extension strength (average 1.2 Kg), MAS (average .67) and ROM (average 3.2°) but there were no significant differences between groups. Gait speed increased for all subjects in the BTX group (average $15.0 \pm 9.1\%$) while in the STR group, one subject increased and one decreased speed (Table 1). Step length increased in 7/8 legs in the BTX group (average $11.7 \pm 26.7\%$). In contrast only one leg in the STR group showed improvements the step length.

	BTX1	BTX2	BTX3	BTX4	STR1	STR2
Speed	2.2	15.0	22.1	20.8	-29.8	1.3
Length	2.8	9.3	22.8	11.9	-18.0	0.4

Table 1. Percent change in walking speed and step length.

For subjects in BTX group, there was a decrease in toe-off variability (6/8 legs), increase in amplitude of hip and knee angle trajectory (4/8 legs), and decrease in variability of the hip angle trajectory during stance and around toe-off (6/8 legs). None of the legs in the STR group showed changes in these parameters. For the knee angle, results were equivocal.

Compared to the STR group, the BTX group generally showed improvement in their gait measures. Previous research has implicated step length as a constraint on walking speed (Abel & Damiano, 1996). This relationship is illustrated in our results by increases in both walking speed and step length. Furthermore, reduction in variability of both hip angle trajectory and toe-off timing are an indication of greater consistency in the gait patterns. The reduction in variability along with the increase in the amplitude of angle trajectories are generally viewed as positive outcomes of therapeutic interventions for treating cerebral palsy.

SUMMARY

Strengthening of knee extensors combined with botulinum toxin injections to the hamstrings appeared to improve gait parameters to a greater extent than strengthening alone. Strength, ROM, and MAS did not show significant changes between groups in this small initial sample.

EFFECT OF EXPRESSIVENESS ON THE KINEMATICS OF ARM GESTURES

Teerin T. Meckmongkol¹ and M. Melissa Gross^{1,2}

¹Movement Dynamics Laboratory, Division of Kinesiology, and ²Institute of Gerontology
University of Michigan, Ann Arbor, Michigan, USA, mgross@umich.edu

INTRODUCTION

Body movements can communicate emotions while serving other demands of motor tasks. Point light displays of body movements are sufficient for observers to detect differences in affect during walking (Montepare and Zebrowitz-McArthur, 1988), arm gestures (Pollick et al., 2001), and dance movements (Dittrich et al., 1996; Brownlow et al., 1997). Although researchers have shown that information about emotions is conveyed in body movements (Walbott, 1998), how task kinematics are modified by emotion is virtually unknown.

The purpose of this study was to determine how expression affects the kinematics of arm gestures. Ballet arm gestures were studied because they can be performed precisely and reproducibly by skilled dancers, thus minimizing kinematic differences not related to expression. To ensure that dancers performed the movements with different expressions, other participants assessed the expressive differences between randomized pairs of the dancers' performances.

METHODS

After obtaining informed consent, eight professional-level female ballet dancers (mean age 24 yrs) were asked to perform two arm movements that are well-defined in ballet repertoire (port de bras to arabesque and to second position) with two different performance styles: technical and expressive. Video data were collected at 60 Hz from reflective markers placed over trunk and upper extremity landmarks. Kinematic data were filtered (4 Hz) and 3-D angular displacements were calculated for the head, upper spine, lower spine, shoulder, elbow and wrists. Paired Student's *t* tests were used to detect differences in performance style for each of the arm gestures.

An additional 36 participants (24 female, 12 male; 20-50 yrs) viewed a videotape prepared from the same trials used in the kinematic analysis. The videotape consisted of 16 randomized pairs of expressive and technical performances (two from each dancer). Participants were asked to decide if the pairs were performed in the same or different styles (i.e., technical or expressive). Analysis of variance was used to detect differences in accuracy among observers and gestures.

RESULTS AND DISCUSSION

In general, joint range of motion increased with expressiveness. However, the specific body segments affected by expression depended on the arm gesture. For the port de bras to second, head tilt and head rotation increased 48% and 19%, respectively, in the expressive compared to the technical

performances (Fig. 1). The upper spine range of motion in the frontal plane also increased with expression (26%). In contrast, range of motion increased with expression for the lower spine and shoulder, but not the head and upper spine, in port de bras to arabesque. Lower spine range of motion in the frontal, sagittal, and transverse planes increased 27%, 61%, and 59%, respectively. Shoulder abduction also increased with performance (25%). Although relative changes in joint range of motion with expression were large (19-61%), the absolute differences in range of motion were quite small, varying from less than 5 degrees for the spine to 18 degrees for head rotation. Elbow range of motion did not depend on expressiveness for either movement.

Head Tilt During Port de Bras to Second Position

Figure 1: Head tilt increased in expressive (right) compared to technical (left) performance. Data are from one participant.

Observers were able to discriminate accurately between performances of paired arm gestures with an accuracy rate (75%) that greatly exceeded chance (41%). Accuracy among observers ranged from 43% to 93% and was similar for dancer (*n*=6) and non-dancer (*n*=30) observers.

SUMMARY

Task kinematics were modified in characteristic ways when dancers performed ballet arm movements with expression. Although the magnitude of the kinematic changes with expression was small, the differences were statistically significant and were detected by observers.

BIOMECHANICAL ANALYSIS OF FIXATION OF SPLIT-DEPRESSION FRACTURES OF THE TIBIA PLATEAU

Mark J. Blyth, S.D. Deo, Hanspeter Frei, Peter O'Brian, Piotr A. Blachut, Thomas R. Oxland

Department of Orthopedics, University of British Columbia, Vancouver, British Columbia, Canada, toxland@interchange.ubc.ca

INTRODUCTION

Tibial plateau fractures comprise 1% of all fractures. They occur across the age spectrum, but pure joint depression fractures tend to occur in the older, more osteoporotic age group (Koval 1995). The main indication for operative treatment of tibial plateau fractures are significant depression or displacement of the joint surface by more than 10mm and/or joint instability. Traditionally the depressed articular portion of the fracture is elevated and reduced and fixed with a 4.5mm periarticular plate system. The 3.5mm plate system was developed to reduce the soft tissue irritation caused by the higher profile of the 4.5mm plate, but the quality of this fixation has not been established. Therefore the purpose of this study was to compare the strength of fixation of the 3.5mm with 4.5mm periarticular plate system.

METHODS

In five cadaveric tibial pairs, a split-depression fracture was simulated surgically (Figure 1). The articular fragment was fashioned by creating a block allowing it to sit evenly distributed over two screws of the 4.5mm plate and three screws of the 3.5mm plate (Figure 1). In addition a metaphyseal defect was included in the fracture model. The fractures were fixed with either the 3.5mm or 4.5mm periarticular plate system (Zimmer, Warsaw, IN, USA). A ramp load up to 150N was applied to the articular fragment by a servohydraulic testing machine, followed cyclic loading for 5000 cycles with an amplitude of +/- 100N. The axial fragment displacement was measured by a precision optoelectronic camera system and analyzed after the initial ramp and after cyclic loading. Wilcoxon matched paired test was used to compare the two fixation methods.

Figure 1: Left: Simulated split-depression fracture. Right: Fracture is fixed with a 3.5mm periarticular plate with three screws holding the articular fragment.

RESULTS AND DISCUSSION

There were no differences in the axial displacement of the articular fragment after the initial ramp loading between the two plates. After 5000 cycles the displacement of the fragment was significantly greater with the 3.5mm compared with 4.5mm plate. The results are summarized in Table 1.

The depression of the articular fragment occurred by failure of subchondral bone at the level of the screws by a cheese-wire effect in all cases.

Table 1: Displacement of the articular fragment at 150N and after 5000 cycles.

Specimen	Displacement @ 150N [mm]		Displacement after 5000 cycles [mm]	
	3.5mm	4.5mm	3.5mm	4.5mm
A	1.9	2.3	6.6	5.5
B	2.2	2.9	5.4	5.1
C	3.3	1.8	16.4	13.7
D	1.4	1.7	12.3	6.6
E	1.7	1.1	8.4	3.2
Median	1.9	1.8	8.4	5.5
Min/Max	1.4 / 3.3	1.1 / 2.9	5.4 / 16.4	3.2 / 13.7

SUMMARY

The purpose of this study was to compare the strength of fixation of the 3.5mm or 4.5mm periarticular plate system in a tibial split-depression fracture model. Compressive loads were applied to the articular fragment of the model and the axial displacements measured. The displacement of the articular fragment observed after cyclic loading was significantly greater with the 3.5mm plate. No differences between the two plates were found after the initial ramp loading. In each case depression of the articular fragment occurred by failure of subchondral bone at the level of the screws by a cheese-wire effect.

MAXIMUM TOE FLEXOR MUSCLE STRENGTH IN HEALTHY YOUNG AND OLDER ADULTS

Mari Endo, B.S.E.¹, James A. Ashton-Miller, Ph.D.¹⁻³, and Neil Alexander, M.D.³⁻⁴

¹Department of Mechanical Engineering, ²Department of Biomedical Engineering, ³Institute of Gerontology, ⁴Department of Internal Medicine, University of Michigan, Ann Arbor, Michigan, USA, marichan@engin.umich.edu

INTRODUCTION

The maximum strength of the toe flexor muscles determines the forward extent of the functional base of foot support (FBOS) while balancing on one or two feet. Maximum toe flexor strength (S) is therefore important in preventing forward falls in forward leans and reaches, and when stopping abruptly to avoid a collision during gait. We could find no published data on S, or on whether it is affected by age or gender. The FBOS is known to decrease by 16% per decade for persons over 60 years of age (King et al., 1994), but the underlying reason has not been elucidated. In Study 1 we therefore tested the (null) hypothesis that neither age nor gender affects the single-equivalent maximum isometric toe flexor strength (S), developed by all five toes about a reference axis through the first metatarsal joint (MTJ). In Study 2, we quantified the individual contributions of each toe to S in young adults (YA).

METHODS

Study 1: 40 healthy adults (20 YA, age: 22.8 yrs; 20 older adults (OA), age: 73.2 yrs.) participated. S was measured for each foot in 3 trials. The subject reached towards, but did not touch, a force-sensing target (T) while standing unipedally on a force plate (FP, Fig. 1). Subjects were instructed to maximize S with each successive trial by moving their center of reaction (R) as far forwards as possible, using visual feedback (VF).

Figure 1: Set-up

Study 2: Using similar methods and gender-matched groups of 10 healthy YA (age: 24.1 yrs.), we measured the maximum individual moment contributions of each toe to S about an axis through the first MTJ. The entire foot, with the exception of the toe to be measured, was supported on a flat horizontal support plate mounted just above, but not in contact

with, the FP. A short rigid column,

whose diameter was the width of the toe to be measured was interposed between the toe and the FP, and constrained by a vertical low-friction hole in the support plate. Using this set up, we measured the maximum flexor moment developed by each toe about its MTJ, as well as the first MTJ (denoted S1: large toe to S5: small toe, see inset Fig. 1).

RESULTS AND DISCUSSION

Study 1: There was not a significant bilateral difference in S ($p=.228$), so only dominant foot data are reported. The hypothesis was rejected in that OA had 28.9% smaller S than the YA ($p=.008$), and the females had 39.1% smaller S than the males ($p<.0005$). However, after normalizing S by a measure of body size (body weight [N] x height [m]), the gender difference was no longer significant, but the age difference remained significant. Hence, S is proportional to body size irrespective of gender. Three young females performed the test on two separate days and the test-retest differences lay within 10%. The functional toe length (FTL), the maximum distance the subject could move R forward of the MTJ, was 29.6 % smaller in OA than YA (Table 1).

Table 1: Mean (SD) S and FTL on the Dominant Foot

	Men		Women	
	Young, n=10	Older, n=10	Young, n=10	Older, n=10
Absolute S [Nm]	24.3 (4.9)	16.1 (6.6)	13.8 (3.5)	10.8 (3.3)
Normalized S	0.017 (0.003)	0.012 (0.005)	0.014 (0.004)	0.010 (0.004)
FTL [mm]	31 (6)	21 (9)	23 (7)	18 (5)

Study 2: The gender difference in the individual (percent) contributions of each toe to S were not significant. The large toe contributed the most, 61.0%, to S (Fig. 2). The clinical significance is that individuals with amputated or impaired large toes should be advised that they might be at an increased risk for forward falls.

Figure 1: Individual Contributions to S: YA, n=10

SUMMARY

(1) A new method is presented for measuring toe flexor strength. (2) S decreases by 29% with age. (3) S is proportional to body size in healthy males and females. (4) The large toe contributes 61% of S in healthy young adults. (5) The age-related decline in S helps explain the age-related decline in FBOS with age.

MOVEMENT SYNERGY BETWEEN THE ANKLE AND HIP JOINTS DURING SINGLE LEG STANCE

Wen Liu, Kevin McIntire, Kari Bowman, Stacia Noland, Sarah Spurlock, Carrie Thompson
Dept. Physical Therapy and Rehabilitation Science, University of Kansas Medical Center, Kansas City, Kansas
Email contact: wliu@kumc.edu

INTRODUCTION

Patterns of postural response to disturbances have been observed despite the fact that postural control in upright stance requires a complex interaction of musculoskeletal and neural systems. Many studies on the postural control during two-leg stance have reported an ankle strategy for a small perturbation (Nashner, 1977), a hip strategy when feet are constrained (Horak and Nashner, 1986), and a stepping strategy if there is no constrain (McIlroy and Maki, 1993) for a large perturbation. However, very few studies examined patterns of postural control during single leg standing (Gauffin et al., 1993), and it is not know how the hip and ankle joints may contribute to the balance of single leg stance. The purpose of this study was to examine three-dimensional motions of the hip and ankle joints during signal leg standing tasks under various conditions in a group of healthy young subjects. Results of this study will help future researchers in better understanding balance deficit due to joint injuries (hip or ankle joint) or neurological diseases.

METHODS

A total of 8 healthy young subjects participated in this study (8 females, age: 22 to 24 years old). None of the subjects had a history of severe ankle, knee, and/or hip injury. Prior to participation, each subject signed an informed consent.

A three-dimensional motion analysis system (OPTOTRAK, Northern Digital Inc., Waterloo, Ontario) was used to measure marker coordinates during balance tasks. Three active markers were fixed with double sided adhesive tape on each of four body segments of the right side: the calcaneus, shank, thigh, and pelvis. In addition, 6 bony landmarks were digitized using the OPTOTRAK digitizing probe in order to established joint anatomical coordinates system for the hip and ankle, using the system recommended by the International Society of Biomechanics. The Biodex Stability System (Biodex Medical Systems, Shirley, NY) was used to provide unstable standing condition for subjects. The movable balance platform provides up to 20 degrees of surface tilt in a 360-degree range. An actuator is used to pre-set the degree of platform instability, ranging from a completely fixed surface to a very unstable surface.

The testing protocol is based on a previous study using the Biodex Stability System (Rozzi et al., 1999). To familiarize subjects with the Biodex, a 20 second practice trial of each test condition was allowed. The subject performed a total of 5 trials for each of 4 conditions: 1) Eyes open fixed platform (EOFP), 2) Eyes closed fixed platform (ECFP), 3) Eyes open level 8 (EOL8), 4) Eyes closed level 8 (ECL8). The level 8 is the least unstable level of movable platform. The conditions were chosen in a random order. Subject balanced for 20 seconds during each trial. The OPTOTRAK system recorded

3D coordinates of markers. An RMS of joint angular motions at the ankle and hip were calculated for each trial.

RESULTS AND DISCUSSION

Internal/external rotations at the ankle and hip joints were observed to go opposite direction with similar magnitudes (Fig. 1). This is confirmed by similar group means of RMS data for the int./ex. rotation for both joints under all four conditions (Fig. 2). Significant differences were found in group mean of the RMS of 3D joint motions of the ankle and hip between the eyes open and eyes closed conditions, and between the fixed and unstable platform conditions. Results of this study demonstrated first time a consistent movement synergy in axial rotations between the ankle and hip joints during single leg stance, under various conditions where joint motions varied significantly. Gauffin et al. (1993) examined only motions of the ankle during single leg stance.

Fig. 1 Internal (+)/external (-) rotations of the hip and ankle joints shows opposite direction with same amplitude.

Fig. 2 Group mean of RMS of int./ex. rotations of the hip and ankle joints in four conditions

CONCLUSION

This preliminary data appears to show an equal but opposite axial rotations between the ankle and hip joints to maintain balance during single leg stance. Future research is required to examine the risk of losing standing balance when this synergy is lost due to joint injuries, such as an ankle sprain.

REPROGRAMMING SIT-TO-STAND AND SIT-TO-WALK MOVEMENT SEQUENCE UNDER DIFFERENT TEMPORAL CONSTRAINTS

Renato Moraes¹, Fariba Bahrami² and Aftab E. Patla¹

rmoraes@ahsmaail.uwaterloo.ca

¹ Gait & Posture Laboratory, University of Waterloo, Waterloo, Ontario, Canada

² Department of Electrical and Computer Engineering, University of Tehran, Tehran, Iran

INTRODUCTION

The study of whole body movement sequences and on-line modifications in these actions have received little attention by researchers in biomechanics and motor control areas. Magnan, McFayden and St-Vincent (1996) studied the sit-to-stand (STS) movement when gait initiation was added. They found that sit-to-walk (STW) and STS were similar until the seat-off event. Further, postural control is the most important aspect to be considered during the transition between STS to gait initiation. The question that we examine in this study is how the nervous system reprograms STS for example to a STW movement and vice-versa under different temporal constraints. The focus is on the center of mass (COM) trajectory when subtly an initial task must be modified (STS to STW or STW to STS).

METHOD

COM of the three participants (22-25 yr) was calculated using a model with 7 segments (2 feet, 2 legs, 2 thighs and HAT). A light device with two colors (red and green) was placed in front of the participant. Participants were asked to initiate the task when one of the two lights was on. Red light cued participants to perform STS while green light corresponded to STW. In some trials the light changed at seat-off or 100 ms after the seat-off. When this change happened participant must perform the new behavior indicated by the light color. Participants performed 40 trials in each control condition (STS and STW) and 5 trials in each condition when the light changed (STS to STW cue at seat-off, STS to STW cue at 100 ms after seat-off, STW to STS at seat-off, STW to STS at 100 ms after seat-off). Trials were completely randomized.

RESULTS AND DISCUSSION

In most trials participants were not able to adjust the behaviour under the time constraints when light changed (see Table 1). Failure was most pronounced in the conditions where participants must change from STS to STW; participants first completed STS and after that began to walk. On the other hand, the main reason for STW to STS transition failure was the need to take a step before final postural equilibrium.

Table 1: Failure proportion in each condition (n = 15)

Condition	Failure proportion (%)
STS to STW (seat-off)	80.0
STS to STW (100 ms)	86.0
STW to STS (seat-off)	53.3
STW to STS (100 ms)	73.3

COM vertical displacement was similar in all participants in all conditions tested. However, COM horizontal displacement

differed between STW and STS to STW as we can observe in Figure 1. When performing STW the COM horizontal displacement was almost linear after seat-off. On the other hand, COM horizontal displacement in the STS to STW transition has a sigmoid shape after seat-off. When STS to STW transition was performed the COM horizontal displacement after seat-off was reduced in comparison to STW. In this case, participants finished the first task (STS) and then performed the second task (e.g., walk).

Figure 1: COM profiles during reprogramming of STW movement sequence.

SUMMARY

These findings clearly illustrate the difficulties associated with reprogramming common functional tasks (STS or STW) under temporal constraints. Postural control is severely compromised under these circumstances and could lead to a fall.

SOMATOSENSORY INPUT IN THE CONTROL OF HUMAN POSTURE IN PATIENTS WITH MORBUS PARKINSON

Beate Prätorius, Stefan Kimmeskamp & Thomas L. Milani
University of Essen, Department of Human Locomotion
45131 Essen, Germany; thomas.milani@uni-essen.de

INTRODUCTION

Postural instability is a major symptom of the Parkinson's disease and is considered to be responsible for frequent falls in Parkinson patients. Posturographic measurements with sensory perturbations are often used to investigate the physiology of the underlying mechanisms of postural instability. However, studies investigating the sway characteristics of PD patients and healthy adults have often led to a variety of different, sometimes even contradictory results. On the other side, it has been shown that somatosensory input information has a major influence in the control of human balance. Studies have focused on the specific role of vestibular, visual or muscular sensory information, but only little research has been performed so far to study the role of cutaneous sensibility from the foot soles (2). The purpose of this study was to determine the influence of somatosensory input on balance control in Parkinson patients.

METHOD

30 patients (pa) with Parkinson disease (age: 67 SD: 6,8) and 20 age matched healthy subjects (co) (age: 64 SD: 4,2) participated in this study. Subjective sensibility thresholds under five foot structures (heel, midfoot, I. & V. metatarsus head and Hallux) for different mechanoreceptors (intensity – Ruffini corpuscles, vibration – Meissner corpuscles) were determined by using a vibration exciter (30 Hz) and Semmes Weinstein-microfilaments. The sensitivity of intensity mechanoreceptors were analysed by using a 4-2-1-algorithm as described in (1). Control of human posture was measured by pressure sensitive insoles (Novel GmbH, Munich). The balance task included parallel stance, tandem stance, single limb stance and functional lean forward. Center of Pressure (COP) data were collected over a maximum period of 30 seconds for all balance tasks. The COP-data were collected at a frequency of 50 Hz for the left and the right insole. The raw data were smoothed with a fourth-order, zero-phase shift low-pass filter (Butterworth) with a cut-off frequency of 6 Hz. Based on the COP-data of left and the right foot the COP_net was calculated as described by Winter (1995). Prior to the measurements a neurological examination was undertaken to classify the motor impairment according to the UPDRS-Score. Sensitivity thresholds and balance data were averaged and analyzed with inferential statistics (t-test). A sensitivity parameter for each subject was determined by averaging vibration resp. intensity thresholds of five foot locations. Sensitivity variables and balance control variables were compared by regression analyses.

RESULTS & DISCUSSION

For healthy adults significant differences between the five foot regions were evaluated in intensity as well as vibration threshold data. For the Parkinson group, however, this result could

not be confirmed. Furthermore, sensitivity parameter revealed significant differences between Parkinson patients (pa) and healthy subjects (co) (Fig.1).

Healthy adults show highly significant lower sensitivity thresholds for intensity ($p < .01$) as well as vibration ($p < .0001$) stimuli. In addition, a highly significant relationship ($p < .01$) was observed between UPDRS-scores and vibration sensitivity in Parkinson

patients. Lower vibration sensitivity of the foot sole is related to higher scores respectively increasing level of disease. High UPDRS-scores are highly related to the risk of falls

in Parkinson patients. These results confirm the hypothesis that somatosensory information from the foot sole may play an important role in stabilizing human balance. Furthermore,

Figure 1: Vibration threshold differences

Figure 2: Regression UPDRS versus vibration threshold

reduced foot sole sensibility in Parkinson patients seems to be a further risk factor to fall. Therefore, foot sole sensitivity should be considered for rehabilitation purposes and Parkinson's disease research.

INFLUENCE OF GLUCOCORTICOID PRETREATMENT ON DE-REPRESSION OF GENE EXPRESSION IN MENISCIAL EXPLANTS AFTER REMOVAL FROM BIOMECHANICAL LOADING

Takashi Natsu-ume, Alison Kydd, Helen Tsao, Cyril B. Frank, Nigel Shrive, and David A. Hart
McCaig Centre for Joint Injury and Arthritis Research, University of Calgary, Calgary, Alberta CANADA T2N 4N1
hartd@ucalgary.ca

INTRODUCTION

Recent studies using both ligament (Majima et al., 2000, 2000a) and meniscal (Natsu-ume et al., 2002) explant systems have revealed that removal of these tissues from the rabbit knee leads to the rapid de-repression of a subset of genes (MMPs, TIMPs, cytokines, enzymes) which could contribute to tissue turnover/degradation. This de-repression could be blocked by in vitro intermittent cyclic loading protocols (1 MPa, 0.5 Hz, 1 min on/14 min off for 4 hr). Many of the involved genes affected by mechanical loading have AP-1 sites in their promoter regions, and therefore, can be effectively transrepressed by glucocorticoid treatment. Therefore, the present study was undertaken to determine whether pretreatment of rabbits with glucocorticoids would prevent the subsequent de-repression of these genes in explants of intact menisci following short-term in vitro culture under non-loading conditions.

METHODS

Skeletally mature female NZW rabbits received either diluent (N = 4) or an optimal dose of DepoMedrol (10mg/kg) (N = 4) via the IM route into the hindlimbs 24 hr prior to sacrifice. At the time of sacrifice, the medial and lateral menisci of each knee were immediately removed and those from one leg immediately frozen in liquid nitrogen to serve as the Time Zero controls. The menisci of the other leg were cultured in the absence of mechanical stimulation for 4 hr in vitro under established conditions (Natsu-ume et al., 2002). At the end of 4 hr, the menisci were immediately frozen in liquid nitrogen and served as the Unloaded Experimentals. Total RNA was isolated from individual menisci, quantified, and all samples were subjected to reverse transcription (RT) at the same time. mRNA levels for specific genes were then assessed in the RT samples using semiquantitative PCR, again all at the same time, using validated rabbit-specific primer sets. All assays were in the linear range of the PCR amplification and the image analysis system used to assess the density of the amplicons. Values for individual genes were normalized to beta-actin mRNA levels to yield a semiquantitative assessment. Statistical analysis was performed using ANOVA.

RESULTS AND DISCUSSION

Comparison of mRNA levels between the Time Zero samples from the diluent treated and DepoMedrol treated animals indicated that mRNA levels for MMP-1,-3 and -13 were significantly depressed in the DepoMedrol treated samples, but values for TIMP-1, IL-1, IL-6, collagens and proteoglycans were

not depressed. Thus, expression of the MMPs in menisci is very sensitive to systemic in vivo glucocorticoid treatment as predicted from the literature. Results for the medial and lateral menisci were very similar.

Comparison of untreated Time Zero controls vs 4 hr of unloading revealed that mRNA levels for MMP-1 and -3 were elevated, as were levels for TIMP-1, iNOS, IL-1, and IL-6. These results are consistent with previous studies (Natsu-ume et al., 2002). Similar comparisons for the cultured DepoMedrol treated samples vs Time Zero controls revealed that mRNA levels for MMP-1 and -3 were significantly elevated, as were levels for TIMP-1, IL-6 and iNOS. Values for IL-1 were not affected by unloaded conditions in the treatment group.

The results presented indicate that pretreatment of animals with glucocorticoids has an impact on tissue mRNA levels for some, but not all molecules in menisci. However, such pretreatment did not overtly influence the de-repression of mRNA levels following unloading the tissue in vitro for nearly all of the molecules assessed in the study (with IL-1 a notable exception).

SUMMARY

While glucocorticoids are effective in depressing gene expression in vivo for several relevant molecules, the response to unloading conditions for nearly all of the affected molecules was unaltered. Therefore, it is likely that the mechanobiology signal transduction systems involved either do not use the same mechanisms as glucocorticoids to repress gene expression, but can override them, or they can effectively compete for the same promoter sites and negate the influence of the drugs. Current studies are designed to distinguish between these possibilities, and to further characterize the molecular mechanisms associated with biomechanical loading at the cell and gene levels.

DYNAMIC, BIOMECHANICAL CHARACTERISTICS OF HUMAN ANKLE LIGAMENTS

R.Hopcroft¹, C.Oakley², S.Suman², P.Manning¹, R.Lowne², W.A.Wallace¹

mszrwh@gwmail.nottinham.ac.uk

2. Transport Research Laboratory, Berkshire, England

INTRODUCTION

Improved techniques in finite element modeling are playing an increasingly important role in predicting injury. At present, biomechanical knowledge regarding the characteristics of human ankle ligaments is limited.

This study reports the results of tests performed to investigate the dynamic nature of these properties and quantify them for the ankle.

The ligaments deemed critical to ankle joint stability are:

- Deltoid
- Calcaneofibular
- Anterior talofibular
- Posterior talofibular

METHOD

Twenty-four ligaments from six donated post mortem human surrogates were isolated for testing. Morphometry of length, width and thickness were measured in situ and again after

removal from the specimen. This enabled calculation of elastic modulus and load under static in situ conditions in the anatomical position. Each ligament was tested to a sub injury level over a spectrum of applied loading rates and lengths of stretch. After each high load rate a pseudo-static test was performed as a control to confirm no injury had occurred.

It was recognized that the deltoid ligament exists anatomically as distinct superficial and deep parts. These were tested together as a complex. In the clinical setting, each part does not have a role significantly different from the other in terms of overall stability.

The load was applied via a drop weight rig (fig 1). The length of stretch was predetermined before each test to ensure a sub-injury test when required. The mass of the drop weight was sufficiently great to ensure any loss of kinetic energy was insignificant over the length of stretch. Thus a uniform rate of loading was produced throughout each individual test.

RESULTS

This method of testing has been validated for reliability and repeatability before embarking on the main program. The analysis of twenty-four ligaments will be presented. The early data clearly demonstrates the dynamic response of these visco-elastic structures. The analysis of the test program, qualifying the ligament's characteristics at high loading rates will be presented.

DISCUSSION

The analysis presented offers a valuable insight into the biomechanical properties of ligaments at the rates of loading encountered during injury caused by high-energy impacts. This biomechanical data is vital to develop future finite element models.

DEVELOPMENT OF A NOVEL TYPE OF OESOPHAGEAL STENT BASED ON DEPLOYABLE TUBULAR STRUCTURES

Kaori Kuribayashi, Stephen Jordan and Zhong You

Department of Engineering Science, University of Oxford, Oxford, OX1 3PJ, UK
e-mail: zhong.you@eng.ox.ac.uk

INTRODUCTION

Stent treatment has been shown to improve the quality of life in patients with inoperable malignant oesophageal cancer by allowing patients to swallow and maintain oral nutrition (Song, 1991). However, the currently used mesh stents have many problems, e.g., tumours ingrowth through the mesh, less compact folding and migration problems associated with the covered stents, etc. In addition, the cost of the stents is very high. As a result, plastic rigid tubular stents are still used. In this paper, we present a new type of oesophageal stent with an integrated cover. The concept is based on the knowledge of deployable structures and ancient origami technique.

A NEW HELICAL OESOPHAGEAL STENT

As opposed to the mesh stent, the new type of the stent is a tubular thin wall structure. To achieve foldability, the rigid wall is divided into a number of semi-rectangular units. Within each unit and in between neighbouring units, folds are introduced, so that the stent can be folded both longitudinally and radially (Kuribayashi, 2001). A schematic diagram is given in Fig. 1 in which the major folds *A* and *B* form two separate sets of helices orthogonal to one another. As shown in Fig. 1(b), the helical line *B* is around the tube, therefore the folding and expanding processes are synchronised between units. This makes the stent easy to deploy in the oesophagus.

OPTIMUM GEOMETRY

The optimum geometry of the stent, i.e., the optimum locations for the folds, is defined by the angle α . When a perfect thin-walled tube is under torsion, it will lose stability and a wavy buckling pattern will form giving valley and peak folds. Such a pattern is utilised to define the location of helices to achieve the easiest folding.

Geometrically, for the arrangement of folds shown in Fig. 1,

$$\alpha = \frac{\pi}{2} - \tan^{-1} \left(\frac{b_1 b_2}{a_1 b_2} \right) = \frac{\pi}{2} - \tan^{-1} \left(\frac{2}{2m+1} \right)$$

in which m is the number of units in circumference direction where $m > 3$. Comparing both m and α with that obtained from buckling analysis using Donnell's formula (Timoshenko, 1961) yields the optimum number of folds and their angles. For instance, for a 60 mm long and 25.4 mm diameter tube, when the thickness of the tube is 0.025 mm, $m = 8$ and $\alpha = 82.4^\circ$, while the thickness of 0.08 mm gives $m = 6$ and $\alpha = 79.7^\circ$.

FABRICATION

The novel stent can be made of the same biocompatible materials as the existing mesh stents, i.e. the stainless steel or shape memory alloys. A sheet of these materials is chemically etched to produce folding patterns. After that, the sheet is rolled and joined together forming a tubular stent. Figure 2 shows a model of the stent based upon the above design. It was made from a stainless steel sheet of 0.10 mm in thickness. The thickness was halved in the locations of the folds by etching. Folding of the stent was easily accomplished. The proposed concept has been proven useful for future stent designs.

FUTHER WORK

The automatic expansion technique for the stainless steel stent is currently under development. In parallel, we are also investigating the use of shape memory alloy sheets to produce self-expanding stents.

EFFECT OF AGE ON ABILITY TO BRAKE A FALL WITH THE OUTSTRETCHED HANDS

Paula J. Stotz, Sarah C. Normandin, Stephen N. Robinovitch

Injury Prevention and Mobility Laboratory, School of Kinesiology
Simon Fraser University, Burnaby, B.C., Canada, steve@sfu.ca

INTRODUCTION

Evidence suggests that an elderly individual's risk for hip fracture in the event of a fall depends on his or her ability to "brake the fall" with the outstretched hands. For example, studies have shown that risk for hip fracture during a fall is reduced approximately 3-fold if impact occurs between the ground and one or both hands (Schwartz et al., 1998; Nevitt and Cummings, 1993). Studies have also shown that, in the event of an unexpected sideways fall, young individuals tend to avoid hip impact by rotating the body forward during descent, and impacting the ground with both outstretched hands (Hsiao and Robinovitch, 1998). Ability to achieve this depends in part on one's ability to move the hands into an appropriate position during the descent stage of the fall, in preparation for impact. In this study, we examined whether differences exist between young and elderly women in this ability during simulated forward and sideways falls.

