages t_{min} and t_{max} . The volumes of individual trabeculae with known averaged thickness can be approximated by integrating Eq.(2) to find the solid of revolution about the x axis.

Figure 1: Micrograph of a trabecula (left) and base thickness versus minimal thickness for 201 trabeculae (right).

The histogram of thickness distribution (Fig.2) shows that the thickness of trabeculae may range between 30 and 286% the average thickness. Substitution of characteristic human trabecular dimensions of 1000 and 283 μm in Eq.(2), for the averaged length and thickness, respectively, enabled classification of typical trabecular surfaces (Fig.3). This classification is useful for development of computational simulations of adaptive changes in trabecular morphology.

Figure 2: Histograms of lengths (left) and averaged thickness (right) measured for 201 trabeculae.

Figure 3: Classification of trabecular surface profiles (for trabeculae of 1000 micron in length).

INTRODUCTION

Combat jet pilots exposed frequently to rapid-onset high-sustained +Gz force are at the risk of G-induced loss of consciousness (G-LOC)(Burton, 1988). The anti-G straining maneuver (AGSM) offers an effective protection against G-LOC and has been the standard high-G tolerance training throughout the world. The AGSM involves a forced exhalation against a partially or completely closed glottis with straining of limb and abdominal muscles during high-sustained +Gz exposures (Comens et al, 1987). By tensing different muscle groups and increasing the intrathoracic pressure, AGSM can significantly increase one's arterial blood pressure to maintain sufficient cerebral blood flow, thereby avoiding G-LOC (McCloskey, 1992). ROC Air Force teaches AGSM to all its fighter pilots as part of their high-G tolerance training. The aim of the present study is to examine the electromyographic (EMG) characteristics of AGSM in order to establish an objective assessment for its training effectiveness.

METHODS

A telemetry EMG (Biotel 99, Glonner Electronic, Steinkirchen, Germany) connected with a data acquisition system (InstruNet, GWI Co., Somerville, MA) was used to obtain the surface electromyography from the subjects. Twenty male subjects who were in good health with no history of any disease were divided into two study groups. Group 1 composed of 8 senior aviation physiological training officers who were already familiar with the techniques of AGSM and had been exposed to high G environments before the study. Group 2 consisted of 12 flight cadets who were undergoing the high-G tolerance training in the Air Force Academy and learned how to perform the AGSM for the first time. For each subject, an Integrated EMG (IEMG) monitored seven groups of respiratory muscles during the performance of AGSM for 30 seconds. The duration of a breathing cycle, the firing rate, the firing sequence, and peak strength of each muscle group were analyzed using a programmable software developed with Matlab 6.0 (MATH Works Inc., Natick, MA).

RESULTS AND DISCUSSION

Data analysis indicate that the mean period of a breathing cycle by the trainers (2.20 ± 0.36 seconds) was significantly longer ($p < 0.001$) than the trainees' (1.86 ± 0.37 seconds). The mean firing rate for the cheek muscle between these two groups were also significantly different (Table 1; $p = 0.001$). In addition, significant differences were found between the two groups in the mean peak strength of the latissimus dorsi muscle ($p = 0.001$), the rectus abdominis muscle ($p = 0.003$), and the sternocleidomastoid muscle ($p = 0.01$). However, the firing sequence was not significantly different between the two groups. We compared the pooled IEMG data for differences between the seven muscle groups and found only the pectoralis major muscle ($p = 0.03$) to be significantly different.

SUMMARY

Our study applied the analytic capability of EMG to examine the physiological differences of AGSM performed by the experienced and the inexperienced. The results indicate that the trainers were able to hold each of their AGSM respiration cycles significantly longer than the trainees could. Furthermore, the peak strengths of the latissimus dorsi muscle, the rectus abdominis muscle, and the sternocleidomastoid muscle reflect the depth of inspiration movement. Most importantly, EMG data among the respiratory muscles studied revealed that the behavior of cheek muscle could be an excellent indicator for the effectiveness and efficiency of the anti-G straining maneuver.

THE EFFECT OF POSTMORTEM FREEZING STORAGE ON THE TENSILE PROPERTIES OF TENDON

Ng Boon Ho¹, Chou Siaw Meng

School of Mechanical and Production Engineering, Nanyang Technological University, Singapore

¹E-mail: pa10264950@ntu.edu.sg

INTRODUCTION

Postmortem storage has been employed in biomechanical evaluation of living tissues simply because it is not feasible to perform tests on live animal or immediately after sacrifice. It is also often not possible to obtain fresh human specimens instead of fresh frozen cadaveric specimens. Further, cadaveric tendons and ligaments have been used as allografts for transplantation in recent years. Proper storage of allografts is necessary to preserve the biomechanical properties and biological viability for successful transplantation.

Of the many storage methods currently adopted, freezing is most popular for soft tissues preservation as it provides ease of storage and can be carried out at relatively low costs. Researchers have investigated the response of soft tissues to freezing storage but results have been inconclusive. The aim of this study is therefore to elucidate the influence of postmortem freezing storage on the tensile properties of tendons.

MATERIALS AND METHODS

Two hundred and seventy-five chicken FDP tendons were used in this study. Five pieces of tendon specimens were tested within 4 hours after death and the results obtained were recorded as fresh control. Other specimens were divided into 54 groups and stored at 0°C, -20°C or -40°C (8 groups each) within 6 hours after death. A 5565 Instron Universal Testing Machine was employed for the tensile tests and the cross-head speed was set at 60mm/min. Tendons were tested every 5 days for 3 months. Samples were tested in quintuplicate. Mean values of UTS, Strain at Maximum Stress, Elastic Modulus and Energy at Maximum Stress were compared to fresh control at 99% confidence level using the Student's T method.

RESULTS AND DISCUSSION

Upon thawing, tendons which were stored at 0°C became soft and produced unpleasant smell after 5 days. However, no statistically significant changes was found in the cross-sectional area following freezing storage and no variations in the gross shape of the stress-strain curve was recorded for all durations. The tensile properties of digital flexor tendon were not affected during freezing storage at 0°C, -20°C or -40°C for up to 90 days. Generally, there existed no significant deviations from fresh control in the values of UTS, Strain at Maximum Stress, Elastic Modulus and Energy at Maximum Stress. Statistics comparison between groups of same duration showed no discernable differences in tensile properties after storage at 0°C, -20°C and -40°C.

The tensile properties of digital flexor tendon were not affected during freezing storage at 0°C, -20°C or -40°C for duration up to 90 days. These findings were consistent with similar works on ligaments by Viidik and Lewin (1966) and

Woo et al. (1986). However, our findings were contradictory with other reported data (Matthews and Ellis, 1968; Dorlot et al., 1980; Turner et al., 1988). Presumably, the differences could be attributed to the employment of different freeze-thaw processes. The comparison between frozen specimens and fresh control in this study has proven that tensile properties of tendon remained unchanged in unprogrammed freezing and rapid thawing processes. The comparison also illustrated that saline solution does not alter the tensile properties of tendon which is contrary to the findings of Viidik and Lewin (1966).

Since results showed no significant changes in tensile properties through out the storage duration, it suggests that tendons can be preserved by freezing for many months, even years, without compensating its tensile properties. However, the duration limit of freezing storage should be determined empirically.

Figure 1: Correlation of tendon strength with the duration of freezing storage.

SUMMARY

Based on the results obtained in this study, we conclude that freezing storage up to 90 days does not alter the tensile properties of digital flexor tendon.

STRAIN RATE EFFECT ON THE TENSILE PROPERTIES OF FLEXOR TENDON

Ng Boon Ho¹, Chou Siaw Meng

School of Mechanical and Production Engineering, Nanyang Technological University, Singapore

¹E-mail: pa10264950@ntu.edu.sg

INTRODUCTION

Tendon, ligament, bone and other biological tissues are known to be viscoelastic material. The change in failure properties of soft tissues at different strain rates is of particular interest in analyzing mechanisms of injury. Bhatia et al. (1992) estimated the extension rates at 60 to 70 mm/min close to tendon speed during gentle active mobilization while Crowninshield and Pope (1976) reported that the traumatic loading of the knee joint in man might occur at strain rates ranging from 50 to 150000 %/s. However, the actual physiologic strain rates during soft tissue injury still remain unknown. Many studies have been conducted to investigate the effect of strain rate on the structural properties of ligament-bone complex but contradicting results were obtained. Further, relatively few studies have evaluated the effect of strain rate on the mechanical properties of tendon. Flexor tendon works under dynamic loading, thus the dependence of tensile properties on strain rate should be determined.

MATERIALS AND METHODS

Seventy-five chicken FDP tendons were used in this study. Tendons were wrapped by saline-soaked gauze and stored at -40°C within 6 hours after death for 16–20 days before testing. A 5565 Instron Universal Testing Machine was employed for the tensile tests. Tendons were tested at 15 different strain rates, namely 0.05, 0.1, 0.25, 0.5, 0.75, 1, 2.5, 5, 7.5, 10, 25, 50, 75, 100 and 150%/s, and samples were tested at each strain rate in quintuplicate. Mean values of UTS, Strain at Maximum Stress, Elastic Modulus and Energy at Maximum Stress were compared at 99% confidence level using the Student's T method.

RESULTS AND DISCUSSION

Results showed that strain rate has little effect on the shape of stress-strain curve. The toe regions were not affected by strain rates but stiffness increased with increasing strain rate. The hypothesis advocated by Piolett et al. (1999) that the strain rate effect mainly acted in the toe region with minimal influence on the linear part of the stress-strain curves was not justified in this study.

Generally, UTS slightly increased as strain rate increased with the lowest mean value observed at the lowest strain rate, 0.05 %/s. The values of Strain at Maximum Stress of all groups did not differ significantly from that at 0.05 %/s except at 1 %/s strain rate. In addition, the increase of strain rate resulted in higher Elastic Moduli and the differences were statistically significant against 0.05 %/s except for lower strain rates of 0.1, 0.25, 0.5 and 1 %/s. In terms of Energy at Maximum Stress, there existed no statistically significant deviations following the increase of strain rate. These findings were consistent with the work of Danto and Woo (1993).

The reason for the strain rate sensitivity of tendon is unknown. A rate sensitive interfibrillar matrix of ground substance is suggested to help maintain the structural integrity of tendon at high strain rate. It is anticipated that lower strain rates permit shearing or gliding between collagen fibres. The shearing eliminates stress sharing among the collagen fibres and this results in uneven stress distribution. As such, only part of the collagen fibres contributes to resisting the applied load. On the other hand at higher strain rates, the rate sensitive interfibrillar matrix of ground substance helps distribute stress among the collagen fibres by limiting interfibrillar shearing. With stress sharing, more collagen fibres are involved in resisting the applied load, thus resulting in stiffer tendon.

Figure 1: Correlation of tendon stiffness with strain rate.

SUMMARY

Based on the results obtained, we conclude that strain rate affects the tensile properties of tendon significantly. Within the range 0.05 to 150 %/s, the stiffness of tendons increased with the increase of strain rate, with no change in UTS and Strain at Maximum Stress. However, the change in tendon tensile properties was not significant with small change of strain rate.

STRAIN CHARACTERISTICS OF THE FOOT ARCH IN NON-ATHLETES AND ATHLETES DURING WEIGHT-BEARING, WALKING AND RUNNING

Seung-Jae Kim

Department of Leisure & Air Sports, Hanseo University, Seosan, Chungnam, Korea

Assistant Professor, sjkim@hanseo.ac.kr

INTRODUCTION

The medial longitudinal foot arch is a unique structure in humans and is reported to have elastic strain energy second only to the Achilles tendon during locomotion (Ker et al., 1987). In vitro and in vivo studies on the foot arch have been performed to identify static and dynamic characteristics (Kogler et al., 1995; Cashmere et al., 1999). However, the actual strain of the foot arch during static and dynamic loading is not well known. This in vivo study tries to answer the following questions: “What strain characteristics does the foot arch have in static and dynamic situations?” and “Is there any training effects of the foot arch?” Therefore, the purpose of this study was to investigate strain characteristics in the foot arch of non-athletes and athletes during weight-bearing, walking and running.

METHODS

Twenty-three male subjects were divided into two groups, 13 non-athletes (NAT) and 10 athletes (AT), in order to investigate training effects of the foot arch. The age of the NAT group which had never been trained as specific athletes was 24.2 ± 2.2 yrs and the age of the AT group which had been trained for 6.8 ± 1.0 yrs as rugby athletes was 21.4 ± 1.6 yrs. Four anatomical landmarks of the longitudinal foot arch, the medial malleolus, bottom of the midline of the posterior calcaneus (CL), navicular tuberosity (NV) and head of the first metatarsal (MT) were marked using black water paint. The arch height was defined as the distance between NV and the ground and the arch length as the distance between CL and MT. The arch height and the arch length were measured with a right-angled square in non weight-bearing and weight-bearing conditions and with a Photosonic 16 mm high speed camera filming at 60 frames/s during walking ($1.5 \text{ m/s} \pm 5\%$) and running ($4 \text{ m/s} \pm 5\%$). Strain in weight-bearing, walking and running was calculated as a change in the arch height and the arch length divided by their height and length in the non weight-bearing condition, respectively. The maximum vertical loads during walking ($961 \pm 151 \text{ N}$) and running ($1934 \pm 234 \text{ N}$) were measured using a Bertec force-plate. The differences of the NAT and NT groups and the three loading conditions were tested with repeated measures of general linear model in SPSS under .05 level of significance. Post-hoc comparisons were performed with Duncan's test.

RESULTS AND DISCUSSION

Maximum arch height strain among weight-bearing, walking and running showed significant differences in NAT and AT except for the

relation between weight-bearing and walking (Figure 1a). Especially, the relation showed a contradictory result that regardless of increasing the loading condition from weight-bearing to walking, maximum arch height strain was negatively decreased in AT. This point needs further research to explain. Maximum arch length strain among weight-bearing, walking and running showed significant differences (Figure 1b). Maximum strain of both the arch height and the arch length between NAT and AT did not show any significant differences according to the three loading conditions.

Figure 1: (a) Maximum arch height strain and (b) maximum arch length strain in NAT (■) and AT (▲) during weight-bearing ($715 \pm 91 \text{ N}$), walking ($961 \pm 151 \text{ N}$) and running ($1934 \pm 234 \text{ N}$).

SUMMARY

Maximum arch height strain was negatively increased related to increased loading conditions, except in one AT condition. However, maximum arch length strain was positively increased according to the increased loading conditions. The author cannot find any statistical evidence to support that there will a training effect in strain characteristics of the foot arch, however, a question about a training effect of it is proposed from an exceptional phenomenon of the arch height in AT during walking.

INTRODUCTION

Receptor/ligand interactions are basic issues to cell adhesion, which are important to many physiological and pathological processes such as inflammatory reaction, tumor metastasis, etc. Selectin/carbohydrate ligand binding have been found to mediate the rolling of leukocytes on endothelial monolayer, the first step of inflammatory cascade, due to the fast kinetic rates. Kinetic rate and binding affinity constants are essential determinants of cell adhesion. Using a well-developed small system probabilistic model and a micropipet aspiration assay, we previously measured the E-selectin/ligand binding on apposed surfaces (two-dimensional (2D) interaction), and compared the 2D kinetics of E-selectin binding to carbohydrate ligands expressed on a human promyelocytic leukemia cell line (HL-60) or a human colon adenocarcinoma cell line (Colo-205). Here we further measured the kinetics of P-selectin/ligand interaction, and compared to that of E-selectin/ligand binding.

MATERIALS AND METHODS

Micropipet aspiration assay has been described previously. Briefly, anti-P-selectin monoclonal antibodies (mAbs) 1478 and S12 were coated on the surfaces of human RBCs using CrCl₃ protocol, which are used to capture P-selectin constructs with Lec/EGF (P-Lec/EGF) and with whole extracellular domains (sPs), respectively. Capture mAbs-coated RBCs were then incubated with respective P-selectin constructs before binding to cultured HL-60 cells expressing carbohydrate ligands. Binding probability, P_a , on contact duration, t , of selectin/ligand interaction at the contact area, A_c , was measured experimentally using the micropipet technique, and the kinetic rates and binding affinity were predicted using the small system probabilistic model,

$$P_a = 1 - \exp\{-A_c m_r m_l K_a^0 [1 - \exp(-k_r^0 t)]\} \quad (1)$$

where K_a^0 and k_r^0 are zero-force binding affinity and reverse rate, respectively, and m_r and m_l the site densities of selectin and ligands respectively.

RESULTS

Control and blocking experiments were designed to address the binding specificity for P-Lec/EGF and sPs, respectively, binding to the ligands on HL-60 cells. Adhesions were abolished when the P-selectin capture mAb 1478 or S12 was replaced by an isotype-matched irrelevant mIgG1 or when the P-selectin construct was substituted by the E-selectin construct. Adhesions

were completely blocked by the anti-P-selectin and anti-PSGL-1 blocking mAbs (PL1). Inclusion of EDTA (5 mM) in the medium also abrogated adhesions (data not shown). These experiments showed that the binding was specifically mediated by P-selectin/ligand interaction.

A typical curve for dependence of binding probability on contact duration was shown in Fig. 1. Using Eq. 1, the zero-force binding affinity and reverse rate of P-selectin/ligand binding can be estimated from the measured data. These numbers were used to compare with E- and P-selectin dissociating from HL-60 cells, as well as with the data from a flow chamber assay.

Figure 1. Comparison between measured (Δ) and predicted (curve) adhesion probability, P_a , on contact duration, t , for sPs binding to ligands on HL-60 cells. The theoretical prediction is based on Eq. 1. Each cell pair was used to repeat 100 cycles to estimate the P_a for that cell pair ($N = 17$).

ACKNOWLEDGEMENTS

PROBABILISTIC MODELING OF ROSETTE FORMATION ON SELECTIN/LIGAND INTERACTIONS

Juan Chen¹, Emily Moses², Cheng Zhu², and Mian Long^{1*}

¹National Microgravity Laboratory/CAS, Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, *E-mail: mlong@imech.ac.cn, and ²George W. Woodruff School of Mechanical Engineering and Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA 30332, USA.

INTRODUCTION

Rosetting, a simple assay for specific cell-cell adhesion, has been routinely used by immunologists to examine the functionality of the interacting receptors and ligands and to discriminate subclasses of leukocytes. It has not been regarded, however, as a quantitative method, since the measured rosette fraction has not been quantitatively related to the underlying molecular properties. Previously, we have developed a small system probabilistic model and a micropipet aspiration assay to measure and compare the kinetics of E- and P-selectin/ligand binding on apposed surfaces. Here, we use the same concept to model the rosetting experiment and estimate the binding affinity of selectin/ligand interaction from rosette size distribution.

MATERIALS AND METHODS

Rosetting requires two types of cells, typically one of larger size but smaller number and the other of smaller size but larger number. The system used here consisted of a human promyelocytic leukemia (HL-60) cells expressing carbohydrate ligands rosetting with human RBC coated (via CrCl₃ coupling) with anti-selectin monoclonal antibodies (mAbs) capturing selectin constructs. Cells were washed, mixed at a ratio of 100 RBC per HL-60 cell, centrifuged at 500 rpm for 5 min, and incubated on ice for 1~2 hr. The cell pellet was gently resuspended, and the rosette size distribution was determined visually under a light microscope. Upon the probabilistic model, rosette size distribution, p_n , the fraction of n RBCs per HL-60 cell, followed the Poisson distribution:

$$p_n = \langle n \rangle^n \exp(-\langle n \rangle) / n! \quad (1)$$

Here, the mean rosette size, $\langle n \rangle$, the average number of RBCs per HL-60 cell, followed quantitatively the formulation (as long as $\langle n \rangle$ is small),

$$\langle n \rangle = A_c m_r m_l K_a N \quad (2)$$

where A_c is the contact area, m_r and m_l the site densities of receptor and ligand respectively, K_a the binding affinity, and N the maximum number of RBC that are geometrically possible to simultaneously contact with a HL-60 cell ($N \approx 12$).

RESULTS

A typical experiment is shown in Fig 1. Excellent agreement was found between theory (*solid curve*) and experiment (*solid bars*) for HL-60 cells rosetting with P-selectin-coupled RBCs. The Poisson simplifying approximation was justified, as the

mean rosette sizes were small ($\langle n \rangle = 0.25$) compared to the maximum rosette sizes, N . Using an anti-P-selectin blocking antibody, G1, the rosette size distribution shifted left (*open bars*), which also fitted extremely well with theory (*dotted curve*).

Figure 1. Comparison between measured (*bars*) and predicted (*curves*) rosette size distribution of HL-60 cells with RBCs. The prediction is based on Eq. 1. Bars are the standard deviation.

Cellular binding affinity, $A_c m_r m_l K_a$, was obtained using, Eqs. 1 and 2, to be $0.021 \mu\text{m}^2$ for P-selectin/ligand interactions. The value obtained using the present rosetting experiment is consistent with those determined from a micropipet aspiration assay using same molecular and cellular system (data not shown), since the contact area A_c between a HL-60 cell and a RBC in a rosette was in general several folds smaller than that in the micropipet experiment. This supports the validity of these techniques as well as the theoretical models for them, and indicates the reliability of the measured binding affinities.

ACKNOWLEDGEMENTS

We thank Rodger P. McEver for generous gifts of the P-selectin constructs and the relative mAbs. Supported by NSFC grants 10042001 and 10072071, a CAS grant KJCX2-L02 and a TRAPOYT Award (ML) as well as by NIH grant AI44902 (CZ).

SEPARATION PATTERNS IN AN ARTERIAL BRANCH MODEL

Mehran Tadjfar and Ryutaro Himeno

Advanced Computing Center
Institute of Physical and Chemical Research (RIKEN)
2-1, Hirosawa, Wako-Shi, Saitama, JAPAN

INTRODUCTION

In vascular flow study, the flow into arterial branches is of great importance. The tendency for plaque to form around and near the regions of vessel bifurcation is a well-known fact. The role that local hemodynamic factors play in the plaque formation and its local distribution is also accepted. The exact mechanisms of how the hemodynamic factors influence plaque formation and its further development are still subject to debate. See Caro (1994), and Ku (1997). However, it is hypothesized that low wall shear stress regions and regions of high particle residence time are locations of high risk for vascular diseases. Here, we use CFD methods to study the flow separation into a branch model (Fig. 1).

METHODS

The unsteady, three-dimensional, incompressible Navier-Stokes equations are solved using a fast, parallel, and time-accurate finite volume solver (See Tadjfar 2001). The solver is capable of dealing with moving boundaries and moving grids. It is designed to handle complex, three-dimensional vascular systems. The computational domain is divided into multiple block subdomains. At each cross section the plane is divided into twelve sub-zones to allow flexibility for handling complex geometries and, if needed, appropriate parallel data partitioning. A second-order in time and third-order upwind finite volume method for solving time-accurate incompressible flows based on pseudo-compressibility and dual time-stepping technique is used.

RESULTS AND DISCUSSION

The steady flow separation patterns into a 45°-branched tube are studied (Fig 2). The major factors influencing this flow are; The area ratio, defined as the ratio of total cross sectional area of the daughter tubes to the cross sectional area of the mother tube, and the Reynolds number of the incoming flow. At the area ratio of sufficiently higher than one, the flow will separate in the daughter tubes. The magnitude of the area ratio necessary to initiate flow separation is dependent on the value of the incoming flow Reynolds number.

Figure 1: Grid model of the 45°-branched tube.

Figure 2: Streamwise velocity contours (backflow part), looking down into the left daughter tube. ($Re = 1000$ and $AR = 2.0$).

EFFECT OF CELL DENSITY ON VIABILITY OF ARTIFICIAL TISSUE AFTER CRYOPRESERVATION

Masanobu Ujihira¹, Yumi Sukegawa², Satoshi Nogawa¹, Takako Nagoshi¹ and Kiyoshi Mabuchi³

³ Graduate School of Medical Sciences, Kitasato University, Sagami-hara, Kanagawa 228-8555, Japan

INTRODUCTION

Generally, post-thaw viability of cells in cell suspension is higher than that in biological tissue in cryopreservation. Successful cryopreservation with biological tissue is limited due to the complexity of the structure (e.g., Karlsson and Toner 1996), for example, sample size, variety of cells, and cell density. One factor responsible for the difference in the viability between cell suspension and biological tissue is cell density. However, the effect of cell density on post-thaw viability remains unclear.

In this study, we clarified this effect by first preparing artificial tissue that imitated biological tissue, for various cell densities, and then freezing the tissue at various cooling rates. We then observed the structure of artificial tissue stained with hematoxylin and eosin (HE) by optical microscope.

MATERIALS AND METHODS

Human dermal fibroblasts (normal cells obtained from the Kitasato University Hospital) were three-dimensionally cultured for 2 days (5% CO₂, 37°C) in a collagen matrix (Koken Cellgen CS-100, $\phi 20 \times 1$ mm) to imitate biological tissue (artificial tissue). Different cell densities for the artificial tissue were used, from 10⁵ to 10⁷ cells/cm³. Five artificial tissues were prepared at each cell density for each experiment; one of them was used for the control (no freezing and thawing) or the observation.

Four artificial tissues were first stacked in a test chamber consisted of a cylindrical test chamber made of polystyrene foam ($\phi 24 \times 4$ mm), then frozen with cooling rates of 0.3 to 50°C/min in a solution of Dulbecco's Modified Eagle Medium (Gibco BRL), 20% Fetal Bovine Serum (Tissue Culture Biologicals), and 10% dimethylsulfoxide, then kept frozen at -196°C for 2 hours, and finally thawed. The collagen matrix was dissolved using collagenase. Post-thaw viability of fibroblasts was evaluated by using a trypan blue exclusion assay. Viable cells were counted by using an erythrocytometer and optical microscope [(Relative Viability) = {(The number of viable cells) / (The total number of cells in the control)} / (The mean viability of the control) $\times 100$ (%)].

The artificial tissue was embedded with paraffin, and sliced by using the microtome. A sliced sample was adhered to the preparation after the HE stain, the structure of the fibroblast in the collagen sponge in each cell density was observed under an optical microscope (Olympus EX50).

RESULTS

The post-thaw viability was high when the cell density was low (10⁵ cells/cm³) and decreased with increasing cell density [Fig. 1, error bars show standard deviation (SD) for n=8]. The post-thaw viability in 10⁵ cells/cm³ was highest at a cooling rate of 3°C/min. The cooling rate indicating highest viability decreased with increasing cell density (1°C/min in 10⁷ cells/cm³). The mean viability in the control tissue was 83.2 \pm

9.6% (mean \pm SD for n=20). Though cellular contact was not observed with 10⁵ cells/cm³, it was observed with 10⁶ and 10⁷ cells/cm³.

DISCUSSION

Two factors are responsible for those results. The first factor is interaction between cells (Acker *et al.* 1999, cell-to-cell contact). From the observation results, cells contacted at cell densities above 10⁵ cells/cm³. Cell-to-cell contact would induce intracellular freezing. Therefore the post-thaw viability decreased with increasing cell density for higher cooling rates ($>3^\circ\text{C}/\text{min}$). The second factor is obstruction to dehydration during extracellular freezing. When the cell density was high, fibroblasts in the artificial tissue may have overlapped due to the decrease in the amount of extracellular unfrozen solution during extracellular freezing. The cooling rate indicating highest viability decreased with increasing cell density. In addition, these factors may induce mechanical stress, and may destroy cell or cell membrane for slower cooling rates ($<3^\circ\text{C}/\text{min}$). Therefore the post-thaw viability seems to decrease with increasing cell density.

SUMMARY

When the cell density is high, cell-to-cell contact can induce intracellular freezing, and dehydration may be obstructed during extracellular freezing. Therefore, the post-thaw viability and the cooling rate indicating highest viability decreases with increasing cell density.

EFFECT OF FLOW PATTERN ON VASOACTIVE MEDIATORS SECRETION OF CULTURED ENDOTHELIAL CELLS

Zulai Tao, Jiang Hu, Jia Hu and Yuxin Gao

National Microgravity Lab/CAS, Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, China, hujohn@sina.com

INTRODUCTION

The recent finding that atherosclerotic lesions occur mainly at specific sites around arterial branches and bifurcations indicates that local flow patterns are involved in atherogenesis. Since the synthetic and secretory functions of vascular endothelial cells are influenced by wall shear stress, it is interesting to study how the secretory patterns of these vasoactive mediators are changed in different flow patterns.

METHODS

Bovine aortic endothelial cells (BAEC) were isolated and cultured. Cells between passages 5 and 11 were used for experiments.

Three kinds of parallel-plate flow chamber were constructed, including rectangle chamber, bifurcation chamber and sudden-expansion chamber. The chamber was connected to a closed-loop flow system and the perfusion medium was driven by syringe pump. The flow field was simulated using the software Fluent. Cells were grown on the glass cover plate and subjected to fluid flow. The release of PGI₂ and ET-1 was determined by assaying perfusion medium samples by radioimmunoassay.

RESULTS AND DISCUSSION

The release of PGI₂ was induced by wall shear stress and was magnitude-dependent for rectangle flow chamber. For bifurcation and sudden-expansion chamber, the release of PGI₂ was lower compared to rectangle chamber at the Re number 37.2 (see figure 1). The release of ET-1 was more complex, with low shear stress inducing the secretion and high shear stress inhibiting the secretion. For different flow chamber at the Re number 37.2, the release of ET-1 in bifurcation and expansion chamber was also lower than rectangle chamber (see figure 2). In conclusion, the secretory pattern of PGI₂ and ET-1 was different under different flow pattern.

Figure 1: Cumulative PGI₂ release in different flow chambers at Re number 37.2.

Figure 2: Cumulative ET-1 release in different flow chambers at Re number 37.2.

SUMMARY

Three kinds of flow chamber were constructed and flow patterns were simulated. BAEC monolayers were subjected to these different flow conditions and the release of vasoactive mediators was determined. It was showed the secretion of PGI₂ and ET-1 was affected by flow patterns.

RELATIONSHIP BETWEEN FREQUENCY COMPONENTS OF PHYSIOLOGICAL TREMOR AND ELASTIC LOAD

Masato Takanokura¹ and Kazuyoshi Sakamoto²

¹Department of Industrial Engineering and Management, Kanagawa University, Yokohama, Japan, takanokura@ie.kanagawa-u.ac.jp

²Department of Systems Engineering, The University of Electro-Communications, Tokyo, Japan

INTRODUCTION

Physiological tremor (hereafter referred to as tremor) is an involuntary and continuous oscillation of a limb segment of the healthy human. When no external load is applied to the limb segment, the tremor is composed of two frequency components. It has been proposed that the two frequency components of the tremor are produced by two nervous systems, i.e., the stretch reflex system via the spinal cord and the supraspinal system. The frequency component caused by the stretch reflex system depends on the resonant frequency of the mechanical system of the limb segment. Therefore, some researchers observed that the frequency and the amplitude of the frequency components of the tremor changed with the kind of the limb segment or with the mass of the weight load (e.g., Takanokura and Sakamoto, 2001). The elastic load is an important factor that determines the resonant frequency of the mechanical system. The aim of this study is to investigate the relationship between the frequency components of the tremor in the finger and the elastic load.

METHODS

Subjects were ten healthy males aged 22 to 28. During the experiment, a right index finger of the subject was maintained in a stretched position. The other fingers, the hand, and the forearm were put on a board. The elastic load was applied to the index finger by a tension spring. The subject was asked to pull the tension spring by the index finger and to maintain the finger in a stretched position. When the index finger became horizontal, the tension spring was extended to 5mm from the natural length. Twelve kinds of the tension spring were used. The elastic coefficient ranged from 0.05-0.78N/mm. The tremor was measured by an acceleration sensor (9G111BW, NEC Sanei, Japan). The sensor was placed on the tip of the index finger. The measured signal was fed into a charge amplifier, and then it was stored on a personal computer at a sampling frequency of 200Hz. To quantify the frequency component of the tremor, the power spectrum was calculated by using the autoregressive (AR) model, and the frequency at the peak of the spectrum (i.e., peak frequency) was evaluated.

RESULTS AND DISCUSSION

Figure 1 shows the peak frequency of the tremor spectrum. Under the condition without the elastic load (i.e., 0N/mm), the tremor was composed of two frequency components at around 10Hz and 23Hz. The component at 10Hz did not change with the elastic load. When the elastic load was applied to the finger, the component at 23Hz was split into two components. One of the components did not change with the elastic load,

and its frequency was about 23Hz. The other component was shifted to the higher frequency domain. Takanokura and Sakamoto (2001) proposed that the load-dependent component of the tremor was produced by the stretch reflex system, and its frequency depended on the resonant frequency of the mechanical system. Since the resonant frequency increases with the elastic coefficient of the spring, the load-dependent component is shifted to the higher frequency domain. It is considered that the load-independent components at 10Hz and 23Hz are produced by the supraspinal system because these components do not depend on the elastic load. This hypothesis agrees with the suggestion of McAuley et al. (1997) who also observe the three frequency components at 10Hz, 20Hz, and 40Hz under the existence of the elastic load. They suggested that all the components were produced by the supraspinal system. In this study, the load-independent components at 10Hz and 23Hz are also caused by the supraspinal system. However, the load-dependent component is produced by the stretch reflex system because this component depends on the resonant frequency of the mechanical system.

Figure 1: Dependence of peak frequency of tremor spectrum on elastic coefficient of spring.

SUMMARY

The relationship between the frequency components of the tremor and the elastic load is investigated. When the elastic load is applied to the finger, the tremor is composed of three frequency components. The load-independent components at 10Hz and 23Hz are caused by the supraspinal system. The load-dependent component is produced by the stretch reflex system, and its frequency depends on the resonant frequency of the mechanical system.

INFLUENCE OF PLASTIC STRAIN ON THE FATIGUE WEAR OF UHMWPE IN KNEE PROSTHESES

Changhee Cho¹, Teruo Murakami¹, Yoshinori Sawae¹, Nobuo Sakai¹,
Hiromasa Miura², Tsutomu Kawano² and Yukihide Iwamoto²

INTRODUCTION

The wear phenomenon of ultra-high molecular weight polyethylene (UHMWPE) in the knee and hip prostheses is one of the major restriction factors on the longevity of these implants. In the retrieved knee prostheses with anatomical design in particular, the most predominant types of wear on UHMWPE tibial components are pitting and delamination. These fatigue wear of UHMWPE are believed to result from the repeated plastic deformation due to high contact stresses. In this study, elasto-plastic contact analyses of the UHMWPE tibial components were performed using FEM to investigate the plastic deformation behavior in the UHMWPE tibial components.

MATERIALS AND METHODS

Two types of analyses were performed in this study. First, static and kinematic contact analyses of simplified knee prosthesis models that consisted of a hemispherical rigid surface with a radius of 30 mm and UHMWPE plates with various thicknesses were performed to investigate the factors that influence the plastic deformation behavior and the fatigue wear mechanism of UHMWPE. Second, in order to investigate the pattern of the generation and progression of the fatigue wear in the UHMWPE tibial component, contact analyses of the UHMWPE tibial components based on geometrical measurement for two retrieved knee prostheses were performed. Figure 1 shows an example of retrieved knee prosthesis (Press-Fit Condylar type, left side, 74 months *in vivo*) in this second type analysis. Nondestructive cross-section observation on the retrieved UHMWPE tibial components was also performed using a micro focus X-ray CT apparatus.

In this study, UHMWPE was assumed to be an elasto-plastic material and simple tensile tests of UHMWPE were carried out in a temperature-controlled container to establish a finite element material model of UHMWPE.

Figure 1: Components of a retrieved PFC type knee prosthesis, (a) UHMWPE tibial component, (b) femoral component.

RESULTS AND DISCUSSION

In the static and kinematic contact analyses of simplified knee prosthesis models, it was found that the magnitudes of the maximum von Mises stress and maximum plastic strain below the surface increase non-linearly with decreasing thickness of the UHMWPE tibial component. It was also found that the lower slip ratios, which mean higher range of rolling motion cause higher plastic strain both on and below the surface than higher slip ratio. These results suggest that thickness of UHMWPE and slip ratio in the knee prosthesis have a significant effect on its fatigue wear mechanism (Cho, C.H. et al, 2001). In the contact analyses of the UHMWPE tibial components based on geometrical measurement for retrieved knee prostheses, it was found that the maximum plastic strain occurred at approximately 1 mm below the surface (Figure 2). This depth nearly corresponds to the location of subsurface cracks found in the retrieved UHMWPE tibial components (Figure 3). This result suggests that the maximum plastic strain below the surface is closely related to the subsurface crack initiation and delamination in the UHMWPE tibial components.

Figure 2: Contour plot of plastic strain in the lateral side of the PFC type UHMWPE tibial component.

Figure 3: X-ray CT image of the UHMWPE tibial component including subsurface cracks (at line A-B in Figure 1).

SPEED AND CADENCE DIFFERENCES BETWEEN CORNERING AND STRAIGHT TRACK RIDING IN 4KM

INDIVIDUAL PURSUIT

Baiming Zhang, Danny P. K. Chu and Kenneth Mau

Sports Science Department, Hong Kong Sports Institute, Hong Kong, China

Zhangbm@hksdb.org.hk

INTRODUCTION

In track racing, there are two types of track lengths, 250m and 333m. Many coaches and athletes thought that the 4km pursuit track cyclists would maintain a steady velocity to in each round. However, the findings showed that there was a fluctuation of speed during cornering and straight track riding. This fluctuation was produced by the cyclist involuntary. The objective of this study was to determine the differences of speed and cadence of 4km pursuit cyclist between cornering and straight track riding.

METHODS

Totally six elite level track cyclists were employed. There were six trials of 4km pursuit training for each cyclist. The power output, cadence and speed were recorded during the training. A video camera (50Hz) was synchronized with the Schroeder Rad Mebtechnik (SRM) System. The function of video was to provide visual reference for the selection of the cornering and straight track riding data (except starting lap).

RESULTS AND DISCUSSION

Table 1 shows the average speed, cadence and their variations during cornering and straight track riding. The average speed and cadence in straight track riding from 250m and 333m tracks were significantly smaller than in cornering ($p < 0.001$). Moreover, the variation of speed and cadence was significantly

increased ($p < 0.001$) with the curvature of the track (i.e. from 333m to 250m). The change in speed and cadence in 250m track was double the 333m track. The reason may due to the increase of centripetal force when riding on a small curvature track. So, the ground reaction force on bike increased. The frictional force between the surface and rear tire would be increased. The frictional force on the rear tire could increase the speed of bike.

The pursuit cyclist could make use of this phenomena - "acceleration in cornering and speed maintenance in straight track". The use of external force for acceleration would have a better result.

SUMMARY

The speed and cadence of 4km track cyclists depended on the whether the cyclist was cornering or straight track riding. The speed during cornering was faster. The speed variation was inversely related with the radius of curvature of track. The radius of curvature in 250m track is smaller than 333m so the speed in 250m track was double the 333m track.

INTRODUCTION

In dental implantology the classical procedure consists of 1) a healing phase of several months during which the implant is not loaded directly, i.e. the repair zone between the (submerged) implant and bone, containing demineralized bone substance and coagulum, experiences only stresses caused by deformations of the mandible under functional loads, and 2) a subsequent loading phase after the connection of the implant with a suprastructure (two-stage healing). Recently, also a one-stage (early loading) procedure which omits the primary healing phase, has come into use.

This contribution presents a Finite Element (FE) model for the ossification process of the repair zone for the two-stage as well as for the early loading procedure.

METHODS

The geometrical FE model consists of a realistic mandible with a cylindrical titanium implant (diameter: 4 mm) at the site of a premolar (insertion depth: 16 mm). The mandible is loaded by a realistic force distribution of the chewing muscles such that an average periodic chewing force of 100 N is transferred at the premolar site. In the different cross sections of the mandible realistic distributions of cortical and spongy bone are chosen. The thickness of the repair zone around the implant amounts to 500 μm , and a perfect bond between its material and the implant is assumed. The following Young's moduli are used: $E_T = 110$ GPa for titanium, $E_C = 18$ GPa for cortical and $E_S = 2$ GPa for spongy bone, and $E_0 = 500$ MPa as initial value for the material in the repair zone.

Ossification characterized by an incremental increase ΔE_C and ΔE_S of Young's modulus of elements in the cortical and spongy section of the repair zone, is only allowed if the "stimulus", here chosen as the equivalent stress σ_{eqv} , falls into a so-called "stimulus window" determined by a lower and an upper bound. Too small stimuli ("underloading") and too high stimuli ("overloading") lead to bone resorption, i.e. a small reduction of the actual values of Young's modulus. Furthermore, bone apposition has to follow revascularisation, i.e. through "bridging" from the intact bone surface in the direction towards the implant: An increase of Young's modulus is only allowed in an element if it is connected over at least one node via a "bridge" with elements of the intact bone's surface, and if these bridging elements have experienced at least one increase of their Young's modulus under preceding stimuli.

RESULTS AND DISCUSSION

The degree of ossification after the n^{th} loading step is defined as $\kappa_{C,S}(n) = \{\sum E_i(n) V_i\} / (E_{C,S} V_{C,S})$ in the cortical (C) and in the spongy (S) section of the repair zone. Here $E_i(n)$ denotes the Young's modulus of the i^{th} element after the n^{th} loading step, V_i its volume, E_C and E_S the target values of the Young's moduli as given above, V_C and V_S the total volume of the repair zone in the cortical and spongy section, respectively.

Parameter studies show that for proper choices $\sigma_{eqv,l}$ and $\sigma_{eqv,u}$ of the lower and upper bound of the stimulus window, all healing processes lead asymptotically to a non-perfect state of ossification (κ_C and/or $\kappa_S < 100\%$). The lower bound of the stimulus window determines dominantly the attainable degree of ossification of spongy bone, the upper bound that one of cortical bone. The special choice $\sigma_{eqv,l} = 0.3$ MPa and $\sigma_{eqv,u} = 5$ MPa leads to ossification processes as illustrated in Fig. 1. In the two-stage procedure rather high degrees of ossification, κ_C and κ_S , are reached at the end of the first interval (submerged implant), but in the subsequent loading phase κ_C decreases drastically, whereas κ_S experiences a further increase. In contrast to this, in the one-stage procedure κ_C and κ_S grow monotonically to similar asymptotic values.

Figure 1: Two-stage and one-stage ossification process.

SUMMARY

The model can simulate certain clinically observed facts: The decrease of κ_C in the second interval of the two-stage procedure clearly corresponds to the well-known crestal bone loss around the neck of the implant and must be attributed to overloading according to this model. The clinically reported success of one-stage implantation is sustained by the computed values κ_C and κ_S . In this case, however, the relative displacements between implant and bone are distinctly higher than in the two-stage procedure.

OPTICAL MOTION CONTROL OF EUGLENA FOR BIO-MEMS

Akitoshi Itoh¹ and Yoji Toyoda²

¹ Department of Mechanical Engineering, Tokyo Denki University, Tokyo, Japan, aitoh@cck.dendai.ac.jp

² Graduate School Student, Tokyo Denki University

INTRODUCTION

If the motion of microorganisms can be controlled, we can apply it as living micro machines. In fact, many microorganisms have the properties of "taxis". The authors have investigated to control the motion of protozoa by applying the galvano-taxis. The results showed that we could control the motion of paramecium and some ciliates by changing the electrical field. The authors also succeeded to rotate the micro impeller by using controlled paramecium. However, this method could not be applicable for mastigophora or sarcodina. Therefore, this study investigates the motion control of protozoa by applying phototaxis. The experimental protozoa are typical photo-responsive mastigophora, "*Euglena gracilis*". The body length of euglena is about 40-50 μ m.

BASIC REACTION PROPERTIES OF EUGLENA

Phototaxis of euglena can be classified to two categories, positive phototaxis and negative phototaxis. These phototaxis are occurred by the positive/negative photophobic response, which is the response if the brightness of environment is changed (step-up/step-down). In that case, euglena turns its swimming course about $2/3\pi$ rad. If the optical intensity is gradually changed, euglena swims to/against the light source. This orientation phototaxis is occurred by the stastical accumulation of photophobic response.

After the basic property experiment, it was clarified that the application of the photophobic response is more suitable than that of orientation phototaxis for the individual control of euglena. The response rate of the negative photophobic response is higher than the positive photophobic response. Therefore, the application of negative photophobic response is suitable to control behavior by changing the optical field.

THE EXAMINATION OF THE CONTROL METHOD

The authors decided the control method as follows. (1)Every area of the experimental pool is illuminated by the strong light. (2)The dark spot is made to capture euglena within it. (3)The motion of the euglena is controlled by moving the dark spot.

Fig.1 A trace of a euglena in a dark spot

Fig.2 A sequential motion control experiment

The preliminary experiment showed that euglena could be captured in the dark spot by using this control method.

Therefore, the effect of the diameter of the dark spot on the captured time of euglena and on the generation ratio of photophobic response at the bright/dark boundary was investigated. The swimming route of a euglena in 40 seconds when the euglena was captured in the dark spot of $\phi 0.4$ mm was illustrated in Fig.1. Euglena certainly showed photophobic response in the bright/dark boundary. The turning angle of the swimming direction, however, was not fixed in $2/3\pi$ rad, but euglena turned in the various angles.

In some cases, when a euglena turns in the bright/dark boundary, the euglena does not return to the dark field, but escapes to the bright field. Therefore, the returning ratio to the dark field is 80% in the largest. The larger the diameter is, the more the average capturing time and the returning ratio to the dark field increases. Hence, we have to build the control system on the assumption that sometimes euglena escapes from dark spot.

MOTION CONTROL EXPERIMENT

Based on the above results, an experimental system was constructed by using a personal computer and a XY moving table. In this system, a dark spot can be moved by moving the mask on XY table. In this system, the image of the microscope is captured to the personal computer, and the position of the dark spot and that of euglena can be automatically detected.

First, an experiment was done in a condition that a dark spot was sequentially moved without detecting the position of the euglena. To investigate the suitable moving time of the dark spot, the capturing time of a euglena was measured in the condition that the dark spot was moved constantly with reciprocating motion. The results showed that the moving distance of 0.01 - 0.03 mm/s is suitable for the sequential control of euglena. Therefore, a sequential motion control experiment was done. Sometimes euglena is completely followed to the dark spot. However, the capturing of euglena in the dark spot is not stable. Fig.2 is an image processed frame shot of an experimental video.

Therefore, a visual feedback program was made. In this program, the computer always detected the position of the euglena, and if the euglena is escaped from the dark spot, dark spot was moved to the position of the euglena to capture again.

INTRODUCTION

Statistical observations by Deenitchin et al (1998) suggested that complex cystic duct geometry is frequent among cholelithiasis patients. Reduction in gallbladder (GB) motility involves its inefficient emptying. Jazrawi et al (1995) showed that gallstone patients had lower GB turnover rate (GB evacuation fraction). Nakayama and van der Linden (1975) observed stratification of the bile in GB and are often regarded as a precursor to gallstone formation. These studies suggest that fluid mechanics of the biliary system may be an important factor in GB diseases. This paper describes the results of CFD simulations in studying the influence of the cystic duct geometry on its resistance and its relation to the GB turnover rate.

METHODOLOGY

Initially, cystic duct was idealised by a 2D channel with staggered baffles to capture the important flow features. A series of such models with varying geometrical and flow parameters was used to study their contribution towards the cystic duct resistance. Then more realistic geometries were employed from patients' 2D X-ray images. Patient A had gallstone and Patient B had a healthy GB. Qualitatively, the former cystic duct was longer with more folds (spirals) than that of the latter. The results were compared with those from idealised models to assess the usefulness of the latter. The numerical simulations were performed using the finite volume based CFD software, Fluent5.

Figure 1: (Top) a typical idealised geometry of the cystic duct and (bottom) computational grid of Patient A's biliary system.

RESULTS AND DISCUSSION

Boundary conditions were obtained from physiological flow rate measurements. Laminar, steady state flow of Newtonian bile was assumed. The cystic duct resistance, R_n , is defined as:

$$R_n = \Delta P / Q$$

where ΔP = pressure drop across duct, Q = flow rate,

The relative resistance R_d :

$$R_d = R_{n=i} / R_{n=0}$$

where $R_{n=i}$ is the resistance of duct with i -number of baffles.

Figure 2: R_d vs Re for various number of baffles (n)

CFD results show that R_d increases with Reynolds number (Re), increasing number of baffles and decreasing baffle spacing. R_d of the two models from patients falls well in the range of the idealised models. Patient A showed higher resistance than patient B, suggesting that its more complex geometry hinders bile flow to and from GB. This may result in reduced GB turnover rate, possibly contributing to gallstone formation. Further simulations on more patients and the GB motility would be required to establish the role of fluid mechanics in GB diseases.

SUMMARY

Numerical simulation of the human cystic duct shows that the flow resistance increases with complexity of the duct geometry. This finding provides promising evidence that fluid mechanics of the biliary system may be a contributing factor to gallbladder diseases. Further work should include *in vivo* and *in vitro* study of the GB motility and the biliary system.

THE DEVELOPMENT OF A PRELIMINARY FINITE ELEMENT MODEL OF THE FIFTH RIB.

Michael Dean¹, Anthony Bull², Alison McGregor¹

INTRODUCTION

Stress fractures of the fourth to ninth rib account for between 5% and 14% of injuries amongst competitive rowers, particularly at an elite level (Wajswelner et al 2000). Little is known regarding the aetiology of these fractures but they are thought to be associated with the nature of the sport and its training regimes (Christiansen & Kanstrup 1997). This is further compounded by an inadequate understanding of thoracic biomechanics particularly in terms of force transmission between the upper limb and thorax and how this is influenced by spinal mobility. Previous studies of this problem have only been of an analytical nature (Satou & Konisi 1991). In an attempt to understand these injuries a series of anatomical and mechanical studies were undertaken with the main aim of the study being to develop a finite element (FE) model of the rib.

METHODS

Three cadaveric dissections were undertaken to record the musculoligamentous attachment points and fibre orientation of the left and right fifth ribs in relation to the wider thorax, providing a data set of six ribs. Two additional geometrical data sets were obtained from cadaveric rib CT scans. The three dimensional geometry of the rib was then measured using a custom made box gantry to record the position of predetermined points along the rib. A finite element model was created using the ProEngineer preprocessor. Loading and boundary conditions were applied based on the anatomical details and analysed using ANSYS.

RESULTS

There was considerable inter and intra individual variation in the musculoligamentous attachments to the fifth ribs. There was a similar large variation in the geometry of the ribs for example a 3mm difference in rib length was noted between the left and right sides. However, the application of simple loading conditions analogous to the force transmission through the thorax, to the upper limb during the drive of the rowing stroke showed a force concentration at the anatomical mid axillary line that is a common stress fracture site in rowers.

Figure 1~ Finite Element model of the fifth rib with stress concentration at the mid axillary line.

DISCUSSION

A preliminary FEA model of the rib has been constructed, and the application of different loading conditions to this model has suggested that it may be of value in understanding the mechanical failure of this structure. This is of value due to the immense difficulty of accurately imaging or studying the thorax using conventional imaging or biomechanical methods. Using the experience gained from this study we hope to apply conventional imaging and biomechanical techniques in novel ways to create further FE rib models with interfaces to the rest of the thorax and spine. This will be of use, not only in elucidating the pathogenesis of rib stress fractures in rowers, but also from a wider biomechanical standpoint in particular respiratory and impact biomechanics.

TIME-DEPENDENT MATERIAL PROPERTIES OF THE PORCINE KIDNEY CAPSULAR MEMBRANE

Jess G. Snedeker¹, Romain Voide¹, Mehdi Farshad², Franz Schmidlin³, Peter Niederer¹

¹ ETH Zurich, Switzerland, www.biomed.ee.ethz.ch

² EMPA Dübendorf, Switzerland

³ University Hospital, Geneva, Switzerland

INTRODUCTION

A thin capsular membrane helps protect the human kidney during blunt abdominal trauma. Identifying material properties and developing appropriate constitutive models is essential to examining the role of this membrane during impact. While some static mechanical properties of the capsular membrane have been established in the literature (Herbert et al. 1971, and Farshad et al. 1998), presently available renal capsule material test data do not account for the dependency of the stress state on strain rate.

METHODS

Since adult human kidneys are not sufficiently available for material testing, adult pig kidneys were selected as a human analog due to the anatomic and geometric similarity to the human organ. All material tests were performed within 36 hours of animal euthanization. Samples were delicately excised from each kidney using a sheet metal template to yield symmetric samples that could be used for method validation. Tissue samples were kept moist within a physiologic saline solution. The samples were then placed in the clamps of a uniaxial testing machine (Zwick GmbH.).

In order to validate the sample preparation protocol, quasi-static tensile test results were compared between axisymmetric samples taken from the same kidney. The elastic moduli and ultimate breaking stresses of paired samples were compared to verify test repeatability. Preliminary tests were also performed to examine rate dependent properties. The tissues were tested at stretch rates of 0.5%, 5%, and 50% L/s.

RESULTS

The pig kidney capsule exhibits highly variable material behavior both within a single kidney and between different kidneys. Despite this, the experimental protocol yielded similar results for paired samples (figure 1).

Figure 1. Results of paired samples from the same kidney.

As expected, the capsular membrane behaved viscoelastically, becoming stiffer with increasing deformation rates (figure 2).

Figure 2. The pig renal capsule becomes stiffer as strain rate increases. Dashed lines indicate standard deviations.

Breaking stress and the corresponding breaking strain were also observed to depend on the rate deformation. Various rate dependent properties are listed in Table 1.

Table 1. Time dependent properties of the pig kidney capsule.

Strain Rate	# Samples	E (MPa)	Max. Stress (MPa)	Max. Strain (%)
0.5 % L/s	17	55 ± 14	11.6 ± 2.7	24.8 ± 5.2
5 % L/s	7	65 ± 29	14.8 ± 4.7	26.9 ± 14.3
50 % L/s	8	73 ± 43	22.6 ± 9.6	29.7 ± 5.1

SUMMARY

Dynamic testing of the porcine renal capsule reveals a heavy material property dependence on deformation rate. To accurately model the kidney under traumatic loads, considerations for the viscoelastic capsule must be made. Future work is to include the development of a viscoelastic finite element trauma model of the renal capsule that is based upon the results of the present study.

INTRODUCTION

Modelling studies are currently used to achieve better understanding of the mechanical environment of the natural and replaced hip joint. It is generally accepted that neglecting certain muscle actions will significantly alter the stress and strain distributions predicted by the finite element model within the bone. However, it is not clear whether each muscle force has to be modelled as distributed over the entire muscle attachment area, or it is acceptable to concentrate the force resultant into a given point, i.e. the attachment area centroid. Modelling the whole muscle insertion requires additional anatomical knowledge and may significantly complicate the model. However, the large size of certain insertion areas may violate the validity conditions of the St. Venant's Principle. Thus, the simplification may significantly alter the calculated stress and strain distribution within the bone tissue.

METHODS

A novel finite element model of the human femur was developed based on the CAD geometric description of the "Muscle Standardised Femur" (Viceconti et al., 2001). During the FE mesh generation procedure, each muscle attachment area was meshed separately on the femoral bone surface. The solid mesh was generated after the complete surface mesh had been defined. Two load cases, representing an instant at 10 % during gait cycle were analysed. The applied force data set was based on the muscle model by Brand et al. (Brand et al., 1986, 1994). In load case 1 (LC1), the effect of all muscle forces attached to the femur were taken into account and applied as concentrated forces at the muscle attachment area centroids. Load case 2 (LC2) represented the physiological load configuration where all muscle force actions were assumed to be uniformly distributed over the areas of their insertions. The displacement boundary conditions were applied to restrict rigid body motion, six degrees of freedom were constrained at the knee.

RESULTS AND DISCUSSION

Calculated displacement of the femoral head was not influenced by the mode of load application. For LC1 the femoral head moved an overall 2.3 mm medially (1.9 mm), posteriorly (1.2 mm) and distally (0.5 mm) relative to the knee. For LC2, the overall displacement differed only slightly, the head moved 2.4 mm in the same direction.

Peak tensile and compressive principal strains in the femoral diaphysis region exceeded 8800 $\mu\epsilon$ and -9,600 $\mu\epsilon$ for LC1. The peak principal strain values occurred in the femoral shaft region in the vicinity of the

concentrated load application nodes. For LC2, the largest tensile and compressive principal strains were below 680 $\mu\epsilon$ and -930 $\mu\epsilon$. When data from those elements containing concentrated muscle force application nodes were excluded, peak tensile and compressive principal strains for LC1 exceeded 1500 $\mu\epsilon$ and -1900 $\mu\epsilon$, respectively. Although this is a substantial decrease, the difference between the peak values for simplified and the physiological load cases still exceeded 100 %.

On the internal bone surface no high peak strains were observed for LC1. Principal strains were compared in the internal surface nodes in the region of the concentrated load application. As an example, close to the vastus medialis attachment, compressive and tensile principal strains were still 25% (50 $\mu\epsilon$) and 40% (30 $\mu\epsilon$) higher respectively than those for LC2 at a distance of 20 mm (approximately 2.5 times the cortical thickness).

Non-zero normal stress residuals were observed on the internal bone surface around the load application regions. At the gluteus maximus attachment area, peak values of normal stress residuals three times larger for LC1 than for LC2.

CONCLUSION

The results of the current study suggest that when modelling the musculo-skeletal system with FE analysis, St. Venant's Principle should be applied with caution. When the aim of the study is to determine the physiological strain distribution inside the intact bone, realistic representation of the muscle loads transferred to the human femur during activities should be considered. Future work is required to investigate the effects of simplified loading on femurs after joint replacement.

SELF-SUSTAINING OSCILLATORY ELECTROMECHANICAL ACTIVITY IN THE GUT

Roustem Miftakhov and Michael Vannier

Department of Radiology, University of Iowa, 200 Hawkins Drive, Iowa City, IA 52241, USA; email: roustem-miftakhov@uiowa.edu

INTRODUCTION

Electromechanical conjugation, a fundamental neuromuscular phenomenon in the gut, is responsible for the major motor functions, mixing, grinding, and propulsion of the intraluminal content. It has been speculated that the electrical processes in muscle (slow waves, spiking activity) result from regulatory pacemaker input provided by interstitial cells of Cajal and/or intrinsic nerves. Electrophysiological recordings from the smooth muscle demonstrate self-oscillatory behavior of the syncytium due to randomly occurring and spatially distributed sites of electrical discharges. This implicates the role of intrinsic mechanisms in the regulatory electromechanical activity.

The aims of this study are: i) to model the gut as a biologically active cylindrical tube, and ii) to study numerically the dynamics of the electromechanical wave processes within it.

MODEL DESCRIPTION

The following assumptions are made in the formulation of a model: i) a segment of the gut is formed of the two smooth muscle layers, the longitudinal and circular layers; ii) the longitudinal layer possesses properties of electromechanical anisotropy, while the circular layer demonstrates isotropic characteristics; iii) spatially distributed, weakly connected oscillators define the electromyogenic properties of the syncytium; iv) strong connections among oscillators are provided by the propagating wave of excitation along the syncytium; v) the dynamics of oscillatory activity depends on ion channel function: L - and T - type Ca^{2+} , Ca^{2+} - K^{+} , Na^{+} , voltage dependent K^{+} and Cl^{-} channels; vi) the mechanical activity is due to a cascade of intracellular reactions of myosin contractile proteins.

The problem leads mathematically to a combined system of partial and non-linear ordinary differential equations. Boundary and initial conditions assume that both ends of the shell are rigidly fixed and the excitatory signals are applied at the left boundary. Hybrid finite difference and finite element methods of second order accuracy, with respect to spatial and time variables, are used to solve the problem.

RESULTS AND DISCUSSION

The 100 mV 1 s discharge of a pacemaker located on the left boundary produces a wave, 68 – 70 mV, which propagates along the surface of the syncytium towards the right boundary at a constant velocity 0.5 cm/s. The anisotropic electrical

properties of longitudinal layer make the front the wave an ellipse, while in the circular layer it forms a ring. Following the activation of contractile proteins, active forces of contraction change the shape of the gut.

The stimulation of the gut by a series of impulses (amplitude 100 mV, duration 1 s, and frequency 0.33 Hz) creates the two spiral waves propagating towards the distal end (fig. 1a, b). After their collision and reflection from the right boundary a strong spike of amplitude 90 mV is produced. It propagates backwards, reaches the middle of the segment and produces a circular wave (fig. 1c). After the wave covers the entire surface of the gut another set of spiral waves is generated. The process is repeated as above (fig. 1d). The pattern of electrical activity causes retrograde propagation of the mechanical wave of contraction-relaxation. The system converts to normal electromechanical activity after application of a sodium channel blocker compound.

SUMMARY

A new numerically discovered phenomenon of self-sustained electromechanical activity in the smooth muscle syncytium could explain normal and pathological motor patterns produced by the organ and observed *in vivo* and *in vitro*. The basis of the theoretical results needs to be established and verified experimentally. It would have enormous implication for our understanding of motor disorders of the gut.

Figure 1: Dynamics of the generation of sustaining self-oscillatory activity in the smooth muscle syncytium of the gut.

GROUPING OF SCOLIOSIS PATIENTS BY SPINAL CURVE SEVERITY FROM TORSO SURFACE DATA

Jacob L. Jaremko¹, Philippe Poncet¹, Janet Ronsky¹, James A. Harder¹, Jean Dansereau², Hubert Labelle², Ronald F. Zernicke¹

¹McCaig Centre for Joint Injury & Arthritis Research, University of Calgary, Calgary, AB

²LIS-3D Laboratoire, Ecole Polytechnique & Ste. Justine Hospital, Montreal, PQ

INTRODUCTION

Because spinal curvature in scoliosis often progresses sufficiently to require treatment by bracing or surgery, scoliosis patients are currently monitored by full-spinal X-rays on which the Cobb angle of lateral spinal curvature is measured [1]. If it was possible to detect scoliosis curvature reliably from torso surface shape alone, the harm associated with radiation from these X-rays [2] could be avoided. The relation between surface and spinal deformity, however, is complex and difficult to characterize by linear methods [3-5]. An artificial neural network (ANN) performs nonlinear multivariate regression analysis using several layers of nodes and links analogous to biological neurons. An ANN "learns" generalizable relations between input and output data through repeated presentation of data sets. Here, we trained an ANN to estimate the Cobb angle of scoliosis deformity from asymmetry of the 360° torso surface shape and other non-radiologic data. Since brace treatment in scoliosis would almost certainly begin before the Cobb angle reached 30° and surgery would generally be performed when a curve reached 50° [1], we computed the accuracy with which the ANN categorized patients into three groups based on curve severity (0-30°, 30-50°, >50°).

METHODS

Patients: We had 48 consecutive, consenting scoliosis clinic patients aged 8-18 (38 female) who had never had spinal surgery. The neural network was trained using 89 scans of these patients collected in four semi-annual sessions, and tested using 26 scans of those patients who attended a fifth session. Cobb angles varied from 10-71°.

Imaging: A 3-D torso surface model of each patient was generated from surface coordinates acquired by four laser cameras, and a postero-anterior X-ray was taken as the patient stood in the same position [6].

Indices: Indices were recorded for each visit of each patient. Genetic algorithm optimization gave a neural network that estimated the Cobb angle from 17 input indices including clinical parameters such as height and body mass index, the maxima and range of surface asymmetry measures such as back surface rotation, cross-sectional eccentricity, spinous process line and cross-section centroid lateral deviation, and asymmetry between left and right halves of cross-sections (Figure 1).

RESULTS

The ANN categorized 83/89 training-set records (93%) and 24/26 test-set records (92%) into the correct group based on curve severity (Cobb angle 0-30°, 30-50°, >50°; Table 1).

DISCUSSION

Neural network analysis of torso surface asymmetry correctly classified >90% of patient-records (whether or not those records had been used for network training) into one of three groups representing those likely to be treated by observation (0-30°), bracing (30-50°) or surgery (50°+). This accuracy encourages further work to detect scoliosis progression in individual patients without repeated X-rays.

INTRODUCTION

The abdomen is the largest cavity of the human body and ranks third with regard to injured body regions. Blunt abdominal trauma leads mainly to injuries of the kidney, the liver and the spleen, all of which may result in morbidity or mortality in the injured person. Trauma research has historically focused on other regions of the body (e.g. head, thorax). Therefore the mechanisms of renal trauma are largely unknown. To this end, a high-resolution finite element model of the kidney has been constructed, as well as models of several neighboring organs, specifically the liver and spleen.

METHODS

An image segmentation and organ reconstruction software package was employed to transform 2D Visible Human Female Project (National Library of Medicine) dataset images into 3D polygonal representations. NURBS surfaces were then mapped to the polygonal organ surfaces, and were finally used within commercial meshing software to create robust 3D finite element meshes of the kidney, liver, and spleen.

A combined linear viscoelastic and Ogden hyperelastic material model was developed for the kidney using a least squares fit to experimental test data of pig organs in dynamic compression (Melvin et al. 1974). Since the current project focuses specifically on traumatic effects in the kidney, a more simple Hookean material was used for the spleen and the liver.

RESULTS

Specific information pertaining to the finite element models is listed in Table 1.

Table 1. Abdominal organ FE model specifications.

Organ	Element Type	# of Elements	Material Model (Units MPa)
Kidney	20 Node Hex	165,000	Ogden/Viscoelastic
Liver	4 Node Tet.	14,800	E=2.0, $\nu=0.4$
Spleen	4 Node. Tet.	1,400	E=2.0, $\nu=0.4$

The material model derived for the kidney was an incompressible, isotropic, third order Ogden hyperelastic material ($\mu_1 = 0.15$, $\alpha_1 = 0.3$, $\mu_2 = 0.53$, $\alpha_2 = 0.4$, $\mu_3 = -0.01$, $\alpha_3 = -9.5$) combined with a viscoelastic relaxation function that was implemented via a single term Prony series with constants $g_1 = 0.93$ and $\tau_1 = 2.5e-4$.

Each model was tested for mathematical robustness within a simulation of quasi-static, parallel-plate compression that

modelled the experiment used for identifying the material properties of the actual organs. The resultant von Mises stress distributions for all three organs are illustrated in Figure 1.

Figure 1. Von Mises stress distributions (clockwise from bottom) for the VHF kidney, liver, and spleen in parallel plate compression, at a nominal strain of 25%. The kidney is compressed along the z-axis, the liver and spleen along the y-axis. The organs are not similarly scaled. Stresses are MPa.

SUMMARY

Working finite element models of the VHF kidney, liver, and spleen have been created. Future models will include other soft organs and tissues, particularly the stomach, pancreas, abdominal fat, and fascia. A completed abdominal model can then be subjected to typical loading patterns derived from accidental impact situations, and exploited to analyze injury mechanisms, evaluate tolerance criteria, and eventually advance injury protection strategies.

POSTURAL CONTROL AND STRENGTH AMONG ELDERLY WITH AND WITHOUT A FEAR OF FALLING

Brenda Brouwer, Kristin Musselman and Elsie Culham

School of Rehabilitation Therapy, Queen's University, Kingston, Ontario, Canada, brouwerb@post.queensu.ca

INTRODUCTION

Almost 60% of community dwelling elderly have a fear of falling; well over the 30% of seniors who will experience a fall in a given year (Maki et al 1991). Fear of falling (FF) is of concern as it undermines self-confidence and contributes to self-imposed inactivity or restriction of activities, which may lead to deconditioning. This study explored whether those fearful of falling exhibit deficits in balance ability or physical function compared to non-fearful seniors and whether performance differed based on a 12 month fall history.

METHODS

Seniors recruited from the community were screened to ensure they had no medical conditions affecting balance. They self identified as either restricting their activities due to a concern about falling (FF group) or not (control). The Activities-specific Balance Confidence Scale (ABC) was used to measure FF in terms of subjects' confidence in performing specific daily activities (0 = no confidence; 100 = total confidence). Subjects with a FF were subdivided into those who had and had not fallen in the past 12 months. Participants provided consent and procedures were ethics approved.

Three tests of physical performance were completed in random order: 1) subjects shifted their weight on a force platform by moving about their ankles keeping knees and hips straight. The limits of stability (LOS) were the maximum displacements (cm) of the center of pressure (COP) in anterior, posterior, left and right directions relative to a resting COP position. 2) Isokinetic (600/sec) flexor and extensor torques were measured about the ankle, knee and hip joints during 5 reciprocal, maximal, concentric contractions. Peak torque (gravity corrected) was normalized to body weight. 3) Natural cadence gait speed was calculated from the time to traverse the central 10 meters of a 15-meter walkway.

RESULTS AND DISCUSSION

Groups matched in age and gender make-up (Table 1). As expected, the FF group had lower ABC scores than controls ($p<0.001$). There were no differences attributable to fall history ($p>0.05$).

Table 1: Subject demographics (mean \pm 1 SD)

	Age (yrs)	Male:Female	ABC score
Control (n=25)	76.3 \pm 5.2	9:16	90.5 \pm 7.9
FF (n=25)	76.4 \pm 5.1	9:16	67.5 \pm 15.3
No falls (n=13)	74.7 \pm 5.3	2:11	70.9 \pm 11.0
Falls (n=12)	78.2 \pm 4.5	7:5	64.3 \pm 18.3

Subjects with a FF were less willing to shift their COP, particularly in anterior and combined anterior-posterior (AP)

directions ($p<0.05$; Figure 1). In those who had fallen in the past, LOS were less, but not significantly so. Those with a FF also walked more slowly than controls ($p<0.02$).

Figure 1: Mean maximal COP displacement (cm) in anterior - posterior (AP) and mediolateral (ML) directions. Gait speed is in m/sec (right axis)

The control group was stronger than the FF group for all muscle groups ($p<0.01$). Differences were most pronounced at the proximal joints (Figure 2).

Figure 2: Peak torque (Nm/KgBW) for control and fear of falling (FF) groups. (Subgroups are not shown, as there were no differences based on fall history). PF=plantarflexors; DF=dorsi-flexors; KE=knee extensors; KF=knee flexors; HE=hip extensors; HF=hip flexors.

SUMMARY

Seniors with a self-identified FF had reduced balance confidence accompanied by declines in LOS, walking speed and lower limb strength compared to controls. Deficits appeared more prominent in those who had a prior fall, but not significantly so. The findings indicate limited balance ability and function in the presence of a fear of falling.

SOLEUS H-REFLEX GAIN IN ELDERLY AND YOUNG ADULTS WHEN LYING, STANDING AND BALANCING

Gordon R. Chalmers¹ and Kathleen M. Knutzen

Dept. of Physical Education, Health and Recreation, Western Washington University, Bellingham WA, USA. ¹chalmers@cc.wvu.edu

INTRODUCTION

In young adults, the soleus Hoffmann (H-) reflex decreases in size, or gain, when changing from lying to standing (Koceja et al, 1995; Koceja et al, 1993). A decrease in H-reflex size is associated with tasks having greater postural instability (Angulo-Kinzler et al, 1998). In contrast, elderly adults upon standing, on average, show either no change, or an increase in the maximum soleus H-reflex in a reflex recruitment curve (Koceja et al, 1995; Angulo-Kinzler et al, 1998). The goal of this study was to determine in elderly adults if the lack of ability to decrease soleus H-reflex gain when standing is also observed if the elderly adults are challenged with a standing task of greater postural instability.

METHODS

Subjects, 12 young (22 ± 1.4 years, mean \pm SD) and 16 elderly (71 ± 4.3 years), were tested in three positions: lying supine, standing with feet spaced at a natural distance apart (wide standing), and standing with the left foot placed directly in front of and touching the right foot (narrow standing). In each position, 12 target right soleus contraction levels were randomly presented, and the subject was provided with feedback on their right soleus EMG. For each contraction level, the subject performed a bilateral isometric ankle plantar flexion contraction and when the feedback EMG level matched the target level a stimulus was delivered to the posterior tibial nerve (voltage producing a M-wave amplitude 25% of the maximum M-wave). For each stimulus, the peak-to-peak amplitude of the M-wave and the H-reflex wave, and the rectified and smoothed background EMG over 0.1 seconds prior to the stimuli were determined. Soleus H-reflex gain was defined as the H-reflex wave amplitude at a given level of motoneuron excitability, the latter reflected by background EMG (Simonsen et al, 1995; Matre et al, 1999) (Fig 1).

each posture tested, from a young subject. The Y-axis provides the peak-to-peak amplitude of the H-reflex wave and the M-wave. The X-axis provides the background EMG level over 0.1 seconds prior to the delivery of a stimulus. Tests performed in a lying posture (box symbols and solid regression line), stable wide standing posture (circle symbols and large dash regression line), and unstable narrow standing posture (triangle symbols and small dash regression line) are shown. Large filled symbols and regression lines are for H-reflex wave amplitude data, small empty symbols are for corresponding M-wave amplitude data. Note that M-wave amplitude of the stimuli did not vary with body position. The vertical solid line marks the background EMG level used when comparing H-reflex amplitude across the three postures. For this subject, the H-reflex amplitude for the wide standing and the narrow standing postures were a 10% and 32% decrease from the H-reflex amplitude in the lying position.

RESULTS

Compared to a lying position, the mean soleus H-reflex gain was significantly lower in the wide standing position for the young subjects ($-19 \pm 14\%$, $p < .0125$), but not the elderly ($-8 \pm 38\%$), and was significantly lower in the unstable narrow standing posture for both the young ($-30 \pm 19\%$, $p < .0125$) and elderly subjects ($-28 \pm 25\%$, $p < .0125$).

DISCUSSION

For the range of postural tasks examined, soleus H-reflex gain modulation in the elderly adults had a higher threshold for initiation, but responded dramatically, and similarly to that observed in young adults, when the task difficulty was sufficient.

EXPERIMENTAL DETERMINATION OF THE CENTER OF RESISTANCE OF HUMAN INCISORS IN COMPARISON WITH FINITE ELEMENT SIMULATIONS

Christina Dorow¹, Natasa Krstin¹, Franz Guenter Sander²

Department of orthodontics, University dental clinic of Ulm, Ulm, Germany

¹ Scientific research assistants, christina.dorow@medizin.uni-ulm.de

² Head of department

INTRODUCTION

During an orthodontic treatment, systems of forces and moments are applied to the tooth crown which lead to an initial tooth deflection being mainly controlled by the material properties of the periodontal ligament (PDL). The PDL is a soft biological tissue that attaches the tooth root to the alveolar bone and has an important influence on tooth mobility.

In an orthodontic therapy usually a bodily tooth movement is desired. For that reason the orthodontic force systems have to be designed in a way that no tilting or tipping of the tooth root occurs. The center of resistance (CRE) of a tooth is defined as the point where a force has to be applied to achieve a pure translation of the tooth. Its location is dependent on the shape of the root as well as on the material properties of the embedding of the tooth, i.e. the PDL. Knowledge of the position of the CRE is therefore very important for planning an orthodontic therapy.

METHODS

For the experimental determination of the CRE of human incisors a novel experimental setup has been developed. Tooth deflection was measured by two fiber optic displacement sensors pointing at different locations on the labial surface of the incisor crown. The sensors were fixed to the maxilla using a bite plate. A constant moment was applied to the tooth crown via a motor drive, a stainless steel wire and a bracket that was attached to the tooth crown between the two fiber ends (the experimental setup is shown in figure 1). From the signal of the sensors a two dimensional deflection of the incisor could be calculated and the CRE could be determined.

Realistic and individual three-dimensional geometry models of the measured teeth were generated using computer tomography (CT) data. A novel algorithm has been developed to generate a Finite Element mesh of a tooth unit including PDL and alveolar bone. In a Finite Element simulation the reaction of the tooth to external moments was calculated and the location of the CRE was determined and compared to the experimental results.

RESULTS AND DISCUSSION

When a “square wave” moment was applied to the bracket tooth deflection showed creep and recovery which are typical properties of viscoelastic materials. Using the displacement measured by both sensors and the longitudinal axis of the tooth, the CRE of the incisor could be calculated. From CT data of the measured teeth geometry models were generated

(see figure 2) in order to calculate their centers of resistance using the Finite Element Method. The material properties of the PDL were varied and their influence on the location of the CRE was examined.

Figure 1: Experimental setup showing the two fiber optic displacement sensors, the motor drive, the wire segment and the orthodontic bracket.

Figure 2: Finite Element Model of a tooth unit including maxillary incisor (blue), PDL (violet) and alveolar bone (red).

SUMMARY

Using viscoelastic material properties for the PDL, the Finite Element simulation was able to represent the measured creep behavior of the incisor. Assuming linear elastic material properties, an elastic modulus of the PDL could be determined by comparing the calculated location of the CRE with the experimental result.

OPTIMIZATION OF PASSIVE TISSUE MODEL PARAMETERS OF INTRINSIC LARYNGEAL ADDUCTORY MUSCLES

Eric J. Hunter, Ingo R. Titze, and Fariborz Alipour
National Center for Voice and Speech and Department of Speech Pathology and Audiology,
University of Iowa, Iowa City, Iowa, eric-hunter@uiowa.edu

INTRODUCTION

This research addresses an automated curve fitting strategy to obtain the passive properties of laryngeal muscles in terms of muscle model parameters. The passive properties are important in global shaping and displacement of the larynx, as well as in the control of pitch in speech.

METHODS

Using previously measured stress-strain data from five fresh excised canine laryngeal muscles strained sinusoidally (Figure 1), one-dimensional first-order Kelvin model parameters (Titze, 1996) were obtained through optimization. Optimization was performed using the Nelder and Mead Simplex method when stress-strain patterns predicted by the model were compared to measured cyclic stress-strain patterns. Average parameters were obtained for each muscle type.

Figure 1: A typical optimized model fit of the muscle data (Specimen 5, LCA). The original muscle data are represented by the solid line.

RESULTS AND DISCUSSION

Optimized parameter values from the single curves were averaged for the five samples of a laryngeal muscle type. After the model overestimated the predicted average stress when using these average values, an average curve representing the five single curves was made for each muscle type and parameter values were optimized for this average curve (Table 1). Fitting the average curve resulted in

parameters that best fit the passive characteristics. It was noted that a ratio of the parallel and series time constants was nearly constant regardless of the optimization method.

Table 1. Optimized model parameters for four laryngeal muscles.

Parameters	IA	LCA	PCAo	PCAv
σ_0 (Pa)	1370	784	1560	791
σ_2 (Pa)	6502	270	3690	31.7
ϵ_1	-0.5	-0.5	-0.5	-0.5
ϵ_2	-0.000181	-0.0131	0.0223	-0.179
B	6.077	15.5	10.9	15.9
t_p (sec)	0.0904	0.0953	0.084	0.115
t_s (sec)	0.0506	0.0524	0.0484	0.0612
t_p/t_s	1.79	1.84	1.75	1.89

SUMMARY

The automated curve-fitting strategy was able to quantify the stress-strain data with parameters of a muscle model. With the parameters, the model could closely match the measured stress-strain curves. The passive properties could then be used in biomechanical speech models of vocal fold posturing and pitch control. The parallel and series time constants seem to be related to each and may not be independent as the model supposes. The muscle model could be simplified if the time constants are dependent.

DIRECTIONAL DEPENDENCE OF EARLY FATIGUE DAMAGE IN CEMENTED TOTAL HIP REPLACEMENTS

Kenneth Mann, Sameer Gupta, Amos Race, Mark Miller, Richard Cleary¹, David Ayers

Musculoskeletal Science Research Center, Upstate Medical University, Syracuse, New York, USA
¹Operations Research, Cornell University, Ithaca, New York, USA
mannk@mail.upstate.edu

INTRODUCTION

Determining where fatigue damage or micro-cracks develop in the cement mantle may provide clues into the beginning stages of cement fracture. In the present study we investigate the fatigue damage in a cemented femoral stem model using cadaveric femurs subjected to stair climbing loads. We *hypothesized* that the crack distribution would depend on the circumferential position around the cement mantle. That is, there would be a *directional dependence*. We further hypothesized that the crack distribution would be different for the proximal and distal regions of the cement mantle.

METHODS

Six Charnley Cobra flanged femoral components (DePuy, Inc.) were cemented into fresh-frozen human cadavera using modern cementing techniques. Each construct was loaded using a previously described stair climbing apparatus [Race, 2001] for a total of 300,000 cycles. After loading, each specimen was sectioned in 10mm intervals from the level of the implant collar to the distal tip of the stem. Specimens were grouped as either proximal (sections at 10-50 mm) or distal (sections at 80-110 mm). Crack lengths and angular position of the cracks relative to the center of the stem section were documented for all transverse sections.

The resultant data were analyzed using *circular statistics* [2] where a cyclical scale of 0-360 deg was used. For each cemented implant, a resultant vector with length r_j and angle θ_j was calculated using:

$$r_j = \sqrt{X_j^2 + Y_j^2} \text{ and } \theta_j = \tan^{-1}\left(\frac{Y_j}{X_j}\right) \text{ for } j = 1, 6 \text{ (six cemented implants)}$$

$$\text{where : } X_j = \sum_{i=1}^{n_j} l_i \cos \theta_i / n_j \quad Y_j = \sum_{i=1}^{n_j} l_i \sin \theta_i / n_j \text{ and } n_j = \text{total \# cracks}$$

Crack length (l_i) and crack angle (θ_i) were measured for each crack (Fig 1). The measure r represents the dispersion of cracks around the cement mantle; the higher the r , the less uniform the distribution. The θ_j is the mean angle or preferred direction of the crack distribution. Nonparametric statistical analysis was used on these parameters to determine if: (1) the cracks had a non-uniform distribution around the mantle; and (2) the distribution was different for proximal and distal regions of the mantle.

RESULTS AND DISCUSSION

There were a total of 2388 cement cracks in the six cemented femurs (1831 proximal and 557 distal) with an average length of 0.49mm. The frequency of cracks distributed around the cement mantle was not uniform (Fig 1) suggesting a regional variation of cracks with angular position. There was one outlier in this group; this specimen had an inferior cement mantle with substantial stem-cement voids and was excluded from the statistical tests.

Figure 1: Distribution of cracks (left) and definition of crack angle (right).

The mean angle for all cracks was 249 deg. (Table 1) (posterior-medial direction) and the population of cracks was not uniformly distributed around the mantle ($p < 0.01$). The orientation of the mean angle was also significantly different ($p < 0.02$) for the proximal and distal regions of the cement mantle. In the proximal region, cracks were most often located along the posterior-medial aspect of the mantle. Distally, cracks were most often located along the anterior aspect of the mantle.

Table 1: Ranges and mean of crack distribution of vector strength (r) and orientation (θ).

	r range of 6 bones	θ range of 6 bones (deg.)	r (average)	θ (average) (deg.)
Proximal	0.07-0.28	162.7-296.6	0.14	251.0
Distal	0.04 - 0.16	69.3 - 169.4	0.07	112.3
Total	0.03 - 0.21	158.4 - 326.6	0.09	248.6

DISCUSSION

After fatigue loading, cracks in the cement mantle were not uniformly distributed around the perimeter, nor were the distribution of cracks the same for proximal and distal regions of the constructs. Using circular statistics, we found that both of our initial hypotheses were true. Further work is needed to relate the crack distribution and morphology of the mantle, particularly in the vicinity of trabecular bone that is interdigitated with cement.

CAN PIECE-WISE LINEAR INTERFACE MODELS BE USED TO PREDICT THE FAILURE RESPONSE OF THE CEMENT-BONE INTERFACE?

Kenneth Mann, Leatha Damron, Amos Race, Mark Miller, and David Ayers

Musculoskeletal Science Research Center, Upstate Medical University, Syracuse, New York, USA
mannk@mail.upstate.edu

INTRODUCTION

Failure of the cement-bone interface is one of the primary mechanisms for clinical loosening of cemented total joint replacements. The etiology of this failure process is poorly understood and predictive models have been insufficient in terms of capturing the mechanics of the failure process. The main goal of this work was to determine if a series of model-specific finite element models (that incorporated a non-linear fracture mechanics approach) could reproduce the failure response of experimentally loaded cement-bone constructs. A secondary aim was to determine how specific changes in the cement-bone interface models, due to lack of specificity of interface parameters, affected the global structural response of the finite element models.

METHODS

A series of eight experimental and corresponding 3-D finite element models were created from human proximal femora. The experimental specimens were CT scanned to document the QCT density of the endosteal trabecular bone, cemented with PMMA using contemporary surgical techniques, followed by sectioning to create the test specimens. Specimens were tested under displacement controlled loading using a custom test fixture (Fig 1A). The corresponding load versus global displacement was measured to represent the structural response to complete failure. Ultimate strength, energy to complete failure, and post-yield softening response were calculated.

Figure 1: Experimental (A) and finite element (B) cement-bone specimens.

Finite element models were created for each of the specimens using macrophotographs of the specimens (Fig 1B). Piece-wise linear interface elements were placed at the extent of cement penetration into the bone. The constitutive models were based on a non-linear fracture mechanics formulation that is an extension of the Dugdale-Barenblatt [Kanninen, 1985] approach to predicting fracture. In the normal direction, the interface supports tensile loads up to a peak tensile stress

followed by a softening region until the interface no longer supports any load. A similar model was applied in the shear direction, except the shear model is anti-symmetric. Interface parameter values were assigned to the interface elements based on the amount of bone (CT density) that was interdigitated with the cement (q-int) [Mann, 1997]. Thus the finite element models and interface parameters were based on geometry, material, and interface properties that were assigned using parameters that did not require *a priori* physical loading of the experimental specimens.

RESULTS AND DISCUSSION

There was a strong correlation ($r^2=0.8$) between experimentally measured and finite element predicted ultimate loads (Fig 2). The average error in predicting ultimate load was 23.9%. In comparison to the ultimate load predictions, correlation and errors for total energy to failure ($r^2 = 0.24$, avg. error = 38.2%) and displacement at 50% of the ultimate load ($r^2 = 0.27$, avg. error = 52.2%) were poor. The results indicate that the non-linear constitutive laws could be useful in predicting the initiation and progression of interface failure of cemented bone-implant systems. However, improvements in the estimation of post-yield interface properties from the quantity of bone interdigitated with cement are needed to enhance predictions of the overall failure response.

Figure 2: Comparison between measured and predicted ultimate loads. Error bars indicate results using interface constitutive models based on +99% confidence interval values of the q-int data.

EFFECTS OF CYCLIC PRESSURE ON SELECT BONE CELL FUNCTIONS PERTINENT TO BONE HOMEOSTASIS

INTRODUCTION

Clinical observations (Leblanc *et al.*, 1990; Courteix *et al.*, 1998) have provided evidence that mechanical loading on the skeleton affects bone homeostasis. To date, however, the mechanism(s) that link mechanical stimuli and bone homeostasis, especially at the cellular- and molecular-levels, are yet to be elucidated.

It has been reported in the literature that, when the human skeleton is under loading, the fluid pressure within bone (intraosseous pressure) at such sites as the vertebrae and femoral heads increases proportionally to the applied load (Downey *et al.*, 1988). It is, therefore, possible that the functions of bone cells, which are subjected to changes in intraosseous pressure, are affected under skeletal loading. In an attempt to model this complex mechanical environment of bone *in vivo*, the present *in vitro* study exposed bone cells, namely, osteoblasts and osteoclasts, to controlled regimes of cyclic pressure and examined select cell functions pertinent to bone homeostasis.

METHODS

Rat osteoblasts were isolated, cultured and characterized as described elsewhere (Nagatomi *et al.*, 2001). Bone marrow cells (used as a source of osteoclast progenitor cells) were harvested and cultured using a method adapted from the literature (Hata *et al.*, 1992).

A custom-made, cyclic pressure system (Nagatomi *et al.*, 2001) was used in the present study to expose osteoblasts and bone marrow cells to cyclic pressure. Osteoblasts (in DMEM containing 10% FBS, 50 µg/mL L-ascorbate and 10 mM β-glycerophosphate) on etched glass coverslips and bone marrow cells (in DMEM containing 10% FBS and 10 nM 1,25-(OH)₂ vitamin D₃) on devitalized bovine bone slices were exposed to cyclic pressure (10 – 40 kPa at 1.0 Hz frequency) for 1 hour daily for up to 19 consecutive days. Controls were similar cell preparations maintained under standard (no pressure) cell culture conditions for the duration of the experiments.

At the end of the prescribed time periods, mRNA expression for type-I collagen, alkaline phosphatase and osteocalcin by osteoblasts was determined using RT-PCR techniques. Concentrations of collagen and calcium in the extracellular matrix of osteoblasts were determined using commercially available kits. Bone resorption activity by osteoclasts was quantified by measuring the total planar surface area of resorption pits on the surfaces of bone slices.

RESULTS AND DISCUSSION

The results of the present study demonstrated that cyclic pressure stimulated functions of osteoblasts pertinent to new bone formation. Specifically, the results of RT-PCR revealed that mRNA expression for type-I collagen (the main constituent of the organic phase of bone) and alkaline phosphatase (an enzyme important for mineralization of the extracellular matrix) under control conditions declined over the 19-day time period, but was enhanced when osteoblasts were exposed to cyclic pressure (10 – 40 kPa at 1.0 Hz) for 1 hour daily for up to 19 consecutive days. In addition, compared to controls, deposition of collagen into the extracellular matrix of osteoblasts and concentration of calcium (one of the main constituents of the inorganic phase of bone) in this matrix both significantly ($p < 0.05$) increased following exposure to the same regime of cyclic pressure for 19 days.

Furthermore, exposure of bone marrow-derived osteoclasts to cyclic pressure (for 1 hour daily for 7 consecutive days) resulted in significant ($p < 0.05$) decrease in bone resorption. Since the numbers of osteoclastic cells were similar in controls and in cultures exposed to cyclic pressure, it was concluded that the decreased bone resorption observed in the present study was due to reduced osteoclast activity under the mechanical stimulus (and not due to reduced number of cells).

SUMMARY

In summary, the cyclic pressure tested in the present *in vitro* study affects important functions of both osteoblasts and osteoclasts, the cells that affect bone homeostasis. These results, therefore, not only make contributions to bone cell physiology, but also provide cellular/molecular level insights into the relationship(s) between mechanical loading and bone homeostasis.

DAMPED KNEE CONTROL FOR TRANSFEMORAL PROSTHESES IN DEVELOPING COUNTRIES

K. McKee and Dr. C Mechefske

Department of Mechanical and Materials Engineering
The University of Western Ontario, London, Ontario, Canada
kmckee@julian.uwo.ca

INTRODUCTION

A rising concern among many international rehabilitation organizations operating in developing countries is to produce a reliable yet inexpensive knee joint for transfemoral prostheses. After an investigation of the transfemoral prosthetics used in both western countries and developing countries was conducted, a novel design concept for a knee joint was devised. A low-cost mechanism involving a dual elastomer system was formulated to replicate the motion of a hydraulic knee control damping cylinder made by Cadence Technologies in Ohio. The hydraulic controller is an industry standard, costing approximately US\$1500, and the motion it provides served as the benchmark for this project. The elastomer system devised costs approximately US\$18. Comparisons between viscous damping and hysteretic (material) damping were made by considering analytical representations, computational solutions, and experimental analysis. Upon completion of the damping investigation, prototype knee joints were developed, fabricated, and affixed to the ICRC (Red Cross) transfemoral prosthesis.

METHODS

The elastomer system is intended to be maintained in a limited workshop by people with limited technical skills. It must be distributed in remote areas, attached by personnel in a rural clinic, withstand a harsh climate, require little maintenance, and stand up to regular rigorous use. Figure 1 illustrates the dual elastomer concept that was initially designed to be attached posterior to the knee axis of a transfemoral prosthesis.

Figure 1: The two-elastomer cylinder design concept

The analytical representation used spring and dashpot models to arrive at a general comparison between the viscous damping of the hydraulic knee controller and the hysteretic damping of elastomer. A second order differential equation was produced and solved to determine the position at any time in the gait cycle. Hysteretic damping for an elastomer was represented by a spring and dashpot in parallel, and characterized by the hysteresis loop on a stress versus strain plot (Kelly, 1993). The computational solution calculated the geometry, material

properties, and loss modulus of the elastomer product necessary to replicate the hydraulic knee control cylinder. The experimental analysis involved comparing the spring and damping coefficients for the Catech cylinder and the elastomer prototype by cycling the damping cylinders in an Instron materials testing machine.

RESULTS AND DISCUSSION

Two different prototype knee joints were developed, fabricated, and affixed to the ICRC (Red Cross) transfemoral prosthesis. After design review meetings with two international aid organizations, a third prototype was developed that uses the stainless steel pylon of the ICRC prosthesis as a central shaft for a sliding mechanism.

The elastomer system is much lower in cost and easier to maintain than the hydraulic knee controller. The experimental results showed that the spring return provided by the elastomer meets the amount of spring return in the Cadence system. It was also found that significant damping does exist, however, the current prototype does not provide the target amount of damping as in the hydraulic controller. It is reasonable to accept a lower amount of damping than the target since the design has constraints on cost and size of the elastomer components.

Figure 2: Prototype

SUMMARY

A novel design solution has been formulated for the knee joint of transfemoral prostheses in developing countries. The goal of this study was to include analytical, computational, and experimental comparisons between viscous damping and hysteretic damping. In the future it is hoped that the prototype knee joint will be successful during reliability testing and field trials in a developing country.

PARAMETRIC IDENTIFICATION OF LOWER LIMBS DURING WALKING OF A MAN

Jolanta Pauk and Krzysztof Jaworek

Technical University, Automatics & Diagnostics Chair, 15 –351 Bialystok, Poland
jpauk@cksr.ac.bialystok.pl

INTRODUCTION

Identification of different process during human movement depends on data's likelihood and their biomechanical analysis and interpretation. There is a model, which describes relations between velocity of movement, personal data (weight, high and age) and period of time in this paper. The aim of this paper is present coefficients, which allow classify objects to two groups: normal and pathologies.

METHODS

The identification is realised by using of regression's function. We have analysed ankle, knee and hip powers from two groups of adults: 15 normal and 30 hemiplegics. Kinematics and kinetics data were obtained from Centro di Bioingegneria (S.A.F.L.O) in Milan (Italy). Below is the method of identification.

$$\underline{Y}_n = \underline{U}_n \cdot \underline{a}, \quad \underline{a} = (\underline{U}^T \cdot \underline{U})^{-1} \cdot (\underline{U}^T \cdot \underline{Y}),$$
$$\underline{Y}_n = \begin{bmatrix} Y_3 \\ Y_4 \\ Y_5 \\ \vdots \\ Y_{153} \end{bmatrix} \quad \underline{U} = \begin{bmatrix} Y_2 & Y_1 & Y_0 \\ Y_3 & Y_2 & Y_1 \\ Y_4 & Y_3 & Y_2 \\ \vdots & \vdots & \vdots \\ Y_{153} & Y_{152} & Y_{151} \end{bmatrix}$$

where:

n- sample size, \underline{Y}_n – model's output, \underline{a} - exploring coefficients, \underline{U}_n -model's input.