METHODS

A total of 18 young (Y) women (mean age 22 ± 3 yrs) and 18 elderly (E) women (mean age 78 ± 6 yrs) participated in the experiment. During the trials, the subject stood facing or sideways to shoulder-height padded targets, and was instructed to contact the targets "as quickly as possible" after hearing an aural cue. For both orientations, the target distance was adjusted so impact occurred with the elbows flexed at 45 degrees. Force plates (MU2535, Bertec Corp) mounted behind the targets acquired contact forces at 960 Hz, and a 60 Hz seven-camera motion measurement system (ProReflex, Qualisys Inc) acquired the 3D positions of various skin surface markers. Subjects performed ten trials in the forward direction and 10 trials in the sideways direction, in a randomized sequence. Data were analyzed to determine: (a) the time between the go cue and the onset of hand movement (reaction time (RT)), and (b) the time between the onset of hand movement and contact of the target (movement time (MT)). We used independent sample *t*-tests to determine whether differences in these parameters existed between Y and E. Reported values are for the dominant hand.

RESULTS AND DISCUSSION

We observed age-related slowing in MT but not RT. There were no differences between Y and E in mean RT for forward trials (mean Y value = 225 ± 36 ms; mean E value = 241 ± 50 ms; $P = 0.3$) and sideways trials (mean Y value = 233 ± 36 ms; mean E value = 274 ± 77 ms; $P = 0.05$). However, mean MT was significantly slower for E than Y in forward trials (mean Y value = 292 ± 36 ms; mean E value = 371 ± 77 ms; $P < 0.001$) and in sideways trials (mean Y value = 410 ± 62 ms; mean E value = 537 ± 144 ms; $P < 0.001$).

Strict time requirements exist for braking a fall with the outstretched hands. Previously, we found that the time interval between the onset of a destabilizing perturbation and contact between the hands and the ground during a fall averages 680 ± 116 ms (Hsiao and Robinovitch, 1998). This is close to the mean total contact time (sum of RT and MT) observed in the current study for Y in forward trials (517 ± 59 ms), Y in sideways trials (642 ± 79 ms), E in forward trials (613 ± 86 ms), and E in sideways trials (810 ± 166 ms).

Total contact time was determined more strongly by MT than by RT (Fig. 1). For both Y and E, there was greater between-subject variability in MT than in RT, and no correlation between these two variables ($P = 0.5$ for forward trials, and $P = 0.2$ for sideways trials).

Figure 1: Reaction time and movement time components of contact time for forward and sideways trails.

SUMMARY

Strict time requirements exist for braking a fall with the outstretched hands. Age-related declines in ability to perform this task appear to be due more to slowing of movement time than reaction time.

FINGERTIP PULP MECHANICS DURING VOLUNTARY TAPPING

Devin L. Jindrich, Theodore Becker and Jack Tigh Dennerlein (jax@hsph.harvard.edu)
Harvard Occupational Biomechanics, Harvard School of Public Health, Boston, MA.USA

INTRODUCTION

Increased use of computer keyboards is associated with increased incidence of musculo-skeletal disorders (MSDs) of the upper extremity. Epidemiology studies indicate that one possible risk factor for the development of MSDs is the mechanical load to the soft tissues. To understand and predict the mechanical load on the soft tissues of the hand and arm during tapping activities, we seek to build a lumped parameter model of the finger, hand and wrist. We first chose to characterize the mechanics of the fingertip pulp during tapping because forces at the fingertip must be transmitted to more proximal segments through the fingertip pulp.

The mechanics of the fingertip pulp has been modeled during static and dynamic loading using sinusoidal and ramp inputs (Pawluk and Howe, 1999; Serina *et al.*, 1997). However, tapping movements contain high-frequency components that may not be well characterized by existing models (Pawluk and Howe, 1999). We therefore conducted experiments to determine whether a simple model of the fingertip pulp adequately describes its mechanical behavior during dynamic tapping tasks similar to those experienced during typing.

MATERIALS & METHODS

We measured vertical force at the fingertip using a stiff force sensor, and position of the fingertip using an optical measurement system and a light-emitting diode glued to the fingernail (Figure 1). Eight subjects tapped on the force sensor while fingertip position was measured. Subjects were instructed to minimize contact time for each tap and tap once per second. Position signals were filtered and differentiated to yield velocity and acceleration.

Figure 1. Experimental apparatus used to measure tap mechanics.

A simple dynamic model was fit to the resulting force and position data. Following Pawluk (1999), functions for the instantaneous elasticity $T^{(e)}(x)$ and relaxation $G(t)$ were used to characterize the behavior of the fingertip pulp.

Force caused by instantaneous elasticity was modeled as an exponential function of position $T^{(e)}(x) = \frac{b}{m} [e^{mx} - 1]$, and force change due to relaxation was modeled as an exponential function of time $G(t) = c_0 + c_1 e^{-vt}$.

RESULTS

When subjects were instructed to tap on the force sensor in a comfortable manner, with the rest of the hand relaxed, the fingertip pulp was rapidly compressed during the first 10 ms of the tap, then maintained relatively constant amount of compression (Figure 2).

Figure 2. Pulp compression over time for a representative tap.

Force production was characterized by an initial force peak, corresponding to the compression of the fingertip, followed by a decrease in force caused by rapid relaxation of the fingertip pulp (Figure 3).

A simple model of fingertip pulp mechanics exhibiting instantaneous elasticity and rapid relaxation was able to reconstruct the mechanical behavior of the fingertip pulp to root-mean-squared errors of 10% (Figure 3). These errors are similar to the 4-10% errors achieved for simpler inputs (Pawluk and Howe, 1999).

Figure 3. Measured and re-constructed force over time.

FITTING MUSCLE PROPERTIES

Tobias Siebert¹, Heiko Wagner¹, Richard Marsh² and Reinhard Blickhan¹

¹Institute of Sports Science, Friedrich Schiller-University, Jena, Germany
tobias.siebert@uni-jena.de

²Department of Biology, Northeastern University, Boston, USA

INTRODUCTION

Muscle properties specified for example by the force-length-, force-velocity relationships, and the stiffness of the series elastic element can be either determined separately in rather specialized experiments or by fitting a model to dynamic experiments. The two approaches are compared in an experiment on a frog *M. dorsal semitendinosus*. Fitting to a family of dynamic (kinetic) measurements saves time and gives acceptable results.

METHODS

The *M. dorsal semitendinosus* (*Rana pipiens*) was dissected. The muscle was connected with a lever arm system (Cambridge technologies 300B), which allows static and dynamic investigation of force and length with supramaximal stimulation. A series of isometric experiments was performed to measure the force-length dependency. The stiffness of the series elastic component and the force velocity relationship was measured by step-release isokinetic experiments (Curtin 1998). Isokinetic experiments started at L0 and were performed with different shortening velocities.

Muscle model: We describe the muscle with a Hill-type muscle model consisting of a force-velocity relation, a force-length relation and a linear series elastic component. The properties of the muscle model can be determined using a non-linear regression method. In order to enhance the precision of the fitting method, we used a software package (JOP kinematics) which allows to fit up to eight different data sets simultaneously with a single set of muscle properties. The fitting of 4 isokinetic frog data results in one set of muscle properties.

RESULTS AND DISCUSSION

The model calculations performed with one parameter are consistent with the isokinetic experiments (Fig. 1a). Isokinetic experiments were performed on the ascending limb of force-length relationship, therefore we obtain high correlation for this part (Fig. 1c). Deviation of 15% maximum force are found in lower part by fitting a parable function. Difference in descending limb of force length relationship are due to description of the asymmetric force length curve by a parable. A higher correlation in descending part may be possible by performing isokinetic experiments on the descending limb and usage of asymmetric force-length function. Differences in force-velocity relationship are found in the region of high velocities (Fig. 1b). They depend on the quality of force-length description. Stiffness of the series elastic component is determined as $k=828\text{N/m}$ (experimental) and $k=894\text{N/m}$ (fitting, Fig. 1d). Parallel elasticity was neglected.

This method was used to determine muscle properties of another muscle (*M. triceps brachii* of *Rattus norvegicus*) by fitting 8 isokinetic traces. Stiffness of series elastic component is 25.6 kN/m , $v_{\max} = 0.2\text{m/s}$, $F_{\max} = 37\text{ N}$ and $P_{\max} = 0.56\text{ W}$.

SUMMARY

It is possible to obtain a suitable set of muscle properties by fitting a hill type muscle model to isokinetic data. This strongly reduces the experimental effort.

INTRODUCTION

Osteoarthritis (OA) is a degenerative joint disease that negatively affects the integrity of articular cartilage and underlying subchondral bone. It has been suggested that OA exists in 80% of the individuals over the age of 55 (Altman, 1987). It is a particularly debilitating disease when it affects the knee, as its symptoms inhibit basic daily activities such as walking. Gait analysis has proven to be a vital tool for understanding the effects of QA on functional tasks. However, it may also be a valuable adjunct in understanding the etiology, diagnosis and treatment of knee OA as well. The present study reports the preliminary results on the use of gait analysis for individuals with OA through the calculation of muscle power and mechanical work values of the lower limb. The analysis was restricted to a 2-D sagittal plane analysis of the lower limb during a fast pace (150% preferred speed) walk. It was hypothesized that there would be alterations in the lower limb energetics in patients with moderate OA of the knee compared to normal. Specifically, we conjectured that OA might cause a redistribution of relative work contributions (RWC) among joints in the lower limb.

METHODS

All subjects completed informed consent and SF-36 health survey forms, and the OA subjects completed the WOMAC prior to the completion of any test trials. Each subject performed, in random order, five trials of their normal preferred speed (C1), and a fast walk (C2) (150% of the normal speed). All OA subjects were diagnosed as either a 1 or 2 on the Kellgran & Lawrence scale prior to participating in the study. The *Qualisys* Pro-reflex motion capture system and a *Kistler* force plate were used to record the kinematic and ground reaction force data for 7 (Norm) and 4 (OA) subjects. The mechanical work and powers were calculated for the sagittal plane motion of the entire stride using BIOMECH software for the five walking trials. Standard link segment marker locations and data smoothing techniques (Butterworth low-pass digital filter @ 6 Hz) were used. Muscle powers (W/kg) and the work (J/kg) done at the hip, knee and ankle were calculated for each trial. Work at each joint was expressed as a percentage of the total work done in the lower limb for the gait cycle. The within subject average value for the five trials were used in an ANOVA to test for between group differences.

RESULTS

There was no significant difference in the walking speeds of the two groups for the C1 and C2 conditions (Table 1). Shown in Table 2 is the RWC for each joint expressed with respect to the total lower limb work (the summed positive and

negative work accumulated over the entire stride) for the C2 condition. There were statistically significant differences for the RWC at the hip ($F=104.9$, $df=1,3$, $p=0.002$) and the knee ($F=22.69$, $df=1,3$, $p=0.018$) between the two groups. The OA group performed less work (37.8% vs 46.8%) at the knee than the controls and an increase in the work (29.6% vs 23.4%) at the hip.

Table 2: Relative work done (%) at each joint (C2 condition).

Joint	Positive Work		Negative work		Total Work	
	Norm	OA	Norm	OA	Norm	OA
Hip	31.7	35.2	13.3	20.6	23.4*	29.6
Knee	23.2	22.2	75.4	63.0	46.8*	37.8
Ankle	44.9	42.6	11.3	16.4	29.8	32.5

DISCUSSION

Subjects with moderate OA tend to be active individuals who exhibit locomotor patterns that temporally and kinematically, appear quite "normal". The purpose of this pilot work was to compare the kinetic patterns of the lower limbs during fast walking. Although there was no difference in the speed of walking the muscle energetics information from the lower limb suggests that the OA group did perform the task employing a strategy to reduce the work done at the affected joint. The OA knee experiences a reduction in the mechanical work done during the first three major power phases of the knee during the gait cycle. Initial outcomes from this study suggest that employing a kinetic analysis of the gait pattern may be a sensitive technique to discriminate between normal and OA subjects.

CONCLUSION

There is a redistribution of the total work done among the joints in the lower limb during the entire gait cycle for individuals with OA of the knee. The key change appears to be a 9.0% decrease in the total RWC in the OA knee. This change is reflected in the form of absorption compared to the normal knee and a redistribution of work to the hip.

TECHNIQUES FOR AVOIDING HIP IMPACT DURING UNEXPECTED SIDEWAYS FALLS

Jessica Maurer, Brady Warnick, Lisa Inkster, and Stephen N. Robinovitch

Injury Prevention and Mobility Laboratory, School of Kinesiology, Simon Fraser University, Burnaby, B.C., Canada, steve@sfu.ca

INTRODUCTION

Falls are the underlying cause of 90% of all hip fractures in the elderly (Grisso et al., 1991). Considerable evidence now exists that the configuration of the body at impact is a stronger predictor of hip fracture risk than bone density (Greenspan et al., 1994; Nevitt et al., 1993). Of particular importance is whether impact occurs to the hip, which increases fracture risk 30-fold. Our previous studies suggest that young individuals tend to avoid hip impact during a sideways fall by rotating forward and braking the fall with the outstretched hands (Hsiao et al., 1998). Presumably, an alternate technique for achieving this is to rotate backward to land on the buttocks. In this study, we examined whether these two strategies are equally effective in allowing subjects to avoid hip impact during an unexpected sideways fall.

METHODS

Fourteen women between the ages of 18 and 35 (mean age 24 ± 6) participated in the study. In all trials, a sideways fall was initiated by suddenly releasing a tether, which supported the subject at a 15 deg lean (Fig. 1). This caused the subject to fall unexpectedly onto a soft gymnasium mat. Subjects were instructed to try to “land as softly as possible” and to “avoid impacting the hip” by either rotating forward to land on the knees and outstretched hands (FR trials), or rotating backward to land on the buttocks (BR trials). Subjects were also instructed to keep their knees extended during descent. Three trials were acquired for each condition in a randomized sequence.

Figure 1: Stick figure image of sideways falls

We used a 6-camera, 60 Hz motion measurement system (MacReflex, Qualysis Inc) to acquire from each trial the 3D positions of 22 skin surface markers. From these data, we determined values of the following variables at the instant of pelvis impact: (1) hip proximity angle, (2) pelvic tilt angle, (3) vertical hip velocity, and (4) whole-body kinetic energy. The hip proximity angle (α) reflects how near the site of pelvis

impact is to the lateral aspect of the hip (Fig 2). The pelvic tilt angle (β) indicates how near the pelvic ellipse is to being parallel to the ground at impact. Paired t-tests were used to determine if there were differences in these variables between FR and BR trials.

Figure 2: Pelvic contact angles

RESULTS AND DISCUSSION

There were no differences between FR and BR trials in mean values of hip proximity angle, vertical hip velocity, and kinetic energy at impact (Table 1). However, pelvic tilt angle was significantly greater in FR than in BR trials.

This suggests that individuals can avoid impact to the hip during a sideways fall by rotating backward during descent (to impact the buttocks) or by rotating forward (to impact the knees and hands). Previous evidence of a tendency for forward rotation (Hsiao et al., 1998) may reflect subjects' desire to coordinate landing by visualizing the impact surface. However, it is likely that a range of environmental, intrinsic, and situational variables affect the feasibility and utilization of the FR and BR strategies.

Table 1: Fall severity indices from forward rotation (FR) and backward rotation (BR) trials (mean \pm SD)

	FR value	BR value	P value
Hip Prox Angle (deg)	68.6 ± 12.5	61.5 ± 17.9	0.533
Pelvic Tilt (deg)	64.1 ± 8.6	26.2 ± 9.5	< 0.001
Hip Velocity (m/s)	$3.02 \pm .35$	$-3.26 \pm .29$	0.091
Kinetic Energy (J)	358 ± 216	282 ± 78	0.168

SUMMARY

During an unexpected sideways fall, young females can avoid hip impact by rotating forward or backward during descent.

DIFFERENCES IN PROPULSION KINETICS BETWEEN WHEELCHAIR DEPENDENT AND NON-WHEELCHAIR DEPENDENT USERS

W. Mark Richter^{1,2}, Peter W. Axelson², Rory A. Cooper³

¹Stanford University, Stanford, CA (wrichter@stanford.edu) ²Beneficial Designs, Inc., Minden, NV

³Human Engineering Research Laboratories, Highland Drive VA Medical Center, Pittsburgh, PA

INTRODUCTION

Investigation of handrim kinetics during manual wheelchair propulsion provides insight into the demands on the wheelchair user and may ultimately serve to prevent the development of overuse injuries of the upper extremity. Studies enlisting the participation of non-wheelchair dependent users risk drawing conclusions that are not relevant to the wheelchair user population.

In a comparison of the metabolic demand of wheelchair dependent (WD) users and non-wheelchair dependent (NWD) users, Brown et al. found that WD users used less metabolic energy to complete the same propulsion task. In a study comparing propulsion kinetics of WD and NWD users, Robertson et al. found WD users tended to have lower peak tangential and vertical forces as well as longer times to reach those peak values. The researchers concluded that WD users might have developed these propulsion techniques to reduce the stress on the upper extremity. This study reevaluates the kinetic differences between WD and NWD users.

METHODS

Five WD and five NWD subjects participated in the study. Subjects propelled a wheelchair on a stationary dynamometer at a steady state target velocity of 3 m/s. The resistance of the dynamometer was set to simulate propulsion up a 2% grade. WD subjects used their own wheelchair in an unaltered configuration. NWD subjects used a Quickie Carbon wheelchair (Quickie, Fresno, CA). Handrim kinetics were measured using a SMART^{Wheel} instrumented wheelchair wheel (Three Rivers Holdings, Scottsdale, AZ).

Kinetics during ten consecutive pushes from each trial were used in the analysis. Handrim forces were normalized by subject body weight (bw) to remove subject weight as a factor in the results. The force components in the plane of the wheel were transformed from an inertial lab frame to a wheel fixed frame such that the resulting components were radial (Fr), tangential (Ft), and axial (Fa). Peak force components over the entire push and the average rate of force application (dF/dt) over the first ten percent of each push were determined and averaged. Results for each subject group were compared using a two-tailed paired samples t-test and considered to be statistically significant for $p < 0.05$.

RESULTS

Resulting values of peak force and initial rate of force application are given for the WD and NWD groups in Table 1. The general trend in the data suggests that the WD users tend to exhibit larger peak forces and a higher rate of force application than the NWD users. Statistically significant differences were seen in the rate of force application in the radial and axial directions. The WD users applied force components 101% and 115% faster than the NWD users in the radial and axial directions, respectively. While propulsion

velocity tended to be less for the WD users, the difference was not statistically significant. Had the propulsion velocity been higher for the WD users, it would have provided a possible reason for the trend in increased force on the handrim.

Table 1: Propulsion kinetic characteristics for wheelchair dependent (WD) and non-wheelchair dependent (NWD) users

Parameters	WD	NWD	Significance (p)
Velocity (m/s)	2.68	3.09	0.053
Push Frequency (Hz)	1.15	1.09	0.697
Peak Fr (bw)	0.112	0.081	0.070
Peak Ft (bw)	0.072	0.064	0.435
Peak Fa (bw)	0.047	0.040	0.305
Avg Initial dFr/dt (bw/s)	2.070	1.030	0.035*
Avg Initial dFt/dt (bw/s)	0.434	0.389	0.725
Avg Initial dFa/dt (bw/s)	1.012	0.470	0.034*

DISCUSSION

While the results of this study appear to be in contradiction to those found by Robertson et al., the two studies are not directly comparable. The variation in results found by Robertson et al. may be explained by the use of non-body weight normalized forces. Body weight of WD users tends to be less than NWD users due to lower extremity atrophy, which would likely result in a reduced net force required propel the wheelchair.

The decreased rate of force application in the NWD users is believed to be the result an actively positioned and stabilized trunk. This conclusion may be supported by results of the Brown et al. study. Metabolic demand of NWD users would be expected to be greater than WD users due to the use of the large muscle groups of the trunk being used during propulsion. Results of this study indicate that kinetic propulsion characteristics of WD users are different than NWD users and as a result, future propulsion biomechanics studies should restrict participation to WD users.

fbuczek@shrinenet.org

INTRODUCTION

In clinical gait analysis, we strive to identify movement strategies that result in propulsive (anterior) ground reaction forces (F_x). We feel this framework better prepares us to answer treatment questions from referring physicians. We have found two prominent opinions regarding the source for F_x : the position of the body's center-of-mass (COM) forward of its base of support (a clinical interpretation advocated by Perry, 1992), and the use of mechanical power at joints of the lower extremities to perform work on the body, causing changes in its mechanical energy (an engineering interpretation after Winter, 1991). We hypothesized that COM position alone would be insufficient to explain F_x .

METHODS

Because the theory suggested by Perry (1992) essentially models the body as an inverted pendulum, we simulated a shaft of negligible mass and a load at its tip. By summing moments in the XY-plane (X anterior, Y vertical), and noting that the moment of inertia I about the pivot equals mr^2 , we derived an expression for the angular acceleration α of the pendulum:

$$\alpha = (-g \cos \theta) / r, \quad (1)$$

where g is the acceleration due to gravity, θ is the pendulum inclination angle, r is the radius from pivot to COM, and m is the mass of the load. Using polar coordinates and summing forces in the X direction, we derived an expression for F_x at the pivot:

$$F_x = -mr(\omega^2 \cos \theta + \alpha \sin \theta), \quad (2)$$

where ω is the angular velocity of the pendulum shaft. To illustrate these relationships, we simulated pendulum mechanics by numerical integration of Equation (1), and substitution of results into Equation (2). To best simulate the initiation of gait within the context of this theory, initial conditions included $\theta = 89^\circ$, $\omega = 0$ radians/s, and $\Delta t = 0.017$ s. We simulated three pendulum radii (0.660, 0.825, 0.990 m) paired with three pendulum masses (25, 45, 65 kg), chosen to approximate 50th percentile anthropometry for a 7 yr old child, a 12 yr old girl, and an 18 yr old boy, respectively. Anterior translational velocities were obtained ($v = \omega r \sin \theta$), and simulations were terminated at $\theta = 60^\circ$, approximating opposite foot contact. For comparison, F_x data were obtained from our normal database for a subject whose pendulum radius and mass (0.910 m and 63 kg) matched the 18 yr old simulation.

RESULTS AND DISCUSSION

Inverted pendulum simulations produced maxima in v , F_x (N), and F_x (% bodyweight) comparable to normative data (Kadaba et al., 1989; Winter, 1991). However, the time Δt_{\max} (from onset of positive F_x to its maximum value) was greater for the simulations than for our representative normal subject (Table and Figure). Although this limitation in Perry's model may be partially overcome by using an initial ω as in steady-state gait (future tests), there remain no mechanisms to change walking velocity (α is dependent upon r which is largely dictated by stature), nor to achieve swing phase. Input of mechanical energy seems necessary as suggested by Winter (1991).

Table: Simulation results compared to representative normal

	v_{\max} (m/s)	$F_{x\max}$ (N)	$F_{x\max}$ (%bw)	Δt_{\max} (s)
Sim1	1.10	75.7	30.9	1.05
Sim2	1.27	136	30.8	1.17
Sim3	1.36	196	30.8	1.27
Nrml	1.39	142	22.9	0.183

KEY Sim1: $r = 0.660$ m, $m = 25$ kg Sim2: $r = 0.825$ m, $m = 45$ kg
Sim3: $r = 0.990$ m, $m = 65$ kg Nrml: $r = 0.910$ m, $m = 63$ kg

Figure: Positive F_x values begin at 0.33 s for normal and simulation graphs; the former peaks at 0.52 s, the latter at 1.60 s.

SUMMARY

Center-of-mass position alone, as simulated using an inverted pendulum, is insufficient to fully explain F_x during gait.

EFFECT OF HAMSTRINGS INCLUSION ON CALCULATION OF JOINT CONTACT FORCE AND STRESS

Janet Ronsky and Nicole Baker

Department of Mechanical and Manufacturing Engineering, Human Performance Laboratory
University of Calgary, Calgary, Alberta, Canada, jlrnsky@ucalgary.ca

INTRODUCTION

A method for non-invasively quantifying human patellofemoral (PF) joint contact stress has been developed (Ronsky, 1994). Load applied at the heel during a magnetic resonance (MR) scan is used as input to a mathematical model to estimate PF joint contact force and stress. Previous work neglected the hamstrings contribution to joint contact force. In the ACL-deficient knee, hamstrings may be more active than in healthy knees to provide joint stability (e.g. Solomonow et al., 1987). The purpose of this work is to quantify hamstrings forces during the MR rearfoot loading task and to compare joint contact force and stress calculated with and without hamstrings forces.

METHODS

Five female subjects (age = 25.4 ± 4.3 years, height = 164.4 ± 4.3 cm, weight = 56.6 ± 10.9 kg) with no knee injury history or knee pain volunteered for this study and gave informed consent. Knee health was verified by an orthopaedic surgeon. All experimental procedures were approved by the University of Calgary Conjoint Faculties Research Ethics Board.

Muscle forces were estimated using an EMG-force calibration procedure (Kellis and Baltzopoulos, 1997). Standard surface EMG protocol was used to record muscle activation patterns of the medial and lateral hamstrings (MH and LH) of right limbs. Each subject performed maximal and sub-maximal isometric knee flexion contractions on a Biodex dynamometer (Shirley, NY) at flexion angles of 15° , 30° and 45° (0° = full extension). Root mean square EMG values were normalized to MVC. Total knee flexor force was partitioned into MH and LH groups based on relative physiologic cross-sectional areas (e.g. McGill and Norman, 1986). A 2nd-degree polynomial was fit through the corresponding EMG-force data points.

Direct acquisition of surface EMG during the MR scan was not possible because the electrode leads caused image distortion. With EMG electrodes maintained in the same positions, MH and LH activity was recorded in the laboratory using a mock-up of the MR rearfoot loading device. The exercise is a supine leg press performed at approximately 7% MVC. Three repeat trials (right limbs only) were performed on three separate days. A confidence interval of muscle force magnitudes was calculated from the repeated measurements.

A 2D sagittal-plane model of the lower leg and PF joint was used to calculate joint contact force based on rearfoot loading quantified during imaging. Internal joint geometry and lines of action of patellar and hamstrings tendons were digitized directly from MR images (4 subjects, both limbs). Muscle forces

estimated from right limbs were assumed to be valid for use in the left limb model of the same subject. PF articular surfaces were digitized from MR images and reconstructed using a thin plate spline (Boyd et al., 1999). Contact area was determined using a surface proximity threshold. Average PF contact stress was calculated as contact force divided by area.

RESULTS AND DISCUSSION

The predicted hamstring forces during the MR loading task ranged from 0-59 N (10% MVC) for LH and 0-45 N (6% MVC) for MH. The inclusion of hamstrings forces resulted in an average increase of $25 \pm 18\%$ in contact force and stress magnitudes. This is an increase of 21 ± 6 N for contact force and 0.09 ± 0.04 MPa for contact stress (Figure 1).

Figure 1: PF joint contact stress calculated without and with estimated hamstrings forces. Bars represent the average 5-95% confidence interval of hamstrings forces based on repeat tests. Sample sizes vary depending upon availability of MR images.

This method may be used to non-invasively estimate subject- and knee angle-specific muscle forces without having to assume a value for muscle stress. Future application of this work will be to compare PF contact characteristics between normal and ACL-deficient knees using this method to quantify hamstrings forces for input to the PF joint contact force model.

TECHNIQUES FOR SAFE LANDING DURING AN UNEXPECTED FALL: MODULATION OF IMPACT VELOCITY VIA THE “SQUAT RESPONSE”

Stephen Robinovitch, Leslie Torburn, Lisa Inkster, and Rebecca Brumer

Injury Prevention and Mobility Laboratory, School of Kinesiology
Simon Fraser University, Burnaby, B.C., Canada, steve@sfu.ca

INTRODUCTION

Falls are the number one cause of accidental injuries in the elderly, including 90 percent of hip fractures (Grisso et al., 1991). One's risk for hip fracture in the event of a fall depends on bone strength, and on the force applied to the bone at impact. The latter depends, in turn, on the configuration and velocity of the body as it contacts the ground. Previous studies (Hsiao and Robinovitch, 1998) suggest that young subjects utilize specific protective responses to avoid injury during a fall. These include absorbing energy in the lower extremity muscles during descent (as occurs during squatting or sitting), and braking the fall with the outstretched hands. The purpose of this study was to test whether, during an unexpected backward fall, the utilization or inhibition of these responses affects the velocity of the hip and the kinetic energy of the entire body at the moment the pelvis strikes the ground.

METHODS

Seventeen women between the ages of 18 and 35 (mean age 23.58 ± 5.62) participated in the study. In all trials, a backward fall was initiated by suddenly releasing a tether (Fig 1), which supported the subject at a 5 deg lean. This caused the subject to fall unexpectedly onto a soft gymnasium mat. Four series of trials were acquired with each subject (Table 1). In all series, subjects were instructed to “land as softly as possible” and to “avoid impacting the hip.” However, the series differed in whether the subject was further instructed to utilize or inhibit (i) braking the fall with the outstretched hands, and (ii) absorbing energy in the lower extremity muscles and tendons during descent (“squat response”). Throughout the session, the series (i.e., instruction) was randomized, with the constraint that 3 trials were acquired for each of the four series.

Figure 1. Tether-release falling experiment. M = gym mat; FP = force plate; W = walkway; H = harness; T = tether; B = brake. The lean angle before release was $\theta = 5$ deg.

In each trial, we used a 6-camera, 60 Hz motion capture system (Qualysis Inc) to acquire the 3D positions of 22 skin surface markers. We then used custom routines (MATLAB) to calculate from these data the vertical velocity of the right greater trochanter and the kinetic energy of the entire body at

the moment the pelvis impacted the mat. We used repeated-measures ANOVA (with $\alpha = 0.05$) and post-hoc paired t-tests (with $\alpha = 0.008$) to determine if there were differences in outcome parameters between the series.

RESULTS AND DISCUSSION

Use of the squat response caused a decrease in hip velocity and whole-body kinetic energy at impact. When compared to Series D (no squat, no hands), Series B (squat, no hands) involved smaller hip impact velocities (21 ± 13 percent decline, on average; $P = 0.001$), and smaller kinetic energies at impact (41 ± 26 percent decline, on average; $P < 0.001$). When compared to Series C (no squat, hands), Series A (squat, hands) involved smaller kinetic energy at impact (29 ± 19 percent decline, on average; $P < 0.001$).

On the other hand, braking the fall with the outstretched hands did not affect hip velocity or kinetic energy at impact. There were no differences between Series A and Series B in hip impact velocity ($P = 0.21$) or kinetic energy ($P = 0.84$), or between Series C and Series D in hip impact velocity ($P = 0.81$) or kinetic energy ($P = 0.05$).

Table 1. Impact velocities and kinetic energies (means \pm SD).

	Series A: Squat, use hands	Series B: Squat, no hands	Series C: No squat, use hands	Series D: No squat, no hands
Velocity (m/s)	2.96 ± 0.71	2.74 ± 0.33	3.51 ± 0.99	3.58 ± 0.94
Kinetic energy (J)	176 ± 52	172 ± 59	262 ± 87	312 ± 116

SUMMARY

During an unexpected backward fall, use of the “squat response” during descent can decrease hip impact velocity by up to 21 percent and kinetic energy at impact by up to 41 percent. Braking the fall with the outstretched hands has little effect on pelvis velocity or kinetic energy during a backward fall. It may, however, influence these variables during a sideways or forward fall, and affect risk for head impact.

DEVELOPMENT OF 3D MODULAR DENTURE FE MODEL

YU Li-niu¹, ZHANG Fu-qiang², WANG Cheng-tao¹

1. School of Mechanical Engineering, Shanghai Jiaotong University, Shanghai, 200030, China;

2. School of Stomatology, Shanghai Second Medical University, Shanghai, 200011, China

INTRODUCTION

The geometric complexity of denture in oral cavity prolongs the process of 3D finite element modeling and lowers the efficiency of the whole solution if geometrical comparability is required in finite element analysis of denture. Generally, the procedure of model building consists of selecting specimen, extracting geometrical information of specimen (for example, using CT-scan), inputting it into software and reconstructing 3D model in computer. Every step is time consuming. However, the number of analyses to be performed is limited due to the case by case modeling method. Cutting short of the model building time is an effective way to improve the efficiency of the finite element analysis. Model modularization is implemented in this study to facilitate the generation of 3D denture finite element model; and this has found practical applications in oral rehabilitation.

METHODS

A skull sample with good occlusion and a healthy denture was selected and scanned by CT. The geometrical information in the CT images was extracted and the wireframe model of the denture was exported. Using FE software (ANSYS), a new solid model was created. Then whole denture solid model was divided into several separated parts, including the dental crown, root, periodontal ligament, alveolar bone. A single model unit was constituted with all the coherent parts of each tooth. Every model for each tooth was exported and saved in IGES format. A set of denture model library with normal physiological condition was established. Based on it, the new model library about alveolar bone absorption and tooth loosens were created.

RESULTS AND DISCUSSION

The 3D modular models can be used in various combinations based on needs to build a specific FEA model rapidly for oral rehabilitation. The 3D modular denture FE model can be

clinically applied to 3D FEA of fixed-partial and removable partial restoration:

- (1).when all or some of abutments suffered from alveolar bone absorption of different degree;
- (2).when all or some of abutments were loosen in different degree;
- (3).some abutments were loosen while others have alveolar bone absorption.

Fig.1 Solid model of mandible with denture

Modularization of denture FE model proves to reduce the modeling time from several weeks to several hours. At the same time, the large number of analyses can be performed in a short time frame. The 3D modular denture FE model will retain the same precision of material, load and constraint as convention methods. The 3D modular denture FEA model makes it possible for FEA to be widely accepted as a useful tool for oral rehabilitation due to its efficiency and convenience.

CYCLIC STRETCH INCREASES GENE TRANSFER AND EXPRESSION IN ALVEOLAR EPITHELIAL CELLS

David A. Dean^{1,2}, Winna Taylor¹, Kerimi E. Gokay¹, Chris Capaccio³, and Matthew R. Glucksberg³

¹Division of Pulmonary and Critical Care Medicine, and ²Department of Microbiology and Immunology, Northwestern University Medical School, Chicago, IL 60611 dean@northwestern.edu and ³Department of Biomedical Engineering, McCormick School of Engineering and Applied Science, Northwestern University, Evanston IL 60208

INTRODUCTION

Mechanical stretch induces numerous biological responses in cells, including alterations in the cytoskeleton, activation of cell signaling pathways, and upregulation of transcription factors. Intriguingly, these responses are directly related to the process of gene delivery to cells and tissues. Exogenous DNA, either viral or non-viral, must cross the plasma membrane into the cell, travel through the cytoplasm and the cytoskeletal networks, enter the nucleus, and be transcribed for gene transfer to be successful. Using a system to apply equibiaxial stretch to cultured alveolar epithelial cells, we investigated the effects of cyclic stretch on gene delivery.

METHODS

Human A549 cells (derived from an alveolar epithelial carcinoma) were grown on laminin-coated BioFlex stretch plates to 60% confluency and transfected with two plasmids, one expressing luciferase and the other expressing green fluorescent protein (GFP). The cells were either unstretched before and after transfection, stretched for 24 hours prior to transfection and left unstretched afterwards, unstretched before transfection and stretched immediately following DNA addition, or stretched both prior to and after transfection. All cells were stretched at 1 Hz at a 10% area strain using the Flexercell 3000FX with loading posts for equibiaxial strain.

Transfections were carried out using lipoplex (Lipofectin-complexed plasmid) or by electroporation of the adherent cells. Lipoplex transfections were carried out under standard conditions. For electroporations, 10 µg of DNA in 1 ml of serum-free medium was added to washed cells and one 20 msec square wave pulse of 100V/cm was applied to the cells using a Petri Pulsar Electrode (Genetronics, San Diego, CA). Serum-containing medium was added back to the cells 10 minutes later. Cells were removed from the stretch device for no more than 5 minutes to perform the transfections. Twenty-four hours post-transfection, the cells were observed for GFP expression, and subsequently lysed for measurement of luciferase activity and protein levels.

RESULTS AND DISCUSSION

When cyclic stretch was applied immediately following lipoplex- or electroporation-mediated transfection, gene transfer and expression were greatly increased (Figure 1). Observation of GFP expression indicated that both the number of cells expressing gene product and the amount of gene expression in individual cells were increased with stretch. Stretching the cells prior to transfection had no effect on gene transfer and/or expression. Only when stretch was applied after DNA addition did the stimulation become evident. To determine whether prolonged exposure to stretch was needed for this enhancement, the cells were stretched for 30 minutes

immediately following transfection and then grown statically for 23.5 hours or stretched for 24 hours. We found that only short periods of cyclic stretch were needed following transfection in order to observe maximal enhancement of gene transfer and expression (Figure 2).

Figure 1. Cyclic stretch applied immediately following transfection greatly increases gene transfer. $p < 0.02$

Figure 2. Short-term application of stretch post-transfection is sufficient for maximal enhancement of gene transfer. $p < 0.01$

Because enhancement of gene transfer by stretch is seen with lipoplex and electroporation-mediated transfection, it is unlikely that stretch is exerting its effects at the plasma membrane. It is also unlikely that the enhancement is due to increased transgene transcription because stretch prior to transfection had no effect whereas stretch for 30 min after transfection did. Our continued experiments will focus on the ability of stretch to alter cytoplasmic movement of the incoming plasmids and their nuclear import.

REARFOOT MOTION & TIBIAL ACCELERATION IN THE RUNNING ATHLETE

Neil Manson¹, William Stanish^{1,2}, Kelly McKean² and Andrew Milne³

¹Division of Orthopaedic Surgery, Dalhousie University

²Orthopaedic & Sports Medicine Clinic of Nova Scotia, Halifax, NS, kmckean@tupdean2.med.dal.ca

³Department of Medicine, Dalhousie University

INTRODUCTION

Musculoskeletal injury is extremely prevalent in the running athlete causing significant pain and severely limiting performance. The knee has been identified as the most common site of injury (Macintyre et al., 1991), however a new pattern is emerging suggesting impact loading injuries to the lower leg are the most prevalent. Alterations in gait biomechanics and muscle stimulation (Nigg & Liu, 1999) have been hypothesized in reducing impact forces, however the mechanisms are not well understood. Higher impact forces have been documented with medial shoe inserts, to decrease pronation angle, in a healthy population (Perry & LaFortune, 1995). However, the correlation between tibio calcaneal motion and the shock attenuated by the lower segment of the musculoskeletal system has not been documented in relation to specific injuries. Furthermore, it is unclear whether biomechanical parameters are predictive of injury or, conversely, are the result of injury. In order to design effective footwear and orthotic treatments this cause and effect relationship must be examined.

The purpose of this study is to determine the relationship between rearfoot motion and tibial acceleration according to prospective and retrospective injury frequencies.

METHODS

Forty-two well-trained, intercollegiate running athletes (males = 24, females = 18) were monitored through biomechanical analysis, retrospective and prospective survey data and physician assessment. Biomechanical data was collected at the onset of the study. Markers were placed on the rear tibio calcaneal segments (Nigg, 1986). A skin mounted accelerometer was attached to the anteromedial surface of the right tibia (Lafortune et al., 1995). Subjects ran on a treadmill at 3.8m/s in a fatigued state. Measurements included i) rearfoot motion in the coronal plane using 2D video (60Hz), ii) shock transmission at the tibia using uniaxial accelerometers (1000Hz) and iii) retrospective injury frequencies. Athletes reported injury, location and associated factors for a 1 year follow up period. A CASM qualified physician corroborated diagnosis. Peak tibial acceleration and average range of rearfoot motion were quantified for each athlete. Correlation analysis was used to determine the relationship between these two biomechanical variables based on injury reports.

RESULTS

Retrospective data revealed an injury rate of 79% (33/42). Injury to the lower leg (i.e. shin splints, stress fractures) comprised 18% (6/33) of all injuries. A negative correlation between peak tibial acceleration and average range of rearfoot

motion was found in this group ($r^2 = .63$). Such a mechanism was not apparent in athletes not reporting injury ($r^2 = 0.01$).

Prospective analysis revealed an injury rate of 62% (26/42). The lower leg was the most prevalent injury location comprising 31% (8/26) of injuries. No correlation was found between biomechanical parameters for either group based on prospective injury data.

Figure 1: Rearfoot motion and tibial acceleration in a group of competitive runners following lower leg injury ($r^2 = .631$).

DISCUSSION & CONCLUSIONS

This important correlation between rearfoot motion and tibial acceleration has not previously been documented in the injured athlete. Increasing the angle of the calcaneus relative to the shank during the stance phase may aid in redistributing impact forces and ultimately alleviating pain. Altered biomechanics may be implicated as a compensatory mechanism opposed to a predictive measure. These findings have important implications in the design of shoe and orthotic devices to treat this new focus of running injuries.

DYNAMIC STABILIZATION OF RAPID HEXAPODAL LOCOMOTION

Devin L. Jindrich

Department of Integrative Biology, University of California at Berkeley, dljindrich@yahoo.com

Current address: Harvard Occupational Biomechanics, Harvard School of Public Health, Boston, MA, USA.

INTRODUCTION

Simple mechanical models are capable of describing the sagittal-plane mechanics of constant average speed walking and running (Blickhan and Full, 1993). However, much less is known about the mechanics of changing the speed or direction of movement. If movement is altered by an external perturbation, animals must stabilize themselves to continue moving at a desired velocity by generating forces appropriate to overcome the effects of the perturbation.

Two (non-exclusive) mechanisms which legged animals use to stabilize rapid locomotion are 1) changing the placement of the foot relative to the body at the beginning of a step, and 2) altering the forces generated by the legs during stance. During slow movements, the nervous system can act to change leg placement or continuously alter force production. However, during rapid locomotion, neural control of stability may become increasingly difficult because of neural feedback delays (Hogan, 1990). As stance periods decrease, continuous modulation of forces by neural mechanisms may become less advantageous. However, intrinsic properties of musculo-skeletal systems, termed 'preflexes' (Brown and Loeb, 2000), may contribute to stability during high-speed movements.

This study sought to test two hypotheses: 1) changes to foot placement at step transitions are necessary to stabilize rapid locomotion, and 2) musculo-skeletal 'preflexes' contribute to dynamic stabilization of rapid locomotion. To test these hypotheses, I directly measured stabilization of rapid locomotion in a hexapod, the cockroach *Blaberus discoidalis*.

MATERIALS & METHODS

Stable locomotion may be described as a pattern of positions and velocities over time, which repeats with a characteristic frequency such as the stride frequency, to which an animal returns following a perturbation. To measure the stabilization mechanism used by cockroaches during running, I perturbed the animals by subjecting them to a brief (< 10 ms), laterally-directed force impulse 80% of the magnitude of the animals' forward momentum at their preferred speed. A miniature cannon was attached to the back of the animals (Figure 1 A).

Figure 1. A. The perturbation apparatus. **B.** Center of mass velocity (blue arrow) 10 ms before and 10 ms following a perturbation to the left.

As the animals ran forward at constant average speed, the cannon was fired, and the reaction force due to accelerating the projectile perturbed the animal (Figure 1 B). Three-dimensional video analysis recorded the movements of the animal following the perturbation. Movement kinematics from perturbed trials were compared to reference trials.

RESULTS

Hypothesis 1. Cockroaches did not require changes in leg placement at step transitions to recover from lateral perturbations of 80% of their forward momentum (Figure 3). In all trials where the perturbation occurred in the first half of the stance phase of a tripod of stepping legs, lateral velocity recovered to within unperturbed values before the touchdown of the following tripod.

Hypothesis 2. Lateral velocity began to decrease (indicating that a force generated by the legs in stance acted in the opposite direction) 13 ± 5 ms following the perturbation. This time period is comparable to the fastest neural reflexes measured in cockroaches, supporting the hypothesis that musculo-skeletal 'preflexes' contribute to stabilizing rapid locomotion.

Figure 3. Lateral velocity (relative to unperturbed velocity) following perturbation for a representative trial. The perturbation occurred early in the stance period of the left front, right middle, and left hind (LF, RM, LR) legs. Lateral velocity returned to the reference velocity before the legs of the alternate tripod touched down.

THREE DIMENSIONAL RECONSTRUCTION OF THE KNEE FROM BIPLANAR X-RAYS.

S. Laporte¹, W. Skalli¹, J.A. de Guise², D. Mitton¹

¹ Laboratoire de BioMécanique, ENSAM / CNRS UPRESA 8005 / Paris, France

² Laboratoire de recherche en Imagerie et Orthopédie, ETS / CRCHUM / Montréal, Canada

INTRODUCTION

Three dimensional accurate reconstructions of the knee are the principal prerequisites for computer assisted surgery or personalized biomechanical finite element models (4). Currently these models are obtained from CT-Scan reconstructions with millimeter slices; nevertheless this method is quite irradiant for the patient.

The purpose of this study is to propose an alternative 3D reconstruction method for the knee based on identifiable 2D contours from biplanar radiographs (1,3) with accuracy close to the CT-Scan models.

METHODS

Technical prerequisites to the method are a calibration of the biplanar radiographic environment and a surface generic object representing the structure to be reconstructed (femur, tibia and patella). The method principle is to deform an initial solution of the structure to reconstruct, in term of shape and location, in order to make it coherent with projected 2D contours and information in the X-Ray images.

The method was applied to 8 dry femurs (5 left, 3 right). Two calibrated X-Ray films of each femur (postero-anterior (PA) and lateral (LAT)) were acquired at the Saint-Vincent de Paul Hospital using the Explicit Linear Calibration protocol (ELC) (1). A generic model of the distal femur defined by 556 points and 1100 triangular surfaces was used for reconstruction.

The obtained models were compared with those obtained from 3D computerized millimetric tomography with an overall accuracy of 1 mm (2). These models were superimposed by using geometrical transformations (rotations and translations) and a least square matching method. The quantitative comparison of the shapes between the two models was made using the point to surface distance with the CT-Scan models as reference (3). The mean errors, RMS (Root Mean Square) and maximum errors were calculated for the whole set of 556 points and for the 225 points of the articular surface.

RESULTS AND DISCUSSION

Quantitative comparisons between the CT-Scan and the biplanar reconstructions using the point to surface distance for the 8 femurs are given in table I.

Table I: Shape errors (Point to surface distances, mm) for the 8 reconstructed femurs by NSCC versus CT-Scan reconstructions.

Errors (mm)	Global Surfaces (556 points)		
	Mean	RMS	Max
	1.0	1.4	5.0
Errors (mm)	Articular Surfaces (255 points)		
	0.9	1.1	4.2

The given results indicate that the proposed method is close to CT-Scan reconstruction with less irradiation (i.e. only two radiographs).

The equivalent study is currently conducted to evaluate accuracy on 6 dry tibiae and 6 patellae.

A study is also in progress to evaluate the method feasibility in vivo situation.

SUMMARY

This paper presents a method for accurate 3D reconstruction of the knee from biplanar X-Ray images using 2D contours extracted from the radiographs.

This technique appears to be an interesting alternative to CT-Scan 3D reconstruction, with the advantage of low radiation. Once fully validated, it will be of great usefulness for clinics and 3D applications such as finite elements studies.

COMMON FUNCTION OF FOREARM MUSCLES DURING GRIPPING

Peter J. Keir, PhD and Jeremy P.M. Mogk

School of Kinesiology and Health Science, York University, Toronto, Ontario, Canada

Webpage: <http://www.yorku.ca/kaahs/pjkeir> Email: pjkeir@yorku.ca

INTRODUCTION

Understanding the biomechanics and motor control of the hand and wrist are complicated by the redundancy of the forearm musculature. Issues regarding co-contraction, common neural drive and crosstalk all play a role in our ability to examine function. This complicates the process of modeling the function and actions of these muscles. As part of a larger study examining the muscle activation levels associated with gripping in numerous postures, we examined the common signal in the muscles of the forearm using the cross-correlation function.

METHODS

Ten healthy volunteers participated in this handgrip study (5 men, 5 women, mean age 24.1 years). Maximum voluntary power grasp efforts were performed with a neutral wrist and forearm using a grip dynamometer (MIE Medical Research Ltd., Leeds, U.K.). Maximum EMG levels for each muscle were obtained through a series of isometric maximal efforts.

Target grip forces of 5, 50, 70, and 100% MVC and 50 N were performed in nine postures. Three wrist angles (flexed 45°, straight, extended 45°) and three forearm postures (pronated, neutral or mid-prone, and supinated) were used.

Bipolar surface electrodes were affixed over six forearm muscle bellies. These included flexor carpi radialis (FCR), flexor carpi ulnaris (FCU), flexor digitorum superficialis (FDS), extensor carpi radialis (ECR), extensor carpi ulnaris (ECU), and extensor digitorum communis (EDC). Raw EMG and force data were collected at 1000 Hz. All trials were videotaped in two planes. Normalized cross-correlation functions were calculated between each muscle (Winter et al, 1994).

RESULTS AND DISCUSSION

Participants were unable to accurately repeat target force levels of 70 and 100%, especially in the flexed and pronated posture, therefore we have limited our comparisons to the 5 and 50% target forces. Initial examination of EMG indicated that the extensors had higher activation levels than the flexors at both target forces. Although co-contractions between the flexors and extensors were quite obvious, the raw EMG signals were not correlated. The R_{xy} ($t=0$) values were highest for the wrist flexors (FCR-FCU), followed by the wrist extensors

(ECR-ECU). Cross-correlations were significantly higher for the 50% target force ($p = 0.0002$), mainly due to an increase in the correlations between flexors. The increase was not seen in the extensor muscles. A comparison of the wrist flexor correlations at 5% and 50% demonstrates this well (Fig. 1). It was thought that, if common neural drive was present, it may result in high R_{xy} . We had already determined that electrode pairs within 3 cm result in correlations of approximately 0.6, while at 6 cm they dropped to 0.3 (i.e. explained variance under 10%). From this we can attribute the R_{xy} values to common signal and not to crosstalk between muscles due to the spacing between electrode pairs.

Figure 1: Cross-correlations (at $t=0$) between FCR and FCU in each of the nine postures. a) 5% MVC, b) 50% MVC.

SUMMARY

As part of a larger study, we analyzed the magnitude of EMG signals and the cross-correlations between each of six muscles in the forearm. We found that although co-contractions were present, only the two wrist flexors showed correlated raw EMG signals explaining upwards of 50% of the variance, suggesting the presence common neural drive. Evaluation of muscular control (and common neural drive) of the forearm may be furthered by the use of more detailed analysis techniques (e.g. Nordstrom et al, 1992; Schmied et al, 1993) and the muscular response to fatigue.

ELECTRICAL CONDUCTIVITY OF LUMBAR ANNULUS FIBROSIS

MA Justiz, H Yao, A Vega, WY Gu

Tissue Biomechanics Laboratory, Department of Biomedical Engineering
University of Miami, Coral Gables, FL, USA. wgu@miami.edu

INTRODUCTION

Specific electrical conductivity is one of the material properties of intervertebral disc (IVD). Its value depends on ion concentrations and ion diffusivities within a tissue (Chammas et al, 1994; Hellferich, 1962), which in turn are functions of tissue composition and structure. Investigation of the electrical conductivity of IVD and understanding of its relationship with tissue water content and fixed charge density will provide insights into electromechanical phenomena (e.g., streaming potential) (Gu et al, 1999). The objective of this study was to measure the electrical conductivity of IVD tissues and to study the effects of tissue water content and fixed charge density on the electrical conductivity of annulus fibrosis (AF) in physiological saline. The measured results are also important for understanding strain-dependent ion transport in IVD.

METHODS

A total of 35 porcine lumbar AF specimens were divided into two groups: one control group (n=10) and one trypsin-treated group (n=25). The specimens in the control group were subjected to one dimensional free swelling in PBS, and their electrical conductivity and porosity were measured over time for a period of about 45 minutes. The specimens in the treated group were immersed in a trypsin solution (372 U / ml PBS) for 45 minutes at room temperature and the electrical conductivity and porosity were measured after treatment. Electrical conductivity was correlated to tissue porosity for control and treated specimens. The influences of porosity and fixed charge density were studied.

Conductivity measurement. An apparatus for measuring the conductivity of hydrated soft tissues in the condition of zero fluid flow (no convection) was previously developed (Justiz et al, 2001). Briefly, the apparatus consisted of two (stainless steel) current electrodes, two (Ag/AgCl) voltage sensing electrodes, a specimen chamber, a Keithley sourcemeter, and a current-sensing digital micrometer (for height measurement). The apparatus was calibrated using a conductivity standard and found to be accurate (less than 5% nonlinearity) for specimen height in the range of 2.2 – 6.0 mm. The conductivity of specimens was measured with constant direct current of 3 μ A (density: 0.015 mA/cm²) at room temperature (22 \pm 1°C). Following electrical conductivity measurement, specimens were lyophilized to determine their water content.

RESULTS AND DISCUSSION

The average value for control specimens was 5.60 \pm 0.89 mS/cm (mean \pm SD, n=10) before swelling and 9.11 \pm 0.90 mS/cm (mean \pm SD, n=10) after swelling, while tissue porosity was increased from 0.74 \pm 0.03 (mean \pm SD, n=10) before swelling to 0.83 \pm 0.02 (mean \pm SD, n=10) after swelling. These results were similar to those for cartilage (Chammas et al, 1994; Hasegawa et al, 1983; Maroudas, 1968). The trypsin treatment reduced AF porosity by 3.6% (p<0.05) and conductivity by 13% (p<0.05) compared to those for control specimens after swelling. However, the conductivity values for treated specimen were similar to those for control specimens of similar water contents. There was a significant, linear correlation between conductivity and water content for control AF specimens ($R^2 = 0.87$, 86 measurements).

Ion diffusivities increase with increasing tissue water content (e.g., Mackie and Meares, 1955). This is believed to be responsible for the linear correlation of conductivity with tissue water content observed for AF specimens in this study. The trypsin treatment reduces both fixed charge density and tissue porosity. The average decrease in conductivity for treated group compared to control group after swelling is mainly due to the decrease in ion diffusivities. The result indicates that the fixed charge density does not significantly affect measured conductivity for AF specimens in PBS. This agrees with the finding for cartilage (Hasegawa et al, 1983).

NUMERICAL SIMULATION OF SICKLE CELL BLOOD FLOW IN THE TRANSVERSE ARTERIOLE – CAPILLARY NETWORK

Brian Carlson¹ and Stanley Berger²

Department of Mechanical Engineering, University of California at Berkeley

¹Postdoctoral Researcher, bcarlson@me.berkeley.edu

²Professor of Mechanical Engineering and Bioengineering, saberger@me.berkeley.edu

INTRODUCTION

Sickle cell crisis, a recurrent symptom of sickle cell disease, has been hypothesized to result from inadequate oxygen supply to the tissues, a consequence of microvascular stasis. Microvascular networks are numerically simulated for sickle and normal blood to observe differences in capillary flow characteristics as a function of driving vascular pressure. The motivation is to understand the relationships between the network driving pressure, network geometry, and the dynamics of sickle oxygen transport.

METHODS

Ten randomly generated microvascular networks are calculated for normal and sickle blood flows over a range of network input pressures. For sickle cell blood, two input oxygen concentrations are used: with and without precapillary oxygen loss. Network exit pressure is held constant.

The skeletal muscle microvascular networks are represented using a Strahler scheme of vessel ordering based on values obtained for the rat spinotrapezius muscle (Engelson et al, 1985). Hematocrit values in the network vessels are heterogeneous and described as a function of vessel diameters, input hematocrit, and fractional volumetric blood flow at each bifurcation (Pries et al, 1990). Effective relative blood viscosity also varies from vessel to vessel and here the ‘*in vivo* viscosity law’ (Pries et al, 1994) is used.

In the arterioles, flow is assumed to be Poiseuille while in the capillaries a Lighthill lubrication theory and Krogh cylinder analysis are used to model the blood flow and oxygen transport (Berger and King, 1980). Continuity of volumetric blood flow and red cells at each bifurcation leads to a system of nonlinear equations. These are solved using a Steepest Descent algorithm coupled with a simple Newton solver.

RESULTS AND DISCUSSION

The average total volumetric flow through the simulated networks in both cases of sickle blood is 37 to 52% greater than in the normal blood case. This agrees with higher cardiac outputs observed in patients with chronic anemia (Roy et al, 1963). The anemia inherent to the sickle cell disease, on the other hand, decreases the red cell flux through the networks

and 16 to 24% lower cell fluxes are observed in the simulated networks with sickle blood as contrasted to normal blood.

The ability of the network effects to compensate for reduced flow is insufficient to sustain flow in all capillaries in the case of sickle blood while with normal blood no blockages are observed even with a 18% drop in input driving pressure. In both sickle blood cases at full network driving pressure average capillary blockage percentages vary from 8 to 10%, while with an 18% drop in the input driving pressure, 32

36% of the capillaries become blocked (Figure 1).

Figure 1: Fraction of capillaries blocked as a function of total network pressure drop across simulated networks. Blocked capillary fraction is the average value for the 10 networks.

SUMMARY

Network effects are inadequate to prevent capillary stasis in sickle cell disease even at full network driving pressures. Normal blood continues to flow in all vessels at all network input pressures. Vasodilation may be useful to minimize or prevent capillary blockage in sickle cell disease.

SIMULTANEOUS STRAINS AND DISPLACEMENTS ANALYSIS OF IMPLANTED FEMURS BY IN VITRO STUDY AND FINITE ELEMENT MODELLING

Amadou Diop¹, Nathalie Maurel¹, Arnaud Besson²

¹Ecole Nationale Supérieure d'Arts et Métiers, 151 bd de l'Hôpital, 75013 PARIS, amadou.diop@paris.ensam.fr

²Hôpital Roger Salengro. CHR B, 59000 LILLE

INTRODUCTION

In order to implement and validate a finite element model of femurs including bone remodelling aspects around prostheses, it is necessary to first validate such a model on immediate postoperative situation. For this, in vitro tests were carried out on fresh cadaveric femurs implanted with ABG prosthetic stem and corresponding models are in progress.

METHODS

Six fresh human cadaveric left femurs issued from 4 males and 2 females (66 to 86 years) were included. For each femur, an ABG cementless stem with adapted size was implanted and CT scans were performed before testing.

For mechanical tests, the femurs were embedded at mid-length and were oriented 12° frontally, then 30° sagittally. Successive loads with increasing magnitudes were applied on the head of the prosthesis using an universal testing machine: 600N (450N for the first femur), 800N, and loading until failure.

Global medial and lateral displacements of the head of the prosthesis were measured using linear transducers, while the vertical one was directly given by the machine cross-head motion. Axial rotation between femur and prosthesis was measured using a CCD camera and 2 plates (one fixed on the bone and one fixed on the femur). Axial and transversal linear micro-motions between femur and prosthesis were obtained using a CCD camera provided with a zoom, one metallic ball fixed on the bone and one other fixed on the prosthesis.

Six strain gages (45° rosettes) were stuck on femurs. 2 were placed distally (R1:anterior, R2:lateral) and 4 were placed proximally: (R3:anterior, R4:lateral, R5:posterior, R6:medial). Principal strains (ϵ_1, ϵ_2) and their direction were then obtained.

Using the data issued from CT scans and the geometry of the prosthesis, personalised finite element models of two of the tested femurs were developed (8-nodes hexaedric elements were used). The same boundary conditions as for experiments were introduced. Different parameters were tested (bone materials, modelling of the bone-implant interface).

Figure 1: Experimental set-up and finite element models of an implanted femur.

RESULTS

The medial displacement was negligible comparing with the vertical and anterior ones. Except for one femur, which failed during the test, the axial micro displacements were always lower than 100µm and the axial rotations were comprised between -0.3° and +1° (at 800N). The maximal strains were recorded for the anterior distal gage and were tensile ones.

Results of models were coherent with those issued from the experiments but still need to be improved to obtain reliable validation simultaneously for all the experimental measurements.

Figure 2: Model versus experimental results for two different models of the same femur, loaded at 450N. A: two distinct materials ($E_{cortical}=20000\text{MPa}$; $E_{spongious}=800\text{MPa}$); B: non homogeneous bone (data from CT scan grey levels).

DISCUSSION - CONCLUSION

The main interests of this study are to combine in vitro tests and finite element analysis and to deal with global information (displacement of the head) and local information (main strains on 6 locations, micro motions and rotations between the prosthesis and the femur). The importance to use simultaneously these two kinds of information appeared during the validation of our first finite element models. Indeed, a model can be well validated regarding one parameter but can present great differences with experiments when analysing others (figure2).

We thank Benoist-Girard SAS Homedica Stryker for its financial support and for supplying the implants.

ZATSIORSKY-SELUYANOV'S SEGMENT INERTIA PARAMETERS FOR POSTURE ANALYSIS.

Danik Lafond and François Prince

Laboratoire du mouvement, Centre de réadaptation Marie-Enfant, Hôpital Ste-Justine, Quebec, CANADA.

Department of Kinesiology, University of Montreal, P.O. Box 6128, Downtown Station Montreal, Quebec, CANADA, H3C 3J7

INTRODUCTION

Zatsiorsky et al. (1990) used gamma-scanning techniques to determine segment inertia parameters (SIP) in young healthy adults. To the authors' knowledge, even though these data are available since 1990, the Zatsiorsky-Seluyanov segment inertia parameters (SIP) have not been widely used to estimate body's center of mass (COM) location during posture or balance studies. This situation may be explained by the following reasons; a) the error associated with the use of the cadavers SIP is underestimated and b) the Zatsiorsky-Seluyanov's SIP can't be applied to a simplified COM-model. A paper from de Leva (1996) reported Zatsiorsky-Seluyanov SIP related to joint centers. However, for posture and balance studies, it is useful to report the SIP relative to easily palpated bony landmarks instead of joint centers. In addition, SIP from combining segments like total arm or total leg, which help to reduce the number of segments to estimate COM, are not available. The purpose of this study is to report a complete table of the mass fraction and COM location of the several segments often used in posture analysis.

METHODS

Using the anthropometric data from de Leva (1996) and Zatsiorsky et al. (1990), we have defined the adapted COM location of several segments (see Table 1). This general formula was used to define combined segments COM:

$$\bar{P}_j = \frac{\sum_{i=1}^N \bar{l}_{CoM_i} \cdot m_i}{\sum m_i}$$

where \bar{P}_i is the mean proximal longitudinal distance of the segment's COM, m_i = subsegment mass fraction, \bar{l}_{CoM_i} = mean subsegment COM longitudinal position relative to the new proximal bony landmark position

RESULTS

The mass fraction and the proximal COM location of simple and combined segments are presented in Table 1. An exemple of a combined segment is the HAT. The HAT segment is composed of the head, total trunk and arms. The COM proximal location of this segment is related to the acromion (ACR) and greater trochanter (GTRC) landmarks. Using this table, researchers may use simplified segment model to estimate body's COM instead of a 16-segments model if they use de Leva (1996) SIP. For example, a 3-segment model is defined by the HAT and total arms segments.

EFFECT OF SWELLING PRESSURE ON DYNAMIC COMPRESSIVE STIFFNESS OF LUMBAR ANNULUS FIBROSIS

H Yao, MA Justiz, D Flagler, WY Gu

Tissue Biomechanics Laboratory, Department of Biomedical Engineering
University of Miami, Coral Gables, FL, USA. wgu@miami.edu

INTRODUCTION

The intervertebral disc (IVD) is subjected primarily to compressive loading in vivo. It has been hypothesized that the compressive mechanical load on the normal IVD is mainly supported by the fluid through a high osmotic pressure and/or a fluid pressurization effect (e.g., Mow et al, 1998; Soltz and Ateshian, 2000; Urban and McMullin, 1988). It is not clear, however, how the osmotic pressure affects the dynamic behavior of the IVD tissue in compression. The objective of this study was to investigate the effect of swelling pressure on the compressive stiffness of IVD tissues under dynamic loading conditions. In this study, the swelling pressure, equilibrium and dynamic moduli, hydraulic permeability, water content, wet tissue density, and dry tissue density of control and trypsin-treated annulus fibrosis (AF) were determined to further delineate the load supporting mechanisms in the IVD under compression (Iatridis et al, 1998).

METHODS

Specimen preparation. A total of twenty-two paired specimens (5mm diameter) were prepared from all regions of annulus fibrosis (AF), harvested from the lumbar discs of a 85 kg domestic pig. Eleven specimens (thickness: 1.930 ± 0.146 mm) were used as the control group while the other eleven (thickness: 2.074 ± 0.090 mm) were treated with the trypsin enzyme. For the treated group (n=11), each of the specimens was immersed in a solution containing 372 units of trypsin per 1 ml of phosphate buffer saline (PBS, pH7.4) at room temperature (21°C) for 1 hour. For the control group, the specimens were immersed in PBS (without trypsin) for the same period of time.

Mechanical Testing. All mechanical tests were performed in PBS (pH 7.4) using a Perkin-Elmer Dynamic Mechanical Analyzer (DMA). A uniaxial, confined compression mode was used in this investigation. A Swelling pressure test, dynamic scan test (0.01-5.0 Hz), creep test, and free-swelling test were performed for each of the specimens.

The free swelling strain, swelling pressure, equilibrium and dynamic compressive moduli were directly obtained from the above tests. The hydraulic permeability was obtained by curve-fitting creep data to the biphasic theory (Mow et al, 1980). The tissue hydration, wet and dry tissue densities of control and trypsin-treated AF specimens were determined

after mechanical testing using a method described in the literature (Gu et al, 1996).