RESULTS AND DISCUSSION

The results human movement identification is reported below. They are average values over all subjects in each group.

Table 1: Identification's coefficients (mean \pm SD)

	I coefficient	II coefficient	III coefficient
Normal	-2.765 ± 0.203	3.248 ± 0.512	-1.975 ± 0.515
Hemiplegics	-1.905 ± 0.435	0.956 ± 0.949	0.342 ± 0.03

Figure 1: Analyse of normal human movement.

The graphs show human movement (red line – real data, green line – data from model)

Figure 2: Analyse of hemiplegics human movement.

SUMMARY

This method of identification represents human movement in very accurately way during walking a man in sagittal plane. It could be used in bioengineering as assessment of walking recovery.

QUANTIFYING BONE TRABECULAR DIRECTION FROM RADIOGRAPHS

Henri D fossez ¹, Peter Walker ¹, Mike Wroblewski ², Bodo Purbach ², Richard Hall ¹.

¹ School of Mechanical Engineering, University of Leeds, Leeds, LS2 9JT, UK, menhjp@leeds.ac.uk.

² Wrightington Hospital NHS Trust, Hall Lane, Appley Bridge, Wigan WN6 9EP, UK.

INTRODUCTION

Increasing evidence supports the necessity to assess bone trabecular structure in addition to mineral density to explain more fully its mechanical properties (Hagiwara, 2000). Radiographs are still routine tools for the examination of initial bone quality. Image-processing techniques developed to describe the trabecular structure from x-ray have regained popularity. This study assessed the precision and accuracy of the matrix, spatial frequency and fractal techniques for the detection of the trabecular direction from a set of test images.

METHODS

A femoral image obtained from a pelvic radiograph digitised at 512 dpi and representative of 1 cm² inspired the creation of test images controlling the trabecular thickness (10 pixels), separation (10 pixels) and orientation (60⁰). A Laplacian noise was then added at varying intensities (Table 1), as described by Pitas (1993). A software was developed using IDL to implement five image-processing techniques including (a) the Co-occurrence Matrix and the (b) Range Length Matrix analyses presented by Dubus et al (1998), (c) the Spatial Frequency analysis employed by Hagiwara et al (2000) which was modified by pre-processing the image with a Hanning windowing to avoid artefacts in the power spectrum P employed as log[1+P] in order to monitor the high frequencies which otherwise rapidly decrease, (d) the Minkowsky Fractal analysis defined by Jiang et al (1999), and (e) an in house derivation of method (d) only using the processed area intensity. Precision and accuracy were computed at each noise level using 25 images with random noise patterns.

RESULTS

All methods inferred the trabecular direction in the non-noisy image with extreme accuracy and precision (table 1). All

methods with the exception of (b) performed well up to a noise of 500 ((a,c) accuracy>99%, SD<3⁰, (d,e) >82%, <4⁰). Method (b) even failed at the smallest noise level, whilst (a) was correct to a higher noise of 1000. Finally method (e) performed nearly as well as (d), but required less computation.

DISCUSSION

Although method (a) presented the best results, it relied on having a prior knowledge of the trabecular thickness and separation for defining an optimal dimension for the matrix, whereas method (c) presented the second to best results and did not require any trabecular prerequisite. This made (c) the most efficient method. Method (b) relied on the number of pixels of same intensity being in succession. Also even a small noise reduced the long-range values representative of the trabeculae, leading to the observed failure. Finally all methods inferred a mean direction at 90⁰ in the noisiest image; as expected since the trabeculae had completely disappeared.

SUMMARY

The Spatial Frequency analysis (c) was the most robust method to infer the textural direction in images including an ideal singular trabecular direction, up to a Laplacian noise of 500. Such high levels of noise are not expected in clinical x-rays; hence these methodologies allow the potential to infer the trabecular direction in clinical studies. This however relies on monitoring the trabeculae that follow a single direction.

BIOMECHANICAL COMPARISON OF THE TRIAGE MEDICAL COMPRESSION SCREW TO THE SYNTHES SCREW FOR USE IN LOWER EXTREMITY FRACTURES AND FUSIONS

Richard Oka¹, Marty Padgett², Andrew Mahar¹

¹ Department of Orthopedics, Children's Hospital, San Diego, CA

² Triage Medical Incorporated, Irvine, CA

INTRODUCTION

Orthopedic surgeries involving the foot and ankle have relatively high complication and failure rates. This is related to the magnitude of cyclic load transmitted and applied through this complex joint. First metatarsal fusions, supplementary talar arthrodeses and fixation of medial/lateral malleolar fractures require significant device stability. The compressive ability of fixation screws may lead to earlier callus formation, earlier healing, and thus an earlier return to weight bearing. Devices that increase compressive force across a joint/fracture and that demonstrate greater stability, then, would be considered clinically superior. It was the goal of this study to compare a new type of compression anchor screw to a clinical standard in tests of compression, pullout and three-point bending.

METHODS

Commercially available polyurethane foam (Pacific Research Laboratories, Vashon Island, WA) in 7-lb./ft³ and 12-lb./ft³ density molds was selected to simulate cancellous bone. A cortical shell was not included in any of the tests. Based on the type of testing, foam was allocated to different test strategies. Both screw types -- Triage 3.5 x 40-50 mm. & Synthes 3.5 x 50 mm. -- (Figure 1) were inserted into the same foam for each test.

Figure 1: Examples of Triage HCA screw (right) and standard Synthes screw (left).

All screws were inserted manually using the appropriate surgical tools. New screws were used for every test.

For pullout strength in 7-lb./ft³ and 12-lb./ft³ foam, an MTS 858 machine applied a displacement at 0.5mm/sec. Maximum tensile force was recorded.

For compression force testing, a miniaturized load cell was inserted between the screw and the 7-lb./ft³ foam. Maximum compressive force was recorded.

For three-point bending stiffness testing, an MTS 858 machine applied displacement at 2mm/min orthogonal to the screw axis and halfway through the unthreaded shaft until failure (permanent deformation occurred after 1 mm deflection). Bending stiffness was calculated using the linear portion of the curve – using data points from 0N to 250N of applied load.

For each type of testing, data was recorded for 20 tests, (10 per Triage and Synthes screws) averages were calculated within groups, and then compared using a one-way ANOVA ($p < 0.05$).

RESULTS AND DISCUSSION

Results for all tests are shown in Table 1. The Triage screw withstood greater pullout force than the Synthes screw (26% more in 7-pound foam, 18% more in 12-lb foam). The Triage screw also demonstrated 82% more compressive force and 23% more bending stiffness than the Synthes screw. In all cases, the statistical differences in performance were highly significant, with p -values below 0.001.

	Triage		Synthes	
Pullout (N)	3.5 x 40-50 mm		3.5 x 50 mm	
7-pound foam	98.42	(4.1)	76.85	(8.1)
12-pound foam	214.20	(8.7)	181.92	(7.3)
Compression (N)				
7-pound foam	95.1	(6.5)	52.37	(4.6)
Three-Point Bending Stiffness (N/mm)	965.44	(104.7)	783.46	(30.7)

Table 1: Test data for both groups.

CONCLUSION

Many of the values for both screw types far exceed requirements for a protected environment. However, with greater values for pullout, compression and bending stiffness; the Triage compression screw appears capable of promoting faster recovery to weight-bearing and thus appears to be a better alternative than the current clinical standard.

TESTING THE APPLICABILITY OF REFERENCE BODY SEGMENTAL PARAMETER DATA TO INDIVIDUAL SUBJECTS: AN INVERSE DYNAMICS AND NUMERICAL OPTIMIZATION APPROACH

Akinori Nagano, Masae Miyatani, Daisuke Takeshita, and Senshi Fukushima

University of Tokyo, Tokyo, Japan, cc07725@mail.ecc.u-tokyo.ac.jp

INTRODUCTION

The most basic formula used in inverse dynamics is

$$\vec{F} = m \cdot \ddot{\vec{r}} \quad (\text{Eq. 1})$$

This formula is typically used to calculate segment inertial forces from acceleration data in inverse dynamics. The basic assumption underlying this procedure is that the values of segment mass, m in (Eq. 1), are readily available (Winter, 1990). Typically body segmental parameter values are estimated by referring to preceding anthropometric studies such as de Leva (1996). However, as there are differences in these parameter values among different individuals, it is not guaranteed that these data reported in preceding studies are always applicable to all individuals.

METHODS

Four movements were performed by a healthy male subject (27 years old, 174 cm, 80 kg): squat jump, counter movement jump, a single squat from standing still, and continuous squats. Two-dimensional kinematic data were recorded at 200 Hz from the right side of the body (MEMRECAM C²S, NAC, Japan). Anatomical landmarks were digitized automatically, to identify trunk, upper legs, lower legs, and feet segments. Ground reaction force vector (GRF) data were collected using a force platform (9281B, Kistler, Switzerland) at 1000 Hz. Arms were kept on the waist throughout data collection.

Body segmental parameter values reported by de Leva (1996) (mass of segments (m) and position of mass center of segments (p_m)) were used as initial guess for these parameters. Acceleration vectors of segments were determined from video data, which were multiplied by the mass of segments to calculate inertial forces. Finally all the inertial forces ($i = 1$ through N (# of segments) in Figure 1) and body weight were summed together to obtain the values of ground reaction force

calculated through inverse dynamics (GRF_{inv}). GRF_{inv} values were compared with the GRF data measured using a force plate (GRF_{FP}). RMS difference ($GRF_{\Delta RMS}$) between GRF_{inv} and GRF_{FP} were used as the objective function of the numerical optimization process, which modified the values of body segmental parameters to minimize $GRF_{\Delta RMS}$ (Figure 1).

RESULTS AND DISCUSSION

Values of body segmental parameters were modified only slightly through numerical optimization. Therefore, for this subject, the difference of body segmental parameter values from the reference data (de Leva, 1996) was small, suggesting the applicability of those reference data to this subject. This procedure seems to be a useful way to test the applicability of reference body segmental parameter data reported in preceding studies to individual subjects.

INTRODUCTION

Determining the number of trials that need to be collected to analyse trunk movement is a primary concern in clinical evaluation because non-able-bodied subjects are limited in the number of body motions they can perform without undue pain or exhaustion. To our knowledge, no study has been carried out to determine the minimum number of trials that need to be assessed for 3D main trunk motions as well as the simultaneous motion occurring in other planes, known as coupling motion, using a video-based system.

This study was undertaken to obtain the minimum number of trials required for biomechanical analyses of 3D trunk principal and coupling maximum range of motion (ROM) movements.

METHODS

The ten young able-bodied male subjects who participated in this study had an average age of 27 ± 2 years, height of 1.76 ± 0.2 m and weight of 78 ± 12 kg.

Three different trunk segments were defined as follows: whole trunk (from first vertebra to pelvis; T1-Pelvis), thoracic segment (T1-L1) and lumbar segment (from first lumbar to pelvis; L1-Pelvis). Reflective markers were placed over the spinous processes of T1 and T12 and on the pelvis as shown in Figure 1. The T1 and pelvis markers defined the trunk segment while the T1-T12 and T12-pelvis markers were used for the thoracic and lumbar segments respectively. A high resolution motion analysis video-based system was used to collect the 3D maximum ROM of three different defined trunk sections for five main motions, namely, flexion, right and left bending, and right and left rotations.

Figure 1: Position of the four cameras and the subject in the calibration space.

Intra-class correlation (ICC)¹ was applied to assess the reliability and to obtain the minimum number of trials required to assess trunk main and coupling motions for the three trunk segments. The ICC values vary from zero to one and like Pearson correlation coefficients, an ICC value close to 1 indicates excellent reliability while a zero value indicates a lack of reliability. The number of trials for the ICC was estimated at 5 in order to have a power of 0.80. For each ICC, the 95% confidence interval (CI) was within \pm two standard deviations.

RESULTS and DISCUSSION

Our data are in general agreement with previously published data for back flexion^{2,3}, right and left lumbar bending⁴, right and left lumbar rotation⁵ and for coupling movements⁶.

The ICCs were in general over 0.80 in different data sets, though some variations existed between trunk segments. Using a cut-off of 0.90 as an indicator, one trial needs to be collected to provide high reliability at the trunk segment, and four trials at the thoracic and lumbar segments. The ICC obtained for parameters at the trunk segment have larger values than the thoracic and lumbar segments, and the thoracic segment has larger ICC values than the corresponding ICCs calculated for the lumbar segment. One explanation may be a variation due to muscle activity in these segments. For coupling motion, variations within and between subjects' performance resulted in lower reliability. Nonetheless, a reliability of 0.74 was observed for the trunk segment with at least four trials.

SUMMARY

As a minimum a single trial is required to have a reliability of 0.84 using a video-based system for five trunk motions measured at three trunk segments. Higher reliability is achievable by collecting five trials. Nonetheless, this finding should be verified in non-able-bodied subjects. For coupling motions, at least four trials are needed for trunk segments, while for the thoracic and lumbar segments more than five trials should be assessed.

QUANTITATIVE ASSESSMENT OF BALANCE ABILITY AMONG DIFFERENT SPORTS ATHLETES

Alex J. Y. Lee¹ and Wei-Hsiu Lin²

¹General Education Center, Yu-Da Institute of Business Technology, Taiwan, R.O.C.

Fax: 886-2-37-620525 **Email:** jylee@ms1.ydu.edu.tw

²Department of P.E., Tzh-Chi College of Technology, Taiwan, R.O.C.

INTRODUCTION

Balance has been defined as the ability to maintain the center of gravity (COG) over the base of support. It is not only for athletes to perform excellent performance, but also on injury prevention. Previous studies most focus on the difference between injured and uninjured athletes, or determine the effects of specific injury on balance control, or the influence of different training on balance control. In order to determined the long-term specific training effects on balance control. Our study compared the difference between selected sports athletes in 1) static standing steadiness, 2) unstable standing steadiness and 3) unstable dynamic standing steadiness on balance control ability.

METHODS

Three different sports athletes were recruited as subjects: the archer group(21.6 ± 1.3 , N=10); the gymnast group(21.6 ± 1.3 , N=10) and the control group(nonathletes, 21.6 ± 1.3 , N=10). We used Kistler force platform with Bioware 2.0, KAT-2000 with Katwin by BREG, Balance Trainer by TAKEI and the tension meter FB50K by IMADA to measure all subject's static and unstable balance performance. One-way ANOVA was used to examine the statistical differences among each group. Statistical significance was set at $\alpha = 0.05$.

RESULTS

Table 1 is the descriptive characteristic of each group. Table 2 is the Pearson's correlation analysis between each variable.

The one-way ANOVA analysis showed that (1) the static standing steadiness of archer were significantly better than the control group, (2) the unstable static balance ability of gymnast group was significantly better than the control group, but the archer group better than control group only in KAT-2000 test, (3) the unstable dynamic balance ability of gymnast group was significantly better than the control group.

SUMMARY

We observed that distinct specific athletes have different balance ability. It was reflected from the different balance test protocol. As a athlete, coach or related researcher must realized the difference were come from individual difference or the training effect of specific exercise participation. According to the results of this study, we suggested that long-term regular specific sport training could significantly alter human body's balance ability. Further research could focuses on the mechanisms of such effects and the alternation. In order to improve the athlete's overall ability, some non-specialized training program must be considered.

DIGIT RESISTANCE WITHIN SHORT TERM AFTER FDP TENDON REPAIR IN CANINE IN VIVO

Chunfeng Zhao, Peter C. Amadio, Philipps Paillard, Tatsuro Tanaka, Mark E. Zobitz, Kai-Nan An
Biomechanics Laboratory, Department of Orthopedics, Mayo Clinic/Mayo Foundation
200 First Street SW, Rochester, MN 55905

INTRODUCTION

Postoperative mobilization after flexor tendon repair is effective for reducing adhesion formation. However, safe performance of postoperative therapy can be disrupted by gap formation and tendon rupture. The balance between repaired tendon strength and digit resistance is important to understand. In the short term after surgery, the rough surface and bulk of the repair, soft tissue edema, increased joint stiffness, and later onset adhesion formation increases the work of finger flexion. The purpose of the current study is to investigate digit resistance after short-term flexor tendon repair using an *in vivo* canine model.

METHODS

48 mongrel dogs were used for this study. The second and fifth flexor digitorum profundus (FDP) tendons were exposed through a mid-lateral incision in the paw between the proximal and distal annular pulleys. One FDP tendon was transected at the level of 5 mm proximal to the distal edge of the proximal pulley in digit extension position, and repaired using a modified Kessler technique using 4/0 loop Supramid suture (S. Jackson, Inc. Alexandria, VA) reinforced with a epitendon circumferential running suture. The other digit was closed after tendon exposure without laceration and served as a sham group. The paw and forearm were dressed and immobilized with casting tape to maintain 45° wrist flexion and neutral position after surgery. Dogs were sacrificed at 1, 3, 5, and 7 days (n=12 each). The repaired and sham operated digits and contralateral control digit were harvested by transecting at the mid-level of metacarpal bone.

The testing device consists of a testing frame, actuator, linear potentiometer, and two load transducers (Figure 1). The frame holds the digit to be tested by placing a K-wire through the metacarpal bone. The distal FDP is detached and connected to a small load transducer (BG-1000G, Kulite Semiconductor Products, Inc, Leonia, NJ) that is fixed to distal phalanx. A weight (0.5N) is attached to the extensor tendon. The proximal FDP is connected to a second load transducer which is then connected to the actuator and linear potentiometer. The FDP tendon is pulled proximally (2mm/s) causing digit flexion. Excursion and proximal (F_p)

and distal (F_d) forces are recorded. Motion of metal markers embedded in the proximal, middle, and distal phalanx were collected with fluoroscopy during testing and digitized to determine joint angular motions.

RESULTS

F_p represents the force required to flex the digit with the area under this curve representing total work of flexion (WOF). F_d represents the force transferred to the distal bone to move the digit. The area between F_p and F_d is internal work expended due to resistance between tendon and sheath (IWO). An end range of motion was chosen for all digits as 40 degrees of flexion.

WOF was not different in control and sham groups at any time point. After repair, WOF was lowest at 5 days ($p<0.05$), while there was no difference among 1, 3, or 7 days. WOF for the repair group was higher than the control group at 1, 3, and 7 days, and higher than the sham group at 1 and 7 days ($p<0.05$). There was no significant difference among control, sham, or repair group at 5 days ($p>0.05$). IWO in the repair group was higher than the control and sham groups at all time points ($p<0.05$). Within the repair group, IWO at 5 days was lower than 7 days ($p<0.05$).

DISCUSSION

Resistance to digit motion includes both tendon gliding resistance (internal) and digit joint motion resistance (external). In the normal state, these two resistances are small due to the smooth gliding surfaces and lubricant effects within the tendon sheath and at the joints. After tendon repair, the total WOF increases due to suture technique, soft tissue edema, and effects of wound healing. In the control group, IWO comprised 17% of the total WOF while after repair IWO increased to 36% of WOF. The IWO did not change within 5 days after surgery, although at 7 days there was a significant increase, we believe due to formation of minor adhesions. During rehabilitation the therapists provide forces to overcome external resistance making the internal resistance an important factor influencing tendon gliding. For the dog model used in this study the results suggest that a passive motion therapy should begin no later than day 5 postoperatively.

LEARNING PROCESSES AND BIOMECHANICAL CHANGES WHILE HANDLING ASYMMETRICAL LOADS

Micheline Gagnon

Département de kinésiologie, Université de Montréal, Montréal, Québec, Canada, micheline.gagnon@umontreal.ca

INTRODUCTION

Low back pain has been a long-standing health problem in manual workers. Experts adopt very different strategies when compared to novices (Authier et al., 1996) and these strategies appear biomechanically safer (Gagnon et al., 2000). As non-directive and free practice did not improve handling strategies in novice workers (Gagnon et al., 2002), it was then hypothesised that a training program focusing on specific experts' strategies would lead to significant biomechanical changes for back loadings and mechanical work in novices.

METHODS

Ten novice workers (men age: 24 yr) were trained in manual handling. The subject viewed a video contrasting experts and novices for handling elements including load manoeuvres (box tilts plus hands placement), feet orientation and trunk asymmetry; the video was commented for mechanical principles. Then the subject practised freely, loading and unloading boxes in a wide range of conditions, and was invited to experiment his own strategies. The experiment itself included the displacement of 3 symmetrical 15-kg boxes from a low 22-cm shelf to another 22-cm shelf at 90° to the subject's left. This sequence was repeated 25 times; a similar session was repeated 3 weeks later. As it was also of interest to investigate the performance of handling asymmetrical boxes, three more sequences were included with 2 asymmetrical 15-kg boxes (height: 30 cm; antero-posterior: 33 cm; width: 42 cm) with the c.g. 30 % forward and 86 % upwards: a pre-test before the training session (trial 1), a post-test following the 25 trials with the symmetrical boxes (trial 2) in the first session and a post-test in session 2, i.e., following the 25 trials with symmetrical boxes (trial 3). The subject was free to choose his lifting techniques. This paper is limited to the analysis of asymmetrical boxes (only one box for each trial per subject).

The 3D kinematic and kinetic data were obtained using 5 video cameras and a large 2.4 x 2.4 m² force plate. The net back (L5/S1) loadings included the net 3D moments with axes corresponding to trunk/pelvis orientation. The subject was analysed at take-off (when the box just left the shelf) and deposit (last moment before box contact on the other shelf); the box itself was analysed during transfer (between take-off and deposit) for its trajectory and mechanical work. Analyses of variance with repeated measures on learning were used to determine if the three trials differed significantly; probability values were Greenhouse-Geisser corrected ($P < 0.05$).

RESULTS AND DISCUSSION

Significant differences were only found between the pre-test trial (T1) and the post training trials (Table 1). For T2 and T3,

mechanical work done on the load was reduced (about 60 J), due to its reduced path during transfer (46 and 69 cm) and reduced knee flexion at take-off and deposit (about 40°). At take-off, net L5/S1 extensor moments decreased for T2 and T3 (about 25 Nm) and, although not statistically significant, torsion moments then tended to increase; this was attributed to decreased frontal distances but increased lateral distances between the load and L5/S1 for these trials and also to an increase orientation of the feet towards the deposit as shown by the larger angle of feet relative to the take-off shelf (about 30°). Trunk posture was symmetrical and not affected by learning (data not shown). These results are explained by some ergonomic changes, especially the increased use of box tilts (on edges and/or corners) at take-off and deposit which allowed the load to be higher and nearer the subject.

SUMMARY

Contrasting experts/novices' strategies for specific handling elements such as box tilts, feet orientation and trunk posture is an efficient means to train novice workers. They improved very quickly for mechanical work and trunk efforts; however, their change of strategies may not have been optimal, in some cases, as suggested by the slight increase of torsion moments. Formation programs should be based on the observation of workers rather than theoretical concepts alone. These results may guide the specialists involved in formation programs.

EFFECTS OF SUSTAINED PRESSURE AND STRAIN ON VASCULAR SMOOTH MUSCLE CELL FUNCTION

Sheila Dela Cruz¹, Roman Ginnan², Harold A. Singer², Rena Bizios¹

¹Rensselaer Polytechnic Institute, Biomedical Engineering, Troy, NY, delacs@rpi.edu

²Albany Medical College, Center for Cardiovascular Sciences, Albany, NY

INTRODUCTION

Various vascular pathologies involve proliferation of smooth muscle cells, but the underlying mechanisms are not fully understood. *In vivo*, the blood vessel wall tissue (including constituent cells) is exposed to various mechanical stimuli such as pressure, strain, and fluid shear stress. Changes in pressure or strain levels due to elevated blood pressure may affect vascular smooth muscle cell functions (Osol 1995). Although the effects of select mechanical stimuli on vascular tissue and cells have been studied individually (Wilson 1993), to date, the effects of combined mechanical stimuli (*i.e.*, models that address the complexity of the pathophysiological milieu) have not been explored yet. The present *in vitro* study used custom made laboratory setups to expose cells to either sustained hydrostatic pressure or combined pressure and strain stimuli and investigated their effects on select vascular smooth muscle cell functions.

METHODS

Rat aortic smooth muscle cells isolated and characterized using established techniques (Geisterfer 1988) were cultured in media composed of 44% Dulbecco's Modified Eagle Medium and 44% Ham's F-12 medium supplemented with 10% fetal bovine serum, 1% antibiotic/antimycotic, and 1% L-glutamine under standard cell culture conditions (that is, a sterile, humidified, 37°C, 95% air / 5% CO₂ environment).

Cell proliferation was examined under the following experimental conditions. For pressure experiments, these cells were seeded on sterile, fibronectin-coated (3 µg/cm²) glass coverslips. For simultaneously applied pressure and strain experiments, smooth muscle cells were seeded on sterile, fibronectin-coated (3 µg/cm²) biomedical grade silicone sheets. After 24 hours of culture on these two different substrates, these cells were exposed to either sustained hydrostatic pressure (10 cm H₂O or 30 cm H₂O) or combined pressure and strain (10 cm H₂O and 4% strain or 30 cm H₂O and 10% strain), respectively, for up to 7 consecutive days. Control samples were cells seeded on respective, similarly prepared substrates and similar cell-culture conditions, but maintained under 0.3 cm H₂O hydrostatic pressure. All experiments were carried out in a sterile, humidified, 37°C, 95% air / 5% CO₂ environment. At the end of the prescribed time periods, smooth muscle cells were trypsinized and counted using a hemocytometer.

Extracellular-related kinase (ERK) 1 and 2 activity was examined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS PAGE) and western blot analysis. ERK 1 and ERK 2 activity in controls was compared with that

observed in cells exposed to sustained pressure for 10 minutes, 1 hour, 2 hours and 3 hours.

RESULTS

Vascular smooth muscle cell proliferation was similar in controls and in preparations exposed to sustained pressure of either 10 cm H₂O or 30 cm H₂O for 1 and 3 consecutive days. In contrast, after 5 and 7 days, cells that were exposed to either 10 cm H₂O or 30 cm H₂O hydrostatic pressure exhibited significantly ($p < 0.05$) increased cell proliferation compared to controls. For all time points tested, smooth muscle cell proliferation under 10 and 30 cm H₂O sustained pressure was similar.

Compared to respective controls (no mechanical stimuli), simultaneous exposure to sustained pressure of either 10 cm H₂O or 30 cm H₂O and up to 10% strain for 7 days resulted in significant increases ($p < 0.05$ and $p < 0.01$, respectively) in cell proliferation.

SUMMARY

The data of the present study provide evidence that vascular smooth muscle cells responded to sustained hydrostatic pressure in a time-dependent manner (up to 7 days) that was responsive to pressure but independent of the magnitude (that is, either 10 or 30 cm H₂O) of the applied stimulus. Simultaneous exposure of vascular smooth muscle cells to pressure and strain also resulted in increased cell proliferation. These findings may provide cellular-level explanations for the smooth muscle cell proliferation observed in certain pathological syndromes that involve changes in the mechanical milieu of the vasculature.

EXHAUSTIVE BACK EXTENSION TESTS LEADS TO GRADUAL INCREASE IN INTRA-ABDOMINAL PRESSURE.

Morten Essendrop, Bente Schibye

National Institute of Occupational Health, Denmark
Department of Physiology
me@ami.dk

INTRODUCTION

During back extension when back muscles are isometric contracted at a constant force level until exhaustion the EMG amplitude of the lumbar back muscles remains constant (Bunkens, 1996) or even decreases (Klausen et al., 1978). Even though there is an increase in amplitude for the thoracic part of the back muscles, it is difficult to explain the indications of decreased force output from the lumbar back muscles when the external torque is constant. IAP has been hypothesized to have an influence on the distribution of forces in the lumbar region during back extension (Daggfeldt, 1997). The aim was to study whether IAP increases as the low back muscles fatigue during exhaustive back extension.

METHODS

Ten subjects performed a modified Sorensen test (Jorgensen 1986). Instead of lying completely horizontal, only the trunk was horizontal while the legs were supported on a bench inclined 10° below horizontal (fig. 1). The test was stopped when the subjects could no longer keep the trunk horizontal. Surface EMG was measured bilateral from the lumbar part of m. erector spinae at the level of L3 bilateral, and unilateral from m. internal and external oblique. Sampling rate was 1000 Hz. IAP was measured intra-gastrically with a pressure transducer, inserted through the nose. The measured parameters were compared at five time point: at the start of the test, after 25, 50, 75 % of the endurance time, and at the end of the test. One-Way Repeated Measures Analysis of Variance was used for the comparison.

Figure 1. Modified Sorensen test.

RESULTS AND DISCUSSION

The mean endurance time was 270±155 sec. IAP increased significantly through out the test ($P<0.001$) (fig.2). Also the amplitude of the EMG from the abdominal muscles increased

($p<0.002$). For the lumbar part of the m. erector spinae muscles the amplitude of the EMG tended to decrease ($p=0.016$ right side, $p=0.075$ left side) and the EMG median power frequency decreased ($p<0.001$) (fig.2), indicating a decrease in force output from the lumbar part of m. erector spinae. The effect of an increase in IAP and/or increased activity in the abdominal wall could be 1) an increase in stiffness and stability of the spine (Cholewicki et al., 1999; Radebold et al., 2000) 2) a production of an extension torque of the trunk, that if not out-ruled by a flexion torque from abdominal muscle activity, might unload the lumbar spine (Daggfeldt, 1997).

IAP development

Figure 2. Development in intra-abdominal pressure (left y-axis) and in median power frequency of m. erector spinae (right y-axis), from the start of the endurance test until the end.

SUMMARY

Trunk extension until exhaustion increases IAP and abdominal muscles activity, as the low back muscles become fatigued.

JOINT MOMENT CONTROL OF MECHANICAL ENERGY FLOW DURING NORMAL GAIT

Karen Lohmann Siegel, Thomas M. Kepple, and Steven J. Stanhope

National Institutes of Health, Physical Disabilities Branch, Bethesda, MD, USA, karen_siegel@nih.gov

INTRODUCTION

Joint power represents the net effect of a joint moment on the mechanical energy of the whole body, not any one particular body segment. Segmental power techniques (Robertson and Winter, 1980) can account for passive transfer of energy to adjacent segments, but the joint moment responsible for the energy transfer cannot directly be identified. The purpose of the present study was to apply a new technique that can quantify the flow of mechanical energy throughout the body produced by a single joint moment in order to examine the function of the lower extremity during normal gait.

METHODS

While 5 healthy adult subjects walked barefoot at a self-selected speed, ground reaction forces and the movement of reflective targets on the feet, shanks, thighs, and pelvis (HAT) were sampled at 60 Hz using a 2-force platform, 6-camera motion capture system. After applying a low pass filter (6 Hz), segmental velocities and joint moments and powers were calculated from the sampled data. Using a method previously described by Kepple et al (1997), each joint moment or gravity was entered individually into a 7-segment biomechanical model of the subject. Model output included the reaction forces produced at all joints. These output joint reaction forces and the measured gait data were used to calculate segmental power associated with each of the net muscular moments or gravity using the equations described by Robertson and Winter (1980) and Siegel et al (1996). Mechanical energy transfer was calculated from the area under the segmental power curves during selected intervals of stance phase.

RESULTS AND DISCUSSION

Net joint moments were responsible for transferring greater amounts of energy between segments than expected based on the net joint powers. Pairs of moments worked together to balance energy flows through the lower extremity and HAT segments; knee moments vs. gravity in early stance (Fig 1), ankle vs. hip moments in early and middle stance (Fig 2), and knee vs. hip moments in late stance (Fig 3). Each joint moment had a similar effect on the energy level of all segments within the lower extremity, and an opposite effect on the energy level of the HAT. The only exception to this pattern was during the push off phase of gait when the ankle moment was responsible for simultaneously adding energy to all lower extremity segments as well as the HAT (Fig 3).

SUMMARY

Joint power is unable to account for energy transfers due to gravity and underestimates both the type and the amount of

work done by the net joint moments on individual segments. Results of this more comprehensive segmental power analysis demonstrated a high level of intralimb coordination showing how muscles with contradictory effects are recruited simultaneously to provide precise control of mechanical energy flow within the body during normal walking.

REAR WHEEL IMPACT CHARACTERISTICS IN OFF-ROAD CYCLING

Morris Levy¹ and Gerald A. Smith²

¹Biomechanics Laboratory, University of Minnesota Duluth, USA

²Oregon State University, USA

INTRODUCTION

There has been significant innovation in bicycle design associated with the rapid development of mountain biking. Making the appropriate choice in suspension fork is often based on subjective statements, with little mechanical testing results available. Recent studies by Orendurff et al. (1996), Pritlove et al. (1998) and Levy et al. (2000) have used similar methods to quantify fork performance while riding over an obstacle. In a study related to this report, Levy et al. measured front wheel antero-posterior impulse as a primary indicator of fork performance. This project was carried out as a follow-up study in which rear wheel peak force and impulse were compared for five fork-frame suspension conditions.

METHODS

Suspension conditions were described by a combination of a particular front suspension fork with either a rigid or suspended frame. The suspended frame (Specialized model FSR) was composed of a dual dampening system (air-spring) located under the seat post, connecting the horizontal bar of the frame to the back wheel. Additional hinges located close to the back wheel axis and above the pedal axis completed the suspension setup. A standard rigid fork/rigid frame system (R-R) was compared with two front suspension forks: air-oil (A-R), and linkage (L-R) design. In addition, the suspended frame was used with the air-oil and linkage design forks (designated A-S and L-S, respectively).

One subject performed repeated trials with each suspension condition. He was instructed to ride passively over the bump slightly elevated out of the saddle. Thirty trials per condition were performed at speeds ranging between 5 and 8 m/s. Each suspension condition was tested across a bump of 6-cm height secured on top of a Kistler force plate. The reaction forces were recorded at 1000 Hz for a period of 0.5 seconds. The data were smoothed using a second-order Butterworth filter with a cutoff frequency of 180 Hz. Braking impulse was calculated by numerically integrating the force-time curve.

RESULTS

Separate ANCOVAs (using speed as a covariate) revealed significant differences both in force and impulse ($p < 0.001$). Post-hoc comparisons of force showed significant differences between all conditions except the A-R/A-S and L-R/L-S conditions. All rear wheel braking impulse comparisons were

significantly different from each other except the A-S/L-S comparison. In addition, most pairwise comparisons of the total braking impulse showed significant differences. Only the A-R/L-R comparison was not significant.

DISCUSSION

The rigid condition of fork and frame yielded significantly lower peak anterior-posterior forces and impulse than all other suspension conditions when the back wheel contacted the bump. These results are in contrast to front wheel impacts for which rigid forks produce significantly greater force and impulse than suspension forks (Levy et al., 2000). This suggests there is some interaction between front and rear wheel impacts which distributes the total impulse differently perhaps due to a shift of the rider's body positioning. Combining results from our previous study, total braking impulse summed across front and rear wheel impacts were significantly less with suspension components than with rigid fork/frame. While the suspended conditions yielded higher rear wheel braking impulse than the rigid fork condition, the total braking impulse was still significantly smaller with the suspension forks and frames.

SUMMARY

This project compared rear wheel antero-posterior forces and impulses when riding over an obstacle in off-road cycling. The Rigid fork-Rigid frame rear wheel forces and impulses were smaller than all other conditions, while the total impulse (front and rear wheel impacts) was significantly smaller for the various suspension conditions. Total impulse is distributed differently with different suspension conditions, possibly due to a shift of the rider's body positioning.

MEASUREMENT OF POISSON'S RATIO IN RABBIT ACHILLES TENDON

Allen H. Hoffman¹, Matthew E. Johnson¹ and Peter Grigg²

¹Mechanical Engineering Department, Worcester Polytechnic Institute, Worcester, MA 01609, ahoffman@wpi.edu

²Department of Physiology, University of Massachusetts Medical School, Worcester, MA 01655

INTRODUCTION

Poisson's ratio of tendons and ligaments is determined by the transverse deformation under quasi-static uniaxial tension. A negative Poisson's ratio indicates that the transverse dimension increases under axial loading. Many tendons and ligaments are neither circular nor rectangular (Woo et al, 1990; Wren et al, 2000) and this adds to the complexity of determining Poisson's ratio. Tendon properties also depend upon tissue hydration (Haut and Haut, 1997). The purpose of this study was to investigate Poisson's ratio in fresh rabbit Achilles tendons bathed in an osmotically neutral solution.

METHODS

Achilles tendons were harvested from 1-2 kg immature New Zealand white rabbits. The lower legs were amputated at the knee. Each gross Achilles tendon was removed in a closed dissecting chamber maintained at 100% humidity and subdivided into 3 individual tendons that were immediately stored under mineral oil. Individual tendons that were tapered, were discarded. Tendons were mounted axially in a testing apparatus by gripping suture knots tied at the ends of the tendon and were maintained under mineral oil throughout the experiment. Loads and axial displacements were measured using a load cell and an LVDT. The apparatus allowed the tendon to be rotated about its long axis while loaded. The width of the tendon cross section was measured optically using a silhouetting technique. In each experiment an initial state was established, without preconditioning, by applying a small preload (~ 0.07 MPa) and allowing the tendon to equilibrate for 10 minutes. Then the length was recorded and width measurements were made in 6 transverse planes at equally spaced 30° orientations. At each orientation, the 6 width measurements were averaged. Next, a stress of approximately 0.35 MPa was applied for 30 minutes and another set of width measurements was taken. The primary time constant associated with creep at this stress was about 5 minutes.

RESULTS

Nine tendons from 4 rabbits were tested. The tendon cross sections were well approximated by an ellipse. Fig. 1 is an MRI image of a tendon cross section, from another study, at a stress of approximately 0.07 MPa and provides further evidence of the elliptical shape. Relative to the initial state, the average additional applied stress of 0.36 ± 0.08 MPa resulted in a strain of 6.9 ± 3.0 % and an axial modulus of 5.9 ± 2.4 MPa ($n=9$). Tendon volume was calculated as the product of length times cross-sectional area. All 9 tendons showed an increase in volume. The average volume increase under load was 7.6%. Since the tendons were elliptical, Poisson's ratio could only be directly measured with respect to the principal

axes of the ellipse (Table 1). Negative Poisson's ratios were observed in 8 of 9 tendons. In 7 tendons a negative Poisson's ratio along one axis was accompanied by a positive Poisson's ratio along the orthogonal axis. The Poisson's ratios measured with respect to the principal axes of the ellipse were different, indicating that rabbit Achilles tendons exhibits orthotropic behavior under uniaxial tension.

Table 1. Poisson's Ratio in Mineral Oil

SUMMARY

This study demonstrates that measurements of Poisson's ratio in tendons and ligaments must carefully account for the shape of the tissue cross section. Negative Poisson's ratios were routinely observed. Although tendons and ligaments are often assumed to be isotropic and incompressible, our results show that the validity of these assumptions may be limited. Since the level of hydration affects tendon properties, these results only apply to neutral osmotic solutions.

EARLY CEMENT DAMAGE AROUND A FEMORAL STEM IS FOCUSED ON THE CEMENT/BONE INTERFACE

Amos Race, Mark Miller, David Ayers and Kenneth Mann

Musculoskeletal Science Research Center, Upstate Medical University, Syracuse, New York, USA
racea@mail.upstate.edu

INTRODUCTION

There is very little information available regarding mechanical aspects of cemented implant loosening and the initiation and development of cement damage. Previous studies have come to a variety of conclusions about the development of cement damage and the relative importance of voids, the stem/cement interface and the cement/bone interface. It is likely that the cement damage process is dependent on the type of stem, the type of cement, the pattern of loading and the boundary conditions of the system. No previous study has quantified cement damage in a cadaveric model. The present study examined the standard Charnley "Cobra" stem with Simplex-P cement under "stair-climbing" loads in a human cadaveric model. Measures of cement damage were derived from the length of cracks in serial transverse sections. Cracks were quantified in order to answer the following two research questions: Does cement damage correlate with applied load? Are cracks preferentially associated with the stem/cement interface, the cement/bone interface or voids?

METHODS

Charnley flanged 45 stems with a satin finish ($R_a=0.75\mu\text{m}$) were used. Cadaveric femora were selected which were of an appropriate size for the implants (mean age 73yrs, range 59-82). Femora were broached using standard techniques under the supervision of an experienced surgeon. The prostheses were cemented using Simplex-P with contemporary techniques: "bottle brush" lavage, distal plug, vacuum mix, retrograde fill and pressurization. The final position of each prosthesis was controlled by a custom jig. Two non-loaded controls (age 49yrs and 86yrs) were prepared in an identical manner. An MTS axial load frame was used with a custom fixture which produced forces on the femoral head and abductor muscle insertion site which were representative of the peak loads and long axis torques that are experienced by a stem during stem stair-climbing. Loads were applied sinusoidally at 2Hz for 300kcycles at room temperature. Specimens were wrapped in moist gauze to prevent dehydration. All specimens were transversely sectioned at 10mm intervals, from the collar to the distal stem tip. The sections were then stained with a fluorescent dye penetrant and examined using an epi-fluorescence stereo-microscope. In order to confirm that the sectioning and staining process did not introduce artifacts, blocks of surplus cement were sectioned, stained and imaged. Images were recorded using a digital camera and imported into ImagePro for analysis; cracks were identified visually and the auto-trace feature of ImagePro was used to trace them and record their lengths. Crack length data were written to a spreadsheet along with sets of four binary flags indicating the involvement of each crack with stem, void, bone and broached area of cement.

RESULTS AND DISCUSSION

Epi-fluorescence microscopic examination revealed cracks in all of the transverse stem/cement/femur sections. The isolated cement samples which were subjected to the sectioning and staining procedure showed no micro-cracking. In the six cyclically loaded specimens a total of 2419 cracks were

Figure 1: Graph of total crack length versus load applied to the femoral head during fatigue testing.

recorded, mean crack length was 0.38mm (SD 0.34, range 0.05 to 4.00); total crack length per specimen averaged 152mm (SD 46, range 74 to 205), made up of an average of 403 micro-cracks (SD 120, range 190 to 562). In the two non-loaded control specimens there were 449 micro-cracks with a mean length of 0.24mm (SD 0.15, range 0.05 to 1.00); total crack length per specimen averaged 54mm (47 & 61), made up of an average of 225 micro-cracks (216 & 233).

Total crack length was significantly correlated with femoral head load ($R=0.799$, $p=0.0028$, Fig 1). There was substantially and significantly more damage at the cement/bone interface than at the stem/cement interface ($p<0.05$). Only a small fraction of micro-cracks involved voids, significantly less than the large fraction involving the cement/bone interface ($p<0.001$).

This study provides an early snapshot of the cement damage process. We found that small micro-cracks are present in cement before loading is applied and that the total number and length of micro-cracks increased with the magnitude of cyclic loading. This suggests that the cement curing process itself may contribute to the initiation of cement failure and that methods of preventing these early micro-cracks may improve the clinical outcome of cemented constructs. The majority of the micro-cracks were associated with the cement-bone interface. Whether these initial micro-cracks coalesce into discreet fracture surfaces that affect the structural integrity of the cemented construct remains to be seen. The role of cement cracks that emanate from bone in the loosening process is a poorly understood phenomenon as most research efforts have focused on the fracture process from voids or from the stem-cement interface. There most certainly would be an interaction between local cement micro-cracks and the remodeling response of adjacent bone due to changes in loading and possibly due to crack generated debris.

THE MOVEMENT OF A MAN'S BOTTOM LIMB IN THE MULTIBOND GRAPHS REPRESENTATION

Józef Wojnarowski, Jerzy Margielewicz

Department of Mechanics, Robots and Machines
Silesian Technical University, Gliwice, Poland; wojnarowski@rmt7.mt.polsl.gliwice.pl

INTRODUCTION

As a result of the process of evolution, the man accepted the perpendicular attitude, producing suitable motorial mechanisms, protecting the maintenance of these attitudes. The structure of connections of bottom limbs, from the point of view of equilibrium and of movement treating, can be fashioned as a system of turned pendulums. It can be proved, that for the maintenance of equilibrium the man uses, specified stability mechanisms, and in the movement treating, the stabilisation of a man is assured by hesitations being characteristic for oscillations. Both, the perpendicular attitude and the characteristic attitude for a man being in movement, are disturbed by a system of external and internal forces. The first of them are consequence of the realization of conscious assignments of movement of a man, the second result from the external environment.

METHODS

A kinematic and dynamic analysis of a model of a man's bottom limb when using the bond graph method, is presented. The conclusion and the main idea of this work is the presentation of a dynamic model of a man's bottom limb. This model makes it possible to examine kinematic and dynamic characteristics resulting from extorsions to muscles. The man's bottom limb is modelled as an open variable kinematic chain of a configuration varying in time. Differential equations describing such an attitude in a specified unit of time, are strongly non-linear ones. Contrary to manipulators and industrial robots, values exorting the movement are a result of muscles. A non-classic approach of modelling the dynamics of a man's bottom limb, is presented. The method of bond graphs [2] proposed by H. Paintera in 1961, was originally formulated to analyse steady and unsteady electrical systems. This method has been enlarged to be used for mechanical systems by D.Karnopp and R.Rosenberg [1]. For the procedure of modelling, the method of bond graphs presents the most concise way to describe joined elements or reactions between them for a specified system. The method of bond graphs is considered as a topological method, as it describes the structure sequence of a system, as during modelling, as also during the analysis. For modelling the kinematics, special attention was paid to determine the velocity and acceleration of specified points of the limb. Based on the kinematic scheme of a man's bottom limb (Fig. 1a) multibond graphs are designed (Fig. 1b), in which zero – numerated nodes represent adding of angular and linear velocities, whereas one- numerated nodes represent velocities of specified ponds of the bottom limb.

Figure 1: A bottom limb: a) Kinematic scheme, b) Multibond graphs

The method of multibond graphs (Fig. 1b), as a structure of zero - numerated nodes and one- numerated nodes as also of transformers, represents a set of equations, which can be directly described in an open way, or when using a computer program - to carry out respective computations.

SUMMARY

The described method of modelling the walking process, when using the multibond graphs for a kinematic and dynamic analysis, allows it for simulation tests to neglect the stage of generation of differential equations of the movement. This method allows also to modify, in a simple way, the structure of multibond graphs, in adding additional movement elements of the bottom limb.

MODELING OF FORCE RESPONSE OF FINGERTIPS IN KEYBOARD STRIKES

John Z. Wu¹, Ren G. Dong, Aaron W. Schopper, and W. Paul Smutz

National Institute for Occupational Safety and Health, Morgantown, WV, USA. ¹ E-mail: jwu@cdc.gov

INTRODUCTION

An extended exposure to repeated loading on the fingertip has been associated with many vascular, sensorineural, and musculoskeletal disorders in the fingers, such as carpal tunnel syndrome (Beck-Foehn, 1992) and hand-arm vibration syndrome (Bovenzi et al., 1988). A better understanding of the pathomechanics of these sensorineural and vascular diseases in fingers requires a formulation of a biomechanical model of the fingertips and analyses to predict the mechanical responses of

the soft tissues to dynamic loading. In the present study, a model based on finite element techniques has been developed to simulate the mechanical responses of the fingertips to dynamic loading.

Figure 1: Model of the response of a fingertip to keystroke.

METHODS

The mechanical responses of the fingertip were analyzed using a multi-layered two-dimensional finite element model (Fig. 1). The fingertip was assumed to be composed of a skin layer (representing epidermis and dermis), subcutaneous tissue, bone, and nail. The dimensions of the fingertip were assumed to be representative of the index finger of a male subject. The skin tissue, including epidermis and dermis, was assumed to be hyperelastic and linearly viscoelastic. The subcutaneous tissue was assumed to be a biphasic material composed of a fluid phase and a hyperelastic solid phase. The nail and the bone were considered as linearly elastic. The numerical experiment (Fig. 1) was designed to simulate the experiments reported by Rempel et al. (1994). The keyboard was composed of a hard plastic keycap, a rigid support block, and a nonlinear spring. The contact between the fingertip and the keycap was assumed to be frictionless. A gap of 3.5 mm was considered between the support block and keycap at the undeformed state. The force-displacement relation of the nonlinear spring was determined on the basis of the experimental data of Apple Extended II keyboard with Alps KCM QSIH switches (Rempel et al., 1994). The numerical tests were performed in a quasi-static manner, assuming negligible inertia effects of the mass of the model.

RESULTS AND DISCUSSION

Fig. 2 shows the comparison of the numerical simulation with the experimental data reported by Rempel et al. (1994). The

time history of the force response during a keystroke typically demonstrates three phases (Fig.2a): I - keyswitch depression, II - impact of the fingertip on the keycap, and III - compression and release of the fingertip pulp. During the first phase, the finger depresses the nonlinear spring (representing the switch activation), and the deformation of the fingertip is small. A relative large impact force occurs during the second phase, which is associated with the deceleration of the participating masses, i.e. the masses of fingers and arm. Since the effects of the inertia were neglected in the proposed model, the impact force was not predicted in our simulations. The second peak force in the time history is associated, mainly, with the compression of the fingertip pulp, and occurs over a greater time duration than the first force peak. The effects of inertia are negligible during the third phase. The predicted force responses of the fingertip during keystroke phases I and III agree well with the experimental data (Fig. 2).

Figure 2: Comparisons of the time-histories of the force response and the displacement excitation of the fingerpad during keystroke obtained in the simulations with those experimental data reported by Rempel et al. (1994). **(a)** Force response of the fingerpad. **(b)** Displacement excitation curves of the arterial bone within the fingertip.

SUMMARY

The proposed model is capable of predicting the time-dependent behavior of the fingertip under dynamic loading, for example, time-dependent force response, energy dissipation, and time-dependent stress/strain distributions within soft tissue of the fingertip. The limitation of the proposed model is that the effects of finger and hand inertia, which participate in the impact interactions between the fingertip and the contacting plate or keyboard, are neglected.

ORIENTED MITOSIS-DRIVEN EPITHELIUM RESHAPING: A FINITE ELEMENT STUDY

G. Wayne Brodland¹ and Jim H. Veldhuis²

Department of Civil Engineering, University of Waterloo, 200 University Avenue West, Waterloo, Ontario, Canada N2L 3G1

INTRODUCTION

During cell division, the orientation of the mitotic plane is typically determined by the long axis of the mother cell. In certain cases, however, the mitotic planes tend to occur at a fixed angle with respect to a global reference frame (Hertzler and Clark). The latter pattern is called oriented mitosis, and it has been hypothesized as driving certain kinds of in-plane reshaping in epithelia.

THE FINITE ELEMENT MODEL

To test this hypothesis, a cell-level, finite element-based model was developed (Chen and Brodland, 2000). In that formulation, the internal volume of each n -sided cell is represented using n , triangular finite elements. These elements are assigned a viscosity μ , a value that is assumed to embody the effective viscosity of the cytoplasm with its embedded filamentous networks and organelles. To model the interfacial tensions that arise along each cell edge, rod-like elements are used. These tensions embody the actions of microfilaments, microtubules, the cell membrane and cell-cell adhesions (Chen and Brodland, 2000). To study mitosis, the original formulation was enhanced so that cells could be divided according to one of several user-specified patterns.

RESULTS

Figure 1A shows the initial configuration of a square patch of 50 cells that was used for the simulations reported here. When the cleavage plane was determined by the long axis of the mother cell, the patch remains square and if the daughter cells are programmed to grow following division, the patch grows isotropically. When all cleavage planes are horizontal and daughter cells do not grow, the patch narrows and elongates (Fig. 1B). When oriented mitosis and growth occur together, the patch changes shape and its area increases (Fig. 1C).

DISCUSSION AND CONCLUSIONS

When oriented mitosis occurs and the number of cells has doubled, geometric considerations predict a maximum patch aspect ratio of 2:1. The simulations show that oriented mitosis actually produces this amount of reshaping. The simulations also show that the degree of reshaping is independent of the rate of daughter cell growth. Thus, oriented mitosis is found to be not only effective, but highly efficient, in reshaping epithelia. Since the simulations show the degree of reshaping that can be attributable to oriented mitosis, they provide a benchmark against which experimental studies and hypotheses about epithelium reshaping can be compared.

CELL-CELL INTERFACIAL TENSION AND CYTOPLASM VISCOSITY CAN BE DETERMINED USING PARALLEL-PLATE COMPRESSION TESTS

Jim H. Veldhuis¹ and G. Wayne Brodland²

Department of Civil Engineering, University of Waterloo, 200 University Avenue West, Waterloo, Ontario, Canada N2L 3G1

²Professor, brodland@uwaterloo.ca

INTRODUCTION

One of the standard ways to determine the surface tension of embryonic tissues (Foty and Steinberg, 1995) is to compress a mass of tissue between a pair of parallel plates (Fig. 1). Cell-level computer simulations of the test cycle led to a more complete understanding of the mechanics of the test.

Figure 1: The Parallel-Plate Compression Test

THE FINITE ELEMENT MODEL

These tests were based on a cell-level finite element-based model (Chen and Brodland, 2000). In that formulation, the internal volume of each n -sided cell is represented using n triangular finite elements. These elements are assigned a viscosity μ , a value that is assumed to embody the effective viscosity of the cytoplasm with its embedded filamentous networks and organelles. To model the interfacial tensions that arise along each cell edge, rod-like elements are used. These tensions embody the actions of microfilaments, microtubules, the cell membrane and cell-cell adhesions (Chen and Brodland, 2000).

RESULTS AND DISCUSSION

The cells shown in Fig. 1 were actually produced by taking an approximately circular mass of cells and compressing them between parallel plates. When the plates are brought to rest, the reactive force due to deformation of the viscous cytoplasm suddenly stops, and the load drops from the value shown as B_1 in Fig. 2 to that shown as B_2 . As the plates are held at a fixed spacing, the cells anneal. That is, the interfacial tension γ_{cc} that acts along the boundaries between individual cells causes

all elongated cells to shorten and increase in width until their aspect ratios approach one. Formulas that relate cell shape to stress, like those developed by Brodland et al. (2000), can be used to calculate the strength of this interfacial tension from the change in load between B_2 and C. Finally, the surface tension γ_{cm} of the cells can be determined from the load at C using the methods of Foty and Steinberg (1995).

Families of simulations of this type confirm that the load-deflection curve produced in parallel-plate compression tests is produced by three properties of the cells: the effective viscosity of the material in the cells, the strength of the cell-cell interfacial tensions, and the strength of the surface tension at the boundary between the cells and the surrounding medium. They also show that these contributions correspond to the values labelled, respectively, as F_{cyto} , F_{cc} and F_{cm} in Fig. 2.

Figure 2: Contributions to the Load-Time Curve Attributable to the Mechanical Properties μ , γ_{cc} and γ_{cm}

HUMERAL TORQUE IN YOUTH BASEBALL PITCHERS: IMPLICATIONS FOR DEVELOPMENT OF HUMERAL RETROTORSION

Michelle B. Sabick¹, Michael R. Torry¹, and Richard J. Hawkins²

¹Steadman ♦ Hawkins Sports Medicine Foundation and ²Clinic, Vail, CO, USA, Michelle.Sabick@shsmf.org

INTRODUCTION

The effect of repetitive throwing on developing athletes is not well understood, in part because there is little data describing the biomechanics of youth pitchers, and in part due to unique aspects of the developing skeleton such as joint laxity, underdeveloped musculature, and open epiphyseal plates. Increased humeral retrotorsion, the angle between the axis of the femoral head and the axis of the elbow joint, has been noted in the throwing arms of pitchers, but its cause has not been determined. If this adaptation is due to throwing as some suggest (Pieper, 1998), it likely results from a torque about the long axis of the humerus. The large joint forces generated during the pitching motion have been previously documented, but the relationship between pitching biomechanics and torque on the humerus has not been studied. The aim of the current study is to evaluate the proposed mechanism of development of humeral retrotorsion in light of biomechanical data.

METHODS

Fourteen youth baseball pitchers were filmed at 120 Hz using two high-speed video cameras. The locations of 21 body landmarks were digitized and their three-dimensional locations were calculated using the DLT method (Abdel-Aziz & Karara, 1971). Joint kinetics at the shoulder and elbow were computed using inverse dynamics (Fleisig et al., 1996; Werner et al., 1993). The net humeral forces and torques were defined as the difference between force and torque values at the proximal and distal ends of the humerus. Kinetic data was normalized in time to facilitate comparisons among players.

RESULTS AND DISCUSSION

A description of the subject population is provided in Table 1. The largest net force acting on the humerus was an axial force causing tension. This force was largest in magnitude, -378 ± 81 N, just after ball release. The largest net torque about the humerus was a torque about the long axis of the humerus that reached a "maximum" value of -35.3 ± 6.6 Nm (Figure 1). The negative value of this torque signifies that it tended to rotate the distal end of the humerus externally relative to the proximal end. This humeral axial torque peaked during the late cocking phase of the pitch. After ball release, the humeral torque was negligible for the remainder of the motion.

During the cocking phase of the pitch, there is an internal rotation torque at the shoulder while the forearm and hand are externally rotating, resulting in a torque about the shaft of the humerus. This torque is consistent with the development of increased humeral retroversion, in which the distal humerus displays increased external rotation relative to the proximal

humerus. The peak humeral torque developed in these subjects was 66-78% of the torque required to fracture the adult humerus (Schopfer et al., 1994; Lin et al., 1998). The magnitude of torque required to deform the youth humerus is unknown. However, the cartilage of the epiphysis is known to have poor resistance to torsion, and is not as strong as bone (Bright et al., 1974).

Table 1. Description of the subject population.

	Age (yr)	Height (m)	Mass (kg)	Ball V (m/s)
Mean	13	1.54	43.8	21.6
S.D.	--	0.08	8.6	1.8
Range	--	1.42 - 1.69	33.7 - 66.4	17.9 - 23.7

Figure 1. Humeral torque throughout the pitching motion.

SUMMARY

The direction of the axial torque acting on the humerus during the late cocking phase of the throwing motion is consistent with the development of increased humeral retrotorsion. The magnitude of this torque is the same order of magnitude as the torque required to break the adult humerus. Given that epiphyseal cartilage is weaker than bone in torsion, this torque may be sufficient to cause adaptive changes in the proximal humeral epiphysis resulting in increased humeral retrotorsion noted in throwers, supporting the assertions of Pieper (1998).

GAIT ANALYSIS BY PATIENT WHO HAVE AN ACL DEFICIENT KNEE

Zsolt Knoll MD.¹, Rita Kiss PhD.², László Kocsis PhD.³

¹ Senior surgeon, Fund MEDICaMENTOR, Budapest, Hungary knoll@elender.hu

² Senior researcher, Hungarian Academy of Sciences, Research Group of Structures, Budapest, Hungary

³ Assoc. Professor, Biomechanics Laboratory Budapest University of Technology and Economist, Budapest, Hungary

INTRODUCTION

At present, not too much is known about the function of the knee during the activities of daily living in patients who have a deficient anterior cruciate ligament (ACL) (Andriacchi 2000, 1993, 1997) The goal of our study was a better understanding of the changes in function of the knee that occur while patients who have a deficient ACL in one knee walk.

MATERIALS AND METHODS

Twenty patients who had unilateral, isolated deficiency of ACL diagnosed arthroscopy or MRI data. The study population consisted of twelve men and eight women. The mean age was 34.70 ± 3.1 years; the mean height 1.74 ± 0.12 meters and the mean weight 78.1 ± 20.2 kilograms. Each patient was examined clinically with IKDC test. The measuring of the human motion was investigated by zebris CMS-HS ultrasound-based motion measurement system during treadmill-walking. The triplets are attached to the sacrum, right and left thigh, and right and left calf. The anatomical models consider each limb segment to be a rigid body, linked to each other by a joint. The triplets are attached to the segments and virtually linked by a pointer to the anatomical points in such a way, that the registered movement of each triplet enables the calculation of the position of the selected anatomical points, and thereby representing the movement.

RESULTS AND DISCUSSION

Firstly basic gait parameters (step-length, step-width, gait-cycle time), were calculated from coordinates of anatomical points (Whittle, 1998). The flexion-extension motion is characterized by the knee's angle-time function. The newly defined ACL-movement is a displacement between two ACL characterized points namely a displacement between tibial tubercle and femoral lat. epicondyle. The calculated parameters are summarized in Table 1.

Table 1: The gait parameters of healthy and ACL deficient limb

Knee	ACL deficient	Healthy
Step-length [mm]	349 – 670	405 – 700
Step-width [mm]	8 – 80	4 – 71
Maximum of the knee angle [degree]	41.1 – 76.4	45.9 – 81.7
Minimum of the knee angle [degree]	0.5 – 18.8	1.7 – 27.4
ACL movement [mm]	7.50 – 41.9	5.7 – 31.1

The step-length of the affected limb was smaller (12-45%) than healthy. The length of the stance phase of the deficient limb was longer (8-27%) than healthy. The flexion-extension motion plot of knees with ACL deficiency (angle of the knee) showed a flattening of the support phase and a reduction of the peak knee flexion (5-34%) and extension (2-20%) (Figure 1). The ACL-movement of affected knee was significant greater (3-293%) than normal.

Figure 1: The flexion-extension motion plot of the healthy and the ACL deficient knee

SUMMARY

The findings in this study indicate that when the ACL is deficient the movement of the knee may be performed in an abnormal manner. The special developed gait-analysis can be useful for evaluating patients who have an ACL injury because it detects subtle changes in the movement of the knee.

OPTIMIZATION OF ANKLE JOINT ANGLE AS FUNCTION OF TRUNK ANGLE IN CYCLING

M. de Zee¹, S. Tørholm¹, M. Damsgaard¹, H.H.C.M. Savelberg², and J. Rasmussen¹

¹Institute of Mechanical Engineering, Aalborg University, Aalborg, Denmark

The AnyBody Group: <http://anybody.auc.dk>

²Department of Human Movement Sciences, Faculty of Health Science, Maastricht University, Maastricht, The Netherlands

INTRODUCTION

Savelberg *et al.* (2001) showed experimentally that manipulating the trunk angle, or rather manipulating the muscles spanning the hip joint, affects both the kinematics and the recruitment of the leg muscles during cycling. Their subjects showed more plantar flexion during the upstroke with the upper body leaning backward compared to other trunk positions (upright, forward). The change of muscle recruitment was not only restricted to the muscles spanning the hip joint, but affected the muscles in the lower leg as well. This implies that the human body is able to optimize the intermuscular coordination for different bicycle and/or body configurations. The aim of this project is to simulate the experiment of Savelberg *et al.* using the general body modeling system AnyBody based on inverse dynamics, which is capable of analysis and optimization of complicated 3-dimensional musculo-skeletal models. It has been shown that AnyBody is able to optimize movement for partially unknown motions like the ankle angle during cycling (Rasmussen *et al.*, 2001). In this study we shall optimize the ankle angle for different trunk angles in cycling using two different objective functions. The simulation results will be compared with Savelberg *et al.* (2001).

METHODS

AnyBody's model of the lower extremities comprises all the significant muscles crossing the ankle, knee and hip, totaling 64 muscles in the two legs. Muscle data are compiled from (Delp, 1995). The muscles are Hill type with force/length and force/velocity dependency according to an adaptation of (Zajac, 1989).

The cycling computer simulations were done at a cadence of 70 rpm and an average mechanical output of 200 W. The ankle angle was optimized for three body configurations: 1) trunk angle 50° (forward), 2) trunk angle 90° (upright), and 3) trunk angle 105° (backward), see also figure 1.

For each optimization we used two different object functions:

1. Minimize the sum of rms muscle stresses over the cycle
2. Minimize metabolic energy consumption

Figure 1: The three body configurations for which the ankle angle was optimized.

RESULTS

Figure 2 shows the optimized ankle angle curves for the three different body configurations optimized with the different objective functions.

Figure 2: Ankle joint angle as function of trunk angle. Solid lines: optimized by minimizing muscle stress. Dashed lines: optimized by minimizing metabolic power.

DISCUSSION

The results shows that the objective function of minimizing muscle stress shows the same tendency as the experimental results of Savelberg *et al.* with regards to the backward position. The absolute differences, though, are smaller than in the experiments. The optimization results imply that during cycling minimizing metabolic power is not the most important criterion for the human body during cycling, which is in line with other literature (Chen *et al.*, 1999). We believe that minimizing muscle stress is a better objective function for cycling, but more verification is still necessary.

THE EFFECT OF UHMWPE MATERIAL AND KNEE DESIGN ON *IN VITRO* WEAR OF FIXED BEARING AND ROTATING PLATFORM MOBILE BEARING TOTAL KNEE REPLACEMENTS

Hannah M J McEwen¹, Richard Farrar², Martin H Stone³ and John Fisher¹

¹ Medical and Biological Engineering, University of Leeds, Leeds LS2 9JT, U.K. email: j.fisher@leeds.ac.uk

INTRODUCTION

Reduction of ultra high molecular weight polyethylene (UHMWPE) surface wear in total knee replacement (TKR) bearings may delay the onset of osteolysis and subsequent loosening of components. The rotating platform (RP) mobile bearing TKR design decouples bearing motions by allowing linear rotation at the tray-insert counterface, hence reducing the multidirectional motion at the femoral-insert articulation. The aim of this study was to compare the effects of TKR design and bearing material on UHMWPE wear using a physiological knee simulator.

MATERIALS AND METHODS

Twelve ($n = 12$) LCS RP mobile bearing TKR (DePuy) were investigated. Six RP inserts were machined from GUR1050 UHMWPE and were sterilised using gas plasma methods (1050 GP), as used commercially. The remaining six inserts were machined from GUR1020 UHMWPE and were packaged in foil pouches prior to sterilisation by 4.0 MRad γ -irradiation in a vacuum (1020 GVF). These were compared with six ($n = 6$) PFC Sigma (DePuy) fixed bearing TKR with curved 1020 GVF UHMWPE commercially used inserts. Testing was completed on a six-station force/displacement controlled knee simulator using the inputs specified in Table 1 (frequency = 1Hz). The test lubricant was 25% (v/v) newborn calf serum with 0.1% (m/v) sodium azide solution in sterile water. Components were tested in the simulator for five million cycles. Volumetric wear was calculated from the mass loss of the inserts, adjusted using unloaded soak controls, and using densities of 0.932 and 0.934 mg/mm³ for the 1050 GP and 1020 GVF bearings, respectively. The wear rate for each test was defined as the slope of the linear regression line of cumulative wear versus number of cycles completed.

Table 1: Kinematic inputs for knee simulator studies.

	FE	AF	AP	TR
PFC Σ	0 – 58 °	max 2600 N	0 – 10 mm	$\pm 5^\circ$
LCS RP	0 – 58 °	max 2600 N	-262 – 110 N	$\pm 5^\circ$

FE = flexion-extension (ISO14243 1999); **AF** = axial force (ISO14243 1999); **AP** = anterior-posterior translation with displacement control (Lafortune *et al* 1992) for PFC and force control (ISO14243 1999) for LCS; **TR** = tibial rotation (Lafortune *et al* 1992)

RESULTS AND DISCUSSION

The PFC Sigma fixed bearing knees exhibited a significant ($p < 0.01$) threefold higher wear rate in comparison to the LCS

RP mobile bearing knees while no significant difference ($p = 0.20$) in wear rate was observed between the two RP mobile bearing materials (Fig. 1).

Figure 1: Mean wear rates with 95% confidence limits.

The RP mobile bearing design decouples knee motions between the femoral-insert and the tray-insert articulating surfaces. Most of the rotation occurs at the tray-insert interface, which is a simple unidirectional rotation motion that is known to produce low wear (Marrs *et al* 1999, Wang *et al* 1996). Consequently, the femoral-insert articulation experiences very low rotation so the motion at this articulation is also generally unidirectional and similarly has a low wear rate. The unique design of the rotating platform mobile bearing knee translates complex input motions into more unidirectional motions, thus benefiting from a reduced wear rate due to decreased cross shear on the molecularly oriented UHMWPE in comparison to the more multidirectional PFC Σ fixed bearing knees. Crosslinked polyethylenes exhibit improved wear rates when subjected to multidirectional motion (Wang *et al* 1996) but this advantage is not realised when the motion is more unidirectional (Marrs *et al* 1999). There was no significant advantage observed when the moderately crosslinked 1020 GVF bearing material was utilised for the RP bearings in comparison to the non-crosslinked 1050 GP.

CONCLUSIONS

Under high rotation kinematics, the use of RP mobile bearing knees significantly reduced the volumetric wear rate of UHMWPE in comparison to fixed bearing components. The use of crosslinked UHMWPE bearing materials had no significant effect on LCS RP wear. Thus, TKR design is an important factor in the reduction of UHMWPE wear.

COMBINATIONS OF CYCLE LENGTH AND RATE ARE CHOSEN TO MINIMIZE THE MUSCLE POWER REQUIRED IN HUMAN RUNNING

Toshimasa Yanai¹ and James G. Hay²

¹School of Physical Education, University of Otago, Dunedin, New Zealand, tyanai@pooka.otago.ac.nz

²Department of Sport and Exercise Science, University of Auckland, Auckland, New Zealand

INTRODUCTION

Experimental data on many forms of human cyclic locomotion suggest that the graphical forms of the relationships of cycle length (CL) vs speed (S) and cycle rate (CR) vs S are common across all forms of such locomotion, except those in which one of the two factors (CL or CR) is held constant throughout the

Figure 1: Typical CR vs S and CL vs S relationships for longitudinal (within-subjects analysis of human running.

range of Ss studied (Figure 1). There are many practically-feasible combinations of CL and CR that a subject might choose to use when locomoting at a given speed. It appears, however, that a subject consistently select that combination that is consistent with the characteristic curves shown in Figure 1. The obvious question that follows from this observation is “What is the criterion they use in making their selection from the many available combinations of CL and CR for each S?”

The purpose of this study was to test the hypothesis that, in human running at a given speed, subjects select the combination of cycle length and cycle rate that minimizes the peak power generated by the muscles.

METHODS

A two-dimensional model of a runner consisting of a trunk and two legs was defined. A force actuator controlled the length, and a torque actuator controlled the amplitude and frequency of the backward and forward swing, of each leg. The sum of the peak powers generated by the actuators was determined for a range of CRs (1-4 Hz) at each of a series of Ss (2-10 m/s). The combination of CL and CR requiring the least sum of the peak powers at each S was taken to be the ideal combination. Two constraints were imposed: the maximum amplitude of the forward and backward swing of the legs ($\pm 50^\circ$), and the minimum ground contact time needed to maintain steady state running (0.12 s).

RESULTS AND DISCUSSION

The CR and CL vs S relations derived on the basis of the strategy that minimizes the peak power generated by the actuators (Figure 2) generally showed a similar pattern to those exemplified in Figure 1. CL was the primary factor

accounting for increases in S in the low-speed range and CR was the primary factor in the high-speed range. The results thus supported the hypothesis of the study. The natural process of selecting CR-CL combinations for human running might, therefore, be said to have similar characteristics to the process of solving a constrained optimization problem.

The constraints played important roles in determining CR and CL vs S relationships. The anatomical constraint stopped CL from increasing beyond approximately 3.2 m (Figure 3). With a near-constant CL in the high-speed range (from 6.5 to 10 m/s), CR increased in a near-linear fashion throughout the range. When the temporal constraint was imposed in addition to the anatomical constraint, CL started to decrease at S approximately 7.5 m/s. With CL decreasing, CR increased rapidly at the high-speed end (from 7.5 to 10 m/s).

Figure 2: CL and CR vs S relationships that minimized the peak power required

Figure 3: Effects of the constraints

SUMMARY

The results of this study demonstrated that CR-CL combinations that minimized the peak power generated by the actuators matched well the CR-CL combinations naturally selected by human subjects. The results also showed that the anatomical constraint prevented the CL from increasing beyond a certain limit; and the temporal constraint forced the CL to decrease, and the CR to increase substantially, at high speeds. The results suggest that a runner may be able to improve the performance through some form of physical training that makes the anatomical constraint less restrictive. Future studies to examine the practicality of this suggestion and the effectiveness of such a training approach are indicated.

AUTOMATED MARKERLESS ANALYSIS OF HUMAN WALKING AND RUNNING BY COMPUTER VISION

ChewYean Yam, Mark S. Nixon, John N. Carter

Image, Speech and Intelligent System, Electronics and Computer Science, University of Southampton.

INTRODUCTION

Very often, analysis of gait kinematics exploits invasive data acquisition techniques, e.g. attaching a goniometer and accelerometer, using a multiple exposure camera technique [Murray67] with reflective markers [O'Malley93] on the subject's body. These can be expensive, laborious and inconvenient. More importantly they encumber the natural manner of walking and running. Human walking and running is a highly sophisticated system involving multiple factors interacting simultaneously. Naturally, it is difficult to model human locomotion realistically. A considerable amount of work (in biomechanics) seeks to model human walking [Mochan80], running [McGeer90] or both [Alexander92] aiming to understand or explain the mechanism underlying these movements, but not for realistic modelling or imitation.

We have developed an automated non-contact and markerless analysis system using computer vision techniques. A structural motion model derived from forced coupled oscillators, which can describe the spatio-temporal characteristics of human running and walking gaits [Yam02], serves as the basis of an evidence gathering technique used to extract leg motion. Naturally, concern over marker movement is now replaced by concern of the features extracted. In this respect, evidence gathering approaches have known optimal performance, especially in respect of noise and occlusion.

METHOD

The fronto-parallel views of 20 healthy subjects (5 females and 15 males, age:22-45, weight:45-100kg, height:156-192cm) walking (2.8-5.5km/h) and running (6.5-13.9km/h) normally on a treadmill at their preferred speeds are filmed with a digital camera. The video clips are digitised into image files. Edge maps are obtained via the Sobel edge detector. Temporal template matching that considers the whole sequence of edge maps is applied to extract the motion of a whole gait cycle. The structural motion model serves as the basis of this evidence gathering technique. The length of the thigh and lower leg, their absolute rotation angles and the hip's motion can be extracted and computed simultaneously. These measurements can then be used for further analysis. The process is automatic following pre-selection of some control parameters.

RESULTS AND DISCUSSIONS

Fig. 1 shows the extracted rotation angles of a subject's thigh (when walking) and lower leg (when running) superimposed on manually labelled data. The gross motions are captured well and appear very close to the manual labelled data which could however be erroneous. **Fig. 2a** shows an image with the

extracted motion superimposed. This technique extracts the front of the legs and we shall later determine its relationship to the conventional labelling on the bone structure. Due to temporal (1/2 period) and spatial (sequence of oscillation) symmetry, this technique can extract both legs, and hence handle self-occlusion. Here, only the thigh and lower leg rotation are considered, with potential extension to ankle rotation.

Fig. 1: Automatically extracted absolute angles of (a) thigh when walking and (b) lower leg when running.

Fig. 2: (a) Automatically extracted leg motion; (b) phasor plot of lower leg rotation when running; different symbols represent different subjects.

Fig. 2b shows the 2nd harmonic Fourier description for lower leg motion. It suggests individuality, in that people's movement clusters in different places. Experimentation shows that running actually has more variability than walking. The capability to extract individual characteristics in gait patterns suggests that it is indeed appropriate for future investigation in analysis of gait biomechanics. This non-contact, markerless and automated feature extraction process is invariant to gait mode (walking or running) and speed, so is feasible for analysis, especially with a large subject population.

THE KINEMATICS OF HIP JOINT SIMULATOR MICROSEPARATION

T Stewart¹, S Williams¹, J L Tipper², R M Streicher³, E Ingham², J Fisher¹

INTRODUCTION

It has been recently discovered that hip joint separation occurs during normal gait (1). Reproducing this motion in hip simulators results in contact of the femoral head with the rim of the acetabular insert at heel-strike. For ceramic prostheses this results in localised intragranular fracture of the femoral head in the form of a stripe of wear and localised intragranular fracture of the insert rim at the point of impact. The result produces similar wear mechanisms, wear volumes, and wear debris to those found in retrieved ceramic components and their surrounding tissues and is now the most clinically relevant means of testing ceramic bearings (2,3). The purpose of this study was to compare the biomechanics and wear of two methods of microseparation simulation on one hip design.

MATERIALS AND METHODS

28mm Biolox Forte Alumina components were used.

Method 1-Leeds MKII Hip Simulator. A small lateral to medial load was applied to the acetabular insert with a spring, which, during the swing phase when the joint load was reduced, produced medial (~400 μ m) and superior translation of the insert as it tracked around the head (Position 1 to 2). Upon reapplication of the joint load at heelstrike this resulted in contact between the head and the superior rim of the insert (Position 2) before joint relocation (Position 1). Severity was altered by adjusting the swing phase axial load which, when reduced made it easier for the spring to overcome friction and to produce superior translation between the head and insert. The increased momentum and impact energy modelled greater laxity and a more severe microseparation condition.

Method 2-Prosims Hip Simulator. An inferior load was applied to the femoral head using an actuator, which, during the swing phase when the joint load was reduced, produced a separation of (~700 μ m) between the components. Upon separation this resulted in contact of the head with the inferior rim of the insert producing lateral displacement of the head as it tracked around the insert rim (Position 1 to C). Upon re-application of the joint load at Heel-Strike this resulted in superior translation of the head which then collided with the superior rim of the insert (Position 2) before relocation (Position 1).

Figure 1. Centre of contact.

RESULTS

Wear results from the two methods are shown in Figure 2.

Figure 2. Long Term Wear of AL-AL Under Microseparation.

DISCUSSION

The two methods of microseparation investigated have anatomical positioning of the components with the insert mounted superior to the head, however, they have different mechanics, wear patterns, and wear volumes. In Method 1, medial translation of the insert produced a superior wear scar on the head and insert in the form of a stripe. The loading vector in this method was vertically downwards through the insert, essentially perpendicular to the contact. Impact was, therefore, very direct and included the momentum of the insert and its holder. A deeper and more pronounced stripe of wear resulted. In Method 2, inferior translation of the head produced little effect at the inferior rim of the insert, however, superior translation of the head at heelstrike produced a wear scar at the superior rim of the insert. The loading vector in this method was along the axis of the femoral head and tangential to the contact at heelstrike (30° Flexion). Impact was a glancing blow with very little effect of momentum. A long, thin, less pronounced stripe of wear resulted.

In-vivo wear results from the current generation of prostheses are limited, however, wear volumes ~0.5 mm³/million cycles have been reported suggesting that both methods are capable of producing repeatable clinically relevant wear results (3).

INTRODUCTION

Extremely low wear ($<0.1 \text{ mm}^3/\text{million cycles}$) has been reported for Zirconia femoral Heads articulating against Alumina Inserts for hip prostheses under normal laboratory hip simulation conditions and this bearing combination has been introduced into clinical use (1,2). However, improved testing conditions which model mild and severe swing phase joint separation are now available. This has shown for Alumina bearings to produce more clinically relevant wear results (3,4). The purpose of this study was, therefore, to evaluate the wear performance of Zirconia heads against Alumina inserts using microseparation simulation techniques.

MATERIALS AND METHODS

Two commercially available materials were tested: Zirconia ("ZR", ISO 13356) and 3rd Generation Hot Isostatic Pressed (HIPed) Alumina ("AL", ISO 6474). A six station anatomical hip simulator was used with 25% bovine serum lubricant. The procedure of microseparation involved applying a small lateral to medial load to the acetabular insert with a spring, which, during the swing phase when the joint load was reduced, produced a medial (400 μm) and superior translation of the insert relative to the head. On heelstrike, with re-application of the joint load, this resulted in impact between the head and the superior rim of the insert before joint relocation. Conditions were altered by adjusting the swing phase load in the simulator from 400 N for mild conditions, to 50 N for severe conditions. The reduced load made it easier for the medial separation force to overcome friction and to produce superior translation between the head and insert, thus producing more momentum and impact energy. The variable swing phase load represented varying degrees of joint laxity.

RESULTS

The simulator produced a regular pattern of micro-separation over the 5 million cycle test duration. Under mild microseparation a very faint stripe of wear was formed on two of the three Zirconia heads, which increased the surface roughness R_a from $< 0.005 \mu\text{m}$ to $\sim 0.08 \mu\text{m}$. The third femoral head was visibly undamaged. Stripes on the two Zirconia femoral heads under mild conditions were $\sim 0.75 \text{ mm}$ wide and $\sim 10 \mu\text{m}$ deep. Under severe microseparation prolonged squeaking was observed from the bearings. A large stripe of wear was formed on all three of the Zirconia heads, which increased the surface roughness R_a from $< 0.005 \mu\text{m}$ to between 0.09 and $2.1 \mu\text{m}$. After 2 million cycles one acetabular insert and one femoral head fractured along the worn stripe and rim areas. Stripes on the Zirconia femoral heads under severe conditions were $\sim 5 \text{ mm}$ wide and up to $250 \mu\text{m}$ deep (components are shown in Figure 1).

X-ray Diffraction of the femoral heads after severe microseparation revealed up to 35% phase transformation of the Zirconia from tetragonal to monoclinic had occurred within the worn stripe area.

Figure 1. Fractured Alumina Insert (Middle) and Zirconia Head (right) after severe microseparation.

DISCUSSION

Under mild microseparation simulation conditions the wear of Zirconia heads against HIPed Alumina inserts was very low ($0.05 \text{ mm}^3/\text{million cycles}$) suggesting potentially superior performance in-vivo to Alumina against Alumina. However, under severe microseparation conditions gross femoral head and insert rim wear were observed on the components after 1 million cycles producing a wear rate of $10.6 \text{ mm}^3/\text{million cycles}$. The high wear additionally produced fracture of one acetabular insert across the worn rim area, and fracture of one Zirconia femoral head across the stripe wear area. The results suggest that Zirconia may have a threshold stress level, which if exceeded may result in catastrophic wear. Zirconia femoral heads against Alumina acetabular inserts are not recommended for clinical use.

WEAR OF CERAMIC MATRIX COMPOSITE HIP PROSTHESES IN SIMULATORS MODELLING LAXITY

T Stewart¹, J L Tipper², R M Streicher³, E Ingham², J Fisher¹

¹Mechanical Engineering, The University of Leeds, Leeds LS2 9JT, UK, T.D.Stewart@Leeds.ac.uk

²Division of Microbiology, The University of Leeds, Leeds LS29JT UK

³Stryker SA, Scientific and Clinical Affairs, Florastr. 13, CH-8800 Thalwil, Switzerland.

INTRODUCTION

Next generation ceramic matrix composites are now available for hip prostheses as alternative to Alumina (AL). These new Zirconia Toughened Alumina (ZTA) materials are reported to offer improved toughness without a significant reduction in hardness, making them more flexible for designers (1). There is, however, no published experimental data on the wear of ZTA-ZTA and ZTA-AL under microseparation conditions that have been shown for AL-AL to provide clinically relevant wear rates, wear mechanisms and wear debris (2,3). The purpose of this study was to evaluate the long-term wear performance of ZTA-ZTA and ZTA-AL in a hip joint simulator incorporating severe swing phase microseparation.

MATERIALS AND METHODS

Two commercially available materials were tested: Zirconia Toughened Alumina (ZTA- BioloX Delta) and 3rd Generation Hot Isostatic Pressed (HIPed) Alumina (AL-BioloX Forte). A six station anatomical hip simulator was used with 25% bovine serum lubricant and three components of each type. The procedure of microseparation involved applying a small lateral to medial load to the acetabular insert with a spring, which, during the swing phase when the joint load was reduced, produced a medial (400 µm) and superior translation of the insert relative to the head. On heelstrike, with re-application of the joint load, this resulted in impact between the head and the superior rim of the insert before joint relocation. A swing phase load of 50 N was used to model a severe level of joint laxity.

RESULTS

The simulator produced a regular pattern of micro-separation for the 5 million cycle test duration. During the initial 1 million cycles a stripe of wear was formed on all of the heads of both ZTA-AL and ZTA-ZTA bearing combinations, which increased the surface roughness R_a from $< 0.005 \mu\text{m}$ to $\sim 0.1 \mu\text{m}$. Wear volumes are summarised in Figure 1 along with previous wear results of AL-AL where bedding-in and steady-state wear rates of 4.0 and 1.84 $\text{mm}^3/\text{million cycles}$ were reported under the same severe testing conditions (3). The wear of ZTA-AL was significantly less than the wear of AL-AL with a bedding-in wear rate of 0.99 $\text{mm}^3/\text{million cycles}$ during the initial 1 million cycles followed by a reduced steady-state wear rate of 0.51 $\text{mm}^3/\text{million cycles}$. The wear of ZTA-ZTA was significantly less than the wear of AL-AL and also less than the wear of ZTA-AL with a bedding-in wear rate of 0.32 $\text{mm}^3/\text{million cycles}$ during the initial 1 million cycles followed by a steady-state wear rate of 0.12 $\text{mm}^3/\text{million cycles}$.

Figure 1. Average Wear Rates \pm SE, $n=3$

DISCUSSION

Long term *in-vitro* microseparation of ZTA heads against ZTA inserts and ZTA heads against Alumina inserts produced overall average wear rates 3 and 12 times lower than previously observed with Alumina ceramic bearings under the same severe conditions representative of high joint laxity. The results suggest that ZTA heads articulating against ZTA inserts and ZTA heads articulating against AL inserts may have better resistance to microseparation wear compared to AL on AL. The overall production of less wear debris from the new alumina matrix composite material, combined with its reported improved toughness makes it a potentially more flexible alternative to the more traditional Alumina for hip prostheses.

EFFECT OF A DUAL CAGE ON THE MECHANICAL BEHAVIOR OF THE LUMBAR SPINE

Antonius Rohlmann, Thomas Zander, Michael Fehrmann, Georg Bergmann

Biomechanics Laboratory, University Hospital Benjamin Franklin, Free University of Berlin, Berlin, Germany

INTRODUCTION

Degenerative changes in the lumbar spine sometimes require an intercorporeal fusion. The respective disc has to be removed partly and replaced by a bone graft or an implant. The main task of a disc replacement is to keep the two adjacent vertebral bodies at a defined distance in order to avoid the postdiscectomy syndrome. The implants are primarily spacers and, because of their design, they are called cages. They are often implanted in pairs together with cancellous bone. The concerned spinal level is often additionally stabilized by a posterior or anterior implant.

The aim of this study was the analytical investigation of changes in intersegmental rotation and in stress distribution due to insertion of a dual threaded cage and additional stabilization using an internal spinal fixation device.

METHODS

A three-dimensional nonlinear finite element model of the whole lumbar spine was created [Smit, 1996; Zander et al, 2001]. Each annulus fibrosus consisted of volume elements and superimposed spring elements; the latter represents the fibers of the annulus. The nucleus pulposus was simulated by means of an incompressible fluid-filled cavity. The facet joints were modeled to transmit only compression forces. All seven ligaments were included in the finite element model. According to their function, they were modeled as tension-only spring elements with nonlinear elastic behavior.

Figure 1: Element mesh of a dual cage (Proximity Lumbar Interbody Fusion System), adjacent vertebrae and internal fixator

After verification of the finite element model of the intact lumbar spine with experimental data the disc L2/3 was partly removed. In the intervertebral space a model of a paired cage (Proximity Lumbar Interbody Fusion System of Sulzer Medica) was inserted in anterior-posterior direction (Figure 1). This threaded cage has a central longitudinal hole and four flattened sides and is made out of titanium. A monosegmental internal spinal fixation device bridging the cage was added to the finite element model using beam elements.

The model was successively loaded with pure moments of 7.5 Nm in the three anatomical main planes and optionally with a

preload on the cage. The preload was simulated by reducing the distance between the pedicle screws at the longitudinal rod of the fixator by 0.5 mm. A follower load [Patwardhan et al, 1999; Rohlmann et al, 2001] of 250 N simulated the stabilizing effect of the local muscles acting directly on the lumbar spine. This compressive load has a path tangentially to the spinal curvature and a stabilizing effect against buckling. The finite element program ABAQUS was used.

RESULTS

A monosegmental internal fixation device reduced the overall deformation of the lumbar spine model by about 20% during flexion and lateral bending. The additional implementation of a dual cage had then only a minor effect. For the loading case extension, the sum of intersegmental rotation was also reduced by a fixator but it increased again after insertion of a dual cage. The implants had only a minor influence on the sum of intersegmental rotation for the loading case torsion. They also had only a small effect on the adjacent segments.

In the vertebral endplates, which were in contact with the cage, stress distribution was strongly affected by the cage. A preload on the cage had a drastic influence on the maximum stresses in the interface between cage and vertebral body.

DISCUSSION

When a dual cage is implanted together with an internal spinal fixation device, intersegmental rotation is markedly reduced in the corresponding segment for the loading cases flexion and lateral bending and slightly reduced for the loading cases extension and axial rotation.

The contact area between cage and vertebral body is smaller than between disc and vertebral body. Additionally, a cage is stiffer than a disc. These are the main reasons for the noticeable increase of stresses after insertion of a dual cage. A preload, applied by shortening of the fixators, causes a small intersegmental rotation at that level. This in turn reduces the contact area between cage and vertebral body. Together with the increased load due to the preload these are the reasons for the much higher peak stresses compared to the case without a preload. During implantation of a cage the preload should be chosen advisedly to prevent subsidence of the cage into the vertebral body. For the same reason, vertebral endplate should not be weakened more than absolutely necessary.

EFFECT OF A LAMINECTOMY ON THE MECHANICAL BEHAVIOR OF THE LUMBAR SPINE

Thomas Zander, Antonius Rohlmann, Georg Bergmann

Biomechanics Laboratory, University Hospital Benjamin Franklin, Free University of Berlin, Berlin, Germany

INTRODUCTION

Severe spinal stenosis is often treated by dorsal decompression. Depending on the degree of stenosis mono- or bilateral hemifacetectomy, hemi- or bilateral laminectomy or even laminectomy on two levels is indicated. The operative resection of a facet capsule and of posterior bony parts of a vertebra reduces the spinal stability which may lead to an increase of deformation and loads at that level. The amount of instability produced by these procedures is still a matter of debate.

The aim of the present finite element study was to determine the influence of different degrees of resection of posterior elements on the mechanical behavior of the lumbar spine.

METHODS

A three-dimensional, nonlinear finite element model of the human osseoligamentous spine segment L2 to the superior part of S1 was created (Figure 1).

Figure 1: Outer mesh of the finite element model of the spine segment with laminectomy

The element mesh of the vertebrae is based on the model used by Smit [1996]. The nucleus pulposus was simulated by an incompressible fluid-filled cavity and the annulus fibrosus by volume elements with superimposed spring elements representing the fibers. The facet joints could only transmit compressive forces. The capsule of the facet joints and the six ligaments of the lumbar spine were included. The mainly nonlinear material properties of all tissues were taken from the literature. The model was successively loaded in flexion/extension, right/left lateral bending, and right/left axial rotation with pure moments up to 7.5 Nm. Different situations were studied, including left hemifacetectomy, bilateral hemifacetectomy, left hemilaminectomy, laminectomy, and two level laminectomy. This was done by successive resection of posterior parts of the vertebrae at the affected level. The finite element model is described in detail elsewhere [Zander et al. 2001]. The finite element program ABAQUS was used. The intact computer model was validated by reference to experimental data from *in vitro* measurements [Rohlmann et al. 2001; Zander et al. 2001].

RESULTS

Calculated intersegmental rotation angles at the level L4/L5 lay in nearly all cases within the ranges measured by Quint et al (1998) for the corresponding situation. The highest values were found for flexion. A laminectomy had only a negligible effect on intersegmental rotation for extension and lateral bending. Intersegmental rotation increased markedly after laminectomy for flexion while for axial rotation it increased already after a hemifacetectomy. In the latter case further resection of posterior elements had only a minor influence on the intersegmental rotation angle. Extending the laminectomy to the segment L5/S1 had only a negligible effect on intersegmental rotation angles for all loading cases studied. A degenerated disc, however, reduced intersegmental rotation, especially for flexion.

A laminectomy had only a negligible effect on the maximum von Mises stresses in the annuli for the loading cases extension and lateral bending. It increased stresses for flexion while stresses rose already after a hemifacetectomy for axial rotation.

The degree of resection of dorsal osseous and ligamentous elements had only a minor effect on intradiscal pressure for the loading cases flexion, extension, and lateral bending. Merely for axial rotation intradiscal pressure increased markedly after hemifacetectomy. Intradiscal pressure in the adjacent discs was not affected by a laminectomy.

DISCUSSION

The influences of different degrees of resection of posterior vertebral parts on the mechanical behavior of the lumbosacral spine was studied using the finite element method.

A good agreement between our numerical results and the experimental data measured by Quint et al. (1998) could be ascertained. During axial rotation, a hemifacetectomy had already an influence on the mechanical behavior of the lumbosacral spine. The resection of further parts had only a minor effect during this loading case. During lateral bending and extension, the parameters studied were only slightly affected by the different degrees of resection. During flexion, the mechanical behavior of the lumbar spine was only slightly influenced by resections up to a hemilaminectomy.

INTRODUCTION

Softening of articular cartilage (AC) and degradation of superficial collagens are signs of incipient osteoarthritis (OA). We have developed a handheld ultrasound indentation instrument enabling assessment of cartilage mechanical and acoustic properties (Laasanen 2002). In this study, capability of the instrument to distinguish between normal and degenerated AC was studied. In addition, we evaluated feasibility of high frequency ultrasound imaging to quantify tissue repair after autologous chondrocyte transplantation (ACT) and to detect spontaneous, enzymatic or mechanical cartilage damage.