RESULTS AND DISCUSSION

The trypsin treatment reduced the tissue swelling strain (-22%), swelling pressure(-66%), equilibrium (-57%) and dynamic moduli, and water content (-3%), but increased hydraulic permeability (88%) and phase angle shift significantly. There was a significant positive correlation ($R^2=0.82$, n=22) between swelling pressure and equilibrium modulus of the AF specimens. No significant differences in wet tissue and dry tissue densities were found between the control and the treated groups. The dynamic compressive stiffness of the AF specimens increased with increasing loading frequency in the range tested (0.01 – 5 Hz). This result was similar to that for cartilage (Lee et al, 1981). The magnitude of the dynamic stiffness was found to be proportional to the square root of the ratio of equilibrium modulus to hydraulic permeability at each of the loading frequencies tested.

Fluid pressurization is responsible for the increase in dynamic stiffness of AF in compression (Soltz and Ateshian, 2000). The dynamic stiffness is related to the equilibrium modulus of the tissue (Lee et al, 1981; Soltz and Ateshian, 2000). The fact that aggregate modulus linearly correlates with swelling pressure suggests that the swelling pressure plays a significant role in supporting mechanical compressive loads not only in static cases (Urban and McMullin, 1988), but also in dynamic cases.

INTRODUCTION

Fibrillin-based microfibrils serve as important structural elements in connective tissue. Mutations affecting the calcium-binding domains of fibrillin result in structural changes in the microfibrils. Marfan syndrome, a connective tissue disorder affecting the cardiovascular system is caused by these mutations (Dietz *et al.*, 1991). Calcium also has a marked effect on microfibrillar structure and mechanical properties (Eriksen *et al.*, 2001). Mechanical testing and characterization of arteries from Marfan tissues is limited by elastin, the insoluble protein that binds to a microfibrillar scaffold. Lobster arteries possess a high density of microfibrils, and like all invertebrates, have no elastin (Davison *et al.*, 1995). These vessels have non-linear stress-strain curves, similar to those of vertebrate arteries containing elastin and collagen (McConnell *et al.*, 1997). Our lab has recently found that lobster arteries containing only microfibrils can be isolated by guanidine/collagenase digestions. In this study we have investigated the effect of calcium on the mechanical function and structure of lobster microfibrils.

METHODS

Lobsters were euthanised by injection of KCl solution (100 mg /100 g lobster). The abdominal aorta was sectioned into 2 mm rings. Wall thickness was measured from 40 µm thick frozen sections. The mechanical properties of fresh and guanidine/collagenase digested aorta equilibrated in calcium-based solutions (1mM Ca²⁺, 13mM Ca²⁺ (physiological) and 30mM Ca²⁺) were measured. The samples were mounted on two u-shaped tungsten hooks, which were fastened to the base of a bathing tank and to the lever arm of a dual mode motor lever system (300B-LR Model, Aurora Scientific). Motion of the lever arm was controlled from a function generator, displacement and force data were collected with a PC and BioBench Data Acquisition software. Stress relaxation tests were performed at low (0.1), moderate (0.6), and high (1.25) strains. Cyclic uniaxial testing involved imposing a sinusoidal oscillation of 0.8 Hz and dynamic strain amplitude of 0.1. Displacement and force data were converted to strain and stress using a custom built LabVIEW program. Fresh and chemically digested samples were subjected to amino acid compositional analysis after hydrolysis in 5.7 M HCl for 24 h at 110°C under vacuum. Samples at each calcium concentration were processed for transmission electron microscopy using either osmium tetroxide-glutaraldehyde or glutaraldehyde-osmium tetroxide fixation sequences. Thin sections were analyzed and photographed using an electron microscope operated at 80 kV. Measurements of microfibril

periodicity and bead diameter were made from the micrographs. Mean and standard deviation were calculated and compared using a one-way ANOVA (p=0.05). Where appropriate, Tukey's test (p=0.05) was performed.

RESULTS AND DISCUSSION

The results show that fresh vessels were significantly stiffer than digested when tested at low calcium concentrations and strains of 0.6. At strains of 1.25, fresh vessels with intermediate calcium concentrations were significantly stiffer than fresh vessels at low calcium concentrations. Testing at low strains (0.1) showed no significant differences between fresh or digested vessels at any of the tested calcium levels. As expected amino acid compositional analysis displayed significant differences between fresh and chemically digested samples. Amino acid comparisons between digested samples and human fibrillin showed compositional similarity. Ultrastructural differences were also found between groups. The periodicity of fresh and chemically digested vessels incubated with physiological or high calcium concentrations was significantly larger than those vessels incubated with low calcium. These results show that solution based changes in calcium concentration do affect both the protein structure and mechanical behavior of lobster microfibrils. We have also demonstrated amino acid compositional similarity between isolated lobster microfibrils and human fibrillin. These similarities suggest that the structural and mechanical changes occurring in lobster based microfibrils are good approximations of those in Marfan based tissues.

SUMMARY

This study has shown that calcium has a significant effect on the structural and mechanical properties of microfibril-based tissue. This information will help to quantify and further understand the changes that occur in Marfan syndrome patients.

A PRELIMINARY EVALUATION OF A LIMB-SEGMENT MODEL FOR LIFTING TASKS

Pei Lai Cheng, Angela J. Tate, Delphine Périé, and Geneviève A. Dumas

Human Mobility Research Center, and Department of Mechanical Engineering, Queen's University, Kingston, Ontario, Canada.

INTRODUCTION

Limb-segment models have been used to estimate the loads at lumbosacral level (L5/S1) for lifting tasks. Previous models (Plamondon et al. 1996, Lariviere and Gagnon 1998) used motion data measured by optical-electronic motion analysis systems and anthropometric data obtained by regression equations. The optical-electronic system is limited to simple tasks in which markers can be seen by all cameras. The regression equations of the anthropometric data are limited to a small population. We developed a limb-segment model using kinematic data recorded by an electromagnetic motion tracking system (Motion Star®, Ascension Technologies) and individualized anthropometric data. Therefore, it can be used for complex tasks and for a larger group of population. The objective of this paper is to report a preliminary evaluation of the performance of the model for different lifting tasks.

METHOD

The whole body model, involving 11 segments, was divided into a hands-down and a feet-up models, which were separated at L5/S1. The hands-down model involves 7 segments, upper trunk, middle trunk, four upper limb segments and the load in the hands. The feet-up model has 5 segments, the lower trunk and 4 lower limb segments; it also includes the ground reaction force measured at a force platform.

One male subject (24 years, 196cm, 71.2kg), participated with written consent, and performed 4 freestyle lifting tasks (lifting a 12kg box from the floor to a shelf 83cm high). The 4 tasks included symmetrical and asymmetrical (90° to the right) lifts at slow and fast speeds. Each task was recorded 3 times. The anthropometric parameters of the subject were determined using an individualized photogrammetric method (Jensen 1978).

The body motion and ground reaction forces were recorded by the Motion Star® at 86.1Hz, and a AMTI force plate at 86Hz. The data were processed by a calibration procedure (Day et al. 2000) and filtered at 2.5Hz. The forces and moments at L5/S1 from both models were calculated using inverse dynamics. To evaluate model performance, the mean and peak differences of the forces and moments at L5/S1, and correlation coefficients between the hands-down and feet-up models results were calculated within a lifting cycle.

RESULTS

The average results of three recordings for each task are given in Table 1. Most differences of the force and moment components are below 15N and 15Nm with largest values of 18.8N and 20.4Nm for peak differences.

Table 1. The average difference of force (N) and moment (Nm) at L5/S1 between hands-down and feet-up models, f for fast, s for slow, 0 for symmetrical, 90 for asymmetrical, x forward, y upward and z to the right.

		Fx	Fy	Fz	Mx	My	Mz
Mean	f0	6.8	6.4	-3.4	0.4	-2.9	18.6
	s0	16.6	-14.5	-1.9	6.9	-4.3	11.0
Difference	f90	6.1	-1.2	-3.7	5.5	-4.0	17.3
	s90	16.7	-10.6	-1.1	-0.6	-3.0	14.0
Peak	f0	-3.9	-2.4	-5.6	4.8	-2.8	-1.6
	s0	5.7	-0.4	-3.3	14.0	-1.3	4.8
Difference	f90	-6.3	-18.8	0.7	15.6	-3.0	-20.4
	s90	5.7	7.0	-0.4	-2.9	-4.3	9.5
Correlation Coefficient	f0	0.96	0.82	0.99	0.92	0.85	0.85
	s0	0.98	0.91	0.97	0.75	0.95	0.91
	f90	0.98	0.94	0.98	0.86	0.97	0.94
	s90	0.98	0.91	0.99	0.85	0.78	0.71

DISCUSSION

The magnitudes of the mean and peak differences between the hands-down and feet-up models are similar to previous results (Lariviere & Gagnon 1998).

Paired T-tests results of the mean, peak difference and correlation coefficient show that there is no significant difference ($P>0.05$) between fast and slow lifting, and between symmetrical and asymmetrical lifting, which indicates that the model performance is consistent for different speeds and orientations of lifts. The mean correlation coefficient over all tasks is 0.91 (SD 0.07) in the range from 0.71 to 0.99, indicating that the curves have very good agreement between the two models.

In conclusion, this preliminary evaluation indicates that a model with individualized anthropometric data and using motion data recorded by an electromagnetic motion tracking system is generally acceptable for estimating the loads at L5/S1 during lifting tasks. Since this model is intended for use in a larger project, a more comprehensive validation of the model with more subjects needs to be performed.

MODELING LOCOMOTION IN CRUSTACEAN LARVAE

Matthew D. Ford and M. Edwin DeMont

Biology Department, Saint Francis Xavier University, Antigonish, Nova Scotia, Canada, edemont@stfx.ca

INTRODUCTION

The early life cycle of most crustaceans involves a free-swimming planktonic larval stage, which use pairs of reciprocating appendages to produce thrust. Most work on modeling crustacean dispersal has assumed that individual larva move passively following the ocean currents but actively maintaining themselves in the water column until a suitable habitat has been found. We are studying the dynamic swimming mechanics of crustacean larvae at intermediate Reynolds numbers using a combination of direct force measurement, flow visualization and computer programming. The ultimate goal is a complete understanding of the forces being produced and acting on a swimming larva. To broaden the relevance of the project the differences in swimming abilities between species that use different numbers of paired swimming appendages is also being considered.

METHODS

The equation of motion developed for the swimming larvae balances the thrust and unsteady forces produced by the appendages with the drag and unsteady force of the body. In order to solve the equations of motion the kinematics of the appendage angles and body are required and were collected at 250 fps in a small tank using a RedlakeTM high-speed motion scope. The fluid force coefficients on the oscillating appendages are also required to solve the equation of motion. To measure these fluid force coefficients geometrically scaled up physical models of the appendages were built. The models were built from plastic and then oscillated and translated in a tank of glycerin while maintaining the same Reynolds number and Strouhal number as the free swimming larvae. Fluid forces were measured by attaching strain gages on each model appendage. With this information a numerical solution was produced using a fourth order Runge-Kutta method, which was programmed in Matlab. The computer model was based on work by Williams (1994b) which examined swimming in *Artemia* (one pair of swimming appendages). Our work expanded this to encompass both the green crab (two pairs of swimming appendages) and the lobster (five pairs of swimming appendages).

RESULTS AND DISCUSSION

The swimming appendages of both the lobster and green crab larvae beat in a specific coordinated pattern. For example, the green crab moves one appendage completely through the power stroke with the second appendage not beginning the power stroke until the first has finished. The appendages are coupled on the recovery stroke. The drag coefficients measured on the models are in agreement with those measured by Williams (1994a) on the *Artemia* and when applied to the

computer model match the measured velocity of the green crab within acceptable error (figure 1).

Figure 1: Comparison of measured body velocity (♦) to that predicted by the computer model (■).

Figure 2: The forces acting on a green crab larva during locomotion include thrust force generated by front appendage (♦), thrust generated by back appendage (■), body drag (▲) and the unsteady force on the body (×).

Improvements made over previous work (Williams, 1994b) include approximating the appendage angle kinematics as a Fourier series and more rigorous calculations of the body morphometrics. The computer model also calculates all the forces acting on the swimming larva (figure 2).

SUMMARY

This work will lead to a better understanding of larval dispersal in crustaceans. This work will also enhance knowledge of the often neglected but biologically important realm of intermediate Reynolds number swimming mechanics, in which many marine organisms move.

ANTERIOR-CRUCIATE LIGAMENT FORCES IN THE INTACT KNEE DURING NORMAL GAIT

Kevin Shelburne¹, Marcus Pandy², Frank Anderson³, and Mike Torry¹

¹Steadman-Hawkins Sports Medicine Foundation, Vail, Colorado, U.S.A. kevin.shelburne@shsmf.org

INTRODUCTION

Few researchers have described knee ligament function in walking despite the many clinical investigations which show that knee ligament injuries, particularly injury to the anterior cruciate ligament (ACL), are the source of persistent neuromuscular adaptations in gait. Furthermore, most rehabilitation protocols following knee ligament injury and repair require normal kinematic and muscle activation patterns during ambulation before the patient may return to full activity. Understanding how the ACL is loaded during normal walking may help to establish more focused and efficient exercise regimens for rehabilitation following ACL injury.

To our knowledge only Morrison (1970) and Collins and O'Connor (1991) have reported ACL forces during gait. The paucity of data on ACL loading is due to the difficulties inherent in the measurement and calculation of muscle and ligament force *in vivo*. In this study, muscle forces obtained from a dynamic optimization solution for normal walking (Anderson and Pandy, 2001) were used as input to a three-dimensional model of the knee (Pandy et al., 1998) to determine knee-ligament forces during gait. The model calculations were analyzed to explain the pattern of ACL loading predicted for gait. Peak ACL force for walking was compared to estimates of ACL force obtained for rehabilitation exercises performed subsequent to ACL injury and repair.

METHODS

The right leg was modeled using four rigid bodies: thigh, shank, hindfoot, and metatarsals. All joints were represented as described by Anderson and Pandy (2001), except the knee, which was modeled as a six degree-of-freedom joint. The geometry of the distal femur, proximal tibia, and patella was based on cadaver data reported for an average-size knee. The contacting surfaces of the femur and tibia were modeled as deformable, while those of the femur and patella were assumed to be rigid. Thirteen elastic elements were used to describe the geometric and mechanical properties of the knee ligaments and capsule. Details of the knee model are given by Pandy et al. (1998). The model leg was actuated by thirteen musculotendinous units.

A combination of forward and inverse dynamics was used to determine knee-ligament forces in the model. Joint motion, ground-reaction forces, and the corresponding muscle forces obtained from the dynamic optimization solution for gait derived by Anderson and Pandy (2001) were input to the leg model. The dynamical equations of the motion for the three-

dimensional knee model were then used to determine knee-ligament forces at each instant during the gait cycle.

RESULTS AND DISCUSSION

Figure 1 shows the calculated ligament forces for a complete cycle of gait, beginning at heel strike. The simulation results predict that the ACL is loaded throughout the stance phase of gait. The ACL is loaded throughout stance because the net shear force applied to the tibia is directed anteriorly during this time. Furthermore, the net shear force applied to the tibia is due mainly to the anterior pull supplied by the patellar tendon (not shown). The predicted peak ACL force during gait (344N) is similar to that found for maximum isokinetic knee extension at 300 deg/sec (340N, Serpas et al., in press) and is roughly twice as large as that reported for the leg lift exercise (160N, Shelburne and Pandy, 1997).

Figure 1: Force in the ACL and PCL during gait shown with the anterior tibial shear force applied by the patellar tendon.

SUMMARY

Our calculations show that the ACL is loaded throughout the stance phase of walking, and that the force transmitted to the ligament rivals that predicted for maximum knee-extension exercise performed at high speed.

ASSESSMENT OF CROSSTALK IN SURFACE EMG OF THE FOREARM

Jeremy P.M. Mogk and Peter J. Keir, PhD

School of Kinesiology & Health Science, York University, Toronto, Ontario, Canada (pjkeir@yorku.ca)

INTRODUCTION

Given the proximity and functional redundancy of the forearm muscles, crosstalk is of concern in EMG studies. Further complicating this issue is the potential for muscle movement relative to the electrodes with forearm rotation, which may alter which muscles are recorded. The amount of common signal (or crosstalk) between recording sites may be assessed by means of the cross-correlation function (Winter et al., 1994). The purpose of this study was to evaluate the magnitude of common signal between electrode pairs placed around the proximal forearm. The effects of recording site distance, forearm rotation, grip force level and grip type were examined.

METHODS

Eight healthy male volunteers participated in this study (mean age: 23.7 years; range: 22 – 25 years). Maximum voluntary pinch and power grasp efforts were performed with a neutral wrist and forearm posture using a grip dynamometer (MIE Medical Research Ltd., Leeds, U.K.). Pinch and grasps at 25, 50, 70, and 100% MVC were performed in neutral (mid-prone), fully pronated and supinated forearm postures. Seven electrode pairs were placed circumferentially around the upper third of the right forearm (Figure 1). A landmark electrode pair was placed over FCR, and the remaining six at 3 cm increments medial and lateral to the landmark pair. Cross-correlation functions were calculated using the raw EMG between each electrode pair and the three channels on either side, where applicable, without crossing the ulnar border. An additional cross-correlation was calculated between channels on either side of the ulnar border (channel 1 vs. 7). Raw EMG and force data were collected at 2000 Hz. All trials were videotaped for feedback and analysis.

Figure 1. Cross-section of the right forearm indicating approximate location of the seven electrode pairs.

RESULTS AND DISCUSSION

Peak cross-correlation magnitude (R'_{xy}) decreased as the distance between electrode pairs increased, with similar values between grip types (Table 1). While channels 1 and 7 appeared to have similar AEMG amplitudes, virtually no common signal was present (“Ch. 1 vs. 7” – Table 1), suggesting no crosstalk between the flexor and extensor muscle compartments across the ulnar border. This was further evaluated by calculating “crosstalk” ratios using EMG amplitudes (Perry et al., 1981). Individual variability was much greater with the ratios and difficult to interpret. Forearm rotation did not significantly alter R'_{xy} , mainly due to the large variance observed between participants, particularly in the flexors. This variance may indicate greater movement of the flexor muscles than the extensors with forearm rotation.

Table 1. Mean peak cross-correlation (R'_{xy}) and explained variance (R^2) for each electrode spacing, pooled across effort level.

Electrode Spacing	Pinch		Grasp	
	R'_{xy}	R^2	R'_{xy}	R^2
3 cm	0.601	0.361	0.623	0.388
6 cm	0.307	0.094	0.314	0.099
9 cm	0.182	0.033	0.152	0.023
Ch. 1 vs. 7	0.111	0.012	0.089	0.008

SUMMARY

This study has provided insight into electrode placement on the human forearm. Almost 40% common signal may be expected from recording sites 3 cm apart, but less than 10% is expected at 6 cm. In our grasping tasks, activation levels were similar on either side of the ulnar border, however, the correlations indicated that only about 1% of the signal was common. These findings were consistent regardless of forearm posture. Using standard EMG sites, signal contamination due to crosstalk can be minimized in studies of forearm EMG.

SEGMENTAL POWER DURING PROPULSION IN WHEELCHAIR USERS WITH GREATER EVIDENCE OF SHOULDER INJURY OVERTIME

Alicia M. Koontz^{1,2}, Michael L. Boninger¹⁻³, Rory A. Cooper¹⁻³, Jeffrey D. Towers³, Lin Ma^{1,2}

¹VA Pittsburgh HealthCare System, Human Engineering Research Labs, Pittsburgh, PA 15206, www.herl.pitt.edu

³Department of Physical Medicine and Rehabilitation, University of Pittsburgh, Pittsburgh, PA 15213

INTRODUCTION

Propelling a wheelchair is an arduous task and has been implicated in the development of shoulder pain and injury. Up to 54% of individuals with a spinal cord injury (SCI) complain of shoulder pain that adversely affects their mobility and independence (Pentland, 1994). The aim of this study was to follow a group of wheelchair users with paraplegia over a period of two years to track the progression of shoulder injury and determine if segmental power generated and absorbed during propulsion is related to an increased risk of injury.

METHODS

Protocol: Eight men and six women with a SCI between the levels of T3 and L5 provided informed consent prior to participation. Their average age and years post injury at the start of the study were 32.8 ± 8.8 and 10.4 ± 6.7 , respectively. A standardized magnetic resonance imaging (MRI) exam designed for detection of rotator cuff abnormalities was conducted on both shoulders, at baseline and at a two-year follow-up visit. All images were read by a musculoskeletal radiologist blinded to the subjects' characteristics and biomechanical data. For the biomechanical analysis, subjects' personal wheelchairs were fitted bilaterally with SMART^{Wheels}, force and torque sensing pushrims (Three Rivers Holdings). Skin-mounted markers of the OptoTRAK 3D motion analysis system (Northern Digital, Inc.) were placed on prominent locations of the upper extremities and chest. Wheelchairs were secured to a dynamometer and a video monitor was used to display the propulsion speed. After an acclimation period of five minutes, subjects were instructed to propel at a steady-state target speed of 0.9 m/s (2mph) for about a minute before 20 seconds of three-dimensional kinetic data (sampling rate of 240Hz) and kinematic data (60 Hz) were collected.

Data Analysis: Shoulder MRI findings were assessed at baseline and at the two-year follow-up visit using a modified grading scale of pathology based on accepted radiological criteria. Distal clavicle edema, acromioclavicular (AC) joint degenerative disease, AC edema, acromion edema, osseous spur formation, coracoacromial (CA) ligament edema, and CA thickening were scored from 0-3, where 0 is normal, 1 is minimal, 2 is moderate, and 3 is marked. MRI pathology scores for each individual, on both left and right sides, were totaled to produce a single summary variable for each visit. The differences between total scores at the two visits were then calculated. A positive value indicated a greater number of abnormalities. Segmental power was determined by first calculating the segment's, s , total mechanical energy, E , (Robertson, 1980) and solving the difference equation:

$$P(s, t_1) = \dot{E}(s, t_1) = [E(s, t_2) - E(s, t_0)] / 2\Delta t$$

Power data were normalized by dividing by the subject's hand, forearm, and upper arm segment masses in kilograms. All calculations were implemented in MATLAB (Mathworks Inc.). Peak generated (positive) and absorbed power (negative) were averaged over five push cycles. Because of high correlation, the left and right sides were combined. The power data obtained from the baseline measure of propulsion was used in the analysis.

Statistical Analysis. Subjects were divided into two groups based on differences in total MRI scores at baseline and at two-year follow-up. Chi-square analysis was used to compare the groups with respect to gender and MRI score. An independent samples t test was used to determine if differences existed between MRI+ and MRI- groups with respect to age, body mass index, years from SCI, and power data. The significance level for all tests was set at 0.05.

RESULTS

Seven subjects showed an increase in MRI abnormalities (MRI+) (mean +8.14 points) and seven subjects showed little change or improvement (MRI-) (mean -1.00 point); $p=0.002$. There was no significant difference in age, body mass index, or years from SCI. There were significantly more women in the MRI+ group (MRI+: 6 women, MRI-: 0 women); $p=0.001$. The MRI+ group generated and absorbed more segmental power during propulsion at baseline with the largest relative difference noted for the upper arm ($p=0.07$) although none of the group comparisons were statistically significant (Table 1).

DISCUSSION

The findings of this study suggest that wheelchair users who generate and absorb more segmental power during propulsion may be more likely to develop shoulder abnormalities overtime. This was not too surprising as results from a previous analysis showed that the MRI+ group pushed their wheelchairs with pushrim forces greater than 5% of their body weight (Dicianno, 2000). The reasons for this remain unclear but are likely related to wheelchair set-up, rolling resistance and technique. The fact that 6 of the 7 subjects in the MRI+ group were women indicate that women may be a greater risk for developing shoulder injuries and that preventative interventions should target this population of wheelchair users.

INTRODUCTION

Some studies of the coordination strategies for maximal-range human throwing have used models of the hand with two or three links, actuated by muscles with some bounds on the forces produced (e.g., a force-velocity relation) Alexander (1991, 1997), Herring & Chapman 1992, Chowdhary & Challis (2001). It is usually assumed that the throwing motion (for the 2-link hand model) consists of a few phases – with either one or more muscles being fully activated. Under such an assumption, these works show the need for a positive optimal delay between the activation of the proximal muscle and that of the distal muscle to maximize velocity, corroborating the ubiquitous proximal-distal sequencing in animal coordination.

To better understand this sequencing and to test the validity of the bang-bang assumption, we construct an extremely simple model of throwing – one that is perhaps too simple for experimental comparison, but one that is amenable to solution without simplifying assumptions on the nature of the optimal strategy, so that it may guide understanding of models with greater realism.

PROBLEM FORMULATION

The model consists of two masses m_1 and m_2 , the proximal and distal body parts respectively. F_1 and F_2 are forces produced by “muscles”, acting on the masses as shown in Fig. 1.

Figure 1: A one-dimensional throwing problem. It is close to the shot-putting model of Alexander (1991) but is also partially analogous to a segmented arm.

The model is formally identical to a 2D model of a throwing arm if all the mass is concentrated in the elbow and hand and if small angles are assumed. We seek the strategy – time history of the two forces, not necessarily piecewise constant or maximal – that leads to the maximum possible velocity of the second mass, subject to the following constraints (in non-dimensionalized form, with $m_1=1$): $F_1 \leq 1$, $F_2 \leq F_2^{\max}$, $0 \leq x_1 \leq$

1 , $0 \leq x \leq x^{\max}$. That is, the forces and ranges of motion have given bounds and can only push in one direction.

METHODS AND SOLUTION

The problem is not accessible to the Pontryagin maximum principle directly because of the state-variable constraints. So we solve it numerically – by using piecewise linear forcing functions and solving the resulting linear programming problem. We solved this optimal control problem for all relevant parameter ranges. Guided and confirmed by numerical simulations, we have obtained the exact closed-form expressions of the optimal solutions for all parameter ranges. It turns out that the bang-bang solution, with the proximal-distal sequence is an optimal solution for a large parameter range, however *not* the only optimal solution. A whole family of solutions produce the same optimal value as that as the bang-bang solution. In another parameter range, the *distal* muscle needs to be fully active for all time, while the proximal does not. Again the solution is not unique. One feature of all the solutions is that when the maximum velocity is reached, x reaches x^{\max} – surprisingly the same is true of x_1 in only 3 out of 5 parameter ranges. Muscle reversal is not used in any of the optimal solutions, even when allowed.

DISCUSSION

We hoped that complete understanding of this simple problem would help us deal with more realistic models. Research in progress indicates that some of the results from this model carry over to a model with two links and torque-bounds. One such is the inherent non-uniqueness in the solutions. So the lowest order approximation, a model like this, predicts that optimal coordination strategies are not tightly constrained. And a natural prediction is that much more complex models should have shallow, and perhaps multiple, local optima.

INTRODUCTION

We undertook to implement a protocol for a multicentric in vivo kinematics analysis of the shoulder in order to better understand the behaviour of this articulation and to get a standardised clinical evaluation tool providing quantitative data for normal or pathologic subjects and for patients after prosthetic surgery.

METHODS

Flexion, abduction in the "scapular plane" (30° from the frontal plane) and external rotation were studied using the Vicon optoelectronic system provided with 6 cameras. For this, due to the great relative motions between bone and skin, two kinds of movements were analysed:

- Global movements of the arm to define the maximal global amplitudes of the shoulder;
- Static positions of the arm (at 0, 30°, 60°, 90°, 120° and 150° for flexion and abduction or at 0°, 15°, 30° and 45° for external rotation) to define, in each case, the angular positions of the different bones of the shoulder.

The subject was positioned using rests at feet, head and hip. For flexion and abduction the subject was up and for external rotation the subject was sitting.

Flexion was performed in a plane parallel to the sagittal plane and abduction in a plane oriented at 30° from the frontal plane. These two planes go through the antero-external angle of the acromion. They were materialised using a bar in rotation around an axis which was perpendicular to each of these planes and which went through the antero-external angle of the acromion. This bar can be fixed at wanted positions for static studies. The movements were produced with the arm in active extension using a handle positioned on the bar.

External rotation was performed with the forearm put on a plane perpendicular to an axis oriented at 10° from a vertical axis in the frontal plane. This axis went through the antero-external angle of the acromion. The plane of rotation was materialised using a bar in rotation around this axis.

For global movements, the mobility of the arm was determined using 2 markers fixed on the guiding bar.

For static positions of the arm, positions of scapula, clavicle and sternum were recorded using personalised palpators. The principle of palpation was described and used by Van der Helm and al. We adapted it to optoelectronic measurements (figure 1). Each palpator was provided with 3 reflective markers during measurements and with 6 reflective markers for their calibration. For the humerus, in flexion and

abduction, a fixed palpator was positioned using the two gutters around the olecranon to determine two anatomical points. In external rotation the position of the epicondyle and epitrochlea were calculated from their initial position, from the immobile position of the olecranon obtained using a probing system and from the angular position of the mobile bar. The third point necessary for the spatial determination of the position of the humerus corresponded to the centre of the humeral head calculated as described by Meskers et al. The kinematics calculations were performed using the sequence proposed by the ISG.

Figure 1:
Palpation of
scapula during
flexion.

Figure 2: Latero-rotation of
scapula during abduction in
scapular plane (repeatability
measurements with different
operators)

RESULTS

The first tests were performed on normal subjects. The results seem to be coherent (in physiological point of view and in comparison with literature), and precision and repeatability evaluations are in progress (figure 2).

Once validated, this protocol should be applied to a great number of normal subjects (in order to get a reference data basis), to pathologic patients and finally to patients with prostheses.

THE EFFECT OF ANALYSIS METHOD AND CALIBRATION CAGE GEOMETRY ON THE SPATIAL VARIATION OF RSA RECONSTRUCTION ACCURACY

Anthony M.T. Choo and Thomas R. Oxland

Departments of Orthopaedics and Mechanical Engineering
The University of British Columbia, Vancouver, British Columbia, Canada
amchoo@interchange.ubc.ca

INTRODUCTION

Traditional roentgen stereophotogrammetric analysis (RSA) solves for the stereo parameters in separate steps using fiducial and control planes (FCP) (Selvik, 1989). The direct linear transformation (DLT) is popularly used in camera and video photogrammetry to solve for these parameters in a single optimization (Abdel-Aziz and Karara, 1971).

In addition, the typical calibration cages used are asymmetric (Figure 1). The projective cage (PC) is skewed and the biplanar cage (BC) has a smaller control than fiducial plane. Finally, PC reconstruction involves extrapolation beyond the calibrated volume.

The objectives of this study were to quantify the behaviour of the reconstruction accuracy over a range of object positions. Specifically to assess its dependence on:

1. FCP and DLT analysis methods
2. calibration with PC and BC geometries examining the effect of calibration marker distribution

METHODS

Simulations were conducted in Matlab (v.5.0, The MathWorks Inc., Natick, MA). Calibration with PC and BC were modeled. The target object consisted of nine points distributed at the corners of a 10-cm sided cube and a single point at the cube's centroid. Normally distributed random errors were used to model manufacturing inaccuracy (0.01-mm) and radiographic measurement error (0.24-mm). In addition three hypothetical biplanar-type cages of varying asymmetry were used to probe the interaction between analysis method and cage geometry.

Figure 1: a) projective cage (PC) - object outside calibrated space; b) biplanar cage (BC) - object within calibrated volume

RESULTS AND DISCUSSION

For PC, the transverse errors ranged from 0.24-mm to 1.1-mm from 35-cm to 110-cm positions above the calibration cage. Axial errors ranged from 1.7-mm to 5.8-mm. The error magnitudes were the same regardless of analysis method. For

BC, the errors were lower and ranged from 0.14-mm at the cage centre to 0.48-mm at the cage boundary. In addition, differences between FCP and DLT were now perceptible.

Further investigation with the hypothetical cages showed it was the even distribution of calibration markers that enabled DLT to be more accurate. By solving for the stereophotogrammetric parameters simultaneously, the method of least-squares was able to balance all measurement errors. The separated solution in FCP limits error balancing producing a sub-optimal solution.

Whereas FCP utilized strictly planar calibration markers, DLT was able to use markers from all planes. The effect of this “full” DLT method combined with a symmetric marker distribution was an improvement of up to 62% (Figure 2).

Figure 2: Accuracy was improved by using all calibration points of a perfectly symmetric cage.

SUMMARY

This study elucidated some of the subtle differences between FCP and DLT. The most accurate reconstruction is achieved using DLT with a symmetric distribution of calibration markers surrounding the volume of interest. This has implications in the utilization of RSA for motion analysis over a general unconstrained region of interest.

A SIMULTANEOUS ANALYSIS OF MULTIPLE WAVEFORM AND CONSTANT GAIT MEASURES: APPLICATION TO KNEE OSTEOARTHRITIS

J.L. Astephen¹, K.J. Deluzio^{1,2}, U.P. Wyss²

¹School of Biomedical Engineering, Dalhousie University, Halifax, Canada

²Department of Mechanical Engineering, Queen's University, Kingston, Canada

INTRODUCTION

Knee Osteoarthritis (OA) is a common, debilitating musculoskeletal disease process whose pathology is linked to multiple correlated biological and mechanical factors. The interrelationships between these factors, which have been largely ignored in previous gait analysis studies, house important information about the OA disease process. Deluzio (2001) recognized the temporal correlation structure within individual time-varying kinematic and kinetic gait measures and determined discriminatory features between normal and OA waveforms. More powerful discrimination of gait patterns is possible by recognising the multidimensionality of the problem. Multiple waveform gait measures (i.e. the adduction moment), constant gait measures (i.e. stride characteristics) and OA-related parameters (i.e. alignment) are important to OA and are correlated. In a review of gait analysis techniques, Chau (2000) recognised the current need for interpreting multiple gait signals and quantitatively comparing gait waveforms.