MATERIALS AND METHODS

The ultrasound indentation instrument (Fig. 1) consists of a contact ultrasound transducer installed to the tip of an Artscan 200 instrument. Dermascan-C 20 MHz ultrasound instrument was used for B-mode ultrasonic imaging. Bovine patellar AC were visually classified to four different grades: 0-intact ($n=11$), 1-slightly discoloured ($n=5$), 2-superficial defect ($n=6$), 3-deep defect ($n=8$). Osteochondral samples ($n=30$, dia.=19 mm) were drilled from the classified sites. Dynamic moduli of the samples were measured with the novel instrument by manually inducing several instantaneous compressions (prestress 215 kPa, strain 4%). Thickness and deformation was determined from ultrasound signal using the time of flight principle with predetermined sound velocity (1627 m/s). Dynamic modulus was calculated by assuming instantaneous incompressibility of cartilage (Hayes 1972). High-resolution material testing device was used for reference measurements (Töyräs 1999) with a stress-relaxation protocol (10% prestrain, 10% step, 2 mm/s) in unconfined compression. Ultrasound reflection coefficient was determined as a ratio of the maximum amplitude recorded from saline-cartilage interface and amplitude recorded from a perfect reflector. To evaluate capability of ultrasound for detecting superficial cartilage damage, 12 extra samples were prepared. The samples ($n=6$, dia.=6 mm) were gently damaged by sliding a sample against a 120 grit abrasive (pressure 56 kPa, total sliding distance 20 mm) or ($n=6$, dia.=16 mm) digesting with collagenase (Töyräs 1999). Cartilage healing after ACT was studied in pigs ($n=8$). Full thickness cartilage lesion (dia.=6 mm) was created on the femoral groove and subsequently repaired using ACT (Brittberg 1999). In control animal, lesion was created but left unrepaired. After follow up of three months the tissue repair was analysed with ultrasonic and microscopic techniques.

Figure 1. Ultrasound indentation measurement geometry.

RESULTS AND DISCUSSION

Linear correlation between ultrasound indentation modulus and reference dynamic modulus was $R=0.993$ ($p<0.0001$, $n=30$) (Fig. 2A). The instrument distinguished different degenerative grades (Fig. 2B). Large SD of intact cartilage dynamic modulus revealed insensitivity of visual grading of cartilage quality. Ultrasound imaging illustrated sensitively spontaneous, enzymatic or mechanical degradation (Fig. 3) and provided high resolution images on cartilage repair in ACT repaired porcine joints (Fig. 4).

Figure 2: Linear correlation between cartilage modulus (ultrasound indentation) and the reference modulus (A). Mean values (\pm SD) of modulus and ultrasound reflection coefficient in intact or degenerated cartilage (B).

Figure 3: Ultrasound images of articular surface in normal (A), collagenase degraded (B), mechanically degraded (C) and spontaneously degenerated cartilage (grade 1) (D).

Figure 4: Ultrasound and light microscopic (safranin O-stain) images of intact (A), repaired (B and C) and unrepaired (D) porcine joints.

SUMMARY

The ultrasound indentation instrument was capable of quantifying absolute cartilage stiffness and diagnosing progression of tissue degeneration. Ultrasound imaging detected spontaneous, enzymatic or mechanical degradation sensitively and provided high resolution images on cartilage and subchondral bone in ACT repaired porcine joints.

EFFECTS OF SOUND VELOCITY VARIATION ON CARTILAGE ULTRASOUND INDENTATION MEASUREMENTS

MS Laasanen^{2,3}, J Töyräs¹, S Saarakkala³, J Rieppo², RK Korhonen^{1,2} and JS Jurvelin^{1,3}

INTRODUCTION

Earlier studies report sound velocities (c) of 1600-1800 m/s for articular cartilage (Myers 1995; Töyräs 1999). Some discrepancy exist, while velocities up to 2428 m/s were reported for human ankle cartilage (Yao 1999). In this study, we measure c in normal, enzymatically degraded and osteoarthrotic (OA) bovine cartilage and evaluate relationships between c and cartilage composition or mechanical properties. Further, effect of variation of c on determination of cartilage thickness (h) and dynamic modulus (E) with an ultrasound indentation instrument (Laasanen 2002) was analyzed.

MATERIALS AND METHODS

Three sample groups were harvested. **Group 1:** Cartilage disks ($n=30$, dia.=4 mm) were obtained from femoral medial condyle ($n=6$, FMC), lateral patellofemoral groove ($n=6$, LPG), medial tibial facet ($n=6$, MTF), patella ($n=6$, PAT) and talus ($n=6$) of intact bovine joints. **Group 2:** 30 bovine patellar cartilage samples (11 visually normal and 19 having visible degenerative changes, dia.=4 mm) were prepared. **Group 3:** Patellar cartilage disks (bovine, $n=18$, dia.=4 mm) were harvested and digested with trypsin ($n=6$, inducing severe proteoglycan (PG) depletion), chondroitinase ABC ($n=6$, slight and specific PG depletion) and collagenase ($n=6$, specific collagen degradation) (Laasanen 2002). Cartilage c (groups 1-3) and E (groups 2 and 3) were measured with a high-resolution mechano-acoustic material testing instrument under unconfined compression (Fig. 1A). PG concentration was determined using the digital densitometry (Panula 1998). Finally, the effect of recorded variation in c (group 1) on the error in h and E , as determined with ultrasound indentation instrument (Fig 1B), was simulated by modelling cartilage to be instantaneously incompressible and isotropic (Hayes 1972). Sound velocity of 1630 m/s (bovine knee mean) and 1721 m/s (talus mean) were used in the simulations.

Figure 1: Mechano-acoustic material testing instrument used for determination of cartilage dynamic modulus and sound velocity (A). Tip of the ultrasound indentation instrument (B).

RESULTS AND DISCUSSION

Sound velocity correlated positively with PG concentration and with E (Fig. 2). It showed, however, only a minimal topographical variation in bovine cartilage (Table 1). Realistic

variation of c induced minimal errors (<3%) on h and E , as determined with the ultrasound indentation technique (Table 1). Degradation of collagens or PGs induced only minor decrease in c , while E decreased significantly (Table 2).

Figure 2: c correlated positively with PG content (optical density of safranin-O stained sections) in visually normal cartilage (A) and with E in normal/degenerated cartilage (B).

Table 1: c and h of bovine knee and talus cartilage. Simulated errors of h and E in ultrasound indentation (mean \pm SD) when assuming a constant sound velocity (joint mean c).

	MTF	FMC	PAT	LPG	Talus
c [m/s]	1602 \pm 35	1638 \pm 18	1627 \pm 58	1652 \pm 16	1721 \pm 26
h [μ m]	1346 \pm 276	1310 \pm 380	1543 \pm 186	1398 \pm 137	435 \pm 53
h error [%]	1.97 \pm 2.00	0.95 \pm 0.66	2.88 \pm 1.90	1.33 \pm 0.98	1.14 \pm 0.85
E error [%]	0.22 \pm 0.15	0.27 \pm 0.30	0.28 \pm 0.31	0.24 \pm 0.25	0.85 \pm 0.64

Table 2: c and E (mean \pm SD) before and after degradation.

	Trypsin	Chond. ABC	Collagenase
c before [m/s]	1618 \pm 22	1605 \pm 10	1606 \pm 31
c after [m/s]	1596 \pm 13*	1605 \pm 18	1580 \pm 23
E before [MPa]	5.37 \pm 4.02	3.11 \pm 0.61	3.66 \pm 1.85
E after [MPa]	3.30 \pm 2.82*	2.40 \pm 0.62*	2.26 \pm 2.30

* $p < 0.05$ Wilcoxon's signed-ranks test.

SUMMARY

Although c was found to correlate with cartilage composition and modulus it was nearly constant in tested cartilage. Enzymatic degradation of tissue PGs and collagen decreased c only minimally (mean -1.0%). We could not verify the high c , reported earlier for human cartilage (Yao 1999). Current results propose that a constant (joint mean) c may be utilised to obtain a clinically acceptable accuracy for h and deformation during ultrasound indentation measurement. This enables a reliable ultrasound indentation measurement for determination of cartilage modulus *in situ* and possibly *in vivo*.

INTRODUCTION

To date the living mechanics of the spine, particularly the neck, are not well understood. This is in part due to inadequate methods with which the movements of the neck can be assessed. The ability to record and measure intersegmental motion is paramount if we are to understand conditions such as whiplash injury, and instability. Radiographic assessment has formed the basis for this research, particularly lateral x-ray views of cervical flexion and extension and more recently the use of videofluoroscopy images. Both of these methods have been fraught with problems including ionizing radiation exposure, magnification errors and image quality. The ionising nature of the radiation particularly limits serial studies of neck function and studies of large populations. The evolution of open or interventional magnetic resonance (IMR) scanners allow dynamic imaging of patients in the scanner in weight loaded positions. Therefore, the aim of this study was to investigate the use of IMR imaging to assess intersegmental motion of the cervical spine.

METHODS

20 normal subjects (10 females, 10 males, mean age 25.4 ± 3.7 years) were recruited into this study. Subjects with a history of neck pain that required intervention, current neck pain or problems within the past 6 months were excluded from participation in the study. Subjects were scanned using a General Electric Signa SPI0 Interventional MRI scanner. This is an open MRI scanner consisting of 2 connected but opposing ring "doughnuts" magnets. The gap between these magnets is 56cm generating a uniform field of 0.5Tesla. The patients were scanned in sitting with their neck in neutral and

in flexed and extended positions. Sagittal images of the spine were obtained in each position. From these sagittal images, measurements of intersegmental motion were made using the methodology described by Dupuis *et al.*, 1985, the repeatability of such measures from MRI has been previously reported (McGregor *et al.*, 2001).

RESULTS

It was possible to get clear images of the cervical spine in neutral, flexed and extended positions from which measures of motion could be obtained. The table below illustrates the mean \pm standard deviations of A-P angular rotations and associated horizontal translation occurring at each level during flexion and extension. Greatest angular motion was noted to occur between C4-C7, which is in agreement with previous studies whilst greater translation occurred in the upper cervical region.

DISCUSSION

These preliminary findings suggest that interventional MRI has the potential to assess cervical spine kinematics and the findings appear to be in agreement with previously published data. This combined with the non-invasive nature of this imaging medium suggest that long term follow-up studies of cervical instability and fusion patients are possible in the future.

WRENCHES AT THE DIGIT-OBJECT INTERFACE DURING PREHENSION

Fan Gao, Vladimir M. Zatsiorsky¹, Mark L. Latash
Department of Kinesiology, The Pennsylvania State University, PA 16802, USA
¹ vxz1@psu.edu

INTRODUCTION

To construct multifunctional hand prostheses and robotic hands, engineers should be aware of the wrenches (forces and moments) acting on individual digits during manipulative tasks. This knowledge is also essential for understanding object manipulation. The available data on digit-object interactions are limited.

METHODS

Subjects ($n=8$) stabilized a handle with an attachment that allowed for change of external torque from -1.5 Nm to 1.5 Nm, Figure 1. Wrenches (forces and moments) exerted by the digit tips on the object were recorded.

Figure 1. Schematic drawing of the handle.

RESULTS

In all tasks, the index finger did not contribute, or contributed very little, to load holding: its force was directed either downward or horizontally, Figures 2 and 3. With the exception of the large (>-0.375 Nm) supination efforts, the middle, ring and little fingers produced forces in the same direction. The force vectors were almost parallel. The points of force application were systematically displaced with the torque, with the exception of the little finger. Across all torque conditions, the shear forces of the four fingers combined (IMRL force) and the shear force of the thumb increased or decreased in opposite directions while the normal forces of the thumb and IMRL changed in sync from 19.2 N at a zero torque to 46.3 N at a torque 1.5 Nm. During the large supination torques the IMRL shear force was directed downward and the thumb supported the entire weight of the apparatus. The relationships between the shear and normal force of the thumb and IMRL had a V-like shape. The total

moment of the normal finger forces accounted for approximately $2/3$ of the torque exerted on the object.

Figure 2. Force vectors at the digit tips, group average.

Figure 3. Force polygons. The vertical downward arrows represent gravitational forces, other arrows represent the forces of the thumb, index, middle, ring and little fingers, respectively, in a counterclockwise sequence.

DISCUSSION

As compared with other dexterous tasks, the task explored in this study looks rudimentary. The subjects were asked to hold a handle while resisting an external torque and load. The task is similar to those used in robotic manipulation: a gripper grasps an object and rotates it. Relatively simple control strategies are used to perform these tasks in robotics applications: all the fingers receive a similar command for grasping and the resistance is provided by apparent stiffness of the digits – when the fingers deflect from a nominal position they exert larger forces (Mason, Salisbury 1985; Doersam, Fischer 1998). The finger force direction is not specifically controlled and depends on the peripheral interactions between the fingertips and the object. The human interaction with a hand-held object seems more complex.

INTRODUCTION

Patellofemoral pain syndrome is one of the most widely diagnosed disorders involving the knee and includes a number of conditions resulting in pain of the anterior portion of the knee (Fulkerson, J.P. et al 1985, Goldberg, B.1997). Imbalanced and over-stretched joint capsule and surrounding tissue of the patellar may cause the patella to be translated to one side or the other, onto the edges of the intercondylar notch, as the knee flexes and extends. Thermal modification has been used to alter mechanical properties of soft tissues in order to regain their lost functions (Wall, M.S. et al 1999). The objectives of this study were to test biomechanically the thermal shrinkage of the knee capsule and its effects on the patella tracking in the intercondylar notch by comparing the lateral translation of the patella. The lateral translation and stiffness of the knee capsule were compared among healthy subjects, cadaver knees pre and post thermal shrinkage, and cadaver knee post open surgery.

METHODS AND MATERIALS

Knee capsule thermal modification was performed on cadaver specimens using Mitek VAPR. The tissue shrinkage was applied to the medial portion of the capsule. Lateral translation of the patella was measured with lateral force applied to the patella before and after the process. Open medial reefing of the medial capsular structures was conducted at last during open surgery. Nine fresh frozen cadaver specimens were used for the study. The test was repeated after open surgery. To establish the baseline for the lateral stiffness of the knee capsule, nine healthy subjects were tested on both legs after they filled out consent forms.

Lateral translation of the patella was recorded using a LVDT translation sensor (Macro Sensors, Pennsauken, NJ). The lateral force applied to the patella was recorded using a Flexiforce force sensor (Tekscan, South Boston, MA). A custom made adaptor was used to hold the sensor and apply force. Both force and translation sensors were connected to a computer via a data acquisition board (Data Translation, Boston, MA). Data were collected and stored for further analysis. A custom made frame was used to hold specimens during test. Subjects were lying on an exam table during test.

Each test was repeated three times. Subjects were instructed to relax during tests. The peak force applied, the peak translation and the stiffness were analyzed. Repeated measure analysis of variance (ANOVA) was used to compare the differences.

RESULTS

No significant differences were found between genders and between left and right knees for healthy subjects. There were no significant differences of the peak force, peak displacement and stiffness between healthy subjects and the cadaver knees. No significant differences of the cadaver knees were found between pre and post thermal shrinkage. Cadaver knees after open surgery showed significant higher stiffness than healthy subject, cadaver knee pre thermal shrinkage and post thermal shrinkages ($p < 0.001$). No significant differences of the force applied were found among cadaver pre, post thermal shrinkage and open surgery. Cadaver knees post open surgery showed significant less displacement than healthy subjects, cadaver pre thermal shrinkage and post thermal shrinkage. No significant differences of the displacement were found among healthy subjects, cadaver knees pre and post-thermal shrinkage. Table 1 shows the forces, displacements and stiffness.

Table 1 Forces (F), displacements (D) and stiffnesses (S) for healthy (H) subjects and cadaver (C) knees pre thermal shrinkage (TS), post thermal shrinkage and post open surgery (OS).

GROUP	F (N)	D (mm)	S (N/mm)
H Subjects	17.57 ± 4.79	10.67 ± 3.72	1.91 ± 0.92
C pre TS	23.22 ± 4.50	10.55 ± 1.92	2.27 ± 0.54
C post TS	22.90 ± 3.23	10.87 ± 1.88	2.15 ± 0.43
C post OS	25.26 ± 3.90	5.73 ± 1.86	5.10 ± 2.53

SUMMARY

The application of thermal energy to the medial capsular structures of human cadaver knees caused no statistical or clinically appreciable differences in lateral patellar displacement or medial structure stiffness compared to pre-treatment values. Open medial reefing of the medial capsular structures caused a 46% decrease in lateral patellar displacement compared to pre-treatment values and a 222% increase in medial structure stiffness compared to pre-treatment values. Further clinical study is needed to investigate the long-term effect of thermal modification.

PREDICTION OF SCRATCH RESISTANCE OF METALLIC BEARING SURFACE, ARTICULATING AGAINST UHMWPE, DUE TO 3RD BODY WEAR PARTICLES

M. Mirghany, H. Ensaff, Z.M. Jin

Department of Mechanical and Medical Engineering, University of Bradford, Bradford, BD7 1DP, UK.

INTRODUCTION

Within a hip prostheses, the metallic surface of Stainless Steel (SS) articulating against ultra high molecular weight polyethylene (UHMWPE) experiences scratches. These are related to the presence of entrapped particles such as UHMWPE, SS, bone and bone cement. The main type of debris that causes scratches on the metallic surface has not been clearly identified. Most clinical studies (Que and Topoleski, 2000) suggested that metal and bone debris are capable of plastically deforming the metal surface and causing scratches. However, materials as soft as UHMWPE were also claimed to be capable of causing SS to deform plastically under certain contact condition (Davidson et al. 1994).

The purpose of this study was to use the finite element (FE) method to investigate the resistance of plastic deformation of the articulating surfaces due to entrapped debris in SS-on-UHMWPE combinations, in particular to examine the metallic bearing surface as a first indication of the likelihood of producing scratches.

MATERIALS AND METHOD

A simple 2D axi-symmetric FE model was constructed to simulate an entrapped wear particle between two bearing surfaces. Both spherical and diamond-shaped wear particles were considered. The length of the bearing surfaces was chosen to be at least 4 times that of the radius of particle. The load was applied to the bearing surfaces through a contact pressure, determined from a particular hip implant. Therefore, for a spherical particle with a radius of 10 μm and maximum contact pressure of 15 MPa, the load applied to the FE model would be 0.042 N. The contact problem thus formulated was solved using ABAQUS 5.8. All the materials considered were treated as elastic-perfect-plastic with properties given in Table1. Potential failure (plastic deformation) of the metallic surface was assessed by comparing the von Mises stress prediction with the yield stress.

RESULTS AND DISCUSSION

Figure 1 shows the prediction of von Mises stress against the load applied for both the bearing surfaces and a spherical bone particle with a 10 μm radius. The corresponding deformation of the wear particle and the bearing surfaces is also shown under a load of 0.003 N (1.06 MPa). It is clear that even under these small loads, all the materials considered are deformed plastically, clearly indicating the potential scratch damage on the SS surface due to the bone wear particle. This was also found to be true for the metallic wear particle, under even smaller loads and sharp-edged cement particles. However, no

plastic deformation of the metallic bearing surface was found for spherical cement particles.

CONCLUSION

Both SS and bone particles have been predicted to cause plastic deformation of the SS bearing surface when articulating against UHMWPE. This supports the presence of scratches observed from clinical studies previously reported.

INTRODUCTION

Degeneration of the intervertebral disc (IVD) is a major factor associated with low back pain and is a prerequisite to disc herniation. Although mechanical forces are important modulators in remodeling IVD tissue, the underlying molecular mechanism remains to be investigated.

The aim of this work was to study at molecular level the effects of cyclic tensile stretch (CTS) on proteoglycan (PG) production by annulus fibrosus (AF) cells.

METHODS

AF cells of rabbit IVD were cultured at high density on flexible-bottomed culture plates. CTS was applied with use of a pressure-operated instrument to deform the plates (Flexercell Strain Unit).

The ³⁵S-labeled PGs newly synthesized and secreted from AF cells were measured under basal conditions and after CTS application. The cell content of aggrecan and biglycan messenger RNA (mRNA) was determined by Northern blotting. The elution profile on Sepharose 2B columns revealed PG aggregability after ³⁵SO₄ incorporation. Nitrite oxide (NO) production was evaluated by use of Griess reaction.

RESULTS AND DISCUSSION

The amount of ³⁵S-labeled newly synthesized PGs that accumulated in the cellular pool or were secreted in the culture medium did not change when CTS was applied with 1% elongation at 1 Hertz frequency.

In contrast, with 5% elongation at 1 Hertz frequency, the level of newly synthesized PGs in the cellular pool and in the culture medium was significantly reduced after 8 hours of stimulation (30% and 21% respectively) and further reduced at 24 hours (43% and 41% respectively). Introducing the protein synthesis inhibitor cycloheximide had no effect on this result. Neither aggrecan and biglycan expression nor PG physical properties were modified. The level of NO production significantly increased by 3.5 times after 8 hours of 5% elongation. Introducing the nitric oxide synthases inhibitor N^G-methyl-L-arginine (L-NMA) eliminated the effects of CTS on NO and PG production.

synthesized (black columns) and secreted (white columns) PGs by stretched AF cells as compared with unstretched cells (C).

SUMMARY

Under our culture conditions, CTS regulates PG production by AF cells in a dose dependant manner through a post-translational event depending on NO production. These results suggest that CTS can participate in the regulation of the IVD matrix by decreasing PG production through NO regulation. This result could be of interest in developing local therapeutic strategies aimed at inhibiting IVD degeneration.

INTRODUCTION

While there is little data describing the biomechanics of youth baseball pitchers, understanding the mechanics of this group is important for several reasons: (1) the population of youth pitchers is much larger than that of elite athletes, (2) injuries due to overuse and poor throwing mechanics are common in youth pitchers, and (3) the pitching mechanics of less skilled pitchers may lead to different stresses on the upper extremity than occur in professional pitchers. Unique aspects of the developing skeleton make it susceptible to a spectrum of injuries not commonly seen in adult athletes. Although these injuries are most likely due to the musculoskeletal changes occurring during growth, they may also be, at least in part, due to pitching technique. The aims of the current study were to compare youth pitching biomechanics with that of elite adult pitchers and to identify important differences that might explain common injuries seen in the youth pitcher population.

METHODS

Twenty-five professional and 14 youth baseball pitchers were filmed at 120 Hz using two high-speed video cameras. The locations of 21 body landmarks were digitized and their three-dimensional locations were calculated using the DLT method (Abdel-Aziz & Karara, 1971). Three-dimensional position data was filtered using a fourth order Butterworth filter with a cutoff frequency of 13 Hz. From the marker coordinates, the kinematics of the pitching elbow and shoulder were calculated using a standard technique (Fleisig et al., 1996; Werner et al., 1993). Kinematic data was normalized in time to facilitate comparisons and so group mean values could be calculated.

RESULTS AND DISCUSSION

Descriptive statistics for the two groups are provided in Table 1. There are three important findings from our kinematic data. First, the peak shoulder internal rotation and elbow extension angular velocities of the youth pitchers were greater than those of the professional pitchers. Second, the youth pitchers used less shoulder external rotation than the professional pitchers. Peak shoulder external rotation in youth pitchers was $166 \pm 9^\circ$, compared with $182 \pm 13^\circ$ in professionals ($p < 0.001$). The most striking difference between the groups was in their trunk motion. The peak rotational velocities of both the upper trunk and pelvis were greater in youth baseball pitchers than in professional pitchers. Peak upper trunk rotational velocity was $2102 \pm 324^\circ/\text{s}$ in youth pitchers and $1193 \pm 176^\circ/\text{s}$ in professional pitchers ($p < 0.001$, Figure 1).

Table 1. Mean (S.D.) values describing the subject groups.

	Age (yr)	Height (m)	Mass (kg)	Ball V (m/s)
Pro	26.8 (2.9)	1.88 (0.05)	88.7 (9.2)	38.8 (2.0)
Youth	13 (0)	1.54 (0.08)	43.8 (8.6)	21.6 (1.8)

Figure 1. Upper trunk angular velocity of the two groups.

In contrast to the published literature (Fleisig et al., 1999), we found several significant kinematic differences between youth and professional pitchers. Our data support the observation that youth baseball pitchers control their trunk motion in a less efficient way than elite pitchers (Ireland & Hutchinson, 1995). Peak pelvis rotation velocity occurred near the time of stride foot contact in the professionals, while it occurred much later in the youth pitchers. Proper timing of pelvis and upper trunk rotation are necessary to effectively transfer energy from the trunk to the throwing arm (Fleisig et al., 1996). Therefore, increased trunk rotational velocity may be a compensation for improper timing of segment rotations or insufficient muscle strength (Ireland & Hutchinson, 1995) in youth pitchers. Improper energy transfer from the trunk to the upper extremity may lead to the increased shoulder internal rotation and elbow extension velocities in youth pitchers compared to the professionals. Our data also indicates that trunk rotation is related to the peak shoulder distraction force during the pitch.

SUMMARY

Significant kinematic differences were found between youth and professional pitchers. The greatest differences were in trunk rotation, likely to make up for a lack of upper body strength or proper timing in youth pitchers. Improper trunk control may have implications for shoulder injuries in youth pitchers, such as proximal humeral epiphysitis.

MECHANICAL AND PERFORMANCE ASPECTS OF A NEW SPEED SKATE DESIGN

Scott Van Horne, Darren Stefanyshyn, Ruth Morey Sorrentino

Human Performance Laboratory, University of Calgary, Calgary, AB, Canada

INTRODUCTION

Speed skating has seen many innovations in the last five years. The most note worthy is the induction of the klapskate. The klapskate permits the shoe to rotate on a hinge relative to the blade. Therefore, allowing plantar flexion with the blade remaining flat, gliding on the ice (Houdijk, 2001).

Raps Co. has recently developed a new skate, coined the "3D", where the klap mechanism is mounted at an offset angle, meant to create a more natural push movement. The klap mechanism is rotated 10 degrees about an axis through the transverse plane, and rotated 14 degrees about an axis through the frontal plane. Therefore, as the Raps klap opens the foot is either more everted throughout the rotation or the blade is more vertical, than with the regular klap.

The 3D was speculated to affect biomechanics in the frontal and transverse plane. More specifically it was speculated that the 3D mechanism would cause a decreased horizontal impulse during the end of the push phase, when the klap is opening, resulting in a less effective push and a slower overall speed. Also, it was speculated that the 3D would cause a greater maximum frontal plane ankle moment, and a greater ankle eversion.

The purpose of this study was to analyze kinetics and kinematics of the lower leg and foot throughout a speed skating push, and to test the above speculations.

METHODS

Eight experienced speed skaters participated in the study. All eight performed a test speed skating push with their own boot and klap mechanism compared to the Raps boot with 3D mechanism (exp1). Subjects performed 6 trials with each condition, kinematic and kinetic data were collected in the lab while, on a modified slideboard apparatus. Five subjects performed on-ice, pre-test and post-test, 100m and 400m, time trials for three conditions: (1)their own boot and mechanism, (2)their own boot and 3D mechanism, (3)their own boot and regular Raps mechanism (exp2). The 3rd condition was included to control for different types of metal used in the mechanism and blade. A two week training period on the 3D mechanism was implemented between the pre and post-test. All performance tests were done on a 400m oval track. Exp 1 was analyzed with a paired t-test ($\alpha = .05$). Exp 2 was analyzed with an ANOVA ($\alpha = .05$).

RESULTS AND DISCUSSION

In exp1, when subjects wore their own boot and mechanism opposed to the Raps boot and 3D mechanism they had a 2.1% higher horizontal impulse (integral of the force-time curve). No significant differences were found in the maximum frontal plane moment at the ankle joint or in the minimum angle scribed by the ankle joint about the frontal axis (ankle eversion), indicating that the mechanics at the ankle were unaffected by the 3D mechanism.

Figure 1: Time to complete a maximal effort 400m lap. Data presented are averages and standard deviations for five subjects. * indicates a significant difference between conditions 1 and 2. # indicates a significant difference between conditions 2 and 3.

In exp 2 a significant difference was found during the pre-test and post-test between condition 2 and conditions 1 and 3, during the 400m time trial. Pre-test results had subjects with the 3D taking an average of 2.7 seconds longer. Post-test results had subjects with the 3D taking an average of 1.2 seconds longer. The 100m time trial showed no significant differences. The above results indicate some sort of detriment of the 3D occurring potentially during the turns, and during constant velocity skating. If during the turn, the horizontal force is decreased the resulting velocity will be decreased or the radius of the skating path will be increased, both resulting in a slower overall lap time. Also, if a smaller horizontal impulse is generated during the straight there will be less acceleration of the center of mass perpendicular to the direction of the pushing blade, and a decreased forward velocity.

Table 1: Mean values and standard deviations for different push-off mechanics with 3D and regular klap. Significance indicated by *

Variable	Vertical Impulse (Ns)	Horizontal impulse (Ns)	Frontal Ankle Moment (Nm)	Frontal Ankle Angle (°)
3D klap	351.65 (28.60)	176.65 (25.92) *	89.65 (24.10)	84.87 (6.63)
Regular klap	358.80 (35.24)	180.33 (25.77) *	86.92 (20.50)	83.22 (5.13)

INFLUENCE OF A FOLLOWER LOAD ON THE MECHANICAL BEHAVIOR OF THE LUMBAR SPINE

Antonius Rohlmann, Thomas Zander, Georg Bergmann

Biomechanics Laboratory, University Hospital Benjamin Franklin, Free University of Berlin, Berlin, Germany

INTRODUCTION

The spine is stabilized mainly by muscle forces, and little is known about these forces. Several groups have recommended pure moments in the three anatomical planes without an axial preload. The great advantage of pure moments is that all levels bear the same constant load. The reason for no preload is that even low preloads lead to buckling of multisegmental specimens and thus to uncontrolled motion. Patwardhan et al. [1999], by introducing a follower load, were the first to present a feasible technique for the experimental application of a physiological spine load. A follower load is a compressive load applied along a follower load path that approximates the tangent to the curve of the spine, thus subjecting the whole specimen to nearly pure compression. It has a similar effect as the short local muscles. The aim of this study was to show analytically the influence of a follower load on the mechanical behavior of the lumbar spine.

METHODS

A three-dimensional, nonlinear finite element model of the human osseoligamentous lumbar spine was created (Fig. 1).

Figure 1: Outer mesh of the finite element model of the lumbar spine with follower load.

The element mesh of the vertebrae is based on the model used by Smit [1996]. The nucleus pulposus was simulated by an incompressible fluid-filled cavity and the annulus fibrosus by volume elements with superimposed spring elements representing the fibers. The facet joints could only transmit compressive forces. The capsule of the facet joints and the six ligaments of the lumbar spine were included. The mainly nonlinear material properties of all tissues were taken from the literature. First, the model was successively loaded in flexion/extension, right/left lateral bending, and right/left axial rotation with moments up to 10 Nm. In a second step the model was loaded by an additional follower load [Patwardhan et al, 1999; Rohlmann et al, 2001] of 250 N to simulate the stabilizing effect of the local muscles acting directly on the lumbar spine. The load was generated by four forces acting on the circumference of each vertebral body, their lines of action leading to the corresponding points of circumference of the adjacent vertebral bodies (Fig. 1). The finite element model is described in detail elsewhere [Zander et al. 2001]. The finite element program ABAQUS was used. The computer model

was validated by reference to experimental data from *in vitro* measurements [Rohlmann et al. 2001; Zander et al. 2001].

RESULTS

Flexion/extension

A follower load had only a minor influence on intersegmental rotation but it increased intradiscal pressure strongly to physiological values. Intradiscal pressure was higher for extension than for flexion.

Lateral bending

For lateral bending too, a follower load had only a negligible effect on intersegmental rotation. Without a follower load, intradiscal pressure increased with increasing bending moment, up to a moment of about 2 to 3 Nm. For higher bending moments intradiscal pressure decreased. When a follower load was also applied, intradiscal pressure decreased with increasing moment. For all bending moments intradiscal pressure was significantly higher when a follower load was applied.

Axial rotation

Again, a follower load had only a minor influence on intersegmental rotation. Intradiscal pressure increased slightly with the applied torsional moment. A follower load shifted the pressure curves to physiological values.

DISCUSSION

The effect of a follower load on intradiscal pressure and intersegmental rotation of the lumbar spine was determined using the finite element method. Good agreement was achieved with experimental data [Rohlmann et al, 2001]. Both methods showed that a follower load has only a minor effect on intersegmental rotation.

In this study, a follower load of only 250 N was applied but even when it was increased to 1000 N the computer model remained stable. A follower load should not simulate the body weight but the short local muscle forces which stabilizes the spinal segments and which depend on several factors. The body weight has to be stabilized by the global muscles.

A follower load increases the intradiscal pressure to physiological values, stabilizes the spine so that additional single forces representing a muscle can be applied, and in contrast to a preload, has only a minor influence on lumbar lordosis.

INTRODUCTION

Ischemia is a central pathomechanism in many acute and chronic diseases. Both persistent ischemia and subsequent organ reperfusion are frequently associated with leukocyte infiltrates, and this inflammatory response play a major role in causing ischemia associated organ dysfunction and damage(Yamazaki et al,1993). Leukocyte infiltration requires a chain of reactions between endothelial cells (EC) and leukocyte that initially retards intravascular leukocyte flow and finally leads to leukocyte transmigration through the endothelial monolayer. These events are mediated by sequential interaction of different endothelial adhesion molecules with cell surface receptors on leukocytes. A crucial step between the initial contact and final transmigration of leukocytes is their tight adhesion to EC, which is mainly mediated by the endothelial transmembrane receptors intercellular adhesion molecule-1 (ICAM-1) and vascular adhesion molecule-1 (VCAM-1). One of the cytotoxic products of neutrophil, promotes the adhesion of neutrophil to EC(Ichikawa et al,1997). The objectives of the present study were to investigate the effects of H₂O₂ on adhesion molecules expression in cultured human umbilical endothelial cells (HUVEC).

METHODS

Endothelial cells were isolated from human umbilical cord veins by collagenase treatment as described by Jaffe and modified. The Endothelial cells between 2 and 4 passage were treated with H₂O₂ at different concentrations. Surface expressions of ICAM-1, VCAM-1 and E-selectin were labeled by incubating the cells with fluorescence monoclonal antibodies of anti- ICAM-1, VCAM-1 and E-selectin in dark. Data acquisition and analysis were performed using an flow cytometry.

RESULTS AND DISCUSSION

The results showed that: 1) after treated with 250 $\mu\text{mol/L}$ H₂O₂, ICAM-1 expression increased(Fig.1). VCAM-1 expression was maximally induced 2h after stimulation, and then gradually descended. It was also observed that 3h after stimulation, the E-selectin expression began to be up-regulated significantly, and peak induction was obtained 5h after H₂O₂ stimulation. 2) Concerning the treatment of HUVECs with different concentrations of H₂O₂, ICAM-1 and VCAM-1 were maximally induced by 250 $\mu\text{mol/L}$ H₂O₂. E-selectin peak induction was obtained by 350 $\mu\text{mol/L}$ H₂O₂(Fig2).

These results have extended previous observation which showed that adhesion molecules expression on endothelium was a critical factor in the H₂O₂-induced neutrophil adhesion to the endothelium. This study may contribute to the comprehension of the adhesion and transmigration of leukocytes in ischemia-reperfusion injuries (Willam et al, 1999).

Fig.1 Time course of adhesion expression induced by H₂O₂

Fig.2 The effects of different concentrations of H₂O₂ on expression of adhesion molecules

SUMMARY

Cytotoxic product, H₂O₂, of neutrophils contributed to ischemia reperfusion injury can increase the expression of adhesion molecules in ECs. Therefore, H₂O₂ may promote the inflammation process.

TIME-DEPENDENT EFFECTS OF INTERLEUKIN-8 GENE EXPRESSION IN ENDOTHELIAL CELLS EXPOSED ON FLUID SHEAR STRESS

Zhang Wensheng¹ Chen Huaqing¹ Chen Youqin¹ Yang Yuan² Liu Xiaoheng¹

¹Institute of Biomedical Engineering, West China Medical Center, Sichuan University, Chengdu 610041, chq@wcums.edu.cn

INTRODUCTION

Vascular endothelial cells not only are the natural barrier, which separates flowing blood from the wall of vascular vessels, but also mediate a variety of physiological and pathological processes. Fluid shear stress plays an important role in vascular biology. In vivo, endothelial cells are continuously exposed to mechanical shear stress generated by the flowing blood. Previous studies have identified that the exposure of vascular endothelial cells to fluid mechanical forces can modulate the expression of many genes involved in vascular physiology and pathophysiology (Papadaki, 1997). In order to investigate that IL-8 mRNA expression of endothelial cells is not only regulated by chemical factors, but also by mechanical stresses, we employed quantitative reversal transcription-polymerase chain reaction (qRT-PCR) to assay the expression of IL-8 mRNA and its time course in human umbilical vein endothelial cells (HUVECs).

METHODS

Endothelial cells were isolated from human umbilical cord veins by collagenase treatment as described by Jaffe and modified. The cells were grown in M199 medium and the cells used were mainly prior to passage 3 or 4. Cell culture was maintained in a humidified 5% CO₂/95% air incubator at 37°C. A flow system was established according to the design previously described (Chen HQ, 2001). The same cultured medium was used to shear HUVECs. Shear stresses of 2.2, 4.2, and 6.1 dyne/cm² under laminal flow were generated by a peristaltic pump. Cells from static controls or from shear experiments were washed twice with PBS, and total cellular RNA was isolated by TRIzol reagent according to manufacturer's manual. Quantitative RT-PCR assay involves LightCyclerTM technology. Experimental protocol were performed by instruction manual of LightCycler-RNA Amplification Kit SYBR Green I.

RESULTS AND DISCUSSION

Quantitative RT-PCR analysis revealed that IL-8 mRNA did not express in HUVECs untreated with fluid shear stress. IL-8 mRNA expression increased (7.7×10^6 , 7.0×10^6 , and 5.1×10^6 copies, respectively) when HUVECs exposed to the three shear stress for 1h, and it reached the summit (increased ~3.3, 2.1, and 2.9-fold, respectively) when HUVECs exposed to shear stress for 2h. Then IL-8 expression gradually decreased to 73%, 87%, and 89% respectively against 2h shear stress treatment at 3h of stimulation by shear stress and remained at a constant level (2.3×10^6 ~ 2.2×10^5 copies) throughout the time course of the study. The increase of IL-8 mRNA expression by shear stress was

time-dependent (Fig 1). IL-8 gene expression in response to shear stress was very similar to NF- κ B in response to shear stress. The induction of IL-8 gene expression by fluid shear stress is probably due to the activation of NF- κ B. Shear stress can activate AP-1 and NF- κ B latent in the cytoplasm through mechanical signal transduction pathways (Lan, 1994). It is reasonable to conclude that translocated AP-1 and NF- κ B may activate IL-8 transcription (Roebuck KA, 1999). These considerations suggest that IL-8 expression induced by shear stress in HUVECs may play an important role in the genesis and development of both inflammation and arterio-atherosclerosis.

SUMMARY

This in vitro study demonstrates the expression of IL-8 gene can be regulated by shear stress. Shear stress induces the HUVECs to express IL-8 mRNA in a time-dependent fashion.

EFFECTS OF SHEAR STRESS AND LYSOPHOSPHATIDYLCHOLINE ON ADHESION MOLECULES EXPRESSION OF ENDOTHELIAL CELLS

Chen Youqin Chen Huaqing Zhang Wensheng Liu Xiaoheng

¹Institute of Biomedical Engineering, West China Medical Center, Sichuan University, Chengdu 610041, chq@wcums.edu.cn

INTRODUCTION

Numerous studies suggest that normal function of the endothelium is critical in limiting the development of atherosclerosis. Impairment of these endothelial cells-mediated processes has been postulated to play a central role in the pathogenesis of atherosclerosis. Extensive monocyte recruitment is an early phenomenon associated with the development of atherosclerotic lesion (Ross, 1999). Although the molecular mechanisms are not completely understood, monocyte recruitment into these early lesions may involve changes in endothelial adhesion for monocyte, in which adhesion molecules expressed by endothelial cell play an active role. In vivo, the function of endothelial cells is not only affected by the chemical factors, but also by the mechanical factors. The purpose of this article was to investigate the induction of adhesion molecules expression by synergistic effects of Lysophosphatidylcholine (Lyso-PC) and shear stress in cultured human umbilical vein endothelial cells (HUVEC).

METHODS

Endothelial cells were isolated from human umbilical cord veins by collagenase treatment as described by Jaffe and modified. A flow system was established according to a described design (Chen et al, 2001). The Endothelial cells between 2 and 4 passage were seeded on a 25mm×75mm slide to confluence, which can provides $1.5-2.0 \times 10^5$ cells for the following protocol. The slide of endothelial cell monolayers subjected to shear stress (2.2 or 4.2 dyne/cm²) or treated with 30 µg/ml Lyso-PC for 5hr, and were either exposed simultaneously to Lyso-PC and shear stress for 5hr, or two stimuli were applied sequentially. The medium was maintained at a constant pH by gassing with 5% CO₂ and 95% air, and the temperature was maintained at 37°C. By immersing the flow system in a water bath. Laminar shear stress was generated by a peristaltic pump. Surface expression of ICAM-1, VCAM-1 and E-selectin was studied by incubating the cells with fluorescence labeling monoclonal antibodies of anti- ICAM-1, VCAM-1 and E-selectin in dark. Data acquisition and analysis was performed using an flow cytometry.

RESULTS AND DISCUSSION

Comparing with the control group, shear stress or Lyso-PC can alone up-regulate the expression of ICAM-1 and VCAM-1, but can not increase the expression of

E-selectin. When the shear stress and Lyso-PC are applied simultaneously on HUVECs, the expression of ICAM-1 and VCAM-1 are increased more significantly than that in the control group, but are not higher than that in the only Lyso-PC group. Activating the cells with Lyso-PC prior to shear stress, or with shear stress prior to Lyso-PC incubation, result in a significantly higher expression of ICAM-1, VCAM-1 and E-selectin, especially at low shear stress (2.2 dyne/cm²). We suggest that shear stress or Lyso-PC up-regulated ICAM-1 expression, which accounts for the increase of neutrophil adhesion to endothelial cells in the inflammatory response (Sampath, 1995). The increase of VCAM-1 expression can be correlated to the increase of monocyte adhesion in the low shear stress regions of arteries, and may play an important role in monocyte recruitment into the atherosclerotic lesions (Mohan, 1999). However, a sequential action of the shear stress or Lyso-PC induced an even greater expression of ICAM-1 and VCAM-1, thus it can be seen that the response of shear stress in combination with endothelial activation may increase the ability of these cells to recruit leukocytes under settings of inflammatory and atherosclerosis even under an otherwise unfavorable mechanical environment.

SUMMARY

A sequential action of the shear stress and Lyso-PC induces high expression of ICAM-1 and VCAM-1. Thus it could be understood that the flow shear stress in combination with endothelial activation by chemical factors may increase the ability of endothelial cells to recruit leukocytes even under the mechanical environment unfavorable for cell adherence.

THE ASSESSMENT OF SPINAL MOTION DURING ROWING

Peter Holt¹, Peter Cashman², Anthony Bull², Alison McGregor¹

INTRODUCTION

Low back pain is a common problem amongst competitive rowers at all levels. It is not clear why this occurs. Currently little is known regarding the kinematics of the spine during rowing and its relationship to rowing technique and to the loads generated during rowing. The present study sought to address this and to examine the effects of fatigue and stretching on these movements.

METHODS

A method was developed for measuring rowing technique on a Concept IIC rowing ergometer by combining the use of an electromagnetic motion capture system, The Flock of Birds (Ascension Technology, USA) to record the motion of the spine and pelvis (Bull & McGregor 2000) and a load cell (Oarsum, Australia) to record the force produced at the ergometer handle. The outputs from these two systems were synchronised and continuously recorded using custom software. Thirteen elite national and international oarsmen (mean age 22.4, S.D. 0.1 years) were recruited into this study. Using the experimental system, rowing stroke profiles were quantified in terms of lumbopelvic kinematics and stroke force profiles during a one hour training rowing piece, with recordings being taken at the start of the session and at quarterly intervals during the hour session. Seven of the athletes returned the following week and repeated the experimental protocol with the addition of a brief rehydration and stretching break of 3 minutes 30 minutes into the rowing piece, to establish whether this would have any impact on the stroke profiles.

RESULTS

The figure alongside depicts a typical force curve output starting at the catch position together with a measure of the lumbar spine motion during the stroke with quantification of lumbar spine motion relative to the stroke force profile. Using this data, the rowing stroke was divided into key stages, and the curve gradients, angles of curvature and force magnitudes were obtained. These variables were calculated for each of the 4 sample periods over the one hour test and were compared using analysis of variance. This revealed marked changes and increases in the amount of spinal motion ($p < 0.001$) during the hour rowing piece ($-0.7^\circ \pm 1.4$ at

the start of the training piece and $-2.3^\circ \pm 2.3$ at the end). This led to a later percentage value for maximum spinal extension as the back had to move through a greater range to achieve the same finish position ($36.3^\circ \pm 4.3$ to $38.0^\circ \pm 8.5$). This suggests that in trying to maintain a consistent stroke force profile athletes were utilising greater ranges of spinal motion as they fatigued. The inclusion of a break in the middle of the training program appeared to reduce some of these changes.

DISCUSSION

The findings of this study provide a clearer understanding of the mechanics of rowing. Subtle but definite changes in the kinematics were noted as a result of fatigue and these changes may be associated with potential injury mechanisms. The effect of including the brief break during training suggests that such changes in technique are reversible, but further detailed work is required in this area.

INTRODUCTION

The cervical muscle's involvement in whiplash has just recently been addressed (Brault, 1998; Magnusson, 1998, 1999). Epidemiological results show women have higher rates of whiplash than men (Spitzer, 1995). We hypothesized that the cervical muscle responses influence the biomechanics of whiplash and would be different between genders.

METHODS

The 24 subjects (12M, 12F) were seated on a car seat mounted on a sled propelled by a spring and latch release mechanism and was accelerated less than .5 g. The sled mass was normalized by gender. There were 6 randomized unexpected trials (4 release, 2 w/o release). Auditory and visual cues were masked. Bilateral surface EMG recorded sternocleidomastoid (Scm), paraspinals (Para), and trapezius (Trap) using bipolar pre-amplified electrodes acquired at 1000 Hz. Normalized EMG were analyzed using Wavelet Analysis. The Motion Monitor (Innovative Sports Training, Inc.) and a 6° of freedom magnetic sensor tracking system (Ascension Tech.) collected 3-D kinematics and were synchronized to EMG. Sensors were attached to sled, head, T1, T12, and sacrum. An accelerometer on the sled insured reproducibility of acceleration.

RESULTS AND DISCUSSION

Significant anthropometric differences between genders were identified (Table 1). Results show a significant interaction of gender to muscle with respect to duration of muscle contractions ($p = .00018$) and reaction times with respect to head and torso motion for all directions (x ant. -post., y med.-lat., z sup. -inf.) ($p < .0001$) (Fig.1-2). The coplanar and coupled motions of the head and cervical spine in reference to the torso is due to the anatomical structure of the cervical vertebrae and floppy nature of the head. Females showed an increase in torso angular acceleration, angular velocity, and greater kyphotic torso and cervical lordosis positions. The frequency of head and neck movement was ~2-3Hz and is representative of the range for whiplash research (~2-8 Hz). Synchronization of EMG with kinematics indicates eccentric muscle responses which when coupled with the frequency and smaller muscle mass may increase female's risk of injury.

Table1: Mean Subject Age and Selected Anthropometry (SD)

	Female (N=12)	Male (N=12)	P (* $p < 0.05$)
Age (yrs)	24.67 (5.71)	30.33 (8.42)	0.0668

Cer. Flex. (°)	72.8 (2.2)	66.5 (5.2)	0.0008*

Figure 1: Male Muscle Response: x= ant. -post. y= med.-lat., and z =sup.-inf.; 1=ScmR, 2=ScmL, 3=ParaR, 4=ParaL, 5=TrapR, and 6=TrapL

Figure 2: Female Muscle Response: x=ant. -post., y= med.-lat., and z =sup.-inf.; 1=ScmR, 2=ScmL, 3=ParaR, 4=ParaL, 5=TrapR, and 6=TrapL

SUMMARY:

The cervical muscle's response to perturbations is rapid enough to effect biomechanical responses. In frequency ranges of 2-8 Hz the amplitude of the head acceleration is augmented, and oscillation about a center of rotation low in the body may induce large angular movements due to the linear component of acceleration delivered to the cervical vertebrae. Female muscle onset times are related to the timing and frequency of the movement of the torso and head. These factors plus angular accelerations, increased kyphosis, and eccentric contraction may increase female cervical injuries (Ono, 1997).

THE PROXIMAL-DISTAL SEQUENCE IN OVERARM THROWING AND THE EFFECT OF BALL WEIGHT

Roland van den Tillaar and Gertjan Ettema

Department of Sport Science, Norwegian University of Science and Technology, Trondheim, Norway
rolandv@svt.ntnu.no

INTRODUCTION

In overarm throwing, the temporal proximal-distal sequence (TPDS) of the different segments of the upper body is theoretically of major importance for the generation of high speed (e.g. Herring & Chapman, 1992). However, experimental data are inconclusive on this issue: whereas Jöris et. al. (1985) found supporting evidence, other studies have found that in overarm throwing this sequence does not occur between the shoulder and elbow segments (Hosikawa and Toyoshima, 1976). In the present study, this issue was further investigated under various loading conditions (i.e. ball weight). It was hypothesized that heavier ball weight may create relatively higher reaction forces that could affect movements in the slender distal and more bulky proximal segments differently.

METHODS

Seven Norwegian experienced male handball players performed maximum speed throws, using 7 different balls that only differed in weight (0.2-0.8 kg.). Each ball was used 5 times, in random order. The throwing target was a 0.5 by 0.5m square at approximately shoulder height (1.65m) at a 4m distance. Displacement of ball and segments (wrist, elbow, shoulder and hip) was recorded using a ProReflex motion capture system (five infrared cameras, 240Hz.) Linear velocity (v) and acceleration of ball and velocity of segments was calculated using a 5-point differentiating filter on the absolute 3D displacement. The force applied to the ball was calculated as the product of its acceleration and mass. The moment of ball release was identified as the time where a sudden and dramatic separation of wrist and ball occurred. Angular velocity (ω) of elbow, wrist and shoulder were also analysed.

RESULTS AND DISCUSSION

Ball weight had a negative effect on ball velocity ($r=-0.91$ or higher). This relationship with ball weight was also apparent for maximum linear velocity of the wrist and elbow, as well as the maximum elbow extension velocity and internal rotation of the shoulder. The maximum force applied to the ball increase with ball weight ($r=-0.64$).

The maximum linear velocity of the shoulder occurred later in time than that of the elbow (t-test, $p<0.001$) (figure 1). Furthermore, the maximal angular velocity of the wrist occurred earlier than that of the elbow ($p<0.001$), which is confirming finding by Hong et. al. (2001). The maximal internal rotation velocity of the shoulder did not occur before ball release (figure 1), which was also found by Matsuo et al. (2001).

No effect of ball weight on relative timing of the aforementioned kinematic events were found. The

sequential order of segment movements remained unaltered when changing ball weight.

An explanation for the early maximum elbow velocity could be that the elbow extension causes an enhanced reactive force on the elbow segment, reducing its speed: in figure 1 this is indicated by the coincidence of onset of elbow extension and maximum elbow segment linear velocity. The shoulder segment is not necessarily influenced by this in the same manner.

Figure 1: Example of linear and angular velocity.

Also the early occurring maximum wrist flexion velocity is not according to TPDS. The reason of this may be because of the biarticular characteristic of the majority of the wrist flexors that have a significant elbow flexion action as well (Ettema, et al., 1998). Elbow extension may therefore initiate early flexion of the wrist.

SUMMARY

Ball weight does not have a substantial effect on coordinative timing aspects in overarm throwing by experienced handball players. The timing is not in accordance with the generally accepted proximal-distal joint sequence. It is therefore concluded that, within the boundaries of the experiment (i.e. throwing a relatively light object) the proximal-distal sequence in overarm throwing does not hold. Furthermore, this movement sequence seems the result of a built-in coordination strategy rather than of external reaction forces (generated by the ball mass).

EFFECT OF DIFFERENT PEDAL RATES ON ENDURANCE AND PHYSIOLOGICAL RESPONSES DURING CYCLING AT HIGH SUB-MAXIMAL EXTERNAL POWER

Jens Steen Nielsen¹, Ernst Albin Hansen¹, and Gisela Sjøgaard²

Email: js.nielsen@sportmed.sdu.dk

¹Institute of Sports Science and Clinical Biomechanics, University of Southern Denmark, Odense

²National Institute of Occupational Health, Copenhagen, Denmark

INTRODUCTION

Freely chosen pedal rate (FCPR) increases with increased external power (Hansen et al. 2002). Interestingly, at low sub-maximal external power the FCPR is considerable higher than the pedal rate at which oxygen uptake is the lowest, i.e. the most efficient pedal rate. However, as the external power increases the FCPR and the most efficient pedal rate seem to merge. Accordingly, it was recently shown that FCPR and the most efficient pedal rate were similar during cycling at external power corresponding to 80% of the maximal oxygen uptake (VO_{2max}) (Brisswalter et al. 2000). Efficiency is an important factor affecting endurance during cycling at sub-maximal external power. It was therefore hypothesized that cycling at high sub-maximal external power with FCPR would result in a prolonged endurance compared with higher as well as lower pedal rates. The purpose of the present study was to examine this hypothesis.

METHODS

Twenty males (26.3 ± 3.5 years, 178 ± 5 cm, and 73.3 ± 7.5 kg) volunteered. A progressive test was performed on a Monark cycle ergometer (Monark AB, Varberg, Sweden) with a pedal rate of 80 rpm for determination of VO_{2max} and external power corresponding to 90% of VO_{2max} (W90%). Another test was performed on a racing bicycle placed a motorized treadmill (Woodway GmbH, Weil am Rhein, Germany) for 5 min at W90%. This test was performed to determine the FCPR. The set-up allowed the subjects to freely choose a pedal rate in the range of the pedal rates typically used during road cycling. The subjects were allowed 3 min to experiment with the gear ratio before selecting their FCPR. During the final 2 min the FCPR was maintained while external power, heart rate (HR), and pulmonary gas exchange were measured. Subsequently, 3 endurance tests were performed on a Monark cycle ergometer at the FCPR (determined on the treadmill), FCPR-25%, and FCPR+25%, in randomized order. The tests were performed at the same weekday and hour of the day. Endurance was determined as the time from start to the point of time where the subjects were unable to maintain the target pedal rate minus 10%. Douglas bags were collected between the 3. and the 5. min for measurement of oxygen uptake (VO_2), pulmonary gas exchange and respiration exchange ratio (RER). At the 5. min also blood lactate concentration (using an YSI Model 1500 Sport, YSI Incorporated, Yellow Springs, USA), heart rate (HR), and rating of perceived exertion (RPE) were measured. In all tests the external power and HR were measured with a SRM crank dynamometer (Schoberer Rad Messtechnik, Jülich, Germany).

RESULTS AND DISCUSSION

The progressive test resulted in VO_{2max} of 4.418 ± 0.61 l/min, maximal HR of 190 ± 10 beats/min, blood lactate concentration of 12.2 ± 2.0 mM, and RER of 1.20 ± 0.05 . Further, W90% was determined to be 325 ± 47 W while FCPR at W90% was 78 ± 11 (59-96) rpm. During treadmill cycling with FCPR the VO_2 , RER, and V_E were 4.115 ± 0.57 l/min, 1.11 ± 0.07 , and 127.5 ± 24.3 l/min, respectively. During the endurance tests pedal rates were 58 ± 8 , 78 ± 11 , and 96 ± 13 rpm at FCPR-25%, FCPR, and FCPR+25%, respectively. There was no difference between external power in endurance tests performed with the three different pedal rates. Endurance time at FCPR-25% and FCPR were 19% and 25% longer compared to FCPR+25% (Tab. 1).

	FCPR-25%	FCPR	FCPR+25%
Endurance (sec)	547 ± 170	589 ± 239	441 ± 188^a
VO_2 (l/min)	4.016 ± 0.55	4.091 ± 0.57^b	4.298 ± 0.54^a
V_E (l/min)	116 ± 25	121 ± 27	134 ± 31^a
Lactate (mM)	7.4 ± 2.0	8.1 ± 2.1	10.1 ± 2.5^a
HR (beats/min)	175 ± 8	176 ± 11	181 ± 7^a
RPE	17.0 ± 1.4	16.7 ± 1.2	17.2 ± 1.8

Tab. 1 Results from the endurance tests. ^a=significantly different from FCPR-25% and FCPR. ^b=significantly different from FCPR-25% and FCPR+25%.

SUMMARY

We showed that endurance time during cycling at high sub-maximal external power was 19-25% longer at FCPR and FCPR-25% compared with FCPR+25%. The shorter endurance time at FCPR+25% compared with FCPR could be explained by the higher energy expenditure at this pedal rate as identified by higher values of HR, VO_2 , blood lactate concentration, and V_E . Interestingly, VO_2 was lower at FCPR-25% compared with FCPR and endurance time could therefore be expected to be longer at FCPR-25% compared with FCPR. However, decreasing the pedal rate results in higher mean and peak pedal forces that might cause a higher peripheral strain feedback during pedaling and thereby limit the time to exhaustion i.e. the endurance.

NEUROMOTOR ACCOMMODATION TO MULTIPLE TRANSFEMORAL PROSTHESIS ALIGNMENTS

Mark D. Geil, Ph.D. (mark.geil@hps.gatech.edu)

Georgia Institute of Technology, Atlanta, Georgia

INTRODUCTION

The alignment of a lower-limb prosthesis involves the spatial orientation of the components with respect to one another. Prosthetists usually conduct dynamic alignment based on observation of gait and a few simple measures. It is unclear what outcomes of gait the practitioner considers most desirable, and while a set of gross gait deviations is avoided, the goals of dynamic alignment are generally prosthetist-specific. This investigation sought to quantify gait outcomes when multiple practitioners “optimally” aligned the same prosthesis for the same subject. The investigators hypothesized large variability in self-selected walking speed, ground reaction force, and joint kinematics.

METHODS

The study measured the kinematics and kinetics of the gait of a single subject walking with a prosthesis aligned by five different prosthetic practitioners. The subject was a 36 year old active male unilateral left transfemoral amputee 10 years post-trauma. The prosthesis included an ischial containment socket, Mauch knee, and Otto Bock 1C40 foot. Informed consent was obtained.

Although all were actively practicing, practitioners ranged widely in certification and years of experience. The subject in the study was a certified prosthetist, and was included among the five practitioners. For each analysis, the prosthesis was disassembled distal to the socket. Each practitioner assembled and aligned the components based on whatever measurement and gait observation he or she deemed necessary. The subject was then allowed time to become accustomed to the alignment and an instrumented gait analysis was conducted.

After a static trial quantified weight-bearing alignment, kinematics were measured at 60 Hz and kinetics at 300 Hz while the subject walked at a comfortable, self-selected speed. Wherever possible, markers remained on the prosthetic components upon disassembly; care was taken to return any removed markers to the same location for each analysis.

RESULTS

Instrumented gait analysis revealed quantifiable static frontal and sagittal plane differences in the alignments conducted by different practitioners. Despite the differences in the alignments of the practitioners, mean self-selected velocity of

gait showed only small differences between practitioners’ alignments, with a range of 0.116 m/s (Table 1). Ground reaction forces were also similar, with a three-hump pattern specific to amputee gait (Hubbard and McElroy, 1994).

Given the differences in static alignment, differences in intersegmental angles during gait were surprisingly small, suggesting that the alignment of the different practitioners produced a consistent gait pattern. Angles for the prosthetic knee were most consistent, while the contralateral knee (Fig. 1) showed only slight differences in the alignment of P5 in late swing/early stance phase. Ankle angles in the varying alignments were also very similar. Alignment changes to the ankle angle are apparent in differences in the swing phase portion of the prosthetic ankle angle curves, as the ankle is non-weight bearing and is not affected by remote joints.

Figure 1: Representative intersegmental contralateral knee angle vs. time for each practitioner’s alignment.

DISCUSSION

Several researchers have spoken of the goal of “optimum alignment.” The data in the present study illustrate the difficulty of defining this optimum. Practitioners in the study appeared to use differing alignment strategies, including bilateral static joint angle symmetry vs. zero pelvic obliquity. Nonetheless, kinematics were very similar, disproving the hypothesis. This result suggests the potential for alignment deviation as a tool to assess an amputee’s neuromotor control strategies for optimizing gait. Furthermore, until optimum alignment can be more clearly defined, automated or computerized alignment may not be necessary.

THE INFLUENCE OF FATIGUE ON FUNCTIONAL STABILITY OF THE KNEE JOINT

Sven Bruhn / Walter Rapp / Christoph Scheuffelen / Albert Gollhofer

Institute for Sport and Sport Science, University of Freiburg, Sven.Bruhn@sport.uni-freiburg.de

INTRODUCTION

Stability of the knee joint in functional situations relates on active stabilisation by muscle contraction. Neuronal activation and mechanical output of muscle contraction are depending among others on the history of fatigue and recovery of the related muscles. Thus it can be assumed, that functional joint stability is influenced by muscle fatigue (Rozzi et al., 1999). The purpose of the study was to measure the influence of muscle fatigue on functional stability of the knee joint.

METHODS

15 mail students underwent a fatiguing incremental step test. Work load was enhanced 20W every minute until exhaustion starting from zero. Power output, heart rate and EMGs of knee stabilizing muscles were recorded during testing. The EMGs were integrated over the medium ten seconds of each loading minute and mean power frequency of this time period was calculated with the raw EMGs.

Pre and post fatigue, functional stability of the knee joint was measured while the leg was axially loaded using a dynamic stimulus. 19 single stimuli were applied. Each single stimulus was averaged over the 15 subjects. Anterior tibial displacement as well as the compensating reflexes of knee joint muscles measured with a new instrumentation.

RESULTS AND DISCUSSION

During the incremental test, iEMGs continuously enhanced indicating increasing demands on muscle power output. Mean power frequency of the raw EMGs increased first, indicating higher frequencies of motor units discharge and additional recruitment of motor units with fast twitch muscle fibres as a reaction on higher demands on muscle power output. During the last increments, the mean power frequency of m. vastus medialis decreased indicating the exhaustion of the first fast twitch muscle fibres (fig. 1).

Mean power frequency was reduced during the stability test both before and after the destabilizing stimulus was induced. After the fatiguing incremental test, it took nearly twice as much activity (iEMG) for the subjects to stand upright, than before. On the other hand, the reflex activity was reduced in relation to the activity during upright stance after fatigue (fig. 2) (Wojtys et al., 1996).

Activation and Frequency of Vastus Medialis (Subject CG)

Figure 1: Amount and frequency of neuromuscular activation of m. vastus medialis of subject CG during the fatiguing test.

Reflex Activity of Semitendinosus (N=15)

Figure 2: Reflex activation (iEMG) in relation to muscle tone pre- and post-fatigue 120ms after the stimulus was induced.

SUMMARY

Functional stability of the knee joint after fatigue has to rely on passive stabilizers rather, than on active stabilisation by voluntary or reflex activity of the knee joint muscles. As the mechanical output of the active component of the functional stability seems to be reduced in case of fatigue and because the strength of the passive stabilisers is limited, fatigue can significantly enhance the risk of injury.

THE EFFECTS OF STICK CONSTRUCTION IN THE PERFORMANCE OF ICE HOCKEY WRIST SHOT

T-C Wu¹, D. Pearsall^{1,2}, A.N.H. Hodges¹, R. Turcotte¹, R. Lefebvre³, D. Montgomery¹, H. Bateni²

¹Department of Kinesiology & Physical Education, ²Physical & Occupational Therapy, McGill University, Montréal, Québec, Canada

³Bauer-Nike Hockey Inc., St. Jerome, QC, Canada

INTRODUCTION

In the game of ice hockey, a stick is one of the most vital piece equipment because it is used for shooting, passing, and stick handling in playing the game (Pearsall et al, 1999). A wrist shot is swung forward in snapping or pushing action to propel the puck upwards of 20 m/s, and this movement may be broken into four or five phases: draw back (optional), (a) blade positioning, loading, (b) pushing and (c) follow through, Figure 1. Several factors are thought to influence the outcome of the shot such as skill level, body strength, stick material type and ice surface condition. The purpose of this study was to investigate the performance of the wrist shot as affected by different stick types.

METHODS

Ten interuniversity or college level male subjects volunteered to participate in a shooting test of this study. Each subject used his own gloves and skates and performed the shooting task which consisted of three wrist shots with three different constructions of stick shaft: a medium (M), a stiff (S) and a carbon composite (C) on a force platform (AMTI). Subjects had a thirty second rest interval and a two-minute pause between stick types. The order of subjects and the types of stick were randomized. Each stick had nine reflective markers placed every 0.10 m. A hockey net was placed 8 m away and a sports radar gun (SR 3000) was placed behind the net to record the puck velocity. In addition, a high speed camera (Redlake, 480 frames/second) recorded the movement and deflection of the stick as seen in the sagittal plane. All the data were analyzed by APAS, Biobench, Statistica and Excel software programs.

RESULTS AND DISCUSSION

With regards to various stick models in the wrist shot, several variables were analyzed including velocity, vertical force, stick bending (θ) and attacking angles (β), and shaft deflection (δ). In the wrist shot, no significant difference was observed in all the variables, Table 1. The results may suggest that the stick characteristics were quite similar among all three different stick types. However, a high positive correlation of $r = 0.6 \sim 0.7$ was observed between shot velocity and vertical force, stick bending and shaft deflection. This indicated the important relationship between stick mechanical construction and shot performance.

Figure 1. The phases of the wrist shot include the (a) blade positioning; loading; (b) pushing and (c) follow through.

Table 1. Stick mechanical measures for stick types

	C	SD	M	SD	S	SD
V (m/s)	14.7	4.5	14.7	4.4	14.1	4.3
F_v (N)	44.5	26.0	43.6	28.9	44.8	36.5
θ (deg)	10.4	5.6	12.4	6.1	9.4	4.8
β (deg)	50.6	31.6	50.5	32.2	58.9	29.8
δ (m)	0.03	0.02	0.04	0.02	0.03	0.01

SUMMARY

These research results showed similar findings as Pearsall et al, 1999 & 2001 on the slap shot performance. They both suggest different stick stiffness properties did not significantly nor substantially affect puck velocity. Some questions still remain unanswered from this study. For example, in this experiment the criteria for the performance was based on peak velocity of the shot; however, other performance criteria such as accuracy of puck shot placement as well as passing, receiving, and stick handling should be examined with respect to stick design. Therefore, more in depth studies are needed to address the importance of the stick mechanical construction.

FUNCTION AND TRIGGER OF CHANGES IN SYNERGY OF LUMBAR AND THORACIC ERECTOR SPINAE MUSCLES.

Jaap H. van Dieën¹; Claudine Lamoth¹; Onno G. Meijer¹; Wiebe de Vries¹; Lorimer Moseley²

¹Institute for Fundamental and Clinical Human Movement Sciences, Faculty of Human Movement Sciences, 'Vrije Universiteit', Amsterdam, The Netherlands; ²Prince of Wales Medical Research Institute, University of New South Wales, Sydney, Australia

INTRODUCTION

In a recent study, trunk muscle synergies were found to be different in low back pain (LBP) patients compared to controls (Dieën et al., submitted). Across a range of tasks, the activation of the lumbar erector spinae muscle (ES) relative to the thoracic ES was higher in the patients. Furthermore, it was shown by model simulation that this altered synergy would enhance trunk stability. In the present paper, we will present data from two experiments to further explore the functionality and specificity of this behavior. The first experiment gave support to the adaptive nature of the behavior, by showing that it was displayed in healthy subjects in response to a challenge of trunk stability. The second experiment addressed the trigger of this behaviour in LBP. Pain and fear of pain were experimentally induced to study their effects on the ES synergy. It was found that especially fear of pain is a potent trigger of the mode of behaviour found in LBP patients.

METHODS

In the first experiment 9 subjects performed symmetric and asymmetric lifts of 15 kg containers, with a stable or unstable content (ice or water). After lifting, the load was held at hip height. EMGs of lumbar and thoracic erector spinae muscles were recorded. The dependent variable was the ratio of mean lumbar over mean thoracic rectified and averaged EMG amplitude averaged over 1s of the holding phase.

In the second experiment 9 subjects walked on a treadmill at velocities of 2.2, 3.8, 4.6 and 5.4 km/hr. EMGs were recorded as in experiment 1. The experimental conditions were walking, walking after injection of isotonic saline in the lumbar back muscles (no pain), walking after injection of hypertonic saline (severe pain), and walking while expecting electric skin stimulation in the low back area above tolerance (fear of pain). The latter stimulus was not actually applied. The dependent variable was the ratio of mean lumbar over mean thoracic EMG amplitude averaged over strides.

Repeated measures 2-way ANOVAs were used to test for effects of the independent variables on the ratio of lumbar over thoracic EMG amplitudes after logarithmic transformation. In case of sphericity violations, Wilk's λ was used as the test statistic.

RESULTS AND DISCUSSION

The ratio of lumbar over thoracic ES activity was higher when holding the unstable load, as compared to holding the stable load ($F = 6.4$, $p = 0.036$; Figure 1). Symmetry of the lift had no effect. This finding supports the adaptive nature of the relative increase of lumbar ES activity.

Figure 1: Mean lumbar over thoracic EMG ratio in holding stable and unstable loads. Bars indicate one SD.

In experiment 2, the ratio of lumbar over thoracic ES EMG was significantly affected by the stimulus condition ($\lambda = 0.157$, $p = 0.008$; Figure 2). This was mainly due to a difference between the skin stimulation condition and all other conditions. There was no significant velocity effect. The finding that the skin stimulation condition triggered the change in synergy suggests that it is an aspecific response to fear.

Figure 2: Mean lumbar over thoracic EMG ratio in walking under various stimulus conditions. Bars indicate one SD.

Although the adaptive nature of the relative increase in lumbar ES activity was supported, this behavior was shown to be an aspecific response that could be induced by fear of pain alone.

ACUTE BOUT OF ECCENTRIC EXERCISE IN THE RABBIT TA SHOWS CONCOMITANT FIBER LENGTH SHORTENING AND A SUBSEQUENT SHIFT IN THE FORCE-LENGTH RELATIONSHIP

Tim Butterfield¹, Walter Herzog

Faculty of Kinesiology, University of Calgary, Calgary, AB, Canada

¹timb@kin.ucalgary.ca

INTRODUCTION

It is well accepted that eccentric exercise can cause severe muscle injury and soreness. However, there is anecdotal evidence that eccentric training (conditioning) of muscle dramatically reduces the incidence and severity of muscle injury and might completely abolish muscle soreness following a given protocol of eccentric exercise. One theory for such a repeated bout effect involves an increase in serial sarcomere number. This adaptation may be due to overstretch and damage of activated sarcomeres on the descending limb of the force-length relationship, resulting in an increase serial sarcomere number and a shift in the force length relation to the right (Morgan, 1990). Koh and Herzog (1998) found a small but significant 3% increase in sarcomere number when rabbit TA was subjected to chronic eccentric exercise, but through a relatively short range of motion (70°-105°). Quantification of muscle fiber lengths compared to whole muscle lengths in the cat medial gastrocnemius during eccentric contraction has been studied by Griffiths (1991) and indicates that fibers may actually shorten during eccentric contraction. The aim of this study was to investigate the fiber length changes during isometric and eccentric exercise in the rabbit TA and the effects of an acute bout of eccentric exercise on the force-length relationship.

METHODS

1 New Zealand White Rabbit was anesthetized and placed supine in a sling, after a nerve cuff electrode was placed on the left sciatic nerve, an E shaped force transducer was placed on the distal tendon of the left TA, and sonomicrometry crystals were inserted into the proximal and distal regions of a superficial fascicle in the left TA to measure fiber lengths throughout the experiment. The left foot was strapped into a foot-plate attached to a stepping motor specifically designed for the rabbit. An external torque cell attached between the foot-plate and motor allowed the recording of torque at the ankle joint. Supramaximal stimulation was determined after connecting the nerve cuff electrode to the stimulator (1.6 V, frequency 150 Hz). Range of motion around the ankle joint was determined to be 55° to 155°. Peak isometric forces at 21 different angles were measured by stimulating the peroneal nerve at every 5° of ankle joint plantar flexion starting at 55°. Three single twitches were given immediately before and after a 2 second isometric contraction with a two minute rest between bouts. Immediately following, an eccentric exercise protocol was utilized consisting of 5 sets of 10 eccentric contractions with a two minute rest between sets. Supramaximal stimulation (1.6 V, frequency 150 Hz, pulse duration 0.1ms, train duration 550ms) was applied to the

sciatic nerve at the onset of plantar flexion through a range of motion of 40° at the ankle joint (65° to 105°) at 72.3° sec⁻¹ with 180° considered full plantar flexion. Immediately following the eccentric protocol, the isometric protocol was repeated without allowing time for recovery between stimulations. The rabbit was euthanized with an overdose of pentobarbital, and both hindlimbs were fixed in 10% neutral phosphate buffered formalin solution at 155° ankle joint angle.

RESULTS

Single twitch forces resulted in potentiation effects in joint torque, which diminished over time and at longer muscle lengths. A shift to the right of the force-length relationship was seen in the peak isometric force of the TA after the eccentric protocol, however no shift was seen for joint torque measurements. During isometric contractions, at every angle, fiber lengths decreased. During the eccentric exercise protocol average fiber lengths also decreased, with the decrease in fiber length being greatest at the onset of contraction but elongated as plantar flexion increased, but fiber length never returned back to the starting length. The net fiber length, therefore, remained shorter than the starting length throughout the entire set of repetitions. These results will be systematically explored in a set of greater than six animals.

AN APPROXIMATE ANALYTICAL SOLUTION FOR THE PLANAR SPRING MASS MODEL OF LOCOMOTION

S. R. Bullimore¹, S. G. Usmar, and J. F. Burn

Department of Anatomy, University of Bristol, Southwell Street, Bristol, BS2 8EJ

¹Corresponding author: sharon.bullimore@bris.ac.uk

INTRODUCTION

The spring mass model (Blickhan, 1989; McMahon and Cheng, 1990) has been one of the most influential models of locomotion in recent years. The animal is represented by a point mass, supported on a massless, linear, perfectly elastic spring. This simple model predicts the mechanics of locomotion in running, hopping and trotting animals remarkably well (Blickhan and Full, 1993; Farley *et al.*, 1993). Two forms of the model have been described. In the *one-dimensional* model, the spring bounces vertically, modelling hopping in place. In the *planar* model, the spring rotates through the vertical, modelling forward hopping or running. The equations of motion for the one-dimensional model can be solved analytically, so that algebraic relationships between the input and output parameters can be derived. However, this powerful approach cannot be applied to the planar model because its equations of motion are non-linear and have to be solved numerically. The aim of the present study was to derive an approximate analytical solution for the planar spring mass model and to validate it by comparison with a numerical solution and with experimental data.

METHODS

An approximate analytical solution to the planar model was obtained by making a simplifying assumption and employing standard techniques for solving second order differential equations. A numerical solution was obtained using a fourth order Runge-Kutta algorithm (step size: 0.0001 s). These two solutions were evaluated for various input parameter values and initial conditions. For each combination of values, the contact time and minimum spring length predicted by each method were compared.

In addition, kinetic and kinematic data were collected from 3 running humans, 3 trotting horses and 3 trotting dogs. The kinematic data were used to determine input parameter values and initial conditions for the model. The peak forces and stance times predicted by the analytical solution were compared to the experimental data and the percentage error in each prediction was calculated.

RESULTS AND DISCUSSION

The predictions for contact time and spring length obtained from the analytical solution were very similar to the predictions of the numerical solution (figure 1). This suggests that the analytical solution is a good approximation to the true solution of the planar spring mass model.

The analytical solution also predicted stance time and peak vertical ground reaction force in humans, horses and dogs to within 10 % of measured values. This suggests that it is a good predictor of ground reaction forces in humans and quadrupedal mammals.

Figure 1: Comparison of a numerical solution and an approximate analytical solution to the planar spring mass model, showing the close correspondence between the two.

SUMMARY

An approximate analytical solution was obtained for the planar spring mass model of locomotion. The predictions of the solution were similar to those of a numerical solution and to ground reaction force data obtained from three different species. The derivation of an approximate analytical solution to the planar spring mass model will allow the implications of this important model to be explored in greater depth than has previously been possible.

TIBIOFEMORAL CONTACT POINTS RELATIVE TO FLEXION ANGLE MEASURED WITH MRI

Dan K. Ramsey¹ Per Wretenberg^{1,2}, and Gunnar Németh^{1,2}.

¹ Department of Surgical Sciences, Section for Orthopaedics, Karolinska Institute, Stockholm, Sweden dan.ramsey@kbh.ki.se

INTRODUCTION

Magnetic resonance images (MRI) is a non-invasive method to accurately record knee structures of living subjects with precise 3D coordinates. Iwaki et al. (2000) and Hill et al. (2000) used MRI to measure tibiofemoral contact points but only in the sagittal plane.

METHODS

MR-images (1.5 tesla (T) Sigma System) were taken from the right knee of sixteen subjects with no history of knee dysfunction. A customized adjustable orthosis positioned the knee at 0°, 30° and 60° flexion. The leg was strapped to minimize movement and prevent external rotation at the hip. Angles were verified from the sagittal MR images. Co-ordinates for the contact areas were obtained from MRI and the centroid calculated. Position of the contact point was referenced to the most lateral and distal patellar tendon insertion site, the anatomical reference point (Figure 1).

Figure 1: Position of the contact point with respect to the anatomical reference frame for each plane.

Co-ordinates were expressed relative to the inherent MRI reference frame. When the knee was flexed, the co-ordinates were transformed mathematically and aligned with the anatomical reference frame (Figure 2). Movement was reported as changes of the contact point's position relative to the fixed anatomical coordinate system for each angle.

Figure 2: Method to correct contact position.

RESULTS AND DISCUSSION

Figure 3 illustrates the relative position of the tibial contact points with respect to the anatomical reference point for 0°, 30° and 60°.

Figure 3: Mean tibiofemoral contact positions for each plane at 0°, 30°, and 60°.

Overall, contact points on the lateral tibial condyle were positioned further posteriorly. Displacements posteriorly were slightly greater than medially. Comparing movements, contact motion progressed posteriorly 12.5 mm vs. 13.8 mm, inferiorly 6.2 mm vs. 9.7 mm and laterally 0.6 mm vs. 1.4 mm for the medial and lateral condyles respectively. The predominant posterior displacement suggests femoral rolling. With increased flexion to 60°, the contact points moved anteriorly 1.0 mm vs. 6.4 mm, superiorly 2.4 mm vs. 4.7 mm and continued laterally 2.5 mm vs. 2.4 mm for the medial and lateral condyles respectively. Only the lateral contact point displaced anteriorly, indicative that motion along medial femoral condyle was almost pure sliding. Iwaki et al. (2000) and Hill et al. (2000) suggest the posterior and inferior deflections may result from a combination of factors. When flexing to 30°, the contact point is drawn down along the sloping tibial plateau. Due to the differing radii of the anterior and posterior femoral condyles, the bony contact point is transferred posteriorly because the femur “rocks” from the anterior onto the posterior articular surface

FINITE ELEMENT (FE) ANALYSIS ON THE PERFORMANCE RANGE OF TOTAL KNEE REPLACEMENT (TKR) – A PRELIMINARY STUDY

Kheng Hooi Tan, Andrew New and Mark Taylor

Bioengineering Sciences Research Group, School of Engineering Sciences, University of Southampton, Southampton, United Kingdom. Email: rtan@ses.soton.ac.uk

INTRODUCTION

Replaced knees are likely to undergo a wide range of loading and kinematics in different patients as shown in several video-fluoroscopy studies (Stiehl et al., 1999; Banks et al., 1993). However, at present, TKR performance especially in terms of kinematics and wear of the polyethylene component, are only evaluated under a limited range of kinematic conditions, as a standard gait cycle (Walker et al., 1997, Walker et al., 2000). Therefore, there is a need to examine the TKR over a wide range of patient to assess the 'performance envelop' of replaced knees. Such kinematics studies can then be used to study the effects on polyethylene stresses and wear as a result of variable loading conditions. The aim of this study was to predict the performance range of TKR in terms of kinematics and surface contact pressure as a result of a range of applied forces.

METHOD

A previously developed three-dimensional explicit FE model (Godest et al., 2002) of a PFC Sigma total knee was used. The femoral component was modeled as rigid body using four noded shell elements. The polyethylene was modeled using hexahedral elements with an elastic-plastic material model. The femoral component was allowed to translate in the proximal-distal direction, to rotate about its transverse (flexion-extension) and frontal (varus-valgus) axes. The tibial component was allowed to translate in the anterior-posterior, medial-lateral directions and to rotate about its longitudinal axis. An inferiorly directed axial force tending to compress the insert (F_c) was applied at the center of gravity of the femoral component and an anterior-posterior force (F_{ap}) applied to the tibial component. Torque was applied to the joint via two nodes that were tied externally at the medial and lateral side of the tibial component. Medial and lateral springs were used to represent the soft-tissue structures of the knee. The standard loading states were defined according to the experimental protocol used in the Stanmore knee simulator (Walker et al., 1997). The effects of loading parameters were simulated by multiplying the standard loading states by factors of 1.3 and 0.7 to serve as upper and lower bounds respectively. These values were chosen as they give forces appropriate of the range likely patient masses. There were 3 variables (A-P force, I-E torque and axial force), each with an upper and a lower bound; hence there was a total of eight analyses.

RESULTS AND DISCUSSIONS

The performance range of the knee model is shown in Figure 1. The results were compared with the control model. The plots for A-P displacement are not shown because they showed a consistent pattern for all the gait analyses as reported by Godest et al. The maximum A-P displacement

output was when the model was subjected to high A-P force, low axial force and low torque. The minimum A-P displacement output was when the model was subjected to low A-P force and high axial force. High axial force thus appeared to give more stability to the model. The difference between the maximum and minimum peak A-P displacement was 2 mm. For the I-E rotation, the model subjected to high torque, high A-P force and low axial force exhibited the highest rotational angle changes. While low torque, low A-P force and low axial force cause the lowest rotational angle. The difference between the highest and the lowest rotational angle was approximately 4.4 degree. The highest contact pressure occurred in the model subjected to low axial force. The reason for this was that the relative component motions were higher as a result of the high A-P force, causing a smaller contact area. The lowest contact pressures were generated in the model subjected to low torque, A-P force and axial load.

Figure1: Performance range of PFC knee model. High bound (\uparrow), low bound (\downarrow).

CONCLUSION

Variations of approximately 2 mm in A-P displacement and 4 degrees in I-E rotation were observed. A performance envelop was obtained for each of the kinematic functions. In general, the trends in the A-P displacements and I-E rotations are similar, regardless of variations in the applied loads whereby only the magnitudes changed. This study highlights the importance of examining the performance envelop. However, systematic variations in the applied loading conditions are not sufficient to explain the wide variations in kinematics observed *in vivo*.

VARIABILITY OF THE LOWER EXTREMITY SEGMENTAL COUPLINGS INDICATES THAT ELDERLY GAIT IS LESS STABLE DURING STANCE

Max J. Kurz, Nicholas Stergiou and Cory M. Millhollin

HPER Biomechanics Laboratory, University of Nebraska at Omaha

Email: mkurz@mail.unomaha.edu Web: www.unocoe.unomaha.edu/hper.htm

INTRODUCTION

Previous investigations have suggested that the elderly have an unstable gait pattern (Winter et al., 1990). However, the definition of stability in elderly gait is not well understood. The variability of segmental couplings can be used to determine the stability of a movement pattern (Diedrich and Warren, 1995). A low amount of variability in the segmental couplings indicates a stable movement pattern; while high amount of variability in the segment couplings indicates an unstable movement pattern (Diedrich and Warren, 1995). Evaluation of the variability present in the lower extremity segmental couplings can provide scientific evidence of the stability present in the elderly gait pattern. Therefore, the purpose of this investigation was to evaluate the variability present in the lower extremity segmental couplings for the elderly gait. We hypothesized that the elderly would have greater variability in the lower extremity segmental couplings during the stance phase due to an unstable gait pattern.

METHODS

Ten young (Age = 25.1 ± 5.3 yrs.), and ten elderly women (Age = 74.6 ± 2.55 yrs.) participated in this investigation. Sagittal kinematics (60 Hz) were collected while walking at a self-selected pace on a treadmill. Dynamical Systems Theory (DST) tools were used to evaluate the variability present in the lower extremity segmental couplings. Phase portraits were constructed from the angular positions and velocities of the lower extremity segments. Relative phase (RP) curves were utilized to define the lower extremity segmental couplings during the stance phase. RP curves were calculated by subtracting the phase angles of the distal and proximal segments for the following relationships: foot-shank, and shank-thigh. Mean ensemble RP curves were calculated for all RP segmental relationships. Mean variability in the RP relationships was calculated by averaging the absolute values of the standard deviations for all points of the mean ensemble RP curve. Statistical differences between the two groups (Elderly vs. Young) were noted with independent t-test ($p < .05$).

Table 1. Mean (SD) RP variability for both groups. All values are in degrees.

	Foot-Shank	Shank-Thigh
Elderly	6.6 (1.8)*	9.9 (2.4)*
Young	4.8 (.9)	6.3 (1.4)

* significantly different between groups at .01 alpha level

RESULTS AND DISCUSSION

Our hypothesis that the elderly would have greater variability in the lower extremity segmental couplings during stance was supported by this investigation (Table 1). The elderly had greater variability in both lower extremity segmental relationships. An increase in variability of the couplings is associated with decreased stability (Diedrich and Warren, 1995). Based on this investigation, it was evident that elderly gait is less stable during the stance phase (Figure 1). Differences in variability of the segmental couplings were most pronounced during the early and late portions of the stance phase (Figure 1). A decreased amount of stability during these portions of the stance phase may be due to the loose-packed position of the joints where there is greater dependence on the surrounding joint musculature.

SUMMARY

The elderly lower extremity displays a more variable segmental coupling pattern. The increased variability indicated that the elderly have a less stable gait pattern during the stance phase. Examination of the interactive behavior of the segments offers new insights on the stability of elderly gait patterns that may not be evident otherwise.

NUMERICAL MODELING OF PULSATILE TURBULENT FLOWS IN STENOTIC VESSELS

INTRODUCTION

Blood flow under pathological conditions, such as atherosclerosis, involves narrowing of the artery lumen, referred to as a stenosis, which together with flow pulsatility can result in periodic generation of turbulence despite relatively low Reynolds numbers for such flows (typical Reynolds number range is 1 to 4000 depending upon the size of the vessel (Ku 1997, Berger et al., 2000)). This turbulent flow can affect flow resistance and mixing rates, and can ultimately impact platelet coagulation rates. Vessel compliance can also affect flow stability and turbulence generation. Due to difficulties in making *in vivo* measurements of local velocity profiles and shear stress under pulsatile flow, computational fluid dynamics (CFD) has begun to play a major role in improving our understanding of biofluid flows in general and blood flow in arteries in particular. Recent CFD work has focused on pulsatile stenotic flows accounting for fluid-structure interaction, non-Newtonian effects, and irregular geometry. However, the effects of transitional or turbulent flow have not been addressed to a similar degree.

METHODS

Pulsatile turbulent flow in stenotic vessels has been numerically modeled using the Reynolds-Averaged-Navier-Stokes equation approach. The commercially available CFD code, FLUENT, has been used for these studies. Four different laboratory experiments and geometries were modeled. The first two involved pulsatile turbulent flow in a round tube and a plane channel, while the second two involved pulsatile flow through two different axisymmetric stenoses. Two different two-equation turbulence models (standard and RNG) were employed to study their influence on the results.

RESULTS AND DISCUSSION

It was found that the tube and channel flow results were in reasonable agreement with previously measured experimental data and previous numerical simulations regardless of the turbulence model used. For the stenotic flows, the experiment by Ohja et al. (1981) and by Ahmed and Giddens (1984) were modeled. The results showed that the RNG turbulence model was in much better agreement with the data than the standard two-equation turbulence model with regard to predicting the centerline velocity distribution (see Fig. 1), the vortex shedding process, and the spatial distribution of the turbulent kinetic energy distal to the stenosis. For the stenotic flows,

wall shear stress peaked in the region of the stenosis and minimum values were observed in regions distal to the stenosis where flow separation occurred.

Figure 1. Centerline velocity vs. time for Ohja et al. showing better agreement using RNG model.

INDIVIDUALS WITH ACL RECONSTRUCTION DISPLAY ALTERED COORDINATION STRATEGIES WHILE WALKING AND RUNNING

Max J. Kurz, Nicholas Stergiou, and Melissa M. Scott
HPER Biomechanics Laboratory, University of Nebraska at Omaha
Email: mkurz@mail.unomaha.edu Web: www.unocoe.unomaha.edu/hper.htm

INTRODUCTION

Although it has been suggested that segmental coordination is necessary for a stable gait pattern (Hamill et al., 1999; Stergiou et al., 2001), few studies have attempted to determine if ACL reconstruction affects lower extremity coordination during the stance phase. Potentially, evaluation of the lower extremity coordination during the stance phase may provide information about the health and dynamic stability of the reconstructed leg. The purpose of this investigation was to evaluate the segmental coordination of ACL reconstructed individuals while walking and running. We hypothesized that individuals with ACL reconstruction would have different segmental coordination strategies during the stance phase while walking and running.

METHODS

Ten fully rehabilitated subjects (3.4 yrs on average after the surgeries were performed) who had undergone ACL reconstruction using an autogenous patellar tendon graft, and ten healthy controls participated in this investigation. Sagittal kinematics (60 Hz) were collected while the subjects walked and ran on a treadmill. The stance phase was evaluated for fifteen consecutive footfalls for each subject. Phase portraits were constructed from the angular positions and velocities of the lower extremity segments. Relative Phase (RP) curves were utilized to define coordinative strategies during the stance phase. RP curves were calculated by subtracting the phase angles of the distal from proximal segment for the following relationships: foot-shank and shank-thigh. Mean ensemble RP curves were calculated for both segmental relationships. From the mean ensemble curves the Mean Absolute Relative Phasing (MARP) was evaluated. MARP were calculated by averaging the absolute values for all points of the mean ensemble RP curve. Statistical differences between the two groups (ACL reconstructed vs. control) were noted with an independent t-test ($p < 0.05$).

RESULTS AND DISCUSSION

Our hypothesis that individuals with ACL reconstruction would have different coordination strategies during the stance phase while walking and running was supported. During walking, differences between the groups were noted for both the foot-shank and the shank-thigh (Figure 1). During running, differences between the groups were noted only between the foot-shank (Figure 1). No differences were found for the shank-thigh relationship during running. This lack of difference may be due to the increased inertial contributions of the segments during running. An alternative explanation is that coordinative changes in the other joints, such as the ankle and possibly the hip, helped to maintain stability at the knee.

SUMMARY

Individuals with an ACL reconstruction display different coordination strategies during the stance phase while walking and running. These control strategies may be related to the surgical reconstruction of the joint. Analysis of the coordination patterns during the gait cycle offers a noninvasive way to assess ACL surgical interventions.

INDIVIDUALS WITH ACL RECONSTRUCTION DISPLAY ALTERED LONG-RANGE FRACTAL GAIT PATTERNS

Max J. Kurz and Nicholas Stergiou
HPER Biomechanics Laboratory, University of Nebraska at Omaha
Email: mkurz@mail.unomaha.edu Web: www.unocoe.unomaha.edu/hper.htm

INTRODUCTION

Previous investigations have indicated that gait patterns are fractal (Hausdorff et al., 1995). A fractal gait pattern suggests that subtle variations in the gait pattern are not “noise”. Instead, these variations are due to long-range power-law correlations from preceding footfalls (Hausdorff et al., 1995). Breakdown of the fractal-scaling pattern has been found to be dependent on the health and dynamic stability of the neuromuscular system (Hausdorff et al., 1995). Currently, there are several clinical measures of static knee stability (i.e., KT 1000), but there are no such measures for dynamic stability of the ACL reconstructed joint. We speculated that a lower fractal-scaling value would be related to a decreased dynamic stability and health of the reconstructed joint. To test our hypothesis, we evaluated the effects of ACL reconstruction on fractal-scaling for walking and running gait patterns.

METHODS

Ten fully rehabilitated subjects (3.4 yrs on average after the surgeries were performed) who had undergone ACL reconstruction using an autogenous patellar tendon graft, and ten healthy controls participated in this investigation. Sagittal kinematics (60 Hz) were collected while the subjects walked and ran on a treadmill for 40 seconds. The unfiltered time series for the ankle and knee joint angles were used to classify the fractal nature of the gait pattern. Log-log power spectral density (PSD) plots were constructed from the kinematics. The slopes of the plots can characterize the presence of long-range fractal correlations in the gait patterns (Hausdorff et al., 1995). A slope of zero indicates random noise in the time series. Slopes greater than zero indicate more self-similar or fractal gait pattern. Statistical differences between the two groups were examined with an independent t-test ($p < .05$).

RESULTS AND DISCUSSION

Although there were no significant ($p > .05$) differences between the two groups for both conditions, the ACL reconstructed subjects had lower slope values for both knee

Figure 1. Exemplar knee joint log-log PSD plots during walking where A is an ACL reconstructed knee and B is a control knee.

and the ankle joints while walking and running (Table 1). A lower slope value suggested a more variable gait pattern that is less dependent on previous fluctuations in the gait pattern (Figure 1). Previously, it has been suggested that lower slope values are due to neuromuscular deficiencies and, a lower slope value can be an indicator of decreased stability of the gait pattern (Hausdorff et al., 1995). It is possible that these trends seen in the reconstructed ACL subjects may be due to such neuromuscular deficiencies and a lack of stability in the reconstructed joint (Buzzi et al., 2001).

SUMMARY

Individuals with ACL reconstruction display a more random fractal-scaling gait pattern. A more random pattern suggests that the joint has less neuromuscular control and stability. Analysis of the fractal properties of gait patterns offers a noninvasive way to assess the dynamic stability and health of the joint.

BIOMECHANICAL EFFICACY OF A PROTEIN POLYMER HYDROGEL FOR INTER-VERTEBRAL NUCLEUS AUGUMENTATION AND REPLACEMENT

Andrew Mahar¹, Richard Oka¹, Jon Whitledge², Joseph R. Cappello², Jim Powell², Tina McArthur², Joseph Cappello²

¹ Department of Orthopedics, Children's Hospital, San Diego, CA

² Protein Polymer Technologies, Inc., San Diego, CA

INTRODUCTION

Degenerative intervertebral discs are a common clinical occurrences in the lumbar spine. This pathology may present with low back pain and/or pain in the lower extremities and the worst cases require surgical treatment. The removal of the nucleus pulposus (nucleotomy) is often performed through a posterior-lateral approach without any replacement of the material. While this surgery may be successful, the optimal situation would be to remove the painful disc and replace the material with something that maintains disc height and provides axial support. Previously, collagen repair devices have been theorized but with little reported biomechanical data. Therefore, new materials based on injectable protein polymer hydrogels (IPPH) have been developed. This study compared axial strain during mechanical loading of human cadaveric vertebral segments with those augmented by two IPPH disc nucleus augmentation materials.