The objective of this study was to develop a multivariate discrimination technique that simultaneously considered multiple constant and time-varying measures to detect differences in normal and OA gait patterns.

METHODS

Three-dimensional gait analysis was performed on a group of 54 elderly patients with severe knee OA and a group of 63 elderly asymptomatic subjects. Three components of knee joint angles, moments and forces were calculated with the QGAIT gait analysis system. (Costigan, 1992) For each subject, the static Hip Knee Ankle (HKA) angle, the standing knee flexion angle, and the medial and lateral condyle joint spaces were measured with a standardized X-ray technique called QPR. (Siu, 1991) Body Mass Index (BMI) was also calculated. The full gait cycle data of the 9 waveform gait measures and the 5 constants were simultaneously included in a principal component analysis (PCA). PCA is a statistical analysis technique that exploits the correlation in the data in extracting important features (PCs) that explain a maximal amount of the variability in the data. A stepwise linear discrimination procedure used a subset of the features extracted with PCA to: (i) define the multidimensional hyperplane that optimally separates the 2 groups and (ii) determine the discriminatory power of each feature. The most discriminatory PCs were interpreted in terms of the relative contribution of each of the 9 waveforms and 5 constants, and the relative importance of each percentage of the gait cycle.

RESULTS AND DISCUSSION

The multidimensional technique was successful in discriminating between OA and normal gait patterns, with a misclassification error <8%. A hierarchy of discriminatory power among the features was established through inspection of the linear discriminant function. The most discriminatory feature (PC1) described an alignment difference between the 2 groups; the next most discriminatory feature (PC20) described a difference in the loading response phase of the gait cycle. (Figure 1a)

We were able to interpret the features by: (i) determining the relative contribution of each of the 9 waveform gait measures and the 5 constants to each feature, and (ii) determining the relative contribution of each percentage of the gait cycle to each feature. Figure 1b describes the former interpretation for PC1. Dominant contributions come from the adduction moment, the lateral-medial bone-on-bone force and the HKA angle, all considered related to alignment and OA. The measures were weighted more equally in PC20, but as Figure 1a shows, this feature isolated a unique portion of the gait cycle corresponding to loading response, previously hypothesized to be important to knee OA. (Radin, 1991)

Identifying 2 major features important to knee OA, this study confirmed the power of exploiting the interrelationships between measures in the analysis of gait data and the utility of including parameters in the analysis.

Figure 1: (a) PC20 describes loading response gait phase (b) Relative contribution of factors to PC1.

INFLUENCE OF METATARSOPHALANGEAL JOINT BENDING AND SHOE SOLE LENGTH ON JUMP HEIGHT PERFORMANCE

Jean-Pierre R. Roy and Darren J. Stefanyshyn

Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada (jproy@kin.ucalgary.ca)

INTRODUCTION

Energy implications during physical activity play an important role on performance. It has been shown that mechanical energy is dissipated at the metatarsophalangeal (MP) joint during running, sprinting and jumping (Stefanyshyn and Nigg, 1997, 2000). Stefanyshyn and Nigg (2000) also showed that performance in vertical jumping could be improved by decreasing the energy that the MP joint dissipated. This was achieved by reducing the amount of bending of the shoe. In the present study we hypothesized that by eliminating the energy dissipated at the MP joint and increasing the resultant moment or angular velocity at the ankle joint, the subject would show improved vertical jump heights. The purpose of the study was twofold: to investigate the effects that eliminating the bending of the MP joint will have on vertical jump height and to examine the effects that an increased shoe sole length will have on vertical jump performance.

METHODS

Seven male subjects were recruited for the study (mean age 23.7 ± 1.1 yr, mean height 181.2 ± 3.5 cm and mean mass 79.8 ± 5.5 kg). A total of fifteen trials were collected for each subject, five trials for each of the three shoe conditions (control, stiff (C2) and stiff with anterior extension (C3)).

The subjects performed a maximal effort standing counter movement jump while standing on the force plate. The order each subject received the various shoe conditions was randomly assigned to avoid any learning effect. Kinetic data were collected with a force platform (Kistler, Winterthur, Switzerland) sampling at 1000 Hz. Vertical jump heights were measured using a Vertec height measurement system (Sports Import, Columbus, Ohio). A one-way repeated measures ANOVA was used to compare the dependent variables between the conditions ($\alpha = 0.05$).

RESULTS AND DISCUSSION

The results for all shoe conditions are found in Table 1. This

table represents the ensemble mean of each subjects maximal value attained for a given shoe condition. The results show that shoe C2 increased vertical jump height and impulse by 1.1 cm and 2.65 Ns respectively over the control shoe. Furthermore, peak force values were greatest for shoe C3, increasing by 38.79N over the control shoe. However, these differences were not significant, and could be due in part to the limited sample size. It can also be speculated that the lack in significant results may be partially due to the subject's inability to generate the additional plantar flexor force necessary to achieve a greater resultant moment when jumping in the test shoes.

Supplementary data, such as high speed video and EMG will shed more light on these speculations, and on the results found. Centre of pressure data were collected during this study, the analysis of which will be completed in future work.

The product of resultant joint moment and joint angular velocity determines the joint's mechanical power. The authors in this study speculated that by increasing the moment arm about the anterior aspect of the ankle (by modifying the sole characteristics of the shoe), a greater resultant moment would be generated by the plantar flexors and hence greater mechanical power production at the ankle. Although this added mechanical power was not directly quantified, it was indirectly gauged by increased vertical jump heights.

With a greater sample size and additional data, the hypothesis that footwear may be capable of generating a greater resultant plantar flexor moment in the human ankle, may be supported.

THE LOADING RESPONSE PHASE OF THE GAIT CYCLE IS IMPORTANT TO KNEE OSTEOARTHRITIS

J.L. Astephen¹ and K.J. Deluzio^{1,2}, U.P. Wyss²

¹School of Biomedical Engineering, Dalhousie University, Halifax, Canada

²Department of Mechanical Engineering, Queen's University, Kingston, Canada

INTRODUCTION

The pathogenesis of knee osteoarthritis (OA) is complex and involves many correlated biological and mechanical factors. Modern gait analysis is used to calculate mechanical measures such as knee joint loading and orientation, which play a substantial role in the progression of OA. Previous studies have reported several differences in gait measures with knee OA, such as higher adduction moments (Kaufman, 2000) and lower ranges of motion in the sagittal plane. (Deluzio, 2001) However, these studies can be difficult to interpret due to the numerous individual measures reported. (i.e. joint angles, moments, stride characteristics) There are interrelationships between the time-varying and constant gait variables measured, as well as with other parameters related to knee OA. (i.e. obesity) Important biomechanical features of OA may lie in the relationships between these variables, undetectable in univariate analyses.

The objective of this study was to detect biomechanical factors of knee OA using a multidimensional analysis technique that simultaneously considered multiple time varying and constant gait measures, and other parameters important to knee OA.

METHODS

Three-dimensional gait analysis was performed on a group of 54 elderly patients with severe knee OA, and a group of 63 elderly asymptomatic subjects. Three components of knee joint angles, moments and forces were calculated with the QGAIT gait analysis system. (Costigan, 1992) For each subject, the static Hip Knee Ankle (HKA) angle, the standing knee flexion angle, and the medial and lateral condyle joint spaces were measured with QPR, a standardized X-ray technique (Siu, 1991). Body Mass Index (BMI) was also calculated. The full gait cycle data of the 9 waveform gait measures and the 5 constants were simultaneously included in a principal component analysis (PCA). PCA is a statistical analysis technique that exploits the correlation in the data in extracting important features (PCs) that explain a maximal amount of the variability in the data. A stepwise linear discrimination procedure used a subset of the features extracted with PCA to: (i) define the multidimensional hyperplane that optimally separates the 2 groups and (ii) determine the discriminatory power of each feature. The most discriminatory PCs were interpreted in terms of the relative contribution of each of the 9 waveforms and 5 constants, and the relative importance of each percentage of the gait cycle.

RESULTS

The multidimensional analysis technique successfully identified discriminatory gait features, with a misclassification <8%. A hierarchy of the features was determined through inspection of the linear discriminant function.

The second most discriminatory feature, PC20, was a low-variance feature that described an important OA gait pattern difference. Early stance, or loading response, was completely isolated as the portion of the gait cycle important to PC20. (Figure 1) The feature consisted of relatively equal contributions from most of the 9 gait measures, as well as BMI.

DISCUSSION

The shock absorbency required during loading response can be compromised by such things as knee instability, muscle weakness or obesity, all characteristics of an OA population.

Although it has been previously speculated (Radin, 1991), this is the first time that loading response has been quantitatively identified as important to knee OA. This is largely because the difference is not isolated to one variable; it lies in a combination of many variables during this single phase of the gait cycle. With contributions from multiple variables, PC20 describes a multidimensional gait phenomenon during loading response, and required the power of a simultaneous technique for its detection. The importance of BMI, a relative obesity measure, to the feature also confirmed the utility of including parameters in the analysis.

In this same phase of the gait cycle, Radin (1991) identified an impulsive foot-ground reaction at the instant of heel strike in subjects with mild knee pain, presumably consistent with pre-OA. In recent work, we also found different muscle activation patterns during loading response of a moderate-OA group of subjects. We believe that this combination of variables involved during loading response may be important to the onset and development of knee OA.

Figure 1: PC20 isolates the loading response phase of gait.

AN ANNULAR STRAIN ENERGY FUNCTION WITH A PHYSIOLOGIC BASIS

Diane R. Wagner^{1,2} and Jeffrey C. Lotz¹

¹Orthopaedic Bioengineering Laboratory, University of California, San Francisco CA, jlotz@itsa.ucsf.edu

²Department of Mechanical Engineering, University of California, Berkeley CA

INTRODUCTION

The physical properties of the annulus fibrosus are critical to the intervertebral disc's biomechanical function: alterations with degeneration and aging can contribute directly to joint dysfunction and pain. A prerequisite for understanding disease etiology and progression is a constitutive model that links tissue architecture to material properties. To this end, we have developed a strain energy function with individual terms that represent specific tissue features. We applied this strain energy function to data from a wide range of experimental protocols to develop a comprehensive formulation for the multi-axial annular elastic behavior.

METHODS

We chose a Cartesian basis where the 1, 2, and 3 directions are aligned with the anatomic radial, circumferential, and axial directions, respectively. We assumed that there are two mechanically equivalent fiber families which are coplanar and oriented at $\pm\Phi$ from the axial direction. With these assumptions, Spencer (1984) showed that the strain energy W can be expressed as $W = W(I_1, I_2, I_3, I_8, I_9, I_{10}, I_{11}, \cos^2 2\Phi)$.

In the current study, we assumed that the annulus derives its material properties from three components: the proteoglycan matrix, the collagen fibers, and the collagen cross-links. We therefore considered a strain energy function consisting of a sum of separate terms: $W = a_1(I_3 - 1/I_3) + a_2(I_1 I_3^{-1/3} - 3) + a_3(\exp(b_3(I_9 - 2)) - b_3 I_9) + a_4(\exp(b_4(I_{11} - I_9^2 + 2I_{10})))$. The 1st and 2nd terms represent, respectively, the spherical and deviatoric responses of the matrix. The 3rd term models the collagen fibers with a mechanical response that is stiffer in tension than in compression. Finally, we assumed that the primary function of the collagen cross-links is to constrain the collagen fibers from sliding past one another. Consequently, the 4th term of W is a function of the shear strain along the fiber direction and represents the contribution of the cross-links.

We derived appropriate stress-stretch relations for each experimental protocol, including both zero-stress responses associated with the traction free faces in the uniaxial experiments (Mathematica). The data to which we applied this strain energy function included: radial and axial confined compression (Klisch and Lotz, 2000), radial tension (Fujita et al, 1997), circumferential tension and compression (Wagner and Lotz, 2002), axial tension (Duncan and Lotz, 1998), and biaxial tension (Bass, 1999). We limited the biaxial data to the axial stress response with circumferential strain held at 0%.

Because the stress in any direction is dependent on the stretch in every direction, we had to define the 3 principal stretches in the uniaxial experiments, even though they were not all

measured. We estimated ν_{12} , ν_{13} , ν_{21} and ν_{31} to be 0.18, 0.18, 0.25 and 0.25. Because a preliminary analysis indicated that the results of the fit were very sensitive to the Poisson's ratios ν_{23} and ν_{32} and to Φ , we considered these parameters to be best found through the statistical non-linear fitting algorithm.

To determine the values of the material parameters $\{a_1, a_2, a_3, b_3, a_4, b_4, \nu_{23}, \nu_{32}, \Phi\}$, we conducted a non-linear regression to the mean response of the stress versus stretch data from the experimental datasets (PV-Wave).

To validate this constitutive formulation, we compared the predicted circumferential stress-stretch response in biaxial tension (circumferential strain held at 0%) with the corresponding experimental data.

RESULTS

The best fit values for the nine material parameters were $\{0.126, 0.00394, 0.000169, 28.9, 0.00111, 10.1, 1.65, 0.40, 55.9^\circ\}$. These coefficients resulted in stress-stretch curves that lie within one standard deviation for all experimental deformations. Additionally, the theoretical prediction for the circumferential stress-stretch response in biaxial tension matched the experimental data well (Figure 1).

DISCUSSION

We have developed a strain energy function that accurately predicts the mean stress response to multiple experimental deformations. Since the terms are meant to represent separate contributions from annular constituents we hope that this formulation may be used in the future to elucidate structure-function relationships of the annulus and the pathomechanics of aging and degeneration in the intervertebral disc.

INTRODUCTION

Atherosclerosis is an inflammatory disease characterized by endothelial dysfunction, monocyte infiltration/differentiation, smooth muscle cell (SMC) proliferation, lipid deposition, elevated wall permeability to macromolecules, and arterial wall remodeling (Ross, 1999). The localized nature of these processes points to hemodynamics as a major contributing factor. The objective of this study is to provide a rigorous assessment of possible correlations between different hemodynamic factors and the progression of atherosclerosis.

MATERIALS AND METHODS

MRI-based *in vivo* Geometry. *In vivo* carotid bifurcation geometries were obtained in four patients P1-P4 (ages 61-73) using multi-slice black blood spin echo magnetic resonance imaging (MRI) with 2mm thick slices and 0.39mm in-plane resolution. An in-house edge detection protocol was used to convert the MRI data to a series of 2D vessel boundaries. Lofting across these 2D cross-sectional structures at each level of the carotid bifurcation was carried out using a solid modeling software SolidWorks (Concord, MA). Interpolation across the outer contours of these slices produced the external 3D solid body, while the 3D structure that results from interpolating across the inner contours gave the 3D fluid volume. Subtraction of these two yielded the 3D vascular structure (not used in the simulations, but used later in matching the histological slice location to the histology specimen).

FEM Model. Given the 3D fluid geometry, as well as the velocity profiles at the inlet (common carotid) and the outlet of internal carotid, obtained based on fully developed Womersley profiles with centerline velocities from ultrasound measurements, a computational model was developed employing a commercially available finite element package (ADINA, Watertown, MA). Blood was treated as an incompressible, Newtonian fluid and the flow was assumed laminar. The arterial wall motion was neglected considering that the plaques in diseased arteries significantly reduce strain levels. The lumen was then meshed using unstructured tetrahedral elements of edge size 0.4 mm.

Histological Processing. Histology specimens (advanced plaques) from diseased arteries were harvested from the same patients after carotid endarterectomy. Regions containing macrophage, SMC, lipid and collagen, each characteristic of the inflammatory/remodeling process, were correlated with the fluid mechanical parameters of importance, namely average wall shear stress (WSS), oscillatory shear index (OSI), and

maximum wall shear stress temporal gradient (WSSTG). Stringent criteria ($p < 0.1\%$) were used to identify a correlation highly statistically significant. Correlations with $p > 5\%$ were not recorded.

RESULTS AND DISCUSSION

Strong correlations existed in the vicinity of the carotid bulb, immediately downstream of the observed stenosis, although the sign of the correlation coefficient depended on the severity of the stenosis. Two patients (P1 and P2) had non-constricting ($< 50\%$) stenoses. The results showed that the WSS (OSI) downstream of the stenosis of P1 generally exhibited strong negative (positive) correlations with presence of SMC, lipid and collagen, but no significant correlation with macrophage presence. Interestingly, P2 exhibited the opposite tendency at the same location, showing strong correlations with macrophage density but no significant correlation with the other parameters. This suggests that the inflammatory process, although at different stages in each case, is localized to downstream of the stenosis. In P3 with an 80% stenosis, the WSS at that location correlates positively with lipid, macrophage and collagen. The difference is believed to be due to the extensive re-modeling and the advanced stenosis present. No statistically significant correlations were found in P4.

Fig. 1: Average WSS(Pa) over the cardiac cycle in Patient P3.

INTRODUCTION

Valve homografts are superior to mechanical valves in hemodynamics, anticoagulation, and resistant to infections. However, they are still required to have more durability with potential growth and invisible immunogenicity. Tissue-engineered heart valves with autologous cells keeping intact tissue structure and biomechanical properties may provide these advantages. We are investigating efficient processes of acellalization of heart valves to have bioscaffolds made of native collagen, elastin, and basal membrane by detergents and/or other cell lysis methods. In this paper, our recent study on biomechanical properties of acellalized porcine heart valves both in vitro and in vivo was reported.

METHODS

For the in vitro study, porcine hearts were isolated and stored at 4 °C immediately. The pulmonary valves were excised and washed with Hank's balanced salt solution. The valves were then immersed in a 1% of tert-octylphenyl-polyoxyethylene (Triton[®] X-100) with 0.02% EDTA, 20 µg/ml of RNase A, and 0.2 mg/ml of DNase I in phosphate buffered saline (PBS) free of Ca²⁺ and Mg²⁺ (Bader A, et al, 1998). They were maintained in a 37 °C incubator equilibrated with 5% CO₂ and 95% air atmosphere under gentle shaking. After a predetermined period of time, they were rinsed with PBS and subjected to light microscopy, scanning electron microscopy, and mechanical property measurement. For the in vivo study, minipig (Nippon Institute for Biological Science) pulmonary valves were excised and acellularized as mentioned above. They were washed in PBS for 3 weeks and then replaced by minipig native valves. They were explanted 1 month after transplantation and examined histologically and mechanically.

RESULTS AND DISCUSSION

H.E. staining of porcine valves treated with Triton showed that the structure across the whole thickness of the leaflet after 6 hrs of incubation was completely cell free. However, nuclei of surrounding tissues located more than 1 mm in depth from the surface were stained even after 48 hrs of incubation. In scanning electron microscopy, gaps between endothelial cells were observed in more than 3 hrs of incubation, however residues of endothelial cells on collagen fibers were still attached even after 48 hrs of Triton treatment. The mechanical measurement showed increases in both of tensile strength and Young's modulus of the acellularized leaflets (Figure 1),

however they had no bad effects on the valve replacement. This was supported from elastica-van Gieson staining which showed collagen and elastin fibers were well maintained in the bioscaffold tissue. The grafts were well functioning and their surfaces were recellularized after 1 month of transplantation. They were showed endothelial cells by the anti-vWF immunostaining (Figure 2). The leaflets transplanted had no significant changes of biomechanical properties.

Figure 1: Breaking strength of the porcine pulmonary valve leaflets treated with 1% Triton X-100.

Figure 2. H.E. staining (left) and anti-vWF immunostaining (right) of the acellularized pulmonary valve tissue transplanted into minipig for 1 month.

METABOLIC COST OF GENERATING HORIZONTAL FORCES DURING WALKING

Jinger S. Gottschall and Rodger Kram

Locomotion Laboratory, Department of Kinesiology and Applied Physiology
University of Colorado, Boulder, Colorado, USA
gottscha@ucsu.colorado.edu

INTRODUCTION

During steady-speed locomotion, the need to generate muscular forces creates a metabolic demand. Kram & Taylor (1990) and Farley & McMahon (1992) found proportional relationships between vertical force and the rate of oxygen consumption during running. Previously, Pugh (1971) demonstrated that generating horizontal forces to overcome an external horizontal force, such as a head wind, proportionately increases the metabolic cost of treadmill running. More recently, Chang & Kram (1999) quantified that generating propulsive horizontal forces accounts for more than one third of the metabolic cost of normal human walking. The purpose of this study was to determine the metabolic cost of generating horizontal forces during normal human walking.

When comparing the peak ground reaction forces of running and walking, the peak vertical force in running is roughly two times that of walking. In contrast, the peak horizontal force in running and walking are similar. The metabolic cost of generating propulsive forces during walking has not been previously determined, and in fact there is little consensus as to which muscles are primarily responsible for propulsion (Neptune, et.al., 2001). Thus, our two aims were: to determine the portion of the metabolic cost of walking required to generate horizontal forces and to analyze the propulsive function of the ankle muscles.

METHODS

Participants (n=10) walked at 1.25 m/s normally and with either aiding or impeding applied horizontal forces (AHF), at the waist, equal to 0, 5, 10, and 15% body weight. The waist belt was connected in series with spring elements stretched over a series of low friction pulleys. We monitored the applied horizontal force via the digital readout of a force transducer. We measured net (gross - standing) rates of oxygen consumption ($\dot{V}O_2$) and recorded ankle muscle EMG activity (anterior tibialis, medial gastrocnemius, and soleus).

RESULTS AND DISCUSSION

With an aiding AHF of +10%, $\dot{V}O_2$ decreased by $53\% \pm 6.5$ (mean \pm SD) compared to normal walking. From these data, we infer that generating horizontal propulsive forces constitutes at least 50% of the metabolic cost of normal walking. In contrast, with an impeding AHF of -10%, $\dot{V}O_2$ increased 150% compared to normal walking, presumably because of the extra mechanical work involved.

Figure 1. Rates of oxygen consumption (mean \pm SD) with an aiding, applied horizontal force.

Running and walking differ substantially in terms of the fraction of energetic cost due to propulsive forces. Specifically, generating horizontal propulsive forces during running constitutes 33% of the total metabolic cost, while during walking these same forces constitute 53% of the total. Further, oxygen cost during running continued to decrease with aiding forces greater than +15%. In contrast, during walking, oxygen cost decreased to a minimum with an aiding force of +10% and increased to 70% of normal with an aiding force of +15%.

SUMMARY

By applying various amounts of aiding horizontal force, our data suggest that generating horizontal propulsive force constitutes about half of the metabolic cost of human walking.

COMPRESSIVE BIOMECHANICS OF FRACTURE AND NEUROLOGIC INTEGRITY IN THE PEDIATRIC SPINE

David Nuckley, Suzanne Hertsted, Christopher Tainter, and Randal Ching

Applied Biomechanics Laboratory, University of Washington, Seattle, Washington, USA
Contact: dnuckley@u.washington.edu

INTRODUCTION

The majority of spinal cord injuries occur due to compressive injury mechanisms. Studies have been conducted to determine the failure tolerance for the adult cervical spine under compression [Sances, 1984; Yoganandan, 1990]. In addition, transient spinal canal integrity has been investigated to assess the potential neurologic injury tolerance associated with compressive spinal impacts [Carter, 2000]. Although these studies provide important tolerance data for the adult spine, very little data are available on the pediatric spine.

In order to develop useful safety measures for children, the biomechanical effects of maturation must be carefully studied. This experimental study measured the compressive mechanical and neuro-protective response of the cervical spine to examine age-related injury tolerance.

METHODS

Twenty-two fresh cadaveric baboon cervical spines were obtained through the Washington Regional Primate Research Center. The male specimens ranged in age from 1 to 30-human equivalent years based upon radiographic assessment of their skeletal maturity. Each specimen was dissected free of all musculature, then sectioned into two functional spinal unit segments: Occiput-C2, C3-5, and C6-T1. These were then wired and embedded in polymethylmethacrylate to ensure even load distribution. A spinal canal occlusion transducer replaced the spinal cord and dura to monitor the mid-sagittal diameter of the spinal canal [Raynak, 1998].

Compressive inputs were provided by a servohydraulic testing frame (Model 810 Bionix, MTS Corp., Eden Prairie, MN) at rates of 1.0 ± 0.2 -m/sec of haversine displacement to 70% strain. An inferiorly mounted six-axis load cell measured the force/moment response and the displacement was recorded using a LVDT. These data and the spinal canal mid-sagittal diameter were recorded at 40,000-Hz and filtered with a CFC 1000 (Butterworth low pass 1650-Hz cutoff) digital filter. The failure load was defined as the first reversal in the compressive load, and occlusion data were referenced to this failure event.

RESULTS AND DISCUSSION

These experiments revealed significant changes in the compressive failure load in developing spinal tissues (ANOVA $p=0.003$). The failure load increased with increasing maturity (Figure 1) and also demonstrated differences between the spinal levels tested. The C3-5 functional spinal units had larger failure loads than the Oc-C2 and C6-T1 levels. The level most susceptible to injury was the C6-T1 in adolescent and adult tissues and the upper C-spine in the very young.

Figure 1: Compressive Failure Load as a Function of Spinal Development. Decreased susceptibility to injury occurs with increasing maturity (2nd order polynomial).

Concomitant with these compressive failures, the spinal canal mid-sagittal diameter was occluded by up to 90% from intact and demonstrated different occlusions for each spinal level investigated. Further, developmental differences were observed which affect the potential for spinal cord injury.

SUMMARY

Developmental processes affect the failure tolerance of individual spinal segments. These mechanical failures generate a significant potential for spinal cord injury as well as instability of the spine. The relationship between mechanical failures and the potential for spinal cord injury will be elucidated by the complete examination of this data set. Future comparison with human adult data will validate this model and support property scaling which will facilitate the use of these data. Further, size and material properties will be evaluated across maturation for their contribution to compressive tolerance. Ultimately, these data will support modeling efforts and the development of injury prevention schemes to minimize these compressive injuries to children.

EFFECT OF REDUCED RANGE OF MOTION ON THE ACCURACY OF THE FUNCTIONAL METHOD OF HIP JOINT CENTER LOCATION

INTRODUCTION

Motion analysis often requires a determination of the location of the hip joint center (HJC). Errors in HJC location that are as small as 3 cm may lead to substantial inaccuracies in inverse-dynamic hip joint moment calculations (Stagni et al., 2000). Cappozzo (1984) described a functional method for HJC location in which the center of rotation between thigh and pelvis is determined from the segments' relative motion. This method may, however, be susceptible to errors when the range of motion (ROM) is limited, though this was not found to be the case in a mechanical linkage (Piazza et al., 2001). The purpose of the present study was to assess the accuracy of HJC location performed using special motion trials in which the hip ROM in healthy subjects was limited and to investigate whether the HJC could be determined from data collected during four common activities.

METHODS

Twenty-two healthy female volunteers participated in the study. Twelve of these were young adults (21-29 y) and 10 were elderly (70-78 y). A Vicon 370 motion analysis system (Oxford Metrics) recorded the locations of pelvis- and thigh-fixed markers as the subjects descended stairs (SD), ascended stairs (SA), rose from a seated position to standing (STS), walked overground (OGW), and performed a special hip motion sequence that incorporated flexion, extension, abduction, and circumduction.

The HJC was determined by finding the points in the pelvis and thigh frames that were separated by the smallest distance as determined in a least-squares sense. A preliminary analysis of the separation between the pelvis- and thigh-fixed HJCs suggested that the average HJC location error found using the hip motion trial was at most 18 mm, consistent with previous reports (Leardini et al., 1999). The HJC determined using this trial was used to evaluate additional errors resulting from flexion-extension (FE) or ab/adduction (AA) ROM in the special hip motion trial being reduced by half (or both being reduced) and from data collected as subjects performed the various activities. ROM reductions were achieved by omitting data frames for which certain hip angles were exceeded. Two-way ANOVA and subsequent corrected pairwise mean comparisons were performed to test for differences in HJC location error and frontal- and sagittal-plane ROM that were related to age (two levels: young and elderly) and type of trial used to determine the HJC (seven levels: FE, AA, FE and AA, SD, SA, STS, and OGW).

RESULTS AND DISCUSSION

No age-related differences were found in HJC location error or ROM, suggesting that the functional method performs equally well for young and healthy elderly subjects. Hip centers calculated from special hip motion trials in which the ROM was artificially reduced were significantly more accurate than those calculated from data collected during the activities (all $p < 0.001$) (Fig. 1). Except for one case, there were no differences within ROM limitations or activities.

These results suggest that the functional method has the potential to be reasonably accurate (within 2.5 cm worst case) and comparable to that found for regression methods (Leardini et al., 1999) even when hip ROM is limited. Use of the various activity trials, however, resulted in HJC location errors that were unacceptably large (greater than 5 cm worst case), suggesting that special motion trials are indeed required for accurate functional HJC determination.

Fig. 1: HJC location errors resulting from different motion trials being used in the least-squares optimization (mean, sd of all subjects). See text for a listing of motion trial types.

INTRODUCTION

Older adults utilize different strategies to develop forward momentum during gait-initiation compared to young adults (Polcyn et al., 1998; McGibbon and Krebs, 2001). This may put older adults at increased risk for falling. The aim of this study was to assess whether older adults who have had a history of unexplained falls demonstrate impaired gait-initiation dynamics compared to healthy older adults.

METHODS

Sixty-three ambulatory community-dwelling older adults and fifteen young adults (7 male, 8 female; mean age 27 ± 3 yr) volunteered for this study. Thirty-one of the older adults had a history of two or more unexplained falls in the previous year and were classified as fallers (6 male, 25 female; mean age 75 ± 7 yr). Thirty-two of the older adults did not have a history of falls and were classified as non-fallers (11 male, 21 female; mean age 76 ± 5 yr). Informed consent was obtained from all participants prior to participation. Electromyographic (EMG) data were collected from the tibialis anterior (TA) and soleus (SO) bilaterally. The subject stood on a force plate in a comfortable stance and initiated gait upon hearing an auditory cue. Five gait-initiation trials were collected at three self-selected speeds: slow, normal, and fast. Force-plate and EMG data were sampled at 1500Hz. Momentum was computed by integrating the ground reaction force in the anteroposterior (AP) direction and normalized to subject lower limb length and body mass. The integral of the AP center of pressure (COP) displacement normalized to leg length was regressed against the forward momentum to provide information on gait-initiation dynamics.

RESULTS AND DISCUSSION

Normally, a muscle activation pattern of SO inhibition followed by TA activation occurs during effective gait initiation (Crenna and Frigo, 1991). Elderly fallers and elderly non-fallers demonstrated similar frequency of use of this pattern ($42 \pm 39\%$ and $39 \pm 37\%$ of the trials, respectively). Compared to the young subjects, the elderly subjects demonstrated the SO inhibition TA activation pattern less frequently ($41 \pm 38\%$ and $82 \pm 29\%$ of the trials, respectively) and had greater tibialis anterior activation prior to toe off. On average, similar amounts of forward momentum generation were found between the elderly fallers and elderly non-fallers ($0.55 \pm 0.17 \text{ sec}^{-1}$ and $0.57 \pm 0.16 \text{ sec}^{-1}$ respectively). However, when a subset of the older subjects were classified according to performance on the Dynamic Gait Index (Shumway-Cook and Wollacott, 1995), those demonstrating clinical impairments also demonstrated a decreased slope for the COP displacement versus momentum profile. This finding indicates that in the gait impaired, less momentum is developed for each

incremental change in COP displacement (Fig.1). Furthermore, compared to the young, the elderly also demonstrated a decreased slope for the COP displacement versus momentum profile.

Figure 1. Clinical gait status and age-related changes in functioning of the gait-initiation motor program: group mean regression lines computed for forward momentum versus AP COP displacement time integral. Elderly, with impairment: $R=0.68$, Elderly, no impairment: $R=0.95$, Young: $R=0.97$.

SUMMARY

Grouping individuals by fall status did not discern differences in gait-initiation dynamics between elderly fallers and non-fallers; however, grouping by clinical gait impairment did. A decrement in the gait-initiation motor program and increases in muscle activity levels were found in the elderly subjects compared to the young subjects. This may be due age-related decrements in muscle strength and increased ankle stiffness due to co-activation of antagonistic muscles at the ankle.

SHEAR STRESS STIMULATES OXIDANT PRODUCTION IN HUMAN CARTILAGE EXPLANTS

James Martin and Anneliese Heiner

Department of Orthopaedic Surgery, University of Iowa, Iowa City, IA, USA
james-martin@uiowa.edu

INTRODUCTION

Cartilage is sensitive to damage caused by reactive oxygen species (ROS). ROS degrade the cartilage matrix, suppress matrix synthesis, and can cause sufficient damage to chondrocytes to provoke cell cycle arrest (senescence) or apoptosis (Tiku et al., 1999; Michel et al., 1992). Chondrocytes can generate high local ROS concentrations, and ROS production is induced by some forms of mechanical stress, suggesting that oxidative damage mediates some of the adverse effects attributed to excessive mechanical loading *in vivo*. However, these findings are based on *in vitro* studies which used stress conditions (unconfined axial compression or fluid shear) unlike those experienced by cartilage *in vivo* (Das et al., 1997; Fermor et al., 2001).