METHODS

Ten adult, human lumbar spines were first radiographed to eliminate pathological specimens. Motion segments were then harvested between T12 through S1. Using the radiographs, measurements of native disc height were calculated. All further displacements during testing were attributed to disc mechanics. The posterior elements were removed leaving an intact PLL and posterior annulus. Individual specimens were tested using force control in a MTS 858 machine ("native"). The testing involved cyclic loading between 35kg and 75kg at 1Hz for 20 cycles. Further testing involved a sequential 30-minute static load at 5kg, a static load of 75kg for 60 minutes and a final 30-minute static load at 5kg (Figure 1).

Displacement and force data were sampled at 5Hz for the duration of the test. This paradigm allowed for evaluation of both creep and recovery tests. Following "native" specimen testing, the nucleus was removed via an anterior annulotomy and replaced with a randomly selected IPPH (polymer A or B) using a custom injection device. Identical testing was then repeated. A single control specimen was tested post-nucleotomy without augmentation. Maximal strain was calculated at the end of the creep test and statistical significance was tested with a one-way ANOVA ($p < 0.05$).

RESULTS AND DISCUSSION

An average of 4.2cc of disc nucleus material was removed from each specimen. The IPPH materials did not extrude during any part of the tests. The strains experienced in the repair groups were greater than the strains for the native state. However, these differences were not statistically significant (Table 1). There were also no significant differences between the two types of protein hydrogels.

Table 1: Strain data for native and repaired discs.	Native Strain	Injected Strain
Repair Polymer A		
Mean (n=5)	0.136	0.188
Standard Deviation	0.023	0.045
Repair Polymer B		
Mean (n=5)	0.148	0.219
Standard Deviation	0.046	0.064
Overall Mean(n = 10)	0.141	0.204
S.D.	0.033	0.055

Nucleotomy Only 0.122 0.346

CONCLUSION

Composition B displayed slightly greater maximum deflection than did composition A, and both were slightly greater than native discs. The mean final recovery for both repair groups was within 0.75 mm of native. The mean spontaneous recovered height was within 1.2mm. These preliminary data indicate that IPPH hydrogels may demonstrate adequate mechanical properties as disc augmentation devices.

MARKOV MODEL SUGGESTS NEUROMUSCULAR AGING AFFECTS SHORT-RANGE CORRELATIONS PRESENT IN THE GAIT CYCLE

Max J. Kurz, Nicholas Stergiou and Kristin McCormick
 HPER Biomechanics Laboratory, University of Nebraska at Omaha
 Email: mkurz@mail.unomaha.edu Web: www.unocoe.unomaha.edu/hper.htm

INTRODUCTION

Step-to-step variability during gait appears to be correlated with the preceding footfalls (Hausdorff et al., 1995). It has also been suggested that this variability is related with the health of the neuromuscular system (Hausdorff et al., 1995). To further understand the effect of aging on the step-to-step variability, we utilized a Markov Model. The Markov Model suggests that the fluctuations in the behavior of the joints are dependent on short-range correlations in the gait cycle (Lay, 2000). Therefore, the behavior of the joints for the next footfall is dependent on the behavior exhibited in the preceding footfalls. The Markov Model suggests that fluctuations in the movement behavior of the joints exponentially decay to a steady state gait pattern (Lay, 2000). In this investigation, we speculated that the Markov Model would identify that neuromuscular aging affects the short-range correlations present in the gait cycle. Modifications in the short-range correlations would in turn result in a different steady state gait pattern.

METHODS

Markov models were developed from the gait patterns of ten young (Age = 25.1 ± 5.3 yrs.) and ten elderly women (Age = 74.6 ± 2.55 yrs.). Sagittal kinematics (60 Hz) were collected while walking on a treadmill. Joint angles were calculated for the ankle, knee and hip. Forward selection regression equations were used to predict the behavior of the lower extremity joints. Such that the ankle joint was regressed on the knee and hip, the knee joint was regressed on the ankle and hip, and the hip joint was regressed on the ankle and knee. The change in the coefficient of determination, as predictors were added to the model, and the remaining unexplained variance ($1-R^2$) of the regression equation were used to develop probability vectors. The probability vectors described the interactive behavior of the respective lower extremity joints. Short-range correlation matrices (M) presented below, were developed from the probability vectors of each of the respective joints. Each column of the matrix represented a probability vector for the ankle (column 1), knee (column 2) and hip (column 3).

$$M_{\text{Elderly}} = \begin{pmatrix} .56 & .82 & .41 \\ .03 & .04 & .10 \\ .41 & .14 & .49 \end{pmatrix} \quad M_{\text{Young}} = \begin{pmatrix} .8 & .05 & .04 \\ .02 & .19 & .76 \\ .18 & .76 & .20 \end{pmatrix}$$

Utilizing the short-range correlation matrices (M), Markov Models were solved for a sequence of footfalls until a steady state gait pattern was achieved:

$$\mathbf{X}_{k+1} = \mathbf{M} \mathbf{X}_k \quad \text{for } k = 0, 1, 2, \dots$$

A steady state was achieved when \mathbf{X}_k converged to a specific value and there were minimal fluctuations from one k to the next.

RESULTS AND DISCUSSION

The results of our investigation suggest that short-range correlations in the gait pattern are affected by age (Table 1). The steady state gait pattern for the elderly suggested that 52% of the gait pattern was dependent on the behavior of the ankle. Thus our model concurs with previous studies that have suggested the elderly have altered gait patterns due to the behavior of the ankle (Judge et al., 1996). Additionally, the steady state gait pattern for the young suggested that the gait pattern was not dependent on the behavior of the ankle (Table 1). Rather the young steady state gait pattern was dependent on the equal contributions of the hip and knee (Table 1). Based on our model, it was apparent that fluctuations in the gait cycle determined the selected steady state gait pattern. Short-range correlations are similar to neuromuscular “memory” of the preceding footfalls. Our model suggests that neuromuscular memory is dependent on age. Changes in neuromuscular memory may be responsible for the altered kinematics in the elderly. The degeneration of the neuromuscular system, that is associated with aging, appears responsible for the loss of neuromuscular memory.

SUMMARY

Short-range correlations are affected by neuromuscular age. Our model suggested that short-range correlations resulted in a steady state gait pattern that was dependent on the behavior of the ankle in the elderly.

SCALE TRANSITION IN BONE ELASTICITY: A CONTINUUM MICROMECHANICS APPROACH

Christian Hellmich¹ and Franz-Josef Ulm²

Department of Civil and Environmental Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA

²Associate Professor

INTRODUCTION

The hierarchical organization of bone and its mechanical implications has attracted researchers for hundreds of years. Continuously improved experimental techniques have revealed features of astonishing complexity, rendering the mechanical understanding (even of the elastic behavior) of this material class challenging.

METHODS

In this contribution we approach the problem within the framework of continuum micromechanics, where a material phase is defined not by the pure presence of matter components, but by their mechanical activation through strains. For bone, we propose a two step homogenization procedure: Within a representative volume element of 100 to 200 nm, hydroxyapatite (HA) crystals build up a crystal foam (polycrystal) where the inter-crystalline space is filled with water and organic matter (homogenization step I). Part of the (organic) collagen molecules are linked to the crystal foam (Ca-bridges), reinforcing the polycrystal in the form of cylindrical inclusions at the ultrastructural scale of mineralized tissues, i.e. 5 to 10 microns (homogenization step II). Within the same homogenization step, we account for the microporous space (Haversian channels, inter-trabecular space) by means of cylindrical pore inclusions, which, interestingly, are suitable for both trabecular and cortical bone.

RESULTS AND DISCUSSION

The proposed micromechanical model allows for fairly precise prediction of ultrastructural and macroscopic elasticity properties of all different kinds of bone. The model is based on three (constant) intrinsic stiffness values for HA, collagen, and water, which are tissue-independent. The input of the model are the tissue-specific volume fractions of HA, collagen, and of the micro-porous space, which are accessible via various imaging techniques or chemical experiments. This is illustrated by evaluation of a large data base (more than 1000 stiffness values).

Continuum micromechanics allows for the development of a general macroscopic bone material law without the use of any regression parameters. Notably, the three basic tissue-independent stiffness constants are directly determined from (tissue-independent) experiments. We expect a high clinical relevance of such a material law for bone failure risk

assessment by means of structural analyses (e.g. in the framework of Finite Element analyses).

KINETICS OF CONTINUOUS HOPPING TO VOLUNTARY EXHAUSTION

Darren J. Dutto

Biomechanics Laboratory, California State Polytechnic University, Pomona, Pomona, CA, USA
e-mail: ddutto@csupomona.edu

INTRODUCTION

Stretch-shortening cycle exercise performed to fatigue has been shown to impair the ability to produce force (Golhofer, 1987). Force production during ground contact is governed by the stiffness of the leg system (Blickhan, 1989). The purpose of this study was to show that during fatigue, hoppers have altered stiffness of the leg while maintaining a specific hopping frequency, and leg kinematics would reflect the change in stiffness.

METHODS

Eighteen, physically active college age students participated. Each subject performed a hopping bout to voluntary exhaustion. Hopping was performed to an electronic metronome at a rate of 2 hz on a force platform. Force data were sampled at 1200 Hz for 5 seconds at the beginning and end of the exercise bout. Sagittal plane kinematics of the right leg were recorded with a Motion Analysis Corp. system at a rate of 120 hz.

Actual hopping rate, peak vertical ground reaction force, contact time, and vertical impulse were determined from the force data. Displacement of the center of mass was calculated by double-integration of the acceleration-time data. Stiffness was estimated as the ratio of peak vertical force and center of mass displacement. Ankle and knee angles and angular velocities during the ground contact phase of the hop were determined. Differences in measured variables were assessed with a univariate ANOVA ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Results from twelve subjects were included, as the remaining six subjects had greater than 3% deviation in hopping rate from beginning to end. The remaining 12 subjects maintained a fairly consistent hopping rate for the duration of the test (Table 1), which on average was 7 min.

Table 1: Summary data and statistical results (mean \pm s.d.)

	Beginning	End	<i>p</i>
Rate (hz)	2.02 \pm 0.01	2.03 \pm 0.04	0.369
Stiffness (kN/m)	22.1 \pm 7.5	17.7 \pm 6.0	0.101
CM Disp. (m)	0.13 \pm 0.01	0.14 \pm 0.01	0.104
Peak Force (BW)	4.1 \pm 0.5	3.4 \pm 0.4	0.002
Contact Time (s)	0.25 \pm 0.03	0.30 \pm 0.03	0.002
Impulse (bw/s)	0.25 \pm 0.03	0.19 \pm 0.04	0.001

Subjects had a decrease in peak impact force and increased foot contact time with fatigue. The vertical impulse decreased

by 20% (Table 1) despite increased foot contact time, resulting in decreased hopping height. The average displacement of the center of mass during foot contact remained constant.

Force-displacement curves show that subjects tended to decrease stiffness of the leg system during ground contact. An example of the force-displacement curves for one subject is shown in Figure 1. A non-significant decrease in stiffness with fatigue was observed (Table 1). Differences in ground reaction force and contact time were associated with reduced stiffness.

Figure 1: Force-displacement curves for one subject. The blue (higher) curve was obtained from the beginning and the red (lower) curve at the end of the test bout. Each curve represents an ensemble average of 10 hops.

Ankle range of motion was observed to decrease by 6° ($p=0.01$) on average and knee range of motion to increase slightly, indicating that perhaps the knee and ankle are changing roles in producing vertical propulsion.

SUMMARY

Fatigued hoppers are able to maintain a set hopping rate despite a reduction in the stiffness of the leg. It appears that stiffness is adjusted to maintain rate, resulting in decreased impulse, peak force, and increased contact time when fatigued.

INTRODUCTION

Cycling and triathlon are growing as competitive sports in Brazil. More athletes are getting involved in these activities and that has demanded a more scientific approach from coaches. The understanding of the complex bicycle-cyclist has, for quite some time, attracted the interest of scientists. The application of force on the pedal is an attractive subject of study given the implications that it has on the effectiveness of the effort that is exerted by the athletes. The aim of this study was to implement a methodology proposed by Lafortune et al. (1983) and used by Ericson et al. (1988) to calculate the effective force exerted on the pedal (EF) and an index of effectiveness (IE). The system will be used for scientific purposes as well as a source of feedback for coaches and athletes.

METHODS

Subjects: One cyclist, one triathlete (both professionals) and one non-athlete.

Instrumentation: Two systems were used: (1) a home-made 2D strain-gauge instrumented pedal to determine the normal and tangential forces and (2) a 2D video system (Peak Performance) to measure the pedal and crank-angles.

Protocol: The subjects performed two bouts of 3 minutes each, using two different gear ratios (53x13; 53x17), at their preferred cadence. The subjects used their own bicycles which were mounted on a stand-roll.

Data Analysis: The MATLAB software was used to calculate mean values of the resultant force (RF), EF and IE (ratio between the EF and RF) for ten revolutions of each trial, using force information from the instrumented pedal and geometry data from the video (Figure 1).

Figure 1: Crank angle (α), Resultant Force (RF) and Effective Force (EF).

RESULTS AND DISCUSSION

Figure 2 shows the mean of the 10 cycles for the IE, expressed as a function of the crank angle (0 degrees = crank vertical and upward). Pronounced differences between subjects are noticed in all quadrants for gear ratio 53x12 (Figure 2a) and in the first, third and fourth quadrants for gear ratio 53x17

(Figure 2b). Negative results indicate that subject is imposing himself extra load to the opposite lower limb.

Figure 2: IE during cycling: (a) 53x12 and (b) 53x17.

Table 1 shows the mean IE calculated for ten revolutions. The cyclist achieved the best mean IE for the 53x12 gear ratio followed by the triathlete and non-athlete. Interestingly, however, the non-athlete obtained the second best IE for the gear ratio 53x17. These results can be used to monitor the cycling technique of these subjects as well as to discuss technical aspects of pedaling with coaches and athletes.

Table 1: IE mean in each gear ratio for full 360 degrees angular displacement.

Subjects	53x12	53x17
Triathlete	0,04	-0,03
Cyclist	0,49	0,23
Non-athlete	-0,14	0,09

SUMMARY

A methodology based on pedal force measurements and geometry of the pedal and crank was implemented to calculate the effective force applied on the pedal and an index of effectiveness during pedaling. The goal was to provide scientific support to cycling athletes and coaches.

MEASUREMENT OF EMBRYONIC HEART MATERIAL PROPERTIES DURING CARDIAC LOOPING

Evan A Zamir and Larry A Taber*

Department of Biomedical Engineering
Washington University, St. Louis, MO
*lat@biomed.wustl.edu

INTRODUCTION

Cardiac looping is a fundamental developmental process that is the first morphogenetic sign of lateral (left-right) asymmetry in the vertebrate embryo. The biophysical mechanism that drives the early linear heart tube to bend and rotate dextrally (rightward) into a c-shaped loop is still unknown, although several genetic and epigenetic factors have been implicated (Harvey, 1998). There have been some theoretical mechanical models of looping (Taber et al., 1995). What has been lacking in models of looping are appropriate material properties for the tissue. Our lab has developed a poking device, which not only gives force-displacement data, but also allows us to analyze the shape of indentation and input that information into a finite element (FE) model to determine material properties. A simulated annealing (SA) algorithm is used to optimize the agreement between the experimental and model results.

EXPERIMENTAL PROCEDURES

The heart poker is a piezoelectric driven cantilever beam assembly with a flexible glass beam attached to a rigid support. When the tip of the beam contacts the heart the beam deflects while the tissue underneath deforms. The force of indentation is proportional to the amount of beam deflection. We measure the displacement of the tip by monitoring a small ink spot that is placed on the tip. The entire experiment is captured on video, which allows us to gather additional information about the two-dimensional shape or contour of the edge of the heart during poking. Preliminary stiffness measurements of the HH stage 12 heart reveal that the inner curvature (IC) is stiffer than the outer curvature (OC). The mean stiffness of the OC was $0.149 \text{ mdyn}/\mu$, compared to $0.373 \text{ mdyn}/\mu$ for the IC.

MODEL AND OPTIMIZATION

To determine the constitutive law or material properties for the heart an appropriate model and optimization method is needed. There are several experimental and computational limitations that influence our choices, but many of these may be overcome in the future. To begin with we are gathering visual information about the indentation from one perspective, so we assume the tissue is isotropic in the model. Ideally, we would poke the heart in one direction, and then rotate the heart and poke in an orthogonal orientation. Because the optimization may take hundreds, if not thousands, of iterations, it is ideal to have as simple a model as possible. In

our case we created an axisymmetric FE model with contact boundary conditions in ABAQUS (see Fig. 1). This model takes on the order of seconds to run, as opposed to a full 3D model, which would take tens of minutes. At least, for the isotropic case, we have verified that the results from our axisymmetric model are nearly the same as those for a full 3D curved tube model. We are using a SA algorithm (Corana et al., 1987) with a least-squares cost function to minimize simultaneously the force and displacement data during indentation. There are two main advantages in using this method, besides the simplicity of the algorithm. The first

indentation.

advantage is that we can search a very large parameter or state space with many possible minima. We have no *a priori* way of knowing what an initial guess for the model parameters should be, so that a traditional non-linear least-squares approach, such as Levenberg-Marquardt, may easily get stuck in local minima that are not the global optimum. The second advantage is that the SA algorithm, in general, does not require the calculation of derivatives, which usually involves finite-differencing in models that do not have analytical solutions, such as ours.

REFLEX RESPONSES GRADED TO BOTH PERTURBATION ACCELERATION AND VELOCITY

Gunter P. Siegmund^{1,2}, David J. Sanderson¹, J. Timothy Inglis¹

¹School of Human Kinetics, University of British Columbia, Vancouver, BC, Canada

²MacInnis Engineering Associates, Richmond, BC, Canada, gunters@maceng.com

INTRODUCTION

Reflex responses to postural perturbations have been shown to vary with platform acceleration, velocity and displacement (Diener et al., 1988; Maki and Ostrovski, 1993). The relative influence of these platform kinematic descriptors on the reflex response has not, however, been evaluated. In the current study, the gradation in reflex response of the neck muscles and kinematic response of the head and torso were studied in seated subjects using different combinations of platform acceleration and velocity. It was hypothesized that the timing and amplitude of both the reflex neck muscle response and the induced head and torso kinematics would vary with both stimulus properties.

METHODS

Following IRB approval, thirty subjects (15F, 15M) underwent 47 forward horizontal perturbations while seated in a car seat mounted on a linear motor. Seven different perturbations were constructed from one of three peak accelerations (low $L_a=7.8$, medium $M_a=14.7$, high $H_a=21.7$ m/s²) to reach one of three constant velocities ($L_v=0.25$, $M_v=0.50$, $H_v=0.75$ m/s). The L_aH_v and H_aL_v combinations were not used. Each subject first underwent 11 M_aM_v perturbations to achieve a stabilized response and was then exposed to a randomized series of 36 perturbations: 12 M_aM_v perturbations, and 4 of each of the remaining 6 perturbations. Onset and root-mean squared (RMS) amplitude of the sternocleidomastoid (SCM) and cervical paraspinal muscles were measured using surface electromyography (EMG). Torso and head acceleration onset were determined from accelerometers, whereas peak mastoid acceleration, neck retraction (horizontal displacement of the mastoid relative to the manubrium) and head extension angle were computed from data acquired with an Optotrak system. One-way repeated-measures analyses of variance, Scheffé post-hoc tests and a significance level of 0.05 were used to assess response differences between the seven perturbations. Linear regressions were then used to quantify the relative influence of platform acceleration and velocity on responses.

RESULTS AND DISCUSSION

The onset and amplitude of the neck muscle responses and the head and torso kinematic responses varied between the different perturbations. Muscle activation occurred earlier at higher platform accelerations and lower velocities (Table 1a) and followed a pattern similar to the duration of the platform acceleration (Table 1b). In contrast, onset of torso and head accelerations occurred earlier at higher platform accelerations, but did not vary with platform velocity (Table 1c,d). SCM EMG amplitude and peak kinematic amplitudes increased with both higher platform acceleration and velocity (Table 1e-h), although the relative influence of platform acceleration and velocity was not the same for all response variables. For

instance, early kinematic peaks (e.g., vertical mastoid acceleration; Table 1f) correlated more strongly with platform acceleration ($r^2=0.80$) than velocity ($r^2=0.47$), whereas late kinematic peaks (e.g., peak retraction; Table 1g) correlated more strongly with platform velocity ($r^2=0.95$) than acceleration ($r^2=0.42$).

Table 1: Mean (SD) of selected variables as a function of platform acceleration (L_a , M_a , H_a) and velocity (L_v , M_v , H_v). Increasing line weights correspond to homogeneous groups of significantly earlier times or greater amplitudes. Amplitude variables normalized to the M_aM_v perturbation.

SUMMARY

Our hypothesis that the timing and amplitude of the muscle and kinematic responses would vary with both platform acceleration and velocity was accepted. Moreover, the combined influence of platform acceleration and velocity on the amplitude of the SCM muscle response indicated sensory encoding of both stimulus properties, and underscored the importance of controlling the detailed platform kinematics when studying responses to postural perturbations.

A COMPARISON OF JOINT MECHANICS BETWEEN ANTERIOR CRUCIATE LIGAMENT INTACT AND DEFICIENT STIFLES: A NEW CANINE MODEL OF ANTERIOR CRUCIATE LIGAMENT DISRUPTION

Mandi J. Lopez^{1,3}, David Kunz², Ray Vanderby, Jr.², Dennis Heisey², John Bogdanske¹, and Mark D. Markel¹

¹Comparative Orthopaedic Research Laboratory and the ²Department of Biomedical Engineering
University of Wisconsin-Madison, Madison, WI. ³lopezm@svm.vetmed.wisc.edu

INTRODUCTION

The canine model of osteoarthritis (OA) following anterior cruciate ligament (ACL) transection is one of the best characterized and most commonly used (Marshall, 1996). It has been suggested that joint capsular thickening in ACL deficient canine knees may stabilize the joint over time (Hulse, 1983). We have developed a model by which the canine ACL is intentionally over-treated with monopolar radiofrequency energy (MRFE) using an arthroscopic approach. The ACL then undergoes progressive deterioration until complete disruption at a predictable time point after treatment. We also undertook this project to evaluate the contribution of joint capsule (JC) after progressive canine ACL deterioration and rupture.

METHODS

Ten skeletally mature female crossbreed dogs, weighing 24 - 37 kg each were used in this study. MRFE (70°C, 25W) was applied to the ACL of one randomly selected knee arthroscopically with a 2 mm diameter electrode (TAC-C probe, Oratec Interventions, Inc.) and an Oratec MRFE generator (Electrothermal System ORA-50tm). The contralateral knee was sham operated. Treated ACL's ruptured approximately 54 days after surgery (Mean 54 days, SEM 1.2). The animals were sacrificed 16 weeks (n=5) or 26 weeks (n=5) after rupture of the MRFE treated ACL, and the hind limbs were stored at -70°C until biomechanical testing. Anterior-posterior (AP) translation was evaluated with load cycles of +/- 40N. Following AP translation tests, medial-lateral (ML) rotation tests were performed with 2 test cycles of 4 Nm. AP laxity and ML rotation were evaluated at 30°, 60°, and 90° of flexion. All testing was first done with intact JC and then with JC removed.

A factorial model with all interactions was used to compare time, capsule status, ligament status, and angle. Because all treatments except time were within-animal treatments, a split plot model for incomplete data was used. Significance was set at $P < 0.05$.

RESULTS AND DISCUSSION

AP translation: A preliminary ANOVA showed a significant interaction to include JC by ACL ($P = .02$) and a trend for ACL by time ($P = .07$) (Fig. 1).

ML rotation: Significant interactions included the presence of JC ($P = .0001$), and angle by ACL ($P = .0012$) (Fig. 2).

Overtreatment of the canine ACL with MRFE using an arthroscopic approach is a highly predictable and reproducible model of OA that avoids variables introduced by surgery to transect the ACL. This study showed a significant

stabilizing influence of JC against AP translation in ACL deficient knees, though this effect did not change significantly in the time period between sample collections. The ACL was also a significant stabilizing influence against ML rotation.

Fig. 1 AP translation (mean \pm SEM) of canine knees with and without ACL or JC (A); and with and without ACL's 16 and 26 weeks post-rupture (B). Columns with different letters are significantly different from one another ($P < .05$).

Fig. 2 ML rotation (mean \pm SEM) of canine knees with and without JC (A) and at different flexion angles with and without ACL's (B). Columns with different letters are significantly different from one another ($P < .05$).

SUMMARY

This study describes a model in which ACL's predictably rupture approximately 8 weeks after arthroscopic surgery. This model avoids significant surgical variables. Based on the results of this study, the JC is a significant stabilizing influence in the canine ACL deficient knee. Further, the best angle to test motion in ACL deficient canine knees appears to be 60° of flexion.

EFFECTS OF DIFFERENT PADDING ON THE IMPACT LOADING OF THE HAND DURING FALLING

Il-Kyu Hwang, Keith Leung, and Kyu-Jung Kim, Ph.D.

Department of Mechanical Engineering, University of Wisconsin-Milwaukee, Milwaukee, WI, USA, kimk2@uwm.edu

INTRODUCTION

Efficacy of wrist guards in preventing forearm injuries has been a subject of debate (Giacobetti 1997). It has been reported (Kim 2001) that the current wrist guards have less effectiveness in reducing the peak impact force with a high frequency mode. Accordingly, other padding materials should be sought for effective absorption of the impact energy during falling. Several materials such as rubber, Sorbothane, etc., have been commonly used in biomechanics/ ergonomics fields for vibration isolation and injury prevention. The purpose of this study was to measure the impact loading of the hand with various padding materials under simulated impact conditions and to analyze their biomechanical effects.

METHODS

A total of fifteen young male and female adults participated in this experiment. The subject with eyes closed was asked to put the forearm at 30° from the horizontal and to maintain the initial tension of 50 N into the load control cable (Fig. 1). Then the cable was released at random and the hand hit a commercial force plate (Type 4060, Bertec, Columbus, OH) covered with a 1-in thick wooden plate. The subject repeated each of the trials three times with different padding conditions such as a bare hand (BH), a Sorbothane glove (SO), a commercial wrist guard (WR), and an air-pocket on the palm (AP). A miniature accelerometer (EGA-F, Entran Devices, Fairfield, NJ) was attached on the dorsum of the hand. The impact force and acceleration of the hand were collected at a sampling rate of 10 kHz. From the impact force profile, the maximum impact force (F_{max}), its occurrence time (T_{max}) after touchdown, and loading rate ($G_{zi} = F_{max} / T_{max}$) were estimated. A logarithmic decrement technique was used to obtain the damped natural frequency (ω_d) and damping ratio (ζ). The impact velocity (v_i) at touchdown was estimated by integrating the acceleration profile. Paired t-tests were used for statistical comparison ($p=0.05$).

RESULTS AND DISCUSSION

The impact parameters under each padding condition were summarized in Table 1. The estimated impact velocities and effective masses for each condition were approximately the same, demonstrating the consistency of the impact trials under the given initial cable tension and arm angle. The impact response from the AP was significantly different from the other padding conditions, while the rest of them made no significant difference with each other. Compared with the BH condition, the AP condition had similar damping ratio but

much lower damped natural frequency (61 Hz vs. 95 Hz). This indicated that the AP introduced a 60% decrease in effective stiffness and 40% decrease in effective damping constant. The impact force profile for the AP condition became flatter with a smaller peak impact force and longer peak time, resulting significantly slower loading rate. This is a highly desirable feature for impact attenuation and subsequent pain on the hand.

SUMMARY

Upon impact testing of the hand with various padding materials the air pocket (AP) demonstrated highly desirable characteristics as a padding material for impact absorption during falling.

Figure 1. Isolated force measurement system for the impact testing of the forearm (left) and corresponding measured impact force and acceleration of the hand (right).

Table 1. Impact parameters under various padding conditions. (S.D. in parentheses)

EFFECTS OF THE RELATIVE FOREARM VELOCITY ON THE IMPACT FORCE OF THE HAND DURING FALLING

Jong-Hoon Nam, Il-Kyu Hwang, and Kyu-Jung Kim, Ph.D.

Department of Mechanical Engineering, University of Wisconsin-Milwaukee, Milwaukee, WI, USA, kimk2@uwm.edu

INTRODUCTION

Falling during various sports activities often results in serious forearm injury. The impact force on the hand is a major cause of such injuries. It has been reported that the impact force has characteristic bimodal shape, having distinct high and low frequency modes. To characterize the nature of the two modes of impact, a few biomechanical models were used to predict the impact response of the forearm (Kim 1997, Chiu 1998). However, little is known on the effect of the faller's activity before landing on the impact force of the hand, especially the upper extremity movement.

METHODS

Our previous experimental data from simulated cable-released falls (Kim 2001) were used for comparison. The impact force profiles were decomposed into the high and low frequency (or passive impact and active braking) force components using spectral techniques. The body was modeled as a linear 2-DOF mass-spring-damper system with two Voigt models in series. The resultant damping matrix was decomposed into proportional damping. The two effective masses m_1 (trunk, head, and legs) and m_2 (arm complex) were assigned to be proportional to the mass moments of inertia of the body and the arm complex. The sum of the two weight forces was set equal to the magnitude of the measured steady state force. The mass moments of inertia were obtained from the anthropometric data. A logarithmic decrement technique for the passive impact force component was used to estimate the damping (ζ_2) and damped natural frequency (ω_2) of the arm complex. The active braking force component was used to estimate the damped natural frequency of the body (ω_1). The damping ratio of the body, ζ_1 was varied between 0.5 and 0.7 to have a best least square fit to the impact force profile. The impact velocity of the whole body was estimated using the law of energy conservation. The ratio of the initial velocities between the arm complex and the body ($VR = v_{arm}/v_{body}$) was varied to find the effect of the arm movement on the impact force transmitted to the hand. The weight and height of the subject were 60.7 kg and 1.72 m, respectively.

RESULTS AND DISCUSSION

The damped natural frequencies for the two impact modes were found to be $\omega_1=8 \text{ rad/s}$, $\omega_2=100 \text{ rad/s}$ and the damping ratio of the arm complex was $\zeta_2=0.22$. To avoid the highly non-linear beginning portion of the impact force, a time delay was introduced (40 msec). The simulation results with various ζ_1 and VR were summarized in Table 1. Best fitting was

obtained with $\zeta_1=0.6$ and $VR=1.2$ (Fig 1). The VR substantially affected the peak impact and peak braking forces. An increased VR from 1.0 to 1.5 would significantly increase the peak impact force from 382 N to 560 N, while the peak braking force would be also increased from 420 N to 460 N. In other words, harder landing would increase both the peak impact and peak braking forces simultaneously. This was also confirmed in our earlier experimental data (Kim 1997) that under time critical situations a subject tended to have harder landing with faster upper extremity movement before landing, resulting in higher peak impact and braking forces after touchdown.

SUMMARY

This simulation study confirmed that the faller's activity before touchdown would affect the subsequent impact absorption of the body.

Table 1 Results of various simulations. $F_{\max 1}$ and $F_{\max 2}$ are the peak impact and peak braking forces after touchdown, respectively.

ζ_1	0.5	0.6			0.7
v_{arm} / v_{body}	1.2	1.0	1.2	1.5	1.2
$F_{\max 1} (N)$	439	382	445	560	453
$F_{\max 2} (N)$	455	420	437	460	428

FLOW IN THE STENOTIC CAROTID BIFURCATION

Stanley A. Berger and Vitaliy L. Rayz

Department of Mechanical Engineering, University of California, Berkeley, CA 94720, saberger@me.berkeley.edu

INTRODUCTION

We have concentrated our studies on the blood flow in the carotid artery bifurcation, a site especially prone to the development of atherosclerotic plaques. Plaque development is strongly influenced by rapid changes of shear stress at the artery wall. Under certain conditions the plaque may rupture, leading possibly to stroke. Fully three-dimensional, unsteady numerical simulations have been carried out for realistic geometries.

METHODS

A three-dimensional model of a severely stenotic carotid bifurcation has been created using MR images of an atherosclerotic plaque. An unstructured grid was then generated on the domain to be used for the numerical solution of the incompressible Navier-Stokes equations. To obtain an optimum grid three models with different grid densities were created and analyzed. Newtonian behavior has been assumed in most of our studies, but we do also consider the possible effects of non-Newtonian behavior. The walls of the artery are assumed to be rigid. The CFD Research Corporation finite-volume package CFD-ACE(U) was used for discretization and solution of the equations. The equations are numerically integrated over each of the computational cells, the resulting integrated equations then solved by an iterative, implicit pressure correction algorithm (SIMPLEC). The boundary conditions are zero velocity at the walls, uniform velocity at the inlet, and fixed pressure at both outlets. For steady flow simulations the initial values for velocity and pressure were set equal to zero. A steady-state solution was used as the initial condition for the unsteady simulations. Steady and transient simulations were made to assess non-Newtonian effects in the flow.

RESULTS AND DISCUSSION

Numerical solutions of the governing equations have been obtained for each of the grid density models for steady Newtonian flow at different Reynolds numbers. The quality of the grids was evaluated by comparing the velocity fields obtained for each grid. A model with 60,781 tetra cells was found to be adequate for the current analysis, and subsequent simulations were done for this grid only. This grid as well as a cross-section plane showing the stream-wise velocity distribution are shown in Figure 1. A large recirculation region can be observed in the carotid sinus upstream of the stenosis. A high velocity jet develops in the narrowest stenotic part of the internal carotid artery. Another large recirculation zone is formed downstream of the stenosis. The unsteady flow simulations show a rapidly growing high-speed jet formed at the stenosis in the systolic part of the pulse. A large recirculation zone can be observed downstream of the plaque.

During diastole the jet diminishes and the flow is more stagnant. In the non-Newtonian flow simulations the jet is less pronounced but the recirculation area downstream of the plaque is increased.

Figure 1. Unstructured 3D grid and stream-wise velocity distribution for steady flow at Reynolds number of 200.

SUMMARY

A three-dimensional model of the carotid artery bifurcation has been created and steady and unsteady Navier-Stokes equations were solved numerically. The results show qualitative agreement with the previous work done for a two-dimensional model as well as with the flow visualization results obtained by co-investigators.

INTRODUCTION

This project was designed to quantify the biomechanics of continuous passive motion (CPM) applied in a prone recumbent posture during treatment for patients with lower back pain. CPM has been available for management of postoperative joint rehabilitation for decades. Only in the past few years has it been applied to low back complaints. Reinecke et al (1994) demonstrated comfort preference with a cycling lumbar support cushion, changing the seated lumbar lordosis. Van Deursen and colleagues (2000) have introduced axial rotation using small alternating motions (0.08 Hz) of a motorized seat pan. Patients reported reduction of back pain. If effective in reducing pain for seated sufferers, CPM may be useful directly in therapy to reduce symptoms and encourage cartilage repair in patients with disc or facet disease. A first step to investigate clinical utility is the determination of mechanism of action and is the intent of this study.

METHODS

The study was conducted in two parts: first, to measure spinal kinematics during CPM and second, to measure the loads transmitted through the spine during CPM. Five volunteer subjects (age 37 ± 9.3 years) completed informed consent and participated in the study. A motorized treatment table (Leader Health Technologies, Inc. Port Orchard, WA) able to provide CPM to the lower body was modified to incorporate an AMTI force plate capable of measuring reaction loads for 6 degrees of freedom (DOF). Subjects laid in prone recumbence on the table with the lumbopelvic junction positioned above the pivot axis of the table to maximize the flexion motion at that level. CPM was induced (10 deg) at the midrange velocity (0.24 Hz) for table settings that were capable of ranging from 0.05 Hz to 0.5 Hz. Load transformation equations were used in conjunction with distance estimates (± 1 cm) from the force plate center to the L5/S1 disc to quantify the loads transmitted through the lumbopelvic junction. Load estimates were expressed as a proportion of body mass index and body weight for pooling of data across subjects. Fidelity of the table-force plate system in reporting accurate reaction loads was independently confirmed (Rogers 2001). Intersegmental motions of the lumbar spine were obtained separately by interposing the table in the imaging window of a fluoroscopic C-arm. Subjects were repositioned in prone recumbence and flexion of the torso was invoked to end-range table motion. An inclinometer recorded the maximum table motion and digitized fluoroscopic images were used to estimate the maximum intersegmental displacements at the L3/4, L4/5 and L5/S1 disc levels.

RESULTS

Inclinometer measure of maximum table motion was 35 degrees for all subjects. Vertebral angular displacement averaged $16.7 (\pm 2.6)$ degrees for maximum table motion of 35 degrees. The ratio of table to available vertebral motion is approximately 0.48. Loads transmitted through the lumbopelvic junction at 10 degrees of flexion angle showed smooth, sinusoidal form with primary components consisting of axial compression / traction (up to 9.4 ± 0.09 % BW), anteroposterior shear (up to 1.16 ± 0.004 % BW) and flexion moments (up to 0.76 ± 0.005 % BMI).

DISCUSSION

Vertebral motions induced during prone, recumbent CPM can be controlled as a function of the table motion settings in flexion. The loads that are induced by movement of the lower body against a fixed upper body are small compared to body weight and body mass index. Van Deursen et al observed loads and motions far smaller that were effective in reducing severity of suffering. Clinical testing of prone CPM, as a means to manage painful episodes and enhance tissue repair during rehabilitation of low back pain patients, seems warranted.

SUMMARY

Prone CPM invokes intervertebral displacements and loads that are proportional to body mass and of sufficient amplitude to be hypothesize that they may be clinically meaningful.

INTRODUCTION

Spinal manipulation / adjustment is inherently mechanical, applying loads to the spine and inducing motions (Triano 2001, Triano and Schultz 1997). An important factor for selecting a doctor is their qualifications (Abbott 1988). A profession's authority relies on the demonstration of skill and effectiveness (Kaiser Family Foundation 2000). Common wisdom holds that successful care is influenced by the skill of the treating doctor; in this case, mechanical skill.

Cohen et al (1995) demonstrated that physicians trained but unpracticed in procedures were no different than novice manipulators in performance. Curtis et al (2000) trained primary care physicians in manipulative methods over 18 hours across three sessions. They state, "By design, the physicians were not experts...." If skilled performance is related to outcome, can methods of training be harnessed to improve it, optimize results and minimize complications? As yet, there is no objective means to assess skill, therefore, the contribution of skill to outcome remains undefined. This project tested the strategy of rehearsal and quantitative feedback as a means of enhancing mechanical skill development using a standard reference performance criterion (Triano et al 2002).

METHODS

An instrumented treatment table (Leader 900 Z with AMTI) recorded manipulation loads acting on an imbedded force plate. Inverse dynamics estimated the loads transmitted at the L5 disc (Triano 2001, Triano and Schultz 1997, Cohen et al 1995). Performance of HVLA by two groups of students was compared over one-trimester. All students were trained in select procedures in the standard curriculum (SC). Students were randomly assigned to one of two groups. In the first group, 19 subjects followed the (SC) training. The second group consisted of 20 subjects who used the hand held Dynadjust instrument (DI), providing automated feedback, adding a daily rehearsal (home practice using 10 repetitions each). Student performance of test procedures was measured at the beginning (T1), middle (T2) and end of the trimester. Difference scores were calculated between test intervals T1, T2, and T3 and tested statistically by Student's-t and Fisher's exact tests. Primary outcomes included changes in preload, peak amplitude, slope and direction of load application.

RESULTS AND DISCUSSION

Lumbar - Peak amplitudes demonstrated significant differences by group. Preload improved 10.5% for SC and 52.5% for DI group ($p=0.0009$). The SC amplitude increased for transverse force ($p = 0.0439$). The DI group significantly

changed for sagittal force ($p = 0.0229$) and lateral bending moment ($p = 0.0182$). The rate of loading decreased 79.3 N/Sec (± 435.6 N/Sec) for the SC while the DI showed a 742 N/Sec (± 345.2) increase ($p = 0.0000$). The flexion rate decreased (50.2 ± 120.4 Nm/Sec) in the SC but over three times as much (173.2 ± 32.4 Nm/Sec) for the DI ($p=0.0074$). Lateral bending slowed 135.4 Nm/Sec (± 286.9 Nm/Sec) in the SC but increased (210.2 ± 29.11 Nm/Sec) in the DI ($p=0.0000$).

Cervical and Thoracic - Similar results were observed in the cervical and thoracic procedures. Amplitudes were significantly different based on training ($0.00458 < p < 0.0773$). Rates and durations likewise differed ($0.0024 < p < 0.0745$).

A skilled task requires the ability to produce specific action on demand (Higgins 1991). Advanced skill can moderate actions to accommodate complex problem solving. Home rehearsal with automated feedback creates larger differences in performance than standard curriculum training, more rapidly increasing the level of skill.

SUMMARY

Independent quantitative measures were used to assess results of training in the performance of mechanical procedures. Students using the Dynadjust instrument demonstrated significantly greater change in performance of select HVLA procedures for cervical, thoracic and lumbar regions. Future work is likely to result in optimizing training and permit even greater improvement.

OBTAINING PREDICTABLE LUMBOPELVIC LOADS DURING SPINAL MANIPULATION

John J. Triano, DC, PhD^{1,2} and Carolyn M. Rogers, MS^{1,2}

1. Texas Back Institute, Plano, TX, 6300 W. Parker Rd, Plano, TX 75093; jtriano@texasback.com

2. Joint Biomedical Engineering Program, University of Texas at Arlington & Southwestern Medical Center, Dallas, TX.

INTRODUCTION

Spinal manipulation has become more widely used for the management of spine-related pain over the past two decades. With the aging of America, more elder patients with degenerative disease, osteoporosis and prior spinal surgery (Triano et al 1997) are receiving treatment than ever before. Little epidemiological data is available with respect to potential risks of these procedures as a function of patient comorbidity. However, common clinical practice provides for modifications to manipulative procedures to accommodate structural changes associated with disease and surgery. This project was devised to systematically explore modifications to manipulation procedures in order to understand how to systematically control loads acting on the spine. Earlier work (Triano and Schultz 1997, Triano 1998, Triano 2000) suggests that patient postures and experienced manipulator effort can alter the loads that the spine undergoes. Quantitative knowledge of these parameters may be helpful in preventing complications from this treatment in patients that are older or have complex spinal conditions.

METHODS

This study was conducted in three parts. First, loads acting on the lumbopelvic region during typical high velocity, low amplitude (HVLA) procedures were measured using a specially instrumented treatment table described previously (Triano and Schultz 1997, Triano 1998). A standard treatment table (Leader Health Technologies, Inc. Port Orchard, WA) was modified to incorporate an AMTI force plate capable of measuring reaction loads for 6 DOF. Load transformation equations were used in conjunction with distance estimates (± 1 cm) from the force plate center to the L5/S1 disc to quantify the loads transmitted through the lumbopelvic junction. Fidelity of the table-force plate system in reporting accurate reaction loads was independently confirmed. The typical procedure used for this study was defined by averaging the measured loads from 22 procedures performed on 11 volunteer subjects by 6 physicians with experience ranging from 1.5 to 24 years. Using a load-transformation computer modeling technique, the effects of systematic variation in patient posture were estimated. Second, relative intersegmental postures associated with lumbopelvic flexion and lateral bending were quantitatively defined. Five subject volunteers (age 37 ± 9.3 years) completed informed consent and participated in the study. Intersegmental motions of the lumbar spine were obtained separately by positioning the lumbopelvic region according to feasible treatment extremes in flexion, extension and lateral bending while in a fluoroscopic C-arm. Displacements at the L3/4, L4/5 and L5/S1 disc levels were determined from digitized fluoroscopic

images. Systematic intersegmental displacements from the measures were introduced to the computer model in the third step of the study, using small angle increments until the total range of displacements was achieved. Results were associated with specific postural variations.

RESULTS AND DISCUSSION

The matrix of 3 dimensional rotations derived from fluoroscopic measures included flexion ($0 < \alpha < 9.2$), axial rotation ($0 < \beta < 55$) and lateral bending ($-10.2 < \delta < 17.2$) defined in terms of reference to the initial anatomical position. Postural variation resulted in sequential transition in the amplitudes of force and moment components acting on the lumbopelvic spine that range from 25% to 261%. In the case of shear force acting across the spine from left to right (frontal plane), the direction of loading was able to be modified without changing the input manipulation load.

Quantitative knowledge of this type is useful in understanding the applications and limitations of manipulative procedures. Long a procedure based on empirical observation alone, this type of data can now be used in further computer modeling to explore how these procedures might effect patients with complex or post-surgical changes. Such models limit the risk to patients while maximizing information that can help develop realistic and safer treatment protocols.

SUMMARY

Systematic modification of patient posture theoretically may be used to control the amplitude of select components of manipulation loads acting on the spine. Capacity of operators performing these procedures to intentionally achieve specific loads systematically may now be assessed.

FLOW AND WALL COMPRESSION IN HIGH GRADE ASYMMETRIC ARTERIAL STENOSIS MODELS DURING PULSATILE FLOW EXPERIMENTS

Shunichi Kobayashi¹, Takeshi Horie¹, Daisuke Tsunoda¹, Hirohisa Morikawa¹, Dalin Tang², David N. Ku³

¹ Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano 386-8567, Japan, shukoba@gipsc.shinshu-u.ac.jp

² Mathematical Sciences Department, Worcester Polytechnic Institute, Worcester, MA 01609, USA

³ School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA 30332-0405, USA

INTRODUCTION

High grade stenoses can limit blood flow and produce conditions in which the artery may collapse. This resultant compression may be important in the development of atherosclerotic plaque fracture and subsequent thrombosis or distal embolization. We used an asymmetric experimental model that closely approximates the arterial disease situation where the entire stenosis is compliant. This study was to examine flow rate, pressure, stenosis severity and eccentricity characteristics inducing collapse under pulsatile flow.

METHOD

The diseased carotid artery was modeled using an elastic hydrogel shaped in the form of a stenosis. Figure 1 illustrates the asymmetric stenosis shape of the hydrogel model. Nominal stenosis severity (percent stenosis) St and eccentricity Ec of the stenosis model are given by,

$$St = (D - D_s)/D \times 100 [\%], \quad Ec = e/((D - D_s)/2) \times 100 [\%],$$

where D and D_s are diameter at straight portion and throat of stenosis, respectively. e is the distance between the center of straight portion and the center of the throat.

Pulsatile flow was perfused through the hydrogel stenosis model. The computer controlled gear pump which works as alternative current component, was connected to upstream tube. The upstream pressures was set as 100 \pm 30mmHg and downstream pressure was changed. Sagittal section image of stenosis was made a video signal by the B-mode of a Duplex ultrasound scanning.

RESULTS AND DISCUSSION

The stenosis model caused a phase difference of flow rate and pressure between upstream and downstream. The phase difference in the stenosis model is accounted by the compliance of the straight portion (tube) of the stenosis model and the resistance of stenosis.

Ultrasound images of sagittal section of stenosis model (70% St , 100% Ec) are shown in Figure 2. For the average down-

Figure 1: Schematic representation of the stenosis models. $L=110$ mm, $L_s=16$ mm, $D=8$ mm, $h=1$ mm.

stream pressure (P_{2ave}) of 0mmHg, the full collapse during the whole cycle occurs. Table 1 shows the P_{2ave} when the first outbreak of collapse is occurred. P_{2ave} increases with an increase in eccentricity and a decrease in stenosis severity. This is accounted by the geometrical stiffness against collapse. Thinner part of the post stenosis tends to collapse. The phase of the first outbreak of collapse was generally around the end of systole (higher flow rate at post stenosis).

SUMMARY

The results indicate that a combination of percent stenosis and eccentricity would be a more accurate indicator for wall compression. The wall compression, in turn, may contribute to plaque rupture.

FLOW DUE TO A PERISTALTIC WAVE IN A TUBE

Mehran Tadjfar and Ryutaro Himeno

Advanced Computing Center
Institute of Physical and Chemical Research (RIKEN)
2-1, Hirosawa, Wako-Shi, Saitama, JAPAN

INTRODUCTION

In the human body the most common method of transporting fluid is through peristaltic pumping. Peristalsis occurs in the transport of urine from kidneys to bladder in the ureter, transport of food bolus through the oesophagus, gastrointestinal tracts, and the ejection of semen from male reproductive organ amongst many. The vast lymphatic system all over the body is using peristalsis to circulate lymph through the blood stream. The lymph vessels have one way valves and smooth muscle medial layer, which contract periodically to perform the peristaltic pumping. Here, we use CFD methods to study the peristaltic flow in a tube initiated by a single wave motion (Fig. 1).

METHODS

The unsteady, three-dimensional, incompressible Navier-Stokes equations are solved using a fast, parallel, and time-accurate finite volume solver (See Tadjfar 2002). The solver is capable of dealing with moving boundaries and moving grids. It is designed to handle complex, three-dimensional vascular systems. The computational domain is divided into multiple block subdomains. At each cross section the plane is divided into twelve sub-zones to allow flexibility for handling complex geometries and, if needed, appropriate parallel data partitioning. A second-order in time and third-order upwind finite volume method for solving time-accurate incompressible flows based on pseudo-compressibility and dual time-stepping technique is used.

RESULTS AND DISCUSSION

Considering an initial sinusoidal activation signal for the muscle wall results in a “tear-drop” wall shape coming out of the interaction (See Carew and Pedley). This shape is the result of some fluid being pushed into the tube (by some relevant mechanism involved in that particular case). After the initial dilation of the tube there is a region of constant maximum stretched diameter caused by some time lag before the surrounding muscle tissues contract the lumen back to its original diameter. This passive filling and active contraction with some associated time lag causes the formation of the “tear-drop” shape on the tube wall. It is the numerical

Figure 1: Grid model of the peristaltic wave in a tube.

Figure 2: The pressure distribution along the centerline of the tube at different times.

solution of the unsteady 3-D Navier-Stokes equations for the “tear-drop” shaped wall waves that is the subject of this study. After an initial transient period a pressure gradient is created that carries the fluid downstream along the tube (Fig 2).

COMPARISON OF TRANSIENT FORCE ATTENUATION BETWEEN THREE TYPES OF HEEL CUSHIONS USED IN RUNNING SHOES

Arnel Aguinaldo, Michael Litavish, and Abigail Morales

Motion Analysis Laboratory, Children's Hospital, San Diego, CA

Correspondence: aaguinaldo@chsd.org, Online: www.sandiegogaitlab.com

INTRODUCTION

As the foot strikes the ground, the momentum from the moving limb rapidly changes, resulting in a transient force transmitted up the skeleton. The repetitive transmission of this force has been suggested to be a contributing factor in the development of joint degradation (Radin, et al., 1972). Although the foot has internal structures that help attenuate this impact shock, footwear with rearfoot cushioning soles have been proven to provide effective impact attenuation (Hennig, et al., 1993). Impact forces are dependent on the mechanical properties of the interface between the ground and the foot, as well as on the activity in which the moving limb is involved. Since various footwear manufacturers use different materials to provide impact attenuation, it is unknown whether shoes with different heel cushions provide the same level of attenuation during walking and running. Therefore, the purpose of this investigation was to evaluate the effects of three types of footwear with different heel midsole cushions on transient forces, measured through the initial vertical ground reaction force following footstrike.

METHODS

Eight male and two female subjects participated in the study after signing informed consent forms approved by the hospital's Institutional Review Board. Each subject walked and ran a 12-meter runway while eight high-speed cameras (Motion Analysis Corporation, Santa Rosa, CA) collected coordinate data from a cluster based marker set used to define the pelvis, thigh, and shank segments. Three force platforms (AMTI, Watertown, MA) with a natural frequency of 450 Hz were used to collect ground reaction forces (GRF) at a sampling rate of 1000 Hz. A heelstrike transient (impact) force was identified, as defined by Whittle (1999), by a quick spike in force superimposed in the upslope of the initial GRF peak occurring in the first 30 ms after footstrike during walking (Figure 1), approximately 15% of the gait cycle. Additionally, plantar-dorsi flexion was measured to verify ankle position at footstrike. Walking and running sessions were conducted with each of the following shoes: Shoe 1 (polyurethane), Shoe 2 (mechanical cushion), and Shoe 3 (EVA material). Transient forces from each shod session were compared to each other and to the barefoot condition using a 4-level repeated measures ANOVA.

Figure 1: Heelstrike transient force (impact peak)

RESULTS AND DISCUSSION

Figure 2a shows the walking heelstrike transients for each condition. There were significant differences found between Shoe 1 and Shoe 2, as well as between Shoe 2 and barefoot conditions. No differences in plantar-dorsiflexion were found for walking. However, there was an increase in plantarflexion ($-3^\circ \pm 1^\circ$) at footstrike during barefoot running. Thus, initial GRF peaks of barefoot running were removed from the statistical analysis, which resulted in a significant difference found in impact peaks between Shoes 1 and 2 (Figure 2b).

Footwear provides an additional layer of protection against impact forces. However, the differences in shoe construction complicate the analysis of how impact attenuation occurs with footwear (Clarke, et al., 1983). Shoe 2 utilizes a midsole system of four columns that are each a two-level dynamic cushion (Iso-Dynamics, Cleveland, OH) designed with a loading response similar to that of a linear hydraulic shock absorber. In this study, Shoe 2 exhibited the lowest heelstrike transient during walking. Conversely, Shoes 1 and 3, which are manufactured with polyurethane and ethylene vinyl acetate (EVA) midsoles, respectively, attenuated walking heelstrike transient less effectively than Shoe 2. Although impact forces during barefoot running were not analyzed, due to the apparent midfoot strike at initial contact, the initial GRF peaks during running showed that Shoe 2 dissipated the vertical impact force more effectively than Shoe 1.

Figure 2: Impact forces during a) walking and b) running

SUMMARY

Impact forces were measured with three shoe types during walking and running. The mechanical cushioned shoe exhibited the lowest transient forces. It was found that impact forces varied with shoe type and, therefore, should be carefully evaluated when selecting shoes for injury prevention.

INTRODUCTION

Endovascular technique using a tubular shaped stent has been developed and successfully used in treating wide neck aneurysms. A self-expandable stent is introduced via a small catheter and placed at the aneurysm neck. A stent can promote thrombosis formation inside the aneurysm sac by stagnating intraaneurysmal flow, and provide biocompatible passage of the parent artery by neointimal formation on the stent wall. Thrombus formation and neointima growth may be affected by the flow characteristics inside the aneurysm. We want to clarify velocity and wall shear stress changes by stenting under physiological flow for the lateral aneurysm models, and explore the effects of stent porosity and aneurysm geometry on the flow fields inside the aneurysm sac.

METHODS

Transparent models with different lateral aneurysm shapes are manufactured using a glass model as a male mold. A male wax model made from the glass model is enclosed in an acryl box, and transparent silicone resin (Sylgard 184, Dow-Corning) is poured. After silicone resin is cured, wax is melted out and an acryl box is removed. Both models have parent artery diameter (D) of 5 mm and neck width of 14 mm, and the lateral aneurysm model 1 (L1) has dome height (the distance between neck and fundus) of 4.8 mm while the lateral aneurysm mode 2 (L2) has dome height of 6 mm. The stents used in this study have porosity of 0.86 (stent 1) and 0.79 (stent 2) respectively, and length of 20 mm. The aneurysm model is inserted into a mock circulation loop, which can generate physiological flow waveform. We use a flow visualization method incorporating photochromic dye in order to observe the flow fields and measure the wall shear rates. We visualize flow motion at five different axial locations along the aneurysm wall – maximally dilated location (pt.3), 0.3D (pt.2) and 0.6D(pt.1) proximal location, 0.3D(pt.4) and 0.6D(pt.5) distal location. Wall shear rates are measured at each location for five different phases of a flow cycle (T: period) – early acceleration ($t/T=0.05$), mid acceleration ($t/T=0.13$), peak ($t/T=0.21$), early deceleration ($t/T=0.26$) and late deceleration ($t/T=0.35$).

RESULTS AND DISCUSSION

Intraaneurysmal flow activity was significantly reduced in the aneurysm models with a stent. The magnitude and pulsatility of shear rate were also decreased significantly in the stented aneurysm models. The shape of the aneurysm sac and the stent porosity did not affect the intraaneurysmal flow patterns and

wall shear rate distribution significantly. The magnitudes of wall shear rates were less than 100 sec^{-1} along the aneurysm wall during a flow cycle in the stented lateral aneurysm models (Figure1). Since intraaneurysmal fluid motion, the magnitude and pulsatility of wall shear rate were significantly reduced in the stented models, insertion of a stent may provide more thrombogenic hemodynamic environment inside the aneurysm. Further study will be performed to elucidate the hemodynamic effects on the thrombus formation and neointima development on the stent wall.

Figure 1: Wall shear rates along the aneurysm wall for five different phases in the lateral aneurysm model without a stent (L1N) and with a stent 1(L1S1).

A TEMPORAL, KINEMATIC AND KINETIC ANALYSIS OF THREE EQUI-VOLUME LOADING PATTERNS

John Cronin and Blair Crewther

Sport Performance Research Centre - Auckland University of Technology. john.cronin@aut.ac.nz

INTRODUCTION

Loads greater than 60-70% 1RM are thought fundamental to the development of maximal strength and an important stimulus for muscle hypertrophy^{4,5}. In strength trained athletes even greater loading intensities (80-100% 1RM) are thought critical for the development of maximal strength³. However, a number of studies have found light load (10-30% 1RM) explosive training to be equally effective in enhancing a variety of performance measures (including strength and increases in CSA) as compared to heavier weight training (75-85% 1RM)^{1,2,6}. In light of the inconsistencies of research in this area, this study investigated whether three training loads (30%, 60% and 90% 1RM) equated by volume, differed in terms of their temporal, kinematic and kinetic characteristics.

METHODS

Twelve (7 males and 5 females) experienced weight trainers (mean age and weight were 30.2 ± 10.6 years and 75.8 ± 13.0 kg respectively) were assessed on an instrumented isoinertial supine squat machine. Testing was conducted over two sessions. In the first session the one repetition maximum (1RM) of each subject was established. The second session involved subjects performing a set at 30%, 60% and 90% of their 1RM. Each set was equated by volume (% 1RM x reps) to ensure that total mass lifted between conditions was identical. The instructions to the subjects for all repetitions were to move the load as “explosively” as possible. The sequence in which each subject performed the three sets was randomised to negate order and fatigue effects.

RESULTS AND DISCUSSION

Significantly ($p < 0.05$) greater total time under tension during the eccentric (41-53%) and concentric phases (27-31%) was observed for the 30% 1RM condition as compared to the other

two conditions. Similarly the lighter loading intensity resulted in significantly greater total eccentric (9-19%) and concentric (14-24%) force output as compared to the other two conditions. If time under tension and high forces are the critical stimuli to strength development then the greater total force and greater total duration under tension of the 30% 1RM condition would seem superior. However, if force x time under tension (impulse) is the critical stimulus for producing strength and hypertrophic change, the concentric impulse associated with the 90% 1RM condition would appear superior (29-42%). It has also been suggested that total work done is important for muscle hypertrophy⁶. Greater total work (9-24%) was associated with the 30% 1RM condition.

SUMMARY

Research studying the temporal, kinematic and kinetic characteristics of a set rather than a single repetition provides better insight into the changes and adaptations that may occur with the repeated application of a training stimulus. Such research is more likely to contribute to our understanding of how various training programmes optimize strength and power development.

³National Rehabilitation Center for the Disabled, Tokorozawa, Japan

INTRODUCTION

Various kinds of orthopedic devices have been developed to assist walks and stances in paraplegic patients up to now. Furthermore, the devices have been combined with functional electric stimulation techniques to reduce the effort needed and to walk farther. In this study we developed a new gait orthosis featuring the rotating knee joint mechanism powered by a linear actuator, and tested it with a spinal cord injury patient.

MATERIALS AND METHODS

Figure 1 shows the schematic diagram and the photograph of the device we developed. A linear motion actuator was mounted at the back of the knee joint of an Advanced Reciprocating Gait Orthosis (ARGO). The actuator consists of a low-inertia DC motor (3557, Faulhaber, Switzerland) and a ball screw (Kuroda Precision Industries Ltd., Japan). The stroke length of the linear actuation and the maximum knee rotational angle were set at 15 cm and 70 degree, respectively. As shown, the mechanism mounted is compact and its weight is 0.8 kg. We used Ni-H rechargeable batteries featuring both lightweight and large capacity (HR-3US, 1600 mAh, Sanyo Co., Japan). From the viewpoint of safety, we adopted an infrared switch to control knee action in case that a user might be caught by a cable and fall down. The switch is placed on an arm crutch handle and pushed by a user itself along with every step. Furthermore, the knee joint of ARGO stays locked throughout extension phase. It is unlocked by the actuator through flexion phase and is locked again at heel strike. We measured the gait of a patient (male, 23 yrs, T12) with this device on, by using the vicon system (Oxford Metrics Co., UK) at the sampling rate of 60Hz.

RESULTS AND DISCUSSION

Figure 2 shows the self-paced gait of the patient with and without the device. As shown, the walking pattern with the device was found to be close to healthy subject's one. The walking speed with the device was about 0.4 m/s, which could be faster by trainings. The knee joint rotated about 40 degree at maximum flexion. The patient expressed that the effort required for walking was drastically reduced due to the device. The fully-charged battery could last for about one hour walk without exchange. The relationship between the foot-floor clearance of the device and the mechanism must be studied through further experiments.

SUMMARY

We developed a new gait orthotic device for paraplegics. The

feature is the motor-driven knee joint mechanism which makes patient's gait close to healthy one. Through preliminary experiments with a patient, we found that the walking speed was about 0.4 m/sec, and we make sure that the effort for walking was reduced by rotating the knee joint during swing phase.

GEOMETRIC MODELLING OF SKELETAL MUSCLE USING HERMITE ELEMENTS

Fernandez, J.W.* Blyth, P. Anderson, I.A. and Hunter, P.J.

Bioengineering Institute, University of Auckland, New Zealand

*jw.fernandez@auckland.ac.nz

INTRODUCTION

This abstract explores the convenience and computational efficiency of cubic Hermite volume elements for use in anatomically accurate finite element models of skeletal muscles. Other three-dimensional studies of skeletal muscle have used linear based elements [Gentaro et al, 2000]. By comparison, Hermite elements use high order interpolation and describe high geometric gradients with low element numbers. This provides a basis for incorporating a fibre distribution also interpolated using cubic Hermite shape functions. Further, the derivative continuity at nodes provides benefits when considering contact mechanics.

METHODS

Using the finite element analysis software CMISS (developed by the Bioengineering Institute, University of Auckland) 9 muscles associated with knee joint function were modelled. The procedure involved the following steps: A bi-linear surface mesh was developed for a specific muscle from axial slices of the visible human data set [Ackerman, 1998]; constant spacing allowed for a consistent mesh (Fig. 1a). Data points were orthogonally projected onto the mesh surface and defined as material coordinates. Using a least-squares fitting algorithm [Bradley et al, 1997] the difference between the original data and orthogonal projections was minimised. This was achieved through an optimisation routine which varied the nodal derivative parameters (Fig. 1b). Following this, volume elements were generated by linearly extruding to a central node, defined as the geometric mean of an axial slice (Fig. 1c).

Figure 1: a) Linear mesh with data points for rectus femoris muscle; b) Fitted surface; c) Volume elements created by extruding to central nodes;

RESULTS

The results in Table 1 were obtained using a 180 MHz O2 computer (SGI, CA, USA). Element numbers were chosen to give a root mean square (RMS) difference of less than 2mm

(with an average of 1.33 mm over 9 muscles). Fitting time averaged 48.4 seconds over 9 fits.

Muscle	nodes	elements	data points	RMS (mm)	time (sec)
Rectus femoris	32	28	1607	0.84	47.00
Vastus lateralis	60	54	2404	1.96	86.00
Vastus medialis	63	56	1779	1.94	90.00
Tensor fascia latae	42	36	442	0.95	34.00
Gracilis	32	28	820	1.85	27.00
Biceps long head	48	42	1534	1.50	54.00
Biceps short head	28	24	846	1.15	31.00
Semimembranosus	20	16	1482	1.27	39.00
Semitendinosus	28	24	879	0.51	28.00
Average	39	34	1310	1.33	48.4
s.d.	14.2	13.1	575.4	0.5	22.7

Table 1: Results for 9 muscles

DISCUSSION

Hermite basis functions dramatically reduce element numbers needed to describe complex geometry (an average of 34 elements for the 9 muscles modelled). A further benefit is the ability to define curvature within a mesh volume, improving description of muscles with high internal geometric gradients, such as the vastus group which wrap around the femur. Additionally our design accommodates muscle bifurcation such as that seen in the gastrocnemius. Currently, the contact between muscles in the human knee is being investigated. The Hermite elements allow for a smooth contact surface and reduce the contact search time with lower element numbers.

SUMMARY

Cubic Hermite elements are suitable for the finite element modelling of limb muscles. They provide realistic visualisation for such applications as virtual surgery. Model customisation using patient specific-data obtained from MRI and CT is also being explored, with the intent of producing a diagnostic and therapeutic tool.

EFFICIENT FINITE ELEMENT CUSTOMISATION OF A GENERIC FEMUR USING THE HOST MESH TECHNIQUE

Fernandez, J.W.* Blyth, P. Thrupp, S.F. Anderson, I.A. and Hunter, P.J.

Bioengineering Institute, University of Auckland, New Zealand

[*jw.fernandez@auckland.ac.nz](mailto:jw.fernandez@auckland.ac.nz)

INTRODUCTION

Patient-specific models are of interest in modelling and surgical planning. Previously published techniques for model customisation have required long processing times [Viceconte et al, 1998]. Here we present a new highly efficient procedure using 24 key landmark points to customise a generic femur to patient data, capturing important features of patient geometry. In addition, the high order elements employed allow for a continuous surface curvature and may prove a useful aid in visualisation. By comparison, other models typically use linear elements [Couteau et al, 2000].

METHODS

Using the finite element analysis software CMISS (developed by the Bioengineering Institute, University of Auckland) a tri-cubic Hermite host mesh was defined to enclose the generic femur, and subdivided into three regions giving separate control of the head, shaft and condyles (Fig. 1). The generic mesh was described by 416 bi-cubic Hermite elements. Twenty-four key landmark data points were chosen along with the corresponding projection points on the data set in question. The landmark points and femur mesh nodes were defined as fixed material coordinates within the host mesh and inherently transformed as the host mesh was deformed. The host mesh was constrained to deform in certain directions. Using a least-squares algorithm the difference between the landmark and projection data was minimised [Bradley et al, 1997]. The fitting procedure varied nodal coordinates and derivatives to achieve the host configuration with the minimum overall root mean square (RMS).

To validate this method, a sample of 5 femur datasets were used (4 scans of cadaveric femurs and the visual human dataset [Ackerman, 1998]), each containing on average 2400 points with varying geometrical features. The 4 femurs were suspended over a laboratory bench and data was collected using a hand-held laser scanner (FastSCAN™, Applied Research Associates, ChCh, NZ).

RESULTS

Using a 180 MHz O2 computer, (SGI,CA,USA) the fitting process took less than 100 seconds. The algorithm yielded an average RMS of 3.09mm with a standard deviation of 0.15mm. Operator time for positioning the projection points was less than 5 minutes.

DISCUSSION

The efficiency of this technique allows for the rapid generation of patient and sub-population specific models in the design and testing of prostheses, and in surgical planning. Particular attention has been paid to ensuring the accuracy of parameters such as neck-shaft angle, femoral head size, and neck length, key features of interest to orthopaedic surgeons and important for stress analysis. Further, the key landmark points used are easily identified on sagittal and coronal MRI images. Other methods such as that described by [Couteau et al, 2000] use segmentation of CT scans to obtain data and hence require long pre-processing times. [Viceconte et al, 1998] analysed this and other methods and report times in the order of 250-520 minutes and operator times of 380-690 minutes. In contrast, by manually selecting 24 points our processing time is significantly reduced.

Figure 1: The yellow (light) generic bone is transformed to the red (dark) customised bone.

SUMMARY

This abstract presents a novel means for customisation of human bone geometry with generation of patient specific models on a PC from minimal MRI or CT scans in under 10 minutes. This accurate surface geometry can be used to generate volume meshes automatically. It has widespread applications from stress analysis to surgical simulation and planning, and may be adapted to other organs such as skeletal muscle.

INTRODUCTION

Many marine animals thrive in near shore, high-energy environments where rapidly changing flow velocities created by surges, currents, and breaking waves present extreme challenges to precision maneuvering and hovering performance. Many near-shore fishes employ one or more pairs of oscillating fins to increase both stability and maneuverability. It is reasonable to believe that these highly maneuverable fishes serve as excellent biological templates for the design of man-made vehicles with extreme maneuvering and stealth capabilities.

Kinematic studies indicate that pectoral fin movements are variable among species and across a range of swimming speeds with complex fin ray patterns. Lindsey (1978) referred to propulsion by oscillation of pectoral fins as “Labriform swimming mode” after Labridae. Labriform swimming consists of *drag-based* labriform swimming mode at low swimming speeds and *lift-based* labriform swimming mode at higher swimming speeds. The former is characterized by the rowing action of pectoral fins forming a high angle to the horizontal axis of fish body. The latter is characterized by the flapping action of pectoral fins forming a small angle to the horizontal.

This paper experimentally discusses the hydrodynamic characteristics of a flapping, rowing and feathering fin system in terms of drag-based labriform swimming mode and lift-based labriform swimming mode.

MECHANICAL PECTORAL FIN

To experimentally and numerically assess the hydrodynamic characteristics of flapping, rowing and feathering fin system in a precise manner, a compact Three-Motor-Driven Mechanical Pectoral Fin (3MDMPF) (Kato et. al., 2002) device with high speed capability and precise movement was manufactured(see Fig.1). The device is equipped with a force sensor measuring normal force acting on the rigid fin and a torque sensor measuring torque around a fin shaft. Potentiometers for measuring angles of rowing motion, flapping motion and feathering motion are installed inside the device.

The rowing angle, the feathering angle, and the flapping angle were varied sinusoidally.

An open water test of the mechanical pectoral fin was carried out in a water-circulating tank, with measurement section of 2.2 m long, 1.4 m wide and 0.9 m deep. The hydrodynamic characteristics were investigated in terms of the following items.

- (1) Phase difference between the rowing motion and the feathering motion, $\Delta\phi_{FE}$, without the flapping motion for drag-based labriform swimming mode,
- (2) Phase difference between the rowing motion and the flapping motion, $\Delta\phi_{FL}$, with $\Delta\phi_{FE}$ of 90° for drag-based labriform swimming mode,
- (3) Phase difference between the feathering motion and the flapping motion with $\Delta\phi_{FE}$ of 0° for lift-based labriform swimming mode,

- (4) Non-dimensional frequency, K , which is defined as

$$K = c \cdot \omega_{fin} / U \quad (1)$$

- (c: chord of fin, ω_{fin} : angular frequency, U : uniform speed)

- (5) Frequency change in still water and

- (6) Non-sinusoidal feathering motion without uniform flow.

SUMMARY

Experimental tests by a compact mechanical pectoral fin device making a flapping motion, rowing motion and feathering motion in a precise manner revealed that the effect of the flapping motion on the propulsive force coefficient and the propulsive efficiency of the drag-based labriform swimming mode is remarkable not only in uniform flow, but also in still water.

The propulsive efficiency of lift-based labriform swimming mode reaches 40% at the maximum, that is larger than in the case of drag-based swimming mode.

Non-sinusoidal feathering motion of the drag-based labriform swimming mode in still water can generate propulsive force in the X direction with small hydrodynamic forces in the Y and Z directions.

INTRODUCTION

Osteoporosis is defined as a systemic skeletal disease caused by low bone mass and microstructure deterioration of trabecular bone. Li *et al.* (1995) has shown that a drug therapy (PTH: Parathyroid hormone) increases the bone mass and thus bone strength. Vertebroplasty is a surgical procedure for the treatment of osteoporotic vertebrae. This procedure includes puncturing vertebrae and filling with Polymethylmethacrylate (PMMA). In the present study, several (intact, aged, hormone treated and bone cement treated) 2D models for the treatment of osteoporotic vertebrae are analyzed and the relative effects of drug therapy and bone cement treatment are compared using finite element analysis.

METHODS

Five 2D finite element models of the same relative density (0.134) were generated for intact vertebral trabecular bones using Voronoi diagram method suggested by Silva and Gibson (1997). For direct comparison with results of Silva and Gibson, these models were allowed to have the same trabecular tissue properties as those used in their models. Displacement boundary conditions were applied to simulate a uniaxial compression test for the longitudinal direction. Five models for aged bones with the relative density of 0.114 were also generated and analyzed for each model using commercial finite element software (ANSYS 5.7; ANSYS, Inc.).

In order to compare the results of hormone-treated model given by Silva and Gibson with those of bone cement-treated model, five models for each case were analyzed. In this study, hormone-treated models have the same relative density (0.134) as that used in models of Silva and Gibson. In bone cement-treated models, to show the effect of bone cement treatment, the same relative density (0.114) as that of the intact bone model was used and bone cement was modeled by shell element.

RESULTS AND DISCUSSION

The results of the present analysis for hormone-treated models show an excellent agreement with those given by Silva and Gibson. Modulus and strength of hormone-treated models were approximately 30% of those of intact models and they were about 60% of those of the bone cement-treated models (Figures 1, 2). From these results, it is found that the bone cement treatment is likely to decrease the incidence of vertebral fractures, compared with the drug therapy. Since this study is a preliminary investigation,

more in-depth studies on the 3D models of human vertebral trabecular bone need to be followed.

Figure 1: Effective Young's modulus and strength of each models.

Figure 2: Deformed state of treated models.

SUMMARY

It is reported that the mechanical properties of vertebral trabecular bone depend on the density and the mass of bones. Silva and Gibson studied the treatment of age-related bone loss using drug therapy. However, the relative effect of drug therapy and bone cement for osteoporosis treatment is not reported yet. In this study, several 2D models of human vertebral trabecular bone are analyzed by finite element method. The mechanical behaviors of the vertebral trabecular bone treated by the drug therapy and the bone cement are compared. This study shows that bone cement treatment is more effective strategy than drug therapy to prevent the degradation of bone strength.

INTRODUCTION

Kinematic studies indicate that pectoral fin movements are variable among species and across a range of swimming speeds with complex fin ray patterns. Lindsey (1978) referred to propulsion by oscillation of pectoral fins as “Labriform swimming mode” after Labridae. Labriform swimming consists of *drag-based* labriform swimming mode at low swimming speeds and *lift-based* labriform swimming mode at higher swimming speeds. The former is characterized by the rowing action of pectoral fins forming a high angle to the horizontal axis of fish body. The latter is characterized by the flapping action of pectoral fins forming a small angle to the horizontal.

To experimentally and numerically assess the hydrodynamic characteristics of flapping, rowing and feathering pectoral fin system in a precise manner, a compact Three-Motor-Driven Mechanical Pectoral Fin (3MDMPF) (Kato et. al., 2002) device with high speed capability and precise movement was manufactured. The device is equipped with a force sensor measuring normal force acting on the rigid fin and a torque sensor measuring torque around a fin shaft. Potentiometers for measuring angles of rowing motion, flapping motion and feathering motion are installed inside the device.

The most important task using 3MDMPF is to establish an optimal match between the fin geometry and the motion in terms of optimal control force generation. The optimal parameters of the fin motion to generate the maximum control force in a particular direction were obtained experimentally by combining the experimental device and Hooke-Jeeves non-linear optimization method.

In this work, the optimal parameters of the fin motions were obtained so as to generate the maximum control force in X, Y, Z directions in terms of effects of uniform flow and motion pattern. Namely, motion parameters were optimized in a uniform flow or in still water, and in drag-based labriform swimming mode or in lift-based labriform swimming mode.

EXPERIMENTAL SETUP

The rowing angle ϕ_R , the feathering angle ϕ_{FE} , and the flapping angle ϕ_{FL} , were varied sinusoidally using the following definitions.

$$\begin{aligned}\phi_R &= \phi_{R0} - \phi_{RA} \cdot \cos(\omega_{fin} \cdot t) \\ \phi_{FE} &= \phi_{FE0} - \phi_{FEA} \cdot \cos(\omega_{fin} \cdot t + \Delta\phi_{FE}) \\ \phi_{FL} &= -\phi_{FLA} \cdot \cos(\omega_{fin} \cdot t + \Delta\phi_{FL})\end{aligned}\quad (1)$$

Experimental device is composed of the cylindrical body with

the 3MDMPF, a computer for data generation and analysis with AD and DA boards and a computer where the optimization program runs and the second data processing for hydrodynamic coefficients.

The uniform velocity and the frequency were taken as 0.2 m/s and 1.25 Hz, respectively. Two kinds of initial conditions corresponding to the drag-based labriform swimming mode and the lift-based labriform swimming mode were given.

Figure 1: Variation of propulsive force coefficients during procedure of optimization for drag-based swimming mode in still water

SUMMARY

We have revealed through the optimization of motion of a mechanical pectoral fin that the lift-based labriform swimming mode rather than the drag-based labriform swimming mode is suitable for generation of propulsive force in uniform flow, while the drag-based labriform swimming mode rather than the lift-based labriform swimming mode is suitable for generation of propulsive force in still water.

INTRODUCTION

Biological fluid dynamics associated with interaction between an oscillating wing or fin and a body is very common in animal swimming and flying. Many fishes thrive in extreme environments as fast currents and present excellent maneuvering performance by means of pectoral fins. Birds and insects beat their wings rapidly for hovering, and darting flight, in performing high stability and maneuverability. These locomotion mechanisms can be transferred from fluid dynamic viewpoint to the basic problem of the interactions among the wing or fin, the body and the surrounding flow. Interaction between an oscillating body and the flow about it has been the main subjects in studying biological fluid phenomena (Liu et al., 1998) but very few studies can be found, that deal with the hydrodynamics of a flapping wing or fin with consideration of the interaction of a body it attaches onto.

METHODS

We developed a computational fluid dynamic (CFD) simulator for biological fluid dynamics about realistic swimming and flying animals, which has been recently upgraded to be able to deal with a multi-body object. The simulator specified for the current problem is based on a solver for unsteady, incompressible Navier-Stokes equations developed by Liu et al., 1998, in which a geometric model and a kinematic model are incorporated. Upon the establishment and modification of the CFD simulator the following issues are taken into account: 1) build-up of a CFD simulator with special focus on modeling of unsteady hydrodynamics of a single flapping fin; 2) build-up of a CFD simulator with special focus on modeling of unsteady hydrodynamics of a body and a flapping fin.

In this paper we first discuss the verification and validation of our method by comparison with the measured hydrodynamic forces of a mechanical flapping pectoral fin with a cylinder body in Fig. 2(Kato et al., 2002) and furthermore address the hydrodynamics in terms of interaction between the fin and the body.

RESULTS AND DISCUSSIONS

Computed results of a body-fin model undergoing rowing and feathering motions in uniform flow at a Reynolds number of 1.597×10^4 and the reduced frequency of 3.0 was illustrated in Fig. 1-2. Time variation of coefficients of hydrodynamic forces C_x , C_y was plotted in Fig. 1. With influence of the inflow, timing of the

occurrence of the maximum thrust, zero thrust and minimum thrust changes slightly compared with those of the fin in stillwater. Flow pattern around the fin are shown in terms of velocity vectors, instantaneous streamlines, and pressure contours at instant when the C_x is max. Unlike the leading- and trailing edge vortex pattern about the fin in still water, the inflow obviously changes the vortex structure around the fin largely, leading to a long wake behind the fin. The interaction between the body and the fin likely extends significant influence on the feature of the wake structure and hence the force generation.

Fig. 1 Hydrodynamic forces

Fig. 2 Flow pattern

SUMMARY

An integrated CFD simulator has been established and validated for computational modeling of biological fluid dynamics associated with realistic multi-body model. An extended study on hydrodynamics of a flapping fin with interaction of a body shows that the hydrodynamic performance of the flapping fin can be affected significantly by the existence of the body.

INTRODUCTION. There has been increasing evidence that stenotic plaque may rupture under physiological conditions and cause fatal subsequent atherosclerotic diseases such as myocardial infarction, cerebral stroke, etc. In our prior studies, computational models with fluid-structure interactions were introduced to quantify pressure and stenosis severity conditions under which critical flow conditions (negative pressure, low and oscillating shear stress, high shear stress at the throat, flow separation) and artery compression which may be directly related to stenosis plaque rupture (Tang et al., 2001). It was found that wall stress/strain distributions are of very local nature and extremely sensitive to plaque structure and mechanical property changes. It is well known that stenotic plaques have complex structures and their mechanical properties vary widely (Beattie et al. 1998). In this paper, finite element models are introduced to perform stress/strain analysis of stenotic arteries where stenosis plaque structure and mechanical properties are added into our consideration.

METHOD. MRI images of human carotid artery plaque were supplied by Dr. Zheng from Washington University School of Medicine. Those images were digitized and smoothed before they were used in the numerical simulation. Mechanical properties of the artery wall, fibrous plaque, calcification and lipid were taken from Beattie (1998), Huang (2001) and our prior studies. Idealized 2-D and 3-D geometries of the stenotic arteries with fibrous plaque and lipid pools were used to find correlations between artery maximum stress/strain and structure of the plaque and imposed pressure conditions.

A finite element software package ADINA (ADINA R & D, Inc., Watertown, MA, USA) is used to solve the models for structure only and stress/strain analysis with fluid-structure interactions. The package has been extensively tested and verified with hundreds of engineering applications. Mooney-Rivlin material is used for the solid material while incompressible Navier-Stokes equations are used for the fluid. Parameter evaluations were performed for several typical cases and results are given below.

RESULTS AND DISCUSSION.

2-D MRI image-based structure analysis. Two cases are considered, one with smaller lipid pool which is further away from the lumen, other with larger lipid pool with a sharp angle close to the lumen area. The latter is more prone to rupture. Different internal pressures are imposed in the lumen. Stress/strain distributions are obtained for the arteries with and without lipid pools to find out the magnitude and location of maximum stresses. Then idealized geometries are used to perform parameter evaluation with incremental changes in

pressure load and position of lipid pool.

Fig. 1. MRI image of human carotid artery with fibrous cap, calcification and lipid pool (left) and contour plot of wall stress showing location and magnitude of maximum stress

3-D simulation for stenotic arteries with lipid pool. Arteries with streamlined asymmetric stenosis are used to simulate blood flow and artery stress/strain distributions under physiological conditions. Lipid pool of varying sizes and shapes are enclosed in the stenosis plaque to evaluate its effect on wall stress and flow behaviors. 3-D images will also be reconstructed from 2-D MRI images and used in the simulation.

Fig. 2. Stress distribution for a 3-d asymmetric stenosis with an irregular lipid pool in the stenosis plaque. Unit: dyn/cm^2 .

CONCLUSION. Stress/strain distribution is very sensitive to plaque structure and mechanical property variations. Maximum stress increases rapidly as the sharp angle of the lipid pool gets closer to lumen. 3-D simulations provide more realistic predictions which may be helpful to identify stenoses which are more prone to plaque cap rupture. However, reconstruction of 3-D domain from 2-D MRI images and solution of those 3-D realistic models are very challenging.

INTRODUCTION

Multi-scale computation in hemodynamics can help enhance our understanding of circulation at different levels. It can also help contribute to the computation-aided predictive medicine. The motivation for developing this approach is a pragmatic one: the scale disparity associated with hemodynamics is too vast to be simultaneously handled with adequate resolution, without modeling, by any existing and foreseeable computational tools. For example, 3D modeling of an isolated artery, even with a faithfully reconstructed anatomic model based on medical-images, requires information supplied from the rest of the blood circulation system in order to define physiological realistic inflow and/or outflow conditions. However, direct simulations of the full circulation system ranging from the large blood vessel to capillaries are not possible with today's computational capabilities. In order to simplify the task, lower dimensional approaches, such as 0D and 1D modeling can provide the information such as flow-pressure relationship, thus offering required boundary conditions for detailed simulations of a particular portion of the circulation system. A combined 0D/1D and 3D modeling can establish an efficient, multi-scale computational model in cardiovascular hemodynamics. In this paper we highlight our recent efforts in developing such a multi-scale computational model along with results of blood flows in human aortic arch with bifurcations.

METHODS

The Patient-Specific Simulator (PASS) for hemodynamics that we developed (Liu, et al., 2001) has formed a foundation for the simulation-based diagnosis and surgery. PASS is an integrated system, involving an image-based morphological model, a realistic physiological model, and a multi-block, computational mechanical model. The morphological modeling system can reconstruct an anatomic model for vessels and/or organs based on medical images of MRA, US, and CT X-ray, and generate meshes for computation. The physiological modeling is measurement-based, in which blood velocity and pressure are measured by techniques such as MRA and Doppler US. It offers boundary conditions needed by the detailed simulation through a quasi-static hydraulic model.

In this study we have incorporated a recently developed 1D computational model for cardiovascular system into the PASS model. The model can handle unsteady viscous flow as well as generalized arterial viscoelastic dynamics (Kitawaki et al., 2001). It has been validated with measurements of pressure waves in a silicone rubber tube, which indicates that our model can predict the wave propagation and reflection more reasonable than several conventional 1D methods. We are aiming at establishing an interactive, multi-scale model in which, not only the global 1D model can provide boundary conditions for the local 3D model in terms of flow rate Q and pressure P , but also that the 3D model with realistic geometry can be used to improve the 1D

model in terms of feedback of the detailed flow information such as pressure drop.

RESULTS AND DISCUSSIONS

We select a prototypic cardiovascular model of human aorta arch involving bifurcations. The velocity-based boundary conditions at inlet and outlets are based on the 1D model in terms of flow rate and pressure. An extensive study is carried out to investigate how the ratio of flow rates among the outlets affects the flows in the aorta model as shown in Fig. 1, in which

a) Free velocity conditions b) Flow rate-based conditions

Figure 1: Comparison of flows in an aortic arch model under two BC conditions

the color denotes the pressure decreasing from red to blue. Given a flow rate ratio between the descending aorta and the bifurcations of 7/3, the computed flow in both the aorta and in the LSA (Left Subclavian Artery) and BTA (Brachiocephalic trunk Artery) show apparent difference compared with the case (a) where the velocities at three outlets are set free. The pressure is fixed to be zero at the outlet of descending artery and is set free at both outlets of LSA and BTA.

COMPRESSIVE STRENGTH IN VERTEBROPLASTY UNDER FATIGUE LOADING AN EXPERIMENTAL AND A FINITE ELEMENT MODELLING ANALYSIS

WW Lu¹, KT Yeung¹, KMC Cheung¹, C.T. Wong¹, M Zhang², KDK Luk¹, JCY Leong¹

INTRODUCTION

Using minimally invasive techniques to inject bone cement for treating fractured or osteoporotic vertebral body (VB) has significant clinical potential. However, the effect of bone cement volume on the stiffness of VB cannot be evaluated in a more quantitative way and is still under investigation. Also, present studies show concern on the effect of one-off compression on VB. This approach, however, has neglected the clinical reality, which VB of patient bear body-weight loading day to day consecutively. In this study, experimental testing and finite element model (FEM) of VB was constructed to investigate the effect of volume of bone cement used under fatigue loading.

MATERIALS AND METHODS

Mechanical properties of VB and bone cement were collected for modeling of FEM. ISO5833 guided the testing procedure for finding the properties of bone cement. Specimens of L1 to L5 VB of over 65-year-old cadaveric female were extracted. Soft tissue and posterior elements were removed. The VB were scanned by DEXA for confirmation of VB osteoporotic properties. The VB specimens were then divided into two groups, one without cement injected and one with bone cement injected, using cement delivery system – Parallax.

The first group of VB specimens (without bone cement injected) was scanned with 1.25mm CT scanning. The CT numbers in Hounsfield units (HU) were converted to bone mineral density (BMD) in g/cm³. The elastic moduli of trabecular centrum were calculated by BMD value¹.

Compression load was applied on VB by MTS machine. It was loaded at 0.5% strain/s and loaded to 1.78% which exceeded yield point of the VB, unloaded, and then reloaded to 10% strain to obtain the real damaged VB. The CT data was imported into a finite-element modeling software, ANSYS, for developing a FEM model of the VB. The elastic constants of yield elements with reduced properties were replaced² as:

$$\% \Delta E_{\text{Elastic constant}} = \frac{227 \times \text{strain}\%}{\text{strain}\% + 6.18}$$

The model was reloaded and the damaged FEM VB was simulated. Structural stiffness was calculated by the steepest slope of load-deflection curve over displacement range, appeared in the loading (S₁) and reloading (S₂) cycle.

Virtual implant of bone cement Different volume of bone cement 2ml, 4ml, 6ml and 8ml was injected into the second group of VB specimens respectively and then CT scanned. With reference to the pattern under CT, bone cement was virtually

implanted into the damaged VB FEM model with different volume. The stiffness of VB with different volume of bone cement implanted was found. The value of stiffness was compared with that of damaged and intact VB without bone cement implanted. VB with bone cement implanted was then performed compressive fatigue loading of about 20,000 cycles, and the data was input in FEM model as fatigue loading condition. FEM model was further validated by comparing the FEM model of a damaged VB with the experimental results.

RESULTS & DISCUSSION

Table I shows the result of compression test on bone cement. (Composite ratio: Resin 4g (Si-HA 3.9g, Fumed Silica 0.1g, BPO 0.011g), Filler blend 6g) It was used for finding mechanical properties for FEM modeling.

It was found that the stiffness of all VB specimen with bone cement injected exceeds stiffness without bone cement in damaged VB. After injection, stiffness of the spine recovered to 112% of the intact condition (p<0.01). Average failure strength of the spine after injection and 20,000 loading cycles was 5056 N. The stiffness was increased proportional to the increased the bone cement volume (r=0.84).

Fatigue loading test is a better way for studying stress behavior as it is close to clinical reality. Performing fatigue loading cycle in FEM model could be used to simulate the VB under long term clinical follow up.

Table I: Compression testing result of bone cement

	F (N)	σ (MPa)	ΔL (mm)	ν

INTRODUCTION

It has been reported that using minimally invasive bone cement injection for treating vertebral body fracture or stabilizing osteoporosis has been used clinically in recent years. Conventional poly(methyl methacrylate) (PMMA) bone cement has been used in orthopaedic surgery for over 40 years. However, it does not encourage bone ingrowth, has a high exothermity, and monomer toxicity. New bioactive bone cement was designed to overcome the disadvantage of PMMA. The purposes of this study were to further character the new injectable bioactive bone cement designed specifically for spinal surgery and to conduct animal trials.

MATERIALS AND METHODS

The bioactive bone cement contains a filler blend and a resin blend. The filler blend contains Strontium-containing hydroxyapatite (Sr-HA), fumed silica and benzoyl peroxide (BPO). The resin blend contains bisphenol A diglycidylether dimethacrylate (Bis-GMA), poly(ethylene glycol) methacrylate (PEGMA) and *N,N*-dimethyl-*p*-toluidine. The materials used were less toxic when compared with methyl methacrylate (MMA), which was the major component in conventional PMMA bone cement.

Strontium-containing hydroxyapatite was synthesized by the wet method and was characterized by Fourier Transform Infrared (FTIR) spectroscopy, X-ray diffraction (XRD) spectroscopy and Electron-dispersive X-ray (EDX) analysis. Strontium can act as a radiopaque.

The ratio of mixture in the resin blend was adjusted so that the mechanical properties suited the usage on surgery. The ratio of the filler and resin blend was adjusted and the setting time and temperature were monitored during the mixing of bone cement.

New Zealand white rabbits ($n=10$) were used for animal test. Bone cement was injected into the hole in ilium at rabbits. X-ray film was taken periodically post-operation to observe the bone cement in the ilium. The rabbits were sacrificed 3 months post-operation. Another four rabbits were performed as a control with conventional PMMA bone cement. The bone and bone cement interface was observed by Scanning Electron Microscopy (SEM) and Electron-dispersive X-ray (EDX) analysis. Histology of the bone with bone cement section stain with giemsa and eosin was performed.

RESULTS AND DISCUSSION

Strontium-containing hydroxyapatite (Sr-HA) was synthesized successfully. The spectra of Sr-HA from Fourier Transform Infrared (FTIR) spectroscopy and X-ray diffraction (XRD) spectroscopy have the pattern as hydroxyapatite. From Electron-dispersive X-ray (EDX) analysis, strontium, calcium

and phosphorus were found which were elements in Sr-HA(Fig. 1).

Setting time and temperature is a key issue for orthopaedic surgery using bone cement. The setting time of the bone cement can be adjusted from 8 to 16 minutes. The maximum temperature was between 45 and 60 °C.

The bone cement can be seen on X-ray film. The bone cement was not absorbed. By Scanning Electron Microscopy (SEM) and Electron-dispersive X-ray (EDX) analysis, the bone and bone cement interface can be observed clearly. The bone cement is bioactive which bond to the bone without soft tissue separation. The EDX pattern of bone cement was similar to that of bone except peaks of strontium and silica were found in the cement. Histology of the bone with bone cement section stain with giemsa and eosin was examined and the bone in growth on the bone cement interface was observed.

SUMMARY

A bioactive bone cement which has many advantages over conventional PMMA bone cement was studied. The bone cement was injectable, with less toxic monomers, have lower setting temperature and reasonable setting time and mechanical strength suitable for orthopaedic surgery.

PULSE EFFECTS OF LOW INTENSITY ULTRASOUND STIMULATION ON BONE CELLS PROLIFERATION

Walter Hong-Shong Chang¹, Jui-Sheng Sun², James Cheng-An Lin¹ and Jimmy Li¹

¹Department of Biomedical Engineering, Chung Yuan Christian University, Chung-Li, Taiwan, ROC. whchang@cycu.edu.tw

²Department of Orthopedic Surgery, National Taiwan University Hospital, Taipei, Taiwan, ROC

INTRODUCTION

Ultrasound wave is a longitudinal sound wave that causes high-frequency compression and expansion of the medium which can lead to pressure variations. The stimulatory effect of ultrasound on the fracture healing has been well established during the last decade [1]; but the mechanism is still pending. Many physical parameters of the ultrasound may be involved in different biological effects. The aim of our investigation is to study the possible mechanism of the pulse effects of ultrasound stimulation on the bone cells proliferation.