We have developed a cartilage culture device – a triaxial compression vessel – capable of recreating lifelike stress conditions. The device modulates matrix deformation, fluid flow, and hydrostatic stresses by simultaneously and independently controlling both axial compression and transverse compression (Fig. 1). Previous studies have shown that cartilage matrix synthesis is suppressed by high shear stress (Heiner & Martin, 2001). We hypothesized that the suppressive effect of high shear stress on matrix synthesis was mediated by ROS release.

Figure 1: a) Schematic (insert = cartilage housing) and b) physical appearance of triaxial compression vessel.

METHODS

Human cartilage explants (4 mm diameter cylinders) were harvested from a normal ankle joint and cultured in a 5% O_2 atmosphere to minimize oxidation. Dihydroethidium (DHEt) (a probe that fluoresces when oxidized) was added to the culture medium before stress treatment. Explants were randomly assigned to high shear stress (n=4) or low shear stress groups (n=4). Two explants from each group were also treated with n-acetyl cysteine (NAC), a potent antioxidant. After exposure to high shear stress (2 MPa axial compression) or low shear stress (2 MPa axial compression + 2 MPa transverse compression) for 15 minutes at 1.0 Hz, the explants were prepared immediately for cryosectioning. Ten μm -thick sections were examined using epi-fluorescent optics. Six

images were recorded for each explant and analyzed using NIH Image (Martin et al., 2002). Statistical analysis was performed using repeated measures analysis of variance on ranks with Dunn's method for multiple comparisons ($\alpha=0.05$).

RESULTS

DHEt fluorescence was significantly increased by high shear stress versus low shear stress, and was significantly decreased by NAC treatment under both stress conditions (Figs. 2, 3).

Figure 2: Micrographs showing DHEt oxidation (bright spots) after axial stress (A), and after axial + transverse stress (B).

Figure 3: Mean frequency of fluorescent cells in six 0.04 mm² fields after axial stress or axial + transverse stress (-/+NAC).

DISCUSSION

High shear stress stimulated significantly higher oxidation levels than did low shear stress, and anti-oxidants blocked this effect. These data indicate that ROS are produced by chondrocytes in response to shear stresses which are closer to physiologic conditions than those used by other investigators.

COLLISION LOSSES DURING BRACHIATION: WHY GIBBONS HAVE LONG ARMS

James Usherwood and John Bertram

Food, Nutrition and Exercise Sciences, Florida State University, Tallahassee, Florida, 32306.

jbertram@garnet.acns.fsu.edu

INTRODUCTION

Gibbons are able to brachiate effectively through complex environments: impressive acceleration, maneuverability and climbing are possible with support only from arms. Mistakes, however, do occur (Schultz, 1944), and are likely to be costly. Energetic costs of brachiation appear to be dominated by inelastic collisions at contact with a new handhold, analogous to the 'jerk' felt by a child falling on a swing after the chain has become loose. Minimizing energetic costs, while avoiding falling, may provide constraints on the paths available to a brachiator, and could explain some of the observed details of brachiation.

METHODS

A simple point-mass model of brachiation (following Bertram et al., 1999), with a pendular swinging phase and a ballistic flight phase, was developed, and programmed in LabVIEW 5.0. Controlled variables were: length from hand to center of mass, energy of the mass at the bottom of the first swing, and hand-hold spacing. Potential flight paths were then derived given a range of release angles, and the energetic consequences of inelastic collision at contact of the 2nd hand-hold calculated.

Modeled kinematics were compared with video (100Hz after de-interlacing) of gibbons brachiating at a range of speeds and handhold spacing. Observed flight-paths and behaviours were assessed within an energetic context.

RESULTS AND DISCUSSION

Despite an infinite number of potential flight paths for a given initial kinetic energy, there is only a limited range of paths that minimize energetic loss due to collision. The energetic cost of missing an 'ideal' path may be considerable, and depends both on the collision geometry and the kinetic energy at collision; even a total loss of kinetic energy, due to a velocity parallel to the arm at contact, may be negligible if the body is high and slow, and potential energy dominates.

Observed kinematics of gibbons show that the theoretical zero-collision-loss paths are often missed. If the power requirements of gibbon locomotion are dominated by collision losses, this observation suggests that something limits the exploitation of no-loss paths. Adaptive paths may show a compromise between modest losses for overshooting a

handhold, and the substantial costs for undershooting, missing the handhold, and falling.

Long arms and the use of a 'double pendulum' mechanism allow gibbons to reduce the energetic cost of collision (Fig.1): longer arms L improve the geometry of collision for a given 'overshoot' e , while the double pendulum allows some of the energy that would have been lost in collision to be transferred to kinetic energy of rotation about the shoulder joint (supported by Bertram et al., 2001).

Figure 1: Gibbon during contact at a handhold while brachiating at speed. Tension occurs well after initial contact, and may show the compromise between the energetic costs of collision, and the consequences of falling. The 'Double pendulum' rotation of the hips about the shoulder (small circle) may reduce the cost of 'overshooting' the no-loss arc (dotted line through large circle).

SUMMARY

Many aspects of gibbon brachiation, including the use of long arms and a 'double pendulum' mechanism, are understandable within a context of minimizing energy losses due to collision, while avoiding the potentially lethal costs of missing a handhold.

ABSOLUTE HEEL SENSITIVITY IS NOT RELATED TO THE DISCRIMINATION OF INITIAL IMPACT LOADS TYPICAL OF HEEL-TOE RUNNING

Ben L. Patritti¹, Mark J. Lake¹ and Carine van Schie²

¹Research Institute for Sport and Exercise Sciences, Liverpool John Moores University, UK, www.livjm.ac.uk

²Diabetes Foot Clinic, Disablement Services Centre, Withington Hospital, Manchester, UK.

INTRODUCTION

The cutaneous receptors of the footsole provide a source of sensory feedback to the body during the ground contact phase of locomotion. Sensitivity of the plantar surface of the heel has been quantified using absolute thresholds (ATs) to perceptible vibration and pressure stimuli (e.g. Nurse and Nigg, 1999). The foot is continually loaded during daily activities at levels substantially above ATs of mechanical stimuli and, as such, AT measurements may not provide a useful indication of our ability to discern much higher locomotor type loads. This sensory faculty can be characterised by difference thresholds (DTs) of the mechanical inputs and is likely to have a greater functional significance to the modification of loads and movement patterns during locomotion. Individual differences of ATs of the footsole (Nurse et al., 1998) and DTs of mechanical inputs of impact loads typical of locomotion (Patritti et al., 2001) have been observed, but it remains unclear whether differences in normal ATs of the foot partly explain differences in impact DTs. Therefore, the aim was to determine whether ATs of the heel for pressure and vibration stimuli bore a relationship to DTs of mechanical inputs of impact loads to the heel.

METHODS

A group of 22 male subjects experienced controlled barefoot impacts onto a range of 9 EVA mats of different density using a human pendulum. Impact severity was characterised by external impact force and shock to the shank measured by a wall mounted force platform and skin mounted accelerometer, respectively. The perceived impact severity of each condition was rated against a central standard using a 2 alternative forced choice (2AFC) paradigm for 20 presentations each in a mixed order. DTs of the mechanical inputs were determined from cumulative normal distribution curves fitted to the psychometric data. Pressure ATs were determined using a set of 10 Semmes-Weinstein monofilaments and a 2AFC protocol. Vibration ATs were determined using 3 devices: a CASE IV using a 4, 2, 1 stepping algorithm, a Neurothesiometer using a method of limits protocol, and a Vibratron II using a 2AFC protocol. All stimuli were applied to the centre of the heel pad. Relationships between ATs and DTs were evaluated using Pearson moment correlation coefficients.

RESULTS AND DISCUSSION

Large differences in both ATs and DTs were observed between individuals (Figure 1), with individuals most sensitive to changes in the rates of loading (ROL) of the mechanical inputs of impact (Patritti et al., 2001). All correlations between

ATs and DTs of the ROLs were non-significant (Table 1) suggesting absolute heel sensitivity does not substantially contribute to the discrimination of impact severity in a normal population.

Table 1: Pearson correlation coefficients between pressure and vibration ATs and DTs of the mechanical input ROLs.

AT Test	Force DT	Shock DT
Vibratron II	0.19 (Fig. 1)	0.19
Neurothesiometer	0.33	0.36
Case IV	0.27	0.15
Monofilaments	0.09	0.02

Figure 1:
Typical scatterplot of vibration AT of the heel and force ROL DT for heel impacts.

This lack of association between ATs of heel sensitivity and DTs of impact indicates that ATs may not be appropriate in characterising the sensory capabilities of the foot to loads typical of locomotion. The poorer sensitivity of the heel to tactile pressure and vibration relative to other sites on the plantar surface and body (Cavanagh, 1999; Nurse and Nigg, 1999) may help to explain the present findings. Cavanagh (1999) suggested that the elevated thresholds of the foot may reflect the setting of the sensitivity of the cutaneous receptors to a higher level as a function of the residual loading experienced almost always during daily activities. Further work investigating DTs of mechanical stimuli during actual locomotion may lend support to this speculation.

COMPUTATIONAL MODELING OF FLOW AND MASS TRANSPORT IN A MICROFABRICATED ARRAY BIOREACTOR FOR PERFUSED 3-D LIVER CULTURE

M.R. Kaazempur-Mofrad,^{1,2} A. Sivaraman,^{1,3} A. Upadhyaya,^{1,2} K. Domansky,^{1,3} M.J. Powers,^{1,3} R.D. Kamm,^{1,2} and L.G. Griffith^{1,3}

Massachusetts Institute of Technology, Cambridge, MA

INTRODUCTION

Under standard *in vitro* cell culture conditions, hepatocytes rapidly lose their liver-specific metabolic and biosynthetic phenotype. This has led to development of a variety of culture techniques, none of which, however, yet replicates a comprehensive environment for the important functions of liver. The overall goal of this work is to develop a 3-D perfusion culture, providing a suitable scaffold for tissue morphogenesis and a homogeneous distribution of flow and mass transfer to meet the metabolic demands of the cells. Detailed analysis of the fluid flow and transport patterns in the reactor is required in order to ensure that the cells enjoy metabolically sufficient oxygenation and physiologically relevant shear stresses.

MATERIALS AND METHODS

Reactor Design. A cross-flow perfusion reactor that addresses these constraints was designed and fabricated, as described in Powers et al. (2002). At the heart of the reactor is the cell scaffold, comprised of a thin (<250 μm) silicon sheet permeated by a regular array of channels and seated atop a microporous filter. The scaffold is maintained between the upper and lower chambers of a flow-through housing. The functional unit of the bioreactor system is an individual channel, attempting to mimic a single capillary bed as the functional unit of liver. The current design allows repeated *in situ* observation of cells via light or 2-photon microscopy during culture of the 3D perfused tissue structures. Further description of the design and the corresponding morphological behavior of primary hepatocytes maintained under perfusion is given in Powers *et al.*, 2002.

Computational Model for Fluid Flow. A computational fluid dynamic (CFD) model was developed to estimate shear stress magnitudes the cells experience under the influence of bulk flow at the surface of the chip and perfusion flow in the micro-channels. The CFD model involved a finite element solution of the full 3-D Navier-Stokes equations using commercial software (ADINA, Watertown, MA). The Reynolds number, based on the width of the upper chamber and the diameter of the tissue flow-channels, respectively, was of order one in the interior of the upper chamber and of order 0.1 within the scaffold micro-channels for finite cross-flow. Boundary conditions for the micro-channel regions in the scaffold were set to reflect the extremes of either zero cross flow rate or experimental values of cross-flow with open channels.

RESULTS

Shear stress in the region near the center of the scaffold is approximately 0.01-0.02 Pa and that near the sidewalls of the reactor is about 0.005-0.01 Pa. The cells in channels closest to the inlet and outlet ports experience shear stresses of about 0.02--0.035 Pa, the maximum observed. Shear stress

distributions at the chip surface for the extreme case where cells have completely plugged channels were not significantly different in value and had no additional features. Various perfusion flow rates were examined, and the corresponding hepatic function was correlated to the computationally determined values of maximum shear stress on the hepatocytes. The results were suggestive of 0.1 Pa as the maximum shear stress under which hepatocytes maintain their physiologic phenotype. The effects of fluid flow inside single tissue-filled microchannels within the silicon scaffold were investigated by defining the channel cross-sectional geometries to reflect the representative geometries of void spaces within the tissue structures observed experimentally. One characteristic model geometry of the flow path was a cylinder of $\sim 100\mu\text{m}$ diameter. Fluid dynamic forces in the reactor were not sufficient to cause flow induced deformation of the tissue, and thus the surface was assumed to be rigid with no slip between the fluid and tissue. Flow fields were studied inside a single channel, where tissue ringed the channel leaving a $100\mu\text{m}$ diameter cylindrical void at the center of the scaffold. The shear stresses at the walls were about 0.07 Pa.

Analytical and computational analysis was performed to ensure that the hepatocytes receive sufficient oxygen for metabolic purposes, even under the most stringent conditions of no perfusion, i.e. in case where all nutrient transport into the channels is via diffusion from fluid in the upper and lower chambers.

SUMMARY

Initial characterization of the present 3-D perfused bioreactor for liver tissue culture proves that this system approximates the perfusion conditions present *in vivo*, ensuring a physiologically relevant environment for hepatic tissue.

QUANTIFYING THE CONTRIBUTION OF INDIVIDUAL MUSCLES TO LUMBAR SPINE STABILITY

Natasa S. Kavcic, Stuart M. McGill

Occupational Biomechanics Laboratory, University of Waterloo, Waterloo, Ontario, Canada

Contact: nkavcic@ahsmail.uwaterloo.ca

INTRODUCTION

Clinically, stabilization exercises are thought to train muscle patterns that ensure spine stability. Co-activation of the global muscles increases the compressive loads on the spine, which has motivated some (for example Richardson and Jull, 1995) to suggest that global muscle activity should be minimized during exertion tasks. However, Granata and Marras (2000) believe the benefit to stability from global co-activation overrides the compressive loading costs. Presently, insufficient research exists which quantifies the integrated roles of both the local and global muscles in stabilizing the spine under different loading conditions. The purpose of this research is to identify which torso muscles stabilize the spine during different loading conditions imposed by different stabilization exercises.

METHODS

The stabilization exercises measured in this study are four-point-kneeling with a leg lift, back bridging, side bridging and sitting on a gym ball. Each stabilization exercise was performed statically for a period of 2 seconds. Spine kinematics and 14 channels of torso EMG were recorded. Reaction forces were measured from the upper body segments that were in contact with the ground.

Data was input into a stability model of an in vivo lumbar spine described by Cholewicki and McGill (1996). In order to determine the stabilizing potential of each single torso muscle, the EMG signal for the muscle of interest in the control trial, was replaced bilaterally by a sinusoid with a cycle duration extending over the entire trial, and an amplitude from 0 to 100% MVC. For these experimental trials, all other input measures were kept constant. The maximum change of the stability index occurring in the experimental trial (E) was expressed as a percentage of the maximum change in the control trial (C).

$$\%change = \left(\frac{E - C}{C} \right) \times 100$$

RESULTS AND DISCUSSION

The muscles that produced the greatest changes in the stability index were dependent on the exercise tested and in turn, the loading applied to the spine. As well, the magnitude of the change in the stability index varied across exercises (Table 1).

In a task requiring minimal muscle activity, such as the sitting trial, the multifidus had a 9-fold effect over the next major contributor. In contrast, in a more demanding task, such as the four-point-kneeling exercise, the internal oblique was the

major contributor to stability with an almost 2-fold effect over the next important muscle, being quadratus lumborum. Clearly, when a variety of tasks are quantified, the relative importance of each stabilizing muscle is dependent on the total level of spine stability created while performing the exercise. For the ball trial the stability index is much lower than that of the other trials, therefore, a single stabilizer muscle has a larger effect on the total stability of the spine.

The idea that different torso muscles function as stabilizers depending on the loading condition has not been shown in previous research. Quint et al (1998) showed that both the psoas and multifidus stiffen the spine during different bending moments, however as with many in vitro studies, only a few muscles were modeled and as a result the interplay of the all the torso muscles were unable to be assessed.

Table 1: The percent difference between the maximum change in the control trial (C) versus the maximum change in the experimental trial (E). The last column is the stability index for the C trial.

	FPN	Bridge	Side Bridge	Sitting
Rectus Abdominis	119.38	176.51	141.45	222.10
External Oblique	1396.12	3184.31	835.55	0.00
Internal Oblique	2624.81	2122.67	642.74	7367.98
Latissimus Dorsi	345.74	764.76	166.30	793.09
Pars Lumb.	431.01	281.90	590.90	16551.10
Iliocostalis Lumb.	353.49	0.00	1313.41	33793.09
Longissimus Thor.	146.12	173.33	1127.68	24912.43
Quadratus Lumb.	1562.79	1205.71	1074.91	12886.74
Multifidus	314.73	41.90	1325.22	281553.31
Stability Index	6.28E-08	3.65E-06	6.88E+00	6.34E-16

SUMMARY

Clinical recommendations to focus on a single muscle to ensure a stable spine is not justified by the data presented here. Depending on the loading condition imposed on the spine, an understanding of the interplay between both the local and global muscles is necessary to reduce the risk of instability. Training neuromuscular patterns for sufficient stability should focus on loading the spine to involve all muscles that coordinate their roles to ensure a stable spine.

INTRODUCTION

The pathomechanics of knee osteoarthritis (OA) are not well understood, nor are the causes for it to progress more rapidly in some individuals than others. Modern gait analysis offers a unique means to measure the biomechanical response to diseases of the musculoskeletal system during activities of daily living. Identifying the mechanical factors of gait associated with knee OA is important in understanding the initiation and progression of OA as well as in planning therapeutic interventions.

The objective of this on-going study is to quantify the knee joint kinematics, kinetics and neuromuscular function of a group of patients with moderate knee OA. This report will focus on the kinematics and kinetics aspects of the study.

MATERIALS AND METHODS

We collected 3-D motion, ground reaction force, and electromyographic data from 7 normal subjects and 5 subjects with moderate knee OA. The moderate OA group was selected from the waiting list for arthroscopies at a local sports medicine clinic. The normal subjects were recruited from the general population and were asymptomatic, without evidence or history of arthritic disease or record of surgery to the lower limbs. Subjects performed, in random order, five trials of their normal selected speed, and a fast walk (150% of the normal speed). A computer timer during the test trials monitored both. All subjects gave their informed consent to this protocol, which passed our internal ethics review board.

Three-dimensional motion and force data were used to calculate three dimensional joint angles, moments and forces. The joint angle waveform data was analysed using principal component analysis (PCA) as described in Deluzio et al. (1997). In this approach each kinematic and kinetic time series for each subject was transformed into a set of three principal component (PC) scores that correspond to the major features of that waveform.

RESULTS

All subjects were within 6.2% of their normal velocity and 7.5% of the 150% condition. There were no differences in

stride characteristics (walking speeds, stride lengths, or stride times) between the two groups (Table 1).

The moderate OA patients walked with normal knee joint kinematic patterns. This was determined by comparing the moderate OA gait data both to the control group, and to historical data of 60 normal subjects. There were no differences in knee angle patterns between the moderate OA group and the control group at either of the walking speeds ($p > 0.6$).

In contrast, we found differences in knee joint kinetics between the moderate OA subjects and the normal control subjects. The magnitude of the adduction moment during stance (PC1) was larger for the moderate OA patients at both walking speeds ($p < 0.05$). The PCA identified differences in the pattern of the flexion moment, but only at the higher walking speed ($p < 0.05$). This difference was found in the second principal component (PC2), which measured the overall amplitude of the flexion moment waveform (the biphasic shape) (Figure 1).

Figure 1. The flexion moment data (A), PC2 loading vector (B)

DISCUSSION AND CONCLUSION

The moderate OA patients walked with a visibly normal gait as measured by stride characteristics and joint angles. However, differences were detected in the joint kinetics, particularly at the higher walking speed. Gait analysis can provide insight into the mechanical factors of knee osteoarthritis (OA) by quantifying the dynamic loading and alignment of the knee during activities of daily living. The PCA technique was able to extract features of gait waveform data that have high discriminatory power.

KINEMATIC MEASUREMENTS OF SNOWBOARDERS' ANKLES

Sebastien Delorme^{1,2}, Mario Lamontagne^{2,3} and Stavros Tavoularis²

University of Ottawa, Ottawa, Ontario, Canada

¹ sdelo005@uottawa.ca, ² Dept. of Mechanical Engineering, ³ School of Human Kinetics

INTRODUCTION

In 1989, there were 1.5 million snowboarders worldwide, 40% of which were in North America. In 2001, it was estimated that Snowboarders made up to 28.5% of those using the slopes. The incidence of trauma from snowboarding is 4 to 6 for every 1000 medical examinations, which is comparable to that of alpine skiing. Compared to injury patterns in alpine skiing, snowboarders are more prone to ankle injuries than alpine skiers (Bladin, 1993; Shealy, 1993). Also, snowboarders with soft boots have more ankle injuries than snowboarders with hard boots (Kirkpatrick, 1998; Pino, 1989). The goal of this project was to design an experimental protocol to measure the kinematics of the ankle during regular snowboard maneuvers.

METHODOLOGY

An electromagnetic motion tracking system (Fastrak, Polhemus, VT, USA), with four 6-degree-of-freedom position sensors, was converted into a fully portable system operating on two 12-volts batteries and connected to a laptop computer. The sensors were attached to the shanks (antero-medial surface of the tibia) and feet (posterior surface of the calcaneus) of the snowboarder. The electromagnetic source was mounted on the snowboard between the two bindings, thus defining the global coordinate system rigidly attached to the snowboard. The bindings were adjusted at 21° and 6° rotation for the forward and backward leg respectively. The motion tracking system control box, batteries and laptop computer were carried by the snowboarder in a 20-pound backpack.

An anatomical calibration procedure was performed to calculate the spatial relationship between each sensor and a coordinate system defined on its corresponding anatomical segment (Della Croce, 1999). Bony landmarks on the shank and foot were palpated and measured with a Fastrak stylus through strategically located holes in the boots.

The trials consisted in snowboarding down a course of 10 turns and performing a sideways stop, on an intermediate-level slope of groomed snow. Each snowboarder was asked to perform 3 trials on a freestyle board with strap bindings and soft boots. The trials were measured with the motion tracking system at 120 Hz (30 Hz per sensor).

The recorded motion signals were smoothed using a two-pass second-order Butterworth filter. The rotation of the ankle through time was expressed in Euler angles with the feet considered as fixed in space.

RESULTS AND DISCUSSION

The analysis of the preliminary data obtained with two subjects showed consistent ankle range of motion in the frontal and sagittal planes. The inversion of the forward ankle and the eversion and dorsiflexion of the backward ankle (Figure 1) allow the snowboarder to shift his weight towards the tail of the snowboard. Radically different ankle range of motions were observed in the transverse plane. One subject had his forward ankle adducted (Figure 1) while the other had it abducted. Since the same standard binding rotation was imposed to all subjects, one might interpret this rotation as a shift of the shanks towards a more natural feet orientation in the transverse plane, which may differ between subjects.

The experimental method has proven successful and will be used to measure the effect of different types of snowboard boots and bindings on the ankle range of motion.

Figure 1: Range of motion of the ankle during snowboarding for one typical subject.

INTRODUCTION

Atherosclerosis is the most common occlusive disease of the lower limbs, which can lead to intermittent claudication, and sometimes amputation at a late stage. Angiography morphological diagnosis is often completed with the assessment of the perfusion dysfunction by means of two parameters across the constriction(s): the pressure drop ΔP and the peak systolic velocity ratio PSVR. However, the accuracy of Duplex ultrasound and the dilution of the contrast agent are the main clinical limitations in evaluating the impact of stenoses, especially in the presence of distributed disease. The present study is intended to model the complex 3D flow field in pathological femoral segments to determine whether these hydrodynamic indexes are influenced by the multiplicity of the stenoses.

METHODS

Numerical and experimental models of flow are performed in idealized models of multistenosed femoral artery (Figure 1). The influence of varying the interstenotic distance, the distal stenosis severity and the inlet flow rates upon ΔP and PSVR are specifically analyzed. The Navier-Stokes equations are numerically solved with finite element method using the FIDAP package (Fluent Inc, Lebanon, NH). Lower limb arteries are often submitted to flows at peak Reynolds numbers above 400. As transition to turbulence may be observed even at such low flow rate, the turbulent two-equation Wilcox model is implemented after testing laminar models. In this model, through dimensional analysis, the turbulent velocity and scale are related to the kinetic energy and turbulent frequency respectively by: $u_t \propto \sqrt{k}$ and $\delta_t \propto \sqrt{k}/\omega$, the turbulent dissipation being expressed by $\varepsilon = k\omega$.

Figure 1: Example of a double stenose mesh.

In vitro experiments are performed on a mock flow bench including a wall-less vascular phantom of the simulated

artery (made of agar gel), and a pumping system (Micropump, Cole-Parmer). Duplex ultrasonic velocity measurements and pressure tapes furnish respectively PSVR and ΔP clinical indexes.

RESULTS AND DISCUSSION

The pressure losses ΔP are showed to be mainly influenced by the most severe stenosis. Moreover, the presence of a double stenosis does not affect markedly this index ($\Delta P=24\text{mmHg}$ for a single 90% stenosis at $Re=588$ versus $\Delta P=26\text{mmHg}$ for a double stenosis 75%-90%). On the contrary, the PSVR is demonstrated to be more sensitive to interstenotic distance, flow rate and stenosis severity. Finally, differences between numerical and experimental results are noticed especially with axisymmetric (i.e. 2D flow) numerical assumptions. In contrast to Ang et al. (1995) or Pincombe et al (1999), successive deflections of the post-stenotic jet through double stenoses are observed, even at low Reynolds number (see Figures 2 and 3) that confirm the unstable and transient nature of such flows.

Figure 2: Duplex color longitudinal velocity in cross-planes.

Figure 3: Longitudinal evolution of PSVR with an interstenotic distance of 3 diameters. Comparison between experiments and 2D/3D numerical values of PSVR.

SUMMARY

By altering the value of PSVR, the presence of multiple stenoses may influence the diagnosis of the peripheral disease.

ASSESSMENT OF A NOVEL FEMORAL COMPONENT REMOVAL TECHNIQUE FOR REVISION SURGERY

M. Browne¹, M.C.Mowlem¹, J. Mountney², S. Kulkarni² and D.S. Barrett²

¹School of Engineering Sciences, University of Southampton, Southampton, SO17 1BJ, UK, doctor@soton.ac.uk

²Orthopaedic Dept, Southampton University Hospitals Trust, Southampton, SO16 6YD, UK

INTRODUCTION

In total knee replacement revision surgery, the femoral component may be found to be rigidly fixed to the bone. Careful and patient use of an osteotome in conjunction with a suitable extraction device may be required to loosen and remove the component. A novel technique has been developed, which has proven to be quick, simple and effective for removing a solidly fixed femoral component with minimal bone loss. In this procedure, the surgeon and the assistant each place an osteotome on the cement-metal interface at symmetric positions, directly opposite each other on the medial and lateral sides. They deliver synchronous blows with a mallet at positions around the interface until the cement fractures. The femoral component can then be removed easily.

The present research examines the events that occur during the traditional (single) and novel (double) osteotome techniques, and explains the effectiveness of the new technique in terms of the impact processes and energy absorption mechanisms experienced by the implant.

METHODS

Polyurethane mouldings, representing a suitable substrate for cementing metal components, were fixed onto a steel rod, of similar weight and length to a lower leg. Stainless steel discs (40mm diameter x 4mm thickness) were cemented onto the polyurethane substrate to form a representative model of an attached implant. The discs were instrumented to allow recording of the mechanical processes caused by the double extraction technique, and to allow comparison with the single osteotome extraction technique. Two accelerometers were used; one mounted on the top of the implant and one on the side. Therefore, the lateral and vertical acceleration of the implant could be monitored. Ten extractions using each technique (20 in total) were performed.

RESULTS AND DISCUSSION

A typical record of a blow from the single extraction technique can be seen in Figure 1. Large amplitude vibrations are seen at a frequency of approximately 15kHz; lower frequency components are also present and show a good deal of movement at the top of the implant. This blow did not result in the extraction of the implant. The double extraction technique shows a small delay between the striking of the two initial blows (Figure 2). This delay is large enough to allow the near complete decay of the high frequency components in the acceleration of the model. A third blow is also observed on the record of the lateral acceleration. The magnitude of the accelerations produced by the first blow is very similar to that

Figure 1 Typical record of the traditional extraction technique

Figure 2 Typical record of the novel extraction technique

observed when using the traditional technique. The accelerations caused by the second blow however, are significantly greater in magnitude. This is caused by the movement of the implant towards the osteotome that inflicts the second blow. The third blow is a result of a reverse in the direction of motion of the implant following the second blow, and as a consequence it contacting with the osteotome that inflicted the first blow again. The maximum lateral movement is reduced by this technique. This results in less energy loss. Accelerations caused by the first and second blows are experienced by the implant; however, the third blow causes no acceleration, as by this time the implant has been extracted.

SUMMARY

The methodology described has successfully demonstrated that the double osteotome technique increases the contact force of the second blow. When the synchronous blows are delivered, less energy is expended in the movement of the tibia and more is contributed to the removal of the component. In many instances a third blow is also noted; this will be a factor in the easier extraction observed in revision procedures.

ANALYSIS OF SAGITTAL BALANCE OF THE SPINE DURING VARIOUS STANDING POSITIONS AND GAIT

Michelle Marks, Chriss Stanford, Andrew Mahar, and Peter Newton

Motion Analysis Laboratory, Children's Hospital, San Diego, California
mmarks@chsd.org

INTRODUCTION

Global sagittal spinal alignment is described by the sagittal vertical axis (SVA), and is measured on a lateral x-ray by the horizontal distance from the posterior superior corner of the sacrum to the plumb line dropped from the center of the body of the C7 vertebra.¹ Measurement of SVA on a lateral radiograph can change with subtle variations in posture.

Numerous positions for lateral x-rays are utilized in the literature², but there is no universally accepted position. Acquisition of a standing x-ray that allows visualization of the spine requires flexion of the shoulders, preventing the patient from assuming a functional position. The purpose of this study was to examine differences in SVA during relaxed standing and walking to SVA during positions assumed during x-ray acquisition.

METHODS

Fifteen healthy females, ages 10-14 years were enrolled in this study. Reflective markers were attached to the skin overlying the spinous processes of C7 and L4, and on the right heel. Positions of the markers were captured by an 8-camera Motion Analysis System (Motion Analysis Corp., Santa Rosa, CA) at 60 Hz during simultaneous acquisition of a standing lateral radiograph, with each subject positioned with 45° of shoulder flexion. The horizontal distance between the C7 and L4 markers was measured using motion capture data. Distances between the markers and landmarks used for SVA measurement were also measured on each x-ray. A correction was developed to match SVA values between measurement techniques. This allowed for measurement of SVA during experimental positions (Table 1) without subsequent exposure to radiation. Mean SVA for each position and during the gait cycle were compared using a repeated measures ANOVA ($\alpha=0.05$). Relaxed standing was chosen as a basis for comparison because it is an easily assumed and functional position.

RESULTS AND DISCUSSION

SVA means and standard deviations for the various postures are displayed in Figure 1a. Positive SVA values indicate a forward positioning of the seventh cervical vertebrae over the

posterior aspect of the sacral endplate. Results of the ANOVA indicate that SVA measures for positions 2 and 4 were significantly less ($p<.01$) than for relaxed standing. Flexion of the shoulders causes C7 to shift posterior relative to the pelvis, suggesting a postural compensation by the trunk to maintain upright posture. In contrast, flexion of the knees exerts a positive influence on SVA, though it does not effectively balance SVA when combined with shoulder flexion.

Figure 1a-b: Mean SVA for standing positions 1-4 (a) and during the gait cycle (b) for 15 subjects.

Figure 1b displays mean SVA throughout the gait cycle. Mean SVA during gait exhibited a significant increase, compared to relaxed standing ($p<.01$). SVA during the gait cycle displays a pattern similar to sagittal plane trunk motion³, with maximum forward alignment occurring prior to heel strike.

SUMMARY

Adolescent females have a positive SVA during relaxed standing and walking. Sagittal balance of the spine may not be assessed effectively on a lateral radiograph, as positions required for visualization of the spine are not representative of functional postures.

COMPARISON OF MODELS FOR THE STRESS-STRAIN RELATIONSHIP OF SOFT TISSUE

Cara L Lewis, Mary K Hastings, Joe W Klaesner, Dequan Zou, Michael J Mueller¹

¹Movement Science Lab, Program in Physical Therapy, Washington University School of Medicine, St. Louis, MO, USA
clewisa@artsci.wustl.edu

INTRODUCTION

Multiple models have been used to characterize the material properties of soft tissue. Common models include the use of a first order or second order exponential or the Voigt model. A parallel three-element model can also be used to quantify soft tissue stiffness with a nonlinearly elastic component (Klaesner et al 2002). The purpose of this study is to model the stress-strain relationship of the soft tissue under the 3rd metatarsal head using an exponential model, the Voigt model, and the parallel three-element model, and to determine the model with the best fit.