METHODS

Osteoblast-like cells were isolated from sequential enzymatic digestion of neonatal rat calvaria. After 6 days culture, confluent osteoblast cells were detached from the petri dish, counted and subdivided into 3-cm wells. All dishes were then underwent ultrasound stimulation at a well-maintained temperature ($37\pm 1^\circ\text{C}$) as described below (Fig.1).

The osteoblasts were stimulated at the intensity of 150 mW/cm^2 (temporal average intensity) with different pulse waveform (continuous wave (CW), 1:1, 1:4, 1:9) for 15 min. The frequency of ultrasound stimulation is 1 MHz and the pulse-repeated frequency at 100Hz. The rate of cell proliferation was monitored by measuring the rate of BrdU incorporation into osteoblasts by immunofluorescence staining.

RESULTS AND DISCUSSION

The results showed that the adding of pulsed ultrasound stimulation can enhance the osteoblast-like cells proliferation. The osteoblasts cell counts increased significantly after treatment of pulsed ultrasound stimulation. The PGE2 concentrations in culture medium also increased significantly. But the treatment of continuous wave of ultrasound did not affect both the osteoblasts cells counts and the PGE2 secretion.

The results suggested that pulsed wave played an important role during the ultrasound stimulation. Cells were excised (or stimulated ???) during cycles of pulse on-off and the proliferation were also activated at the same time. Indeed, it is

exactly this interaction that we believe contributes to the osteogenic potential of pulse strain.

Figure 1: Schematic diagram of the experimental arrangement for the ultrasound stimulation. AC = Absorption Chamber; AR = Absorption Rubber; D = Distance from transducer to cell flask, 240mm; DT = Degas Tank; DW = Distilled Water; ES = Exposure Sample; GT = Glass Tank; R = x-y Roter; SM = Stepping Motor; T = Transducer; TC = Temperature Controller.

SUMMARY

In this study, we established the pulse effects of ultrasound stimulation on the bone cells proliferation. The results showed that pulsed ultrasound stimulation got significantly responses to bone cells proliferation than continuous ultrasound stimulation does.

COMPUTATIONAL FLUID DYNAMICS SIMULATION OF THE RIGHT CORONARY ARTERY MOVING WITH THE CARDIAC WALL

Hiroyuki Hayashi and Takami Yamaguchi

Dept. Mechatronics and Precision Engineering, Tohoku University, Aoba 01, Sendai 980-8579,
hayashi@pfs1.mech.tohoku.ac.jp, takami@pfs1.mech.tohoku.ac.jp

INTRODUCTION

The beating motion of the heart wall, to which the major coronary arteries are fixed, is interesting, due to its possible mechanical influence on the flow inside the artery, and hence its effect on atherogenesis. In this study, we conducted a computational fluid dynamics (CFD) simulation using a simplified model of the right coronary artery, which deforms with heart contractions. The results are discussed with respect to the local hemodynamics characteristics, particularly the streamline pattern and the wall shear stress distribution.

METHODS

The CFD model of the right coronary artery consisted of a coiled pipe with an ordinary helix as a centerline, surrounding a cylinder that simulated the heart. The diameter and height of the cylinder changed over time at a given rate. The volume reduction in one beat of the cylinder was 75%; i.e., the ejection fraction (EF) was 0.75.

Figure 1: CFD model and angiogram of the right coronary artery.

The coupling of the wall and fluid motions was based on a previously reported method, in which the wall motion is assumed quasi-steady compared to the development of the flow. Three different modes of changes in the shape of the CFD model were examined to investigate the effect of the time dependent curvature and torsion of the right coronary artery on the flow. The unsteady inflow velocity perpendicular to the inlet cross section was defined by a cosine function of phase 180° different from the time evolution of the change in volume (Figure 2). The Reynolds number was 300, defined by the maximum inflow velocity and the diameter of the inlet cross section. One cardiac cycle was assumed to last for one second, i.e., the heart rate was assumed to be 60 beats/min.

Figure 2: The time evolution of the change in volume (solid line) and inflow velocity (dots).

Figure 3: Observation posts of the WSS data along the circumference of the cross section midpoint.

RESULTS AND CONCLUSIONS

Representative results are given by the streamline patterns and corresponding WSS distribution at a cross section in the middle of the right coronary artery model at a phase between the early systole and the late diastole, shown in Figure 4. The observation post numbers of the WSS distribution in Figure 4 correspond to the numbers shown in Figure 3.

Many interesting features of the fluid dynamics are evident in Figure 4. Characteristic changes in the streamline and WSS distribution appeared when the flow was decelerated. Useful information about the specific mechanisms for the formation, growth, and breakdown of coronary plaque can be obtained from an analysis of the results under various physiological conditions.

THE EFFECT OF MEDIAL TRANSLATION ON TIBIAL LOAD AND STRESS DISTRIBUTIONS IN TOTAL KNEE PROSTHESES

Jiann-Jong Liao¹, Cheng-Kung Cheng^{1,*} and Chun-Hsiung Huang^{1,2}

¹Orthopaedic Biomechanics Laboratory, National Yang Ming University, Taipei, Taiwan. ckcheng@ortho.ym.edu.tw

INTRODUCTION

Alignment is an important consideration in many clinical situations, such as fracture reduction, deformity correction and total knee arthroplasty. Significant changes in the axial alignment of the femur and tibia may alter the loading and stress distributions in the knee joint[1]. The purpose of this study was to investigate the effect of medial translation on tibial load and stress distributions in two different designs of total knee prostheses.

METHODS

Three-dimensional finite element models of the tibiofemoral joint of knee prostheses for two different designs were constructed. The sagittal radii of the femoral and tibial components were identical in those two knee prostheses. In the frontal plane, the high conformity flat-on-flat design (HFF model) has the same curvatures in femoral and tibial components with a radius of 120 mm. The high conformity curve-on-curve design (HCC model) has a smaller curvature in femoral and tibial components with a radius of 70 and 72 mm respectively. The medial translation (0.25, 0.5 and 1.0 mm) of the femoral component relative to the tibial component were simulated. A compression load of 3000 N was applied to the tibiofemoral joint at 0° of flexion. The contact forces on the medial and lateral tibial components and the maximum von-Mises stress calculate from finite element analysis was used to investigate the effect of medial translation on the tibial load and stress distributions.

RESULTS AND DISCUSSION

The contact force on the medial and lateral parts of tibial component was showed in Figure 1. The difference of contact force between medial and lateral parts increased when the distance of medial translation of femoral component relative to the tibial component increased. The maximum difference of contact force on medial and lateral parts of tibial component relative to total contact force was 89% and 11% in the HFF and HCC models respectively. The HFF design showed a severe asymmetrical load distribution when medial translation of femoral component occurred. The maximum von-Mises stress of the tibial component was showed in Figure 2. In comparing with the neutral position, the greatest increase of von-Mises stress was 92.5% in HFF model. Again, the greater the displacement of the femoral component moved medially, the greater increase in maximum von-Mises stress.

Figure 1: The load distributions on tibial component in (a) Flat-on-Flat design and (b) Curve-on-Curve design when femoral component was translated medially.

Figure 2: The maximum von-Mises stress in the tibial component of those two knee designs under maltranslation conditions.

SUMMARY

The high conformity flat-on-flat design showed a severer asymmetrical load distribution and greater increase of von-Mises stress than the high conformity curve-on-curve design when the medial translation of femoral component occurred. Therefore the flat-on-flat design of knee prosthesis would increase the risk of polyethylene wear under maltranslation conditions.

EFFECT OF LESIONS ON THE THREE-DIMENSIONAL MECHANICS OF THE INTERVERTEBRAL DISC

Rosemary Thompson, Mark Percy and Timothy Barker

Centre for Rehabilitation Science and Engineering, Queensland University of Technology, Brisbane, Australia
rosemary.thompson@ao-asif.ch

INTRODUCTION

Progressive degenerative changes of the intervertebral disc are related to increased age and will thus affect a large proportion of the population. Macroscopically, degeneration in the intervertebral disc can be characterised by concentric tears, radial tears and rim lesions (Thompson et al, 2000). Initiation of degeneration is poorly understood. However, once initiated degeneration affects the mechanics of the intervertebral joint (Nachemson et al., 1979) and this may lead to further degeneration. Hence, it is important to understand how individual intervertebral disc lesions affect the mechanics of the spinal joint during physiological motion and how this may lead to further degeneration.

METHODS

A robotic materials testing facility was used to perform the mechanical tests on sheep spinal motion segments. The robot was a Kawasaki PH260 (Kawasaki, Japan, 1989) and it was controlled by a digital signal processing card (20 MHz PMAC PC, Delta Tau, USA). Three-dimensional force data acquisition was achieved using a JR3 50M31 force transducer (JR3, California, USA). This system offers a solution to the restrictions of a traditional engineering testing facility as it is capable of motion with six degrees of freedom and is able to dynamically test specimens through the full range of motion.

Sheep intervertebral joints were used as they provide a good biomechanical model for the human lumbar spine (Wilke et al, 1997). The L1-L2 and L3-L4 levels in the sheep spine were used to represent the corresponding motion segment in humans. As humans do not have a sixth vertebra, the L5-L6 level was used to represent the L4-L5 level in the human.

Physiologically accurate motions of flexion/extension, lateral bending and axial rotation were performed on pre-conditioned, isolated disc motion segments. These tests created the data for future reference. The following three sets of tests were performed after the creation of an intervertebral disc lesion. The three lesions created were radial tears, rim lesions and concentric tears. Radial tears were created by inserting a thin bladed knife vertically into the left postero-lateral portion of the disc. Concentric tears were placed in the anterior of the disc and created according to Fazzalari et al, 2001. Rim lesions were produced by inserting a blade horizontally into the anterior annulus on the right side. The order of insertion depended on the specimen's level, and each tear was the initial

tear created for at least one of the levels. After the creation of each lesion, all three motions were performed and compared to the original, undamaged test.

RESULTS AND DISCUSSION

The mechanical factors examined from this study were the size of the neutral zone, maximum moment resisted by the intervertebral disc during each motion and the hysteresis of the response. Radial tears and concentric tears had no effect on any of the studied mechanical factors. A right, anterior rim lesion increased the neutral zone by approximately 1.5 degrees and reduced the maximum moment resisted by the intervertebral disc by approximately 20% during extension in L1/L2 specimens. Rim lesions were also found to reduce the maximum moment resisted by the intervertebral disc in lateral bending and axial rotation for all levels by approximately 15% and 25% respectively. Rim lesions did not affect the hysteresis of intervertebral disc motion.

These results suggest that the presence of a rim lesion in the intervertebral disc reduces the capability of the intervertebral disc to control motion and other spinal elements would be required to compensate. This could lead to overloading of the spinal ligaments, muscles and zygapophysial joints, which may result in damage to these structures. This could commence a cycle of degenerative changes to the spinal elements that is instigated by the mechanical response of the intervertebral joint to loading.

SUMMARY

The mechanical effects of intervertebral disc lesions were examined by experimentally introducing lesions into sheep intervertebral discs and comparing the mechanical response of the injured joint to the joint's response prior to the creation of the lesions. Rim lesions were found to reduce the intervertebral disc's mechanical integrity during all motions.

INTRODUCTION

Platelets play an important role in blood coagulation, particularly in the formation of primary thrombi. The aggregation of platelets, which initiates primary thrombi formation, is thought to be mediated by the von Willebrand factor (vWF). The vWF is a long-chain macromolecule that exists in a soluble form in the blood flow and an insoluble form in the vessel wall. The vWF plays a more important role in pathological thrombosis formation than in the normal hemostatic process, due to its ability to sense and react to hemodynamic stress.

In this study, we analyzed the mechanical interactions between platelets, the vessel wall, and the vWF, using both a Stokesian dynamics method (SDM) and a discrete element method (DEM) that can treat solid elements in a flow without assuming continuity.

METHOD

A two-dimensional (2D) mechanical model of a blood vessel, platelets, and the vWF was constructed. The mechanical interactions between individual platelets, and the interactions between the platelets and vessel walls that were mediated by the vWF, were modeled as shown in Fig. 1. Here, the vWF was assumed to act at a relatively remote distance from the direct collision of components, and a vWF molecule was assumed to produce only a tensile force at a certain distance from the other elements (platelets or the wall). Furthermore, it was assumed that only repulsive forces were generated in the direct interactions.

(a) Between platelets (b) Between a platelet and a wall

Fig.1 Mechanical models of interaction mediated by the vWF

A 2D Couette flow model was used in the present study, and the influence of other blood constituents, including red blood cells, was neglected. The fluid force acting on the particles was calculated using the SDM.

RESULTS AND DISCUSSION

The variable strength of the chemical binding between the platelets and vWF's was simulated by changing the number of receptors (N_{re}) on the vWF. The destruction process of the primary thrombus under the influence of the blood flow was then modeled.

Fig. 2(a) shows the results for $N_{re} = 0$. Since the only force acting between the platelets and the vessel wall in this model is the repulsive force, the simulated platelets separate from the aggregation individually. Fig. 2(b) shows the results for $N_{re} = 5$.

When there are both repulsive forces due to direct collisions and tensile forces due to the vWF between platelets or between platelets and the vessel wall, the modeled platelets moved together to form an aggregation in the blood flow. Fig. 2(c) shows the results for $N_{re} = 10$. Larger platelet aggregations are observed, since the number of receptors is twice as large as the former case, resulting in a much larger binding force. The time evolution of the number of aggregations is shown in Fig. 3. The number of receptors, and hence the total binding force between the platelets and the vWF, significantly affects the destruction process of the primary thrombus.

Two simulation methods were used in the present study: the DEM to describe the direct collision mechanism between solid elements, and the SDM to describe fluid-solid interactions. This combination has the potential to simulate the discontinuous movement of blood constituents such as platelets.

BIOMECHANICAL EVALUATION OF A NEWLY DEvised MODEL FOR THE ELONGATION-TYPE ANTERIOR CRUCIATE LIGAMENT INJURY WITH PARTIAL LACERATION AND PERMANENT ELONGATION OF FIBERS

Eiji Kondo¹, Harukazu Tohyama¹, Masanori Yamanaka¹, Akio Minami², Kazunori Yasuda¹

¹Department of Medical Bioengineering & Sports Medicine and ²Department of Orthopaedic Surgery, Hokkaido University School of Medicine, Sapporo, Japan. yasukaz@med.hokudai.ac.jp

INTRODUCTION

The elongation-type anterior cruciate ligament (ACL) injury, in which the ligament is permanently elongated with partial laceration and permanent elongation of collagen fibers, frequently occurs in athletes. For this type of ACL injury, we have had no therapeutic methods except for the reconstruction of the whole ACL to repair the injured site in the substance. To develop new therapeutic methods involving gene therapy for this type of ACL injury, it is necessary to establish a model of this injury. Previous studies have reported a few models for the partial laceration-type ACL injury (O'Donoghue et al., Wiig et al., Hefti et al.). In these models, however, collagen fibers that are not lacerated in the substance remains thoroughly intact. Therefore, it is necessary to develop a more suitable model for this specific ACL injury. We have developed a new ACL injury model with partial laceration and permanent elongation of collagen fibers. The purpose of this study is to biomechanically evaluate this ACL injury model using rabbits.

MATERIALS AND METHODS

A total of 27 skeletally mature female rabbits were used for this study. In each animal, after the anteromedial and posterolateral half of the right ACL were transected with a scalpel at the proximal and the distal one-third levels, respectively, the ACL was stretched by applying an anterior drawer force of 10N to the tibia at 90° of knee flexion (Fig 1). No immobilization was applied after surgery. Nine rabbits were sacrificed at 0, 6, and 12 weeks after surgery, respectively. Seven out of the 9 rabbits were used for biomechanical evaluation, and the remaining 2 were used for histological observation. The left knees were used to obtain normal control data. In biomechanical evaluation, the anterior-posterior (A-P) translation of the knee was measured using a tensile tester with a 5-DOF fixture under ± 10 N A-P loads at 30, 60, and 90° of knee flexion. Then, the cross-sectional area (CSA) of the ACL was measured with a video dimension analyzer. The structural properties of the femur-ACL-tibia complex (FATC) were determined in tensile testing at a cross-head speed of 20 mm/min. In each study, statistical analyses were made using the ANOVA with the post-hoc Fisher PSLD test for multiple comparisons.

RESULTS

(1) At 0 weeks (immediately after surgery), the ACL length of the injured knee was significantly elongated to 110 % of its original length, and the A-P translation was significantly greater than the normal knee (Table 1). At 6 and 12 weeks, the ACL length of the injured knee remained significantly greater than the normal value. There were no significant differences among the 0-, 6-, and 12-week periods. The CSA did not significantly change over time. (2) The A-P translation of the injured knee also remained significantly greater than the normal value at 6 and 12 weeks. (3) Concerning failure modes, each specimen was torn at the mid-substance of the ACL. The maximum load and the stiffness of the injured FATC were significantly lower than the normal control values at 0, 6, and 12 weeks. (4) Histologically, alignment of collagen fibers in the mid-substance of the injured ACL appeared to be irregular with significant cellular proliferation at 6 and 12 weeks.

DISCUSSION

This study demonstrated that this newly devised procedure significantly increased the ACL length and the A-P translation of the knee, and that it drastically decreased the structural properties of the FATC to 28% of the normal value at 0 weeks and 48% at 12 weeks. This fact showed how the quantitative procedure can create serious injury in the ACL substance with partial laceration and permanent elongation of collagen fibers. We believe that the model we have developed is useful to study new therapeutic methods, such as gene therapy, cell therapy, and so on, for the elongation-type ACL injury.

INTRODUCTION

The adhesion of blood-borne cells to activated endothelium is of fundamental importance in the body's response to injury or inflammation. In order to understand better the competition between viscous forces, elastic cell membrane forces and adhesive forces associated with specific receptor-ligand bonds, we consider a theoretical model system in which a two-dimensional cell, modeled as an extensible membrane under tension containing fluid of constant volume, adheres to a plane surface. We treat three situations: *sedimentation*, where an initially circular cell settles onto the wall under the action of adhesive forces (and during which the membrane at the base of the cell spreads dynamically over the wall); *aspiration*, where the cell is removed from the wall under the action of an external force, applied to the top of the cell and acting normal to the wall (and during which the base of the cell peels off the wall); and *rolling*, where the cell tank-treads over the wall in the presence of a shear flow, spreading at the leading edge of the cell's base and peeling at the rear.

METHODS

We model binding kinetics following Dembo *et al.* (1988), using a continuum description of bond mechanics and treating individual molecular bonds as Hookean springs with rates of bond formation and breakage dependent on bond extension. If binding kinetics occurs rapidly compared to flow timescales, the binding forces are equivalent to a contact potential that is long-range attractive and short-range repulsive. The flow in the thin gap between the cell and the wall is described using lubrication theory; viscous stresses in the cell's interior are neglected. The membrane tension is assumed large enough compared to adhesive forces that, in equilibrium, the cell binds to the wall over a region that is long compared to the bond length, but short compared to the cell radius R ; on length scales comparable to R , the cell in this case appears to meet the wall with a small but well-defined equilibrium contact angle θ_0 . The presence of microvilli or glycocalyx is neglected. Numerical simulations of a nonlinear evolution equation for the gap thickness are used to describe sedimentation and aspiration. The simulations are used to motivate and justify calculations based on thin-film asymptotics that relate the effective dynamic contact angle θ to the speed V at which the membrane spreads over, or peels off, the adhesive wall. A force balance on a rolling cell, in which the imposed viscous shear force balances components of the membrane tension acting in different directions at each effective contact line, is used to obtain a relation between the rolling speed V and the

imposed shear rate. Full details appear in Hodges and Jensen (2002).

RESULTS

During sedimentation, the cell moves down onto the wall and the contact region at the base of the cell spreads sideways. Fluid just outside this region is trapped between the membrane and wall, creating a locally high fluid pressure that causes viscous bending of the membrane, reducing the effective dynamic contact angle $\theta(V)$ beneath θ_0 . During aspiration, viscous effects create a low fluid pressure where the membrane peels from the wall, causing bending of the membrane in the opposite sense, elevating $\theta(V)$ above θ_0 . During rolling, the relation between the speed of a tank-treading cell and shear rate is found to be independent of viscosity at low rolling speeds and when binding kinetics is rapid, but viscosity-dependent at higher speeds and when binding is slower.

DISCUSSION AND SUMMARY

The model presented here aims to highlight the potential importance of thin-film hydrodynamics and membrane deformation in controlling spreading and peeling rates of a cell adhering to a plane substrate. In the situation when viscous dissipation in the suspending fluid provides the dominant resistance to spreading and peeling, a cell is predicted to tank-tread at a speed dependent on shear rate but not shear stress. The model may therefore provide an explanation for experimental reports of such behavior seen with rolling neutrophils but not with rigid beads (Smith *et al.* 2001). Substantial model refinements are required before reliable comparison can be made with *in vivo* systems, however.

EFFECTS OF VARUS WEDGED SHOE VERSUS INSOLE ON KNEE JOINT LOADING CHARACTERISTICS

Dieter Rosenbaum, Robert Rödl, Michael Entrup, Dieter Klein

Movement Analysis Lab, Orthopaedic Department, University Clinics Münster, Münster, Germany, diro@uni-muenster.de

INTRODUCTION

In patients suffering from varus gonarthrosis a treatment goal is to relieve pain by unloading the degenerative medial compartment of the knee joint. This may be endeavored with either surgical (high tibial osteotomy) or conservative treatment (braces or shoe modifications). Varus wedged shoes or insoles have been shown to provide a medial thrust of the force vector thereby reducing the adductor moment in the knee (Crenshaw 2000; Ogata 1997; Sasaki 1987; Yasuda 1987). However, the two methods have not been compared yet regarding their effectiveness in reducing the loading of the knee joint. Therefore, the present study investigated the effect of wedged insoles versus wedged shoes with respect to knee joint kinematics and kinetics in a healthy population.

METHODS

Twenty-nine subjects (14 ♂, 15 ♀, age 40.7 ± 15.8 years, body mass 72.9 ± 13.2 kg, height 172 ± 8 cm) participated in the study and walked with customized shoes (Puma Inc., model "Street Cat") in four different conditions: neutral shoes, shoes with a varus wedged sole, shoes with a valgus wedged sole and shoes with a valgus wedged insole.

Motion data was recorded during walking at self-selected, controlled speed on a 12 m walkway with a 6-camera system (Motion Analysis Inc.) and two force plates (AMTI). Temporal-spatial parameters as well as kinematic and kinetic parameters related to the knee and ankle joint were analyzed for each subject and averaged across multiple trials for each condition (Orthotrak).

RESULTS

The results indicate that the shoe modifications lead to significant changes in knee moments (Fig. 1). The medial wedge increased the knee joint loading. The lateral wedge as well as the insole led to the expected decrease of the varus moment with the insole being less effective.

Fig. 1: Increased knee abduction moment with medial wedge and decreased moment with lateral wedge or insole.

However, the changes in the knee joint have to be transferred through the ankle joint complex that is subjected to higher loading (Fig. 2).

DISCUSSION

The results demonstrate the biomechanical effectiveness of conservative treatment of gonarthrosis with shoe modifications even though the clinical impact remains to be investigated in patients. The reduced varus moment will lead to an unloading of the medial compartment in varus gonarthrosis that is expected to reduce the patient's pain situation. However, it has also been demonstrated that these effects have to be passed on though the distal joints which might lead to stress in these regions that has to be tolerated.

A COMPARISON AMONG DIFFERENT TASKS PERFORMED BY DIFFERENT SUBJECTS ON THE PRIMARY STABILITY OF CEMENTLESS STEMS

Alberto Pancanti, Marco Viceconti and Aldo Toni

Laboratorio di Tecnologia Medica, Istituti Ortopedici Rizzoli, Bologna, Italy - <http://www.ior.it/tecno/>

INTRODUCTION

The failure of cementless total hip replacements is mostly caused by aseptic loosening (Malchau, et al, 2000). Many authors consider the bone-implant relative micromotion early after surgery (primary stability) as the main biomechanical cause of aseptic loosening in cementless implants ((Soballe, et al, 1992). Animal and retrieval studies associate the failure of the osseointegration process to primary micro-movements above 100-200 μm (Soballe, et al, 1992). Assuming constant all the other factors, the final outcome of the osseointegration process clearly depends on the forces induced in the operated joint during the early stages after surgery.

All studies on the rehabilitation program stress the importance of the gradual allowance of weight bearing and the use of orthopaedic support (Bilotta, et al, 1992). However, the joint forces are not only function of the allowed weight bearing, but also of the type of task the patient is performing, as well as of the strategy adopted to perform it. An in vitro orthopaedic biomechanics study confirmed that the magnitude of micromotion at the entire contact surface depends also on the magnitude and the direction of the external forces and thus on the tasks subjects are performing (Saponara Teutonico, et al, 2001).

Aim of the present study is to evaluate the influence of the type of task, as performed by various subjects, on the primary stability of a cementless stem.

METHODS

The study was based on the finite element model of a human femur implanted with a cementless anatomical stem, modelling frictional contact at the bone implant interface. The model was fully validated in a previous work against primary stability experimental measurements (Viceconti, et al, 2000). Cancellous and cortical bone were both considered homogeneous materials. The first was assumed isotropic, with a Young's modulus of 1000 MPa; the second was assumed transversally isotropic with a longitudinal and transversal Young's modulus of 16300 MPa and 6600 MPa, respectively. The cementless stem, made of titanium alloy, was modelled with a modulus of 105000 MPa.

Only the hip joint force, acting on the head of the prosthesis, was considered in the load cases representing different activities. In a previous study, it was found that neglecting the muscle forces altered the predicted peak micromotion of only 1% (Pancanti, et al, 2001). Data on four patients performing nine different tasks were available from the telemetry measurements collected by Bergmann and co-workers (Bergmann, et al, 2001). Hip contact forces and the subject-specific anteversion angles were used. A fifth dataset was

obtained by averaging the results of all patients. All force values were expressed as percentage of body weight. The predicted peak micro-movements were used to describe the primary stability and to compare each task performed by each patient.

RESULTS AND DISCUSSION

The critical tasks were found out to be patient-specific (table 1). The largest peak micro-movement was predicted for patient #1, patient #2 and for average patient during stair climbing. However for patient #3 and patient #4, the worst tasks were fast walking and double-single-double stance cycle respectively.

Table 1: Peak bone-implant relative micromotion predicted under the action of the joint loads.

	Patient-1	Patient-2	Patient-3	Patient-4	Average	Range
downstair	-	66	80	97	77	31
fastwalk	-	62	89	81	72	27
kneebend	-	34	69	51	54	34
norwalk	95	60	71	77	69	35
sitdown	75	49	65	58	54	26
slowwalk	-	74	67	77	68	9
st212	-	62	74	113	67	51
standup	80	66	58	63	68	22
upstair	123	77	81	101	80	46
Range	48	43	31	62	26	

The variability predicted between tasks was found comparable to that between subjects. Double-single-double stance cycle induced a variability among patients of 51 μm , while the largest variability among tasks was 62 μm for patient #4.

Considering that the study is based on a generic anatomy, the inter-subject differences can be explained only with the different patients' movement strategies.

SUMMARY

In this work, we tried to compare different tasks performed by different patients on the primary stability of cementless stems by the use of a finite element model, previously validated. Data here reported suggest that no task can be identified as the most critical. In addition the differences between subjects performing the same task resulted as much relevant as the differences between tasks performed by the same patient.

INTRODUCTION

Total hip replacements fail mostly because of aseptic loosening (Malchau, et al, 2000). In controlled experiments the bone-implant relative micromotion appears to influence interfacial bone resorption more than any other biomechanical factor (Soballe, et al, 1992). The osseointegration process observed in stable implants is impaired by interface micro-movements above 30-50 μm , and even reverted to fibrous tissue differentiation if the amplitude is higher than 100-150 μm (Soballe, et al, 1993). The bonding between bone and implant can be broken if the interface shear stress exceed the strength limit, typically of 5-6 MPa (Soballe, et al, 1992).

The present study is aimed to model this process with a single computational model, and to use it to predict the secondary stability of an implant depending on the initial interface conditions obtained during surgery.

METHODS

The study was based on the finite element model of a human femur implanted with a cementless anatomical stem. The model, accounting for the large-sliding frictional contact occurring at the interface, had been previously validated against *in vitro* measurements of primary stability (Viceconti, et al, 2000). The material properties were derived from the literature and the load case was designed to simulate the instant of peak hip force during stair climbing (Bergmann, et al, 2001).

The adaptive algorithm was implemented as a macro-program with the Ansys programming environment (APDL). A first finite element analysis computed the bone-implant relative micromotion at each interface element, initially assumed in *standard* condition (i.e. frictional contact). The finite element analysis was repeated until the process converged to a stable configuration, adjusting in each iteration the status of each contact element on the basis of the following rules: i) elements exhibiting a micromotion higher than 100 μm were modified to simulate the presence of an interstitial gap of 0.7 mm (*loosened* condition); ii) elements with a micromotion below the 30 μm were modified to simulate a fully bonded interface (*integrated* condition); iii) bonded elements with a shear stress higher than 5 MPa were configured back to the standard condition. The proposed adaptation model is fully identified with only three parameters: two threshold micromotion and the shear strength. Four complete adaptation simulations were performed, varying the initial configuration of the model. The first, considered the reference model, was run assuming that initially the entire implant surface was in standard condition. A second simulation was run assuming that initially the entire bone-implant surface was in loosed condition. Two intermediate initial configurations were also considered, assuming that only the two regions with the highest contact

pressure in the reference model (proximal-anteromedial and distal postero-lateral regions) had an initial gap. In the first simulation the gap was simulated only in the proximal region, where in the second simulation it was assumed to be present at both locations. The peak total elastic micromotion induced by the stair-climbing load in the initial model was taken as an indicator of the so-called *primary stability*. The same value, as predicted by the final converged model, was assumed to represent *secondary stability*.

RESULTS AND DISCUSSION

All simulations reached an oscillatory convergence, in which the model switched between two stable configurations. The results of both configurations are reported.

The primary stability of the reference model was 115 μm . With this initial configuration the adaptation simulation converged to a final configuration in which 80-81% of the interface area was integrated, and 18-19% in standard condition. The secondary stability of this final model was 23-29 μm . The gap in the proximal region increased the peak micromotion to 242 μm . However, the simulation produced very similar results, with 80-81% of interface in integrated condition and 19-20% in standard condition. The secondary stability was 21-24 μm . The results remained almost unchanged also when the initial configuration considered an interface gap also in the distal region. Only when the initial condition simulated a generalised interface gap, the primary peak micromotion increased to 1475 μm , which prevented any osseointegration.

From these preliminary results the model seems to provide meaningful results. Although a validation study is currently in progress, the very simple nature of the model relies on a few assumptions proposed by other authors on the basis of experimental observations, ensuring that the predicted configuration are at least plausible. Once validated and included into a MonteCarlo simulation to provide a statistical perspective to the predictions, the proposed algorithm may become a very useful instrument in orthopaedics biomechanics.

INTRODUCTION

Assessment of bone material quality by means of peripheral quantitative computed tomography (pQCT) offers a wide perspective for bone research employing non-invasive procedures. The method of pQCT is able to determine volumetric bone mineral density, cross-sectional bone area, moment of inertia of area, and polar moment of inertia of area. Ferretti et al. (1996) described the mechanical validation of a pQCT-derived index of rat femur using a three-bending test. Jämsä et al. (1998) compared pQCT and a three-point bending test in evaluating the mechanical strength of mouse cortical bones. Hasegawa et al. (2001) investigated the association of grip strength and muscle cross-section with pQCT-derived torsional indexes at two human radial sites. Lind et al. (2001) evaluated the relationships between the torsional properties of rat humerus and geometrical parameters obtained by pQCT. They showed that significant correlation existed between area-related variables, stiffness, and torsion at failure. However, these relationships were not strong enough. The objective of this study was to predict torsional properties of rat femur utilizing pQCT.

MATERIALS AND METHODS

We used forty-eight Sprague-Dawley rat femora at ages of 10, 13, 16 and 24 weeks. The femora were stored at -10°C until pQCT and torsional test. The cross-section of each femur was scanned at mid-diaphysis using pQCT (XCT-960, Stratec, Pforzheim, Germany) in air. CT scans had a slice thickness of 2.5 mm and a voxel size E (0.148 mm). The value of Strain/Stress Index for polar (SSI_p) was calculated using volumetric bone mineral density and geometric parameters of cortical bone as follows:

$$SSI_p = \int_n (r_i^2 \rho_i / \rho_0) da / r_{\max} \quad (1)$$

where r_i is the each distance of voxel to the center of gravity, r_{\max} is the maximum distance of a voxel to the center of gravity, a is the area of a voxel, ρ_i is the each measured volumetric cortical density and ρ_0 is the normal physiological bone mineral density (1200mg/cm³). A biaxial testing machine (858 MiniBionix, MTS, Minnesota, USA) was used to apply the torsion for the mechanical test. Whole bone specimens were tested to failure in torsion at a rate of 0.2°/sec with no axial load during the test. The torsional stiffness and

strength (maximum torque) were obtained from the torque-rotation angle curve.

RESULTS AND DISCUSSION

The torsional stiffness and strength increased with increasing the age of rat. Nevertheless, the maximum rotation angle decreased with increasing the age of rat. Experimentally measured torsional stiffness correlated strongly ($r=0.95$) with SSI_p . The correlation between torsional strength and SSI_p was also strong, $r=0.91$ (Figure 1). In this study, we assessed the validity of using the pQCT-derived index SSI_p as a good predictor of whole bone torsional stiffness and strength over a range of 10 to 24 weeks old of rat bone size. Jämsä et al. (1998) estimated different pQCT variables and their relation to bending strength of mouse femur and tibia, the pQCT-derived index and cross-sectional cortical area were the best predictors of breaking force and stiffness. Their findings were well in accordance with the present study.

SCANNING ACOUSTIC MICROSCOPE MEASUREMENTS OF ANISOTROPY OF DENTINE AND ENAMEL

INTRODUCTION

Knowledge of the mechanical properties of teeth and the tissues from which they are formed is important to aid understanding of their mechanical behavior under physiological loading conditions. Studies on the elastic modulus of dentine are numerous and the values obtained extend over quite a wide range (Stanford et al., 1958; Lehman, 1967; Watts et al., 1987; Rees and Jacobsen, 1994). Nevertheless, studies on enamel are lacking due to the difficulty in preparing and testing extremely small specimens. The purpose of this study was to measure the elastic anisotropy of human and bovine dentine and enamel using a scanning acoustic microscope (SAM).

MATERIALS AND METHODS

216 human dentine and enamel specimens were obtained from 36 molar permanent teeth. 143 bovine specimens were obtained 15 molar teeth. Both human and bovine teeth were sliced into small rectangular specimens with a microcutter and polished with a buffing machine under constant water irrigation. The perpendicular direction of the specimen was aligned with the tooth axis and specimen cross-section was approximately 1×1 mm. A 50 MHz ultrasonic transducer and lens of SAM were used to transmit and receive acoustic waves in pulse echo mode. The delay time between acoustic waves reflected from the bottom of the specimen was measured using a digital oscilloscope. The acoustic velocity is equal to twice the thickness of the specimen divided by the delay time. The elastic wave propagation theory predicts relations between the elastic modulus, E , density ρ , and acoustic velocity, c , of the following form:

$$E = (1 + \nu)(1 - 2\nu)\rho c^2 / (1 - \nu) \quad (1)$$

where ν is the Poisson's ratio. We measured the elastic moduli of longitudinal and transverse directions of dentine and enamel.

RESULTS AND DISCUSSION

There was no significant difference between the longitudinal and transverse elastic moduli for human dentine (Fig. 1). However, the longitudinal modulus was higher than transverse modulus for human enamel. The ratio of elastic anisotropy of human enamel was about 1.1. For bovine enamel, the longitudinal elastic modulus was also higher than transverse modulus and the ratio of elastic anisotropy was about 1.2 (Fig. 2). The enamel is composed of prisms, which are built up in an

orderly fashion. These prisms run roughly parallel to the tooth's surface. Although the enamel prisms across a section of tooth do actually appear as curved lines, particularly around the cuspal region, this effect would be very complicated to anisotropy. The SAM technique is capable of further development and if it could be used in conjunction with localized determinations of the density and composition it would be a powerful tool for elucidating the relationship between structure and elastic properties.

WEAR OF CROSSLINKED POLYETHYLENE UNDER DIFFERENT TRIBOLOGICAL CONDITIONS

Alison Galvin, Joanne Tipper, Martin Stone, Eileen Ingham and John Fisher
Medical and Biological Engineering, University of Leeds, Leeds, LS2 9JT, UK. j.fisher@leeds.ac.uk

INTRODUCTION

Crosslinking has been extensively introduced to reduce the wear of ultra high molecular weight polyethylene (UHMWPE) in artificial joints. McKellop *et al.* (1999) reported that UHMWPE crosslinked with 5MRad of radiation produced an 83% reduction in wear in hip joint simulator studies compared to non-crosslinked material. Muratoglu *et al.* (2000) showed an 85% reduction in wear with 10MRad material. These simulators applied different kinematic conditions, but both used high concentrations (90-100%) of serum in the lubricant. Other studies have shown smaller reductions in wear with crosslinking (Endo *et al.* 2000). Although there is a general consensus that crosslinked UHMWPE reduces wear, there is considerable variation in the percentage reduction achieved in different studies. The aim of this study was to compare the effects of changes in serum concentration, kinematics and counterface condition on the wear of UHMWPE for three different levels of crosslinking.

METHODS

Wear pins were machined from UHMWPE GUR 1050. Crosslinking was achieved using gamma irradiation at 0, 5 and 10MRad. The counterface was stainless steel. Tests were run in a six station multidirectional pin on plate rig. Initial tests used 95% (v/v) and 25% (v/v) serum as lubricants. Three different counterface conditions were then tested at $\pm 60^\circ$ rotation, smooth $R_a \sim 0.007\mu\text{m}$, medium scratches $R_p \sim 0.8\mu\text{m}$, and high scratches $R_p \sim 1.8\mu\text{m}$ with 25% (v/v) serum. The final test used similar counterfaces with $\pm 20^\circ$ rotation. Wear was determined gravimetrically and wear factors were calculated.

RESULTS

Figure 1: Wear factors in 95% and 25% serum lubricant.

The wear rates in the different serum concentrations at $\pm 60^\circ$ rotation on smooth counterfaces are shown in Figure 1. With both concentrations of serum there was a reduction in wear as crosslinking levels increased. The mean wear factors for the different counterfaces at $\pm 60^\circ$ are presented in Figure 2. The wear rate increased with increasing scratch height for each

material. The mean wear factors for the different counterfaces at $\pm 20^\circ$ rotation are shown in Figure 3. They showed a similar pattern to the $\pm 60^\circ$ rotation results.

Figure 2: Wear factors at $\pm 60^\circ$ rotation.

Figure 3: Wear factors at $\pm 20^\circ$ rotation.

DISCUSSION

The largest reduction in wear rate produced by crosslinking was observed with the high concentrations of bovine serum. At lower serum concentrations (25% (v/v)) as defined by the ISO standard, the reduction in wear produced by crosslinking was lower. The results from different counterface conditions at $\pm 60^\circ$ rotation showed that the smooth counterface gave the greatest percentage reduction in wear factor between non and highly crosslinked material. Damage to the counterface increased the wear rates for all the materials with both kinematic conditions. Altering the kinematics to a lower angle of rotation, which introduced less cross shear frictional energy, has implications if using crosslinked polyethylene in the hip and knee, as the different kinematics seen in each joint give different levels of cross shear frictional energy. In conclusion the reduction in wear produced by crosslinking was critically dependent on protein concentration, kinematic conditions and counterface roughness.

PRECISION MEASUREMENTS OF RSA METHOD USING A PHANTOM MODEL OF HIP PROSTHESIS

Tatu J. Mäkinen¹, Jyri K. Koort¹, Kimmo T. Mattila² and Hannu T. Aro¹

University of Turku, Turku, Finland, hannu.aro@utu.fi

¹ Department of Surgery, ² Department of Diagnostic Radiology

INTRODUCTION

RSA (Radiostereometric Analysis) has become one of the recommended techniques for premarket clinical evaluation of new joint implants designs (Kärrholm et al. 1997). The method allows high precision measurements of three-dimensional movements from radiographs (Önsten et al. 2001). However, the method is technically very demanding. A meticulous assessment of possible error sources is mandatory during standardization of the method in each research unit.

METHODS

A phantom model was constructed (Fig. 1). A threaded cup was securely fixed to a plastic pelvis. The femoral component was inserted to the medullary canal of a plastic femur. Care was taken to ensure that there was no movement between bony and prosthetic components. Tantalum markers (n=8 for the femoral and n=13 for the acetabular side) were inserted to the components with glue. A uniplanar type of RSA setup with two portable radiographic units was used. Two series were performed. First, 10 double examinations were performed so that the tubes were not repositioned and position of the phantom model was not changed (Series 1). This correlates to the optimum situation, the best precision obtained with the applied setting. Next, 10 double examinations were performed so that the tubes were repositioned and position of the phantom model was changed between double examinations (Series 2).

Figure 1: Phantom model

This correlates to the clinical situation where patient is examined at different time points. Digital X-ray films were scanned with a high-resolution scanner (UMAX PowerLook 2100 XL, Taiwan) and analysed with UmRSA 4.1 (RSA BioMedical Innovations AB, Umeå, Sweden) software. The calculated displacements of the femoral and acetabular components between double examinations were used to determine the limits of significant migration in the x, y and z axes defined as the 99% confidence limit (CL). Mann-Whitney test was used to analyze the statistical significance of the differences observed between the two series.

RESULTS AND DISCUSSION

In Series 1, the minimal significant (99% CL) translations and rotations varied between 18-103 μm and 0.03-0.33 degrees, respectively (Table I). For translations, the precision was highest along the longitudinal axis (y-axis) and lowest along the sagittal axis (z-axis). In Series 2, repositioning of the X-ray tubes and the phantom between double examinations resulted in statistically significant differences when compared with the values of Series 1 in four out of 12 calculations. Of the four significant differences, three were found in evaluation of the acetabular component, reflecting the limited space for scattering of the acetabular component markers.

SUMMARY

When using RSA-method, standardization and calibration procedures should be performed with phantom models in order to avoid unnecessary radiation exposure of the patients. The present model gives the means to establish and to follow the intra-laboratory precision of the RSA method. The model is easily applicable in any research unit and allows the comparison of the precision values in different laboratories of multicenter trials.

OPTIMAL PEDAL RATE FOR MAXIMAL POWER PRODUCTION IN CYCLING IS NOT RELATED TO FREELY CHOSEN PEDAL RATE AT SUB-MAXIMAL EXTERNAL POWER

Ernst Albin Hansen¹ and Gisela Sjøgaard²

¹Institute of Sports Science and Clinical Biomechanics, University of Southern Denmark, e.hansen@winsloew.sdu.dk

²National Institute of Occupational Health, Copenhagen, Denmark

INTRODUCTION

Cyclists seek to maximize performance during competition, and efficiency is an important factor affecting performance at sub-maximal external power. Efficiency is affected by pedal rate and therefore it is pertinent to reveal factors affecting freely chosen pedal rate (FCPR) during cycling. Recently, we showed that e.g. crank inertial load affects FCPR. Thus, for a group of subjects FCPR was higher at high compared with low crank inertial load (Hansen et al. 2002). Hautier et al. (1996) showed that the proportion of fast twitch fibers in m. vastus lateralis, expressed in terms of cross sectional area, was related to optimal pedal rate for maximal power production. The purpose of the present study was to determine the optimal pedal rate for maximal power production (OPMP) for each subject in a group that was characterized by a large variation in fiber type composition in m. vastus lateralis. Further, to test the hypothesis of a relationship between OPMP and FCPR during cycling at sub-maximal external power.

METHODS

Twenty healthy males of age 26.3 ± 3.5 years, height 178 ± 5 cm, and body mass 73.3 ± 7.5 kg volunteered. The subjects had a needle biopsy taken from the middle section of m. vastus lateralis. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) was used in a MHC analysis performed on each muscle sample. MHC isoform (I, IIa, and IIx) content was determined. Cycling sessions were performed in a custom-built set-up with a racing bicycle placed on a motorized treadmill. Optimal pedal rate for maximal power production (OPMP) was determined in a session consisting of 12 isokinetic maximal cycling bouts at preset pedal rates of 30-140 rpm in steps of 10 rpm (randomized). Treadmill speed and gear ratio were matched to attain the target pedal rates. Peak crank power was calculated from crank arm velocity, determined from the pedal rate, and the peak crank torque. Freely chosen pedal rate (FCPR) was measured in another session consisting of cycling at external power corresponding to 40 and 70% of the maximal oxygen uptake (VO_{2max}), at 80 rpm. These external powers had previously been determined in a progressive test to exhaustion. $p < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

A large range in fiber type composition was documented, the data being presented as mean $\pm 1SD$ (range): 64 ± 16 (21-97)% MHC I, 33 ± 14 (4-65)% MHC IIa, and 3 ± 5 (0-15)% MHC IIx. FCPR was 74 ± 11 (56-88) rpm and 80 ± 11 (61-102) rpm at external power corresponding to 40 and 70% VO_{2max} (at 80

rpm), respectively ($p < 0.05$). Maximum peak crank power was 1412 ± 229 (990-1924) W and occurred at the optimal pedal rate of 122 ± 18 (91-153) rpm. There was a high correlation between % MHC I and OPMP: $OPMP \text{ (rpm)} = -0.87 \text{ MHC I (\%)} + 176.15$, $r = -0.81$, $p < 0.05$ (Fig. 1). There was a low correlation ($r = -0.47$) between % MHC I and maximum peak crank power but no correlation when maximum crank peak power was expressed per kg body weight, thigh weight, or muscle extensor weight. Further, there was no significant correlation between OPMP and FCPR.

Fig. 1: Pedal rate as a function of % MHC I. $n=20$. ■ represent optimal pedal rate for maximal power production (OPMP). ○ and ● represent freely chosen pedal rate (FCPR) at external power corresponding to 40 and 70% VO_{2max} (at 80 rpm), respectively.

SUMMARY

We showed a high correlation between fiber type composition and optimal pedal rate for maximal power production. Thus, subjects with a high % MHC I demonstrated a low optimal pedal rate compared to subjects with a low % MHC I. This confirmed data from Hautier et al. (1996). The optimal pedal rate for maximal power production was no key factor when individuals freely chose a pedal rate during cycling at sub-maximal external power. Subjects with high % MHC I freely chose a pedal rate close to the optimal pedal rate for maximal power production. Subjects with low % MHC I tended to choose lower pedal rates, favoring high gross efficiency.

SELF-EXCITED OSCILLATIONS IN A FLUID-BEAM COLLAPSIBLE CHANNEL

Zong Xi CAI & Xiao Yu LUO

Department of Mechanical Engineering, University of Sheffield, S1 3JD, UK

X.Y.Luo@shef.ac.uk

INTRODUCTION

Flow in collapsible tubes is studied extensively in the recent few decades not only due to its relevancies in physiological applications, but also due to its interesting dynamic phenomena. Self-excited oscillations are frequently discovered in a Starling resistor set up of such a system in laboratories. Some of these oscillations have been reproduced by a two dimensional fluid-membrane model (Luo & Pedley, 1996), which may in principle, be realized a laboratory. The fluid-membrane model, however, suffers from several *ad hoc* approximations: the wall stiffness was ignored, and elastic wall was assumed to move either in the vertical or the normal directions. Although these assumptions may be acceptable for the steady flow simulations, their influences on the unsteady flows, especially on the self-excited oscillations, need to be carefully evaluated.

This paper studies the unsteady flow in a collapsible channel using a new, improved fluid-beam model, where a plane strained elastic beam with large deflection is used. Thus the solid mechanics of the wall is taken care of properly, and the above *ad hoc* assumptions are not longer required.

METHOD

A finite element code for unsteady flow is developed to solve the coupled nonlinear fluid-structure interactive equations simultaneously, and an adaptive mesh with rotating spines is used to enable a movable boundary. Small perturbations are applied on the steady solutions of the system and the time evolution of the unsteady solutions are subsequently computed. In addition, the code is modified to solve the corresponding eigen-value equations so that the linear stability of the system can be also investigated.

RESULTS AND DISCUSSION

The results of the new model are computed and compared with the fluid-membrane models. There are several interesting discoveries. First, the self-excited oscillations in the new model are qualitatively similar to those from the previous fluid-membrane model if the wall stiffness is very small. This implies that the fluid-membrane model is a good approximation for a very thin wall material (which is usually too thin for biological materials, however). Secondly, the critical value of the tension no longer exists in the new model if the wall stiffness is big enough. In addition, small amplitude oscillations are found which seem to exist exclusively in the new model with the wall stiffness included. The occurrences of these small amplitude oscillations are closely predicted by

the neutral stability curve obtained from the linear stability analysis of the system. These oscillations then change into the large amplitude irregular non-linear ones via the period doublings as the tension/wall stiffness is further decreased from the neutral stability points. One finding of interest is that unlike the small amplitude oscillations, these large amplitude non-linear oscillations tend not to oscillate around their corresponding steady solution when perturbed, but they oscillate around a different operation point, see figure below.

Figure: The oscillation of the centre point of the beam, Y , is shifted away from its steady solution. $Re=300$.

SUMMARY

Unsteady flow in a fluid-beam interactive model is simulated by using a finite element code. Both small and large amplitudes self-excited oscillations are discovered. The small amplitude oscillations agree very well with the neutral stability curve obtained from the linear stability analysis. The large amplitude oscillations are of non-linear nature and often present highly irregular and chaotic-like waveforms. Results are also compared with those of the previous fluid-membrane model, and their differences are discussed.

OVERTURNING RESISTANCE OF RIGID TAP ROOTS

S B Mickovski and A Roland Ennos

School of Biological Sciences, University of Manchester, 3.614. Stopford Bldg., Oxford Rd., Manchester M13 9PT, UK

Contact: slobodan.mickovski@stud.man.ac.uk

INTRODUCTION

The vast majority of self-supporting plants are likely to be pushed sideways by a herbivore or even more likely by the wind and either topple or lean permanently – a phenomenon known as ‘lodging’. To neutralise lateral loads these plants are expected to have strong roots with at least one rigid element that will resist with its bending resistance, while the surrounding soil resists with its compressive resistance. Engineers have formulated the theory of laterally loaded piles that can be used to explain the behaviour of tap root systems.

This study combined engineering theory with practical biology by modelling different sizes of simple rigid tap roots, embedding them at different depths in different soil media, and pulling them over, recording the overturning moment along the way.

MATERIALS AND METHODS

Spruce and balsa dowels ($\varnothing=4.2, 6.3, 8.5$ and 12.7mm , all of them 33cm long) were used as model tap roots. Ten replicas of each diameter were embedded in two different soil media (river sand and compost – agricultural soil) at three different depths ($3, 5$ and 7cm). The models were laterally pulled over at a constant rate using INSTRON testing machine. The force vs. displacement was plotted and the type of the soil failure was recorded. Aspect ratios (the ratio between the diameter of the tap root and embedment depth) were calculated presuming that the amount of material required to resist overturning force is minimised when the bending strength of the tap root equals the resistance to rotation.

RESULTS

Log-log regression (Figure 1) showed that the overturning resistance of the model tap roots increased with the third and second power of the embedment depth, in sand ($r^2=0.99$) and in agricultural soil ($r^2=0.86$) respectively. They showed that the model diameter was also a significant factor in resisting overturning, but only in agricultural soils, where overturning resistance was more or less proportional to diameter.

Log [depth] vs. Log [M] graph for models in both media

Figure 1. Log [depth] vs. log [overturning moment] graph for models in sand (○) and in agricultural soil (●)

In sandy soil there was little consistent increase of overturning moment with model diameter. In fact, smaller diameter roots were actually more firmly anchored at low depths in sand. The optimal aspect ratio for the models in sandy soils ranged from 15.5 to 15.7, and for the models in agricultural soil from 14.1 to 14.6. Models that showed the largest resistance, were in all cases those with an aspect ratio of 7 to 9.

DISCUSSION

Results are comparable to the ones predicted in earlier works based on the engineering theory of laterally loaded piles. Sandy soil failed in shear locally around the tap root and it rotated around a point on or very close to the root tip. The resistance to overturning in this case comes from the shear strength of the soil around the tap root and does not change with diameter.

In agricultural soil, the tap root rotated around a point between the soil surface and the root tip and the passive earth pressure below that point acted together with the soil shear strength in resisting overturning.

This kind of root system is unstable and likely to fail under small loads above the ultimate ones, and the strength of the tap root itself is likely to further limit the overturning resistance of tap root dominated systems. The stability of such root systems is naturally improved by reinforcing the base of the tap root (larger cross-sectional area where the stresses are highest) often accompanied by formation of the ‘I’ beam shaped cross sectional area, or developing a hollow shape strengthened around the outside of the root.

Embedment depth to root diameter ratio turned out to be more important in cohesionless soils where the lack of cohesion could be partially replaced by the larger surface areas on which the soil will shear during overturning. Adaptations might include splitting the large rigid root into a group of thinner deeply embedded tap roots with a larger surface area, positioning the tap root under a certain angle from the vertical as in some desert shrubs, or simple proliferation of thick lateral roots.

COMPUTATIONAL FLUID DYNAMICS SIMULATION OF THE BLOOD FLOW IN THE HUMAN AORTIC ARCH WITH ITS BRANCHES

Daisuke Mori¹ Tomoaki Hayasaka² and Takami Yamaguchi¹

INTRODUCTION

We have been studying the flow in the human aortic arch from a hemodynamics perspective with respect to vascular diseases using a computational fluid dynamics (CFD) method (Mori and Yamaguchi, 2001). Initially, we examined the complicated geometry of the arch, focusing on the three-dimensional (3-D) non-planar distortion in its configuration, while not fully considering the major branches at the top of the arch. In this study, we construct an aortic arch model for CFD simulations that incorporates both non-planarity and the major branches, using a set of magnetic resonance (MR) images, and discuss their combined effects on blood flow.

METHODS

The branching structure of the aortic arch can be simplified as a major pipe, i.e., the aortic arch, with three major branches connected to it. Using the differential geometry modeling method (Mori and Yamaguchi, 2001), the aortic trunk and the three branches were each constructed individually based on their centerlines using 3-D reconstructed MR images. There were regions in each model in which the corresponding computational grids overlapped, so we combined the models to form a single computational domain of the arch with its branches. To model each vessel geometrically, we used the interactive clinical interface for MR images developed by Hayasaka et al. (2001). Fig. 1 shows an MR image, and the CFD model constructed from it. In order to use the overset grid, the velocity vectors and pressure for each grid in the overlapping regions must be interpolated and transferred from one region to the other at every computational step. The transferred data were always regarded as part of the boundary conditions in the recipient region. The CFD computations used a commercial program, SCRYU version 1.4 (Software Cradle, Osaka, Japan).

Figure 1: A CFD model of the aorta constructed by curve fitting the centerline to a cubic spline function. (a) 3-D reconstructed MR image. (b) CFD models of the aorta. (c) Overlapping region.

RESULTS AND CONCLUSION

Figures 2 and 3 show the secondary flow at a given cross section, and the wall shear stress (WSS) distribution under a steady uniform inflow condition with a Reynolds number (Re) of 1600, respectively. As shown in Figs. 2a-c, the flow along the arch consisted of a large right-handed rotational flow in the descending part of the arch, and a large left-handed rotational flow at the end of the arch. These characteristics of the global flow are similar to the results obtained using our arch model without branches (Mori and Yamaguchi, 2001). On the other hand, the secondary flow in the branches differed in each branch and showed unique structures, probably due to the asymmetric 3-D structure of the arch. This study demonstrated that the combined method of differential geometrical modeling based on the vascular centerline, with overset meshing for the branches, is a powerful means of conducting a CFD analysis of the blood flow in the aortic arch.

FINITE ELEMENT SIMULATION OF OSSEOINTEGRATED TRANS-FEMORAL IMPLANT UNDER EXTREME LOAD CONDITION

W. Xu, J. Li, A Crocombe and S. C. Hughes

Centre for Biomedical Engineering, School of Engineering,
University of Surrey, Guildford, Surrey, GU2 5XH UK, W.Xu@Surrey.ac.uk

INTRODUCTION

The traditional limb prosthesis is interconnected with residual limb via a "socket". The load put upon the prosthesis limb transfers through soft tissue to the human skeleton. As the result of wearing socket type of prostheses, muscles and skin is likely to be traumatized. The osseointegrated titanium implants have achieved impressive clinical results in the dental and maxillofacial treatment for over 20 years [1]. A similar technique has been recently extended to orthopedic applications for attaching prosthetic limb to the residual stump of the amputee. This technique inserts a titanium implant into the long axis of the principal bone of the stump. The distal end of the implant connected to an abutment that penetrates through the skin to provide direct prosthesis limb attachment. This method could overcome the disadvantages of socket type limb attachment. The preliminary clinical trials, conducted principally in Sweden within the Branemark Osseointegration Centre, Gothenburg and consequently Queen Mary's hospital in London, has shown encouraging result.

However, due to the malfunction of the prosthetic limb and accidentally loss balance of the prosthetic limb wearer, significant overload could be put on to the abutment, implant and bone. At the Queen Mary's hospital five cases have developed a plastic deformation of the abutment. None of these cases led to a failure of osseointegrated connection between the implant and bone. This indicates that the bone-implant osseointegrative interface may somehow withstand higher stress impact. To investigate the interfacial stress under an overload condition, the finite element methods were used.

METHOD

To simulate the stress situation at the bone-implant interface, 3 dimensional bone and implant FE models were created. The bone model was created direct from CT scans of the trans-femoral amputee. A computer program was developed to carry out 3D reconstruction of the solid model of the femur and implant in the format of Ansys parametric language. The detail of the 3D reconstruction of the solid model of the femoral and implant is discussed in a separate paper of authors[2].

Since the load put up on the abutment is caused by a collision while the amputee falls over, the actual load is unknown. To work out the collision load, the deformation simulation of a simple nonlinear FE abutment model was carried out. The result of the simulation in terms of direct reaction force put up on the abutment was used as input for the further study of bone-implant interfacial stress under collision loading.

RESULTS AND DISCUSSION

To investigate the effect of the collision load on bone-implant interfacial stress, Von Mises stress and the equivalent strain were used to represent FE modelling results. In order to compare the stress situation between normal load and collision load condition, two models were evaluated and showed a general pattern with the maximum stress located near to distal femur and the stress near the end part of implant taking a relatively low value with more uniform distribution.

The result shows that the interfacial stress under a normal load situation is much smaller than the collision condition. The stress level under a collision load condition reaches the fracture load of the human bones, although these only take place in few isolated places. This indicates that the osseointegrated interface is able to repair an overload injury through the bone remodelling or other mechanisms.

SUMMARY

The following conclusions were drawn from this study. As it is expected that the stress under the collision load condition is much higher than the normal load condition. The stress level at the collision condition reaches fracture stress of the human bone, although there are only few small areas at the bone-implant interface reaching this level. Since the full recoveries were observed in all overload cases, it indicated that the osseointegrated interface possesses self-repairing capability. Further clinical investigation needs to be carried out for clarification.

PRESSURE-INDUCED EXPRESSION OF IMMEDIATE-EARLY GENE PRODUCT C-JUN OF THE COMMON CAROTID ARTERIES IN RATS

Zonglai Jiang, Zhiqiang Yan, Yan Zhang, Xiangqun Yang
Institute of Biomedical Engineering, Changhai Hospital, Shanghai 200433, China

INTRODUCTION

Mechanical stress have been thought to play a role in vascular remodeling but the mechanism remains to be determined. The proliferation and neointimal formation of vascular smooth muscle cells are the critical events in the arterial remodeling, in which immediate-early response gene product c-Jun, a transcription factor, may play a important role. In order to understand the mechanism of mechanical stress affecting the remodeling, pressure- induced expression of c-Jun in the common carotid arteries was studied in rats.

METHODS

The common carotid arteries were perfused with both high pressure (160mmHg) and normal pressure (80mmHg) for 0.5, 1, 3 and 6 hours in SD rats *in vivo*. Expression of immediate-early response gene product c-Jun in the arteries was examined by immunohistochemistry and computer image processing methods.

RESULTS AND DISCUSSION

The results revealed that c-Jun was weakly expressed at 1h, then increased at 3 h and 6 h after the arteries exposing to normal pressure. While positive immonohistochemical product of c-Jun was existed at 0.5h after the onset of high pressure , then increased markedly up to 6h in the arteries. There was significant difference between two groups (Fig.1). It was shown that expression of c-Jun of the arteries could be induced by the pressure, which was also in response to the pressure sensitively. The immediate-early response gene product c-Jun may play an important role in mechanical stress-mediated arterial remodeling.

Fig.1 The relative area of the positive product of c-Jun
* P < 0.01 vs normal pressure

SUMMARY

To investigate the mechanism of mechanical regulation of arterial remodeling, the pressure-induced expression of c-Jun in the common carotid arteries was studied in rats. The results are shown that expression of c-Jun of the arteries can be induced by pressure, which may play an important role in mechanical stress-mediated arterial remodeling.

EFFECTIVE CONTACT CONDITIONS BETWEEN CEMENTLESS COATED HIP IMPLANT AND BONE

Julia Orlik¹, Alexei Zhurov² and John Middleton²

¹Fraunhofer Institut Techno- und Wirtschaftsmathematik, Kaiserslautern, Germany

²Biomechanics Research Unit, University of Wales College of Medicine, Cardiff, UK, zhurovai@cardiff.ac.uk

INTRODUCTION

Treatment for hip osteoarthritis focuses on decreasing pain and improving joint movement. When conservative methods of treatment fail, it is necessary to replace the affected joint with an artificial joint prosthesis. Nowadays there are two types of hip prosthesis: cemented and cementless. The cementless coated hip prosthesis represents approximately 35% of the European market and is regarded as being particularly promising. The surface of the coating is made rough and porous with the idea that the bone, which is in direct contact with the coating, grows into the microvalleys and pores to provide enhanced stability and rapid osseointegration.

We consider mature femoral cortical bone that is in contact with a hip implant having a rough coating. The bone is assumed to be separated from the implant by a thin layer of microscopic peaks and valleys formed on the surface of the coating. The size of the peaks and valleys is very small compared with the macroscale of the implant stem and bone, which makes the direct application of the FEM for the calculation of the bone–stem contact problem prohibitively costly. A way out is to replace the rough layer with physical microcontact boundary conditions by a surface with some effective macrocontact boundary conditions. The macrocontact conditions can then be used in FEM models, allowing one to avoid extremely costly computations in regions with different size scales.

The aim of the research is to investigate the dependence of the bone–implant contact conditions on the microgeometry and mechanical properties of the coating. To achieve this aim, unlike Hansson & Norton (1999), who use semi-empirical approximate relations, we develop an asymptotic homogenisation procedure based on theoretical results of Yosifian (1999) and extend the approach of Jäger et al (1997, 1998) and Belyaev et al (1998) to elastic contact problems.

ASSUMPTIONS

We assume that the contact areas are known, thus confining ourselves to linear problems. From the mechanical point of view, the contact zones are known only if the micropeaks (punches) either have plane summits and equal heights (e.g., are parallelepipeds or cylinders) or have arbitrary geometry but all free space is filled by bone (i.e., the bone is in ideal contact with the implant).

We make the following assumptions: (i) the problem is linearly elastic; (ii) the microcontact surfaces are known, and consequently, the problem is linear; (iii) either there is no friction or Coulomb's friction law is adopted, and hence, the shear stresses at the contact boundary are either zero or proportional to the normal stress; (iv) the bone and implant materials are homogeneous; and (v) there is a small parameter, ε , the ratio of the characteristic dimension of the interface irregularities to the characteristic length of the bone–implant interaction zone, which allows application of an asymptotic homogenisation procedure. In our theoretical models, we treat the implant and coating as being rigid, since their Young's modulus is much greater than that of the bone.

STATEMENT OF PROBLEM, HOMOGENISATION PROCEDURE AND BASIC RESULTS

We consider two contacting domains with interface having a pattern represented by periodically arranged identical peaks with plane or spherical summits. It is assumed that the domains are bounded and periodic boundary (contact) conditions are imposed. We write out the equilibrium equations and constitutive elastic relations with contact and boundary conditions, and then rewrite the problem in a weak (variational) formulation.

Further, we apply a two-scale asymptotic homogenisation procedure, employing some results of Yosifian (1999), to obtain a homogenised variational equation and write out the corresponding homogenised problem in the strong formulation. This problem involves the averaged contact conditions, which replace the microcontact layer.

At the next stage, we solve the homogenised problem, calculate the macrodisplacements and stresses in the bone domain with the averaged boundary conditions obtained. Then, extending techniques of Jäger et al (1998) to elasticity, we find an approximation to the microstresses in the boundary layer by a formal asymptotic expansion, and finally insert this approximation into a microstrength condition to predict the occurrence of fracture in the bone under the applied loading.

The main theoretical result obtained is a general expression of the effective normal contact stiffness for arbitrary microgeometry of the interface; formulas for some special geometries are also presented.

In computations, we use the finite element software package ANSYS. Various designs are considered using the effective normal contact stiffness obtained above. The results are compared with the cases of smooth interface. Fracture regions are predicted for various loadings.

EFFECT OF CO-CULTURED VASCULAR SMOOTH MUSCLE CELLS ON PDGF-B mRNA EXPRESSION OF ENDOTHELIAL CELLS UNDER SHEAR STRESS

Zonglai Jiang, Yuquan Li, Yan Zhang, Dong Wang

Institute of Biomedical Engineering, Changhai Hospital, Shanghai 200433, China

INTRODUCTION

The effect of vascular smooth muscle cells (VSMCs) on the PDGF-B mRNA expression of co-cultured endothelial cells (ECs) under shear stress had been studied to provide some experimental data for preventing the development of restenosis resulted from VSMCs proliferation in the vascular graft.

METHODS

A new co-culture model of ECs-VSMCs, which mimicked the interior architecture of native vessel and also imitated the interaction patterns between ECs and VSMCs and a flow chamber system for the co-culture model were established, in which 0 ~ 40dyn/cm² steady laminar flow shear stress can be obtained. The level of PDGF-B mRNA of ECs cultured alone (SCss) and co-cultured with VSMCs (CCss) exposed to shear stress were investigated by the methods of *in situ* hybridization and image analysis. Both controls of ECs cultured alone (SC) and co-cultured with VSMCs (CC) were maintained under static conditions.

RESULTS AND DISCUSSION

In static condition, the content of PDGF-B mRNA expression of co-cultured ECs was lowered in comparison with ECs alone-cultured. Under shear stress, PDGF-B mRNA expression of co-cultured ECs was increased in transient manner at 1hr after the onset of shear stress and then returned to the level lower than the static level of co-cultured ECs at 6 hr after being exposed to shear stress. The transient increasing time of PDGF-B mRNA expression of co-cultured ECs reached a maximum earlier than that of ECs cultured alone. Under shear stress, PDGF-B mRNA expression of ECs co-cultured with VSMCs is lowered, which may be favor of inhibiting VSMCs proliferation.

Fig. 6 Gray value of PDGF-B mRNA ISH in ECs

** (SC vs CC, $p < 0.01$) ; ## (CCss vs CC, $p < 0.01$) ; ++ (SCss vs CCss, $p < 0.01$)

SUMMARY

To understand the effect of VSMCs on PDGF-B mRNA expression of co-cultured ECs under shear stress, the level of PDGF-B mRNA of ECs cultured alone and co-cultured with VSMCs exposed to shear stress were studied by the methods of *in situ* hybridization and image analysis. The results shown that PDGF-B mRNA expression of ECs co-cultured with VSMCs is lowered under shear stress, which may be favor of inhibiting VSMCs proliferation.

EFFECTS OF LOW SHEAR STRESS ON MORPHOLOGICAL REMODELING OF ORGAN-CULTURED ARTERY IN VITRO

Bo Liu, Zonglai Jiang, Yan Zhang, Xiangqun Yang

Institute of Biomedical Engineering, Changhai Hospital, Shanghai 200433, China

INTRODUCTION

Changes of blood flow can effect the morphometry of vessel. Shear stress may influent proliferation of vascular cells, but it is difficult to control the stress quantitively of in an intact vessel, however, the mechanism of mechanical regulation of vascular remodeling remains to be understood. To explore the biological influence of shear stress on intact artery, we established an organ-culture system of artery under stress *in vitro* and the relationship between stress and vascular remodeling was studied.

METHODS

The common carotid arteries of pigs were cultured under 20 (S20), 5 (S5) and 0 (S0) dyn/cm² of shear stress in the system for 1, 4 and 7 days, the pressure 100mmHg was maintained during the culture. Uncultured artery was used as control group (C). Morphometry of arteries, such as inner diameter, wall area and wall thickness, were studied with computer image processing methods. The α -actin of vascular smooth muscle cells (VSMCs) was stained by immunohistochemical methods and cells of vascular wall were also observed by transmission electron microscope.

RESULTS AND DISCUSSION

The results showed that arterial remodeling occurred obviously under low shear stress, expressed as decreasing of inner diameter and wall area and increasing of wall thickness and ratio of wall thickness to inner diameter (Fig. 1). Some VSMCs changed from contractile phenotype to synthetic phenotype under low shear stress. The relative area of α -actin decreased. The nucleus became twisted, bigger and rounder, it's array complicated, and nucleoli could be obviously observed in VSMCs. It was shown that the vascular remodeling reduced by low shear stress is different from that of the alteration of pressure in the morphological changes, which suggested that they have different mechanism. Phenotype switch of VSMCs is the base of vascular remodeling under low shear stress.

SUMMARY

To explore the biological influence of low shear stress on intact artery, the common carotid arteries were cultured under low shear stress in the organ-culture system of artery under stress *in vitro*. Changes in the arteries were studied with morphological, immunohistochemical, electron microscopical and computer image processing methods.

Morphological remodeling of them occurred obviously under low shear stress, and it is different from that of the alteration of pressure in the morphological changes, which suggested that they have different mechanism.

CHANGES IN GROUND REACTION FORCE AND JOINT EXCURSIONS DURING A FATIGUING LANDING ACTIVITY

Michael Madigan¹ and Peter Pidcoe²

¹Department of Engineering Science & Mechanics, Virginia Tech, Blacksburg, VA, mlm@vt.edu

²Department of Physical Therapy, Virginia Commonwealth University, Richmond, VA

INTRODUCTION

Past landing studies have investigated the effect of several performance factors on lower extremity loads in an effort to characterize their roles in injury development. Neuromuscular fatigue may also play a role in injury development, but its effect on lower extremity loads has received limited attention in the literature. The purpose of this investigation was to quantify changes in the vertical component of the ground reaction force (GRFv) and joint excursions during a fatiguing landing activity.

METHODS

The fatiguing landing activity was developed with two goals in mind. First, the resulting muscle fatigue pattern should be “functionally realistic” in that it may include multiple muscle groups. This is in contrast to studies that have fatigued a single muscle group. Second, the protocol should allow changes in landing biomechanics to be monitored continuously as fatigue progresses from a pre-fatigued state to exhaustion. This is in contrast to studies that have reported only pre- and post-fatigue data.

Twelve male subjects who were physically active and had no recent history of lower extremity injury volunteered to participate. Subjects were asked to perform a fatiguing landing activity until exhaustion. The landing activity involved an alternating sequence of 2 single-leg landings (25 cm height), and 3 single-leg squats. The landings were the biomechanical event of interest, and the squats were integrated into the activity to facilitate neuromuscular fatigue. Single-leg landings were used to avoid potential asymmetries in bilateral landings. Ground reaction force and lower extremity kinematics were sampled during the landings. A repeated measures ANOVA with posthoc Dunnett’s test was used to determine the significance of changes from initial values for each variable of interest.

RESULTS AND DISCUSSION

As subjects fatigued, the GRFv maximum decreased an average of 12.2% ($p < .01$), the temporal location of the GRFv maximum was not found to vary significantly, the GRFv impulse (calculated from impact to 200 msec after impact) decreased an average of 5.9% ($p < .01$), and the GRFv maximum loading rate increased an average of 4.5%, but was not statistically significant ($p > .05$). Sagittal plane joint excursions increased upon landing as subjects fatigued. Hip flexion increased an average of 2.9° ($p > .05$), knee flexion

increased an average of 5.4° ($p < .05$), and ankle dorsi flexion increased an average of 3.8° ($p < .01$). These changes were found to occur in a curvilinear manner as subjects fatigued with the degree of nonlinearity varying between the variables.

These findings suggest a decreased ability of subjects to decelerate upon landing when fatigued. The decrease in GRFv impulse indicates that less of the downward deceleration occurred during the first 200 msec after impact, and (presumably) more deceleration occurred after this time interval. This is supported by the increase in joint excursions upon landing. The nonlinear rate of change of these variables as fatigue progressed indicates that the decreased ability to decelerate the body did not occur in a linear manner.

The fatigue pattern in the lower extremity was induced by a closed kinetic chain activity (squatting) in an attempt to elicit a fatigue pattern that may be more functional compared to a single fatigued muscle group. A limitation of this study was that the resulting fatigue pattern was poorly defined.

SUMMARY

A closed kinetic chain activity was used to progressively fatigue subjects during a landing activity, and the resulting changes in GRFv and joint excursions were quantified. Results suggested a decreased ability of subjects to decelerate upon landing when fatigued. A nonlinear rate of change of GRFv variables and joint excursions indicated that this decreased ability did not progress in a linear manner.

INTRODUCTION

Arterial venous shunts are commonly used for dialysis treatment of diabetes patients. The procedures are well established. However, many of these shunts create problems and have to be reexamined. The problems that arise include inflammation at the shunt site which must be treated with antibiotics, and stenosis, both within the shunt and downstream in the arteries. In the worst case, the shunt must be replaced for treatment to continue. This, however, can only be repeated once before the shunt site is no longer viable. This increases discomfort, inconvenience and possible danger to the dialysis patient.

METHODS

Several typical shunts were studied to determine whether flow disturbances within the shunt can give rise to these complications. Many studies have already demonstrated the importance of the hemodynamic factors in the pathogenesis of vascular disease. These factors include the pulsatility of flow, the elasticity of the vessel, the non-Newtonian flow behavior of blood, and, very importantly for shunts, the vessel geometry. In model studies, intimal changes have been observed in bends and bifurcations, regions of vessel constriction and vessel stenosis. In these regions, the flow changes abruptly and this contributes to arterial disease.

RESULTS AND DISCUSSION

We prepared several one-to-one, true-to-scale elastic silicon rubber models of different arteriovenous shunts. The shunt models were based on angiographic studies of dialysis patients at the University of Bologna. These models have a similar compliance to that of the human blood vessel. The flow was visualized in these models using a photoelasticity apparatus and a birefringent blood-like fluid. This method is suitable to analyze the spatial configuration of flow profiles, to differentiate laminar flow from disturbed flow, and to visualize flow separation, vortex formation and secondary flow.

It could be seen that arteriovenous shunts create disturbances that are not found under physiologically normal flow conditions. The X-formed AV shunt was shown to be very unsatisfactory, creating significant flow disturbances. High velocity fluctuations were found within the shunt. These could lead, for example, to aneurysm formation. A less

objectionable configuration would be an end-to-end AV shunt. This formation, however, creates other complications. For example, the hand does not get enough blood and parts of the hand lose feeling. The recommended shunt would be an end-to-side anastomosis. In this case, attention should be given to the placement geometry, so that additional flow disturbances are minimized. Several models as well as patient angiographic studies will be discussed.

SUMMARY

This haemodynamic investigation concerns the problems connected with the application to artificial kidney of the patient. The hemolysis-mechanical effects that arise include inflammation at the shunt site which must be treated with antibiotics, and stenosis, both within the shunt and downstream in the arteries. Several typical shunts were studied to determine whether flow disturbance within the shunt can give rise to these complications.

INTRODUCTION

The link between back pain and seated work has been attributed to the required flexed curvature of the lumbar spine (Wilder and Pope, 1996). The ligaments and muscles are the two most frequently proposed sources of low back pain. Given the association of back pain with seated spine postures we were driven to examine whether the flexion relaxation phenomenon occurred in seated postures which could load the passive structures, a potential source of pain. Flexion relaxation (FR) refers to a sudden onset of myoelectric silence in the erector spinae (ES) muscles of the back during standing full forward flexion (Floyd and Silver, 1955). While many studies have documented FR in standing postures, there have been few studies that have examined this phenomenon in seated spine postures.

METHODS

Surface EMG recordings were collected from the right and left thoracic (at the level of T9) and lumbar erector spinae (at the level of L3) on 22 subjects (11 male, 11 female). Lumbar flexion/extension angle was measured using a 3-Space ISOTRAK. Five trials each of standing full forward flexion and seated forward flexion (rounding of the lumbar spine to a “slouched” seated posture) were collected. The flexion-extension cycle was comprised of three different phases (Figure 1).

Figure 1: Lumbar flexion and EMG for one channel illustrating the three phases of the flexion-extension cycle.

Both the EMG and 3-Space signals were 6-point ensemble averaged based on events identified from the 3-Space data (Figure 1). FR was defined in standing flexion if the EMG values during the FR phase were within 1%MVC of the levels during upright standing and in seated flexion when the EMG values during the FR phase were at least 1%MVC less than the levels during upright sitting.

RESULTS

Approximately 80% of all subjects exhibited FR in all muscles during standing flexion. Twenty-one out of the twenty-two subjects tested exhibited FR in their thoracic erector spinae in sitting (Figure 2). However, the lumbar erector spinae muscle group remained at relatively constant activation levels regardless of seated posture. The lumbar spine was flexed on average to approximately 36% of maximum standing flexion during upright sitting and 52% of maximum flexion in the slumped posture. FR occurred during seated flexion at an average angle of 46.6% of maximum flexion. The average angle at which FR occurred in standing flexion was 84.1%.

Figure 2: Sitting EMG levels for subjects classified as exhibiting flexion relaxation

DISCUSSION

The most common theory about why FR occurs in standing flexion involves the passive tissues being stretched to a point where they can support the moment imposed on the low back (Kippers and Parker, 1984; Toussaint et al, 1995). FR occurs in seated flexion at a lumbar flexion angle that is much less than standing FR. This would appear to support the mechanical idea that FR is a response to the passive tissues being able to support the imposed moment, which would be less in seated flexion and thus the passive tissues would be capable of supporting the moment at a smaller lumbar angle. Since the myoelectric activity of the lumbar erector spinae did not increase and the thoracic activity decreased, it is likely that the passive tissues of the vertebral column were loaded to support the moment at L4/L5. Ligaments contain a large number of free nerve endings, which act as pain receptors and therefore could be a potential source of low back pain during seated work.

INTRODUCTION

It is not easy to insert a locking screw into the distal transverse hole for fixing the intramedullary nail and the broken human bone [1]. Generally, the X-ray image is used to detect the transverse holes [2]. But the X-ray exposure has very crucial problem for doctors and patients. In this paper, the central position of the transverse holes in the nail inserted into the pig femur was detected by the linear scanning using a focused ultrasound. Moreover, the interlocking accuracy of locking screw was investigated.

EXPERIMENTS

The pig femur specimen inserted with the nail was made. The nail is a brass bar with the diameter of 12mm and two holes of 5mm. Figure 1 shows the measurement apparatus for detecting a nail hole by a focused ultrasound. The specimen was immersed in the water at 36°C and the focused probe (Frequency:1MHz, Focal distance:70mm, Transducer diameter:13mm) was set on the water surface of 40mm apart from the intramedullary nail in conjunction with a target device (ACE Med.). The focused probe was moved linearly every 0.1mm toward the y-direction using a handle. The wave velocity through water was set at 1500m/s. The ultrasound was propagated toward the specimen, and then the probe position and the echo height were measured by the echo reflected from the nail surface. After determining the center of the nail hole, the locking screw was inserted into the pig femur specimen along a guide sheath.

RESULTS AND DISCUSSION

Figure 2 shows an example of the echo waveform reflected from the specimen. The marks of ①, ② and ③ indicate the echoes from the outside of femur, the inside of femur and the nail surface, respectively. It was found that the echo from the nail surface was able

to catch by the ultrasound. Figure 3 shows the relations between echo heights and measuring positions obtained by the echo ③ in Fig.2. The central position of the transverse nail hole was located at the largest echo height in Fig.3. The reason is that the distance between the focused probe and the top face of nail is the shortest propagation path of the sound wave, and the echo reflected from the top face of nail has the largest power. Moreover, the locking screw could insert into the transverse nail hole with a high accuracy.

SUMMARY

- (1) The central position of a transverse hole in the intramedullary nail inserted into the pig femur specimen can detect by the largest echo height position reflected from the nail surface.
- (2) The locking screw can insert into the hole center with a high accuracy using focused probe.

INTRODUCTION

Muscular dystrophy (MD) is a progressive disease affecting muscle function. In the upper limb, the proximal muscle groups are affected first, and the disease progresses toward the distal muscles. This results in individual having insufficient power to lift their arm against the force of gravity while still having a reasonable grasping capability.

The present study inquires: if movement in a planar workspace is still possible how does the disease affect hand trajectory when performing tasks in that workspace. Several researchers (Abend et al., 82; Flash and Hogan., 85; Soechting and Flanders, 91; Marasso, 81) have shown that in able-bodied subjects, point-to-point hand movements produce essentially straight-line hand paths and uni-modal velocity profile along the path. This is true for almost all point pairs and has been a strong argument for movement planning in terms of hand motion versus joint angles (Marasso, 81).

METHODS

Two male subjects were tested, one with Duchenne's type MD age 14 and the other with Becker's type MD age 19. Subjects were seated at a test table and were asked to reach for several targets, moving to each target and returning to the start position before moving on to the next target until all targets were acquired. Targets were fixed at 30, 60, 90, and 120 degrees attitudes (see Fig 1), at a distance of the length of a fully extended arm. An air bearing was used to "float" the arm so as to minimize friction. Motion of the arm was monitored with MacReflex kinematic data acquisition system.

Figure 1: From the starting position shown the subject reached for targets placed at each attitude 1/2 the distance of the subjects arm length

RESULTS AND DISCUSSION

Both subjects produced essentially straight hand paths, to and from the target and unimodal velocities as illustrated in Figure 2. Subjects tended to use large trunk rotations and tilt to assist them in projecting their hand throughout the workspace. It appears that transfer of momentum from the trunk to the arm may be a key component for compensating for muscular weakness in the arms.

Figure 2: Trajectory Kinematic profile for subject with Duchenne's type MD.

SUMMARY

Mechanisms of compensation are employed to enable the MD subjects tested to move their arms throughout a planar workspace. To the extent that conclusions can be derived from the two subjects tested, mechanisms of compensation were chosen in such a manner that maintains the hand trajectory characteristics similar to those reported in healthy individuals. The fact that the hand path and velocities are similar to healthy subjects supports the contention by Marasso (81) that planning for movement occurs in the hand-space.

INTRODUCTION

A fall onto an outstretched arm is often the cause of wrist, elbow and/or shoulder injuries (Loder and Mathew 1988), perhaps due to the initial large high-frequency component of reaction force between the arm and the ground, rather than the later and smaller lower-frequency component. Lumped-parameter model simulations of a fall onto an outstretched arm have predicted attenuation and delay of the peak impact force applied at the hand by the time it reaches the shoulder (Chiu and Robinovitch 1998). We tested the hypotheses that (a) the deflection of the shoulder occurred significantly after the early peak hand reaction force and (b) the rate of force transmission through the limb is a function of initial elbow angle at impact.

METHODS

A total of 40 subjects (20 young (mean [SD] age 25 [3] years; 20 older subjects: 70 [3] years, with equal gender representation) participated in the study. Subjects were seated in a rigid, high-backed, steel-framed chair with a 4 cm wide spine support designed to securely support the torso in the mid-sagittal plane, while permitting free motion of the scapulae. A ceiling-mounted, instrumented, padded, ballistic pendulum (3.5 Kg) impacted both stationary hands at 1.8 m/s at a location in front of the shoulder with elbow angles of 130, 150, 170 degrees (DeGoede et al. 2002). Three trials were conducted for each elbow angle. Kinematic data from markers located on the arm, forearm and torso were obtained at 300 Hz using an Optotrak® 3020 system, and from the bimanual pendulum force transducers at 1,800 Hz. We assumed that deflection of a kinematic marker is proportional to the force acting at that location. The mean (SD) latencies were found when the hand force and kinematic marker displacements (a) initially exceeded preset baseline rate thresholds ('start'), and then (b) first returned below threshold ('end') were found, along with the timing of the peak force applied to the hand. A repeated measure analysis of variance (rm-ANOVA) was used to test the hypotheses after calculating average latency times for each subject. Two-sided, post-hoc paired t-tests were performed to examine the relationships between initial elbow angle and deflection initiation times.

RESULTS AND DISCUSSION

The peak contact force occurred 7 ± 1 msec after initial contact and the impact impulse lasted a total of 18 ± 3 msec. Upper extremity location systematically affected the impact force propagation latency (rm-ANOVA, $p < 0.001$): (a) the elbow started to deflect as the contact force approached its maximum

Figure 1: Timing of the mean (SD denoted by error bars) initiation (left end of box) and termination (right end) deflections observed at different points along the arm

(start: 7 ± 2 msec; end: 35 ± 6 msec); (b) the shoulder deflected posteriorly just after the end of the impact force impulse (start: 30 ± 5 msec); (c) the torso first deflected at 44 ± 8 msec (Fig. 1). The initial elbow angle also affected the latencies (within-subject, rm-ANOVA $p < 0.001$). In the more extended arm configuration: (a) time-to-peak force and initiation of elbow rotation each increased by approximately 4 msec ($p < 0.001$); and (b) posterior deflections at the shoulder, torso and chair occurred earlier (8, 21, and 16 msec, respectively; $p < 0.001$). Short- (~40 ms) and long-loop reflexes (>80 ms) latencies are precluded from protecting wrist or elbow tissues in a fall, because significant additional delays (~100 msec) are required to increase muscle tension.

SUMMARY

The shoulder did not deflect until well after the impact force at the hand had returned to baseline levels. This validates lumped mass models suggesting that the initial impact force spike is principally due to arm inertial effects. Thus in a fall to the ground the peak force applied to a wrist should be independent of the contralateral wrist impact time.

THE STABILIZING EFFECT OF EXTERNAL ANKLE DEVICES WITH AND WITHOUT THE ADDITIONAL INFLUENCE OF A SHOE

Eric Eils, Simone Imberge, Lothar Thorwesten, Klaus Völker, Dieter Rosenbaum

Movement Analysis Lab, Orthopaedic Department, University Clinics Münster, Münster, Germany, eils@uni-muenster.de

INTRODUCTION

External ankle stabilizing devices (braces, tape) are commonly used for treatment, rehabilitation and prophylactic purposes in sports. There is evidence that the use of these devices reduce ankle sprains in high risk sporting activities like soccer or basketball (1). However, this is only valid for sports where an external device is used in combination with a shoe. Ankle sprains are also among the most common injuries in sports like dancing or gymnastics where no shoe is used (2, 3), and it remains unclear if the stabilizing effects of the brace/shoe complex is transferable to a situation without shoe. Therefore, the aim of the present investigation was to quantify the stabilizing effects of three external ankle devices tested with and without shoe to make recommendations for sports where shoes are not worn.

METHODS

25 healthy subjects participated in the study (26 ± 3 yrs, 178 ± 7 cm, 71 ± 10 kg). A mechanical fixture was developed to measure the mobility of the ankle joint complex in three planes with a standardized torque. Subjects lay supine with one leg fixed in the apparatus, the foot placed on a foot plate and the tibia fixed at two points. Rotation axes for plantar/dorsiflexion, inversion/eversion and internal/external rotation were aligned with the intermalleolar axis, the long axis of the foot on the level of the subtalar joint and the longitudinal axis of the tibia, respectively. To determine the individual torque, the leg was fixed without braces and rotated in each direction to the limits of comfort. The maximum torque for each direction was then used for all conditions and the rotational displacement were measured.

Three stabilizing devices (Semi-rigid-Aircast, Soft-Dynastab, Tape) were applied to the subject's leg by the same investigator. Condition with and without shoe were carried out by using two pairs of shoes where one was cut at the lateral and medial part to remove additional stability of the upper material. The order of the eight testing conditions was randomized. Three trials for each direction were measured and the individual means were calculated. Restriction of motion in relation to the no brace/no shoe condition was calculated for each direction. For statistical analysis a two way repeated measures ANOVA (shoe, external device) with the α -level set to 5% was used.

RESULTS

In the no brace/no shoe condition the following ranges of motion were determined: $42^\circ \pm 11^\circ$ inversion, $31^\circ \pm 13^\circ$ eversion, $47^\circ \pm 8^\circ$ plantar flexion, $35^\circ \pm 6^\circ$ dorsiflexion, and $35^\circ \pm 11^\circ$ internal rotation, and $39^\circ \pm 8^\circ$ external rotation. The corresponding mean torques were $6.2 \text{ Nm} \pm 3.2$ inversion, $7.1 \text{ Nm} \pm 3.1$ eversion, $9.7 \text{ Nm} \pm 4.7$ plantar flexion, $17.6 \text{ Nm} \pm 6.0$

dorsiflexion, $6.7 \text{ Nm} \pm 2.8$ internal rotation, and $6.1 \text{ Nm} \pm 3.0$ external rotation. The ANOVA revealed that both main effects (shoe, external device) were significant ($p < 0.01$) for all directions of motion and a significant interaction between shoe and external devices was found ($p < 0.01$) except for total rotation. Range of motion between shoe and no-shoe increased for all conditions and in all directions (Fig. 1). Tape and Aircast provided highest stability in all directions in combination with the shoe, but without shoe Tape and Dynastab showed best restriction of motion for most directions. Significant loss of stabilization between shoe and no-shoe ($p < 0.001$) was only found for the Aircast for inversion, eversion, plantar flexion and total rotation.

Fig. 1. Passive stability of each condition in five directions of motion (IV=inversion, EV=eversion, PF=plantar flexion, DF=dorsiflexion, Rot=total rotation) with and without shoe. The values are normalized to the no brace/no shoe condition (=100%). The size of the area in the spider web becomes smaller with a more pronounced stabilizing effect. ***= $p < 0.001$.

DISCUSSION

Although changes between shoe and no-shoe were minimal for Tape it may not be recommended for use in sports because it is well described that the stabilizing effect is lost after 20 minutes of exercise (4). The stirrup-design brace obtained a high degree of stability from the shoe and without shoe it showed less stability for most directions than the lace-on brace. Therefore, lace-on braces may be recommended to provide stability for sports like dancing or gymnastics.

A COMPARATIVE STUDY OF CFD AND MRI FOR PULSATILE FLOW IN A CAROTID BIFURCATION PHANTOM

S.Z. Zhao¹, X.Y. Xu¹, P. Papathanasopoulou², I. Marshall²

¹Department of Chem. Eng. and Chem. Tech., Imperial College, UK, s.zhao@ic.ac.uk

²Department of Medical and Radiological Sciences, Edinburgh University, Edinburgh, UK

INTRODUCTION

Local hemodynamics is considered to play an important role in the initiation and development of atherosclerosis (Ku et al., 1985). Flow quantification techniques such as magnetic resonance imaging are commonly used to study arterial hemodynamics. An alternative and complementary approach uses numerical simulations. A combined MR imaging and computational fluid dynamics (CFD) modelling study was carried out for pulsatile flow in a carotid bifurcation phantom. The aim of the study was to quantify differences in velocity and wall shear stress obtained from the two approaches. The geometry and inlet velocity images from MR scans were used as boundary conditions for CFD calculations of the complete flow field in the model, and CFD results were compared with the MR measurements. Wall shear stress (WSS) derived from direct MR velocity measurements was also compared with the CFD predictions.

METHODS

Scanning was carried out on a 1.5-T GE Signa scanner (GE Medical, Milwaukee) equipped with Echospeed gradients. An anthropomorphically realistic healthy human carotid bifurcation model was employed in the experiment. Velocity measurements were made using a retrospectively gated three-dimensional phase contrast gradient-echo sequence that generated velocity-encoded images for each component at 18 frames. Its parameters were TR/TE=25/7 ms, pixel size 0.5 mm and slice thickness 1mm.

Structured computational mesh for the carotid phantom was generated from the high-resolution MRI images after segmentation and smoothing (Long et al., 1998). A commercial package CFX4 was used to solve the Navier-Stokes equations governing the time-dependent flow. For the inlet boundary condition, the MR measurements at the entrance were mapped onto the computational grid at inlet. Time-varying flow ratio between two branches calculated from MR velocity images was used for outflow boundary conditions. Finally, the WSS vectors were calculated from direct MR measurements by a home developed software package (Köhler et al., 1999).

RESULTS AND DISCUSSION

Figure 1 shows MRI and CFD results in the mid-sinus. General features are the occurrence of highly skewed flow with slow velocities at the outer wall and high velocities at the flow divider wall in the bifurcation plane (R-L plane), as well as well-defined M-shaped profiles along the anterior-posterior axis (in A-P aspect). The agreement between MRI and CFD acquired velocities is generally good, given some uncertainties for low velocities due to 5% measurement error. WSSs predicted from CFD were

compared with those derived from MRI alone at peak and minimum flow phases. Reasonably good agreement was also achieved especially at the phase of minimum flow.

Figure1 Velocity profiles in the carotid sinus at peak (t1) and late systole (t2) (a) R-L (b) A-P

SUMMARY

Comparisons of computed and MRI measured velocity profiles in a carotid phantom under transient flow condition have shown good agreement for both well-behaved flow and disturbed flow, with difference in peak velocity less than 8%. We are currently comparing the MR derived WSS vectors with CFD predictions.

TORSIONAL FATIGUE OF CORTICAL BONE

P.O'Reilly¹, D. Taylor¹, T.C.Lee^{1,2}

¹Department of Mechanical and Manufacturing Engineering, Trinity College, Dublin 2, Ireland. ²Department of Anatomy, Royal College of Surgeons in Ireland, Dublin 2, Ireland.