METHODS

Data: Force-displacement data from the soft tissue under the 3rd metatarsal head were collected on 40 subjects (age 55.56 ± 10.08 years; 28 male, 12 female) using a force transducer mounted to a three-dimensional measurement device (Klaesner et al 2001). Only trials with a consistent velocity ($R^2 > .95$) over the force range from 2 to 9 N were accepted. Force and position data for 3 trials were collected and analyzed using software developed in the lab. Data were then converted to stress-strain data. Stress (σ) was determined by dividing the obtained force by the area over which that force was applied (i.e. the tip of the indenter device). Strain (ϵ) was determined by dividing the displacement by the initial thickness of the soft tissue as measured using a CT Scan.

Modeling: Exponential model: MATLAB software was used to determine the appropriate constants to produce an exponential model to fit the data. A first degree polynomial, fitting the strain to the natural log of the stress ($\ln \sigma = p(\epsilon)$), was used to produce coefficients p_1 and p_2 . The first order exponential formula, as listed in Table 1, was used to predict the stress at each data point using the obtained strain. The data were then fit with a second degree polynomial, again using MATLAB. This produced coefficients q_1 , q_2 , and q_3 from which the stress at each data point was predicted using the obtained strain. **Voigt model:** The Voigt model is composed of a spring and dashpot in parallel. The spring constant K and coefficient of viscosity C were computed, and these constants

were used to predict the stress at each strain level. **Parallel three-element model:** The parallel 3-element model quantifies soft tissue stiffness using a single linear spring element in parallel with the Voigt model. During the initial displacement, X_s , the stress is modeled as linear elastic behavior, engaging only the single spring. After the initial displacement, the Voigt model portion, consisting of a linear spring in parallel with a dashpot, engages. A computer program developed in the lab was used to determine X_s and the constants, K_1 , K_2 , and C for this model. Using the constants and the formulas listed in Table 1, the stress at each data point was predicted.

Analysis: The unbiased standard error was calculated for each model for each trial and averaged over the three trials and 40 subjects. The correlation coefficient (R^2) between the predicted and obtained stress was also calculated for each trial and subject, and averaged for each model.

RESULTS AND DISCUSSION

As indicated in Table 1, the Parallel 3-element model has the least error and the highest R^2 . We propose that the parallel 3-element model has the added advantage of having a physiological basis. We speculate that K_1 represents the initial stretching of collagen fibers in the plantar soft tissue, while K_2 is attributed to compression of soft tissue and the constant C to fluid displacement.

SUMMARY

Although all methods resulted in low error, the parallel 3-element model produces the best fit for the stress-strain data. Accurate representation of the material properties of soft tissue is essential for finite element modeling of the foot.

NUMERICAL MODAL ANALYSIS OF CEMENTED FEMUR COMPONENT OF TOTAL HIP REPLACEMENT

Gang Qi¹ and W. Paul Mouchon

Department of Mechanical Engineering, The University of Memphis, Memphis, TN, USA
¹gangqi@memphis.edu

INTRODUCTION

A technique of vibration analysis has been utilized to study loosening of total hip arthroplasties (THA) [Georgiou,2001; Li, 1995]. However, the potential capabilities of this technique on this particular application was not demonstrated clearly in those studies due to the complexity of the problem. The aim of this work is to explore its capabilities using finite element method (FEA) evaluating the femoral component loosening.

METHODS

Various ideal interface failure models were constructed. Each model was composed of four components: bone, cement mantle, interface, and implant stem. The only difference of the models is the failure sizes and locations at the cement-stem interface. The models were constructed in the following manner. A human femur cadaver was first measured. The model was constructed from representative cross sections of the femur. Using these sections, the configuration of the femur was created by the advanced feature generation of a computer aided design (CAD) package, Pro/Engineer (Parametric Technology Corp, Waltham, MA). An uncollared straight stem was selected and modeled. The cement mantle was generated accordingly to fit the shape of the stem and the bone. A minimum of 4 mm wall thickness of the cement was maintained. A thin interface layer of 0.2 mm thickness was generated between the stem and cement mantle. The four components were then assembled automatically using the same CAD package (Fig.1). An Algor (Algor Inc., Pittsburgh, PA) FEA package was used to conduct the study.

RESULTS AND DISCUSSION

The fundamental frequency of the control model was 115.750 Hz. In comparison with the clinical data (102.3 Hz [1]), and with the in vitro result (110-115 Hz [2]), the presented results were close. The model used in this work is a fair representation of the reality. There was no significant difference of the first two natural frequencies between the control model and models with various interface failures. However, these differences became significant at harmonics above the 3rd natural frequencies. The differences increased as the magnitude of the natural frequencies increased. Also, it is observed that the proximal interface failures effected the natural frequencies greater than distal interface failures. Fig.2 shows the first seven natural frequencies compared with the control model. These modal changes revealed a mechanism of the THA construct softening due to the interface failure. Preliminary

runs or FEA with varying data indicate the present finding can be extended to varying THA constructions.

CAD model of THA

Fig.1: The real THA model generated by Pro/Engineer. Left: assembled model; Right: exploded view of the THA model. Dimensions are all in mm.

Differences in the Natural frequencies

Fig.2: Effects of the failure size on first seven natural frequencies when the interface failure were at the proximal area, where control, t14p, t13p, t12p, t23p, and t56p were the data of control 1/4, 1/3, 1/2, 2/3, and 5/6 stem proximal interface failed, respectively.

SUMMARY

The traditional vibration modal analysis could be used to identify THA loosening. This technique will be more sensitive at high frequency range. However, direct modal analysis failed when the failure length was less than 1/6 of the stem length.

COMPUTER SIMULATION OF VIBRATIONAL DIAGNOSIS OF THA LOSSENING

Gang Qi¹ and W. Paul Mouchon

Department of Mechanical Engineering, The University of Memphis, Memphis, TN, USA
¹gangqi@memphis.edu

INTRODUCTION

A numerical modal analysis provides information regarding THA loosening in terms of the magnitudes of the natural frequencies. However, indicators are needed in order to quantify the characterization of the acquired signals. The aim of this work is to conduct a computer simulation using synthesized vibration data to demonstrate a method to diagnose the THA loosening due to cement-stem interface failures.

METHODS

The multi-harmonic sinusoidal signals were synthesized according to the modal analysis. These signals represented the ones acquired by an accelerometer in a real test. Considering the fact that high harmonics may not be detectable, only the first ten natural frequencies were used in the synthesis. To count for unknown interference on the signals, random numbers were generated to emulate the real time white noise and were added to the signals. As an example, the signals of control and 1/5 proximal interface failure models were synthesized. The FFT and wavelet analysis were employed [Qi, 2000]. The phase angle and histograms of the signal wavelet decomposition components were used to illustrate the methodology of signal characterization.

RESULTS AND DISCUSSION

Fig.1 shows the spectra of three synthesized signals. It was observed that the spikes of higher harmonics indicated THA softening due to interface failure. A trend of higher harmonics shifting from right to left of the abscises indicated THA structural softening due to the interface failure.

Fig.1: Spectra of synthesized signals of control (top curve) and 1/5 proximal interface failure (bottom curve).

The phase angle of the spectra can also be used as an indicator to quantify the loosening as shown in Fig.2.

Fig.2: Phase angles of the spectra of the previous figure

Because the difference between the control and 1/5 model was not significant especially at lower frequency range, the wavelet decomposition was employed. Table 1 shows the histograms of the detail coefficients. The mean and maximum values of the decomposed wavelet coefficients provided another potential indicator that could be used to characterize the THA loosening.

Statistical characteristics		Mean	Maximum	Standard Deviation
Control Model	Detail level 1	1.765×10^{-4}	0.1218	0.04183
	Detail level 2	5.001×10^{-4}	0.3394	0.1169
	Detail level 3	14.24×10^{-4}	0.7943	0.3149
1/5 proximal interface failure	Detail level 1	1.112×10^{-4}	0.12	0.04154
	Detail level 2	3.146×10^{-4}	0.3338	0.1161
	Detail level 3	8.9×10^{-4}	0.9106	0.313

Table 1. Wavelet coefficient histogram

SUMMARY

A computer simulation of vibrational diagnosis of THA loosening was conducted. The number of higher harmonics, phase angle, and wavelet coefficients can be used as indicators to quantify the severity of the loosening.

STRAIN RATE SENSITIVITY OF LIGAMENTS DIMINISHES AT TRAUMATIC LOADING RATES

Joseph J. Crisco^{1,2}, Douglas C. Moore¹, Robert D. McGovern¹

¹ Dept. of Orthopaedics, Brown Medical School/Rhode Island Hospital and ² Div. of Engineering, Brown University, Providence RI

E-mail: joseph_crisco@brown.edu

INTRODUCTION

Creep, stress relaxation, and load-displacement tests have provided insight into the viscoelastic properties of ligaments at relatively low rates of loading (e.g. Woo et al., 1981). However, the existing data does not adequately address how ligaments behave when they are loaded at high rates of strain, such as those seen in sports induced trauma or in motor vehicle accidents. This study was performed to determine whether ligaments behave viscoelastically at 'traumatic' loading rates. To do so, 1) the structural and failure properties of ligaments tested via impact were compared to the properties of ligaments tested quasi-statically, and 2) the properties of two impact tests were compared.

METHODS

After approval by our institution's Animal Welfare Committee, both hind limbs were harvested from twenty-seven skeletally mature New Zealand white rabbits and all muscular and ligamentous structures crossing the knee joint were carefully removed, with the exception of the medial collateral ligament (MCL).

Quasi-static Testing. One randomly selected MCL from each pair was tested to failure at 0.167 mm/s (10.0 mm/min) with the knee positioned in 90 degrees of flexion.

Impact Testing. The second MCL from each pair was tested to failure with a drop-mass impact device. To do so, the femurs were attached to a fixed piezoelectric load cell, and a 5 kg mass was dropped down a thin (1.6 mm dia.) guidewire suspended from the tibia. During testing, displacement and acceleration of the tibia was recorded with a fast response (35 μ sec) LVDT and piezoelectric accelerometer, respectively. Twelve ligaments were failed by releasing the drop mass from a height of 10 cm, and fifteen ligaments were failed by releasing the mass from a height of 70 cm.

Data Analysis. The load-displacement-time data from both the quasi-static and the impact tests were processed to yield values for displacement rate, loading rate, stiffness, failure load, displacement at failure, time to failure, and energy to failure. Paired Student's t-tests were used to compare the results generated via quasi-static and impact testing, and unpaired t-tests were used to compare the two impact tests. P values ≤ 0.05 were considered to be statistically significant.

Five MCL pairs were excluded from the analysis due to technical problems during testing.

RESULTS AND DISCUSSION

The displacement and loading rates of the impact-tested groups were significantly different than one another, and significantly greater than those of the quasi-statically tested specimens (Table 1). Accordingly, failure occurred more quickly in the 70 cm impact tests (1.8 ± 0.2 msec) than in the 10 cm impact tests (5.6 ± 0.9 msec), which in turn failed much more quickly than in the quasi-static tests (16.9 ± 6.3 sec). Despite dramatic increases in displacement and loading rate with impact testing, failure load and stiffness increased only nominally over quasi-static testing; there were no detectable differences in failure displacement (Table 1).

There were no differences in the structural or failure properties of the two impact-tested groups (Table 1). This was surprising, considering the displacement and loading rates of the 70 cm impact tests were nearly four times faster than the rates for the 10 cm impact tests.

SUMMARY

Our results suggest that ligaments are only minimally strain rate sensitive, since an increase in loading rate of several orders of magnitude produced no more than a 40% change in its mechanical properties. Furthermore, an incremental increase in impact loading rate did not lead to corresponding changes in ligament structural and failure properties. Taken together, these findings suggest that the strain rate sensitivity of the rabbit MCL diminishes at traumatic loading rates.

TIME DEPENDENT DEFORMATION DURING NANOINDENTATION TEST ON OSTEONIC LAMELLAE IN A HUMAN CORTICAL BONE

Zaifeng Fan and Jae-Young Rho

Department of Biomedical Engineering, ET330, University of Memphis, Memphis, TN 38152, USA
jrho@memphis.edu

INTRODUCTION

Nanoindentation has been utilized to investigate mechanical properties of bone at the microstructural level [4]. Although viscoelastic deformation was apparent in the creep displacements observed during the constant load hold period at peak load, most experiments were not evaluated viscoelasticity of bone. In the present study, the relationship between strain rate and elastic modulus was investigated to reveal time dependent deformation during nanoindentation test on osteonal lamellae in a human cortical bone.

METHODS

A bone sample was obtained from the midshaft of one human tibia (52 years old) with no bone disease. A Triboindenter (Hysitron, Inc. Minneapolis, MN) was utilized to conduct all the indentation tests. The Oliver-Pharr method [3] was used to determine the elastic modulus. Two load-time functions were used in this study:

A. Simple loading unloading (with different loading rates and same peak load)

B. Loading unloading three times in succession followed by a final loading and then a holding period applied before final unloading (with different loading rates and same peak load).

The loading rates of 10 μ N/s, 30 μ N/s, 50 μ N/s, 100 μ N/s, 300 μ N/s, 500 μ N/s and 1000 μ N/s were used to produce varied strain rates for each load function. All the indents were conducted in osteonic lamellae with roughly equal radial distance to Haversian canals [4]. For a geometrically similar indenter, such as Berkovich indenter, the indentation strain rate is typically defined as \dot{h}/h , which is the instantaneous change in displacement divided by the instantaneous displacement at the respective time point [2]. The load-displacement curves obtained from the two load functions are shown in Fig 1.

Figure 1: The load-displacement curves obtained from load function A and B

The shaded area (work) in-between the first loading and the final unloading curve reflects the plastic deformation.

RESULTS

In results from load function A, the elastic modulus and strain rate are found to hold the relationship as

$$E = 48.93 \left(\dot{\epsilon} \right)^{0.100}, \quad R^2 = 0.70$$

where E is the elastic modulus and $\dot{\epsilon}$ is the strain rate.

The ANOVA test result ($P < 0.0001$) indicated that significant differences existed in the works among the different loading rates. For load function B,

$$E = 37.74 \left(\dot{\epsilon} \right)^{0.059}, \quad R^2 = 0.94$$

The ANOVA test results ($P = 0.24$) indicated that no significant differences existed in the works for all loading rates.

DISCUSSION

It has been assumed that the unloading data are fully elastic recovery for quasistatic indentation measurement. The Oliver-Pharr method [3] is based on this assumption. The reason for performing multiple loading unloading was to examine the reversibility of deformation and thereby make sure that the unloading data used for analysis purposes were mostly elastic. The holding period performed at maximum load allows any final time dependent plastic effects to be diminished. In the results from load function B, the works for all different loading rates are found no statistic significance, which indicates that the plasticity variations are mostly diminished by multiple loading unloading and holding period at maximum load. The unloading curves are mostly composed by elastic portion. Interesting, the relationship between elastic modulus and strain rate was similar to that of the previous study [1]. However, the result from load function A was not consistent with the previous observation. The present study suggests that nanoindentation properties of bone should be obtained with carefully designed experimental procedures since it shows time dependent deformation during nanoindentation test on bone.

MUSCLE ACTIVATION LEVELS DURING RUNNING IN VARUS, VALGUS, AND NEUTRAL WEDGED SHOES

Kristian O'Connor¹, Thomas Price², and Joseph Hamill¹

¹Biomechanics Laboratory, University of Massachusetts, Amherst, MA, koconnor@excsci.umass.edu

²Department of Diagnostic Radiology, Yale University School of Medicine, New Haven, CT

INTRODUCTION

Nigg (2001) proposed that altering the motion of the foot from a preferred movement pattern would increase muscle activity. The extrinsic muscles of the foot contribute to supination of the foot and may apply a significant force to control foot pronation in the support phase of running. Altering the boundary conditions of the foot may lend insight into the role of these muscles. Functional magnetic resonance imaging has been used to detect changes in muscle activity post-exercise for static and dynamic resistance tasks (Price et al., 1998). It can also be used to detect differences in specific muscles. The purpose of this study was to use functional MRI to determine the changes in muscle activation caused by running in varus, valgus, and neutral wedged shoes (Milani et al., 1995).

METHODS

Six men performed five-minute running bouts in each of the three shoe conditions. The three conditions were presented in a random order. Subjects ran on a motorized treadmill at 3.6 m/s. MRI scans of the mid-calf were performed before and immediately after each running bout (< 2 minutes). The muscle activation levels were estimated by assessing the transverse relaxation time (T_2) of each muscle. This parameter has been shown to correlate with exercise intensity with higher workloads yielding higher T_2 measurements (Price et al., 1998). T_2 values before and after each running bout were calculated for the tibialis anterior (TA), tibialis posterior (TP), the peroneus (Per), medial (MG) and lateral (LG) heads of the gastrocnemius, the extensor digitorum (ED), and the soleus (Sol) (Figure 1).

Figure 1. Illustration of the selected muscles.

RESULTS AND DISCUSSION

A five-minute run increased the T_2 in most of the muscles examined (Figure 2). The soleus only increased minimally when compared to the rest condition. These six subjects did not demonstrate a systematic change in muscle activation levels in the three shoes.

Figure 2. T_2 changes for each muscle across conditions.

SUMMARY

No differences in T_2 were detected between shoes. These results indicate that there is little change in muscle activation patterns in the muscles that control foot motion when a perturbation is applied to the foot. Thus, it appears that the neuromuscular system may not need to alter control signals in response to these comparatively small perturbations.

INTRODUCTION

The mechanisms leading to loosening of cemented hip replacement and the role played by the polymethylmethacrylate (PMMA) bone cement in the failure process are not fully understood. Bone cement is believed to be one of the weak components of the cemented construct. Volumetric shrinkage during bone cement curing, due to the polymerisation process (the PMMA polymer is more dense than the MMA monomer), has drawn increasing attention, as it has been reported experimentally to be as high as 8% in volume and therefore a potentially significant source of porosity (Gilbert, 2000). It could also account for weaknesses within the cement, which could provide a path for cracks, resulting in crack deviation as observed by Topoleski et al. (Topoleski, 1993). This research aims to measure the residual stresses due to shrinkage in simulated in vivo conditions for further input into Finite Element (FE) models and experimental work.

METHODS

Two self-compensated strain gauges were fixed on a stainless steel rod of 120mm length and 12mm diameter. This allowed measurement of the hoop stresses at the surface of the stem (in contact with polymerising cement). Radiopaque CMW1 bone cement was mixed and syringed into a hollow cylinder made from TufnolTM of 16mm internal diameter. The rod was introduced into the polymerising cement using a servohydraulic Instron machine, and held steady. A thermocouple was used to monitor the temperature in the cement mantle and the hoop strains at the interface were measured until at least 40 minutes after first contact of the liquid monomer with the powder.

An axisymmetric FE model of the experimental setup was generated. A quasi-thermal technique was used to model shrinkage of the cement. By assigning an artificial linear coefficient of thermal expansion of 0.02, the required volume change (6%) in the cement could be induced by reducing the temperature by 1°C. The cement was assumed to be fully bonded to both implant and mould; this is likely to give an upper-bound estimate of curing induced residual strains.

RESULTS AND DISCUSSION

Using the FE model, the coefficient relating the strains at the interface and the stresses in the cement was obtained (Fig 1) and used to convert the experimental strains (Fig. 2) into interfacial residual stresses of around 10MPa in the cement. The curve shown in Fig 2 also shows stress relaxation of the cement following the polymerisation peak, which is thought to

be possibly due to creep or microcracking. The measured strains were much lower than the value obtained from the FE model. This discrepancy was thought to be due to (i) the level of porosity in the cement - porosity has been thought to 'compensate' for shrinkage (Gilbert, 2000) and (ii) possible cracking in the cement. For the present experiment any temperature effect on the gauges is believed to be negligible because the cement mantle was thin (2mm), and did not produce a significant temperature increase due to the heat sink effect of the rod.

Figure 1: Implant strains (left) and cement stresses, Pa (right).

Figure 2: Residual strain measurement during polymerisation

SUMMARY

A combined experimental and analytical method has been developed to estimate residual stresses in the cement mantle. Residual stresses due to shrinkage were found to be as high as 10MPa at the interface between the cement and the stem. Further FE analysis will attempt to develop the material model to more accurately describe the residual strain development, and predict initial stress levels in the cement.

INTRODUCTION

The interaction between blood flow and the transport of cholesterol through the arterial wall is critical in the formation of atherosclerosis in large arteries. A mathematical model has been developed to describe the early stages of the disease (intimal hyperplasia) and the evolution of fatty streaks which are the precursors to the formation of atherosclerotic plaques.

MODEL

The arterial wall is modelled by two layers, the intima and the media, through which cholesterol is transported. In the intima, cholesterol is converted to oxidised cholesterol that is consumed *in situ* by macrophages, which bind to the substrate and turn into fatty foam cells. These processes are described by

$$\frac{\partial c_L}{\partial t} = -\nabla \cdot j_I - k c_L \quad \text{and} \quad \frac{\partial c_{LO}}{\partial t} = k c_L - \gamma c_{LO},$$

where c_L and c_{LO} are the concentrations of native cholesterol (L) and oxidised cholesterol (LO) in the intima. k is the rate of conversion to LO and γ is the constant background decay rate for LO . j_I is the flux of L in the intima and is given by

$$j_I = -D_I \cdot \nabla c_L - c_L U \chi_I \hat{z},$$

where D_I is a diffusion tensor, χ_I is the slip coefficient (the mean velocity of the molecule relative to that of the fluid), $-Uz$ is the mean fluid velocity through the vessel wall, which is taken to be constant. No conversion takes place in the media which has relatively low diffusion and advection coefficients and thus acts a barrier to the transport of cholesterol so that the governing equation is

$$\frac{\partial c_M}{\partial t} = -\nabla \cdot j_M,$$

where $j_M = -D_M \cdot \nabla c_M - U \chi_M \hat{z}$, c_M is the concentration of L in the media, D_M is a diffusion tensor and χ_M is the slip coefficient.

The key concepts are that the permeability, κ , of the endothelial layer (which lines the artery) to cholesterol in the blood depends on the local wall shear stress due to the flow of blood, and that the presence of LO in foam cells leads to swelling of the arterial wall and changes the flow producing a feedback mechanism. Specific functional forms need to be

specified for these two processes. As a first step, the permeability of the endothelial cells is given by the quadratic formula

$$\kappa = \kappa_0 (\tau - \tau_0)^2 + \kappa_{\min},$$

where τ_0 is the value of the wall shear stress giving the minimum endothelial permeability, and τ is the wall shear stress. This functional form gives high permeability at both low and very high wall shear stresses but in most of our simulations $\tau < \tau_0$. The swelling of the arterial wall is described by a simple first order process in which the increase in the height of the endothelium is made proportional to the excess of LO in the intima below it i.e.

$$h(x, t) = \eta \int_{-H_I}^h [c_{LO}(x, z, t) - c_0(x, z, t)] dz$$

when the integral is positive and $h = 0$ otherwise. Here η is a constant, h is the height of the endothelial layer above the mean height $z = 0$, H_I is the depth of the intima, and c_0 is the background concentration of LO within the intima.

RESULTS

Both steady and pulsatile flows have been simulated in a 2D channel, using standard asymptotic results for high Reynolds number flows [1,2], together with steady flow in a 3D model. The results confirm that changes in the structure of the wall with age increase the likelihood of the incidence of atherosclerosis, and show a good correlation between the most common sites of atherosclerosis in man and the persistence of fatty streaks when we use the physiological parameter values for those sites in our model. We also find an unexpected connection with the early stages of the formation of another important arterial disease — abdominal aortic aneurysms.

DETERMINING NEUROMUSCULAR CONTRIBUTIONS TO ACL INJURY RISK VIA COMPUTER SIMULATION

Scott McLean¹, Anne Su¹ and Anton J van den Bogert¹

Department of Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland, USA
mcleans@bme.ri.ccf.org, <http://www.lerner.ccf.org/bme/>

INTRODUCTION

During a number of sporting postures, the knee joint may be subjected to complex dynamic motions (eg., cutting and pivoting), generating large loads that have the potential to cause anterior cruciate ligament (ACL) injury. Cadaveric studies have provided some insight into potential mechanisms of ACL injury (Markolf et al., 1995). However, research of this type cannot reproduce the muscle forces and whole body dynamics typical of in vivo motion in young healthy individuals. The *in vivo* mechanical response of the ACL has been investigated via instrumentation for non-hazardous movement and load conditions (Beynnon et al., 1997). These data cannot be extrapolated, however, to understand injury mechanisms. With proper validation, computer simulation offers the potential to quantify ACL loads during potentially hazardous dynamic motion, while controlling all aspects of neuromuscular control. The purpose of the current study was to simulate the effects of variability in neuromuscular control (NMC) parameters during sidestepping on ACL load and hence, determine their relative contributions to ACL loading and the subsequent risk of injury.

METHODS

A previously described and validated 3D lower limb model capable of estimating ACL load during the stance phase (0-200ms) of a sidestep (McLean et al., 2001) was used in the current study. Model inputs were obtained from initial contact 3D linear and angular kinematic positions and velocities, and GRF data measured across 10 sidestep trials in a single subject. Excitation patterns for each muscle group (n=11) were described by five optimized (simulated annealing) parameters, specifying the level of muscle stimulation at fixed (50 ms) increments from initial ground contact (t=0). ACL force for the optimized system was derived from the A-P constraint force between the tibia and femur, combined with the quadriceps and hamstrings muscle forces acting across the joint. Monte Carlo simulations (N=50000) were performed to determine the effect of measured variability in pre-impact body segment positions and velocities, and variability in quadriceps and hamstring activation on peak ACL force. Data were then submitted to a stepwise linear regression analysis to determine the relative contributions of each of the control variables (9 positions, 12 velocities and 2 activations) to peak ACL load.

ACKNOWLEDGEMENTS

Funded by NIH (AR47039)

RESULTS AND DISCUSSION

Monte Carlo simulations produced a mean peak ACL force of $132 \pm 168\text{N}$, with 101 of these simulations demonstrating a peak ACL force of greater than 800N (Fig 1). Regression

Figure 1: Effects of variability in NMC on peak ACL force.

results revealed that 65% of the control variables had a significant effect on peak ACL load ($P < 0.005$), with quadriceps and hamstring activation and knee angle having the greatest influence (Table 1, Fig 2). The current method presents a means of quantifying the relative contributions of key NMC input variables to ACL force, while concurrently incorporating the effects of dynamic body motion. Computer simulation further enables the impact of each variable on ACL injury risk potential to be identified. Work in progress involves the incorporation of “out of plane” (varus-valgus and internal-external) external torques into the model, in order to provide a more realistic estimate of ACL force.

Figure 2: Peak ACL force versus % variation from optimized quads activation level during a simulated sidestep.

Table 1: Stepwise linear regression of the relative contributions of key NMC variables to ACL loading. The coefficients indicate the sensitivity of peak ACL force average (in N) to one unit change in input variable.

Input Variable	Coeff	T-Value	P
Quad Activation	216.9	174.46	0.000
Hams Activation	-160.3	-127.83	0.000
Knee Angle	731	52.32	0.000

A GENERAL WEIGHTED LEAST SQUARES METHOD FOR INVERSE DYNAMIC ANALYSIS

Anne Su and A.J. van den Bogert, bogert@bme.ri.ccf.org

Department of Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland OH

INTRODUCTION

Results of the conventional recursive method for Newton-Euler inverse dynamics (Winter, 1979) depend on the order in which the linked model is traversed. Kuo (1998) proposed an alternative method, solving joint moments from the overdetermined system of motion equations for the entire system while satisfying the boundary conditions for a postural control model. The method finds a set of joint moments that best agrees (in the least squares sense) with available measurements that have a known error variance. Having redundancy in the system of equations is attractive when certain measurements are unreliable, or even unavailable such as in instrumented treadmills with only vertical force transducers. With complete data, Kuo demonstrated about a 30% noise reduction compared to the conventional analysis. We have further developed this least squares inverse dynamics (LSID) method to be no longer restricted to systems with one fixed segment, which necessitated a new method to derive optimization weights using Monte Carlo simulations. The method was implemented as a general software tool that allows arbitrary 3-D or 2-D models to be defined, and generates and solves the equations automatically.

METHODS

The general computational method is as follows. A kinematic model is set up in Mocap Solver (Motion Analysis Corp., Santa Rosa CA), which solves generalized coordinates $\mathbf{q}(t)$ from marker trajectories. First and second derivatives of $\mathbf{q}(t)$ are obtained using smoothing splines (Woltring, 1986). From Mocap Solver the model is exported as an input file for SD/FAST (PTC, Needham MA), which was used to generate the dynamic equations of motion in the following form:

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} = \mathbf{A}(\mathbf{q}) \cdot \boldsymbol{\tau}_u + \mathbf{B}(\mathbf{q}) \cdot \boldsymbol{\tau}_k + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) \quad (1)$$

where $\boldsymbol{\tau}_u$ are all unknown forces and moments, typically the joint moments, and $\boldsymbol{\tau}_k$ are all known forces and moments, typically the force platform data. The number of unknowns in $\boldsymbol{\tau}_u$ is usually smaller than the number of equations (degrees of freedom), and a weighted least squares solution can be obtained by solving the overdetermined system:

$$\mathbf{A} \cdot \boldsymbol{\tau}_u = \mathbf{b} \Rightarrow \text{minimize } [(\mathbf{A} \cdot \boldsymbol{\tau}_u - \mathbf{b})^T \mathbf{W} (\mathbf{A} \cdot \boldsymbol{\tau}_u - \mathbf{b})] \quad (2)$$

with a weight matrix \mathbf{W} that is the inverse of the error covariance matrix. A Monte Carlo simulation of error propagation is used to compute \mathbf{W} from assumed error levels in marker coordinates and force plate signals. The unknown forces and moments $\boldsymbol{\tau}_k$ are solved from (2) using QR decomposition (Golub and Van Loan, 1989).

The method was evaluated using force plate and kinematic data generated by a 2-D forward dynamic rigid-body walking model (Gerritsen *et al.*, 1998) with known joint moments. Noise of 2.0 mm was added to the marker data and 200 N in the horizontal ground reaction force data. Joint moments were

solved using the LSID software, for three cases: (1) using all available data and a 9-DOF model; (2) using only movement data (equivalent to top-down conventional approach); (3) using only lower extremity movement and ground reaction force (equivalent to bottom-up conventional approach). All data were low-pass filtered (10 Hz) before processing.

RESULTS AND DISCUSSION

Figure 1 shows the joint moments calculated from Case (1), which represents the best results attainable using the LSID method. Results were quantified using root mean square (RMS) values as an indication of how close the calculated joint moments are to the actual joint moments. Table 1 shows a comparison of the RMS values for all cases.

Figure 1: Actual joint moments and LSID results (whole body model).

Table 1: Comparisons of errors in joint moments, using different methods.

method	RMS error (Nm) for right stance phase		
	hip	knee	ankle
whole body model, LSID	39.279	21.296	5.876
whole body model, no force data	80.753	102.153	124.881
lower extremity model, conventional method	60.909	32.790	7.892

It is concluded that the LSID method provides the best estimate of joint moments in the presence of imperfect measurements when compared to the conventional top-down method and conventional bottom-up methods.

LIGAMENT STRENGTH DOES NOT DECREASE WITH SUBFAILURE STRETCHES

Joseph J. Crisco¹ and Manohar M. Panjabi²

¹ Department of Orthopaedics and Division of Engineering, Brown Medical School/Rhode Island Hospital Providence, RI

² Department of Orthopaedics and Rehabilitation, Yale University School of Medicine, New Haven, CT

E-mail: joseph_crisco@brown.edu

INTRODUCTION

Sprains or incomplete injuries comprise 85% or more of all ligament injuries and can lead to degenerative joint disease. Despite this prevalence, there is a paucity of information on ligament sprain injuries. Previously, in an *in vitro* biomechanical experiment we found that stretching the rabbit ACL to 80% of the failure deformation (about 16-20% ligament strain) subsequently increased laxity, but had no effect on failure load and deformation (Panjabi et al., 1996). We define a prior ligament stretch that is less than failure deformation as a subfailure stretch. The purpose of this study was to develop a phenomenological mathematical model of subfailure ligament injury in an attempt to better understand these experimental findings and ligament sprain injury mechanisms.

METHODS

The ligament model was composed of 250 (n) parallel fibers. Each fiber was ideally elastic with two distinct linear phases fully characterized by four parameters: initial stiffness K_1 , toe deformation D_T , final stiffness K_2 , and failure deformation D_F . Both K_1 and K_2 were assumed constant for all fibers, and had values of 0.001% and 1.0%, respectively, of the total ligament stiffness. In contrast, the deformations D_T and D_F were randomly selected from normal distributions of $40\% \pm 10\%$ and $110\% \pm 30\%$, respectively.