INTRODUCTION

Fatigue tests on bone are usually conducted in tension and/or compression. Very little work has been carried out to date on torsional fatigue of bones or machined bone specimens. Torsional loading is of interest because it occurs in vivo and because bone being anisotropic, may be relatively poor at resisting longitudinal shear stresses. In this study the objectives were to construct a rig to deliver pure torsional loading; to compare fatigue test data in torsion and compression and to study the development of damage (cracking) in torsion.

METHODS

The rig was designed to convert the linear displacement of the actuator on an Instron servohydraulic testing machine into a rotational displacement of the bone; the load cell of the Instron was used to sense the load being applied to the bone. Ten chicken metatarsal bones were tested; the bones were gripped by having their ends encased in modelling plaster. The rig was also used to test bovine cortical bone samples of circular cross section (5mm gauge diameter). Sixteen samples were tested. Tests were carried out in load control at 3Hz with a stress ratio of 0.1. Failure was defined in terms of a fixed increase in amplitude, since catastrophic failure often did not occur, especially in the bovine specimens (see below). A Finite Element model was created to enable us to find the maximum stress in the bone during testing; this was validated using strain gauges. Fluoro-chelating dyes were used before and during testing to label damage (cracks) for later examination using optical and scanning-electron microscopy.

RESULTS AND DISCUSSION

Fig. 1 shows the stress range versus cycles to failure for the bovine samples and also for specimens taken from the same source which were tested in axial compression [3]. A similar plot exists comparing the torsional fatigue results for torsional fatigue on chicken metatarsal bones with previous data from compressive fatigue on chicken tibiae. The bovine bone was found to be plexiform structure [1] which greatly influenced the crack propagation. And this is evidenced in histology and electron microscopy photographs. Cracks in the chicken and bovine bone tended to grow to lengths of a several millimetres in a stable manner without causing catastrophic failure. Large amounts of creep[2] or plastic ratcheting were observed on the plots of position displacement for the bovine and chicken bone tests.

Figure 1: Fatigue test data for bovine compact bone specimens, tested in torsion and axial compression. The stress axis shows the maximum principal stress applied.

SUMMARY

Results showed that bone is much weaker when tested in cyclic torsion than in axial compression. Previous work has shown that bone is only slightly weaker in

STUDY OF BLOOD FLOW IN THE HUMAN FEMORAL ARTERY BY CFD

INTRODUCTION

The presence of atherosclerotic plaques has been shown to be associated with particular geometric features of arteries. This is believed to be mediated through local hemodynamic factors such as wall shear stress. Atherosclerotic disease of the superficial femoral artery (SFA) is common and is a major cause of peripheral vascular disease. The SFA is a curved and tortuous artery. We have previously reported that significant gender and anatomical site differences exist for SFA tortuosity and curvature. The present study was designed to examine the effects of femoral artery geometry on wall shear stress distributions with emphasis on clarifying the site-specific nature and gender difference for the incidence of arterial disease.

METHODS

The SFA was imaged by MRI in 18 normal subjects. Velocity and wall shear stress distribution in anatomically realistic models of human SFA were computed using the finite volume method. In order to investigate the effect of geometry alone, all simulations were carried out under the same flow conditions. To understand the influence of overall geometry on wall shear distributions, the lowest wall shear stress (LWSS) at each transverse grid plane was determined for the whole vessel segment. Two wall shear stress measures were then derived from the LWSS for each vessel: the time averaged LWSS and the minimum LWSS occurring in a cardiac cycle. To investigate regional differences of wall shear stress measurements in upper, mid and lower segments of SFA were compared.

RESULTS AND DISCUSSION

In all arteries features, such as highly spiral flow and spiral wall shear stress distribution when the artery enters the adductor canal (as shown in Figure 1), were seen. Particularly noteworthy was the complex secondary flow pattern which may include structures such as a single vortex, a double vortex and C-shaped vortex surrounded by two relatively thin layers developed within a single vessel. The region of artery in the adductor canal was exposed to the lowest shear stress in both men and women. This corresponds well with the strong predilection for atheroma formation at this site in at risk individuals. There was also significant difference in average LWSS and minimum LWSS between males and females (average LWSS: 1.84 ± 0.33 (male), 2.44 ± 0.34 (female), $p < 0.01$; minimum LWSS: 1.02 ± 0.42 (male), 1.79 ± 0.26 (female), $p < 0.001$) due to differences in vessel tortuosity. This study suggests that high vessel curvature and tortuosity result in localized sites of low average and minimum LWSS. Shear stress in SFA is also lower in men than women. These observations may explain

differences in the distribution of atheroma in SFA and the increased burden of peripheral vascular disease in men.

MODEL OF ACTIVE ANKLE-FOOT ORTHOSIS WITH SENSORS CONTROL

Slavyana Milusheva¹, Mihaela Kalaidjieva¹, Nikolay Zlatov², Yuli Toshev¹

¹Institute of Mechanics and Biomechanics, Bulgarian Academy of Sciences, Bulgaria, ytoshv@imbm.bas.bg

²Manufacturing Engineering Centre, University of Cardiff, United Kingdom

INTRODUCTION

Ankle-foot orthoses are used mainly in case of disability of neurological origin (cerebral palsy, stroke, spinal cord injury) or musculoskeletal origin (trauma, ageing). Due to the motor control disorder the observed result is usually abnormal ankle-foot position and forefoot or flatfoot initial ground contact during gait.

METHODS

The principles of active control could be illustrated using Fig.1. Using relatively hard orthosis footpad the system “foot-orthosis” could be determined as pseudo-rigid system. In this case active ankle-foot flexion (dorsiflexion) and extension could be realised using external drive force (electrical, pneumatic or hydraulic).

Figure 1: The vertical (index v) and the horizontal (index h) ground reactions of the right (index r) and left (index l) lower limbs during walking. F1r, F2r, F3r, F1l, F2l, F3l – extreme force values;

t1r, t2r, t3r, t1l, t2l, t3l – time parameters of the extreme force values; T1r, T1l - stance phases; T2r, T2l - swing phases; Td1, Td2 - double supports; Tr, Tl - step phases (stance + swing).

If we suppose that the left limb is abnormal, the control signals to realise suitable ankle flexion/extension must be: (a) In the moment T_{nl} (in the interval $t_{1r} - t_{3r}$) during the stance phase of the normal (right) limb, the first control signal must provoke ankle flexion of the abnormal (left) limb; (b) In the moment HSl (heel strike left) the second control signal must provoke ankle extension of the same left limb (abnormal); (c) In the moment TOr (toe off right) the third control signal must provoke drive switch-off in order to assure the stance phase of the abnormal (left) limb.

The sensors situation is as following: (a) The first sensor is situated under the front foot part of the normal limb (the right) and using adequate software generates control signal in the moment T_{nl} (ankle flexion of the abnormal limb); (b) The second sensor is situated under the rear orthosis part (left limb) and generates control signal in the moment HSl (ankle extension of the abnormal limb); (c) The third sensor - situated

under the toe of the normal limb (the right) generates control signal in the moment TOr (drive switch-off in order to assure the stance phase of the abnormal limb).

Two additional warning/training sensors (WTS) could be mounted on the orthosis to control the transversal (right/left) dynamic equilibrium.

RESULTS AND DISCUSSION

A scheme of our active ankle-foot orthosis (electrical drive) with branched metal splint is shown on Fig. 2. Both branches (positions 4 and 5) have supporting function. On the end of the rear branch (under the heel) is mounted a sensor (position 6) to generate a control signal in the moment of HSl.

Figure 2: Active orthosis model:

1 - buckle; 2 – metal splint; 3 – motor; 4 – rear branched metal splint; 5 – fore branched metal splint; 6 – sensor under the heel; 7 - polypropylene crust for the shank; 8 – belt; 9 – polypropylene crust for the foot.

Using CAD/CAM technology (SolidWorks) different models of the system “ankle-foot-orthosis” are developed (Fig.3). Three types of drives could be used – electrical, hydraulic and pneumatic. The final evaluation should be verify during the clinical experiments.

Figure 3: CAD/CAM model of active ankle-foot orthosis

SUMMARY

New approach for design of active orthoses is presented. One model is proposed and generated using CAD/CAM system.

INTRODUCTION

The adaptation of the growth plate in response to physical loading was investigated in previous studies with clinical intention of bone lengthening. About the effect of physical loading through exercise on the growth plate exists only limited information. There are occasional studies which had shown morphological adaptation (Nyska et al., 1995, Swissa-Sivan et al., 1989). Alterations of the mechanical properties and the relation between mechanical, morphological and biochemical components of the plate were not analysed.

The purpose of this study was to investigate the effects of physical loading on the load-relaxation behavior of the distal femoral growth plate in relation of morphological and biochemical alterations in a rat model.

METHODS

Ninety 3 weeks old female Sprague-Dawley rats were randomly assigned to a high trained exercise (n = 30), a low trained exercise (n = 30) and a non-active control group (n = 30). The exercise groups were trained in a running wheel with voluntary exercise. Food and water was available ad libitum and the rats housed on a 12 h/12 h light/dark cycle.

10 animals of each group were sacrificed after four weeks, the next ten after eight weeks and the last ten after 12 weeks. The rats were decapitated and the femurs were obtained. The bones of the left hindlimb were frozen at -80 °C until mechanical testing on a material test machine (Zwick Z2.5/TN 1S). The femur was placed horizontally so that the distal growth plate was loaded in shear direction. The load was applied by a c-formed stamp adapted individually to the form of the plate from lateral to medial to the whole epiphysis using a 100 N load cell. The specimens were preloaded with 0.5 N and three cycles of a load-relaxation series began. For each cycle a shear load of 6 N was first applied, followed by a relaxation at that strain for 500 s. Then load was reduced to 0.5 N for 500 s. After the three cycles there was a total relaxation for 15 min. Then the three load-relaxation cycles were repeated. We analysed the relaxation behavior after 3 s, 10 s, 60 s and 500 s from each cycle of the two tests series.

The distal epiphysis of the right femur was fixed in Bouin solution, decalcified in EDTA for four weeks and blocked in paraffin. After suitable enzymatic pretreatment immunohistochemical staining with antibodies directed against type I (Sigma, Germany), type II (Calbiochem, Germany), type X (Girkontaite et al., 1996), matrilin-3 (Klatt et al., 2000) and osteonectin (kindly provided by Dr. R. Timpl, Martinsried, Germany) was performed and detected with the AEC method.

RESULTS AND DISCUSSION

The load-relaxation test of the growth plate showed a typical curve for viscoelastic materials (Fig. 1). The plate of the high and low trained groups relaxed in average faster after all analysed periods of time and after 4, 8 and 12 weeks of exercise, whereas the low trained groups differed only slightly from the control groups. Alterations were detected in morphology and expression of matrix proteins.

Load-relaxation curve

Figure 1: Load-relaxation curve from the growth plate of a

high trained, low trained and control rat.

We conclude, that physical loading influences the relaxation behavior of the distal femoral growth plate of rats. The plates of the exercise groups are more permeable. The effects seem to depend on the dose of exercise.

SUMMARY

We investigated the effect of dose running exercise on the relaxation behavior, morphological and biochemical components of the distal femoral growth plate in a rat model. Adaptations are found in all analysed properties.

THE EXPRESSION OF ICAM-1 INDUCED BY SHEAR STRESS UPREGULATED VIA NFκB ACTIVATION

Yong-Ming Liu¹, Sylvaine Muller², Baohua WANG¹, Jing-Wei Yang¹, Hai-Lu Yang¹, Jing-Ping Ouyang¹

¹Department of Pathophysiology, Medical College of Wuhan University, Wuhan, China, hybs@public.wh.hb.cn

INTRODUCTION

Shear stress can influence the structure, function and metabolism of VECs.

Intercellular adhesion molecule-1 (ICAM-1) is an important adhesive molecules inter cell adhesion. The expression and distribution of ICAM-1 can be changed by shear stress. It has demonstrated that ICAM-1 is associated with rearrangement cytoskeleton F-actin. However, the exact mechanisms of signal transduction are not clear.

The nuclear transcription factor NFκB is the p50-p65 heterodimers existing in plasma. It is report that NFκB can be activated by shear stress, and then enters into the nucleus to bind the SSRE promoter region specifically.

The objective of this study is to test the hypothesis that shear stress leads to the upregulation of ICAM-1 via the activation of NFκB.

METHODS

Human umbilical veins endothelial cells (HUVECs) were cultured on the cover slides coated with 0.1% gelatin. The cells were divided into different groups randomly. Except the static control, the cells were exposed to 3 shear stresses (2 Pa, 1 Pa, 0.2 Pa) for 4h, 37°C. The tyrosine kinase inhibitor Herbimycin A (875 nM, 1h) and the Cytochalasin D (5 μM, 1h) which could depolymerize the F-actin of cytoskeleton were used before shear stress.

The changes of expression of ICAM-1 and NFκB were measured by immuno-histochemistry. Reverse Transcription-Polymerase Chain Reaction (RT-PCR) was used to detect the mRNA of ICAM-1.

RESULTS AND DISCUSSION

The expression of ICAM-1 mRNA induced by shear stress (2 Pa) is higher than static ($p < 0.01$). It is reduced after using the Herbimycin A ($p < 0.05$) and Cytochalasin D ($p < 0.01$) compared with shear stress.

As the same, the expression of NFκB is the most significant by 2 Pa shear stress ($p < 0.01$). After using the Herbimycin A and Cytochalasin D, NFκB expression decrease induced by shear stress.

Figure 1: The expression of ICAM-1 mRNA induced by different shear stress (** $p < 0.01$, vs static).

Figure 2: The expression of NFκB by different shear stress.

SUMMARY

Higher Shear stress can increase the expression of ICAM-1 and mRNA. The results suggest that the shear stress, mechanical signal, can be transmitted from the membrane to plasma by tyrosine kinase, and then transduce into nucleus as biochemical signals by cytoskeleton, upregulate the expression of ICAM-1 in molecular level via the activation of transcription factor NFκB.

PEAK HIP JOINT MOMENTS DURING WALKING AND JOGGING ARE CORRELATED WITH PROXIMAL FEMORAL BONE MINERAL DENSITY

Kirsten Moio¹, Dale R. Sumner^{1,2}, and Debra E. Hurwitz^{1,2}

¹Department of Anatomy, Rush Medical Center, Chicago IL 60612

INTRODUCTION

The relationship between mechanical loading and its effect on bone mass is well accepted (Wolff 1892). Many studies have investigated the effects of mechanical stimuli on bone mass and architecture. While it is clear that mechanical loading strongly influences bone mass and architecture it is unclear what relationship exists between bone mineral density (BMD) and joint loads as assessed during gait analysis. Since walking is one of the most frequently performed activities, and one of the most commonly prescribed types of exercise for building bone mass, its contribution to load history and bone mass needs to be identified. Given that the dynamic loads during jogging are greater than those during walking, the loads during jogging may be even more influential on bone mass. The purpose of this study was to test the hypothesis that peak hip joint moments during gait and jogging were correlated with proximal femoral BMD in a group of normal subjects.

METHODS

A group of 31 normal subjects (18 females, 13 males) with an age range of 30-49 yrs. underwent gait analysis using methods described previously (Andriacchi et al., 1997) and dual energy x-ray absorptiometry (DXA). Gait data were collected using an optoelectronic system (CFTC) and a multicomponent force plate (Bertec). The BMD of the proximal femora was determined by DXA (Lunar DPX-L). Univariate Pearson correlations were calculated to determine the individual effects of external joint moments, height and weight on BMD. A stepwise multiple regression model was used to determine how much of the BMD variability could be explained by height, weight, or joint moments during walking and jogging.

RESULTS AND DISCUSSION

During walking the internal and external rotation, and abduction moments had the strongest correlations with BMD (Table 1). For jogging, the adduction, flexion, and external rotation moments had the strongest correlations with BMD (Table 2).

The multiple regression analyses from the walking data indicated that higher correlations were found for the neck and greater trochanter when two moments entered the model. For instance, 40% of the variability in the greater trochanter BMD on the right side was explained by the combination of the external rotation (21%) and internal rotation (19%) moments. For the jogging data, the addition of other variables did not increase the correlations.

SUMMARY

Peak hip joint moments from walking and jogging were correlated with proximal femoral BMD. This suggests that joint loading during gait reflects the loading history, which presumably plays an important role in determining adult BMD.

NEUROMUSCULAR EXCITATION PATTERNS OF HUMAN POSTURE THROUGH AN OPTIMAL CONTROL APPROACH

Luciano Luporini Menegaldo^{1,2}, Agenor de Toledo Fleury^{1,2}, Hans Ingo Weber³

¹ Control Systems Group, São Paulo State Institute for Technological Research - IPT
P.O. Box 0141, CEP 01064-970, São Paulo-SP, Brazil, e-mail: lmeneg@ipt.br

INTRODUCTION

The present work deals with the numerical synthesis of open-loop neuromuscular activations patterns in human postural tasks, using a new biomechanical model and optimal control algorithms. Through the optimal control approach, neuromuscular activations can be estimated as the body performs a movement prescribed by initial and terminal kinematic conditions, at the same time that an objective function is minimized. In this case, the motor task does not have to be physically performed and measured, therefore, the biomechanical system can be virtually modified, by an orthopedic surgery for example, and the functional results evaluated accordingly. As the biomechanical posture model is a highly non-linear, multi-degree-of-freedom and unstable system, several analytical and numerical related problems should be found and addressed in other motor tasks associated to orthopedic surgery simulations.

METHODS

The multi-body model analyzed is a three-link inverted pendulum representing the human body segments of the shank, thigh and HAT (head, arms and trunk), as shown in Menegaldo (2001). This model is driven by 10 muscular actuators, expressed by nondimensional, 2nd order, non-linear equations of activation and contraction dynamics. Musculo-tendon geometry was parameterized through least-squares regression equations using data from a musculoskeletal modeling software (Musculographics Inc., 1997). The optimal control algorithms were developed and implemented based on the Polak's Consistent Approximation Theory framework by Schwartz (Polak, 1997; Schwartz and Polak, 1996). This method is based on a Runge-Kutta discretization of system dynamics, and over the same mesh, control vectors are represented in a spline-coefficient functional subspace. This leads to a very precise control representation. For testing of the algorithms behaviour, the postural task has been the same for all simulations, with the knee initially flexed by an angle $\pi/6$ and trunk kept upright and all muscle forces initially zero. Endpoint constraints have been imposed null to every angle and angular velocity at the final time, except for tolerances.

RESULTS AND DISCUSSION

Simulation results for kinematics and muscle excitation (control), activation and force are shown for two fixed simulation final times. Physiologically feasible patterns of muscle activations have been obtained.

Due to the dynamical characteristics of the problem, several numerical difficulties have arisen, and the numerical

experiments performed suggest the need of careful estimation of the initial control guess, a gradual charge of constraints and an appropriate choice of the optimization tolerances.

SUMMARY

This work shows a biomechanical model of human posture, comprising 10 equivalent musculotendon actuators and three links (shank, thigh and HAT - Head, Arms and Trunk), and the use of optimal control techniques to generate open-loop raising-up movements from a squatting position. The optimal control algorithms are based on the Consistent Approximations Theory (Schwartz and Polak, 1996), where the continuous non-linear dynamics is represented in a discrete space by means of a Runge-Kutta integration and the control signals in a spline-coefficient functional space. The adopted numerical methodology guarantees a fine precision on the control representation, using a control mesh as fine as the integration mesh. Due to the highly non-linear and unstable nature of posture dynamics, specific strategies must be used to achieve numerical algorithm convergence. Results for muscular excitations and angular displacements are shown for two simulation final times, and excitation patterns obtained through numerical simulations are discussed.

⁽²⁾ Hôpital des Enfants, Département d'Orthopédie, Toulouse, France.

INTRODUCTION

Rotational abnormalities of lower limbs are the most frequent causes of examinations in paediatric orthopaedics. The goal of this study is to find the modifications of gait kinematic and dynamic parameters due to the presence of these abnormalities and to research what could be their consequences on joint behavior in adult life.

MATERIAL AND METHOD

Children have been classified in three groups, without sex differentiation :

	RG	ITT	ETT
N	12	12	12
Age (years)	8.3	10.1	10.5
(sd)	(2.9)	(2.1)	(2.7)
Tibial torsion (°)	20	8.1	42.7
(sd)	(4.1)	(4.17)	(10.6)

Table 1: RG=reference group, ITT=insufficiency external tibial torsion group (in-toeing gait), ETT=exagereted external tibial torsion group (out-toeing gait).

Measurements performed were :

- ground reaction forces Fz and Fy (force-plate INCA 44, Captels, Montpellier, France) on a 16 meters long walkway, 3 records were performed for each foot;

- lower limbs motion: hip flexion/extension and adduction/abduction, knee flexion/extension, ankle dorsal flexion and plantar flexion, foot rotation (ELITE opto-electronic system, BTS, Milan, Italy) on the same walkway, 10 records were performed for each leg.

RESULTS

For the vertical component force Fz a significant difference was found only for ITT group, in Fz1 (heel strike) and Fz2 (midstance) components, Fz1 was 15% greater than reference group and Fz2 was reduced of 18%.

Lower limbs motion capture has shown that hip extension and adduction were significantly reduced ($p<0.05$) for the two groups of respectively 20 and 30%. Knee flexion was never modified. For ITT group, since heel strike and during all the stance phase, foot position was internal; during the swing phase an internal movement appear in opposite to the reference group for which the rotation at this time is 30° external sens. For ETT group the amplitude of this rotation was 11° in more. For ankle

flexion, a significant 25% reduction was found for the maximum of plantar flexion in propulsive phase for the two groups ITT and ETT.

DISCUSSION

A very little number of biomechanical works have been found about lower limbs rotationnal abnormalities. Some experimental studies on cadavers like these of Grijalvo and Laville (1) have shown an increasing of stress in the one side patello-femoral contact due to the torsional effect in knee given by rotational abnormality. In 1995, Liu (2) measured a decreasing of the three components of ground reaction force in children with in-toeing walking. We found in opposite, in comparison with reference group, a vertical reception force (Fz1) more important, a Fz2 component less important and no statistical difference for Fz3. In our study, Fy2 was greater than reference group. To our knowledge, not any kinematic studies exist about gait with rotational abnormalities of children. In the clinical field, Turner (3) et Yagi (4) in 1994, in a radiological study in adults, have shown that a relation exists between tibial torsion and knee pathologies. So, the increasing of fore-aft propulsion force (Fy2) and the internal or external position of foot which creates a torque around tibial axis can be on a mechanical point of view the cause of stress increasing in patello-femoral contact and so can be the origin of knee pathologies.

CONCLUSION

External and internal tibial torsion modifie gait kinematic and dynamic parameters. The results of this study are in agreement with experimental works and it seems that these results prove the biomechanical origin of articular cartilage damage.

³ Ph.D. in Physical Education at UFRGS

INTRODUCTION

There is a disparity among scientific results concerning the corporal segments' position in the maintenance of standing position when wearing shoes. Opila et al. (1988) and Lee et al. (2001) found changes in the knee and in the ankle of the evaluated subjects either standing and walking. On the other hand, Franklin et al. (1995) did not find changes in the knee joint with the increase of the heel height. In pursuit of additional information that may contribute with the researchers of this area, this research investigates the changes in the position of the head, shoulder, hips, knee, and ankle corporal segments in the sagittal plane in barefoot individuals, in individuals wearing high-heeled shoes, and in the ones wearing running shoes.

METHODS

Six female individuals were evaluated, with mean age, height, and weight of 23,17 years old ($\pm 6,83$), 160,17 cm ($\pm 5,83$), and 54,02 kg ($\pm 2,98$), respectively.

Adhesive markers measuring 1 cm of diameter were fixed on five anatomical points (external auditory meatus, acromioclavicular joint, center of femur's greater trochanter, femoral epicondyle, and lateral malleolus). A sixth marker was fixed in the leg, 5 cm above lateral malleolus. In this point, a reference vertical straight line was drawn. All the five points were evaluated in relation to that vertical straight line in the three conditions proposed in this study: 1) barefoot; 2) wearing running shoes (with a 2,5 cm-height sole); and 3) wearing high-heeled shoes (8 cm). From that straight line, it were established three levels forward and three levels backward (each level is 1,8 cm in height) that would permit to verify the position of the anatomical points (postural alignment) in the sagittal plane.

The subjects' posture was filmed (Sony DSR PD 150 digital camera) during 15 seconds, with a sampling rate of 30Hz in each condition. The first 5 seconds of images were eliminated,

and it was analyzed one image per second, during the next 10 seconds.

RESULTS AND DISCUSSION

The results of the statistical tests (χ^2 and Fisher) showed that the localization of the anatomical points of external auditory meatus (head), acromioclavicular joint (shoulder), and femur's greater trochanter (hips) stay in levels closer to the reference straight line in the high- heeled condition when compared to the barefoot situation ($p < 0,05$). In the femoral epicondyle's (knee) position, there were significant statistical variances in different levels in the three conditions of the study ($p < 0,05$). Similar results were found in previous studies (Opila et al., 1988; Lee et al., 2001; Franklin et al., 1995).

CONCLUSION

There are changes in the position of anatomical points (postural alignment) in standing position, wearing high-heeled shoes, comparatively to the barefoot condition.

There are variances of the femoral epicondyle's position (knee), which has placed itself in different levels, varying in the barefoot, running shoes, and high-heeled shoes conditions.

THE RESISTANCE OF A KNEE JOINT IN CHILDREN WITH SPASTICITY

M.K. Lebieadowska and J.R. Fisk

Southern Illinois University, School of Medicine, Springfield, Illinois, USA, mlebieadowska@siu.edu

INTRODUCTION

Spasticity coexists with many neurological disorders, including cerebral palsy. The resistance of a joint in spasticity may be increased as a result of velocity (Lance, 1980) or position (Powers et al 1988) dependent on stretch reflexes and/or contractures. The resistance of a limb is evaluated with subjective clinical scales (Ashworth, Tardie). The application of complex torque devices to quantify spasticity in clinical settings is limited. The hand-held force transducer was used to identify the passive stiffness (Stein et al 1996) and rigidity (Prochazka et al. 1997) in patients. The aim of this study was to determine whether or not the resistance of a knee joint can be measured with the hand-held force transducer and electrogoniometer in children with spasticity.

METHODS

We evaluated 20 able-bodied children and 18 children with spasticity related to cerebral palsy. A shank of a child was extended and then flexed. The pulling torque was measured with a hand-held force transducer as a function of the knee angle which was measured with an electrogoniometer (Biometrics, Ltd.). The knee motion, force, and EMG activity of knee muscles were collected at three velocities. Analog signals were digitized at 333 Hz (Axoscope, Axon Instruments, Inc.). The velocity and acceleration were determined by differentiating the motion signal (MATLAB, MathWorks Inc.). The Torque-Angle ($T_q-\alpha$) functions describing the resistance of a joint were determined for each velocity. The torque due to the pathological changes T_{qa} was calculated as a result of the subtraction of mass (m), inertia (I), and viscoelastic properties of a joint (K , B) from the overall torque (Fig.1):

Figure 1 The components of the torque used to move the limb segment with velocity (α') and acceleration (α'').

$T_{qa} = T_q - (I \alpha'' + B \alpha' + mgr \sin(\alpha - 1.58) + K(\alpha - \alpha_0))$
Mass, inertia and passive viscoelastic properties were estimated from the anthropometric measures (Winter, 1990, Lebieadowska and Fisk, 1999). The slope of a $T_q-\alpha$ function at the initial position K_0 , the work done to overcome the torque T_{qa} and the activation of knee muscles were

calculated and the regression equations between velocity of pull were established (Statistica, StatSoft Ltd.).

RESULTS AND DISCUSSION

During knee flexion and extension, the slope K_0 of the $T_q-\alpha$ function was slightly higher in patients, but the increase related to velocity α' was similar in able-bodied children ($K_0 = 0.127 + 0.23\alpha'$, $r = 0.8$, flexion) and in patients ($K_0 = 0.08 + 0.24\alpha'$, $r = 0.58$, flexion). The work W_a done by the examiner to overcome the changes induced by spasticity increased much more rapidly in patients ($W_a = 0.012 + 0.0091\alpha'$, $r = 0.48$, flexion) than in able-bodied children ($W_a = 0.0026 + 0.0058\alpha'$, $r = 0.37$, flexion). The activation A of rectus femoris ($A = 2.56 + 1.49\alpha'$, $r = 0.42$, flexion) and hamstring ($A = 2.8 + 1.27\alpha'$, $r = 0.23$, flexion) muscles increased with the velocity of motion in patients, but not in able-bodied children. A similar increase of slope K_0 and a more rapid increase of work W_a in patients than in able-bodied children suggest that W_a better discriminates patients. The different patterns of muscle activation were identified in our patients. The differentiation between the neural (muscle activation) and mechanical (contractures) origin of the increased resistance was possible in the individual patients. The study showed that the velocity-dependent resistance of a knee joint can be measured with the aid of a hand-held transducer and an electrogoniometer in a pediatric population. The combination of mechanical and EMG parameters should be used to discriminate patients v. able-bodied subjects and to determine the origin of changes.

SUMMARY

The resistance of a knee joint was measured in 20 healthy children and in 18 children with cerebral palsy. It was concluded that the velocity dependence of stretch reflexes can be measured with the aid of a simple hand-held force transducer and an electrogoniometer attached to a joint. The method helps to differentiate between neural and mechanical origin of changes and different types of muscle activation in patients.

EXPERIMENTAL ANALYSIS OF LYMPHATIC CELLS MOTION UNDER TOPOGRAPHICAL CONTROL

INTRODUCTION

The migration of malignant cells starts with the invasion of blood and lymphatic vessels, which then move, through the vessel walls, into the adjacent tissue. This process that is carried out by lymphatic cells is highly unpredictable. They frequently continue moving indefinitely until death, or else they regress (Trinkaus, 1984).

It may be proposed that an understanding of the motility of these cells is a key step in further analysis of metastasis formation. Interestingly the shape of the cells seems to be important. Their rigidity or deformability, which is related to their cytoskeleton, is a significant factor in determining the capability of motion.

To control metastasis spreading, quantitative information on the *in vivo* migration process must be acquired. Therefore, it is necessary to recreate, *in vitro*, the complex nature of the migration process through the vessel walls carried out by malignant and normal cells.

METHODS

Cell type and culture

Two human lymphatic cells were involved in this study: normal *Peripheral Blood T Lymphatic* cell (PBTl) and a malignant cell, *T lymphoma HUT 78* (HUT). Briefly, PBTls were pre-activated with PMA (phorbol-myristate-acetate) (Sigma, ST. Louis, MO, USA). HUT cells line 78 (ATCC, Manassas, VA, USA) were used non-treated or pre-activated by PMA in the same concentration for sixty minutes, as described in by Volkov *et al.* (1998).

HUT 78 or activated PBTl ($10\text{-}20 \times 10^3/\text{well}$) were added on top of a plane bioglass coated with monoclonal antibodies (mAb) to α -chain of LFA-1. This mAb was able to induce cytoskeletal rearrangement in T cells (*polarization*). Cell motility experiments were performed using a bioglass plane or micropatterned (Prina Mello *et al.*, 2001).

RESULTS AND DISCUSSION

Migration of T cell on unconstrained ECM-coated surface

Migration of single-cell was measured, quantitatively, by using a "persistent random walk" method (Othmer, *et al.*, (1988)). A series of tests was carried out to measure the cell-centroid variation on a population of activated cells.

The cells were investigated on unconstrained surface for a hour. Means and standard errors for the motile fraction cells are summarised in Table 1.

TABLE 1. Average results of HUT 78 and PBTl on treated plane surface, under LFA-1 and PMA-LFA-1. (Polarisation = 20 minutes).

Cell type	Receptor	Single Cell		Cells
		Cells tracked	Cell velocity ($\mu\text{m}/\text{minute}$)	% Cell Motile
PBTl	PMA,LFA-1	20 ($n=13$)	5.667 ± 2.243	74.9 ± 10.3
HUT 78	LFA-1	20 ($n=13$)	3.763 ± 1.331	60.4 ± 7.9

Migration of T cell on constrained ECM-coated surface

Quantitative cell migration measurements were carried out to compare HUTs and PBTls when under unidirectional constraint. Cells were activated inside the channel in order to confine their migration. Results are shown in Table 2.

TABLE 2. HUT 78 and PBTl on micropatterned surface.

Cell type	Receptor	Cell tracked	Single Cell	Cells
			Cell velocity ($\mu\text{m}/\text{minute}$)	% Cell Motile
PBTl	PMA,LFA-1	15 ($n=10$)	1.603 ± 0.702	65.2 ± 15.3
HUT 78	LFA-1	15 ($n=10$)	0.560 ± 0.260	72.4 ± 21.3

Experimental distributions of cell speed were following a normal distribution curve, see Fig. 1.

FIGURE 1. Cell speed distributions on micropatterned substrate. HUTs speed distribution (continuous line), and PBTls (dashed). HUTs speed mean $X=0.457 \mu\text{m}/\text{min}$; PBTl mean $X=1.266 \mu\text{m}/\text{min}$.

SUMMARY

A quantitative *in vitro* analysis for cell migration was carried out to observe, and interpret, the *in vivo* response of some T lymphatic cell types to inflammatory process. The difference in migration between PBTls and the HUTs is evident from the results shown. These results highlight a slower dynamic response of the HUTs in comparison to the PBTls on both the two surfaces. Under constrained ECM, the PBTls had a shorter persistence time compared to the HUTs due to their smaller size. PBTls changed their direction more frequently than HUTs, when following the channel. Therefore, it seems that surface topography can discriminate the migration of these two cells, this may prove useful in identifying normal from malignant T cells.

ON THE USE OF 3D MRI VELOCITY MEASUREMENTS FOR COMPUTATIONAL FLOW SIMULATIONS

INTRODUCTION

Magnetic Resonance Imaging (MRI) allows for geometry as well as velocity measurements. This aspect is highly interesting since it provides hemodynamic data (such as wall shear stress) that are of big importance related to the prediction and diagnosis of atherosclerosis.

A drawback for MRI hemodynamic diagnosis is the long acquisition time required and the cost of an MRI session. The coupling of MRI acquisition with computational fluid dynamics (CFD) allows to calculate the velocity profiles when MRI data is not present due to lack of scan time. The combined technique allows the number of scans to be reduced to a set of geometrical scans and a limited number of additional velocity scans, equal to the number of in- and outflow sections contained in the model.

This study aimed to quantify the reliability of MRI velocity scans, and to prescribe the best way of implementing the measured velocity data in the CFD tool.

METHODS

Figure 1a shows the set-up used in this study. It consists of a MRI version of a UHDC Flow Pump Shelley (Numatics 225-3728 24VDC 6.0 Watts, Shelley Limited, London Ontario, Canada), a rigid u-tube manufactured out of agar gel (for good MRI-contrast; internal diameter 8 mm, bend radius 25 mm) and an ultrasonic flow probe for flow rate measurements (HT207 Transonic Flowmeters; Transonic, Ithaca, New York, USA). Steady ($Re=220, 267$ and 882) and unsteady (Dean Number = $66.1, 77.1$ and 191 , Womersley Number = 11) flows were set. An extra inflow tube was introduced for full development of the flow profile.

Calculations with uniform or parabolic inlet flow profiles were compared to calculations with profiles obtained from 3D MRI velocity measurements.

RESULTS AND DISCUSSION

Figure 1 (b-d) shows the secondary flow for simulations with different inflow boundary conditions in the second steady case. Figure 2 (e) shows the measured secondary flow. All simulations compare very well to the measured one, which implies reliability of the MRI measurements (maximal errors around 10% for axial velocities). The simulations using MRI measurements seem to compare better to the MRI measurements. The explanation for this observation can be

Figure 1: a. Set-up; b-d vertical velocity profiles in the tube at 120 degrees through the bend, using as inflow boundary conditions: b. Uniform inflow; c. Parabolic inlet; d. MR measurements as inlet BC; e. Velocity profile at 120 degrees as measured by MR. WHITE=3mm/s, BLACK=-3mm/s.

found in the fact that the computational model uses the accurate geometry specifications provided. Furthermore we must take into account that the phantom is included in a flow circuit applying a theoretically specified flow. In reality, the geometry and (more probably) the flow profile is imperfect, changing the flow in a way detectable by MRI. This means that setting a disturbed flow as boundary condition (measured by MRI), will result in a different flow profile, which is closer to the real profile. This observation denotes clearly the advantage of using scaled MRI velocity data as inflow boundary condition.

If the velocity measurements are not corrected for PVE, the unfiltered errors will compromise the convergence of the simulation. If no scaling is applied to the MRI measured velocities, the flow rate will be incorrect. This seriously influences the hemodynamic parameters.

SUMMARY

When corrected for the partial volume effect and scaled to match the flow rate, the use of MRI velocity measurements as boundary condition is preferred above uniform, parabolic or fully developed flow profiles based on the flow rate.

FOREFOOT STRUCTURAL PREDICTORS OF PLANTAR PRESSURES DURING WALKING IN PEOPLE WITH DIABETES AND PERIPHERAL NEUROPATHY

Michael J. Mueller¹, Mary Hastings¹, Paul K. Commean², Kirk Smith², Thomas K Pilgram², Douglas Robertson³, and Jeffrey Johnson⁴

¹Program in Physical Therapy, Washington University School of Medicine, St. Louis, MO, USA, muellermi@msnotes.wustl.edu

²Electronic Radiology Laboratory, Mallinckrodt Institute of Radiology, ⁴Department of Orthopaedic Surgery, Washington University School of Medicine, St. Louis, MO, USA, ³Radiology Department, University of Pittsburgh Health Systems, Pittsburgh, PA

INTRODUCTION

Structural and functional factors have been shown to predict approximately 50% of the variance of peak plantar pressures (PPP) at the hallux and first metatarsal head during walking in asymptomatic subjects (Morag and Cavanagh, 1999). High PPP during walking in people with diabetes (DM) and peripheral neuropathy can cause skin breakdown. The objective of this study was to determine the ability of selected measures of foot structure and function to predict regional PPP at the great toe and the five metatarsal heads during walking in people with diabetes mellitus (DM) and peripheral neuropathy.

METHODS

Twenty people with DM and peripheral neuropathy (mean age 55 ± 9 years, 6 female, 14 male, BMI = 33 ± 8 , duration of DM = 21 ± 11 years) were tested. Measures of foot structure were taken from 3-dimensional images constructed from spiral x-ray computed tomography (SXCT) with established accuracy and included metatarsal phalangeal angle (hammer toe), soft tissue thickness under each metatarsal head, hallux valgus, forefoot arthropathy, Morton's Index, and calcaneal angle (Smith, et al., 2001). Soft tissue stiffness under the metatarsal head was measured with an indenter device. Ankle dorsiflexion range of motion (DFROM) was measured with a goniometer. Toe out angle was measured during walking using ink and the moleskin method. PPP data were recorded during barefoot walking and during SXCT data acquisition using the F-Scan system (Software v.421, Tekscan, Boston, MA). PPP recorded during walking were registered with metatarsal head location using data from SXCT. Hierarchical multiple regression analysis was used to predict regional peak plantar pressures at the great toe and metatarsal heads from selected structural and walking variables.

RESULTS AND DISCUSSION

Hammer toe deformity was the single most important variable, accounting for 19-45% of the PPP variance at 5 of the 6 forefoot locations. Combinations of structural and walking variables accounted for 47-71% of the variance. Table 1 contains the significant predictors of PPP at each of the 6 locations on the foot in their order of entry into the hierarchical multiple regression equation.

Table 1: Significant Predictors of Regional PPP

Region	Predictor	r	R ² *	p*
Great Toe	Hammer Toe (1)	-.67	.45	.001
	Subject Weight	.21	.56	.001
Met Head 1	Hallux Valgus	.45	.21	.045
	Morton's Index	.63	.41	.011
	Subject Weight	.29	.47	.014
Met Head 2	Hammer toe (2)	.59	.35	.006
	Soft tissue thick	-.50	.53	.002
	Toe out angle	-.15	.67	<.001
	Subject Weight	.35	.71	.001

	Toe out angle	-.07	.53	.019
Met Head 5	Hammer Toe (5)	.64	.41	.002
	Morton's Index	.38	.50	.003
	Toe out angle	-.14	.55	.004

*overall model, Met=Metatarsal,

SUMMARY

Of the variables studied, hammer toe deformity was the most important single variable to predict forefoot PPP in people with DM and peripheral neuropathy. These results, coupled with clinical studies linking hammer toe deformity to plantar ulcers, highlight the importance of this foot deformity for its contribution to PPP and forefoot skin breakdown. In addition to hammertoe deformity, soft tissue thickness and soft tissue stiffness under the metatarsal heads were important for predicting PPP during walking. These variables should be included in computational models to predict plantar stresses to the forefoot and to devise interventions (i.e., orthotic devices or surgery) to minimize the stress.

RELATION BETWEEN KNEE RANGE OF MOTION MEASURED PASSIVELY AND DURING GAIT IN ANTERIOR CRUCIATE LIGAMENT DEFICIENT AND RECONSTRUCTED INDIVIDUALS

John A. Grant¹, Ronald F. Zernicke² and Nicholas G.H. Mohtadi¹

¹Sport Medicine Centre and ²Human Performance Lab

Faculty of Kinesiology, University of Calgary, Calgary, Alberta, Canada, grantja@ucalgary.ca

INTRODUCTION

Gait adaptations are well documented in both anterior cruciate ligament deficient (ACLD) and ACL reconstructed (ACLR) patients and have been related to quadriceps avoidance (Berchuck et al, 1990) or hamstrings facilitation (Beard et al., 1996). While functional gait assessment of a patient's rehabilitation progress may be ideal, it is not generally used in a standard clinical rehabilitation setting. It would, therefore, be important to know if measures that can quickly and reliably be performed in the clinic are associated with functional performance. The purpose of this study was to determine the level of association between clinical goniometric measures of knee range of motion (ROM) and ROM during gait in ACLD and ACLR patients.

METHODS

Thirty-two consecutive patients (17 males and 15 females) booked for ACL reconstruction with a bone-patellar tendon-bone graft at a university sport medicine clinic were invited to enroll. Patients (16-59 yr) were undergoing their first ACL reconstruction. Eighteen right knees and 14 left knees were reconstructed. Worker's Compensation patients and elite athletes were excluded.

Patients underwent assessments 1 wk before and 12 wk after surgery. All patients followed a standardized rehabilitation program in the first 3 post-operative months. ROM exercises started on post-operative day 1 and patients were discharged from hospital the day of surgery with instructions for weight bearing as tolerated.

Patients were first measured for passive knee extension ROM while resting in a prone position with the knee and leg hanging pendant from the end of the exam table. Knee flexion was measured with the patient in supine position. A strap was placed around the ankle, and the patient was instructed to pull the foot towards the gluteal region as far as was comfortable. The included angle between the thigh and the leg was measured with a standard plastic goniometer (each arm was 31.5cm).

Joint markers were affixed to the greater trochanter, lateral femoral condyle, and lateral malleolus of each lower extremity. Sagittal plane video data were collected with a Sony® digital video camera at 30 Hz. The shutter speed was set to 1/3 ms. Patients walked barefoot to eliminate the variation due to shoe wear. Patients practiced walking through the field of view three times before three trials per limb were recorded. Patients walked at a self-selected pace.

Digital video data were digitized using HU-M-AN® software. ROM data were smoothed using a Butterworth filter (cut-off frequency of 5Hz). Maximal flexion and extension values for

each trial were extracted. The average flexion and extension values for the three trials were used for analysis.

Range of motion data were analyzed using Stata 6.0 (Stata Corp., College Station, Texas). Pearson Product Moment Correlations were calculated to determine the strength of the association between passive knee ROM and knee ROM during gait. Correlations were calculated separately for the surgical limb, the non-surgical limb and for the difference between the non-surgical and surgical limbs (NS-S). Correlations were determined for both ACLD and ACLR conditions.

RESULTS

Table 1: Correlation (r) between passive and gait ROM

Comparison	r	n
Pre-Op Extension, Surgical Limb	0.17	32
Pre-Op Extension, Non-Surgical Limb	-0.25	32
Pre-Op Flexion, Surgical Limb	0.32	30*
Pre-Op Flexion, Non-Surgical Limb	0.06	28*
Pre-Op Extension Difference (NS-S)	0.08	32
Pre-Op Flexion Difference (NS-S)	0.35	30*
12 Week Extension, Surgical Limb	0.13	32
12 Week Extension, Non-Surgical Limb	0.37	32
12 Week Flexion, Surgical Limb	0.40	29*
12 Week Flexion, Non-Surgical Limb	0.28	29*
12 Week Extension Difference (NS-S)	0.16	32
12 Week Flexion Difference (NS-S)	0.15	30*

* Missing flexion data; "n" indicates number per group

DISCUSSION

The results of this preliminary study showed that there was little-to-moderate association between maximal knee flexion/extension and that demonstrated during gait in ACLD and ACLR patients. Previous studies showed that ACL-compromised individuals tended to flex more than controls throughout the stance phase of gait (Beard et al., 1996; DeVita et al., 1997). That may have been due to neuromuscular adaptations that reduced anterior tibial translation near full extension rather than actual limitations in knee ROM and those adaptations may have, in part, explained the lack of association shown in the present study.

THE EFFECT OF SPEED ON THE DETERMINISTIC ORIGIN OF THE VARIABILITY PRESENT DURING HUMAN OF LOCOMOTION

Scott M. Keenan¹ and Nicholas Stergiou¹

¹HPER Biomechanics Lab, University of Nebraska at Omaha, Omaha, NE, USA
Email: nstergiou@mail.unomaha.edu Web: www.unocoe.unomaha.edu/hper.htm

INTRODUCTION

Slower speeds have shown to lead to increased variability during walking (Winter, 1983). That was also found to be true with neuropathic patients (Dingwell et al., 2000). However, Dynamical Systems Theory (DST) predicts that the least amount of variability (a highly stable state) will be present at a self-selected pace. When the system is perturbed, then variability increases. Based on DST, variability in locomotion can then be modeled as a parabola. This model has also been supported by energy expenditure data. Dingwell et al., (2000), using a surrogate data technique, have shown that variability in human locomotion is not the result of noise in the system, but it has deterministic origin. The purpose of this study was to expand on the above Dingwell et al work and examine the effect of speed on the deterministic origin of locomotion. We hypothesized that changes in speed may eventually introduce sufficient noise in the system that can mask the deterministic origin of the variability present during human locomotion.

PROCEDURES

Twenty subjects (range: 19-35 yr) attended 5 test sessions on 5 different days. On the first day, the subjects walked on a treadmill to establish a comfortable self-selected pace. This pace was used as the baseline speed for subsequent testing. Following this procedure, the subjects were required to walk for 5 minutes at 5 different speeds: baseline, 10% and 20% faster, and 10% and 20% slower. The same procedure was used for running. A quartz shear piezoelectric accelerometer (PCB Piezotronics) was attached to subjects' distal anteromedial aspect of the right tibia with a tight elastic wrap. The time series from the accelerometer data sampled (180 Hz) were surrogated using a phase randomization technique (Theiler et al. 1992). Phase randomized surrogates of the time series were generated by computing Fourier transforms (FFT) of the original data, randomizing the phase spectra, and computing inverse FFTs. Surrogation removes the deterministic structure from the original data sets, generating a random equivalent with the same mean, variance, and power

spectra as the originals. Subsequently, Lyapunov Exponent (LyE) values were calculated from both the original and the surrogate counterparts and statistically compared. If significant differences are found between the two data sets, then the original is not a randomly derived data set. The LyE for both sets were calculated using the Chaos Data Analyzer software (Sprott & Rowlands, 1992). Mean group values were calculated for LyE for both the original and surrogate data sets and for each running and walking speed. The means were grouped and analyzed statistically using t-tests ($p < 0.01$).

RESULTS AND DISCUSSION

The average baseline speeds were $1.35 \text{ m}\cdot\text{s}^{-1}$ and $2.45 \text{ m}\cdot\text{s}^{-1}$ for walking and running, respectively. Significant differences in LyE between the original and surrogate data sets were found for all speeds and for both walking and running (Table 1). This result confirmed that the original data sets were not randomly derived and had deterministic origin and refuted our hypothesis. As it has been indicated (Pool, 1989), such deterministic behavior may allow the nervous system to adapt to changing conditions, while generating effective movement patterns.

SUMMARY

The time series collected from a tibia located accelerometer were analyzed with nonlinear tools and specifically with a surrogation technique. Our results confirmed that variability in human locomotion has a deterministic origin and changes in speed can not alter such a conclusion. The fluctuations that exist between each stride should not be considered noise but adaptations from stride to stride.

THE RELIABILITY OF THE LYAPUNOV EXPONENT DURING TREADMILL WALKING

Scott M. Keenan¹ and Nicholas Stergiou¹,

¹HPER Biomechanics Laboratory, University of Nebraska at Omaha, Omaha, NE, USA

Email: nstergiou@mail.unomaha.edu Web: www.unocoe.unomaha.edu/hper.htm

INTRODUCTION

Continuous human locomotion has been showed to vary from one stride to the next. The examination of variability has been traditionally conducted using standard deviations across multiple strides. However, such an approach implies that locomotion is a sequence of independent strides. Nonlinear tools, such as the Lyapunov Exponent (LyE), have been shown to provide a more detailed analysis and can possibly reveal information about underlying control mechanisms (Dingwell et al., 2000; Stergiou et al., 2000). The Lyapunov Exponent (LyE) allows biomechanists (Dingwell et al., 2000; Stergiou et al., 2000) to examine variations during locomotion that have been called noise in the past. The LyE is defined as a measure of the rate at which nearby trajectories in phase space diverge (Sprott & Rowlands, 1992). However, no studies have been conducted to evaluate the reliability or stability of LyE. Specifically, the number of continuous footfalls that are required to achieve a stable value for LyE remains unknown. The purpose of this study was to investigate this problem during treadmill walking.

PROCEDURES

Twenty subjects (range: 19-35 yrs) with no known pathologies were asked to walk on a treadmill at a self-selected pace. A quartz shear piezoelectric accelerometer (PCB Piezotronics) was securely attached to subjects' distal anteromedial aspect of the right tibia with a tight elastic wrap. The time series from the accelerometer data sampled (180 Hz) were analyzed using the Chaos Data Analyzer software (Sprott & Rowlands, 1992). The footfalls were analyzed starting with the initial five. Then, five footfalls were added to each subsequent analysis, until all 80 footfalls were included. The LyE was calculated for each one of the analyses groups. All LyE calculations were performed using five embedded dimensions. The embedded dimension, a description of the number of dimensions needed to unfold the structure of a given dynamical system, was calculated from a Global False Nearest Neighbors (GFNN) analysis (Abarbanel, 1996). Mean LyE group values for the grouped footfalls were analyzed statistically using repeated measures ANOVA ($p < 0.05$) with a Tukey test as post-hoc.

RESULTS AND DISCUSSION

The ANOVA results showed significant differences between the LyE values. This indicated the LyE values changed from the initial five footfalls when more footfalls were added to the analysis. The post hoc analysis revealed that at the initial five and ten footfalls, the LyE was significantly smaller in comparison with all the other conditions. There were significant differences between the initial fifteen footfalls and the fifty through eighty footfalls. The initial twenty and thirty footfalls were also significantly different from the seventy and seventy-five. It can be observed (Table 1), that as the number of footfalls and data points increase, the values became statistically similar. It can then be concluded that the differences observed from five through fifteen footfalls may be due to the lack of data points. The data points analyzed for the initial five were 1,000, while the total number for all eighty was 16,000.

SUMMARY

The time series collected from a tibia located accelerometer were used to calculate the LyE. The LyE is a measure of the stability of a dynamical system and its dependence on initial conditions. Our results confirmed that after thirty footfalls the LyE is a statistically stable nonlinear tool. This finding can help narrow the number of data points and footfalls needed for an accurate assessment of the LyE during treadmill walking.

THE SENSORI-MOTOR DEGENERATION REVEALED BY THE CENTER OF PRESSURE MEASUREMENT

Gongbing Shan¹, Christiane Bohn² and Ge Wu³

¹Department of Kinesiology, University of Lethbridge, AB, Canada; ²Institute for Movement Science, University of Muenster, MS, Germany; ³Department of Physical Therapy, University of Vermont, VT, USA

INTRODUCTION

The frequency of falls and fall-related injuries increases with age. An early identification of potential fallers will help to reduce the frequency of falls. Unfortunately our current methods of prediction, which are based on the analyses of data collected across different biomechanical tests, are consequently contradictory and impractical (Daubney et al. 1999; Maki, 1993), because the measurement techniques used are too complicated and diverse (Hill et al. 1999). Hence, a simple, highly reliable method of prediction is desired by practitioners. The purpose of this study was to develop a practical and quantitative way for diagnosing the age-related degeneration of human sensori-motor function in order to predict the potential fallers. Contrary to the current methods, this research utilized the Artificial Neural Network (ANN) to predict the degeneration of sensori-motor function related to age while keeping the measurement simple. Only the Center of Pressure (COP) was utilized in this study.

METHOD

The method is based on the following facts. Because COP is related to one's involuntary control in quiet stance, it should reflect the CNS integration of sensory inputs from the visual, vestibular and somatosensory systems. Therefore, parameters derived from COP captures, i.e. excursion length, maximum displacement, mean and maximum velocity as well as acceleration of COP, can represent the human sensori-motor ability. The redundancy and non-linearity of sensori-motor systems relates these parameters to one another. This relationship looks much like a web. If one point (one parameter) on the web is changed, the others will be changed also. One suitable tool for capturing the "web-relationship" is the ANN modeling. Recent studies (Koike et al, 1995) have showed that the ANN model could predict the behavior of a biological system successfully. Furthermore, body weight (BW) and body height (BH) would also influence the net-like interaction of the human sensori-motor system and should be considered in the building of the ANN model. Based on the above matters, an ANN model of 3 layers was established (Figure 1). For capturing the relationship between COP and age-related sensori-motor function, the ANN model had 26 inputs (P_1 to P_{26} , $i=26$) in the input layer; 60 non-linear neurons in the hidden layer; and 2 linear neurons in the output layer. The 26 inputs were: BW & BH, length, max excursion, mean and max velocity as well as acceleration of the COP in the anterior-posterior and medial-lateral direction with eyes open or closed (BW & BH + 6 parameters \times 2 COP excursions in 2 directions \times 2 visual conditions = 26 inputs). The two targets were age and fall-history (0 – non faller or 1 – faller). After ANN training, the first layer weights (W_{ij}) and second layer weights (W_{jk}) were fixed, so that one could use the model and a new measurement to predict the age (output y_1) of the new subject and fall possibility (output y_2). The predicted age would indicate the declining rate of one's sensor-motor

function, e.g. if a predicted age is 65 years for a 60 year old subject, it would mean that the declination of the sensori-motor system of this subject is faster than those individuals whose data are applied to train the ANN model.

Figure 1: Design of the ANN model.

Two female groups of subjects were tested in this study: a young group (<22 yrs of age, $N=6$) and an aged group (>55 yrs of age, $N=4$). During the test, each subject was asked to stand quietly for 10 s, with either eyes open or closed. The COPs under the feet were measured by an AMTI force plate. Two more female subjects (21 and 68 years old) were also involved in the test and their data were applied for testing the accuracy of the prediction of the ANN model.

RESULTS AND DISCUSSION

Because there were no fallers in the subjects, the ANN was only trained by the data of non-fallers. Hence, the prediction of the model at present state is limited on diagnosing the degeneration of sensori-motor function related to age. The prediction results for the two subjects are: 23 for a 21-years old student and 64 for a 68 years old senior.

The long-term aim of this study is to develop a quantitative method for diagnosing the degeneration of sensori-motor function in order to predict potential fallers. The philosophy is to simplify the present measurements, at the same time to increase the reliability of the prediction. This philosophy would let the outcomes be practitioner-friendly. The primary result reveals that this philosophy has huge potential to reach its final goal. It is clear that the accuracy of the prediction of ANN model depends on the amount of data for ANN training. The more subject data collected, the higher the accuracy. Therefore, a large number subject tests (age from 18 - 65+) and new ANN models are going to be done.

SUMMARY

This study revealed that one could utilize a simple measurement (COP) and ANN model to predict sensori-motor degeneration related to age.

THE INTERNAL-LOAD CHARACTERISTICS DURING VIOLIN PERFORMANCE

Peter Visentin¹ and Gongbing Shan²

¹Department of Music, ²Department of Kinesiology, University of Lethbridge, Lethbridge, Alberta, Canada

INTRODUCTION

Overuse syndrome is a common injury among musicians. It is defined as excessive use of body parts so that the accumulation of small micro-trauma exceeds human physiological limits (Dawson et. al., 1990). Studies on professional musicians, as well as college and high-school-aged music students show that 43% - 66% (Zara, 1992; Brown, 1997) of musicians need to stop performing for extended periods because of overuse syndrome. Regrettably, there is currently little quantitative research in this area, inhibiting the development of effective industry practices that focus on improving economic training and learning. Consequently, this study initiates an examination of internal loads occurring during violin performance, with the aim of supplying the characteristics of the load, and providing a foundation that could lead to the design of practices that reduce incidences of overuse syndrome in musicians.

METHOD

In this study, only shoulder loads were examined, as shoulder injuries account for up to 25% of all injuries and are the most prevalent type of injury among professional violinists (Fry, 1988). The method applied uses EMG and kinematic measurements as well as inverse dynamic modeling. Two channels of EMG (DelSys) were used to capture deltoid muscle activity. A nine-camera VICON v8i system was used to capture upper body movement and synchronize EMG and kinematic data. The captured 3D kinematic data was then applied onto a ten-segment model for inverse dynamic analysis in order to determine the joint moments and forces loading the shoulders. The resultant calculated loads together with EMG measurements were utilized to reveal shoulder load characteristics. The ten segments in the violin model were head, trunk, both upper arms, lower arms and hands as well as bow and violin.

Fig. 1: A 3D reconstruction of violin performance.

Six professionals (two university professors and four Calgary Philharmonic Orchestra violinists) participated in the study. They age from 38 to 46, with no currently known injuries. Both legato (smooth) and spiccato (bounced) bowing techniques were evaluated for six continuous minutes each. For each technique, subjects performed a common skill (a two octave G-major scale) at three separate speeds (two minutes

each): low (legato-50, Spiccato-144 bows/min.), medium (legato-100, Spiccato-432 bows/min.), and high speed (legato-200, Spiccato-576 bows/min.). Multiple EMG and kinematic samples were gathered at each speed, so that internal loads and EMG data could be examined throughout the full cycle of the skill.

RESULTS AND DISCUSSION

Fig. 2: Normalized EMG envelopes and calculated shoulder joint moments of a trial. Measurements began on the G-string (lateral), cycling to the E-string (medial) and back.

EMG and inverse dynamic analysis both reveal that: a) the left shoulder has a relatively constant load (static) regardless of the string used or the bowing technique or speed b) the load on the right shoulder (dynamic) varies in a larger range and is highest on the G-string and the lowest on the E-string (Fig.2), with the lowest level comparable to left shoulder loads; c) legato technique results in higher right shoulder loads than spiccato; and d) higher performance speeds result in lower internal loads and EMG readings, indicating slow-speed bowing to be more physiologically challenging than fast bowing. Interestingly, despite the significant left and right shoulder differences revealed by this study, shoulder injury rates are comparable (Fry, 1988), suggesting that lower intensity static loads (left side) may lead to micro-trauma more easily than dynamic loads (right side).

SUMMARY

The results of this study suggest that overuse syndrome in violinists is exacerbated by: a) slow-speed bowing techniques and excessive G-string use (right shoulder), and b) constant lower-level static loads (left shoulder).

THE SELECTION OF PARAMETERS AND PRE-TEST STATES IN IDENTIFYING THE AGE EFFECT THROUGH THE CENTER OF PRESSURE (COP) MEASUREMENT

Brandie Wilde and Gongbing Shan

Department of Kinesiology, University of Lethbridge, Lethbridge, Alberta, Canada

INTRODUCTION

Much research has been done to study the neural control abilities in aging individuals utilizing COP measurement (Daubney 1999). Multiple parameters derived from the COP test, such as peak-to-peak (P-P) value, curve length (CL), velocity and acceleration of COP excursion, were proposed to identify the age-effect on the sensori-motor system (Suomi 1994, Fitzgerald 1994). Unfortunately, the analyses based on these parameters are often contradictory (Daubney et al. 1999). On the other hand, not until now have the pre-test states been taken into account. A pre-test state refers to the activity just before the test. A study done by Carroll (1992) showed that the first 20-second timely excursion in a center of pressure (COP) measurement varied greatly from the measurements following the first 20 seconds, which suggests there would be a transfer phase between the pre- and test-state. Un-standardized COP tests could be the reason for the conflicting situations in the previous studies. Our intent is to research the influence of the states of the body prior to measurement as well as all possible parameters derived from a COP test in order to determine the most effective way for applying the COP test in analyzing the age-effect on human sensori-motor system.

METHOD

This study explored the influences of three pre-test states, sitting, standing and walking, on COP excursion; as well as eleven parameters to see which one(s) can sufficiently identify the age-effect. The parameters were divided into two groups – absolute and relative parameters. The seven absolute parameters consist of p-p values in anterior-posterior (a-p) and medial-lateral (m-l) direction, CL, mean and max velocity as well as acceleration of the COP excursion. The four relative parameters were normalized p-p values (normalized by foot length) and the swing angles of centre of mass (COM) in a-p and m-l directions, which are defined by $\frac{1}{2}$ p-p values divided by subject COM height. The COM heights were obtained through a regression equation (Shan, 1999), which utilize body weight and height as independent parameters. A random sample of 17 seniors (60-92yrs), and 21 students (20-25 yrs.) were obtained. Measurements of their foot length, shoulder width, height (m) and weight (kg) were taken and utilized to normalize as well as standardize (shoulder width = stand width) the COP tests. By the use of Kistler force platform, a 40 second quiet stance was used for the series of COP measurements. Each measurement was assessed in the first 20 seconds, second 20 seconds and total (40 s) by using the 11 parameters. The three pre-test states were applied as follows: the first following a two-minute period of sitting; the second being after at least a minute's worth of standing; and the third subsequent to a walk, at normal walking pace, for 200 m. Each of these trials was done three times for a total of nine measurements. A vision condition was also added to these

trials. The subjects were asked to follow the same procedure as outlined, however while standing on the platform their eyes were closed. The added 9 trials (eyes closed) resulted in a total of 18 measurements per subject. Finally, ANOVA was utilized to determine the significances among pre-test states, and parameters in the identifying the age-effect.

RESULTS AND DISCUSSION

It was found that the aged individuals had in average a higher p-p value in both directions in the absolute and relative evaluations. Their COM swing angle (relative parameter) was also greater in both directions. However, the students showed higher max and average excursion speed and acceleration to the aged as well as a larger curve length. The results above suggest that the involuntary control of young adults is more dynamic (faster, however in a smaller range) than the aged. It was also noted that there was a more drastic change between the first and second 20 s in the younger subjects as opposed to the elderly. The calm-down effect (the decline of p-p value) is significant ($p < 0.05$) in the young group, while hard to notice in the aged group, which suggests there is a transfer phase (control pattern change) between pre-test and test states for the young group. The transfer phase could be the reason for contradictory results in the previous studies. The ANOVA results reveal that 56 out of 66 parameters ($3 \text{ pre-test states} \times 2 \text{ vision conditions} \times 11 \text{ parameters}$) are significantly different between young and aged in the second 20 s interval, while there are only 40 for both the first 20 s and total. Another indication of the ANOVA results is that the best pre-state possible for the identification of the age-effect is walking. This has a more obvious transfer phase and is almost 100% different between the two groups of subjects. A different avenue to reaching a unique identification is to use relative parameters. The ANOVA results showed that 24 out of 24 parameters are significantly different ($p < 0.05$), while only 32 out of 42 absolute parameters are significant.

SUMMARY

Thus, to determine the age-effect on a subject's balance, a walking pre-state with a measurement after 20 s standing would be recommended. The relative parameters would also be the most effective.

AXIAL STRETCH OF ARTERIES IN ORGAN CULTURE

N. Peter Davis, Hai-Chao Han, and Raymond Vito
George W. Woodruff School of Mechanical Engineering
Georgia Institute of Technology
raymond.vito@me.gatech.edu

INTRODUCTION

In vivo, arteries remodel in response to their mechanical environment. Many studies have shown that artery wall thickness increases when pressure increases and that artery diameter increases as blood flow increases. If axial stretch also leads to remodeling of the arterial wall, this may provide a way to engineer new arterial tissue for use in coronary bypass and other applications where arterial grafts would be beneficial. Lengthening existing arteries that have proven performance as bypass conduits could facilitate completely arterial revascularization.

Organ culture was chosen as the means to investigate the lengthening of arteries by mechanical stretch. Much greater control of mechanical environment is possible with organ culture compared to *in vivo* studies, and the native architecture of the tissue itself is maintained.

METHODS

Carotid arteries (4.8 ± 0.3 mm outer diameter) were harvested from 100-150 kg farm pigs and mounted in a perfusion organ culture system that was modified from a previous design (Han and Ku, 2001) for the application of axial stretch. Culture medium was DMEM plus 10% newborn calf serum. Arteries were perfused at pulsatile physiologic pressure and flow conditions (100 ± 20 mm Hg with average wall shear stress of 15 dyn/cm^2). Axial stretch was applied to arteries during culture using linear motors controlled by a PC running custom C-code. Control arteries were maintained at the physiologic stretch ratio of 1.5 while stretched arteries were cultured with a constant axial stress of 250 kPa. Culture period was 7 days.

Proliferation was detected by BrdU incorporation during the last 24 hr of culture and subsequent antibody detection in 5- μm histologic sections. Vasomotor response was tested on whole arteries the last day of culture while arteries were still mounted in the perfusion circuit. Differences between means were considered significant at $p < 0.05$.

RESULTS AND DISCUSSION

Though stretched arteries reached an average stretch ratio of 2.13 ± 0.07 during culture, neither stretched nor control arteries showed any permanent increase in no-load length. Tissue volume was found to decrease in both groups, but stretched arteries showed a significantly lower volume loss of 15% compared with the 27% loss in controls.

Figure 1 shows that more proliferating cells were located in the intimal and adventitial layers than in the media. Stretched arteries had significantly higher proliferation in the intima

than controls. Overall, stretched arteries showed slightly higher proliferation than controls, but the difference was not significant. Total medial smooth muscle population did not change significantly over the 7 days of culture for either group, indicating that stretch under these conditions produced no cumulative proliferative changes in that layer. Though axial stretch at 250 kPa for 7 days did not appear to be a growth stimulus for the medial smooth muscle population, the intimal layer responded significantly to stretch at 250 kPa for 7 days. Both groups of arteries showed strong contraction to norepinephrine and relaxation to sodium nitroprusside at the end of culture. No morphological differences were observed between H&E sections from either group.

Figure 1. Proliferation within the three arterial wall layers. * $p < 0.05$.

SUMMARY

Arterial integrity and morphology were unaffected by stretch, and vasomotor response was good in both stretched and control arteries. Even though the arteries did not show significant growth under these conditions, they endured considerably larger stretch than the *in vivo* condition without evident damage. Therefore, these arteries are quite resilient under axial stretch, and lengthening might be accomplished by optimizing the stretch protocol.

FORCE DEPRESSION FOLLOWING MUSCLE SHORTENING OF ELECTRICALLY STIMULATED AND VOLUNTARILY ACTIVATED HUMAN ADDUCTOR POLLICIS

Hae-Dong Lee¹ Walter Herzog¹ and Young-Doo Won²

INTRODUCTION

Force depression following active muscle shortening has been demonstrated, using artificial electrical stimulation, for in-vitro and in-situ animal muscle/fibre preparations (Abbott & Aubert 1952; Edman et. al. 1993; Herzog & Leonard 1997; Maréchal & Plaghki 1979) and for in-vivo human muscles (Cook & McDonagh 1996; de Ruiter et. al. 1998). Recently, it was demonstrated that force depression also exists for human voluntary knee extensions (Lee et. al. 1999). However, force depression did not depend on the shortening magnitude and speed (Lee et. al. 2000), in contrast to what has been consistently observed for electrically stimulated preparations. Therefore, in order to fully describe force depression in human skeletal muscles and to investigate the influence of neuromuscular control in voluntary contractions, it is necessary to make direct comparisons of force depression between electrically stimulated and voluntarily activated muscles.

The purpose of this study was to investigate force depression for in-vivo human adductor pollicis during voluntarily activated and electrically stimulated contractions.

METHODS

Subjects (n = 6) performed isometric contractions following active muscle shortening with the thumb adductor muscle using voluntary and electrical stimulation. The shortening conditions were systematically varied [i.e., magnitudes (10, 20 and 30° at a constant speed of 20°/s) and speeds (20, 60 and 300 °/s over a constant magnitude of 30°)]. Each test contraction was repeated three times in a random order, and isometric reference contractions were performed before and after the three test contractions. All isometric contractions were performed at a fully adducted thumb position. Muscle force and joint angle were continuously recorded using a custom-designed dynamometer (Lee et. al. 2001), and muscle activation was monitored with electromyography and the interpolated twitch force (ITF) (Merton 1954). Using ANOVA with repeated measures and Bonferroni post hoc comparisons, force depression (FD), defined as the difference in the steady-state isometric force following shortening and the isometric reference force, the root mean square (RMS) values of EMG, and the ratios of ITF to the resting twitch force (RTF) were compared among the test conditions ($\alpha=0.05$). All results are presented as means \pm 1 S.E.M.

RESULTS AND DISCUSSION

Mean force depression across all tests was $21 \pm 4\%$ and $15 \pm 3\%$ for the voluntary and the electrically stimulated contractions, respectively. Force depression was directly related to the magnitude of shortening and was inversely related to the speed

of shortening (Fig.1&2). These result agrees with observations for electrically stimulated preparations (de Ruiter et. al. 1998), but not with those observed for human voluntary knee extensions (Lee et. al. 2000). Muscle activation of the adductor pollicis was similar across contractions for all voluntary tests, whereas for human knee extensors, activation was not constant across isometric reference and shortening test trials (Lee et. al. 2000). We propose therefore, that force depression during voluntary and electrically stimulated contractions is similar, as long as activation in the voluntary contractions remains constant. Furthermore, we speculate that for small hand muscles, activation may be kept constant and maximal for different contractions, whereas for the big muscles of the limbs, this may not be necessarily correct.

Figure 1. Force-time histories of purely isometric and isometric contractions following shortening with varying magnitudes (10, 20 and 30° at a constant speed of 20°/s).

Figure 2. Force depression following muscle shortening of varying magnitudes (A) and speeds (B) (for collapsed means across each shortening condition: *, $p < 0.05$)

A COMPARISON BETWEEN GAIT KINETICS IN WOMEN WITH PRIMARY OSTEOARTHRITIS AND THOSE WITH OSTEOPOROSIS

Jean L. McCrory, Anne L. Harrison, and Jody L. Clasey

Biodynamics Laboratory and Body Composition Core Laboratory, University of Kentucky, Lexington, KY, USA

mccrory@uky.edu

INTRODUCTION

Osteoporosis (OP) and osteoarthritis (OA) are recognized as major age-related health problems that disproportionately affect women. Of women over age 65, an estimated 33% will sustain an osteoporotic hip fracture and approximately 86% will show evidence of lower extremity OA (Wardlaw, 1998).

Interestingly, many of the predictors for OP and OA are inversely related, which has led to the theory that these diseases are mutually exclusive of one another (Dequecker et al., 1996). By definition, individuals with OP have low bone density. Individuals with OA have been shown to have elevated bone mineral density (BMD) (Stewart and Black, 2000). Hurwitz et al. (1998) related BMD to biomechanics by reporting that people with hip OA had greater femoral bone density and greater hip adduction moments than a control group did. This is in accordance with Wolff's law, which states that bone density is proportional to the amount of force to which the bone is exposed (Woo et al., 1981).

The purpose of this investigation was to determine if the gait kinetics differ between women with OP and women with OA. It was hypothesized that women with knee OA will have greater ground reaction forces and joint moments than the women in the OP group.

METHODS

Thirty-one post-menopausal women aged 50 to 85 received a standing bilateral A-P knee x-ray and a DXA scan of their femoral neck. Women with knee OA rated 2 or 3 on the Kellgren-Lawrence scale were placed in the OA group (n=10, 68.3±7.4yrs, 1.62±0.06m, 79.4±12.8kg). Women with proximal femoral BMD two SD below normal were placed into the OP group (n = 7, 74.4±7.9yrs, 1.64±0.06m, 61.2±10.0kg).

On a subsequent visit, a gait analysis was performed on each subject using a 6-camera Motion Analysis Inc. system (60 Hz, Santa Rosa, CA) interfaced with a Kistler force plate (600 Hz, Winterthur, Switz.). Retroreflective markers were placed on the foot, shank, thigh, and pelvis to determine 3D movement patterns. After subjects had become accustomed to walking on the 20m laboratory runway in the marker set, 5 good trials of the most affected leg (OA group) or a random leg (OP group) were collected. A trial was termed "good" if the subject struck the force plate with the designated foot with no visible alteration in gait mechanics. An ANOVA was performed on the passive and active peaks for the following measurements: ground reaction force, hip and knee compression forces, and hip and knee adduction moments.

RESULTS AND DISCUSSION

With the kinetic variables normalized to the subjects' BW, no variables were significantly different between groups. However, it is more physiologically relevant to compare the non-BW normalized values (in N) between groups because Wolff's law deals with actual magnitude of force exposure. The OA group had greater values ($p<.05$) for the passive and active peaks in ground reaction forces, hip and knee compressive forces, and hip adduction moment (Table 1).

Table 1: Significant kinetic variables

Variable	OA	OP
Psv GRF Pk (N)	847.2±178.1	660.1±115.1
Act GRF Pk (N)	841.6±114.1	688.9±103.1
Psv Hip Comp Fc (N)	712.9±132.2	549.4±96.7
Act Hip Comp Fc (N)	689.4±87.4	561.3±96.7
Psv Knee Comp Fc (N)	810.1±170.6	621.5±111.9
Act Knee Comp Fc (N)	738.2±97.2	621.4±95.4
Psv Hip Add Mom (Nm)	724.1±275.7	542.2±153.6
Act Hip Add Mom (Nm)	632.7±212.1	460.6±161.4

The average femoral neck BMD of the OA group was 109.2±12.1% of aged matched normal while the OP group averaged 89.2±9.7% of normal. Like the women with hip OA studied by Hurwitz et al. (1998), the women in the knee OA group in the current study had large hip adduction moments increased femoral neck BMD. Whalen et al. (1988), in the "daily load hypothesis" theory, stated that BMD is directly related to the GRF magnitude. Future work will involve testing a healthy control group to determine if the values of this group fall between those of the diseased populations of this study.

SUMMARY

Body weight is related to the differences in the gait kinetics between the OA and OP groups. Because the OA group was significantly heavier than the OP group, the magnitude of lower extremity force exposure was significantly larger in the OA group. This supports the theory that these two diseases are on opposite ends of the same continuum.

MODELING OF DISTANCE IN SKI JUMPING USING STATISTIC MODELS WITH RANDOM PARAMETERS

Sandro Jelmini , Reposoir 23, 1007 Lausanne, Switzerland; sandro@balelec.ch
Mathematics Department, Swiss Institute of Technology, Lausanne, Switzerland

INTRODUCTION

Ski jumping, as an outdoor sport is dependent on weather conditions and it is now important for promoters to be able to make the right choice concerning, among others, the inrun given to the jumpers. Statistics offers a solution to make more "objective" choices, using data about the jumpers, the hills and the weather, thus making use of all the information we have about the *history* of the jumpers and the hills. One possibility is to model the lengths of the jumps in ski jumping with a statistical theory called *Bayes Theory*. A simplified approach to the *Bayes Theory* would be the following: the jumpers represent a population for which the distribution (with parameters) is known (approximately at least) or supposed to be known. Each jumper is one individual of this population with his own parameters.

METHODS

Before applying the *Bayes Theory*, some "classical" graphical analyses were made in order to sort the jumpers and the hills and to understand various correlation. The data we used are the World Cup results of seasons 1997/1998 and 1998/1999. All data was sorted into 3 categories: data on the jumpers (6), data on the jumping hills (3) and data on each jump of the competition (2 x 16). Different classical methods were first used to analyze the data. **Histograms and boxplots** give a global view of each jumper and hill distribution. This shows which jumpers are most regular and which have the best mean length. A similar evaluation can be made for hills, showing which hill allows the longest jumps in mean and which are the most difficult to jump. The **Principle Components Analysis** method gives us a graphical idea of different (sub-) classes or sectors in which we could put jumpers on one side and hills on the other. As we create the diagram for all jumpers and all hills at once, the various "clouds" or classes appearing correspond to jumpers that have similar results on similar hills. The table of correlation linked to the PCA gives the correlation between the hills.

The first step to find a **model** using the information we have is to make a simple **linear regression**. Two models were found to estimate the length of a jump with the help of different methods as the stepwise and the ANOVA. The first model taking a particular jumper and the second taking different characteristics of a person. Both models allow us to compare the model with the reality (something that has happened) or to predict the result of a jumper or a person with given characteristics. Comparing the first model with the data we used, the mean difference between the model and the reality for a given jump is less than 2%, i.e. 2.5m on a 125m jump. The more data we have, the more exact this estimation should be, also as a "prediction". The second model gives the estimate length of a jump for a person with given characteristics (height, weight, birth year, year of beginning,...).

The Bayes theory can be use in different levels: standard, empirical or hierarchical. The first and most easy result is to suppose that the length x of a jump for each jumper i , written

x_i , has a Normal distribution with mean μ_i and variance σ^2 ; σ^2 is known but μ_i has itself a Normal distribution with mean ν and variance τ^2 , both known (the results based on the whole population on K120 hills give: $\nu = 111.47$ meters & $\tau^2 = 120.55$). We have: $x_i \sim N(\mu_i, \sigma^2)$ and $\mu_i \sim N(\nu, \tau^2)$ which is the *a priori law* on parameter μ_i .

The posterior distribution of μ_i knowing x is given in S. Jelmini (2000). Taking $\bar{x} \sim N(\bar{\mu}, \Sigma)$ and $\bar{\mu} \sim N(\bar{\nu}, \Lambda)$ with any Σ and any Λ , we find the posterior distribution for a more general case. Suppose now that each jumper "has his own variance". We suppose that the different persons are independent to each other and that two jumps of a same person are independent and identically distributed. If J is the number of jumps on the particular hill h ($h=1, \dots, H$ with H the number of hills), the *a posteriori law* for jumper i is then:

$$\begin{pmatrix} \mu_{ih} \\ \vdots \\ \mu_{ih} \end{pmatrix} | X \sim N_J(\mu_{\pi ih}, V_{\pi ih}) \text{ with}$$
$$\mu_{\pi ih} = \left(\frac{1}{\tau^2} I_J + \Sigma_{ih}^{-1} \right)^{-1} \left(\frac{1}{\tau^2} I_J \begin{pmatrix} \nu \\ \vdots \\ \nu \end{pmatrix} + \Sigma_{ih}^{-1} \begin{pmatrix} x_{ih1} \\ \vdots \\ x_{ihJ} \end{pmatrix} \right) \&$$
$$V_{\pi ih} = \left(\frac{1}{\tau^2} I_J + \Sigma_{ih}^{-1} \right)^{-1}$$

RESULTS

Models and parameters have been found for, among others, different linear regressions and a Bayes model with the same number of jumps for each person (taking only the competitions on K120 hills into consideration). As has been said, the data analyzed for this work came from results of seasons 1997/1998 and 1998/1999. The best results - or at least the most complete results - would obtain through stepwise updates of the database after each jump of each competition. This would provide an "instant" situation of the parameters for each jumper and each competition. It would then be possible during a competition to predict how long the next jumpers would normally jump if they were performing in their "mean" level.

This could be a very interesting model for the FIS (International Ski Federation) to be able to choose a good inrun length, based on all the different parameters (hill, temperature, weather, jumpers, etc.).

INTRODUCTION

In humans, muscle recruitment during static biting and chewing varies depending on bite force (BF) direction. Directional information is provided by periodontal ligament mechanoreceptors. Given that BF directions can vary during biting, it is unknown whether there is an overlying neuromuscular objective which governs the mix of forces produced by the masticatory muscles. The mix of muscle forces determines the magnitudes and directions of temporomandibular joint (TMJ) loads, and thus, is clinically important. The aim of this project was to test hypotheses that could account for the muscle outputs during static BF's that produce moments on molar and incisor teeth. Models of minimization of joint loads (MJL) and muscle effort (MME) were tested. Seven living subjects provided subject-specific data that included: i) effective TMJ eminence morphology and ii) muscle activities, which were used to test the models.

METHODS

Effective Eminence Morphology: The effective eminence morphology of the TMJ represents the sagittal plane projection of the trajectory of the TMJ stress-field as the mandibular condyle translates downward and forward from a molar biting position to an incisor biting position. The shape of the effective eminence was measured using a videographic technique. The shape of the trajectory was digitized and described as a third order polynomial. A numerical model was used to predict the shape of the effective eminence based on MJL and the individual's three-dimensional (3-D) craniomandibular (CM) geometry. A linear regression analysis was used to test the model predictions by comparison with *in vivo* data from the same subject.

Muscle forces during biting: Indwelling and surface EMG were used to measure muscle activity as a surrogate for muscle force. Data were collected from the right and left masseter, temporalis, medial pterygoid, lateral pterygoid, and digastric muscles during biting on the first molar and central

incisor teeth. BF position on a given tooth was varied across the occlusal table to produce a systematic variation of + and – moments about the center of resistance of the teeth. The biting tasks were simulated in the models. Predicted data using the subject specific 3-D CM geometry were based on i) MJL or ii) MME. The data were compared using a statistical analysis consisting of both general linear and mixed methods in order to determine if MJL or MME model predictions fit the actual data better. A random coefficient method is effective in determining which subjects have the actual muscle outputs predicted better by the MME model and which by the MJL model. Therefore, the accuracy of the statistical analysis was based on prediction of muscle outputs, rather than using measures of variance.

RESULTS AND DISCUSSION

A range of eminence shapes was measured. Slope differences varied by as much as 3 to 1 between the subjects. Linear regression analysis resulted in an R^2 of 0.94. T tests indicated no significant difference between predicted and measured effective eminence morphologies. The results showed that in most subjects the MME model predictions fit the actual muscle outputs better than the MJL muscle predictions did ($p < 0.001$, Table 1). However, for molar biting in one subject, the MJL model predicted the measured data. In another subject, both the MJL and MME model results fit the measured muscle activities. A similar pattern of results was found for incisor biting.

SUMMARY

Muscle recruitment during isometric biting appears to be consistent with the objectives of MME but, depending on the individual, location of biting, and direction of BF, single individuals matched predictions of MJL.

Table 1: Multiple Regression Analysis of Predicted and Measured Muscle Outputs During Biting

Molar Biting	Degrees of Freedom	F- Value	P- value
MME Model (after fitting MJL Model)	1	50.64	<0.0001
MME Model and Subject	6	5.02	<0.0001
Incisor Biting	Degrees of Freedom	F- Value	P- value
MME Model (after fitting MJL Model)	1	16.8	< 0.0001
MME Model and Muscle Output	4	3.66	0.0064

IDENTIFYING DYNAMIC INSTABILITY DURING OBSTRUCTED GAIT FOLLOWING TRAUMATIC BRAIN INJURY

INTRODUCTION

Sensation of imbalance has been troublesome for as many as 30% of patients following a traumatic brain injury (TBI) despite an often unremarkable neurological and physical exam (Alves et al., 1986; Cicerone and Kalmar, 1995). Given that additional injuries may occur due to consequences of unsteadiness or imbalance during locomotion, it is important to reveal the influence of TBI on an individual's ability of balance control during balance-challenged activities, such as walking and stepping over obstacles. This information may enhance the development of TBI rehabilitation and education programs and lead to increased safety and faster integration into the community. Therefore, the purpose of this study was to develop a quantitative measurement system to identify dynamic instability during gait of individuals with TBI.

METHODS

Ten subjects (6 men and 4 women, ranging in age from 19 to 62 years, and at least 3 months post injury) with documented TBI and complaints of "imbalance" or "unsteadiness" while walking and ten age, gender, and stature-matched healthy individuals were recruited for this study. Subjects were instructed to walk along a 10m walkway at a comfortable self-selected speed while barefoot. Whole body kinematic data were collected from each subject using a six-camera ExpertVisionTM system during unobstructed level walking and when stepping over an obstacle of height corresponding to 2.5%, 5%, 10%, or 15% of the subject's height. The order of obstacle height was randomly selected. A 13-link biomechanical model of the body was used to compute the kinematics of the whole body's COM (Chou et al., 2001). A two-way ANOVA with repeated measures of obstacle height was used to test for group differences and obstacle height effect on the temporal-distance parameters, range of motion of the COM and its peak velocities in three orthogonal directions during the crossing stride.

RESULTS AND DISCUSSION

Post-TBI subjects adopted a gait pattern with a significantly slower walking speed ($p=0.02$) and shorter stride length ($p=0.018$) than controls during all obstacle conditions. The walking speed was found to decrease linearly ($p<0.001$) as obstacle height increased. Significantly smaller/slower COM movement in the A-P direction ($p\leq 0.012$) was also observed in post-TBI subjects than controls. The A-P COM range of motion and peak forward velocity decreased linearly ($p<0.001$) as obstacle height increased.

Although neither significant group nor obstacle height effects were detected for the step width, significantly greater/faster COM movement in the M-L direction ($p\leq 0.007$) was found in post-TBI subjects than controls during all obstacle conditions (Figure). The M-L COM range of motion and peak velocity were also found to increase linearly ($p<0.001$) with obstacle height.

Stepping over a higher obstacle was found to impose a greater perturbation on the M-L COM motion in the TBI subjects than normal individuals. Also, magnitudes of the M-L COM excursion and peak velocity of the TBI subjects are similar to those reported for the balance-impaired elderly adults (Hahn et al., 2001), which indicate poor balance control in the frontal plane. Our data also imply that the feasible range of COM movement during which balance can be successfully maintained in the sagittal plane has been reduced in the TBI subjects relative to their controls.

SUMMARY

Examining the COM motion provides an objective measurement to better document complaints of instability not observable on clinical examination for individuals who suffered a TBI. Subjects with a TBI may be under a greater risk of sideways instability/falling during obstacle crossing.

PLOWING FORCES AND STRESS DISTRIBUTION ON THE TEMPOROMANDIBULAR JOINT DISC SURFACE

Jeffrey Nickel, Laura Rothe, Laura Iwasaki, Mark Beatty

University of Nebraska Medical Center, College of Dentistry, Lincoln, NE, jnickel@unmc.edu

INTRODUCTION

The development of degenerative joint disease of the temporomandibular joint (TMJ) is related to the degeneration of the fibrocartilaginous disc. It is thought that shear and tractional force-induced stresses on the disc surfaces may account for early disc degeneration. The clinical evidence that the lateral portion of the disc is the location where failure occurs most often suggests that there is an asymmetric distribution of these stresses. Considering tractional forces, movement over the surface of the disc is likely to produce both frictional forces and plowing forces due to deformation of the cartilage. Although it is known that surface friction on the TMJ disc is very low ($\mu_s < 0.005^1$), the magnitude of plowing forces has not been reported. It is possible that plowing forces are very much greater and, therefore, a more important factor in developing stresses on the disc surface. With respect to asymmetric distribution of compressive stresses, no data are as yet reported on the temporospatial distribution of compressive stresses under the TMJ disc during stress field translation over the disc surface. This project tested the hypotheses that 1) plowing forces are significantly greater than frictional forces on the surface of the TMJ disc, and 2) asymmetric distribution of compressive and shear stress occurs under the TMJ disc during stress-field translation.

METHODS

Fifty-six porcine TMJ discs were used in a laboratory apparatus to measure plowing forces on the surface of the disc, and pressure distribution under the disc during movement of an acrylic indenter over the top surface of the disc. Each disc remained hydrated in warm saline until it was statically loaded with 11 N for either 10 s or 1 min., after which the acrylic indenter was moved over the surface of the disc at peak velocities of 117 ± 2.6 mm/s. This velocity is consistent with peak velocities measured *in vivo* in humans. The position and velocity of the movement were controlled by a computer-driven force generator. The indenter was instrumented to measure plowing forces during movement. Beneath the discs, a linear array of 9 pressure-sensitive transducers measured changes in compressive stress in real time. Measurement accuracy was ± 5 Pa. Data measuring the position of the indenter, pressure data, and plowing forces were recorded digitally at a sampling frequency of 300 Hz per channel. Each experiment was performed twice per disc, with 2 hours intervening between experiments to allow for disc rehydration.

To test the hypothesis that plowing forces are significantly greater than frictional forces, data analysis involved identifying peak plowing forces, and calculating a coefficient of plowing ($\mu_{\text{plowing}} = \text{Force}_{\text{plowing}} / \text{Force}_{\text{normal}}$) for comparison to published data of the surface friction on the TMJ disc. Asymmetry in stress distribution under the TMJ disc was determined from pressure data under the leading and following edges of the stress field with respect to indenter position over the TMJ lateral and medial portions. Shear stresses and normalized pressure gradients were calculated and compared to disc position. A general model of shear stress magnitude was calculated from the distribution of peak compressive stress under the disc².

RESULTS AND DISCUSSION

Measured μ_{plowing} were, on average, two orders of magnitude greater than published data of the static coefficient of friction (μ_{static}^1 , $p < 0.001$). Duration of loading affected plowing. Static loading for 60 s increased plowing forces by 23% compared to 10 s of loading. Peak compressive stresses under the disc were in excess of 80 Pa. The first pass of the indenter caused leading edge compressive stress gradients to be nearly twice that of the following gradients ($p < 0.001$). After the third pass, no significant differences in gradients were found. For all cycles, average shear stresses were 2.2 times greater for the lateral half compared to the medial half of the disc ($p < 0.01$, range 0.6 – 6.3).

SUMMARY

Plowing forces are the most significant source of tractional forces on the TMJ disc surface. Peak plowing forces occur just after the start of movement. The viscoelastic character of the disc is the reason for the temporal changes seen in the plowing forces, and compressive stresses after the indenter made multiple passes over the disc. The asymmetric distribution of greater shear stresses are consistent with clinical findings of common sites of degenerative joint disease.

DOWNHILL HIKING WITH THE USE OF A SINGLE HIKING POLE VS. DUAL TREKKING POLES

Julianne Abendroth-Smith¹, Ed.D. and Michael Bohne²

¹ Willamette University, Salem OR; jabendro@willamette.edu

² University of Northern Colorado, Greeley CO USA

INTRODUCTION

Single hiking poles have long been used by hikers, but the use of two trekking poles has recently gained popularity. The purpose of this project was to examine possible benefits of hiking downhill at different gradients while using different poling combinations. Peak GRFs and braking forces (BFs) were examined for conditions of pole use (no poles, one pole, or two poles), gradient (15 and 25 degrees) and gender.

METHODS

Thirteen healthy, well-conditioned adults with recent hiking experience volunteered (7 men, 6 women). All signed informed consents. Procedures included hiking up and down a wooden ramp, with instructions to “hike with purpose”. The single hiking pole was used with the dominant hand while the opposite leg struck the force plate. After practice, ten successful trials per condition (counterbalanced) were collected and analyzed. Force data was collected using a Bertec force plate (1000 Hz), mounted flush with the ramp. Video (60 hz) was obtained for later analysis. Means (SD) were calculated for each condition. All force data was normalized to body mass (N/kg). Peak GRFs and BFs (N/kg) were examined for differences between gradient, pole use and gender, using a 3-way repeated measures ANOVA.

RESULTS AND DISCUSSION

Statistically significant differences ($p < .05$) were noted for changes in GRFs between the two gradients ($F = 31.8$, $df = 1$, $p < .01$). Though not statistically significant, trends were noted for interactions between grade, poles, and gender (Figure 1).

Figure 1. Peak GRFs for men and women at two gradients.

Specifically, GRFs overall were greater than in previously reported studies (Abendroth-Smith & Bohne, 2001; Knight & Caldwell, 2000; Schwameder et al., 1999; Willson et al., 2001). In addition, the normalized forces were less at the steeper gradient for all conditions of pole use. Braking forces were noted to be less than in previous studies (Figure 2). It is unclear whether these experienced hikers exhibited greater

velocities or hiked with greater determination, as if they were hiking a mountain trail.

Figure 2. Peak braking forces at 15 and 25 degree gradients.

A trend was noted for decreasing GRFs at the lower gradient with the addition of one and two poles, although individual variation was great. Similar to previous reported work (Abendroth-Smith & Bohne, 2001), the women demonstrated higher forces with pole use than without, at least for the steeper gradient, with the forces at their greatest for the single pole use. Men, overall, demonstrated the lowest forces with the single pole use at the steeper gradient. No conditions were statistically significant for the braking forces. Women demonstrated greater braking forces at both grades with the dual pole use, while men maintained a similar braking pattern irrespective of pole condition.

SUMMARY

Individual variation in GRF and BF was high in single vs. dual pole use among the participants. Overall, men preferred the single hiking pole, and women, the dual poles, especially at the steeper gradient. Strategies behind pole use as a possible benefit, appear to vary as well. While some participants were able to reduce forces with the use of one or two poles, others demonstrated an increase in forces. The mechanisms behind the strategies are currently unknown, but examining muscle use in conjunction with force output may provide some answers. Lastly, symmetry needs to be examined, especially with the single pole use, to see if any benefits are applicable to both sides of the body.

QUADRICEPS WEAKNESS CAUSES AN INCREASE IN THE PEAK ADDUCTOR MOMENT DURING GAIT

INTRODUCTION

Many knee pathologies are associated with quadriceps muscular inhibition and weakness, and knee osteoarthritis (OA) has been shown to be a long term outcome of such neuromuscular deficiencies (Brandt et al., 1999; Slemenda C., et al., 1997). As reviewed by Suter and Herzog (2000), there is considerable support for the role of muscular inhibition and weakness as a factor in the initiation and progression of knee OA. The difficulty in directly assessing the role muscle weakness may have on knee joint function and its relationship to in vivo knee load stems from the inability of researchers to utilize a repeated measures study design where muscular weakness can be induced and removed (safely) and the effects of muscular weakness evaluated in an otherwise healthy population. Torry et al. (2000) has shown that experimentally induced intra-articular knee joint effusion can reduce quadriceps activation during gait. The purpose of this study was to determine whether muscular weakness of the quadriceps of the human knee joint can increase the magnitude of the adductor moment during the stance phase of the gait cycle.

METHODS

A modified Helen Hayes marker set (Kadaba et al., 1990) and a 120 Hz five camera Motion Analysis system were used to record the 3D kinematic and kinetic gait profiles of 7 healthy subjects (22.4 ± 3.2 yrs; 1.84 ± 0.5 meters, $85.9.8 \pm 13.0$ kg) prior to and after infusion of 20-cm³ of 0.9% saline into the intra-articular knee joint capsule. Quadriceps weakness due to the infusion was confirmed by testing isometric strength via a knee extension exercise (knee position = 30 degrees) utilizing a Cybex dynamometer. After isometric knee extensor torque was recorded, the subject immediately performed the post-effusion analysis, walking at similar speeds for both pre- and post-effusion conditions. Three trials of pre- and post-effusion gait data were collected, filtered (5 Hz), and processed to yield select GRF variables, knee kinematics and the adductor moment using previously described methodology (Sharma et al., 1998). Differences between test conditions were compared with a one-way repeated measures ANOVA ($\alpha = 0.10$).

RESULTS AND DISCUSSION

The 20-cm³ infusion caused a mean decrease in isometric knee extensor peak torque of $10.4 \pm 4.1\%$. After quadriceps weakness was confirmed, the subjects walked with a more flexed knee ($p < 0.01$) and reduced stance time ($p = 0.02$). The peak magnitude of the vertical GRF increased ($p = 0.02$), but the loading rate of this force did not change ($p = 0.50$). The peak adductor moment (Figure 1) increased ($p = 0.01$). However, the impulse of adductor moment and the time to the

peak adductor moment did not change between conditions ($p = 0.50$ and $p = 0.23$, respectively).

These results suggest that 20-cm³ of effusion can cause a 5-15% reduction in isometric peak torque output of the quadriceps muscles. An apparent effect of this quadriceps weakness was a significant increase in the peak adductor moment during gait. Since this moment has been reported to be indicative of medial joint loading (Sharma et al, 1998), muscular weakness of the quadriceps may dispose individuals to higher loads and degenerative changes. These results may also help explain why conservative treatments such as quadriceps strength training may improve functional capacity and reduce pain in osteoarthritic individuals.

SUMMARY

Because the individuals in this study were healthy, the results cannot be attributed to any rival or adaptive factors (injury or surgery) to produce these outcomes. Thus, based on these preliminary results, quadriceps weakness can be considered an independent risk factor for increased adductor during gait. From these data, we speculate that muscular weakness may be a significant risk factor in the initiation and progression of knee joint OA.

Figure 1: Time series plot of knee adductor moment pre and post-effusion. Negative values = adductor while positive values = abductor moments; Black = pre-effusion, gray = post-effusion conditions.

LIGAMENT AUTOGRAFT CELLS DO NOT DIE BY APOPTOSIS

Kate Leatherbarrow, Ian Lo, Linda Marchuk, David Hart and Cyril Frank
McCaig Centre For Joint Injury and Arthritis Research, Calgary, Alberta, Canada
cfrank@ucalgary.ca

INTRODUCTION

Following reconstruction, tendon grafts undergo a modification process involving cell death, revascularization and repopulation of the graft with cells of extrinsic origin, and remodeling (Amiel and Kuiper 1990). Because cells are responsible for maintenance and production of the extracellular matrix, cell death may be in part responsible for grafts being replaced by scar-like tissue, resulting in inferior mechanical properties (Spindler et al. 1996). The purpose of this study was to characterize changes in cellularity of and early ligament autograft and determine if any cells undergo apoptosis.

METHODS

Thirteen New Zealand White rabbits were used. The rabbit MCL autograft was used in this study because it represents an idealized ligament reconstruction, being fresh, extraarticular and anatomical (Sabiston et al. 1990). In the right leg of each experimental animal, the femur-MCL-tibia graft was surgically removed, rinsed in saline, and orthotopically reinserted in the harvest site (Sabiston et al. 1990). Two animals each were sacrificed at time points 4,7,10,14 and 21 days post operatively, as well as 3 normal controls. 6µm paraffin sections were analyzed for *in situ* DNA fragmentation, indicating apoptosis, using the TUNEL assay (Gavrieli et al. 1992) (ApopTag kit, Intergen Co., NY). Nuclei were counterstained with DAPI (Vectashield, Vector Laboratories, CA) and slides were viewed by fluorescence microscopy. Positive controls showed 100% positive staining.

RESULTS AND DISCUSSION

Few apoptotic cells were observed in the normal MCL (Fig. 1A,B). In the 4 day graft, cellularity was similar to the normal ligament with few apoptotic cells (Fig. 1C,D). After 7 days, large acellular areas were observed (Fig. 1E,F), and after 10 days, new cells began to infiltrate the graft. By 21 days, the grafts were repopulated with round cells and were becoming revascularized (Fig. 1G). Apoptosis was observed these repopulating cells as well as in the infiltrating blood vessels (Fig. 1H).

These results suggest that although a dramatic loss of cellularity took place in these grafts, this was apparently not due to apoptotic mechanisms. However, new cells infiltrating the MCL did demonstrate apoptosis. Determining which subset of the infiltrating cells die by apoptosis and which survive to form the mature graft may lead to a better understanding of the mechanical deficiencies of the remodeled graft (Sabiston 1990), and therapies to improve the quality of ligament reconstructions.

Figure 1: TUNEL assay for apoptosis

Figure 1: Normal MCL (A,B) and MCL autografts at 4 (C,D), 7 (E,F) and 21 days (G,H) post-surgery. A,C,E,G are DAPI nuclear counterstained and B,D,F,H are corresponding FITC labeled images for apoptotic cells (Magnification = 100x).

SUMMARY

This study confirms that the early loss of cellularity in fresh rabbit MCL autografts is not due to apoptosis, but that cells repopulating the graft during healing do exhibit apoptotic activity. We speculate that this will be true of other dense connective tissue grafts as well. Further understanding of the biologic processes following graft reconstruction may lead to novel therapeutic interventions, improving the mechanical integrity of all mature grafts.

CYCLIC HYDROSTATIC PRESSURE INCREASES BOTH MMP-1 AND MMP-3 mRNA LEVELS, IN MG-63 OSTEOBLAST-LIKE CELLS UNDER SERUM FREE CONDITIONS.

Vitomir Tasevski, Jovina M. Sorbetti, Nigel G. Shrive and David A. Hart.
McCaig Centre for Joint Injury and Arthritis Research, Faculty of Medicine,
University of Calgary, Alberta, Canada. vtasevsk@ucalgary.ca

INTRODUCTION

The skeleton is exposed to mechanical forces of varying types and degrees. Individual cells respond to these biomechanical stimuli in different ways. The MG-63 osteosarcoma cell line is a commonly used model of human osteoblasts, producing both osteocalcin and bone specific alkaline phosphatase (Lajeunesse, D. et al). The effect of cyclic hydrostatic pressure (HP) on DNA, RNA and specific mRNA levels for both Matrix Metalloproteinase-1 and 3 (MMP-1, MMP-3) was investigated to determine whether HP alters overall osteoblast metabolism and viability, or whether it affects the expression of specific genes involved in bone remodeling.

METHODS

Cells were routinely maintained in DMEM F-12, containing 10% Fetal Calf Serum (FCS). Cells were seeded into NUNC 6-well plates at 2×10^5 cells per well, grown for 2 days in complete media, intensively washed, and maintained in serum free medium, for 20 hours. They were then transferred to a purpose built pressure chamber and subjected, at 37°C, to 30 cycles of cyclic HP for one minute (0-0.8 MPa) followed by 14 minutes at atmospheric pressure (total time = 4 hours). Control cells were maintained in either serum free or complete growth medium, at 37°C, for 24 hours. DNA was solubilised with DNAzol and quantified using absorbance measurement (260 nm). RNA was extracted using Trizol and a QIAGEN RNeasy kit, quantified using SYBRgreen fluorescence measurement and reverse transcribed (QIAGEN Omniscript). Polymerase chain reaction (PCR) was performed on 30 ng of cDNA, with primers directed against human Glyceraldehyde-3-phosphate dehydrogenase GAPDH, MMP-1 and MMP-3. PCR product separated on 2% agarose gels and visualised with ethidium bromide. RFLP Scanalytics software was used to calculate integrated density values for the genes in question. An unpaired t-test with unequal variances was used in the statistical evaluation.

RESULTS AND DISCUSSION

When MG-63 cells were deprived of FCS for a period of 24 hours the quantity of both DNA and RNA measured was significantly reduced ($p < 0.001$) compared to those cells maintained in complete growth media. There was, however, no significant change in DNA/RNA ratio. When MG-63 cells were subjected to cyclic HP for the last 4 hours of a 24 hour serum free incubation, the quantity of both DNA and RNA as well as DNA/RNA ratio was unchanged compared to serum free control cells (Table 1).

Condition.	DNA μ g/well	RNA μ g/well	DNA/RNA Ratio
10% FCS	28.5 \pm 9.12	11.3 \pm 0.60	2.46
Serum free	14.6 \pm 2.36	4.85 \pm 1.32	3.01
Serum free (HP)	17.1 \pm 2.26	5.29 \pm 2.36	3.23

Table 1. Quantity of DNA (μ g), RNA (μ g), and DNA/RNA ratio. Data expressed as Mean \pm 2 SD per well (n=3).

Detected mRNA for GAPDH, MMP-1 and MMP-3 in complete growth media was designated to be 100%. Serum free conditions (24 hours), resulted in a significant decrease ($p < 0.001$) of mRNA for MMP-1 and MMP-3. Cyclic HP for the last four hours of the 24 hour serum free incubation, significantly increased ($p < 0.001$) mRNA for both MMP-1 and MMP-3, with no change seen for GAPDH (Figure 1). The percentage increase was similar for MMP-1 and MMP-3. No change in the expression of transcription factors Cbfa1, c-fos or c-jun was detected under these conditions (data not shown). Whether specific sites within the promotor regions encoding MMP-1 and MMP-3 are sensitive to HP, requires further investigation.

Figure 1. mRNA (Mean \pm SEM) for GAPDH, MMP-1 and MMP-3 in (A) 10% FCS medium, (B) Serum free medium and (C) Serum free medium under hydrostatic pressure (n=6).

SUMMARY

The data indicate that specific mRNA expression of MMP-1 and MMP-3, in MG-63 cells, is increased following exposure to intermittent HP. DNA and RNA as well as mRNA levels for GAPDH, however, remained constant. These results are consistent with the proposal that *in vivo* mechanical loading can profoundly effect osteoblast gene expression and bone remodeling.

INTRODUCTION

The doubled hamstring tendon (HT) graft has been widely used in anterior cruciate ligament (ACL) reconstruction. Several investigators, however, have reported that this graft fixed with sutures has some disadvantages compared to the BTB graft. One of them is that the stiffness of the femur-graft-tibia (FGT) complex with the HT is lower (Yamanaka et al.). To increase the stiffness of the FGT complex with the HT, a new fixation procedure with the Bone-Mulch-Screw/WasherLoc (BMSW) system has recently been developed, and the biomechanical properties immediately after surgery was evaluated by To et al. However, biomechanical behaviors of the FGT complex reconstructed using this system during and after cyclic loading have not been clarified. In order to understand these biomechanical behaviors, Numazaki et al. showed the importance of initial graft tension as a mechanical condition. The purpose of this study is to clarify the effect of initial graft tension on biomechanical behaviors of the FGT complex reconstructed with the doubled flexor tendon (FT) graft and the BMSW system, during and after cyclic elongation.

METHODS

Based on our previous study (Yamanaka et al.), a porcine ACL reconstruction model was used in this study. In this model, a pair of digital FT was trimmed so that their cross-sectional area became 7 and 14 mm², respectively. Twenty-one porcine knees were used. In each knee, ACL reconstruction was performed with the doubled FT graft, which was fixed using the BMSW system (Arthrotek, Naples, FL). Then, the FGT specimens were randomly divided into 3 groups (n=7 in each group). For the 3 groups, a tensile load of 20 N, 80 N, and 140 N, respectively, was applied to the graft for 2 minutes as an initial graft tension. Then, cyclic elongation of 2 mm was applied 5000 times to the FGT complex at 0.2 Hz. Finally, each FGT specimen underwent the tensile failure test at a crosshead speed of 50 mm/min. Statistical comparisons were made using a one-way ANOVA and Fischer PLSD tests.

RESULTS

(1) The peak load values at the first cycle were significantly different among the 3 groups (Fig. 1). The peak load rapidly decreased during the first 1000 cycles in each group. At the 5000th cycle, we found a significant difference in the peak load between the 20-N and 80-N groups, while there were no significant differences between the 80-N and 140-N groups. (2) After cyclic elongation, the initial stiffness (the slope in the toe-region of the load-displacement curve) of the FGT complex in the 20-N group was significantly lower than that in the 80-N and 140-N groups, while there were no significant differences between the latter two groups (Fig. 2). The magnitude of the

initial graft tension did not significantly affect the linear stiffness or the ultimate failure load of the FGT complex (Fig. 2).

DISCUSSION

The present study demonstrated, first, that the cyclic elongation significantly affect biomechanical behaviors of the FGT complex reconstructed using the HT and the BMSW system under each initial tension. Secondly, an increase of initial graft tension from 20 N to 80 N significantly increased the peak load at the 5000th cycle and the initial stiffness of the FGT complex after cyclic elongation. However, an increase of initial tension from 80 N to 140 N did not significantly affect any mechanical parameters after cyclic elongation. Therefore, the increase of initial tension beyond 80 N has no biomechanical benefits for ACL reconstruction using this system.

INTRODUCTION

It is necessary to clarify functional characteristics of various fibroblasts in order to make progression in tissue engineering for the tendon and ligament tissues. Recent studies have shown that fibroblasts repopulating in the skin wound are phenotypically distinct from normal dermal fibroblasts (Schaffer et al.). Few studies, however, have been conducted to clarify the difference in functional characteristics between the fibroblasts repopulating in the necrotized tendon, which are commonly observed in the tendon autograft, and the fibroblasts that exist in the normal tendon. The purposes of this *in vitro* study were: 1) to compare infiltrative characteristics of the repopulating fibroblast (RF) and the normal fibroblast (NF) derived from the patellar tendon (PT), and 2) to compare the effects of the fibroblast infiltration on mechanical properties of the PT matrix between the RFs and the NFs.

METHODS

A total of 36 skeletally mature rabbits were used in this study. **Isolation of fibroblasts:** In 18 animals, the right PT was frozen *in situ* with liquid nitrogen to kill intrinsic fibroblasts of the tendon (Ohno et al). Subsequently, only the RFs repopulated in the right PT, and only the NFs existed in the left PT in each animal at 6 weeks. Each tendon was harvested and incubated in DMEM with 10% FBS for 2 weeks. Thus, the RFs and the NFs were separately obtained from these explants. Cells at the first passage were used for all experiments. ***In vitro* infiltration into the matrix:** The cultured RFs and NFs were seeded into collagen gel so that the concentration became 5×10^6 cells/ml. The bilateral PTs were harvested from the remaining 18 rabbits, and underwent the *in vitro* freeze-thaw treatment using liquid nitrogen. Thus, we prepared a total of 36 acellular PTs. Then, each PT was sharply divided into 3 thin PT matrix specimens (1x2x15mm) along with the long axis. The 3 specimens were implanted into the 3 types of collagen gel clot, in which the RFs, NFs, and no cells (Control) were seeded, respectively. **Evaluation:** Twelve (36 specimens) out of the 36 PTs were evaluated at 1, 3, and 6 weeks after implantation, respectively. At each period, 6 (18 specimens) out of the 12 PTs were analyzed using a confocal laser microscope (CLM), and we counted the total number of cells scattering in a unit volume (750 x 500 x 25 μ m). The remaining 6 PTs (18 specimens) were used for tensile testing to determine the mechanical properties. The strain was measured with a video dimension analyzer.

RESULTS

(1) Infiltration of the RFs was limited only in the superficial portion of the specimen at 6 weeks, while the NFs infiltrated into the deep portion at the same period (Fig. 1). Cells were not

observed in the control specimens. The total number of the NFs significantly increased over time, but that of the RFs did not significantly change (Fig. 2-a). The total number of the RFs was significantly less than that of the NFs at each period. (2) Tensile testing showed that there were no significant differences in the elastic modulus among the specimens involving the RFs, those involving the NFs, and those involving no cells (Fig. 2-b).

DISCUSSION

This study demonstrated that the *in vitro* infiltrative ability of the RF into the tendon matrix is significantly lower than that of the NF. However, infiltration of the RFs and the NFs did not significantly affect the elastic modulus of the tendon matrix. Our previous *in vivo* study showed that the RFs infiltrated into the deep portion of the *in situ* frozen-thawed PT at 6 weeks, and that the infiltration significantly deteriorated the mechanical properties of the tendon matrix (Tohyama et al). These drastic differences between the *in vitro* and *in vivo* studies imply that some unknown factors that exist only in the *in vivo* condition may affect infiltrative characteristics and functions of the RF.

INTRODUCTION

The central one-third portion of the patellar tendon (PT) is resected to obtain a substitute for ligament reconstruction. Many studies have shown that the space made by the resection is filled with a regenerated fibrous tissue. However, much remains unknown on biomechanics of the PT that underwent the segmental resection. In previous biomechanical studies on this issue, the regenerated tissue and the residual tendon were not distinguished. Our recent study using a rabbit model, however, has clarified that the mechanical properties of the residual tendon significantly deteriorate at 6 weeks, and that the properties of the regenerated tissue remarkably improve over time, reaching the properties similar to the residual tendon (Tohyama et al. 2001). Then, we should ask what effects mechanical environments give to the regenerated tissue and the residual tendon. The purpose of this study is to clarify the effect of overloading applied to the PT that underwent the segmental resection of its central one-third portion on the mechanical properties of the regenerative tissue and the residual tendon.

METHODS

A total of 32 skeletally mature female rabbits (3.0 ± 1.0 kg) were used. In each animal, we surgically made a full-thick defect at the central portion of the right PT (3-mm wide and 15-mm long). In the left PT, we performed the *sham* operation. After this treatment, the animals were divided into two groups ($n=16$, each), and they were allowed unrestricted activities in their cage. At 3 weeks after the first operation, the medial portion of the right PT was additionally resected in Group 1 in order to overload the remaining tendon portion and the regenerated tissue. In Group 2, the sham surgery was performed at the 3-week period. Again, they were allowed unrestricted activities in their cage. At 6 and 12 weeks after the first operation, 8 rabbits were sacrificed for mechanical testing. Before sacrifice, the blood-flow in the regenerated tissue was measured with a laser Doppler flowmeter. In each rabbit, we longitudinally divided the patella-tendon-tibia complex (PTTC) specimen into 2 portions, the regenerated tissue and the residual (lateral) tendon. For each PTTC specimen, a tensile test was performed with a tensile tester. Strain was measured using a video dimension analyzer.

RESULTS

In Group 1, the blood flow was $225 \pm 34\%$ and $213 \pm 47\%$ of the sham-operated tendon at 6 and 12 weeks, respectively, while it was $194 \pm 106\%$ and $140 \pm 47\%$, respectively, in Group 2. The ANOVA showed that blood flow was significantly greater in Group 1 than in Group 2 ($p=0.039$), while there were no significant differences between the periods. Concerning the

tensile strength and the modulus of the residual tendon, these parameters of Group 1 were significantly lower than those of Group 2 (Fig. 1). Regarding these parameters of the regenerative tissue, there were no significant differences between Groups 1 and 2 (Fig. 2).

DISCUSSION

This study demonstrated, first, that overloading significantly deteriorated the mechanical properties of the residual tendon. This result is supported by our previous study on the effect of overloading on the PT (Yamamoto et al. 1999). Secondly, the present study showed that overloading did not significantly affect the mechanical properties of the regenerated tissue. The results suggest that the responses to overloading are significantly different between the regenerated tissue and the residual tendon. The difference may be caused by functional differences of fibroblasts that exist in the regenerated tissue and the residual tendon. As to clinical relevance, excessive overloads should be avoided in the early phase after harvesting the central one-third portion of the PT for ligament reconstruction.

BIOMECHANICAL ANALYSIS OF THE EFFECTS OF A POWER CLEAN PROGRAM ON THE FIRST STEP OF THE SPRINT START

Kyle Patterson, Estelle Abdala, Mitell Sison and Alan Hreljac
Biomechanics Laboratory, California State University, Sacramento, California
Communicating Author: kyle_patterson@hotmail.com

INTRODUCTION

The purpose of this study was to examine the effects of a power clean training program on biomechanical aspects of a sprint start out of the starting blocks for novice sprinters. If the effects of the power clean training program are significant, then coaches at the high school and college level could consider using a systematic power clean training program as a part of their strength and conditioning programs.

METHODS

The subjects used in this study were 10 active healthy novice male sprinters ages 20-25 ($M=22.7 \pm 1.9$ y). The participants were split into an experimental group and a control group, each with five subjects. Three days prior to and following the experimental treatment (six week power clean training program), kinematic and kinetic data were collected on all subjects performing the sprint start in the Biomechanics Lab at CSU Sacramento.

RESULTS AND DISCUSSION

Findings suggest that the power clean training program increases the vertical and propulsion ground reaction forces. In addition, the velocity of plantar flexion was increased. According to Young et al. (1995) increase in velocity and increase in GRF lead to a decrease in the propulsion phase of sprinting. This decrease in propulsion phase is needed to increase speed. Thus, the power clean training program could increase speed.

Figure 1: Maximal vertical force for both groups from pretest to posttest. The * represents significance increase from pretest to posttest.

The experimental group showed a significant increase between pretest (683 ± 47 N) and posttest (716 ± 60 N) for the maximal propulsion force. Experimental group showed a significant increase between pretest (1548 ± 78 N pretest vs. 1651 ± 97 N posttest) and posttest maximal vertical force (Figure 1) while there were no differences between the pre- and posttests of the control group. This showed a relationship between GRF and leg strength. Young et al. (1995) established a positive relationship between leg strength and sprinting speed. Therefore, it can be suggested that the power clean training program would have a positive effect on sprinting speed.

SUMMARY

The power clean training program attributed to the increased ground reaction forces of the experimental group as demonstrated by the increase in the vertical force, which can be due to the development of the knee extensors and the plantar flexors.

More power generated by the legs would lead to an increase in ground reaction forces. Statements by Harman (1994) support Weyand et al. (2000) and this study by supporting the development of strength of sprinters and thereby increasing the ground reaction forces as found in this study. Takano (1992) stated that power cleans are important to the development of speed, which may be why the experimental group subjects significantly increased their plantar flexion velocity. Thus, a power clean training program could lead to an increase in speed.

Young et al. (1995) found that more leg strength is essential for increased GRF, which could lead to an increase in speed. This study demonstrates that a power clean training program could lead to increases in ground reaction forces during a sprint start. It is assumed that the training program increased the strength of the experimental group, but is not known because EMG and isokinetic testing were not performed.

NUMERICAL STUDY ON THE FLOW CHARACTERISTICS IN A PARTIALLY OBSTRUCTED TUBE WITH THE COMPLETE BYPASS GRAFT

Tzu-Hsiang Ko

Department of Mechanical Engineering, Lunghwa University of Science and Technology, Taiwan, R.O.C
Associate Professor, thko@mail.lhu.edu.tw

INTRODUCTION

The coronary bypass surgery is usually operated on the patients with severe or moderate stenosis in their coronary arteries. The bypass graft is implanted on the obstructed host artery and induces blood to flow bypass the obstruction. In order to resolve the flow characteristics in the graft and host arteries, many investigators performed studies on the flow phenomena from the hemodynamic view points. In the earlier researches, the end-to-side anastomosis flow model was most frequently employed (Hofer et al., 1996; Ethier et al., 1998). In such a model, the host artery was assumed to be 100%-area severity stenosis, and the “end” was to simulate the completely obstructed wall while the “side” was to simulate the subsection of the bypass graft. Uniform or paraboloid velocity distributions were specified at the side inlet and only the flow fields in the subsections of the bypass and the host artery were analyzed. However, the bypass graft is usually with curvature. The flow entering the bypass graft will be influenced by the curvature and become complex flow patterns accompanied with secondary flow. Neither the uniform nor the paraboloid velocity distribution assumed at the bypass inlet is precisely correct. On the other hand, when the coronary bypass surgery is operated, the stenosis may not be exactly 100%-area severity in the host artery. Blood may still be possible to pass through the contracted region of the host artery as well as flow through the bypass graft. To implement more realistic situations, further investigations on the anastomotic flow with the complete bypass graft and the partially obstructed host artery should be worthwhile. The present paper investigates the flow characteristics in a model composed of the complete bypass graft and a 90%-area obstructed host tube.

METHODS

The geometry of the model is shown as Fig. 1. The flow is assumed as three dimensional, incompressible, laminar and steady. The continuity equation and the Navier-Stokes equation are solved numerically by SIMPLEC scheme. The grid layout is also shown in Fig.1. Uniform velocity distributions are assumed at the inlet and the fully developed condition is assumed at the outlet.

RESULTS AND DISCUSSION

Fig. 2 shows the flow fields on the symmetric plane and three selected slices of the model. Some fluids flow through the contracted area with very high speed. The velocity can be as high as twice of inlet velocity. The calculated results show that only about 14% inlet mass flows through the contracted area

of the host tube, and 86% inlet mass flows through the bypass graft. Four low velocity regions can be found on the flow fields. They distribute on the lower front region of the contracted area, the upper and lower regions downstream of the contracted area, and the entrance of the bypass graft. The recirculations which appear in the four low velocity regions are closely relevant to the blood flow rate. In the entrance region of the bypass, the larger velocity occurs at outer side of the bypass, and as the flow develops toward the downstream, the larger velocity flow transfers toward the inner side of the bypass. This result clearly comes of the curvature effect. The velocity fields shown on the slices A, B and C indicated the development of the secondary flow structures. These flow characteristics prove the assumptions of the uniform or paraboloid flow distribution at the bypass inlet which were made in the end-to-side model are not precisely correct

Fig. 1 The geometry and grid layout of the model

Fig. 2 Velocity distributions (Normalized by inlet velocity)

SUMMARY

The flow characteristics of the complete bypass graft and the partially obstructed host tube are investigated. The flow fields consists of one recirculation zone in the bypass graft and three recirculation zones in the host tube. The secondary flow structure appears in the bypass graft because of the curvature effect. This makes the velocity distribution in the bypass is neither uniform nor paraboloid which is usually assumed in the end-to-side model. The present study provides more realistic information of the flow fields.

FLOW-INDUCED MORPHOLOGICAL CHANGE OF ENDOTHELIAL CELL AND SHEAR STRESS DISTRIBUTION ON THE SURFACE OF THE CELL

Shuichiro Fukushima¹, Hideki Fujioka², and Kazuo Tanishita¹

¹Institute of Biomedical Engineering, Keio University, Yokohama, Japan, fuku@tani.sd.keio.ac.jp

²Biomedical Engineering Department, University of Michigan, MI, USA

INTRODUCTION

Endothelial cells elongate and align due to flow exposure (Levesque and Nerem, 1985). Considering microscopic flow characteristics at individual cell level, which are defined by the cell surface geometry, the morphological change of the cells seems to be adaptive response (Barbee et al., 1995; Fukushima et al., 2001; Satcher et al., 1992; Yamaguchi et al., 2000). To address the mechanisms for the adaptive response, it is necessary to examine how the mechanical environment changes by the adaptation process. Therefore, we measured cell surface geometry during flow exposure, and determined shear stress distribution on the surface.

METHODS

Cultured bovine aortic endothelial cells were subjected to steady flow by using parallel-plate flow chamber. The flow induced macroscopic shear stress of 1.5 Pa on the cell surface when the surface was assumed to be flat. During the flow exposure, the same group of cells was tracked, and the surface geometry of the cells was measured by using confocal laser scanning microscopy (Fukushima et al., 2001).

Flow field near the measured cell surface was simulated by computational fluid dynamics (CFD). To simulate the conditions in the parallel-plate flow chamber, constant nominal shear rate was applied at inflow plane of computational domain so as to maintain a 1.5 Pa wall shear stress at bottom plane.

RESULTS AND DISCUSSION

At the beginning of the flow exposure, the shape of the cells in the confluent condition was polygonal without alignment. After 24 h, cell motility was changed, and the number of elongated cells was increased. The direction of migration was not necessarily the same as that of the macroscopic flow, but is always influenced by the surrounding cells. After 30 h, the number of cells aligned with the direction of the macroscopic flow. Mean height for the 13 cells (Fig. 1) was decreased after 30 h (24 h: $3.2 \pm 1.4 \mu\text{m}$, 30 h: $3.2 \pm 1.5 \mu\text{m}$, 36 h: $2.9 \pm 1.3 \mu\text{m}$).

With such morphological change, mean shear stress for the 13 cells was decreased with time course (24 h: $1.91 \pm 0.57 \text{ Pa}$, 30 h: $1.81 \pm 0.59 \text{ Pa}$, 36 h: $1.78 \pm 0.61 \text{ Pa}$). However, there were some cells on which mean shear stress for each cell was increased, and morphological change of each cell was not always adaptive. The results show the importance of interaction with surrounding cells for the adaptive response as cell layer.

GAIT ANALYSIS AFTER TRIPLE ARTHRODESIS

WL. Wu¹, YM. Cheng², PJ. Huang²

¹Department of Physical Therapy, Foo-Yin Institute of Technology, Taiwan, sc100@mail.fy.edu.tw

²Department of Orthopedic Surgery, Kaohsiung Medical University, Taiwan

INTRODUCTION

Triple arthrodesis is a procedure that fuses the subtalar joint, talonavicular joint, calcaneocuboid joint. At the follow-up examination, Beischer et. al. have found the abnormal moment and power generation at the ankle and decreased angular range of motion in ankle and ipsilateral knee joints are associated with triple arthrodesis. It seems that triple arthrodesis may influence biomechanic mechanics of lower limbs. For more precisely evaluate the potential biomechanic mechanics, the goal of this proposal is to utilize gait analysis combined with foot pressure analysis to study movement disorders after triple arthrodesis.

METHODS

In total, 10 triple arthrodesis surgery cases were recruited for the experiment. The HIRE ExpertVision motion analysis system (Motion Analysis Corporation), an AMTI force platform (Advanced Medical Technology, Inc., Newton, MA) and Pedar foot pressure system (Novel gmbh, Germany) were used in this study. Twenty-one simplified point (Helen Hays) marker set for full body gait analysis was used in OrthoTrak analysis. Joint kinematics and kinetics were computed. In addition, foot contact patterns were recorded using insole pressure system. The database of age-matched normal subjects built in OrthoTrak package was obtained for comparison. Repeated measures analysis of variance was used to compare the differences in the kinematic and kinetic parameters. Differences were considered significant when the P value was less than 0.05.

RESULTS AND DISCUSSION

A clinically apparent valgus alignment of the heel was found in all patients. In temporal/spatial parameters, significant difference between normal subjects and surgical patients were identified. A significantly longer (12%) support time, an increased (11%) step length and a reduced walking velocity (21%) were observed on the patients' feet ($P < 0.05$). We found there are significant differences between patient group and control group in the ankle dorsi/plantarflexion. On the other hand, there were not significant differences between sound side and affected side in surgical group. The range of motion of the surgical group was significant less than the normal group in ankle dorsi/plantarflexion ($p < 0.05$). On average, it was reduced by 9° (50%) compared with the normal group. From the result of passive range of motion examination, we supposed that loss of bilateral ankle range of motion in sagittal plane was not a consequence of a mechanical block to this motion. The passive range of motion was significant larger than the active range of motion in ankle dorsi/plantarflexion. The motions of the ankle joint in coronal plane (Pro/supination) are shown in Figure 1. It

was observed that there are high variations in affected side of the foot, it may present the non-homogeneity in triple arthrodesis gait patterns. It meant that there are more than one pattern existed in the pathological pro/supination movements. During the latter two thirds of the stance phase of gait, the subtalar joint normally inverts (supinated). This locks the transverse tarsal joint and creates a rigid forefoot. For the "Supinated group" patients with triple arthrodesis, motion of the ankle joint in the coronal plane indicated an increase in inversion (supination) before toe-off, progressing to a relatively neutral or slightly everted position shortly before heel strike. Contrarily, motion of the ankle joint in the coronal plane for "Pronated group" patients increased in varus (pronation) direction through whole gait cycle. At toe-off phase, the subtalar joint normally reaches peak inversion. These motions create an effective lever arm through which the triceps surae can exert its action. It explained why the abnormal posture of the arthrodesed foot diminished peak of gastrocnemius-soleus power generation. Our studies also have confirmed that the group of hindfoot supination often results in symptomatic force concentrations beneath the medial metatarsals, whereas hindfoot pronation produces increased lateral metatarsal weightbearing. It is because that the forefoot rotates relative to the hindfoot for maintaining universal metatarsal contact with the floor.

Figure 1: The angular motions of ankle joint in coronal plane. Upper layer: There are high variations in affected side; Lower layer: There are two patterns existed in the pathological pro/supination movements.

SUMMARY

Our results offer objective and quantifiable information to monitor the surgical effect through comparison of analytic and objective parameters.

INTRODUCTION

CAD/CAM in prosthetics only offers controlled socket reproduction technique based on conventional method. Finite element (FE) method, when introduced to a CAD/CAM system, can provide quantitative feedback prior to socket manufacturing. The objective of this paper is to develop a FE model from geometry data acquired from a commercial CAD system, to optimise the modelling time and to validate the modelling technique using a test object.

METHOD

Cylindrical shaped test object was fabricated from viscous RTV silicon. The test object has a co-axial, cylindrical stainless steel mandrel. The test object and mandrel were scanned separately at 1mm layer thickness. An integration program (i-Link), developed in-house, reads CAD model data and parameter files containing load, boundary conditions and material properties in batch mode (Figure 1). It then automatically refines the CAD geometry, maps the parameter data on to the refined geometry and generates FE codes for optimized meshing in ANSYS.

Figure 1: Schematic of the FE modeling and validation process

Effect of different volume layer thickness to describe the geometry was also checked.

The FE model consists of 8-noded hexahedral elements, with 13600 nodes and 10900 elements utilized for the model based on a 5mm volume layer thickness. The Silicon test object material properties was described as M-R hyper-elastic with $C_{01} = -2.013e-3$ and $C_{10} = 2.782e-3$ Mpa. Standard properties ($E=210$ GPa, $\nu=0.31$) were used for the stainless steel mandrel. Vertical loading of 700N was introduced via the proximal section area of the mandrel. Fixed nodal boundary condition at the test object's surface was assumed.

The physical test object was mounted in the UTM machine (Instron-8874) and loaded vertically. Twelve specially constructed strain gauge type transducers distributed uniformly along the socket length in the 4-quadrant captured the pressure. Data were captured at

peak load of 700N. Measured pressure values were compared with the FE predictions from models with different volume layer thickness.

RESULTS AND DISCUSSION

Table 1 shows that interface pressure patterns predicted by the FE model of the test object under vertical loading were similar to the measured patterns.

		Measured (kPa)	Predicted (kPa)	% difference
Anterior	proximal	45.95	45.89	-0.13
	middle	77.82	78.12	0.39
	distal	103.68	108.23	4.39
Posterior	proximal	44.21	45.97	3.98
	middle	80.79	79.56	-1.52
	distal	119.29	114.76	-3.80
Medial	proximal	46.17	43.12	-6.61
	middle	91.76	80.32	-12.47
	distal	104.14	110.45	6.06
Lateral	proximal	53.24	48.92	-8.11
	middle	79.71	80.74	1.29
	distal	114.54	112.82	-1.50

Table 1: Comparison of FE predicted and measured pressure (based on 5mm layer thickness model)

Figure 2 shows the comparison of prediction between models developed with two different volume layer thicknesses.

Figure 2: comparison of predicted values for different volume layer thickness (corresponding to front view)

A comparison between the different layer thickness models revealed that predictive ability improved with finer volume layer. However, the computational time increased significantly (Table 2), which may be a cause of concern when coupled with CAD system.

Volume layer thickness	Computation time (min)	Comparison with experimentally measured values			
		Over estimation		Under estimation	
		no. of sites	Max. (%)	no. of sites	Max. (%)
4mm	23	6	6.32	6	8.28
5mm	17	5	6.06	7	12.47
10mm	14	2	1.03	10	17.75
15mm	10	-	-	12	23.05
20mm	9	-	-	12	29.77
					RMS of % difference
					4.805
					5.458
					8.377
					11.467
					19.228

Table 2: Effect of layer thickness on predictive ability

A finite element model was successfully developed from direct CAD data using an integration program. The model was able to predict interface pressure with reasonable accuracy (<10% error). Hence, efficacy of the FE model generation technique from CAD data was demonstrated and can be further integrated with prosthetic CAD system.

BIOMECHANICS OF TRANSTIBIAL PTB AND PCAST PROSTHETIC SOCKETS

James CH Goh, Peter VS Lee, SY Chong, S Das De

Department of Orthopaedic Surgery, National University of Singapore, SINGAPORE

INTRODUCTION

Difficulties are faced by many prosthetists in consistently producing satisfactory socket fit. Some major causes arise from inadequate training and experience of the prosthetist in the patellar-tendon-bearing (PTB) socket technique. In 1965, Murdoch¹ introduced a pressure-casting concept where fluid was used to apply uniform pressure around the stump, which produced the Dundee socket. However, an indentation to the patella tendon was implemented. In 1968, Gardner² introduced a pneumatic pressure sleeve that wrapped the entire stump during cast taking. Kristinsson³ used the same pressure casting concept by using air as a medium in the Icelandic Roll On Silicone Socket (ICEROSS) system. Rectifications were done by adding padding over the bony areas of the stump during the casting process in a non-weight bearing fashion i.e. not standing. The theory supporting these various attempts in pressure casting techniques is known as Pascal's principle of fluid dynamics. This concept of using hydrostatic pressure still raises many questions in the prosthetic field today. Using similar pressure casting technique, a pressure cast (PCast) system was developed. This system produces a socket without any rectifications. In this study, a comparison between the PCast and PTB sockets was done using stump/socket interface pressure.

METHODOLOGY

Five unilateral transtibial amputees volunteered for this study. Figure 1 shows the PCast setup. The PCast system requires the patient to place his stump in a pressure chamber. He was requested to stand in this normal standing position without any aid. Pressure was applied to the stump. A positive mould was then generated without any rectifications and the final socket fabricated using traditional lamination methods. PCast and PTB test sockets with 16

Figure 1: Subject with stump in PCAST tank.

measurement sites each was made for each subject. The sites were basically openings made in the socket to allow pressure transducers to be mounted such that contact can be made with the stump. The pressure transducer assembly which includes a load cell manufactured by Entran International, USA was similar to that described in Lee et al⁴. The pressure transducers were connected to the VICON 370 3D motion analysis system in conjunction with 2 Kistler force platforms. Pressure and gait data were acquired simultaneously when the subjects were standing and walking at each subject's self-selected speed.

RESULTS AND DISCUSSION

In general, pressure magnitudes were lower in the PCast socket than the PTB socket. Furthermore, the PCast socket exhibited less pressure concentration i.e high pressure at specific areas.

This is expected, as the PCast socket had no rectifications done while the PTB socket made use of certain pressure tolerant

areas for weight bearing. From the pressure profiles, two main observations were made. The first group had higher pressure concentration at the distal end in the PCast socket or higher pressure concentration at the proximal brim in the PTB socket. The second group had similar pressure profile in both sockets especially at toe-off (refer to Figure 2).

Figure 2: Anterior-posterior pressure profile of subject #1 exhibiting similar pressure profile (left) and subject #2 exhibiting high pressure profile at the proximal brim in the PTB socket (right) at toe-off.

The first group exhibited similar results to a study done by Convery et al⁵ on one subject who exhibited a 'ring' of high pressure near the patellar tendon 'bar'. However, in the second group, the hypothesis to 'let nature determine the most realistic and achievable pressure distribution' may hold true; though reasons on why it does not occur in all subjects need more research. But one big advantage in this PCast technique is removing all manual dexterity and inter-prosthetist variances. While the PCast and PTB sockets belong to two different schools of thought, it is still difficult, at this time to conclude which is the best socket as there are constant dynamic forces at work in a socket during gait. There are still questions on the mechanical stability and internal dynamics of the limb, enclosed and acting in such an environment³. The best socket will be the one that suits a patient's activity level, stump condition and rehabilitation needs.

INTRODUCTION

Ankle sprains are one of the most common sports injuries. In particular, lateral ligament injuries such as those of anterior talofibular ligament (ATF) and calcaneofibular ligament (CF) cause ankle instability and may lead to cartilage damage. Several biomechanical studies have described the kinematics (Cass, et al., 1984; Siegler, et al., 1996) and contact pressure distribution (Driscoll, et al., 1994; Christensen, et al., 1994) of the talocrural joint. Nevertheless, few studies have evaluated both kinematics and contact pressure under dynamic conditions. The purpose of this study was to evaluate changes in 3-D dynamic motion and contact pressure distribution in the ankle joint before and after an ATF and CF cut. We also assess the efficacy of the Aircast (Airstrip Ankle Brace, Summit, NJ/USA) on correcting ankle instability.

MATERIAL AND METHODS

Five fresh frozen musculoskeletally intact cadaveric ankles were examined. Each ankle including all of the associated soft tissue was mounted on a specially designed frame that preserved five degrees of freedom motion. The direct linear transformation (DLT) technique was used to measure the 3-D motion of the talocrural joint, and an electric conductive rubber sensor was inserted into the talocrural joint space to determine the contact pressure distribution. The ankle joint was tested from 15 degrees of dorsiflexion to 15 degrees of plantarflexion under application of an axial tibial force 100 N. Four different experimental conditions were examined in succession for each ankle: 1) intact, 2) ATF cut (ATF (-)), 3) CF cut (Both (-)), and 4) with Aircast (Air). A paired t-test was used for statistical analysis and $p < 0.05$ was defined as the level of significance.

RESULTS

The intact talus pronated with dorsiflexion. After an ATF cut, a significant increase in supination was observed for each flexion angle in comparison with the intact ankle. Supination significantly increased after a combined ATF/CF cut in comparison with after an ATF cut alone. The angle of talus pronation with the Aircast was close to that of the intact ankle, and no significant differences were observed in motional properties under the two conditions (Fig.1). For all other motion parameters including abduction-adduction, anterior-posterior translation, and medial-lateral translation, no

significant changes were observed under the four experimental conditions.

The area of contact on the talus for intact ankle moved anteriorly and laterally with increasing dorsiflexion. A similar trend in contact area movement was observed after an ATF cut. However, an area of high pressure was observed in the medial aspect of the articular surface. A similar tendency was demonstrated after a combined ATF/CF cut. However, no significant changes were found in the contact characteristics following the Aircast.

Figure 1: Pronation-supination angle at: (a)10 degrees plantarflexion, (b)Neutral position, (c)10 degrees dorsiflexion.

DISCUSSION AND CONCLUSIONS

The present results showed an increase in supination after a lateral ligament cut and medial shift in the high contact pressure area on the articular surface. These findings demonstrate the mechanics of talus cartilage injury after ankle sprain. Abnormal increases in supination angle after a lateral ligament cut were recovered by the Aircast, which suggests its clinical utility.

FINITE ELEMENT STUDY OF TROCHANTERIC GAMMA NAIL FOR SUBTROCHANTERIC FRACTURE

INTRODUCTION

A trochanteric gamma nail (TGN) is widely used for trochanteric and subtrochanteric fracture fixation. The fracture in the subtrochanteric region shows higher biomechanical stresses than the fracture occurring in the trochanteric region, which may result in a higher failure rate of the implant. This study aimed to investigate the mechanical performance of a TGN fixation of subtrochanteric fracture by a finite element method. Five different locations of the transverse subtrochanteric fracture were determined, starting from the lesser trochanter and more distally with an interval of 10 mm. For each of these fracture locations, the stress distributions in the TGN were evaluated. Analyses were also performed for different conditions of fracture, i.e. stable and unstable types of fracture.

METHOD

A three-dimensional FEM of the proximal femur was created from the average geometry derived from CT-scans of 108 Thai cadaveric femora. Four-noded tetrahedral elements were used to build up the mesh of the proximal femur and the TGN. Linear elastic isotropic material properties were assigned to all materials involved in the model. Different material properties were attributed to different femoral regions and stainless steel was assigned to the material properties of the TGN. The performance of the TGN in the unstable condition is evaluated by assigning a low E-modulus value to the fracture zone. The femoral model was fully fixed at the distal end (no displacement). The one-legged stance load configuration was used in this study. The load condition consisted of a joint reaction force applied to the femoral head and an abductor muscle force applied to the greater trochanter.

Fig. 1 FE model of subtrochanteric fractures and TGN

RESULTS AND DISCUSSION

The results showed that the average Von Mises stress at the distal locking screw hole in the nail has a trend to increase with the fracture location occurring closer to the distal locking screw hole in both stable and unstable fracture conditions, while the stress magnitude in the lag screw hole does not significantly change in the stable fracture condition but it has a trend to decrease in the unstable condition. This is due to the improper functioning of the lag screw when the fracture occurs more distally and closer to the distal locking screw hole.

Fig. 2 Average Von mises stress in the TGN

SUMMARY

From the results, it can be concluded that

1. The distal locking screw hole is the critical region in the TGN for the fixation of a low subtrochanteric fracture as the stress at the distal locking screw hole under one-legged stance exceeds the UTS of stainless steel (1.100 MPa), therefore leading to a possible failure of the nail.
2. The stress magnitude in the TGN for the fixation of an unstable subtrochanteric fracture is usually higher than for a stable subtrochanteric fracture.
3. The following modifications at the distal part of the nail can be suggested: changing into a solid nail or reducing the size of the distal locking screw hole and the distal locking screw.

BEHAVIOR OF MEDIAL GASTROCNEMIUS MUSCLE-TENDON COMPLEX DURING DIFFERENT TYPES OF JUMPING

Masahiro Suzuki¹, Ken Nemoto¹, Sadao Kurokawa², Masamitsu Ito¹
¹Nippon Sport Science University, Tokyo, Japan itom@nittai.ac.jp
²Joshi University of Art and Design, Tokyo, Japan

INTRODUCTION

The purpose of this research was to determine the role of tendinous structures during jumps with counter-movement by observing the behavior of the muscle-tendon complex (MTC) using real-time B-mode ultrasonography.

METHODS

Six healthy males participated in the present study as subjects. They performed following four different vertical jumps:

- 1) counter movement jump from the standing position (CMJ),
- 2) squat jump starting at the lowest position in CMJ, (SJcmj)
- 3) drop jump from the height of 20cm (DJ),
- 4) squat jump starting at the lowest position in DJ (SJdj).

Kinematic, kinetic, electromyographic and ultrasonographic data were collected during the movements.

The movements were filmed at 250Hz with a high speed digital video camera. Ground reaction force was recorded using a force platform. From these data, joint moment and power around the ankle (M_a and P_a , respectively) were computed through a link segment model.

Longitudinal ultrasonic images of the medial gastrocnemius (MG) were scanned using a B-mode ultrasound device with a 7.5MHz probe (Figure 1). These images were scanned at 60Hz and stored in a built-in cinememory of the device for 400ms before the take-off, while they were recorded on videotapes at 30Hz for 600ms from 1s to 400ms before the take-off. Fascicle lengths (L_f) and pennation angles (α) were measured using NIH-image software.

MTC length (L_{MTC}) of MG was estimated from knee and ankle joint angles (θ_k and θ_a , respectively) using the equation proposed by Grieve et al.(1978). Tendinous structure's length (L_t), moment arm length (r), MG tendon force (F_t^{MG}), MG muscle force (F_m^{MG}) were calculated as follows;

$$L_t = L_{MTC} - (L_f * \cos\alpha)$$

$$r = \Delta L_{MTC} / \Delta\theta_a$$

$$F_t^{MG} = k^{MG} * (M_a / r)$$

$$F_m^{MG} = F_t^{MG} / \cos\alpha$$

, where k^{MG} represents the ratio of physiological cross sectional area of MG among plantar flexors.

RESULTS and DISCUSSION

Vertical jump heights of CMJ ($0.44 \pm 0.05m$) and DJ ($0.40 \pm 0.05m$) were significantly higher than those of SJcmj ($0.40 \pm 0.05m$) and SJdj ($0.31 \pm 0.04m$), respectively.

Figure 1 Ultrasonic image of MG.

Figure 2 Changes in L_f during DJ and SJdj. A: Landing during DJ; B: onset of the ankle angle change increase during SJdj; C: onset of the ankle angle increase during DJ.

Behaviors of MTC, fascicle and tendon structure during CMJ were similar to those of SJcmj. There was no significant difference in peak joint power. In DJ, MTC and tendon structures were rapidly stretched immediately after landing, while such a phenomena was not observed in the other jumps. During MTC lengthening in DJ, fascicles were actually shortening at relatively slow velocities (Figure 2). Although elastic energy stored was greater in CMJ and DJ compared with their counterparts, released energy during tendon shortening was greater in SJcmj and SJdj. It could be concluded that jumps with counter movements were advantageous, partly because fascicles could use their higher force regions of force-velocity relationship by virtue of tendon elastic properties during jumps with counter movements.

⁴Department of Orthopedic Surgery, Showa University

INTRODUCTION

Anterior lumbar interbody fusion (ALIF) cages have been accepted as suitable spinal fusion devices for laparoscopic surgery. Since two-ALIF cage insertion is the most common surgical procedure, many studies have been reported on the stabilizing potential of two-cage insertion, indicating that the stability of instrumented specimen was at least the same as that of intact specimen (Kanayama et al., 2000; Tzantrizos et al., 2000). However, little research has been done on effects of the number and direction of inserts on the stability (Tencer et al., 1995). The objective of this study is to examine the change in stiffness with the number and direction of ALIF cages toward reducing operation time and minimizing invasion for ALIF surgery.

MATERIALS AND METHODS

Fourteen fresh porcine functional spinal units of L4-5 and L5-6 levels were retrieved and stored at -20°C in plastic bags until testing. They were dissected of muscle and fat tissues, leaving the intervertebral discs and the osteoligamentous structures intact. After drilling a pilot hole into the disc manually, a threaded interbody fusion cage (Hollow Modular Anchorage, AESCLAP, Germany) was inserted. The cage configurations tested were as follows: (1) a single cage placed centrally and anteriorly, (2) a single cage placed laterally, (3) two cages placed anteriorly, and (4) a single cage placed anterolaterally. Each vertebral body of implanted specimen was fixed in a stainless pot with dental plaster. The bottom pot was secured to the lower base of an Instron-type material testing machine. The top pot was connected to a specially designed loading device, which consisted of pulleys, wires and rod joints and transferred an upward motion of the position-controlling platform of the testing machine to flexion, extension, lateral bending and axial rotation. Maximum torque applied with an axial compression of 70N was 2.5Nm for flexion, extension and lateral bending while 4Nm for axial rotation. Angular motions were detected using a video dimensional analyzing system.

RESULTS

Figure 1 shows the stiffness achieved by the four different cage configurations and the intact stiffness. In flexion, a single cage constructed laterally or anterolaterally and two cages placed anteriorly had significantly higher stiffness than intact, and the single-cage construct was stiffer in anterolateral than

in anterior. In the other loading modes, no significant differences were observed in stiffness between instrumented and intact specimens and among the four configurations of construction.

Figure 1: Mean values and standard errors of stiffness for intact and implanted specimens (* $p < 0.05$ vs intact; # $p < 0.05$ vs Ant-1).

DISCUSSION AND CONCLUSIONS

Significant increase in stiffness observed only for flexion implies that the placement of ALIF cage enhanced anterior support for flexion. On the other hand, since the facet joints played a dominant role in the kinematics of the spine for the other loading modes, the effect of cage insertion was negligible when compared with flexion. There was no significant difference between the anterior two-cage and the anterolateral single-cage constructs. Therefore, although this study addresses only the initial stiffness afforded by different ALIF cage configurations, it is concluded that the anterolateral single-cage construct should be further investigated for clinical implementation.

EFFECT OF CONSTRICTION GEOMETRY ON TRANSIT OF DEFORMED NEUTROPHILS IN CAPILLARIES

INTRODUCTION

On the average, neutrophils are significantly less deformable than erythrocytes and, once they are deformed, they require considerable time to recoil to their initial spherical shape. For this reason, initial cell shape influences the transit time of neutrophils through constrictions in narrow capillaries. In this research, the flow of a neutrophil in a capillary with two constrictions was investigated numerically, in terms of the transit time of the cell through the second constriction after it had been deformed by passing through the first one.

MODELING AND NUMERICAL PROCEDURE

In this research, numerical analysis was performed in an axisymmetric cylindrical coordinate system to obtain the flow of a neutrophil through two constrictions in a cylindrical capillary. The neutrophil was initially a sphere with a radius of 4 μm and was modeled as a Maxwell interior bounded by a thin isotropic elastic membrane. Shear modulus and viscosity of the interior were 186 Pa and 31 Pa·s, respectively. The membrane was pre-stressed and the cortical tension was 3.1×10^{-5} N/m. Since the thickness of the membrane was set at 1 nm and Young's modulus was 10^{-4} Pa, the tension could be treated as an interfacial surface tension between the cell interior and the surrounding plasma. The Poisson ratio of the interior was set at 0.4999.

The capillary segment was a straight cylinder, 5100 μm in length and 6 μm in radius, with two constrictions. The shape of each constriction was an arc, the ratio of the length to the height being 8:1. The throat radius, $R_{\min 1}$ and $R_{\min 2}$, of each constriction was chosen from 2.50, 2.75 and 3.00 μm , respectively. The center of the first constriction was set 100 μm downstream of the upper end of the segment and that of the second one was set at the distance L_c downstream of the center of the first constriction. To mimic the endothelial layer of the constrictions, an imaginary vessel wall was set in each constriction 0.1 μm apart from the actual wall. Plasma flowed through this wall, but the cell was deformed along the surface.

Plasma is an incompressible Newtonian fluid with a viscosity of 1.2×10^{-3} Pa·s and a density of 1.03×10^3 kg/m³. No-slip conditions were assumed at the vessel wall and the cell surface. Pressure of 0 Pa was prescribed for the upstream boundary of the capillary segment, with a pressure drop, ΔP , of 40 Pa along the segment. Adhesion of the neutrophil to the endothelium was not considered here.

RESULTS AND DISCUSSION

Figure 1 shows the time required by the deformed neutrophil to pass through the second constriction. Broken lines are the transit times of spherical cells. In this figure, the transit times approach these lines as the distance L_c between the two constrictions increases, since the cell gradually recoils to its initial spherical shape during on its way to the second

constriction after it has passed the first one. The effect of the throat radius $R_{\min 1}$ of the first constriction on the transit time is large for the small throat radius $R_{\min 2}$ of the second constriction and for L_c .

In a previous study (Huang et al. 2001), transit time of neutrophils passing through the pulmonary capillary network was investigated. The transit of each neutrophil was modeled based on blunt-ended micropipette experiments on spherical neutrophils there. Our last research study (Shirai et al. 2001) showed that the inlet geometry of the pipette affects the transit time and denoted that actual transit can be shorter than that obtained by the micropipette model. In addition to that result, the present result suggests that the transit time of neutrophils passing through the pulmonary network may be much shorter due to the non-spherical shape of the cell entering the second constriction.

SUMMARY

Transit time of a neutrophil through the second constriction after it had been deformed by passing through the first one was investigated numerically. It was clarified that the maximum radius of the deformed cell greatly affects the transit time.

INTRODUCTION

Recently, an increasing number of attempts to adapt multimedia communication to medical care have been reported. It is our belief that while high technology may be necessary for medical practice, spiritual support is more important in medical care. Therefore, we proposed the concept of a Hyper Hospital to offer patients a means of effective human communication during medical care. The original Hyper Hospital was a novel medical system constructed on a computer and multi-media based network, in which the major human-machine-human interface was a virtual reality dedicated to the patients. In the present study, we describe a home-care-type telemedicine network, a recent development in the Hyper Hospital project, based on various modern mobile telecommunication technologies.

Fig.1: Hyper Hospital Network

The Hyper Hospital network is composed of numerous networked units, such as local health care authorities, regional nursing care units, high-tech medical centers, etc., as shown in Fig. 1. Each unit in the network contains its own networks. The network within the home is designed as a combined inter-network with special tasks or functions. These include the collection of information regarding the patient's physiological condition and behavior, and control of a variety of support facilities in the house. Every functional unit in the network is equipped with a server function that allows information to be broadcast over the network using HTTP protocols. The network system has a unified user interface, based on a WWW interface.

INUTA-NET: ONE FUNCTIONAL UNIT

A functional unit is a general term that we use to describe equipment that is connected to an in-house local area network (LAN); each functional unit acts as a server and provides various types of medical and technical support. Face-to-face communication is the best way to obtain information from patients and make them feel at ease. One of the functional units developed to implement this is an electronic pet called the "INUTA-net" (INU means "dog" in Japanese). The INUTA-net is a semi-automatic robot that looks like a toy dog, and is equipped with monitoring and communication interfaces (Fig. 2). It provides remote interactive facilities to monitor a patient, and is controlled by a combination of distant caretakers and family or friends through the network. The design principle of this system is that patients can be monitored closely without introducing nervous or mental stress. The patients

may even enjoy themselves, playing with the 'pet' or talking with people remotely, such as doctors, family members, or friends, by using the INUTA-net communication facility.

Fig.2: INUTA-net

Fig.3 :Web page

A sample web page is shown in Fig. 3. To ensure privacy, all users must provide their usernames and passwords when accessing this page. The picture at the center of the display is a monitor screen from the CCD camera on the INUTA-net. The INUTA-net and the CCD camera can be controlled by clicking on the buttons shown below the screen: the left button moves the INUTA-net, and the right button operates the camera. The INUTA-net has 3 computers, a control PC, a network-managing PC, and a computer built into the camera. All of the computers have server ability, and each constitutes an internal network, using a TCP/IP connection. In this way, the load of each PC can be reduced, and functions can be substituted or added easily. In this study, three additional functions were developed and implemented. First, an emergency alert system was added to allow the patient to report his or her own unusual situation by sending a report in a mail appended to the CCD camera picture. Second, a user identification system was implemented to allow a patient to identify anyone accessing the system. Third, an LCD monitor was included, located in front of the INUTA-net shown in Fig. 2, to display the access log for the system, which provides information such as the frequency and duration of users' access to the Web page. Two logs are displayed: one for the username, and the other for the access time.

CONCLUSIONS

The INUTA-net functional unit was successfully controlled over the Internet through a WWW interface. It is therefore possible to build a home-care telemedical system for the mental and spiritual support of users that allows maximum freedom, and a flexible network construction that can grow and be modified according to the patient's needs.

³ Communicating author, erei@fluidmech.tu-graz.ac.at

INTRODUCTION

Performance in many sports is determined not only by the motor abilities of the athlete, but to a large extent by aerodynamic features of the athlete's body and his equipment (Schmölzer, Müller 2002; Hanna 1996). The aerodynamic problems to be solved with human bodies in the air flow are a challenging task: Both approaches, wind tunnel measurements and computational fluid dynamics (CFD), have to be applied carefully when results with high accuracy are to be obtained. In order to point out the basic problems, we study the aerodynamic characteristics of a simple flat plate by means of wind tunnel measurements and CFD. The same approach can be applied to objects with complex geometries, including human bodies. The accuracy of the lift and drag coefficients obtained with the relevant objects of a particular sport determines the prediction accuracy of flight path calculations.

METHODS

Wind tunnel measurements have been performed in a Göttingen type tunnel of Graz University of Technology. This tunnel has a cross section area of $2 \times 1.5 \text{ m}^2$ and allows wind speed up to 40 m/s. For CFD calculations FLUENT, a CFD-program with finite volume approach has been used. The influence of inaccuracies in lift and drag measurements on the flight path prediction in ski jumping is reported here exemplarily, using a computer model approach that has been described recently (Müller et al 1995, 1996; Schmölzer, Müller 2002).

RESULTS AND DISCUSSION

The classical results of Flachsbart (1932) for drag and lift coefficients of a flat plate (length 1m, aspect ratio 5:1) are taken as reference and are compared with present results (Figure 1). The velocity distribution around the flat plate calculated with CFD is shown in Figure 2. For example, the increase of lift values by 1% throughout the flight phase for the simulation of a ski jump at the new jumping hill in Innsbruck resulted in a jump length increase by 2.5 m. Deviations of lift and drag value measurements depend on wind tunnel blockage effects and interferences between model and mounting devices. These effects determine the accuracy of wind tunnel measurements. Mathematically, the flow field is described by the Reynolds Averaged Navier-Stokes equations (RANS) which exhibit major inherent difficulties. The CFD approach leads to approximated solutions for velocity, pressure and density distributions. The prediction accuracy depends on various factors of influence, e.g. the boundary conditions and especially the applied turbulence model.

Figure 1: Lift (c_L) and drag (c_D) coefficients versus angle of attack - experimental results for the 5:1 flat plate.

Figure 2: CFD simulation: 5:1 flat plate at 44.7° angle of attack. Free stream velocity $U_0 = 30 \text{ m/s}$; $c_D = 0.94$; $c_L = 0.94$

EFFECTS OF CYCLIC STRAIN ON OX-LDL UPTAKE INTO MACROPHAGES

Hiroshi Miyazaki¹, Junzo Tanaka¹, Shinya Nakagawa², and Kozaburo Hayashi¹

INTRODUCTION

Macrophages (M ϕ) play an important role in the initiation and development of atherosclerosis. M ϕ differentiated from monocytes in the intima take up such modified LDL as oxidized LDL (ox-LDL) and, then, turn into foam cells. These M ϕ are always subjected to cyclic strain induced by pulsatile blood pressure. Because cyclic strain affects the morphology and the phagocytosis for latex particles of M ϕ (Miyazaki and Hayashi, 2001), it should also have an influence on the formation of foam cells. In the present study, M ϕ attached to silicone rubber sheet were cultured under the cyclic strains of 5 and 10 % amplitudes, and the effects of strain on ox-LDL uptake were studied.

MATERIALS AND METHODS

Peritoneal M ϕ were obtained from 6-week old female C57BL/6J mice 4 days after the intraperitoneal injection of 3% thioglycollate. They were washed with Ca²⁺- and Mg²⁺-free Hanks' balanced salt solution (HBSS) and, then, were suspended in RPMI-1640 medium supplemented with 10% FCS and antibiotics.

Silicone rubber sheets were placed in a tissue culture dish after making their surface hydrophilic by the treatment with sulfuric acid, and the above-mentioned cell suspension was poured into the dish. After 2 hour preincubation at 37°C, the sheets were rinsed with HBSS to remove non-attached cells. The M ϕ were cultured for 24 and 48 hours under 5 % cyclic strain (S(5)-24h and S(5)-48h groups, respectively), or 10 % strain (S(10)-24h and S(10)-48h groups, respectively) at 1 Hz frequency, or under no strain (NS-24h and NS-48h groups, respectively) at 37°C. Then, the M ϕ of S and NS groups were cultured in a medium containing ox-LDL for another 2 hours under the same strain and no strain conditions, respectively. Control data were obtained from the cells which were cultured with ox-LDL for 2 hours immediately after the above-mentioned preincubation (C group). A negative control group cultured for 2 hours without ox-LDL was also prepared (NC group).

After culture, the cells adhered to each sheet were stained with Oil-Red O. The numbers of the attached cells and stained cells, and the area occupied by lipids were determined in three different areas using an optical microscope and an image analyzer.

RESULTS AND DISCUSSION

The number of attached cells per 1 mm² was smaller in S group than in NS and C groups. Cyclic strain decreased the number of attached cells, and this change was significant at 48 hours. This result suggests that some M ϕ were detached from the sheets by strain. However, there were no significant differences in the numbers of stained cells among all the groups except for NC group; the number of stained cells was much smaller in NC group than in the other groups. The percentage of stained cells was significantly larger in S group than in NS and C groups. There were no significant differences in the percentage between S(5) and S(10) groups. The area occupied by lipids was larger in S group than in NS and C groups, although the differences were not significant. No significant differences were observed between S(5) and S(10) groups. These results indicate that cyclic strains of 5 and 10 % amplitude have almost the same effects on ox-LDL uptake into M ϕ , and suggest that the effects of cyclic strain is saturated at or less than 5 % amplitude.

SUMMARY

Effects of the magnitude of cyclic strain on ox-LDL uptake into murine peritoneal M ϕ were assessed after they were cultured under the cyclic strain conditions of 5 and 10 % amplitudes at 1 Hz frequency for 24 and 48 hours. Cyclic strain enhanced ox-LDL uptake into M ϕ regardless of strain magnitude. However, there were no significant differences in the percentage of lipid accumulating cells and in the area occupied by lipids between 5 and 10 % strain groups.

A QUANTITATIVE ASSESSMENT OF KNEE EXTENSOR SPASTICITY USING ISOKINETIC DYNAMOMETER

Duk Hyun Sung, MD. PhD., Sang Yong Kim, MD., Hee-Dong Park, MD., Soo Jin Yoo, MPE.
Department of Physical Medicine and Rehabilitation, Sungkyunkwan University School of Medicine,
Samsung Medical Center, Seoul, Korea. dhsung@smc.samsung.co.kr

INTRODUCTION

Mechanical pendulum test has been used to quantify spasticity. But velocity dependent increase in tonic stretch reflex, which is a critical characteristic of spasticity, cannot be evaluated with the pendulum test. The purpose of this investigation was to determine the biomechanical parameter to quantify the degree of spasticity that would be useful in the clinical setting.

METHODS

Knee extensor muscles of 60 limbs of 47 patients, which were spastic by clinical modified Ashworth scale (MAS), were studied. The muscle was stretched by a isokinetic dynamometer (Cybex 6000®, Cybex Inc. USA) 5 times with the each velocity of 60°/sec, 120°/sec, 180°/sec, 240°/sec in the range of 0~90° of knee and generated eccentric torque during stretch was measured. Each subjects was asked to relax as much as possible during test period. Four parameters (torque onset angle(TOA), peak torque angle(PTA), peak torque(PT), peak torque area(PTA)) were measured at each stretch velocity (fig 1). Then, linear regression analysis was performed in relationship between each parameter and stretch velocity to find the slope of the linear regression curve. This slope, which reflects the sensitivity to the rate of stretch, was compared with clinical modified Ashworth scale using a Spearman's correlation coefficient.

RESULTS

The slope of TOA and PTA had negative value so that they showed the decreasing trend of their value as stretch velocity increased. On the other hand the slope of PT and PTA had positive value that meant that the slope increased as stretch velocity increased.

The slope of PT and PTA were positively and significantly correlated with clinical MAS score ($p<0.05$). However the slope of the TOA and PTA showed poor correlation with clinical MAS (table 1).

Figure 1. Definition of torque onset angle(TOA), peak torque angle(PTA), peak torque(PT), peak torque area(PTA)

SUMMARY

As clinical degree of spasticity increases, eccentric resistive torque generated by knee extensor increases. The slope of peak torque and peak torque area in linear regression curve between each parameter and stretch velocity can be useful parameters in quantify spasticity of knee extensor.

GAIT ANALYSIS AND ENERGY CONSUMPTION OF NEW DESIGN PROSTHESIS WITH BELOW KNEE AMPUTEES: A PILOT STUDY

Gwo-Feng Huang ,You-Li Chou ,Fong-Chin Su, and Pei-His Chou

Institute of Biomedical Engineering of National Cheng Kung University ,Tainan, Taiwan
Division of Orthopedic Surgery, Kaohsiung Medical University, Kaohsiung ,Taiwan

INTRODUCTION

This study use new is to design a prosthesis equipped with an air cooling system so that the sweat due to high temperature and humidity inside the socket can be reduced. There is a fan with 5cm diameter at the below part of socket which is controlled by a humidity sensitive circuit. The fan switch (power FET2SK2134) will operate and draw out the humid air inside the socket when the humidity inside the socket is beyond 80% relative humidity (RH). The maximal velocity is 0.45m/sec and measured in experiment. The humid air will come out through the holes on the pylon. The fan turned off when the humidity drop to a comfort level again. The purpose of this study is to find out the characteristic of new prosthesis design for clinical physicians and prosthetists reference. Scientifically measure was used the dynamic gait characteristics of the amputee by using motion analysis and to measure the energy consumption for the below-knee amputee when wearing the solid ankle cushion heel (SACH), single axis and multiple axis prosthetic feet.

METHODS

Twenty male unilateral, including 15 right and five left, transtibial amputees were selected as subjects for this study. The 20 subjects tested were divided into two groups, a vascular group and a traumatic group. Using a six-camera motion analysis system, the subjects walked at a self-selected comfortable walking speed for three trials. Energy consumption was detected while walking by metabolic measurement cart. Subjects walked on the treadmill few times for trial and warm up. When subjects' HR reached 60% of the maximum HR (220-Age), measurements of energy consumption parameters were started to record for a minimum of 2 min. Subjects walked on the treadmill at speeds of 1,1.5 and 2 miles per h on slopes of grades 0 , 4 and 8 with the three kinds of prosthetic feet. Subjective results are additionally determined via questionnaire after testing.

RESULTS AND DISCUSSION

The results of motion analysis showed statistically significant differences at $P < 0.05$ between the vascular and traumatic groups in the linear measurements of velocity, cadence, stride length and single limb stance.

Hip, knee and ankle joint motion of three new socket type prostheses were also analyzed via motion analysis and significant differences ($p < 0.05$) were found in the sound side and prosthetic side. Motion analysis system and two forceplates are used to analyze the ground reaction force when heel strike and toe off. There are significant difference

between sound side and prosthetic side at heel strike but not at toe-off with three types of prosthetic (Fig.1). Comparing the HR, respiratory rate (RR) and energy consumption rate, traumatic group is more efficient than vascular group (Table 1). According to the result of questionnaire, multiple axis feet are the most comfortable type and single axis feet are the next. SACH type is the worst ones in comparison with the two types mentioned above.

Fig. 1:The average vertical ground reaction forces that occur shortly after contact (n=20) The prosthetic limb is compared to the sound limb to evaluate symmetry for each prosthetic foot.

Table 1:Energy consumption parameters collected during 2 minutes of walking averaged across all feet tested.

Energy parameters	Traumatic	Vascular	Control	p-value
HR	110.2±8.26	127.3±10.23	108.6±6.35	0.001*
O2 pulse	0.16±0.03	0.12±0.02	0.17±0.02	0.001*
RR	22.3±1.75	27.56±2.28	21.18±2.56	0.001*
Energy rate	12.3±2.18	17.17±1.86	10.38±2.23	0.005*
RER	0.82±0.07	0.92±0.08	0.81±0.05	0.017*

SUMMARY

Using the quantitative measures of motion analysis, some significant differences were found in kinetics and kinematics of the new design prosthesis with various feet tested. These data provide information about the dynamic performance of the various feet, which can be helpful in prescribing the optimal prosthetic foot for individual amputees.

CFD STUDIES OF THE INTRAVENTRICULAR DIASTOLIC FLOW FOR THE ANALYSIS OF COLOR M-MODE DOPPLER ECHOCARDIOGRAMS

Masanori Nakamura¹, Shigeo Wada¹, Taisei Mikami², Akira Kitabatake³, Takeshi Karino¹

Hokkaido University, Sapporo, Japan, nakamura@bfd.es.hokudai.ac.jp

INTRODUCTION

A color M-mode Doppler echocardiogram (CMD) is a spatiotemporal map of flow velocity along one axis and has been applied to clinical evaluation of the left ventricular (LV) diastolic function. We carried out a CFD study of intraventricular flow during early diastole to analyze a relationship between the intraventricular flow and the LV diastolic function, and to clarify how this relationship is reflected on a CMD.

METHOD

The geometry of the luminal surface of the LV at its maximum expansion is determined so that it approximates the general anatomy of a human LV. For simplicity, it is assumed that the geometry is symmetric with respect to the bisector plane of the mitral and aortic orifices, and that the crosssection of the LV obtained by cutting it with a plane radiated out from the line of intersection of the planes containing the two valve orifices is ellipsoid.

The ventricular wall is moved under two assumptions; 1) the movement of the ventricular wall is not affected by the intraventricular blood flow, and 2) a point on the wall moves in the direction of a line connecting the point and the centroid of the crosssection of the LV obtained by the same manner as described above. A spatial distribution of the moving velocity of the wall is fixed throughout the simulation, and it is set that the moving velocity of the wall takes the maximum at the apex and decreases as going away from the apex to the mitral and aortic orifices.

Computer simulations of intraventricular flow during early diastole are carried out for the cases of the LVs with a normal diastolic function and a poor diastolic function by giving large and small volume changes to the LV, respectively. As an initial condition, blood in the LV is assumed to be at a standstill. After advancing a time step and giving a volume change to the LV model, a further expanded model is constructed. The Navier-Stokes and continuity equations are solved by the use of ANSYS-FLOTRAN ver.5.6 (distributed by Cybernet Systems Co. Ltd., Tokyo). As boundary conditions, zero pressure is given to the LV entrance, and a moving velocity of the wall is applied to the ventricular wall based on a non-slip condition. This process is repeated until the time reaches the end of early diastole ($t = 0.24$ sec).

RESULTS AND DISCUSSIONS

Regardless of the diastolic function of the LV, there is the formation of an annular vortex that surrounds the inflow via the mitral orifice and constricts it. Figure 1 shows instantaneous streamlines of the intraventricular flow at a late

stage of early diastole ($t = 0.20$ sec). A comparison of the size and position of the vortex between Fig. 1 (a) and (b) shows that the vortex in the LV with a normal diastolic function is larger and its center is closer to the apex.

A spatiotemporal map of the inflow velocity expressed in the same manner as CMD obtained from the CFD results for each case is shown in Fig. 2 (a) and (b). A blue region indicates the region where the velocity of fluid elements is larger than 70% of the spatiotemporal maximum velocity in the early diastolic phase, called aliasing area. It is clearly seen that the aliasing area for the LV with a normal diastolic function is sharply elongated compared to that for the other case.

The annular vortex forming in the LV narrows and constricts the passage of inflow and helps the fluid elements in the inflow maintain their velocities even when coming in the cavity of the LV. With the development of the vortex, the constricted point of the inflow moves towards the ventricular apex, causing a shift of the high-velocity portion of the inflow towards the apex. This appears as elongation of the aliasing area in CMD. These results suggest that a clinical diagnosis of the LV diastolic function with CMD is based on evaluation of the development of the intraventricular vortex during early diastole.

DYNAMIC STRESS ANALYSIS OF THE ARTERIAL WALL WITH FINITE ELEMENT MODELING

Shervin Ghasemi Majd¹, Mohammad Tafazzoli Shadpour¹, Albert avolio²

¹Department of Biomedical Engineering, Amir Kabir University of Technology (Tehran Polytechnic), Tehran Iran, tafazoli@cic.aku.ac.ir

²School of Biomedical Engineering, The University of New South Wales, Sydney, Australia

INTRODUCTION

Cardiovascular diseases are among leading causes of death. Increase of mechanical tensile stress in the arterial wall leads to an altered arterial function, and structural degeneration. This investigation aimed to determine distribution of arterial wall tensile stress due to a harmonic internal pressure.

METHODS

Finite element modeling was used to evaluate Von Mises stress distribution in a typical model of cross section of human aorta with differing mechanical parameters and arterial wall structures. The applied pressure was sinusoidal in the range of 80-120 mm Hg with the frequency of 60 bpm to simulate physiological pulse for a healthy human being. The model included a 10 degree section of the aortic wall with appropriate boundary conditions to allow the modeling of the entire arterial wall cross section with radial expansion. The model consisted of 2440 elements, 7550 nodes with 8 node quadratic 2D elements and plane strain conditions.

RESULTS AND CONCLUSION

Results showed a general decrease in maximum Von Mises stress on the luminal side compared to the static analysis. This decrease was 23%, for the arterial pulse of 60 bpm, and Young's modulus of elasticity (E) of 300 KPa. The stress profile showed a maximum value (S_{max}) on the luminal side and a minimum value on the adventitia side. An increase in E resulted in an increase of S_{max} value with a non-linear trend (Figure 1).

With the introduction of viscoelastic modulus to the model, a further decrease in the amplitude of the resultant stress wave was observed. Figure 2 shows a typical profile of maximum and minimum values of the Von Mises stress caused by the sinusoidal pressure. A ratio of C/E (the ratio of viscoelastic modulus to elastic modulus) equivalent to 12.5% resulted in a phase lag of 5.4 degrees between applied pressure and deformation, and for the value of 31.4% this was elevated to 14.4 degrees.

It can be concluded that in the stress analysis of the arterial wall, the effects of dynamic pressure and material properties should be considered. It is recommended that a fatigue analysis based on the stress results of application of dynamic pressure may contribute to a better understanding of arterial dysfunctioning with age and hypertension.

Figure 1: Effects of Young's modulus of elasticity of arterial wall on maximum Von Mises stress with a harmonic blood pressure.

Figure 2: Von Mises stress profiles across arterial wall caused by maximum and minimum values of pressure wave.

INTRODUCTION

Tissue engineering technologies has widely been applied to develop artificial bone tissues for the treatments of bone fractures and other skeletal diseases. Among the parameters which affect in vitro bone regeneration, mechanical stimuli have been considered to be a key factor. In this study, we examined the effect of an applied cyclic compressive strain on the growth and differentiation of mouse osteoblast-like cells (MC3T3-E1) cultured in 3-dimensional chitosan scaffolds.

METHODS

MC3T3-E1 cells, a mouse osteoblast-like cell line, were grown in α -minimal essential medium containing 10% fetal bovine serum (FBS), 100 μ g /ml penicillin-streptomycin. Cells were maintained in a humidified incubator at 37°C with 5% CO₂, 95% air and were subcultured every 3 days. For mechanical stimuli studies, these cells were seeded to 3- dimensional chitosan scaffolds (Regen Biotech. Inc., Seoul, Korea).at 1 \times 10⁶ cells/scaffold.

A cyclic compressive strain was applied to the specimens using a specially-designed testing apparatus which also allows the cells to be simultaneously visualized using an inverted microscope. The cyclic compressive strain (2.5%) was applied over a period of 17 days with 150 cycles per day at a frequency of 0.5Hz. Image processing methods are utilized for taking image at indicated times and detecting a level of cell deformation. The amount of protein and alkaline phosphatase activity were evaluated for the degree of differentiation and proliferation at the indicated times (day 4, 7, 10, 14, 17).

Total protein was estimated for finding the level of cell proliferation using Bredford method and alkaline phosphatase was estimated for knowing the time of cell differentiation using a commercially available kit (Sigma, USA).

RESULTS AND DISCUSSION

The total amount of protein produced in the control group was higher than the mechanically stimulated group. This was due to cell death for the nodule formation of the mechanical stimuli group which resulted from cell differentiation. During the MC3T3-E1 cell differentiation, alkaline phosphatase was used as a mark of osteoblast differentiation. The alkaline phosphatase activity increased slightly in the control group, however, no statistically significant maximum point was

observed. In the mechanical stimuli group, it increased significantly and reached its peak level on day 7, statistically significant maximum point ($P < 0.05$), which represents the beginning of cell differentiation. Nodule formation have also been observed through the microscope since day 7. Conclusively, it could be noted that the effects of the differentiation in the mechanically stimulated group was significant.

Figure 1. The amount of total protein produced by cells.

Figure 2. The alkaline phosphatase activity of cells.

SUMMARY

In this study, an osteoblast-like cell line was cultured in 3-dimensional chitosan scaffolds and a cyclic compressive strain was applied to this scaffold. The effects of the mechanical stimuli were significant in the cell proliferation and differentiation process as well as calcification process.

INTRODUCTION

Lipoatrophia Semicircularis (LS) is a highly characteristic dermatosis, which represents as semiannular depressions from loss of subcutaneous fat, symmetrically distributed on the anterolateral aspects of both thighs, and occurs predominantly in young women (De Groot 1994).

In literature different causes are postulated. Bloch and Runne (Bloch and Runne 1978) state that semicircular lipoatrophy represents an ischemic atrophy of the fatty tissue, manifested by repeated microtraumata (corners of wash-basins, dressing tables or desks). De Groot (De Groot 1994) suggests that pressure from a chair on the posterior aspect of the thighs, possibly in combination with direct pressure from a desk on the anterior aspect, caused the condition in these patients. More recently Hermans et al. (Hermans, Hautekiet et al. 1999) found remarkable posture differences between the LS group and the group without LS were found: less use of the lumbar support of the chair, static sitting postures and a too high seat surface of the office chair were characteristics of the subjects with LS. These observations were confirmed by higher pressure measurements for the subjects with LS. The common aspect of all studies is that some relation is made with the mechanical load of the thighs and LS.

Aim of the present study is to gain insight into the factors that play a role in the mechanical load of the anterolateral thighs in relation with different ways of body support by different office chairs.

METHODS

A simple biomechanical model shows that the load on the seat that is mainly concentrated at the ischial tuberosities is effects in an extra load of the anterolateral thighs (figure 1).

Figure 1. Pressure and shear on the buttocks effects in tension on a small area on the upper leg (elipse).

The hypothesis is that this extra tension in the proximal part of the upper thigh will result in deformation of the tissue and as a result of that a reduction of the blood flow.

The blood flow was measured as skin oxygen(tension with the Transcutaneous Oxygen/Carbon Dioxide Monitoring System on three places of the upper leg (figure 2) of 10 healthy young women (between 20 and 30 years of age). The drop in skin oxygen tension compared to standing was recorded in three sitting situations; high shear force, low shear force and sitting without the use of the backrest but with a too high seat surface.

RESULTS AND DISCUSSION

In figure 2 it can be seen that the drop in skin blood flow is highest when high shear forces act on the buttocks, as is predicted by the model.

☐ High shear ☐ High seat ☒ Low shear

Figure 2. Three load situations on the thigh and the effect on skin blood flow.

The above finding might indicate that shear force on the tuberosities plays an important role in the cause of LS.

In a follow-up test 28 LS patients were given a 'low shear' office chair. After 13 weeks LS was diminished in 17 of the cases (60%).

TRANSIENT DYNAMIC BEHAVIOR OF OCCLUDER IN MECHANICAL AORTIC BILEAFLET CARDIAC VALVE (SJ) IN CLOSE PHASE USING FINITE STRIPS METHOD

M.T.Ahmadian¹, H.Mohammadi² (hadi_mohammadi@hotmail.com)

¹. Associate Professor, Mechanical Engineering Department, Sharif University of Technology, TEHRAN, IRAN, ². MS Mechanics

INTRODUCTION Transient dynamic analysis of occluder in aortic bileaflet cardiac valve in close phase is considered. The fluid analysis (Blood) is based on the control volume with moving boundaries in the vicinity of the occluders. Governing equations including continuity and momentum equation in unsteady state are used for calculations of backflow and its velocity. Exerting external forces contain gravity and pressure effect and its dynamic balancing on occluder about pivot axis gives angle, velocity of occluder tip and impact forces between occluder and its housing in a function of time in close phase. Results indicate that the maximum impact force between occluder and its housing is in the range of 75-140 N that takes 35-45 milliseconds (ms). Governing equations are equation of motion for the occluder including momentum as the occluder rotate about its hinge pivot. The model used in this analysis is assumed to have 38 mm leaflet valve diameter such as a St.Jude bileaflet valve.

METHODS For simulation of the aortic space and proper approximation in solution, the following assumptions is maintained. For simplification of analysis and computing, it was assumed that the flow is unidirectional in the axis direction. Due to complexity of the projected area between the circular occluder and circular orifice area at various positions of the occluder during closing the orifice on the occluder, cross sections were also assumed to be rectangular in the initial study. It was also assumed that the flow is laminar and velocity is uniform at every cross section in the control volume as well as the inlet. Thus, the effect of viscous diffusion in the short period of valve closure was neglected. The backflow is separated into flows through minor and major flow orifice at the entrance section. The analysis simulates the valve dynamics in the aortic position and it was assumed that the pressure of the fluid will be the same as that of the ventricle with the occluder in the fully open position at the initiation of valve closing. It was also assumed that the pressure of ventricular chamber is uniform. On the other hand, the fluid through section passes through converging channel between the occluder and the wall. Hence, velocities and pressures vary continuously through the converging channel. Because the control volume has moving boundaries and their shape varies according to time, unsteady conditions and the unsteady Bernoulli's equation" should be considered for the analysis. The steps of the calculations is shown in figure 1.

RESULTS The governing equation of motion for the occluder was solved by forth order Runge Kutta method. The average aortic pressure at closing varied between 10.7-16.0 kpa (80-120 mmHg) and was assumed constant during closing. For the final condition for step II fig.1, the occluder was assumed to have reached the resting position when the occluder angle of the successive time increment is less than "0.5" degree after impact. It takes about 10-18 ms before occluder comes to rest in the fully closed position after

impacting against the housing. The maximum velocity at the occluder tip is in the range of 7-8 m/s. Gao and Hwang have reported that the maximum velocity of the occluder tip of bileaflet valve 4.5 to 4.8 m/s (Dia.=24mm)[1].

Fig 1- Flow Chart of the Computational Scheme

The backflow exhibit oscillation similar to that of the occluder, but the net backflow volume is about 5.5 cc. Sabban and Stein have measured the closing backflow to be about 3 cc(Dia.=24mm)[2].

SUMMARY With the application of continuity and momentum equation, the closing backflow is calculated in the range of 1.5 to 5.5 cc with various initial opening angles in aortic section. As the initial opening angle decrease, the backflow volume decreases. The maximum backflow velocities are in the range of 3-5 m/s. The position of the occluder as a function of time and the tip velocity were calculated by the solving the governing equations of motion with the fluid pressure and equivalent gravitational force as external forces. It was also possible to calculate the relative velocity of the fluid against the occluder tip. The calculation values of the tip velocity and backflow volume are in the agreement with the previous experimental analysis. Hence, the theoretical method employed in this study, appear to be suitable. However, several assumptions to this study must be pointed out.

MEASUREMENT OF HEAT CHARACTERISTICS OF A NEW INCUBATOR WITH A CHEMICAL ENERGY SOURCE USING INVERSE PROBLEM SOLUTION AND FINITE ELEMENT METHOD.

M.T.Ahmadian¹, F.Bahramian²

¹Associate Professor, Mechanical Engineering Department, Sharif University of Technology, Tehran, Iran

²MS Mechanics, E-Mail: f_bahramian@hotmail.com

INTRODUCTION

Generally, babies are kept adequately warm at home and hospitals, some times it is necessary to transfer the baby, in this case, it is important to keep the baby warm during transportation. Most developing countries are unable to afford the high costs of commercial incubators, and sufficient personnel to supervise their use and maintenance are not available. A new transport incubator was designed, which produces heat via an exothermic crystallization reaction initiated by a metal disc in a plastic container. A new incubator was made with blue Styrofoam with $K=0.025$ W/mk. The number of chemical bags was considered as a mechanism for control of the inside temperature of the incubator.

METHOD

In order to develop a thermodynamic model of this device, the first law of thermodynamic is used in a control volume of enclosure.

$$(1) (mc_p)_{air} T = \sum UA(T_r - T) + q_b + q_s + (mc_p)_{in}(T_r - T)$$

$(mc_p)_{air}$: heat capacity of the air, $(mc_p)_{in}$: heat capacity rate of the incoming fresh air or oxygen, T : inside temperature, T_r : ambient temperature, q_s : heat transfer from the sodium acetate, q_b : rate of heat loss from baby, $\sum UA$: total heat transfer coefficient of incubator walls, q_s & $\sum UA$: unknown

Due to the complex geometry and the heat transfer mechanism in the enclosure the value of $\sum UA$ can not be calculated accurately by means of the conventional formula or numerical methods. Therefore, $\sum UA$ is obtained experimentally. The non-linear regression method known as parameter estimation is used to obtain the unknown parameters by using numerical and experimental method.

In experimental part of this method, the inside temperature of enclosure is measured using thermocouples and a Pico TC-08 data logger.

Initially this method is used to find the time dependent behavior of q_s . The rate of heat released by the chemical,

q_s , is partly due to the heat generation from crystallization process, and partly due to the heat capacity of the chemical. As the rate of heat transfer of the chemical is time

dependent, thus the conventional calorimeter method is not appropriate. Therefore, the parameter estimation method is used to find the time dependent behavior of q_s . In order to

obtain q_s , an insulated flask is used and the thermodynamic model of the air in the flask is solved by above method.

$$mc_p \frac{dT}{dt} = UA(T_r - T) + q_s$$

mc_p : heat capacity of the air, T : inside temperature of the flask, T_r : ambient temperature, UA : total heat transfer coefficient from the air inside the flask to the environment.

When q_s is determined Eq.(1) is solved by parameter estimation method.

RESULTS AND DISCUSSION

As the results show, the amount of heat generation of sodium acetate is:

$$(2) q_s = 2.27 + 5 * 10^{-4} t - 10^{-7} t^2 + 6.7 * 10^{-12} t^3$$

The average amount of UA was calculated based on different number of bags in the canopy, shown in Table 1.

Table1- UA for Canopy

No. of Bags	3	4	7
UA(W/k)	1.94±0.30	3.±0.30	5.24±0.66

Considering the value of UA in the table it is clear that UA is increasing with the increasing the number of chemical bag. However other factors such as ambient temperature and the location of the bags do not significantly influence the value of UA . Finally, this model was numerically verified by MSC/NASTRAN Software.

SUMMARY

In this research a thermal model was developed for a new non-electric infant transport incubator. The source of heat comprises a super saturated solution of sodium acetate. In the thermal modeling of the incubator the amount of heat generation is considered. Condition of the chamber in relation to the baby and chemical heat source was studied. The total heat transfer coefficient UA for different ambient temperature was calculated. The proper number of chemical bags with respect to ambient temperature and the conditions of the chamber are estimated in this paper.

LONGITUDINAL EXTENSION OF MUSCULAR CONDUIT ARTERIES AFFECTS DISTENSIBILITY

Martin A. Zulliger, Naomi T. M. R. Kwak, Theodora Tsapikouni, Nikolaos Stergiopoulos

Laboratory of Hemodynamics and Cardiovascular Technology, Swiss Federal Institute of Technology, Lausanne (EPFL), Switzerland

martin.zulliger@epfl.ch

INTRODUCTION

With progressing age large arteries diminish their longitudinal stretch (λ_z). This may eventually result in tortuosity. Further, increased age is also associated with loss of vessel distensibility or compliance, frequently also associated with hypertension. We show data from muscular porcine carotids measured *ex vivo* that suggest a possible biomechanical link between the decrease of λ_z and the loss of distensibility.

METHODS

Muscular segments of porcine carotid arteries (n=8) were harvested at the local slaughterhouse and transported in PBS (with Ca^{++} and Mg^{++}) on ice to our laboratory. Immediately upon arrival, the adventitia was carefully removed and approximately 3 cm long segments were mounted on a longitudinally extensible support in a PBS bath with Ca^{++} , Mg^{++} , and Glucose (11.1 mM) held at 37°C. Then, the arteries were pressurized to a physiological pressure of 100 mmHg.

Using a high-precision ultra-sound tracking device (NIUS, Omega Electronics, Switzerland) pressure-diameter (p-d) and pressure-wall thickness (p-h) curves were measured in three different vascular smooth muscle (VSM) states. In the order we proceeded in, these VSM states were normal VSM tone, totally contracted VSM (KCl, 90 mM), and totally relaxed VSM (sodium nitroprusside (SN), 100 μM). In each state the measurement was performed for both $\lambda_z=1.4$ and $\lambda_z=1.8$ (randomized order) after 5 preconditioning inflation-deflation loops (0-150 mmHg) and allowing time for adequate equilibration and drug exposure.

To form mean curves and to perform Student paired t-tests where appropriate, the Langewouters function (Langewouters, 1984) was fitted to raw data to calculate p-d and p-h values at pressure intervals of 10 mmHg. From these the vessels distensibility D was obtained applying:

$$D = \frac{1}{d^2} \frac{\partial}{\partial p} d^2 \quad (1)$$

Similarly, from the fitted functions, the Hudetz incremental elastic modulus (Hudetz, 1979) was calculated at 0.05 intervals of circumferential stretch (λ_θ):

$$H_{\theta\theta} = \frac{1}{2} \left(\frac{r_o \cdot r_i^2}{\left(\frac{\partial r_o}{\partial p} \right)_{p^*=p}} + p \cdot r_o^2 \right) \cdot \frac{1}{r_o^2 - r_i^2} \quad (2)$$

where $r_i = d/2$ and $r_o = (d+h)/2$ are the inner and outer radii of the artery's wall.

RESULTS

Distensibility was found to differ significantly ($p<0.05$) over the entire physiological range (50-150 mmHg) in its normal tone (Figure 1) and totally passive VSM states. In the totally contracted VSM state distensibility remained uninfluenced by the longitudinal stretch.

Figure 1: Distensibility of porcine carotid arteries (n=8) at different longitudinal stretch under normal VSM tone. Above 50 mmHg less elongated arteries are significantly stiffer ($p<0.02$).

The Hudetz elastic modulus was found to be virtually identical for the totally contracted and totally relaxed VSM state. Normal tone VSM modulus were slightly elevated, though not significantly, at $\lambda_z=1.8$.

DISCUSSION

The apparent passive and active material properties (Hudetz elastic modulus) of the carotid artery remain unaffected by changes in λ_z even though VSM tone might change. Nevertheless, the functional property (distensibility) of the artery is significantly changed, even in its passivated state. Both small λ_z and low distensibility appear with progressing age as well as changes in material composition and properties. The data presented above suggests, that a change in longitudinal stretch in itself is sufficient to change arterial distensibility.

BIOMECHANICAL EVALUATION OF RECONSTRUCTION AFTER TOTAL SACRECTOMY

Hideki Murakami¹, Katsuro Tomita¹, Norio Kawahara¹, Akira Yoshida¹, Jiro Sakamoto² and Jyuhati Oda²

¹Department of Orthopaedic Surgery, Kanazawa University, Kanazawa, Japan

²Department of Human and Mechanical Systems Engineering, Kanazawa University, Kanazawa, Japan

INTRODUCTION

Among sacral tumors, aggressive benign bone tumors such as chordoma, giant cell tumor and chondrosarcoma are the most common. If a malignant tumor or an aggressive benign tumor is excised with an intralesional margin, the likelihood of local recurrence apparently increases and this can lead to fatal disease. Therefore, en bloc sacrectomy with enough tumor free margin is indicated even though the continuity between the pelvis and spine are sacrificed. Radical excision of a sacral tumor involving the 1st sacral vertebra necessitates a total sacrectomy, to be followed by reconstruction of the continuity between the spine and the pelvis. However, the sufficient reconstruction procedure has not been established yet. Some authors have previously described such a reconstruction. One of the methods is a modified Galveston reconstruction (MGR) using the Galveston method. However, there has been no mechanical analysis of these reconstructions. In this study, finite element analysis was carried out to evaluate reconstruction models after total sacrectomy.

METHODS

We have mechanically evaluated two reconstruction methods: modified Galveston reconstruction (MGR) and novel reconstruction (NR) developed by us. In the first method which is commonly used reconstruction, after insertion of pedicle screws into the 3rd, 4th and 5th lumbar vertebrae and two bilateral iliac screws into two iliac bones, these screws are connected by two spinal rods. The second model consists of both posterior and anterior instrumentations. Posterior instrumentation consists of pedicle screws inserted into the 3rd, 4th, and 5th lumbar vertebrae, iliac screws inserted into posterior iliac crest and two rods, which connect them. Anterior instrumentation consists of two screws inserted into inferior endplate of the 5th lumbar vertebra, a sacral rod connected with both sides of the pelvis through these screws and a sleeve augmentation of the pelvis. The three-dimensional MGR and NR models were reconstructed to clarify the stress concentration on the bones and instruments using finite element analysis. A finite element model of the reconstruction model was made based on computed tomographic images taken of a healthy adult male. Material properties were assumed according to the literature. The boundary conditions considered were for 960 N weight applied vertically to upper surface of the 3rd lumbar vertebra and the bottom of the pelvis being fixed. Half region was used in the analysis because of the symmetry.

RESULTS AND DISCUSSION

Generally, a risk of breakage or loosening at the points in which undue stress concentrated is higher. In MGR model, maximum

Mises stress (14 MPa) at the bones was observed at a region of the lateral cortical bone around the inferior iliac screw. This stress is less than the yield stress of cortical bone (83 MPa). However, concerning the instruments, high stress (1042 MPa) was observed at a region of the spinal rod between the L5 pedicle screw and the iliac screw. This stress is higher than the yield stress of the titanium alloy (860 MPa). If the patient were to stand or sit immediately after the reconstruction, there is the risk of fracture of the instruments because of high stress in the spinal rods. A large load was transmitted from the lumbar vertebrae to the pelvis via the posterior rods only and excessive stress was concentrated at the spinal rod. Breakage of the spinal rod at this juncture has been found clinically. So in order to avoid stress concentration in MGR, it is necessary to add anterior support. In NR model, stress concentration was observed at the region of the connection between the sacral rod and the screws. The maximum stress was 400 MPa, which is lower than the yield stress of the titanium alloy. In the bones, stress concentration was observed at the region of the insertion of the sacral rod in the pelvis. The maximum stress was 77 MPa, which is just lower than the yield stress of the cortical bone. Excessive stress concentration was not detected in NR model. A 48-year-old female underwent NR for a giant cell tumor of sacrum. At the 20-month follow-up, she was healthy, with no recurrence or metastasis. The spine and the pelvis were stabilized well and no failure of spinal instrumentation was noted.

SUMMARY

In MGR, there is a strong possibility that the rod might fail. Patients should avoid weight-bearing until the grafted bone is fused. In NR, no particular stress concentration was detected. We concluded that the NR has a low risk of instrument failure and loosening after a total sacrectomy.

THE NEW JUMPING HILL IN INNSBRUCK: DESIGNED BY MEANS OF FLIGHT PATH SIMULATIONS

Wolfram Müller and Bernhard Schmölzer

Institute of Medical Physics and Biophysics, Karl-Franzens University Graz, Austria

Communicating author, wolfram.mueller@uni-graz.at

INTRODUCTION

A modelling concept that considers the relationship of the aerodynamic lift and drag forces ($F_l = \frac{\rho}{2} \cdot w^2 \cdot L$; $F_d = \frac{\rho}{2} \cdot w^2 \cdot D$) on the flying position by means of tabulated input functions for $F_l = F_l(t)$ and $F_d = F_d(t)$ has been described in detail before (Müller et al 1995, Müller et 1996, Schmölzer and Müller 2002). The model is based on the non-linear and coupled equations of motion that are valid for any object in air (with a given air density ρ). The gravitational force and the forces due to the airstream ($w = u - v$, w being the resulting airstream vector, u wind velocity, v velocity of motion of the object) determine the flight path with a given set of initial conditions and parameters. The application of this computer model to the design of jumping hills (Müller 1997) and a detailed analysis of the accuracy of this modelling approach have been described before (Schmölzer and Müller 2002).

METHODS

Here, we focus on the analysis of the landing impact which depends on one hand on the flight velocity and the flight path angle at landing and on the other hand on the geometric properties of the landing hill: At landing, the athlete has to compensate the momentum perpendicular to the landing slope. In order to “translate” the language of physics into terms that can easily be understood, we compare this momentum with the one that corresponds to a jump onto a horizontal plane from a height h_l (equivalent landing height h_l). There are several possibilities to obtain an increased jump length in the simulation. We can vary the approach velocity v_0 , or the velocity perpendicular to the ramp at take-off v_{p0} , apply a wind blowing up the hill, use a shallow ramp angle, shift the $L = L(t)$ or the $D = D(t)$ function, or reduce the mass m . All these simulation protocols would result in similar characteristics in relationship to of h_l on the obtained jump length l . Here, different jump lengths have been obtained by increasing the approach velocity v_0 in the simulation protocol.

RESULTS AND DISCUSSION

We have suggested a jumping hill profile for Innsbruck that deviates remarkably from all other previous profiles: In Innsbruck (I in Figure 1, $K = 120m$) the equivalent landing height h_l increases continuously with increasing jump length l and does not show a kink from which the equivalent landing height would increase rapidly as do all other profiles that have been built before. Figure 1 also shows examples of other profile characteristics: The new jumping hill in Innsbruck I_120 shows several advantages when compared to conventional profiles: 1. No abrupt increase of the landing

impact beyond a certain jump length (increased safety and fairness). 2. Decreased sensitivity to wind (increased fairness). 3. Decreased sensitivity to the approach velocity (makes it easier to run a competition).

Figure 1: Dependency of h_l on the jump length l
I_120: new profile Innsbruck; I_110: old profile Innsbruck;
S_120 Sapporo; I_p planed without computer simulation, has not been built in Innsbruck because of the dangerously rapid increase of h_l from $l = 134m$ on.

SUMMARY

The computer simulation of ski jumping enables the design of “custom-made” jumping hill profiles. The characteristics of a jumping hill can be determined and optimised in all details in advance. This scientifically based approach can save large amounts of money when compared to trial and error approaches that might need to be corrected afterwards.

EVALUATION OF SLOTS FOR DESTRUCTIVE CEREC RESTORED PREMOLAR BY FINITE ELEMENT METHOD

Chun-Li Lin¹ and Yen-Hsiang Chang²

¹Department of Mechanical Engineering, Chang Gung University, Tao-Yuan, Taiwan, cllin@mail.cgu.edu.tw

²Operative Dentistry, Chang Gung Memorial Hospital, Tao-Yuan, Taiwan.

INTRODUCTION

A large field of destructive premolar, such as a remaining tooth fractures after extensive MOD restoration is a common and complicated clinical biomechanical problem. Generally traditional restorative methods (direct and indirect) are employed exhaustively to repair the destructive tooth. In recent years, CAD/CAM technology has added the new option of producing chairside ceramic restorations for repairing a large decimated tooth. However, the long-term success of a ceramic restoration relates to the mechanical integrity arising from the restorative engineering design (Chen et al., 1999; Lin et al., 2001). The aim of this study was therefore to determine the biomechanical aspects of various CEREC restorative tooth designs using linear and nonlinear finite element (FE) analyses.

METHODS

An intact maxillary second premolar was selected. The CEREC system was used to restore the extensive destruction induced by previous MOD restoration failures in which the lingual cusp was lost. The restored tooth was embedded and sliced serially to expose the tooth-resin sections. An in-house program was employed to detect the boundaries for different materials from each sectioned scanning image. Four FE restored tooth models (Fig. 1-a and Table 1) were constructed using a commercial package (ANSYS) through contour stacking, Boolean operations and mesh generation procedures. Bonded (linear) and contact (nonlinear) interfacial fixations were modeled to simulate the adaptations between the tooth structure and restorative material. Interfacial (normal and shear) stresses were then calculated using self developed program for four restored teeth with two occlusal forces (12 simulated models in total) to evaluate the biomechanical interactions.

RESULTS AND DISCUSSION

The extensive ceramic restoration fabricated using the CEREC system without any reinforced design usually has doubtful structural stability and adhesion-bonded strength for long-term use. A reinforced design, such as a slot considered for increasing the tooth/ceramic interface, is an attempt to improve the clinical performance. However, the simulated results

indicated that the stress values (Table 1) at the buccal wall increased with slot designs for both a bonded and debonding interface when a single occlusal force acted on the tooth. This was because the lateral micro-motion of the restorative ceramic was constrained by the slot and induced the lingual bevel surface to receive higher compression under the bending moment effect (Fig. 1-b). In contrast, the interfacial stresses decreased with slot designs when the tooth received uniform occlusal pressure. These results implied that different occlusal forces affect the interfacial stress distribution and might be a more important factor than preparation design. Therefore slot-reinforcement effects seem to be doubtful in a tooth that subjected to a lateral load.

Figure 1: (a) One of the restored FE models, (b) Displacement and max. principle stress patterns for a 1mm slot design with debonding condition.

SUMMARY

Based on the limited data, we conclude that the extensive destruction in a premolar can be restored directly through normal CEREC procedures without other reinforcement designs. Utilizing occlusal adjustments to reduce the lateral bending moment does redistribute the tooth/ceramic interfacial stresses. Further *in-vitro* and *in-vivo* studies are needed to validate the conclusions of this study.

COOPERATIVE FORCE ANALYSIS OF ELEVEN MUSCLES DURING ABDUCTION OF THE SHOULDER

Naomi Oizumi¹, Shigeru Tadano², Youichi Narita², Norimasa Iwasaki¹, Naoki Suenaga¹, and Akio Minami¹

¹Orthopaedic Surgery, Graduate School of Medicine, Hokkaido University, Sapporo, Japan noizumi@med.hokudai.ac.jp

²Devision of Mechanical Science, Graduate School of Engineering , Hokkaido University, Sapporo, Japan

INTRODUCTION

It is difficult to directly examine the muscle force in living subjects. Many muscles are acting cooperatively in a human shoulder, therefore, computed simulation may be useful in analyzing the muscle force. In this study, a method of numerical analysis of muscle force during shoulder abduction was described.

METHODS

Three-dimensional musculoskeletal model was created from normal volunteer's CT data of the shoulder. Muscle vector was modeled by a straight-line vector from the insertion to the origin of each muscle. Analyzed muscles were F1; anterior fiber of deltoid, F2; middle fiber of deltoid, F3; posterior fiber of deltoid, F4; supraspinatus, F5; infraspinatus, F6; subscapularis, F7; teres minor, F8; teres major, F9; long head of biceps, F10; short head of biceps, F11; triceps. Figure 1 shows the three-dimensional model for analysis. Muscle force was calculated from equilibrium equations of force and moment using sequential quadratic programming (SQP) method as optimization. Objective function was determined as the total sum of the square of the muscle force divided by the physiological cross sectional area. For the muscles originated from wide area (F1-6), the optimization method was also used in selecting the proper point of the origin for each abduction angle. Static analyses were performed for every 5° of abduction of the glenohumeral joint in a scapular plane. The analyzing results were compared with the data of electromyography (EMG), which was obtained from the same volunteer.

RESULTS AND DISCUSSION

Results of the muscle force analysis were shown in Figure 2. Middle fiber of deltoid (F2) demonstrated remarkably large force. Supraspinatus (F4), anterior fiber of deltoid (F1), and infraspinatus (F5) followed it. Posterior fiber of deltoid (F3), subscapularis (F6), and teres minor (F7) were acting at late phase of abduction. These results qualitatively corresponded with the integrated EMG activity. The current model for numerical analysis using optimization was useful in predicting muscle forces cooperatively acting for the shoulder movement.

SUMMARY

Numerical analysis of muscle force during shoulder abduction using optimization method was demonstrated in this study. Three-dimensional musculoskeletal model was build from normal volunteer's CT data. SQP method was applied to calculate muscle forces from equilibrium equations of force and moment. The results of analysis qualitatively corresponded with the integrated EMG activity.

STRUCTURE-FUNCTION RELATIONSHIP IN TENDON FASCICLES UNDER TENSILE LOADING CONDITIONS

Screen, HRC¹; Lee, DA^{1,2}; Bader, DL^{1,2}; Shelton, JC^{1,2}

¹ IRC in Biomedical Materials, Queen Mary University of London, London, UK, H.R.C.Crane@qmul.ac.uk

² Medical Engineering Division, Department of Engineering, Queen Mary University of London, London, UK

INTRODUCTION

The collagen within a tendon fibres are interspersed with tenocytes, arranged in rows following the crimp. Under strain, these fibres straighten and align to the direction of loading, creating local strain fields within the tendon matrix (Screen et al, 2002). When subjected to mechanical stimuli, tenocytes initiate matrix remodelling through various mechanotransduction pathways (Banes et al, 1999). In this study we have investigated the relationship between applied strain and local strain fields in tendon, in order to develop an understanding of tendon strain mechanics.

METHODS

Collagen fascicles were teased from the tails of male Wistar rats within 2 hours of death, and kept moist in a paper towel soaked with PBS. Fascicles were then subjected to one of two test procedures, as described below.

Macroscopic examination: Thirty fascicles were subjected to quasi-static tensile testing to failure using a mechanical test machine (Elastomer, MTS). Fascicles were kept moist by continual spraying with PBS, and strained to failure at a rate of $1\text{mm}\cdot\text{min}^{-1}$. Tests were recorded using a CCD camera.

Microscopic examination: The cell nuclei of twenty-five fascicles were stained with the vital fluorescent stain acridine orange ($5\mu\text{l}\cdot\text{ml}^{-1}$ of DMEM), for 1 hour at room temperature. Each specimen was gripped in a novel mechanical test rig, mounted on the stage of a confocal microscope, which enabled visualisation of cells. Tenocytes from a region approximately equidistant from each grip, were imaged, and the nuclei motion used as a measure of strain, as previously described (Screen et al, 2002). Relative displacements between cell nuclei along the same fibre, and between fibres were recorded as intra-group strains and inter-group displacements respectively. Fascicles were strained in 1% increments to a strain of 8-10%, when cells could no longer be visualised.

RESULTS AND DISCUSSION

Stress-strain curves for individual fascicles were repeatable, and similar in form to those characteristic of bulk tendons. Figure 1a shows curves for five individual fascicles. The estimated modulus for a single fascicle was also recorded in figure 1b. The mean maximum modulus of fascicles was found to be $197\text{ MPa} \pm 37.5$, occurring at approximately 8% applied strain. Fascicles failed at a mean strain of $14.3\% \pm 1.88$. Crimp straightening could be detected by macro and micro examination, and was normally distributed, occurring at an average strain of 1%. Nuclei aligned to the collagen fibres under strain (figure 2), and the fascicle was observed to narrow, often to 50% its original width.

Figure 1a. Stress-strain curves for five typical rat-tail fascicles strained at $1\text{mm}\cdot\text{min}^{-1}$ to failure **b.** Modulus curve for a single, representative fascicle

Once nuclei had aligned to the collagen fibres, there was little further increase in intra-group strains with increasing applied strain. By contrast, inter-group displacements continued to increase steadily. This suggests that fascicles stretch by a mechanism involving sliding between adjacent fibres. Video footage of fascicle failure displayed macro sliding between fibres, visible at an average strain of 13%. Sliding appears to provide a continual elongation mechanism for the fascicle, leading to eventual failure.

Figure 2. Relative motion of rat-tail tendon nuclei at 0, 2 and 7% applied strain

SUMMARY

Applied strain was not transmitted wholly to the cell nuclei, as tenocytes only experienced tensile strains of up to 2%. Sliding appears to provide a mechanism enabling further fascicle elongation, hence mechanotransduction pathways may in fact be stimulated by smaller strains than previously suggested (Zeichen, 2000). Cell alignment, or the shear stresses associated with fibre sliding may stimulate mechanotransduction pathways. Equally tightening of the matrix may apply compressive strains to cells, or fibre motion may strain the cell processes and initiate mechanotransduction.

ANALYSIS OF STRAIN FIELDS IN TENDON FASCICLES UNDER TENSILE LOADING

Screen, HRC¹; Lee, DA^{1,2}; Bader, DL^{1,2}; Shelton, JC^{1,2}

¹ IRC in Biomedical Materials, Queen Mary University of London, London, UK, H.R.C.Crane@qmul.ac.uk

² Medical Engineering Division, Department of Engineering, Queen Mary University of London, London, UK

INTRODUCTION

Tendon is composed predominantly of type I collagen fibres, possessing a natural periodic crimp. These fibres are interspersed with cells, termed tenocytes, which are aligned in rows, following the crimp (Kastelic et al, 1978). Under tensile elongation, the fibres straighten, exposing tenocytes to a range of mechanical stimuli. The mechanical environment will induce matrix remodelling by the tenocytes (Banes et al, 1999). In order to examine the associated mechanotransduction pathways, it is important to determine local tissue strains in tendon, and establish the mechanisms for tendon elongation.

MATERIALS AND METHODS

Fascicles were teased from the tails of male Wister rats, aged between 4 and 6 months, within two hours of death. They were then placed in the vital stain acridine orange ($5\mu\text{l.ml}^{-1}$ in PBS), for 1hr at room temperature, to stain the cell nuclei. Samples were gripped in a novel test rig, mounted on the stage of an inverted confocal microscope, which enabled visualisation of the cell nuclei during mechanical testing (Screen et al, 2002). Samples were strained in 1% increments, at a rate of 10mm.min^{-1} . The specimens were held at each strain level, whilst nuclei were imaged. A z-series of horizontal images, taken at $15\mu\text{m}$ intervals, was recorded through the thickness of the tendon. Samples were strained to maximum values of up to 5% strain, and then returned to zero in 1% increments.

The centre coordinate of each nucleus was located in three-dimensional space, and plotted graphically using Matlab. The horizontal z coordinate of each nucleus was taken as the plane in which the nucleus was brightest. Sections through the sample were superimposed, in order to measure intra-group strains between nuclei in two-dimensions, as previously described (Screen et al, 2002).

RESULTS AND DISCUSSION

Three groups of nuclei in different focal planes within the body of the each sample fascicle were chosen for analysis. The application of strain resulted in fibre rotation, and alignment to the direction of strain, as well as fibre translation within the fascicle matrix, as shown in figure 1. Bulk fascicle rotation also occurred under tensile strain, suggesting that fascicular structure is helical in nature. Intra-group strains were recorded during the straightening of the crimped collagen fibres, after which point, little further increase in local strains was measured, as seen in figure 2. Upon removal of applied strain, fibre crimping was restored, returning the local strains intra-group to zero.

Figure 1. 3 D plot, depicting nuclei coordinates with applied strain at 0% (dashed lines) and 1% (solid lines)

As strain was removed, collagen fibres were also seen to return to their initial location within the fascicle matrix. In addition, the fascicle returned to its original helical structure. No permanent damage to the fascicle was visible in any samples.

Figure 2. Intra-group strains in relation to applied strain in four cell groups of a representative fascicle.

SUMMARY

Tensile strain is transmitted through tendons via a straightening mechanism, followed by reorientation and sliding of the crimped collagen fibres. Local strain fields within the fascicle were significantly less than the applied strains, suggesting applied strain is not transmitted wholly at the level of the nucleus. Fibre reorientation under strain may induce other potential mechanotransduction pathways, involving fibre shearing and/or compression.

THE EFFECT OF REMOVING BLOOD AND BONE OIL ON THE MECHANICAL STRENGTH OF CEMENT-BONE INTERAFACE

Shojiro Terashima¹ and Takahiro Seki²

¹ Dept. of Mechanical & Control Eng., Niigata Institute of Technology, Niigata, JAPAN, george@mce.niit.ac.jp

² e-medical Orthopaedic Clinic, Niigata, JAPAN

INTRODUCTION

We hypothesized that removal of blood and bone oil improves the mechanical strength of the cement-bone interface. In this study, using cancellous bone, we compared the mechanical shear strength of cement-bone interface with and without blood and bone oil.

METHODS

Six pairs of ox tibiae were used. Each proximal tibia was osteotomized 20mm below the medial plateau, and vertical holes (7.5 mm diameter) were drilled in the tibiae. Each cut surface was washed using pulsatile lavage to clean out bone debris.

Two cases of experiment were carried out to investigate each influence of blood and bone oil. To examine the influence of remaining blood, one side of the 3 pairs of tibiae was soaked in a fresh human blood to simulate bleeding from the bone (*BLOOD+*), and the other side was left as it is (*BLOOD-*). Likewise, to learn the effect of removing bone oil, one side of the 3 pairs tibiae was cleaned using 1 percent aqueous surfactant used as food additive (*OIL-*), and the other side saline solution (*OIL+*).

Doughy cement (Simplex P) was injected into each hole using a caliber syringe under pressure. Then, 3 cross sections of 10 mm thickness were sliced off from the proximal tibiae, and each cylindrical cement buried in the bone plates was pushed-out by Instron Mechanical Test Machine. The maximum load at failure was converted to an interface shear stress (ISS). 103 and 117 pieces of cylindrical cement were pushed to test the effect of blood removal, as the groups of *BLOOD+* and *BLOOD-*, respectively. Likewise, 139 and 121 pieces of cement were used to test the effect of oil removal using surfactant, as *OIL-* and *OIL+*.

RESULTS AND DISCUSSION

The ISS (means \pm 1 S.D.) of the result of with and without blood or bone oil are shown in the Figure 1. The ISS of *BLOOD+* and *BLOOD-* were 2.3(1.1) MPa and 2.7(1.3) MPa, respectively, so the ISS of *BLOOD-* shows an increase of 18 percent as compared with *BLOOD+*. The ISS of *OIL+* was 2.6(1.5) MPa, and *OIL-* was 3.8(1.9), so the ISS of *OIL-* shows an increase of 46 percent as compared with *OIL+*. Statistically significant differences were found in the ISS between *BLOOD+* and *BLOOD-* ($p < 0.01$, Student's t-test), and *OIL+* and *OIL-* ($p < 0.0001$, Welch's t-test). Removal of blood

and bone oil obviously improved the ISS.

Removal of blood and bone oil remarkably increased the mechanical strength probably through the improvement of microlock between cement and bone by the removal of the interposing material. Some papers described that cleaning out blood and bone debris on the bone surface gives satisfactory strength. However, other authors suggest that bone oil membrane decreases the mechanical strength, more than other factors. One of the reasons for it will be that bone oil on the surface will not be removed completely, even by applying the pulsatile lavage system using only saline solution.

Figure 1: Comparison of Interface Shear Stress (Mean \pm

1S.D.). * $p < 0.01$, ** $p < 0.0001$ by t-test.

SUMMARY

We evaluated the effect of removing blood or bone oil on the mechanical strength of the cement-bone interface using ox cancellous bone. The results suggest that removal of blood or bone oil within the cancellous bone is essential to improve the strength of the bone-cement interface.

COMPUTATIONAL FLUID DYNAMICS AFTER AORTIC COARCTATION REPAIR

Simone Pittaccio¹, Francesco Migliavacca², Gabriele Dubini², Lars Sondergaard¹, Yun Xu³, Marc de Leval¹

¹University College London at Great Ormond Street Hospital, London, UK

³Department of Chemical Engineering and Chemical Technology, Imperial College, London, UK

INTRODUCTION

Coarctation of the aorta is a congenital narrowing of the upper descending aorta, generally adjacent to the site of attachment of the ductus arteriosus, which is sufficiently severe that there is a pressure gradient across the area. It accounts for about 6.5% of congenital heart disease. It can be treated using surgery or interventional cardiac catheterisation, although the surgical approach is far more common. The statistical significance of coarctation on the whole of congenital heart diseases makes it important to try and find a way of assessing the outcomes of its treatment quantitatively. The purpose of this study is to evaluate the local fluid dynamics of repaired coarctations using computational methods based on data collected from single cases.

METHODS

Two patients (age 13 and 21, respectively) were selected among those who underwent a successful surgical treatment for aortic coarctation at Great Ormond Street Hospital, London, UK. The patients were scanned with a Siemens Magnetom Vision MR Scanner (1.5 T). The geometrical data were acquired through a fi3d sequence with gadolinium injection (TR=5.0ms, TE=2.0ms, slice thickness 1.5mm, FoV=188×300, flip angle 25°). Velocity mapping was performed with a cine phase contrast fi2d sequence using the same scanner (max velocity 250cm/s, TR=324.7ms, TE=5.0ms, slice thickness 6.0mm, FoV 300×300, flip angle 30°, 24 images in a cardiac cycle).

Image segmentation was performed using Mimics (Materialise N.V., Leuven, Belgium), while geometrical modelling was made by means of Rhinoceros (Robert McNeel & Associates, Seattle, USA). CFD mesh, consisting of tetrahedral elements, was generated with GAMBIT (Fluent Inc, Lebanon, USA). Pulsatile flow simulations were carried out under Newtonian fluid and laminar flow assumptions using finite element method based CFD solver FIDAP (Fluent Inc, Lebanon, USA). Upstream velocity data obtained from MR velocity mapping were imposed as inlet boundary conditions through a FORTRAN subroutine.

RESULTS AND DISCUSSION

The geometries obtained are realistic. Results of the CFD simulations show that, apart from the influence that a suture line may have on wall properties, blood flow is reverted to a qualitatively and quantitatively normal pattern when an end-to-end anastomosis coarctation repair is considered successful according to surgical and clinical evaluation.

INVESTIGATIONS OF WALL DEFORMATION AND HEMODYNAMICS AT DISTAL FEMORAL BY-PASS ANASTOMOSES

Paul Devereux, Tim McGloughlin and Sean Meehan

Department of Mechanical and Aeronautical Engineering, University of Limerick,
Co. Limerick, Republic of Ireland.
paul.devereux@ul.ie

INTRODUCTION

A major problem with small calibre vascular by-pass grafts is their relatively low patency rates of between 3-5 years (Verhelst et al., 1997). Thrombus formation and the formation of intimal hyperplasia (IH) at both the bed and suture line of the anastomosis are key events in the failure of such grafts. The presence of IH at the suture line is believed to be caused by the compliance mismatch between the host artery and the synthetic graft, with IH formation along the bed of the junction caused by the impinging blood flow (Ballyk et al., 1998). Numerical simulations using both FE and CFD techniques were carried out to assess the effect that arterial wall deformation has on wall shear stress gradients and distributions, along with flow patterns through the anastomosis.

METHODS

Finite element analysis of an idealised 45° femoral anastomosis, using MSC Marc Mentat 2000 software, was carried out to assess the extent of deformation occurring at the junction.

This deformed geometry was then exported to Gambit 2.0 and a grid independent mesh for use in the CFD analysis was created. Once this mesh was generated it was exported to Fluent 6.0 where a steady flow analysis of fluid flow through the deformed geometry was completed. The fluid modelled by Fluent 6.0 incorporated the non-Newtonian behaviour of blood by using the Carreau model of viscosity.

The un-deformed model of the anastomosis was also subjected to a CFD analysis, using the same velocity boundary conditions and fluid properties as for the deformed case.

RESULTS AND DISCUSSION

Upon completion of the finite element analysis, it was evident that relatively large deformations occur along the suture line, the heel, toe and bed. The geometry of the anastomosis is forced to distort in an attempt to accommodate the deformation occurring along the suture line. The heel and toe are forced down towards the bed, with the bed of the junction rising (Figure 1). These deformations are not accounted for when a rigid wall CFD analysis is carried out and it is for this reason that this deformed geometry was recreated in Gambit 2.0 and subjected to a steady flow CFD analysis. A steady

flow analysis with identical inlet and outlet boundary conditions was completed with the non-deformed geometry.

Figure 1: Deformation of femoral anastomosis

It was evident that the flow patterns through the deformed geometry, along with wall shear stress gradients and distributions were significantly different to the results obtained from the non-deformed geometry.

SUMMARY

Investigations of junction hemodynamics have traditionally assumed the arterial wall as being rigid. It is clear from this study that, for more compliant arteries, large deformations may occur which has a significant effect on the junction hemodynamics. Along with the variation in flow patterns through the deformed geometry in comparison to the non-deformed geometry, variations in wall shear stresses gradients and distributions along the bed of the artery have implications concerning the formation of intimal hyperplasia at this location.

MECHANICAL EVALUATION OF SPINE RECONSTRUCTION AFTER TOTAL EN BLOC SPONDYLECTOMY BY FINITE ELEMENT ANALYSIS

Jiro Sakamoto¹, Atsushi Kakuuchi¹, Tomoyuki Akamaru², Norio Kawahara², Juhachi Oda¹ and Katsuro Tomita²

Kanazawa University, Kanazawa, Ishikawa, Japan

¹ Department of Human and Mechanical Systems Engineering, sakamoto@t.kanazawa-u.ac.jp

² Department of Orthopaedic Surgery

INTRODUCTION

Total en bloc spondylectomy is the most efficient surgical treatment to prevent recurrence of malignant vertebral tumors (Tomita et al., 1997). In this surgery, a tumorous vertebra is totally removed and replaced by a titanium mesh cage filled morselized bone graft, and spinal instrumentation is carried out by using pedicle screw system. It is considered that bone fusion and remodeling of the grafting depend on mechanical stress condition. Although initial stability and rigidity of the reconstructed structure have been evaluated experimentally (i.e. Oda et al, 1999), mechanical stress condition has not been sufficiently investigated. In this study, finite-element analysis of the reconstructed structure was carried out and stress condition was discussed.

METHODS

In our previous study (Sakamoto et al, 2001), mechanical loading test of the reconstructed structure was performed using human cadveric spine (T10-L4) of 90 years old male with no spinal diseases. T12 was replaced by the titanium mesh cage. Finite-element model of the reconstructed structure was made based on CT images taken from the experimental specimen. Finite-element analysis corresponding to the loading test was carried out, and effectiveness of the FE model was ensured.

Two types of spinal reconstruction are available in clinical use. One is the multilevel posterior instrumentation (MPI), and another is the short circumferential instrumentation (SCI). MPI has posterior devices at T10-L2 using pedicle screws and spinal rods. SCI has anterior and posterior instruments between T11 and L1 in left side. Mechanical stress occurred in the instruments and the vertebrae were evaluated by finite-element analysis for both the reconstructions. Advantages and disadvantages of the reconstruction were discussed comparing the results. FE model of the MPI is shown in Fig.1. Boundary condition was assumed as natural standing situation.

RESULTS AND DISCUSSION

Stress of the spinal rod was larger in MPI than in SCI. On the other hand, load occurred in the titanium mesh cage was smaller in MPI than in SCI. Fig.2 shows energy stress distribution in upper surface of L1, which connects with the titanium mesh cage. Energy stress of MPI is larger, and stress distribution of SCI is not symmetry. Stress condition in the interface between vertebra and the mesh cage is important for

considering bone fusion. SCI can reduce stress in the posterior instruments, but it is not advantageous in the viewpoint of promotion of bone fusion.

Figure 1: Finite-element model of the spine reconstructed structure in the case of MPI.

Figure 2: Energy stress distributions on upper surface of L1 in comparison between MPI and SCI.

SUMMARY

Mechanical evaluation of the spine reconstructed structure after the total en bloc spondylectomy was carried out by using finite-element analysis. Finite-element models were fabricated for the two typical reconstruction methods, which were MPI and SCI. In the stress analyses, it was observed that SCI was favorable to reduce stress of posterior instruments and MPI was advantageous to promote bone fusion between bone graft and vertebra.

INTRODUCTION

To evaluate the cardiac contractility from a mechanical point of view by analyzing the deformation of the myocardial wall is useful for a quantitative evaluation of the extent of heart disease. In this research work, the deformation of the left ventricular wall in normal humans and patients with a hypertrophy of the myocardial wall is analyzed by using a magnetic resonance tagging technique, and a difference in the cardiac contractility of each heart disease is discussed.

METHODS

Ten normal human volunteers, eight patients with a hypertrophic cardiomyopathy (HCM), and seven patients with a hypertensive heart disease (HHD) were imaged with a 1.5 T superconducting magnet (Signa, GEMS, USA). Multiphase tagged images were obtained in a cardiac short-axis view at an equatorial location of the left ventricle. The deformation of the left ventricular wall was analyzed by tracking intersections of tagged stripes throughout systole. The components of the Green's strain tensor within a triangular region defined by three adjoining intersections were calculated, and the calculated strain tensor in each triangular region was translated to polar coordinates where the origin is a center of the left ventricular cavity.

RESULTS AND DISCUSSION

Figure 1 shows the strain components at end systole in the normal humans. From this figure, it is recognized that the radial strains and the circumferential strains in all regions indicate positive and negative values, respectively. It is also observed that dispersions among ten subjects in the circumferential strains are considerably small. From these results, so far as the deformation of the myocardial wall at a short-axis section in normal humans is discussed, it is considered that the myocardial wall dominantly contracts in a circumferential direction, and that there is no significant difference among subjects about an amount of contraction of the myocardium. Figure 2 shows typical examples of distribution of the circumferential strains at end systole in the normal humans (a and b), the patients with a HCM (c and d), and the patients with a HHD (e and f). As seen in these figures, the circumferential strain in a local region in the patients with a HCM, especially the septal wall in figure 2c and the anterior wall in figure 2d, decreases compared with those in the normal humans, while the circumferential strains in the patients with a HHD are similar to those in the normal

humans. From these results, it is considered that HCM is a heart disease accompanied with a reduction of an amount of contraction of the myocardium in a local region, and that the cardiac contractility in HCM and that in HHD are different, although both of them are heart diseases accompanied with a hypertrophy of the myocardial wall.

Figure 1: Strain components at end systole in normal humans.

MEASURING VASTUS LATERALIS APONEUROSIS & TENDON DEFORMATION *IN VIVO* DURING MAXIMAL ISOMETRIC CONTRACTION BY ULTRASOUND

J. Bojsen-Møller, P. Hansen, P. Aagaard, M. Kjær and S.P. Magnusson. Sports Medicine Research Unit/Team Denmark, Bispebjerg Hospital, Copenhagen, Denmark. E-mail: jbm01@bbh.hosp.dk

INTRODUCTION

Recent development in high definition ultrasonography (US) permits observation of intramuscular connective tissue (CT) displacement during isometric contraction, *in vivo*. Displacement may be regarded as a function of CT deformation, that enables assessment of material properties such as stiffness or compliance. The method has been extensively used in recent years (Magnusson et al. 2001, Kubo et al. 2000), however there is limited information available regarding the reproducibility of the method. Furthermore, the analysis of displacement has been performed manually by digitizing video images frame by frame, which is a labor intensive method associated with potential error due to investigator bias. The purpose of the present study was to evaluate reproducibility of the method, and further to introduce an automated tracking tool.

METHODS

Eight male subjects participated in the study. Using a very rigid test frame, the subjects were positioned in a sitting position with a 90° flexion of the hip and knee joints. The subjects performed two (trial 1&2) isometric knee extensions (10s. ramp, 5min. apart). Knee extensor force and real time US video images of VL aponeurosis displacement were on-line sampled. MVC and VL aponeurosis maximal displacement (MD) was determined, the latter using a newly developed frame by frame automated US video tracking software based on pyramidal implementation of the Lukas Kanade tracking feature (Bouguet, J.Y. 2001). One video sequence from each subject was analysed repeatedly (>6 times) by two experienced observers, and MD was determined as the largest obtainable displacement value. To assess the accuracy of the tracking algorithm software a separate experiment was performed, in which an injection needle (\varnothing 0.5 mm) embedded in sonography gel was moved parallel to the US transducer while a video sequence was recorded. Subsequently individual frames were digitized and the displacement manually measured with respect to the calibration markers (10

mm apart) of the ultrasound image. The tracking software was then applied to the video sequence, and the results were compared to the corresponding digitised values. The values of displacement obtained from the two methods diverged less than 0.2 mm, indicating an acceptable degree of accuracy of the tracking algorithm.

RESULTS & DISCUSSION

Data are presented as mean \pm SD: MVC: trial1; 3025 \pm 706 N, trial2; 3016 \pm 671 N, MD: trial1; 11.4 \pm 2.6 mm, trial2; 11.2 \pm 2.5 mm, MVC and MD yielded no difference between trials: $r^2=0.97$, 0.92 , CV=2.87%, 4.64%, respectively. Inter- and intraobserver US-deformation reliability were $r^2=0.95$ & 0.99 , CV=3.12% & 1.24% and mean differences=0.2 mm & 0.1 mm, respectively. In conclusion, isometric quadriceps MVC force and corresponding VL displacement can be measured in a reproducible (intra-day) manner, and the automated tracking tool may be considered accurate. The present methodology can be used to assess CT material properties, and further to evaluate the response to physical training, which have not previously been thoroughly examined despite the potential influence on sports performance.

IMPROVING THE BALANCE SKILL OF STROKE PATIENTS BY VIRTUAL REALITY TREADMILL EXERCISE

Jen-Suh Chern^{1,2}, Saiwei Yang¹, Wei-Shun Huang¹, Lu-Lu Yan³, Fu-Kang Liu³

¹Institute of Biomedical Engineering, National Yang Ming University, Taipei, Taiwan, swyang@bme.ym.edu.tw

²Department of Occupational Therapy, Chang Gung University, Tao-Yuan Taiwan

³Cheng-Hsin Rehabilitation Medical Center, Taipei, Taiwan

INTRODUCTION

Restoration of functional ambulation is one of the major goals in the rehabilitation for nonambulatory hemiparetic patients. Recent studies found that functional therapeutic task, such as treadmill training could effectively restore walking ability and improve gait pattern. However, there were still 40% of those who restored walking ability in hospital failed to regain walking ability when returned to community. To improve the effect of treadmill training, virtual reality (VR) technology was added to the traditional treadmill-training program to construct a more interactive and diverse balance-training program. The hypothesis is that the additional visual biofeedback from VR scenery could further increase the training effect and balance skill.

MATERIAL AND METHODS

A VR based treadmill system as shown in Figure 1, a VR scenery was synchronized by a speed/position sensor and progressed according to the treadmill speed that was tailored by the therapist in corresponding to each patient's balance control capacity. A 20 minutes program with eight right and left turns was constructed by 3D web Master VR software. A suspension system was mounted for safety.

14 hemiparetic patients were recruited from local medical center and randomly divided to training or control group. The training group underwent treadmill training with interactive VR program and the control group participated in the traditional treadmill training only. All subjects were exposed to 3 weeks training (20 mins a session, three sessions a week). Both groups were tested by the following three tasks pre- and after training as the evaluation parameters of balance skills: stand still for 5 seconds (for quiet stance stability), sit-to-stand, and level walking in the most comfortable speed (for dynamic balancing skill). The loci of COP of the first two tasks were recorded using a pressure mat (RS-scan, Belgium). The change of foot pressure during sit-to-stand and walking was recorded by F-scan (TekScan, USA). Mann-Whitney U test was used to test the difference in training effect between groups.

RESULTS AND DISCUSSION

Both groups failed to show significant improvement in quiet stance stability. However, the experimental group did showed significantly more symmetric posture in the process of sit-to-stand transfer, which means that more weight was loaded over affected lower extremity for the experimental group (Figure 2). In addition, the stance phase of the sound leg decreased from 90% of the gait cycle to 60%, which is more

comparable to the normal pattern.

SUMMARY

The static balance ability failed to show the training effect might be due to the ceiling effect. More challenging test may be required to detect the balance change for subjects with higher balance skill in this study. However, the visual flow stimulation and more physical practice of weight shifting might results in the significant improvement of the body sway and balance ability in training group as shown by the performance of sit-to-stand transfer. In summary, the virtual reality technology can make the treadmill training more divers, more challenging, and more attractive to the participant, which were believed to facilitate learning effect.

INTRODUCTION

Replacement of damaged tissue/organs remains a significant problem. Standard therapies such as transplantation are limited by donor shortages and alternatives such as drug therapies, and surgical reconstruction frequently fail in long term applications (Kim et al., 1999). Scientists have come to believe that tissue engineering may provide a viable solution. The most commonly used approach is the utilization of an exogenous 3-D ECM scaffold to bring the appropriate cell types into contact in a suitable environment (Ratcliffe 2000). This work investigated the biocompatibility and biodegradability of 3 such ECM scaffold materials of biological origin- ECM1, ECM 2 and ECM 3 using L929 mouse fibroblasts for “*in vitro*” studies.

METHODS

Biocompatibility was assessed using the Direct Contact and Indirect Contact assay in accordance with ISO 10993-5: “Tests for Cytotoxicity -In Vitro Methods”. Total cellular protein concentration was assessed using the BCA assay (Bicinchoninic acid assay) and the metabolic activity was assessed by the MTT assay. Cell viability was investigated using the Giesma staining procedure.

The effect of hydrolytic degradation on ECM1 was investigated by a timed degradation study with ECM 1 being incubated in PBS (phosphate buffered saline) pH 7.4 at 37°C. ECM 1 was removed at timed intervals dried and weighed. The sample extract were assessed via the BCA assay to determine if protein is being released during degradation. We also assessed the thermal stability of ECM 1 using Thermogravimetric analysis (TGA).

RESULTS AND DISCUSSION

It was found that the presence both directly and indirectly (elutant extract) of ECM 1, ECM 2, and ECM 3 caused an increase in the production of cellular protein assessed via the BCA assay and also in an increase in cell metabolic activity assessed via the MTT assay. Figure 1 compares the % protein conc vs. % metabolic activity for cells in direct contact with the various ECM materials and control materials (PE -ve and PVC +ve). This suggests that ECM 1-3 have bioactive properties causing a positive effect on cell behaviour. Giesma staining proved that cells were viable and appeared capable of supporting cell adhesion and proliferation which are desirable parameters for a tissue engineering scaffold.

It was found that ECM1 degraded hydrolytically over time. Following a 3 month period the mass of ECM1 had decreased approximately 35%. We also observed that samples subjected to a repeat sterilization process degraded at a faster rate- following 3 month period mass had decreased approx. 60%. TGA analysis was significant as it was found that ECM 1 in its dry form contained 12% water. This has significant implications for storage and shelf life of ECM 1 as it has also been shown to be affected by hydrolysis.

Figure 1: Shows the comparison of results for BCA assay and MTT assay in Direct Contact assay.

SUMMARY

ECM 1, ECM2, and ECM 3 appear to be bioactive materials capable of supporting cell adhesion and proliferation. ECM1 is degraded by hydrolytic degradation and repeated sterilization results in an increased rate of degradation. ECM1 (dry) contains 12% water which has significant implications for storage and shelf life of the materials.

INTRODUCTION

It is well accepted that mechanical strain plays an important role in regulating bone formation and resorption. Therefore, in vivo bone strain measurements have been described by many investigators. However, knowledge of the pattern of the in vivo strain is limited to relatively short-time measurements. Although the short-time measurements determine the peak strain during vigorous activities, a detailed profile of the frequency and duration of the in vivo strains remains unclear.

The purpose of the present study is to determine the long-time pattern of in vivo bone strains. For this purpose, we have newly designed a telemetric system for the determination of the in vivo strains, and applied it to the long-time measurement of the strain pattern induced in the rabbit femur.

METHODS

A telemetric system which we have newly designed eliminates the need for long trailing wires from animals. Therefore, the system can be applied to in vivo strain measurements for free-moving animals. A sender unit (Fig. 1) is composed of a Wheatstone bridge circuit, an amplifier circuit, and a radio transmitter equipped with a VF converter. After the frequency signal, which corresponds to the bone strain, is transmitted to a receiver, the corresponding output voltage signal is recorded.

A single element waterproofing strain gauge was bonded to the anterior part of midshaft of a rabbit femur. The lead wires of the gauge were connected to the telemetric system which was attached to the animal body. Three hours after implanting the gauge, the output voltage from the telemetric system was continuously recorded for 6 hours. After the data collection, the femur with the strain gauge was harvested from the rabbit. The calibration curve, which is described by the relation between the bone strain and the output voltage from the telemetric system, was obtained from a cantilever loading test. The in vivo strains induced in the femur were calculated with this calibration curve.

Figure 1: Telemetric system (sender).

RESULTS AND DISCUSSION

Figure 2 shows the in vivo strain pattern continuously measured for 6 hours. Although the in vivo strains were over a wide range, the femur was subjected to compressive strains much more frequently than tensile ones. The pattern of the in vivo strains measured with the telemetric system corresponded to the observation of activities in the animal. This result indicates that the system which we have designed has the potential for accurate determination of in vivo bone loading conditions. The peak compressive strains obtained from the present study were approximately $-2500 \mu\epsilon$. These values were similar to those measured by nontelemetric strain gauge technique in the past studies. For example, Rubin and Lanyon (1982) reported that peak compressive strains are generally conceded to be about -2000 to $-3000 \mu\epsilon$ in most animals.

Figure 2: In vivo strain pattern measured for 6 hours.

SUMMARY

We have newly designed a telemetric system for the long-time measurements of in vivo bone strains. Using this system, we could continuously measure the pattern of the in vivo strains during the normal activities, such as eating, resting, and walking.

INTRODUCTION

The deceleration stage of 100m sprint, it was known that both contact and flight times are longer than in the constant speed stage. Contact time was divided into eccentric (negative) and concentric (positive) work phase according to the vertical movements of the center of gravity (CG). In the eccentric phase, the foot-contact played the braking role; the CG vertically dropped and decelerated slightly. The effect of kick motion in the deceleration stage of 100m track race was researched.

However there were no research dealing relationships between kick and CG, especially about kick motion of ankle at concentric phase.

Thus the purpose of this study was to clarify the availability of kick motion of ankle and to suggest the better kick in the deceleration stage during 100m sprinting.

METHODS

Subjects were 14 highly trained college male sprinters. Two digital video cameras were set up in the main stand at a frequency of 60 frames per second (SONY LCH-VX2000), and the running form in 80-85m interval was recorded in the 100m track race. DLT method was used to analyze angle of ankle joint at contact phase and displacement of CG.

The Pearson's product-moment correlations between variables were calculated. Statistical significance was set at the $p < 0.05$ level.

RESULTS AND DISCUSSION

The relationship between vertical displacement of CG and displacement of ankle angle at concentric phase were indicated in Fig.1. And the relationship between horizontal displacement of CG at flight phase and displacement of ankle at concentric phase was showing Fig.2. Both coefficients of correlations (Fig1, 2) were significant ($p < 0.01$).

Fig1 Relationship between vertical displacement of CG and displacement of ankle angle at concentric phase

Fig2 Relationship between horizontal displacement of CG at flight phase and displacement of ankle at concentric phase

SUMMARY

Kick motion of ankle at concentric phase has little advantage to run faster. Because of the displacement of CG was significantly increase vertically and less gained horizontally.

INTRODUCTION

The surface layer of articular cartilage plays an important role in its tribological function for synovial joints. Kobayashi *et al* (1996) have found a surface “amorphous layer” using a cryo-scanning electron microscope. These authors further suggested that this amorphous layer mainly consisted of proteoglycan molecules. This is different from the superficial layer of articular cartilage, which mainly consists of a collagen-fibril network and chondrocytes. Similar observations were made by Sasada (1999), Ikeuchi & Oka (1999) and Sawae & Murakami (1999). However, these authors refer to this layer as a “gel layer”, in which the chondroitin or keratin sulphates composing the leaves of the proteoglycan subunit are hydrated. The purpose of this study is to further characterise and compare the tribological properties of the surface layer of healthy and degraded articular cartilage.

MATERIALS AND METHOD

A commercially available D3100 Nanoscope IIIa AFM (Digital Instruments, Santa Barbara) and Hysitron nanoindenter is used to image the surface topography of bovine articular cartilage and to determine the force-distance relationship. AFM investigations on dry or desiccated samples give topographic and nanoindentation results that are unrepresentative of the living tissue. Therefore, in order to eliminate the adhesion and surface tension forces that affect scanning probe testing of the hydrated tissue, a fluid cell is to be incorporated into this experimentation. Phosphate buffer solution (PBS) is used as the hydration media within the fluid cell. Fluid tapping mode is employed for imaging the surface, from which surface roughness data is accumulated. Spherical diamond indenters with different tip radii are utilized for nanoindentation of the surface to examine the variation of biphasic properties of the cartilage sample with and without a gel layer. Chemical and mechanical degradation of the sample is used to replicate degenerated and diseased cartilage specimens.

Mathematical models are developed to predict the force-distance relationship, based on both fluid and solid mechanics. The fluid mechanics approach uses lubrication theory, while the solid mechanics approach is based on the biphasic theory for articular cartilage.

RESULTS AND DISCUSSION

Results from the AFM tapping mode scanning are discussed in the context of asperity amplitude and frequency across the surface using bearing curve analysis. Comparison of results from the nanoindentation of healthy and degraded cartilage reveals how the gel layer affects the properties of the cartilage. These results are discussed in the context of current lubrication theory.

DOES NORMALIZATION OF MUSCLE STRENGTH FOR BODY SIZE DEPEND ON THE FUNCTIONAL PERFORMANCE TO BE ASSESSED?

Slobodan Jaric, Ulrika Aasa, Margareta Barnekow-Bergkvist, Hakan Johansson
Centre for Musculo-Skeletal Research, National Institute for Working Life, Umea, Sweden

INTRODUCTION

Although the relationship between muscle strength and body size has attracted a considerable attention of researchers, the normalization of muscle strength for body size has been arbitrarily applied through the professional literature. A specific problem appears when the tested muscle strength is assumed to serve for assessment of the functional movement performance in various sports, ergonomic, therapeutic and other movement related literature. In particular, since performance of various functional tests may also be related with body size, the optimal normalization of muscle strength for body size may differ when different functional movement abilities are assessed. The present study investigates this problem on two important groups of functional performance/ability tests: the tasks based on overcoming gravitational and inertial resistance of subject's own body, and the tasks of exerting force against external objects.

METHODS

Healthy, male and physically active university students (N=21, aged 20-28 years) were tested on vertical jump, standing football kick, seated medicine ball throw and standing maximal isometric lift. A standard isokinetic apparatus was also used in order to test the isokinetic MVC (60°/s) of muscle groups active in the tested functional tasks. The MVC was thereafter related with the recorded performance of four functional tests as either non-normalized or normalized (per kg of body mass) strength.

RESULTS AND DISCUSSION

Subjects' body mass was 80.4 ± 9.8 kg, while their height was 182 ± 8 cm. The tested strength (averaged across the subjects) revealed the following results: 77 ± 15 Nm in shoulder flexors, 67 ± 12 Nm in elbow extensors, 192 ± 39 Nm in hip flexors, 209 ± 52 Nm in hip extensors, and 231 ± 45 Nm in knee extensors. The averaged across the subjects results obtained in the functional performance tests were as follows: the height of the vertical jump was 38 ± 6 cm, the peak foot velocity in the standing football kick was 14.7 ± 1.7 m/s, the peak hand velocity in the seated medicine ball throw was 4.3 ± 0.5 m/s,

while the force recorded in the standing maximal isometric lift was 1440 ± 220 N.

Table 1 depicts the main result of the study: the relationship between the functional movement performance and strength of the active muscle groups. The tested performance that required exerting muscle force against one's own body (i.e., vertical jump and standing football kick) demonstrated stronger association with normalized than with the non-normalized strength in all five tested relationships ($p < 0.05$; Wilcoxon matched pairs test). The tested performance based on exerting muscle force against external objects (i.e., seated medicine ball throw and standing maximal isometric lift) demonstrated the opposite result ($p < 0.05$).

The obtained results could be interpreted from the prospective of the role of body size in both muscle strength and functional performance tests. It is well known that muscle strength increases with body size. Since the velocity of rapid body movements is likely to be body size independent, the muscle strength applied in order to predict the movement performance should also be size independent (i.e., normalized). However, since the functional performance of acting by force against external object is well known to increase with body size just like muscle strength, normalization of muscle for body size is redundant (or, alternatively, both muscle strength and functional performance should be normalized).

SUMMARY

The results obtained generally suggest that the requirement for normalization of muscle strength for body size may depend of the type of functional movement performance to be assessed. Therefore, further research is needed in order to provide comprehensive and reliable classification of functional performance tests from the prospective of the role of body size.

ACKNOWLEDGEMENTS

The study was supported in part by grants from The Swedish Sport Research Council and The Swedish Council for Work Life Research.

AN INVESTIGATION OF THE BURST FRACTURE MECHANISM USING A COMBINED EXPERIMENTAL AND FINITE ELEMENT APPROACH

Ruth Wilcox¹, David Allen², David Barton¹, Richard Hall^{1/2}, David Limb², Robert Dickson²

¹School of Mechanical Engineering, University of Leeds, Leeds, UK. Email: menrkw@leeds.ac.uk

²Musculo-skeletal Services, St. James's Hospital, Leeds, UK

INTRODUCTION

Following a burst fracture, decompressive surgery is often recommended on the basis of imaging alone. However there is doubt as to whether the fragment position seen on post-injury CT scans represents the true extent of the occlusion produced during the fracture process (Limb et al., 1995). Several experimental studies have modelled the burst fracture in the laboratory, but few authors have studied the detailed dynamics of the event due to the high impact speed. Further, only limited data can be obtained from such models since invasive measurements would affect the fracture mechanism. The aim of this study was to combine experimental data with a finite element model to provide greater understanding of the underlying mechanics of the fracture event.

METHODS

A drop-mass method described previously (e.g. Tran et al., 1995) was used to create burst fractures in bovine spinal segments at different impact energies. During the event, the specimens were filmed by high-speed video along the canal and externally. After fracturing, each specimen was dissected and a detailed examination of the damage recorded. A finite element model, based on CT images of one of the specimens was also created and processed using LS Dyna (Livermore Software, CA). The model comprised an entire motion segment including posterior elements and the posterior longitudinal ligament (PLL). Validation of the model was carried out by comparison of component displacements with the video images. The combined evidence of the finite element and experimental models was used to build an understanding of the fracture mechanism.

RESULTS

The high-speed video footage showed the external damage to the specimen during impact. At high impact energies, the transverse processes were seen to rotate posteriorly and some cracking of the posterior of the vertebral body was observed. Dissection of 38 specimens showed damage corresponding to the burst fracture pattern described by Denis (1983). At the lowest impact energy (20J) no or minimal cracking of the vertebra was recorded. At medium impact energies, a Denis type C fracture was observed, with a wedge of bone and endplate cartilage. At impact energies above 100J, type A fractures were increasingly found, with the fragment including bone from both endplates. There was a positive correlation between the impact energy and mass of the fragment ($r = 0.708$, $p < 0.001$). The posterior longitudinal ligament was always intact.

The dynamic finite element model showed that as the specimen compressed, the articular processes were forced apart. This caused the transverse processes to rotate, as was observed on the video footage. The movement of the articular processes led to a tensile force being transmitted through the pedicles, and produced localised regions of high tensile strain in the posterior of the vertebral body (Figure 1). Fracture was initiated at these sites approximately 2 ms after impact. Further analysis of the fragment projection into the spinal canal showed it being reflected back by action of the PLL.

Figure 1: Maximum principal strain in half the vertebral body

DISCUSSION

Several authors have suggested that the increased pressure in the cancellous bone causes high hoop stresses in the cortex that lead to tensile failure. Although this does occur, it does not explain why the fracture initiates at the particular positions on the cortex. The finite element and experimental models show that the motions of the articular processes cause fracture by generating high tensile strains in the region of the pedicles. The combined experimental and computation approach to investigating the burst fracture has yielded a greater understanding of the dynamics of the fracture mechanism. The results provide further evidence of how the bone fragment may be produced and projected into the spinal canal. The specimen dissections show that the fragment is often attached to the endplate and the posterior longitudinal ligament remains intact, causing the projected fragment to be recoiled back towards the vertebral body, as was also shown in the finite element model. The findings confirm previous experimental work (Wilcox et al., 2001) and demonstrate that the greatest canal occlusion occurs before the fragment is recoiled and will not be represented by post injury imaging of the patient.

A NOVEL EQUIPMENT FOR THE ASSESSMENT OF HAND FORCES

Sandra Morelli, Daniele Giansanti, Gianni Maccioni, Claudia Giacomozzi, Velio Macellari
Biomedical Engineering Laboratory, Istituto Superiore di Sanità, Rome, Italy
Corresponding author: C. Giacomozzi, claudia.giacomozzi@iss.it

INTRODUCTION

A good level of hand muscular activity and ability to manage objects is mandatory for maintaining an adequate quality of life. In terms of forces exerted through the tendons of deep flexors which mainly act on the distal inter-phalangeal joints, most studies only assess the action of the 4 fingers (Li et al., 1998; Li et al., 2001). Thumb was instead rarely included in the studies (Kilbreath et al., 1994; Kilbreath et al., 1995; Li et al., 1998). A special equipment has been purposely designed and constructed at the authors' laboratory to assess the force each finger exerts under isometric conditions. A dedicated software with a visual bio-feedback allows the patient to follow pre-established force profiles according to well defined trajectories. Validation and calibration tests proved the system to be accurate and reliable. It allows to analyse the effects of different strategies of central neural system in managing thumb activation, the reciprocal influence of fingers of one or both hands, the effects of mechanical constraints. The visual feedback, then, renders it particularly attractive in rehabilitation.

Fig. 1. Devices – a) top view of right FK; b) lateral view of right MS; c) detail of the key.

METHODS

Two devices have been realised for each hand: a flat keyboard (FK) with five keys to measure the force each finger exerts against the corresponding instrumented key; a mouse-like support (MS) equipped with one key only, to measure the force the thumb exerts while grasping a mouse-like metallic handle. Each key consists of a quasi-rectangular aluminum bar (63.5mm long, 169mm² of contact surface), instrumented with a full estensimetric bridge which measures its flexion when the finger presses against it. The devices and a detail of the key are shown in Fig. 1. The key on the MS is 90° rotated around the longitudinal axis of the finger. When the hand is fixed aside the mouse, the same key allows the measurement of the force exerted by little finger adductor. During measurement, both devices are inserted in a flat support which maintains hand, wrist and forearm in a fixed position and guarantees for a stable contact between fingers and keys. A dedicated software provides: tools for data acquisition and processing; on-line visual feedback; force profiles programmable as for amplitude, shape and duration. A few

experiments have been conducted on 4 healthy volunteer to test the system “on-the-field”. Each subject was asked to perform different tasks of isometrically pressing against the devices, three times each in random sequence. Maximum force was identified for each task of interest.

RESULTS AND DISCUSSION

Repeatability was tested for each key at 10, 20, 30, 40 and 50N, 10 random measurements for each step, thus taking into account for eventual repositioning errors. The worst response in terms of mean of deviations was around 3% of the measured value (input force 10N). For forces greater than 20N the response always spread less than 1% (range 0.2-1.0). Responses were strictly linear; angular coefficients ranged from 0.744 to 1.233, and R² values ranged from 0.998 to 1.000.

As an example of the system outputs, different strategies of hand force delivering are reported in Fig. 2. Fig. 2a shows the different percentual contribution of the thumb and the remaining 4 fingers to the total maximum voluntary contraction (MVC) expressed on the FK. Fig. 2b reports three cases in which the influence of the contralateral hand while grasping the mouse results in three dramatically different effects (reduction (a), invariance (b), increase (c)).

The system is self-contained, easily transportable and easy to use. We believe it's a promising tool both for diagnosis and therapy, for fields like biomechanics, clinics, forensic medicine and occupational medicine.

Fig. 2. – On the left: the thumb contribution to the total force exerted on the FK is significantly smaller in case b. On the right: the thumb grasping-pressing force during a bilateral task is reduced (a), unchanged (b) and increased (c), with respect to the unilateral task.

A SIMPLE MODEL TO RELATE CLINICAL TO BIOMECHANIC VARIABLES IN PERIPHERAL NEUROPATHY

Claudia Giacomozzi¹, Stefano Cesinaro¹, Velio Macellari¹, Luigi Uccioli², Emanuela D'Ambrogio²

¹Biomed. Eng. Lab., Istituto Superiore di Sanità, Rome, Italy; ²Dept. Internal Medicine, University of Rome, Italy

Corresponding author: C. Giacomozzi, claudia.giacomozzi@iss.it

INTRODUCTION

Peripheral neuropathy is a frequent and serious complication of diabetes. From a biomechanic point of view, it results in significant alterations of gait, widely investigated in terms of foot-floor interaction (Uccioli et al, 2001). From a deeper analysis, however, changes are also found at the level of the ankle articular complex, as for limited joint mobility and reduced muscular strength (Mueller et al, 1995).

The challenge of this study was to associate the alterations of biomechanic parameters measured at the ankle complex to concurrent alterations of physical and clinical parameters of diabetic patients, with or without neuropathy.

METHODS

22 healthy volunteers (9 females, 13 males) have been included in the study as a control group, matched for age and physical characteristics with the diabetic patients. The pathologic group was formed by 60 diabetics, 26 females and 34 males, whose VPT (vibratory perception threshold) was measured according to the existing guidelines (Young et al, 1997) and included in the study as the only clinical independent variable of the model.

Joint mobility and muscular functionality of both patients and volunteers were accurately assessed by means of a dedicated device, designed and constructed at the authors' lab (Giacomozzi et al, 2000). The device allows the measurement of angular excursions of the ankle complex in the three anatomical planes, and of torques expressed around the three corresponding axes when exerting maximal voluntary isometric contractions of the leg muscles. Peak values have been identified for each parameter and for each patient. For control group, a set of statistical regressive models have been considered whose independent variables were sex, age, height, body weight and body mass index (BMI). The best-fitting model was then applied to the pathologic group, too, with the inclusion of clinical variable VPT among the independent factors of the model.

Table 1: Mean values and standard deviations of independent variables of patients and controls which have been included in the regressive model

	Cases	Age (yrs)	Height (cm)	Weight (kg)	BMI (kg/m ²)	VPT (V)
Controls	22	50.41 (±14.6)	168.55 (±8.8)	71.00 (±11.3)	24.86 (±2.6)	-
Diabetics	60	53.97 (±12.8)	168.20 (±9.7)	76.42 (±15.6)	26.97 (±4.8)	13.00 (±8.3)

RESULTS AND DISCUSSION

Mean values and standard deviations of the independent variables are reported in Table 1 for patients and controls. Student's t-test confirmed that there were no statistically significant differences between the two groups for age, height and weight ($p=0.05$ for BMI).

The statistical model which best fitted the biomechanic parameters of the ankle complex functionality was the Piecewise linear regression model with computer-fixed breakpoint. It is a sort of multiple linear regression whose angular coefficient changes from a fixed point on. For any of the angular excursion or torque in any of the three anatomical plane, the model succeeded in explaining more than 90% of variance for controls. The same model, with the same independent variables plus VPT, explained up to 80% of variance in presence of neuropathy.

As an example, Fig. 1 shows the results of the application of the piecewise model to estimate the torque generated by a maximal plantar flexion (sagittal plane), starting from a neutral position (90° between foot and leg). Fig. 1a plots the observed versus the estimated values for controls; fig. 1b plots the same values for diabetic patients; fig. 1c compares the good fitting of the appropriate model for patients, and the bad fitting obtained by applying to patients the coefficients corresponding to the same parameters for controls. This last comparison is important to highlight two main findings: i) relationships among physical and biomechanic characteristics change with respect to a normal condition when diabetic peripheral neuropathy takes place, even if in a early stage; ii) suitable clinical variables must be necessarily included in the model to take into account at least for part of the observed biomechanic alterations.

Piecewise linear model to estimate dorsal flexion torque

Figure 1: a) observed vs predicted values for controls; b) observed vs predicted values for patients; c) bad fitting, of model found for controls, to patients observed values.

ECS ADHESION ON SILICONE RUBBER-RTV 615: A SYSTEMATIC STUDY

J.-P. E. Martinez¹, R. Haklai², S. Einav¹, Y. Kloog², Y. Lanir³

³Department of Biomedical Engineering, The Institute of Technology -Technion, Haifa, Israel

INTRODUCTION

Silicone rubber RTV 615 is a suitable material for the building of artery models since it is compliant, highly transparent and easy to process. However, surface modification is necessary to reduce its hydrophobicity to enhance adsorption of adhesive proteins and cellular adhesion (Ratner et al.1996). Different methods are described in the literature for the treatment of various silicone rubbers, but they were found to be ineffective on RTV 615 or non applicable to tube's lumen. Therefore, a systematic study of ECs adhesion on silicone rubber RTV 615 has been done.

METHODS

The investigated parameters included: surface treatment (acid vs base), time (0', 10', 30', 60'), amination, topography (fine vs rough) and protein contact (collagen, fibronectin, gelatin, serum). Surfaces have been characterized for their roughness, surface energy (Wilhelmy slide method - LaPorte, 1997) and molecular structure (TOF-SIMS) after surface treatment and prior to protein contact. Bovine aortic ECs (BAECs) were seeded. Micrographs (phase contrast microscopy and fluorescence microscopy for Hoechst staining) were quantitatively imaged and analyzed.

RESULTS

The optimal time treatment to reduce surface hydrophobicity was 30', base inducing a change of 10° in the contact angle. Acid and base, respectively, increased the number of adherent and spread cells by 10 and 100 fold. Gelatin has been found to promote the best cellular adhesion after acid treatment and fibronectin after base treatment. After 45 hours culture, ECs reach local confluence aside to empty area so called "capillary forms" on surfaces treated by base followed by fibronectin contact (fig.1, a & b), whereas acid treatment followed by amination and fibronectin contact induced a uniform cell distribution on the surface but without confluence and very few cell-cell contacts (fig.1, c). Full cell confluence was obtained by acid treatment followed by amination and collagen contact (fig.1, d).

CONCLUSIONS

The results show the feasibility to culture ECs on RTV 615, using surface modification methods that are applicable to tube's lumen. They provide formulae to reach cell confluence or, alternatively, uniform cell distribution with no cell-cell contacts.

BAECs Adhesion on RTV

Fig. 1: BAECs adhesion on RTV: a) base treatment and fibronectin - "capillary forms" and local confluence; b) as in a, stained cell nuclei; c) acid treatment, amination and fibronectin - uniform, sparse cell distribution; d) acid treatment, amination and collagen - full confluence.

THE EFFECT OF HORIZONTAL FOOT VELOCITY ON IMPULSE IN HORIZONTAL JUMPING

Steven LeBlanc

School of Health and Human Performance, Dalhousie University, Halifax, Nova Scotia, Canada

Steve.LeBlanc@dal.ca

INTRODUCTION

It has often been stated by researchers and coaches that athletes should use an active landing, or "pawing" action, when performing the horizontal jumps in track and field athletics; namely the long jump and triple jump. This technique is seen as a means of reducing braking impulses, thus reducing losses in the horizontal velocity of the total-body centre of mass during the support phase of the takeoff. To date, this concept has received relatively little attention in the research on jumping (LeBlanc, 1997). The purpose of the present study was to examine the pre-contact horizontal foot velocities relative to the total-body centre of mass (i.e., the level of activeness) and the horizontal and vertical impulses encountered during the support phase during short-approach horizontal jump takeoffs. It was hypothesized that greater levels of activeness would lead to reduced braking impulses while leaving the propulsive and vertical impulses unaffected.

METHODS

Kinematic data was collected using standard two-dimensional video analysis techniques (NTSC 60 Hz), and kinetic data was collected from a force platform (300 Hz). Five experienced, non-elite jumpers performed five trials each of two-, three- and four-step approach long jump-style takeoffs. This resulted in a total of 75 trials to be analysed. The subjects represented a heterogeneous sample of jumpers from all four jumping disciplines (one male LJ, one female LJ/TJ, one male HJ, one female LJ/TJ/HJ, one male PV) in hopes of more clearly identifying trends in the data as compared to previous research (Koh & Hay, 1990a,b).

The statistical analysis examined the relationships between the level of activeness (**rVf**) and five dependent measures: horizontal braking impulse (**FTb**), horizontal propulsive impulse (**FTp**), change in horizontal velocity of the total-body centre of mass (**dVh**), net vertical impulse (**FTv**), and theoretical flight distance (**D**). A regression model (see Equation 1) was used to examine the relationships between activeness and the dependent variables. As well as **rVf**, the model incorporated a subject variable, mass, and the horizontal and vertical touchdown velocities of the total-body CM (**tdVh**, **tdVv**) as predictors. It was deemed to be evidence of a significant relationship if the regression analysis resulted in a model with a large F-value, a large R^2 value, a significant

p-value for **rVf**, and a β coefficient for **rVf** whose sign agreed with the hypothesized relationship.

$$Y = \beta_0 + \beta_1 \text{subj} + \beta_2 \text{rVf} + \beta_3 \text{mass} + \beta_4 \text{tdVh} + \beta_5 \text{tdVv}$$

Equation 1: Multiple regression model.

RESULTS AND DISCUSSION

The subjects used active landings (-2.61 ± 1.11 m/s) in 73 of 75 short approach jumps. The ground contact resulted in a net loss of horizontal velocity of the CM (-1.14 ± 0.30 m/s) and a net gain in vertical velocity of the CM (2.92 ± 0.42 m/s) in all 75 trials. The mean impulses during contact were: **FTb** = -85.11 ± 23.07 Ns; **FTp** = 3.14 ± 1.00 Ns; **FTv** = 343.30 ± 61.54 Ns. Theoretical flight distances were calculated to be 2.01 ± 0.36 m. Based upon the results of the regression analysis, it was determined that **rVf** was significantly related to **FTb** ($F=28.69$, $R^2=65.2\%$, $p=0.002$, $\beta_2=-6.68$), **dVh** ($F=16.97$, $R^2=51.9\%$, $p=0.025$, $\beta_2=-0.07$), and **FTv** ($F=94.42$, $R^2=86.3\%$, $p=0.000$, $\beta_2=13.1$). No significant relationship was found between **rVf** and either **FTp** or **D**.

SUMMARY

It was found that: 1) greater activeness reduced the braking impulse; 2) level of activeness was not related to propulsive impulse; 3) greater activeness reduced the loss in horizontal velocity; 4) greater activeness reduced the net vertical impulse; and 5) level of activeness was not related to theoretical flight distance. From this analysis, it was evident that the use of the active landing technique affects more than just the braking impulse. Further research is necessary to clarify the effectiveness of the active landing technique to improve horizontal jump performance.

ON THE ERRORS SURROUNDING HEMODYNAMIC ANALYSES: COMPARISONS OF VARIOUS INVESTIGATIVE TECHNIQUES

Thomas O'Brien, Michael Walsh, Tim McGloughlin

Biomedical Engineering Research Centre, Dept. Mech. & Aero. Eng., University of Limerick, Limerick, Ireland

INTRODUCTION

Hemodynamic factors have been widely implicated in the development of atherosclerosis. Abnormal wall shear stress (WSS) gradients and distributions along with regions of flow separation are thought to be the principle disease influencing factors in the vascular system (Giddens, 2001). There is a range of experimental and numerical techniques available to researchers to investigate the blood velocity profiles and wall shear stresses at various disease prone sites. Principle among these are; the numerical methods based on the finite element (FE) and finite volume (FV) methods, which are both accurate and efficient, and the experimental *in vitro* technique, laser Doppler anemometry (LDA), with its high spatial and temporal resolution. The purpose of this study was to perform a detailed comparison on the aforementioned techniques with a view to establishing how differences between the results may be reduced and which of the two numerical methods gave closer correlation to experimentally derived results.

MATERIALS AND METHODS

The geometry of interest that was chosen for this study was that of a 6mm idealised graft-artery bypass junction. This geometry was selected as it causes such phenomena as flow separation, recirculation and stagnation. An idealised 45° graft-artery junction was machined and polished into a plexiglas block for 1-D LDA studies. The model was investigated using two different transient inlet velocity boundary conditions, namely a femoral resting pulse and a carotid resting pulse. A non-Newtonian fluid was used. Velocity profiles were determined at various axial and radial positions through the junction.

The numerical studies were carried out on models according to the conditions described above. A 6mm idealised 45° graft-artery junction was generated and meshed in Gambit 1.3 (Fluent, Europe) using approximately 100,000 brick elements. This was then exported as a structured mesh for solution in Fluent 4.5 (Fluent, Europe) and as an unstructured mesh in FIDAP 8.6 (Fluent, Europe). The velocity boundary conditions and fluid properties were as for the experimental analysis. Simulations were performed on a 1GHz, 512Mb RAM, Dell Dimension 4100.

RESULTS

Results were obtained at the mean decelerating velocity for both pulses as this was found to have particularly severe WSS gradients and distributions. Results were compared by plotting the 2D velocity profiles through the junction (figure 1) and establishing the percentage differences between them, using the LDA profiles as a benchmark.

Figure 1: Velocity profiles through junction for resting pulse.

In addition, WSS acting along the bed of the artery were compared for the three methods. The WSS for the LDA investigations were determined by curve-fitting the experimental data (figure 2).

Figure 2: WSS acting along bed of artery for resting pulse.

DISCUSSION

There are significant differences between the three investigative techniques. Comparisons of the two pulse results showed that the LDA method may be pulse point dependant. In addition, the FE velocity profiles gave better agreement to the LDA than did the FV profiles. The FV method gave higher WSS results than the FE method though was approximately 60% more efficient.

COMPARATIVE ANALYSIS OF THE HEMODYNAMICS THROUGH HEALTHY AND DISEASED MODELS OF THE HUMAN ABDOMINAL AORTA

Liam Morris¹, Thomas O'Brien¹, Tim McGloughlin¹, Don Giddens², Patrick Delassus³

¹Biomedical Engineering Research Centre, Dept. Mech. & Aero. Eng., University of Limerick, Limerick, Ireland

INTRODUCTION

Abdominal Aortic Aneurysms (AAAs) are a major cause of death in Western societies. While the factors that effect their development and growth are not fully understood, there are a number of surgical techniques available that seek to prevent rupture of the aneurysm and the subsequent haemorrhaging by attaching a prosthetic graft within the aneurysm (Uflacker *et al.*, 1998). The objective of this study was to quantify the normal conditions that exist within a healthy human abdominal aorta. These results were then compared to corresponding results from an abdominal aortic aneurysm and also for flow through a prosthetic graft that followed the curvature of the diseased aneurysm.

MATERIALS AND METHODS

2D Time of Flight Angiography (TOF) was carried out on a healthy human volunteer using a 1.5T Philips Magnetic Resonance (MR) Imager with a view to determining the geometrical data and velocity boundary conditions for the descending abdominal aorta. Computerised Tomography (CT) was carried out on an abdominal aortic aneurysm using a Siemens CT scanner with a view to determining its geometry. The geometrical models were assembled using Mimics 6.3 (Materialise) and exported as IGES files for meshing in Gambit 1.3. (Fluent, Europe). The prosthetic graft model was generated in ProEngineer 2000i² (Parametric Technologies) according to the dimensions of a commercially available graft (Perouse Laboratoires, France) and its centerline curvature was matched to that of the AAA. Upon determining grid independence, the models were investigated using the numerical solvers FIDAP 8.6 (Fluent, Europe) and FLUENT 6.0 (Fluent, Europe). The pulsatile velocity boundary conditions as determined from MR were applied at the inlets of the models observing continuity between models. Blood was assumed to be a Newtonian fluid with $\mu = 0.0035\text{Pa}\cdot\text{s}$ and $\rho = 1050\text{Kg/m}^3$ (Nichols & O' Rourke, 1998).

RESULTS

The principle results of interest were the magnitudes and gradients of the Wall Shear Stresses (Nerem, 1992) and the velocity profiles acting in each of the models (figure 1). The effects of the geometrical curvature in the diseased aorta were investigated. In addition, the axial forces acting on the prosthetic graft were quantified and compared to normal aortic

conditions. It was found that the peak WSS acting in the healthy aorta was approximately 3Pa as opposed to the prosthetic graft where the WSS was found to be approximately 15Pa in places. WSS gradients were found to be much larger in the diseased and prosthetic models than the healthy one. The aneurysm was found to be particularly tortuous having a major effect on the blood velocity profiles.

Figure 1: WSS for the normal aorta and velocity profiles for the prosthetic graft.

CONCLUSION

There are particularly significant differences between the wall shear stress gradients and distributions in the models described above. The tortuous nature of the aneurysm has major implications for the blood flowing through the aorta and also any surgically implanted grafts.

OSTEOLYSIS OF THE FEMORAL SHAFT AFTER IMPLANTATION OF A CEMENTED HIP PROSTHESIS – BIOMECHANICAL ASPECTS

Holger Grabski, Barbara Behnke, Götz von Foerster and Alexander Katzer
ENDO-Klinik, Holstenstraße 2, D-22767 Hamburg (Germany)

INTRODUCTION

Osteolysis of the femoral shaft is a rare late complication after implantation of a cemented hip prosthesis. The etiology of this secondary phenomenon, which eventually results in loosening of the prosthesis stem, is unknown.

METHODS

To investigate the frequency and possible causes of femoral osteolysis, we analysed the radiographs of 495 patients with the diagnosis “early prosthesis loosening” treated at the ENDO-Klinik Hamburg between 1990 and 2000. 53 of these patients had areas of lysis in the femoral shaft. Of these, one female patient had lysis in both femurs. In 52 the lysis had occurred after primary implantation, and in one after an aseptic exchange operation. Therefore osteolysis of the femoral shaft occurred in 12.9% of “early loosening”, or 0.2% of primary total hip replacements in this 10-year period ($n = 24.764$). For standardized biomechanical in vitro-analysis concerning the cyclic load behaviour of prosthesis stems of different thicknesses in connection with the different cementing fixation techniques the VICON-System was used.

RESULTS AND DISCUSSION

The mean age of the patients was 51.5 years, which is markedly lower than the mean age of coxarthrosis patients. The proportion of male patients was greater than the female. The period of implantation was on average 7.7 years, which is significantly shorter than the general average. There was no predominance of the right or left side, and no correlation to concomitant diseases.

During the exchange operations, arrosion of the femoral cortex, without interruption of the continuity of the bone, and toxic-granulomatous synovitis were observed. Histologically, this was a fibro-histiocyte reaction with foreign body giant cells and zirconium dioxide / polyethylene inclusion and areas of circumscribed necrosis. Florid or purulent foci were not observed. Detailed evaluation reveals that the following factors must be discussed as possible causes of focal osteolysis of the femoral shaft after implantation of a cemented hip prosthesis:

- 1) Thickness of prosthesis stems
- 2) Torsional stability and design of the prosthesis stem
- 3) Cementing technique
- 4) Lateral offset
- 5) The time of intraoperative reduction
- 6) Age and gender of patients

Figure 1: Distribution of femoral shaft osteolysis according to GRUEN's classification

SUMMARY

Regarding the in vivo-findings and in vitro-results, our biomechanical data confirm the recommendation of using maximum thickness in stem prosthesis design in combination with vacuum cementing technique in order to minimize complication rate in total hip arthroplasty by means of isolated femoral shaft osteolysis especially in high demanding and younger patients.

INTRODUCTION

Intra-articular injection of hyaluronic acid (HA), is an increasingly popular treatment for pain relief in knee osteoarthritis (OA). Clinical studies (Huskinson & Donnelly, 1999) have reported the benefits of such treatments, but the mechanism of action is poorly understood. The aim of this study was to develop a series of *in vitro* OA models, which could be used to investigate the potential benefits of intra-articular injections of HA. These results were validated against data from *in vitro* tests on human OA cartilage.

MATERIALS AND METHODS

Start-up frictional properties were investigated as these are dependant on boundary lubrication mechanisms (Forster & Fisher, 1996). Bovine cartilage is readily available and known to give repeatable measurement of friction coefficient (Forster & Fisher, 1996). Bovine femurs from healthy, skeletally mature animals were retrieved within 12 hours of commercial slaughter. Cartilage plates (approx. 30mm x 15mm) and plugs (9mm diameter) were cut from the distal femur. Samples were stored in Ringers solution and frozen (-20°C). Prior to testing, specimens were defrosted at 40°C and treated with Folch Reagent to remove any residual lipids. For all tests the pin was loaded onto the plate for ten minutes prior to measurement. Frictional force was measured with a piezo-electric transducer and data captured on an oscilloscope for analysis. A 25N load was applied, and the sliding velocity of the plate was 4mm/s (fig 1). This model has been used to test lubricants in a boundary lubrication regime (Forster & Fisher, 1996).

Figure 1: Schematic of Test Rig

Three *in vitro* OA models were developed to determine the severity of disease state at which the lubricants are most effective. The 'healthy' model used cartilage as retrieved. The 'intermediate' damage model was developed to represent mild OA. This involved coring a 3mm diameter plug from the plate followed by biochemical degradation with papain (30 mins at 1500units/ml). The third model was a 'highly damaged' model used to represent advanced OA. This used coarse sandpaper to remove greater than 50% of the cartilage thickness. Human samples were retrieved from patients undergoing total knee replacement for OA. Samples were frozen in Ringers (-80°C)

until tested. Human samples were graded using the ICRS System (International Cartilage Repair Society). Ringers was the control lubricant as this has previously been shown to produce friction levels comparable to synovial fluid (Forster & Fisher, 1996). Three HA-based preparations were evaluated: a low molecular weight HA (MW = 700,000); a high MW HA (MW = 3,000,000); and a cross-linked HA (MW = 6,000,000). Results were analysed using one-way ANOVA with individual differences determined using the T-method. All data plotted as averages \pm 95% confidence intervals.

RESULTS

Results for all bovine models showed an increase in friction for each successive damage level, which replicates the human OA results. Results for the 'healthy' bovine model correlated well with those from human samples of ICRS grades 0-1. The use of HA produced a significant ($p < 0.05$) reduction in friction compared to Ringers, for both 'healthy' bovine and low grade human OA cartilage (fig 2). Both 'intermediate' and 'highly damaged' models showed a reduction in friction coefficient for the high MW HA compared to Ringers, but this difference was not statistically significant. High grade human OA cartilage however did show a significant reduction in friction coefficient for the high MW HA.

Figure 2: Comparison of friction coefficient for 'healthy' bovine and human cartilage in Ringers and high MW HA

DISCUSSION

This study shows that boundary lubrication by HA is important for healthy and diseased cartilage. Results from the 'healthy' bovine model showed good correlation with low grade OA cartilage, for all lubricants tested. The inability to demonstrate this in our bovine 'damage' models could be due to a variation in the damage states produced. The results produced by these simple *in vitro* bovine 'damage' models did not replicate the effect of HA on human OA cartilage.

INFLUENCE OF GRAVITATION ON THE SQUAD JUMP: A COMPUTER SIMULATION

Sigrid Thaller and Martin Sust

Institute of Sports Sciences, Karl-Franzens-University Graz, Austria

sigrid.thaller@uni-graz.at

INTRODUCTION

How high can an astronaut jump on the moon? In vertical jumping the force F accelerating the center of mass can be measured via the ground reaction force. This force F consists of the forces produced by the muscles, including arm movements, in the positive direction (up) and the weight of the subject in the negative direction (down). A change in the gravitational field obviously leads to a change of weight, but the inertia of mass remains the same. In addition, the changed velocity of the movement leads to altered muscle forces due to Hill's relation between force and contraction velocity. With the help of a simple mathematical model the influence of the gravitation on the vertical jump is simulated.

METHODS

The squad jump is described by a Hill-type model of an extensor based on Sust (Ballreich, Baumann 1996.). This model consists of three parts, describing the force produced in the muscle (Hill), the innervation of the muscle, and the relation between the force in the muscle and the force acting outside due to the geometry of the joint. These parts together with Newton's law lead to a nonlinear second order differential equation which is solved numerically using MATLAB®. There is only a small number of parameters used: one parameter for the innervation, three for Hill's force-velocity relation, 5 for describing the geometry of the joint, and furthermore, the mass, the gravitation, the initial position and the initial velocity for the equation of motion. Several simulations were performed using different values of parameters for the biomechanical and physiological properties of the subjects

RESULTS AND DISCUSSION

In a first series of simulations we decreased the gravitational constant while we increased the mass such that the weight, i.e. the product of gravitation times mass, was kept constant. All other parameters of the subject were left unchanged. As a result the height of the jump increased with decreasing gravitational constant, while the velocity at take off, i.e. the velocity of the center of mass at the time when the subject loses ground contact, decreased. Figure 1 shows the velocity at take off, the jump height (measured from the ground), and the total energy produced by the muscle, as a function of the gravitation for one subject. The shape of these curves depends on the individual properties of the subject. In order to examine the interindividual differences between the subjects and their influence on the height of the squad jump we performed a simulation of jumps on earth

(gravitation $g = 9.81 \text{ m/s}^2$) and on the moon ($g = 1.65 \text{ m/s}^2$). We were able to find values of parameters in such a way that on earth subject A jumped higher than subject B, whereas on the moon, subject B was better in jumping (Table 2). Subject A is assumed to have a slower innervation and a lower maximal possible contraction velocity of the muscle. Thus on earth, where the time until take off is longer and therefore the velocity of the movement is slower than on the moon, these individual properties of subject A are less limiting than on the moon.

Figure 1: Height, velocity at take off, and energy of the squad jump, as a function of gravitation. The weight of the subject is held constant by adding additional mass.

Table 1: Comparison of height (measured from the ground) of a squad jump on earth and on the moon, performed by two subjects with different individual muscle properties.

	height [m] subject A	height [m] subject B
earth	1.11	1.08
moon	2.36	2.46

SUMMARY

The influence of the gravitation on the resulting height of a vertical jump depends crucially on the individual physiological and biomechanical properties of the subject. In different gravitational environments different properties are limiting factors for the movement.

SYNERGISTIC EFFECT OF SPATIAL RESOLUTION AND NOISE ON THE PRECISION AND ACCURACY OF MEASUREMENTS IN SIMULATED DIGITAL RADIOGRAPHS

Ruth K Wilcox¹, Emma Kennard¹, Richard M Hall^{1,2}

¹School of Mechanical Engineering, University of Leeds, Leeds, UK, ²Musculoskeletal Services, CSB, St James's University Hospital, Leeds, UK. r.m.hall@leeds.ac.uk

INTRODUCTION

The accurate and precise measurement of wear in the clinical environment is necessary for effective patient management. Further, such improvements would increase the power associated with clinical trials in which level of wear was an outcome measure. Recently several groups have devised automated techniques based on digital image processing (Shaver et al 1997, Martell and Berdia 1997) that have shown improved precision when compared to manual methods in the laboratory environment. However, artefacts within the experimental protocols used to simulate wear add additional sources of error. The aim of this study was to investigate the effect of noise and spatial resolution on the accuracy and precision of penetration measurements from simulated radiographs of cemented Charnley prostheses.

METHOD

Ten images were generated using a graphical programming language (IDL, Research Systems Inc., USA). The images depicted a perfect circle and arc to represent the femoral head and wire marker respectively, with the same dimensions as a standard Charnley THR, but differing in head position relative to the socket. Each ideal image was then used to generate 15 more images corrupted by reductions in spatial resolution followed by different levels of white Laplacian noise. The reduction of spatial filtering was chosen to encompass the range of modulation transfer functions exhibited by hospital radiography systems. All 160 images were analysed by a single operator using custom-designed software that had been developed previously in-house employing an algorithm similar to that given by Shaver et al (1997)

RESULTS

The error in penetration depth and direction were calculated for each analysis. The bias and precision for each level of noise were represented by the mean and root mean square error (RMS) respectively and are shown in Figures 1a and 1b for the penetration depth measurements. The errors were found not to be dependent on the magnitude or direction of the wear, except at extremely low levels of penetration depth (<0.1 mm). Here large variations in the penetration angle were apparent and these values were not included in the overall analysis. No discernable pattern was observed in the relationship between the mean error and the level of corruption (Figure 1a). The RMS errors were found to increase with increasing noise and, to a lesser extent, with increasing levels of filtering (Figure 1b). Similar results were observed for the penetration direction measurements.

Figure 1: (a) Mean error and (b) RMS error in penetration depth for different levels of image corruption.

DISCUSSION

The use of simulated radiographs are useful in characterizing the effects of different image processing techniques and noise in a more controlled manner whilst decoupling the effects of the laboratory simulated wear. The precision was found to be strongly dependent on the level of noise whilst the effects of spatial resolution had less of an effect. When combined, effects of changes in spatial resolution and noise appear not to be linear. The results indicate that these new assessment techniques are highly dependent on the level of image corruption that can occur within these images. The reduction in the level of precision in the most severely affected images is probably clinically significant in that the RMS value obtained here is of the order of the penetration likely to occur in the first two years of a Charnley type hip.

INTRODUCTION

Normative data of the vertical ground reaction force (GRF) of stair ascent and descent is rare in the related literature. Most previous investigators (Andriacchi et al. 1982; McFayden, 1988; Savvidis et al. 1999) tested on 2-4 steps only, a test which is not representative to daily housing situations. The goals of the study were: (i) to identify typical patterns of vertical GRF in ascending and descending stairs, (ii) to test the reliability of parameterization of selected points on the vertical GRF curve, and (iii) to test left-right symmetry during stair ascent and descent.

METHODS

Nineteen healthy test subjects (between 27 and 83 years) were tested when walking on level ground, and during ascent and descent on stairs with 20 deg. (flat), 31 deg. (standard) and 41 deg. (steep stair) of inclination; thus a total of 7 test conditions. Each test subject repeated all test conditions 10-12 times. Parameterization of two consecutive steps of the vertical GRF curves was performed with a computer routine adapted from Aebbersold (1980; Fig. 1) and checked for reliable detection. To test gait symmetry, the symmetry index described by Herzog et al. (1989) was used.

Figure 1: (a) Detection and (b) definition of selected parameters of the vertical GRF measured during level walking (after Aebbersold, 1980).

RESULTS AND DISCUSSION

To (i): Generally, during ascent and descent a two-peak wave form of the vertical GRF was detected. In contrast to level gait the second peak (Fz4) was generally higher in stair ascent during push-off (Fig. 2a) and the first (Fz2) in stair descent (Fig. 2d) during touchdown. However, in stair ascent, curves with similar peaks (Fig. 2b) and in stair descent, curves with only one peak (Fig. 2e), as well as complex forms (Fig. 2c, 2f) were also found.

To (ii): GRF parameters defined for level gait (Fig. 1) were reliably detected for each individual in 100%. In stair

Figure 2: GRF curves: (a) Fz4 larger than Fz2, (b) same magnitude of Fz2 and Fz4, (c) complex form, (d) Fz2 larger than Fz4, (e) one peak and (f) complex form.

ascent the correct detection for all parameters was between 87.4% and 100%, in stair descent between 59.7% and 100% on average. Consequently, trials with incorrect detection were omitted from the data pool. To (iii): The remaining data showed significant left-right asymmetries over all parameters, subjects and test conditions in 31.2% (ANOVA $p < 5\%$); the differences being unsystematic, however. When applying the symmetry index, asymmetries were found between 2.9% and 40.2% on average. Parameters bn and en showed larger asymmetries (between 6.8% and 40.2%) than Fz2 and Fz4 (between 3.1% and 18.0%), reflecting the difficulty of an exact definition of certain parameters of GRF on stairs.

SUMMARY

Vertical GRF curves of stair ascent and descent were detected with two peaks, but other wave forms (one peak, complex forms) were also present. In addition the GRF proved to be less reproducible compared to level walking; thus, the parameterization of the GRF was found to be less reliable. The results showed that significant left-right asymmetries occurred in about 30% of the test parameters, the index revealing asymmetry between 3% and 40%. Therefore, asymmetries of around 5% reported for patients may not necessarily be pathological.

INTRODUCTION

We recently developed a mechanical model (Denoth et al, 2002) that can explain phenomena like extra tension, sarcomere popping and homogenisation. The model assumes that random or systematic differences exist in force generation in single sarcomeres and shows that they can lead to non-uniform behaviour, especially if some sarcomeres are working on the descending limb of the force-length curve. Experiments using sarcomere visualisation in single mammalian muscle fibres have given evidence of non-uniform sarcomere behaviour after stretching in active but not in relaxed muscle fibres.

METHODS

Single skinned fibres (~1mm long) from rabbit psoas muscle were set up for visual data acquisition by attaching them on two small stainless steel hooks. One hook was connected to a force transducer (AE 801, AME), the other to a liver arm and a micromanipulator that allowed manual stretching and releasing of the fibre (accuracy of length change was 1µm). The fibre was relaxed and Ca-activated adopting standard procedures (see Coupland et al., 2001, for details on the solutions). Image data acquisition was performed with an inverted microscope (Olympus), a CCD camera with a VCR, a PC video grabber and image processing software (SCION).

RESULTS AND DISCUSSION

We showed in several earlier simulations that only a slight diversity in maximal isometric force in some or every sarcomere leads to non-uniform behaviour such as sarcomere popping (Denoth et al. 2002), phenomena that were predicted

Figure 1: Sarcomere length simulation during stretch-release (40% of resting length) for an activated 5-sarcomere myofibril. Stretch, 1.5 – 2 s; release, 5 – 6 s.

by Morgan (Morgan et al. 1990). While stretching after activation, some sarcomere operate on the plateau and were only slightly stretched, other weaker sarcomeres were shifted into the titin scaffold where they can possibly remain stable after releasing the fibre to its original length (Fig. 1).

The stretch-release experiment on fibres showed similar effects to the simulations. While in relaxed state the observed region showed a homogeneous striation pattern and a sharp peak in image fourier analysis, in active state some sarcomeres remained longer after stretching the fibre (see Fig. 2). Stretches were about 40% of the fibre length as used in the simulation.

Figure 2: Visual images of a fibre in relaxed (left) and active state (right) after stretching, scale bar is 5µm.

The muscle fibre force recording showed transient behaviour unlike the model. The discrepancy may be partly due to the fact that the simulations were only for single myofibrils and did not take account of a network of parallel structures with inter-connections as is the case for a muscle fibre.

SUMMARY

These preliminary experiments show that after large stretches the sarcomere uniformity is disturbed and new stable arrangements are possible where some sarcomeres are much longer than others. Our plan for the future is to investigate the behaviour of single myofibrils at large stretches and also to adapt the mechanical model for non-steady situations.