All load and deformation values are defined as a percentage of the failure (peak) load (100%) and deformation at failure (100%) of the intact ligament model, i.e. the model without a subfailure stretch.

Subfailure stretches of 20, 40, 60, 80, and 100% were modeled and their effects on the load-deformation (L-D) curve of the intact model were studied. L-D curves were calculated by incrementally increasing the deformation D , determining the load each fiber i generated (l_i), and then summing the n fiber loads to determine the load generated by the total ligament (L):

$$L = \sum_{i=1}^n l_i = D \sum_{i=1}^n K(D).$$

For each fiber i , the stiffness K was a function of D , such that

$$\begin{aligned} K(D) &= K_1, \text{ if } D < D_T, \\ K(D) &= K_2, \text{ if } D_T < D < D_F, \\ K(D) &= 0, \text{ if } D_F < D. \end{aligned}$$

In the subfailure models, fibers that had failed with subfailure stretch were identified and their stiffnesses set to zero. The

complete L-D curve was then recalculated from a zero deformation.

RESULTS

Failure load did not decrease even when the subfailure stretch reached 100% (Table 1). Ligament laxity (deformation at 5% failure load) increased for stretches beyond 40%, while fiber failure increased continuously in an exponential manner.

Table 1. Although fiber failure increased continuously, failure load was not affected by subfailure stretches (stretches less than 100%). Increases in ligament laxity initiated at about 40%. Subfailure stretch is the percentage of the deformation at failure (peak) load of the intact model. Failed fibers are a percentage of the total number of fibers, failure loads are a percentage of the intact failure load, and laxities are listed as deformation at 5% of intact failure load.

Subfailure Stretch	Failed Fibers (%)	Failure Load (%)	Laxity (%)
20 %	0.4	100	32.5
40 %	2	100	32.5
60 %	8	100	33.3
80 %	15	100	34
100 %	34	100	36.8

DISCUSSION

The model of subfailure stretches predicted unchanged ligament strength with some increase in ligament laxity. This finding of no change in failure load is in agreement with previous experimental work (Panjabi et al., 1996). One interesting finding was the small effect on the L-D curve due to subfailure stretches less than 80% deformation, despite failure of 15% of the fibers. We postulate that low magnitude subfailure stretches may be a mechanism for stimulating biological maintenance and repair of a ligament. In the future, this finding may be validated by *in vivo* studies which would correlate a biological/inflammatory response to a low-grade subfailure injury.

A THREE-DIMENSIONAL MATHEMATICAL DYNAMIC SIMULATION OF THE KNEE EXTENSION EXERCISE: EFFECTS OF ANTERIOR CRUCIATE LIGAMENT INJURY

Dumitru I. Caruntu and Mohamed Samir Hefzy

Biomechanics Laboratory, Department of Mechanical Industrial and Manufacturing Engineering,
The University of Toledo, Toledo, U.S.A., mhefzy@eng.utoledo.edu

INTRODUCTION

Most of the anatomically based models of the knee joint are either for the tibio-femoral joint (TFJ) or the patello-femoral joint (PFJ). Also, most of these models are static or quasistatic. The only dynamic anatomical model that includes both joints is two-dimensional (Tumer and Engin, 1993). The only 3-D anatomical dynamic model available in the literature is for the TFJ and allows only for rigid contact (Abdel-Rahman and Hefzy, 1998). This paper presents a 3-D anatomically based dynamical model of the knee joint including both TFJ and PFJ. The model allows for deformable articular contact and for the wrapping of the quadriceps tendon around the femur at large flexion angles. Simulations were conducted to study the knee response during a knee extension exercise following an anterior cruciate ligament (ACL) injury.

METHODS

In the analysis the femur was fixed, while both tibia and patella underwent a general 3-D motion due to a forcing function applied to the quadriceps tendon. The twelve degrees of freedom describing TFJ and PFJ motions were defined using two joint coordinate systems (Abdel-Rahman and Hefzy, 1998, and Hefzy and Yang, 1993) and include 3 rotations and 3 translations for each of the tibia and patella. A simplified contact theory was used to allow for deformable contact at the articular surfaces.

Figure 1: Initial and final positions

Along with the posterior capsule, the lateral and medial collaterals, and the anterior and posterior cruciates were modeled using 12 nonlinear spring elements (Abdel-Rahman and Hefzy, 1998). The patellar tendon was modeled as a linear spring. Coons' bicubic surface patches were employed to allow for piecewise mathematical representation of the femoral, tibial and patellar articular surfaces (Hefzy and Yang, 1993). The dynamic response was obtained by solving a

system of nonlinear differential algebraic equations using DASSL, a solver developed by Lawrence Livermore National Laboratory. Model calculations were conducted to simulate a knee extension exercise and to predict the effects of ACL injury. The quadriceps force was specified using Grood, *et al.*'s (1984) experimental data where its value increased from 75 N at 90° of flexion to 200 N at 50°, remained constant to 10°, and then increased rapidly to 350 N at full extension.

RESULTS AND DISCUSSION

Figures 1.a and 1.b show the specified initial positions and the predicted final positions, respectively, of the tibia and patella as they moved along the femur during the dynamic simulation for an intact knee. When both fibers of the ACL were cut, the anterior tibial displacement increased between 2.2 mm and 3.5 mm in the last 30° of knee extension, which is in agreement with Grood, *et al.*'s (1984) data. The maximum increase of 3.5 mm occurred at 15° with an increase of 2.4 mm at 0° flexion. This is in agreement with Shoemaker and Markolf's data (1985) reporting that the anterior laxity at 20° of flexion was somewhat greater than that seen at full extension.

SUMMARY

Since most injuries to the knee involve dynamic loads, this comprehensive 3-D mathematical and anatomically based dynamic model provides a valuable tool to study the underlying mechanisms for different knee injuries. The model was tested by simulating the knee extension exercise, a common rehabilitation regiment. The predicted significant anterior laxity in ACL-deficient knees during terminal extension suggests that this exercise may be detrimental. Keeping in mind that such an activity involves large joint compressive force, secondary ligament restraints may be stretched and/or the joint's articular cartilage could be damaged. Further simulations need to be conducted to determine the effects of extending intact and ACL-deficient knees with resistive weights placed at the foot.

CENTER OF MASS DISPLACEMENT DURING GAIT: NORMAL AND MYELOMENINGOCELE

Elena M. Gutierrez^{1,2}, Åsa Bartonek², Yvonne Haglund-Åkerlind^{1,2}, Helena Saraste^{1,3}

INTRODUCTION

The Center of Mass (CM) motion represents the movement of the body as a whole in a kinematic strategy and can provide information about mechanical work required in forward propulsion. CM analyses in gait have often been limited to displacements, not position, and CM has at times been assumed as stationary in the pelvis (Inman et al, 1981). An understanding of the effects weakness and compensatory mechanisms have on the CM movement can provide information about strategies to optimize forward progression.

METHODS

In this study, 28 self-ambulating subjects with myelomeningocele (MMC, 6-17 years, mean age 10.4 years) and 14 healthy controls (5-12 years, mean age 10.7 years) were tested in 3-D gait analysis and strength was tested with a Manual Muscle Test. The subjects were divided into 5 muscle strength groups with Group 5 having the least muscular weakness (plantarflexors only) and Group 1 the most (below knee plus hip abductors and extensors). Distribution was as follows: Group 5: N=9, Group 4: N=6, Group 3: N=3, Group 2: N=6, Group 1: N=4. Gait analysis with a full-body (15 segment) marker set was performed (Vicon® 512, Plug in Gait Model). The CM was defined as the centroid of the segments. Five stride cycles for each subject were analyzed. Peak-to-peak movement of the CM in the medio-lateral and vertical directions was determined and normalized by each individual's average leg length, and mean displacements were compared for the different muscle-strength groups.

The CM transverse movement within the pelvis was calculated as the CM position relative to the midpoint between hip joint centers and rotated by the pelvic rotation angle, and was normalized to each subject's inter-hip joint center distance. A ensemble average of 5 strides was calculated for each subject.

RESULTS AND DISCUSSION

Medio-lateral CM displacement was larger in the MMC

subjects as compared to normal and increased with muscle weakness (Figure 1). Vertical CM displacement displayed a non-linear relationship to muscle strength group and was greatest in Groups 3 and 4. The CM was observed to travel much further within the pelvis in the transverse plane in MMC subjects than in controls and varied both in distance traveled and in overall position (Figure 2).

Figure 1: Peak medio-lateral and vertical CoM displacement (+ 1 SD) as a function of decreasing muscle strength groups.

The ability to displace CM minimally during gait is sacrificed in MMC due to compensatory movements resulting from muscle paresis. The increase in medio-lateral CM movement in MMC results from excessive lateral trunk and pelvis motion. The vertical CM displacement in MMC is increased in Groups 3 and 4, probably due to weak plantarflexors and lack of loading response, and is decreased in Groups 1 and 2, likely due to reduced sagittal plane motion. The strategy with weak hip abductors and extensors is for a less anteriorly-positioned CM in which, due to large pelvic rotations, forward progression is enabled through lateral movements. There is, furthermore, little doubt that the CM cannot be assumed stationary in the pelvis during gait in persons with MMC.

DIFFERENCES IN ANKLE AND KNEE JOINT STIFFNESS BETWEEN STRENGTH-TRAINED AND AEROBIC-TRAINED ATHLETES WHEN HOPPING AT A PREFERRED FREQUENCY

Gary D. Heise, Michael Bohne, Cheng-Tu Hsieh

School of Kinesiology and Physical Education, University of Northern Colorado, Greeley, CO 80639

E-mail: gary.heise@unco.edu

INTRODUCTION

McMahon and colleagues modeled the leg(s) in contact with the ground during hopping and running as a simple linear spring (Fig. 1). Leg stiffness (k_{leg}), the ratio of maximum force during foot contact to ΔL , has been linked to athletic performance. Mero and Komi (1986) found differences between top sprinters and less-skilled sprinters. Chelly and Denis (2001) showed a relationship between k_{leg} and maximal running velocity in a group of young, team handball players. In addition, Arampatzis et al. (1999) suggested knee joint stiffness plays an important role in efficient running.

Fig 1: Leg spring model (adapted from McMahon & Cheng, 1990).

In light of the aforementioned links to sprinting, an anaerobic activity, we investigated the difference in leg spring characteristics between two groups of athletes during hopping. Specifically, we hypothesized that leg stiffness and joint stiffnesses of the lower extremity would be higher in strength-trained athletes when compared with aerobic-trained athletes.

METHODS

Three strength-trained athletes and three aerobic-trained athletes volunteered as subjects. Each subject attended one test session which included a warm-up and preferred frequency hopping for 3 min. Ground reaction force (GRF) data and sagittal plane video records of hopping were collected.

Hopping frequency and k_{leg} were determined from force platform data (Farley et al, 1991). Joint stiffnesses were calculated from an inverse dynamics analysis. Kinematic data were synchronized with force data to produce net joint forces and torques (NJT) at the ankle, knee, and hip. Joint stiffness

was defined as the ratio of the change in NJT to joint angular displacement (Farley et al., 1998). Statistical comparisons were made with t-tests.

RESULTS AND DISCUSSION

NJT and angular displacement showed linear relationships at the ankle and knee joints, however, the hip joint did not and thus hip joint stiffness was not included in our analysis. Leg stiffness, ankle joint stiffness, and knee joint stiffness were 1.6-2.0 times higher in strength-trained athletes when compared with aerobic-trained athletes (Table 1). Hopping frequency and stiffness values were similar to those previously reported (Farley et al., 1998).

When comparing apparent spring constants, Luhtanen and Komi (1980) showed differences between trained long jumpers and untrained athletes while running. The differences found in the present study are also consistent with those who have identified a correlation between leg stiffness and sprinting performance, an anaerobic activity (Chelly & Denis, 2001; Mero & Komi, 1986). It remains to be seen, however, whether the difference in leg stiffness between groups is influenced more by the change in muscle activation or by the adaptation of muscle and tendon brought about by different forms of chronic exercise.

INTRODUCTION

Excessive subtalar joint (STJ) pronation has been linked to a progressive loss of motion in the first metatarsophalangeal (MTP) joint, referred to as hallux limitus or rigidus (Shereff, 1998). Although not demonstrated through previous motion analysis investigations, a transient restriction in motion at the 1st MTP joint resulting from excessive or prolonged STJ pronation, coupled with inadequate first metatarsal plantarflexion have been theorized to occur during normal gait (Roukis, 1996). Treatments aimed at minimizing the potentially detrimental effects associated with these abnormal movement patterns include foot orthotic therapies, special footwear and surgeries. In spite of the financial implications associated with these therapies, the kinematic relationships have not been verified through inter-segment foot analysis studies. The purpose of this study is to identify differences in kinematic coupling between hallux-first MTP joint dorsiflexion, calcaneal eversion and first metatarsal translation between normal and excessively pronated feet during the stance phase of walking.

METHODS

Fifteen subjects (8 females, 7 males) with a mean age of 22 years (range 19-24), and no history of first MTP joint pathology participated in the study. Eight subjects were classified as having "normal" foot structure; 7 subjects were defined as pronators based on a clinical orthopaedic examination. The Optotrak motion analysis system (Optotrak, Northern Digital, Inc) was used to collect three-dimensional position and orientation data of four modeled rigid body segments (hallux, first metatarsal, calcaneus, and tibia) during the stance phase of walking (Leardini, 1999). A minimum of ten walking trials were collected. Transformation matrices were generated that related the assumed constant orientation of the sensors to the anatomically based local coordinate systems established for the hallux, first metatarsal, calcaneus and tibia. A Cardan angle system of three ordered rotations (Z-Y-X) was used to extract angular information of the hallux relative to the first metatarsal (dorsiflexion/plantarflexion, Z-axis), the calcaneus relative to the leg (inversion/eversion, Y-axis) and the vertical translation (y-axis translation) of the distal metatarsal relative to the global coordinate system. Our findings challenge current theories regarding the link between excessive STJ pronation and the loss of first MTP dorsiflexion joint motion during gait. See Figure 1. Greater MTP dorsiflexion was demonstrated in the group of pronators.

In addition, metatarsal y-axis translation and peak values for calcaneal eversion were similar for both the normal and pronated feet.

Figure 1. Mean and standard deviation values for first MTP dorsiflexion (DF): pronators: 47 ± 3 degrees, normals: 38 ± 4 degrees; Calcaneal eversion: pronators: 7.8 ± 3 , normals: 5.3 ± 2.5 ; Metatarsal head (MTH) translation: pronators: 15 ± 2 mm, normals: 16 ± 3 mm.

SUMMARY

Our findings in a group of young adult pronators suggest that motion in the first MTP joint may be excessive, rather than restricted during normal walking gait. It is unknown whether these movement patterns may precipitate arthritic joint changes or if they vary with the aging process. Additional studies are warranted to further test movement patterns across the life span and re-evaluate the goals of current therapies for abnormal pronation in the young adult foot.

Rupture of atherosclerotic plaque is considered to be the principal initial cause of acute coronary syndromes. The biomechanics involved in plaque rupture are not fully understood, however it has been shown that mechanical stresses applied on different plaque constituents play an important role. Previous approaches have emphasized the direct relation between high stress concentrations on lipid pool boundaries and an increased probability of plaque rupture at the associated locations (Lee et al. 1993). Using 3D reconstructions from *in vivo* intravascular ultrasound (IVUS) clinical data, we present a study of the redistribution of non-ruptured plaque inclusions after angioplasty. The hypothesis is that certain reconfigurations could play a role in plaque vulnerability. For example, lipid extrusion and infiltration within the plaque could lead to a more inflammatory condition, and rearrangement of constituents may affect global structural integrity.

Clinical cases with pre-angioplasty, post-angioplasty and 6-month follow-up data were selected. Segmentation of *in vivo* sequences from IVUS images was manually performed to obtain geometrical contours for the vessel wall and plaque architecture. The contour data was processed in Matlab and exported to Pro/Engineer CAD software to generate a realistic 3D model of the wall and intraplaque complex structure. Mechanical properties of the different constituents (from existing literature), boundary conditions and load due to blood pressure were then incorporated into the model, and structural analyses were performed using Pro/Mechanica. Stresses, strains, and other mechanical measures around boundaries between different constituents were obtained, and regions of high stress concentrations were identified. Post-intervention geometries and locations of maximal stresses, which are possible indicators of increased vulnerability, were compared to those obtained in pre-intervention models.

The 3D reconstructions have introduced an element of perspective to commonly used IVUS 2D visualization methods, and have been useful in determining a global picture of plaque geometry.

Figure 1: Fringe plot showing maximum principal stress on the boundary between inclusion and arterial wall.

Cases with differing geometric configurations and plaque materials were selected to permit a wider range of exploration. Results have indicated that plaque reconfiguration does indeed occur in a manner consistent with previously published results (Baptista et al. 1996), with radial compression forces leading to circumferential extrusion. Initial stress analysis results lead us to believe that there is indeed a relation between regions of high stress in plaque constituents and their increased propensity to displace within the plaque at specific sites. Work currently being carried out seeks to establish whether post-angioplasty stresses in newly reconfigured constituents are higher than pre-angioplasty ones. For lipid pools, this would be expected, as evidenced by results from simplified geometric models. Extrusion of lipid constituents into adjoining tissue may be indicative of lower load-bearing ability, and infiltration may increase the occurrence of inflammatory reaction; both mechanisms could be factors in increased plaque vulnerability. The ongoing work currently being done suggests that it is possible that the redistribution of plaque during angioplasty may lead to local increases in stress around inclusion boundaries, therefore potentially increasing plaque vulnerability.

THE CONTRIBUTION OF ELASTIN AND COLLAGEN TO RESIDUAL STRAIN IN PORCINE AORTA

INTRODUCTION

Arteries are composite structures with elastin and collagen as the two main load-bearing constituents. Arterial aging and diseases result in altered elastin and collagen content. In its unloaded intact state, an artery is not stress free: an unloaded artery ring springs open and becomes a sector when it is cut longitudinally along the vessel wall. Residual strain helps to reduce the stress and stress gradient across the wall (Chuong, 1986). The purpose of this study is to establish the contribution of elastin and collagen to residual strain using a porcine model. The characterization of residual strain as a function of arterial composition is crucial for future studies modeling arteries using strain energy functions.

METHODS

Porcine thoracic aortas were harvested and stored in physiological saline solution with papaverine (PSS). The aorta was cut into 2mm-thick rings. The rings were divided into groups of four rings each. One ring in each group served as untreated reference; the other three were to be digested with enzymes. Three groups were digested with 10 unit/ml of porcine pancreatic elastase buffered in PSS solution at pH 7.4 for 20, 40, and 60 minutes at 37 °C after an 1-hr immersion in the same solution at 4 °C. Another three groups were digested with 400 unit/ml of collagenase buffered in PSS solution at pH 7.4 for 45, 90, and 135 minutes at 37 °C after an 2-hr immersion in the same solution at 4 °C. After the specified digestion interval, the rings were opened by a single cut placed longitudinally along the vessel wall.

Elastin was isolated from another aorta by repeated autoclaving, treating in 6M guanidine hydrochloride and more autoclaving cycles. The purified elastin was then sectioned into 3 2-mm thick rings, which were immersed in a 37 °C PSS bath and cut open

Figure 1: (a) elastase digested: intact state; (b) elastase digested: zero-strain state; (c) elastin ring: intact state; (d) elastin ring: zero-strain state.

The opening angle θ , a measure of the residual strain in arteries, was determined from the direct measurement of the angle in the stress-free state (Figure 1).

RESULTS

Figure 2: Difference in opening angle between elastase

digested rings and reference rings vs. digestion time. Measurement for purified elastin ring is plotted at time = 0. Figure 3: Difference in opening angle between collagenase digested rings and reference rings vs. digestion time. Measurement for purified elastin ring is plotted at time = 180 minutes.

As elastin is removed, the opening angle increases with respect to the reference ring and departs further away from that of purified elastin rings. As collagen is removed, the opening angle decreases with respect to the reference ring, moving it closer to the behavior of purified elastin.

SUMMARY

This study shows that the presence of elastin reduces the opening angle while the presence of collagen increases the opening angle for porcine aortas.

INTRODUCTION

There are approximately 550,000 strokes each year in the United States that result in 150,000 deaths and 300,000 survivors left with significant disabilities (Bartels, 1998). Of these survivors most learn to walk again, but 30% to 60% never regain the full use of their affected upper extremities (UE) (van der Lee et al., 1999). Many rehabilitation strategies are designed to improve functional return after UE hemiparesis.

A more recent therapy, called forced use or constraint induced movement therapy, began with observations of monkeys with severed sensory nerve roots of an upper extremity. Non-use of these limbs was observed, even though motor nerve pathways of the affected limbs were left intact. Because of the sensory loss, the monkeys learned that it was difficult, even painful to use their affected limbs. Because they could function adequately in their caged environment by using their other three limbs, they quit attempting to use their damaged extremities altogether. The unaffected UEs of the monkeys were then immobilized in order to alter this learned non-use behavior. Forced use of the monkey's affected limb led to improved motor function and a change from the learned non-use behavior (Taub et al., 1994). Forced use therapy has since been used with varying degrees of success in the treatment of the affected upper extremity of human cerebrovascular accident (CVA) survivors (Benevento, 1998).

The purpose of this study was to determine the potential rehabilitation effects of forced use when employed in a home environment with persons more than one year post-CVA as determined by kinematic motion analysis.

METHODS

A pretest- posttest control group design was used. A total of 6 participants that met the inclusion criteria patterned after Wolf et al. (1989) were randomly assigned to either an experimental or control group (sound limb constraint using a resting hand splint or no constraint). All participants signed a behavior contract. Five movements from the Wolf Motor Function Test were videotaped (30 hz) for each participant for both the affected and sound limbs before and after treatment, and analyzed using a 2-D motion analysis system. Pretest /posttest differences in angular positions and linear velocities were examined for each movement and compared with the sound side movements.

Figure 1. Abduction of the shoulder to lift the forearm and hand onto a nine-inch box.

RESULTS AND DISCUSSION

No consistent trends or differences were noted between the experimental and control groups for any of the observed movements. Individual changes were noted which could represent improvement. One of the changes of interest occurred during a movement that involved abducting the shoulder in the frontal plane thus lifting the forearm and hand onto a nine-inch box placed adjacent to the participant (Figure 1). An experimental group member's pretest demonstrated a delayed peak velocity, but the posttest and sound side peak velocity occurred at approximately the same time marker. The approximate amplitude for both pretest and posttest velocities were similar (Figure 2). This result suggests a return to a normal movement pattern for this particular movement.

Figure 2. Vertical velocity of elbow during a movement.

SUMMARY

Past studies have shown that forced use can produce statistically significant improvements in hemiparetic patients. Results from this study show a potential trend toward normal movement patterns for some of the participants. However, these observations cannot be directly attributed to forced use. Examination of kinematic variables does allow for a more controlled examination of the relative success of movement for UE hemiparesis.

THREE-DIMENSIONAL FIBER-REINFORCED FINITE ELEMENT MODEL OF THE HUMAN ANTERIOR CRUCIATE LIGAMENT

Ashraf Ali¹, Cy Frank² and Nigel Shrive³

McCaig Center for Joint Injury and Arthritis Research, University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

The knee is one of the most frequently injured joints in the body. Studies estimate that 1.6 to 1.9 million patients, most between the age of 15 and 44 years, see a physician for a knee sprain each year (Butler, 1989). Among those who sustain an acute traumatic hemoarthrosis to the knee, the anterior cruciate ligament is partially or completely torn more than 70% of the time (DeHaven, 1980).

Experimental studies of ACL mechanics are technically difficult, costly, and prone to error. The emerging field of computational biomechanics (finite element (FE) method) offers a new set of tools for studies of solid and fluid biomechanics that can provide information that would otherwise be difficult or impossible to obtain from experiments (Yamamoto, 1998; Hirokawa, 2000).

METHODS

A mathematical Finite Element model for the human ACL is being developed that takes into account most of the complex characteristics of the ACL such as; three-dimensionally correct anatomical shape, helical fibre reinforcement with correct fibre alignment (angle of twist), hyperelastic stress-strain relationships, fibre recruitment, fibril reorientation within the matrix, the role of water during ligament function (poroelastic model), a gradual change in the material properties (ligament to bone) near the insertion sites and time dependent characteristics such as creep and stress relaxation. A preliminary model is shown in (Figure 1). Accurate anatomical dimensions needed for the model will be collected from fresh cadavers.

PATRAN V.5 and ABAQUS V.6.1 are the two commercial FE packages used for data processing and analysis.

Figure 1: Three dimensional preliminary model of the human ACL with helically shaped fibres.

RESULTS AND DISCUSSION

Principal stresses (strains) in the fibres of the ligament can be obtained for different cases of external loading and/or relative deformations of the tibia and the femur. An example is shown in (Figure 2).

The ultimate goal of this modeling is to understand ACL mechanics so that reconstructed and/or synthetic ACLs can be adapted to fulfill normal mechanics more effectively, and to improve the clinical diagnosis and treatment of ACL injuries. The model may also identify means by which to prevent injuries, such as through the use of protective equipment in the case of sports-related injuries.

Figure 2: Principal tensile stresses caused by anterior displacement of the tibia relative to the femur by 3mm.

SUMMARY

A Finite Element model for the human ACL is being developed that considers most of its complex characteristics. The model is able to predict stresses and strains precisely within the ligament caused by different cases of loading. The model presents a new perspective for gaining a better understanding of the details of ACL function, injury mechanisms and the mechanical needs of reconstruction.

PREDICTIONS OF RESIDUAL STRESSES IN BONE CEMENT FOR JOINT ARTHROPLASTY

Chaodi Li, Ying Wang, Steven Schmid, James Mason*

Department of Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, Indiana, USA. *mason.12@nd.edu

INTRODUCTION

Bone cements are widely used to fix the prostheses into bones for joint arthroplasty. Residual stresses are introduced in the cement mantle as a result of curing shrinkage and constraints [Gilbert et al, 2000]. These stresses of sufficient magnitude could cause pre-load cracking and therefore could contribute to starting a damage accumulation failure scenario [Huiskes, 1993; Lennon et al, 2001]. Experimentally determining the residual stresses in complex hip replacement systems is extremely difficult. In the present work, a finite element method was developed to predict the curing-induced residual stresses in the cements.

METHODS

The numerical predictions are based on heat transfer and sequentially coupled thermal-stress analyses.

In the heat transfer analysis, a phenomenological kinetic model was developed for the curing bone cement in which the dependence of polymerization rate and the local temperature are taken into account. This cure-dependent kinetic model has been shown to represent the polymerization behavior of the bone cement accurately for the range of temperatures expected in implant applications [Li et al, 2001]. The kinetic model was then coupled with the heat conduction equation and implemented using finite element method to predict the polymerization reaction and temperature development in the model system. Details of this method have been reported elsewhere [Li et al, 2001]. A sequentially coupled thermal-stress analysis was then performed to investigate the residual stresses in the cements. The residual stresses were determined by the stress-locked approach [Lennon et al, 2001]. In this paper, the reference temperatures for stress locking were selected from the temperatures at the end of polymerization [Lennon et al, 2001].

RESULTS AND DISCUSSION

To demonstrate this finite element method, numerical analysis of a bone-cement-prosthesis system was performed with a simplified axisymmetric model, as shown in Figure 1.

Figure 1: The Bone-Cement-Prosthesis System Model

The model consists of a metallic prosthesis surrounded by a layer of bone cement that is in turn embedded in the bone. This closely models the behavior along the shank of a hip implant, where the cement is usually employed.

Figure 2(a) shows the temperature distribution in the cement at the end of polymerization. The heat transfer analyses indicate that the temperature in the middle of the cement layer increased higher than cement near the cement-prosthesis and cement-bone interfaces. The principle residual stress distribution is shown in Figure 2(b). The maximum stress is about 3.5 MPa. The built-up residual stress depends strongly on temperature developments which are related to curing history. By modifying the cure procedure, the residual stresses have been shown to be redistributed. It is expected that with careful control of curing procedure through implant design, system initial and boundary conditions, a desired low level residual stress in the critical region may be reached.

Figure 2: Temperature (a) and Residual Stress (b) distributions in bone cement

SUMMARY

The method developed in this paper is able to predict the shrinkage residual stresses in bone cement in hip replacement systems. This method provides a numerical tool for the quantitative simulation of residual stress and for examining and refining new designs computationally.

MECHANISM OF INTRA-ARTICULAR CALCANEAL FRACTURES: THE EFFECTS OF ACHILLES TENDON LOADING

Susan E. D'Andrea, Gail P. Perusek, S. Solomon Praveen, Jennifer J.E. Kuznicki and Brian L. Davis
Department of Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland, OH
Contact information: dandreas@bme.ri.ccf.org, <http://www.bme.ri.ccf.org>

INTRODUCTION

Calcaneal fractures are serious, debilitating injuries which are difficult to treat and rehabilitate. The severity of the injury is dependent on the type of fracture. The most difficult to manage are the intra-articular fractures which occur in seventy five percent of all calcaneal fracture cases (Colburn et al., 1989). The mechanism of the intra-articular calcaneal fracture has been attributed to two major factors the magnitude of the angle of Gissane (Essex-Lopresti, 1952) and the eccentric loading of the sustentaculum tali (Burdeaux, 1983). The current study focuses on these two mechanism with regards to calcaneal strain. By examining the influence of foot angle and muscular force on the calcaneal strain, an understanding of the interplay between lower limb configuration and intra-articular fracture can be determined.

METHODS

Experiments were performed on unembalmed human cadaveric legs dissected at the distal third of the tibia. Delta rosette strain gages were affixed in a known orientation at the angle of Gissane and the sustentaculum tali. The foot was placed in a custom made testing apparatus with an impacting surface resting on the forefoot (Figure 1).

Figure 1: Experimental Testing Apparatus

A load cell was attached to the Achilles tendon in series with a freeze clamp. The Achilles tendon was loaded for two seconds in four experimental conditions: i. neutral ankle position, free-moving impactor, ii neutral ankle position, fixed impactor, iii. 10° plantar flexion, fixed impactor and iv. 20° plantar flexion, fixed impactor. Three strains signals for each rosette and Achilles force were recorded for each trial. Data were collected at 1000 Hz using a custom LabVIEW® program.

Offset values were subtracted from each signal and principal strains at the angle of Gissane and the sustentaculum tali were calculated.

RESULTS AND DISCUSSION

Time series strain data showed similar patterns across trials and subjects. Principal maximum and principal minimum strains appeared as mirror images in time. Average peak maximum and minimum principals strain ranged between 400 – 900 $\mu\epsilon$ and -400 – -2400 $\mu\epsilon$, respectively. Significant differences were present between Condition 1. Calcaneal strains were significantly related to the force in the Achilles tendon (Figure 2, $R^2 > 0.98$).

Figure 2: Principal Strains at the Sustentaculum Tali (ST) and Angle of Gissane (AG) versus Achilles Tendon Force

SUMMARY

Preliminary results show a high correlation between the load in the Achilles tendon and the subsequent strain in the calcaneus, particularly at the angle of Gissane. Further work will correlate the geometrical configuration of the calcaneus at the angle of Gissane and the sustentaculum tali to the magnitude of the principal strains. Additionally, results will allow for the direction of the principal strain to be evaluated in light of the orientation of the most common intra-articular calcaneal fracture lines

ISSUES IN THE INTERPRETATION OF CONTINUOUS RELATIVE PHASE

Jeffrey M Haddad¹, Brian T. Peters^{1,2}, Bryan C. Heiderscheit³, Richard E. A. van Emmerik¹ and Joseph Hamill¹

INTRODUCTION

The phase relationship between two signals has traditionally been identified as an important variable in quantifying coordination. Phase information is usually thought of as a reference phase, or the instant in time of one oscillator relative to a second at an arbitrarily chosen point. In the movement sciences this is often termed discrete relative phase (DRP) (Kelso, 1984). Recently, in an attempt to gather phase information across the entire period of a cycle, coordination was quantified utilizing a measure termed continuous relative phase (CRP) (van Emmerik et al. 1999). Whereas DRP is determined from temporal shifts at chosen events in the time series, CRP is typically calculated from position - velocity phase portraits of the component signals. Phase information calculated in this manner may be subject to artifacts if the state spaces used to calculate the phase angles are not circular (Fuchs et al. 1996). The aforementioned artifacts are not necessarily arbitrary in that the data are erroneous, but care needs to be given when interpreting the results of the CRP calculations. The purpose of this paper is twofold, namely: 1) to illustrate the traditional need for state-space normalization prior to calculating phase angles; and 2) to show that the interpretation of CRP information should be limited to describing the relationship between the individual state-spaces of the two signals and not be used to describe a relationship between their original time series data.

METHODS

CRP was calculated from two test signals with known phase and frequency properties. The test signals used were: 1) two sine waves with frequencies of $2\pi^{-1}$ Hz and $4\pi^{-1}$ Hz respectively; and 2) a skewed sinusoidal saw tooth wave. The skewed sinusoid was time shifted by 18° and 126° . CRP between the two sine waves was calculated with and without prior normalization of the state-spaces. CRP of the saw tooth waves was calculated between each phase shifted wave and a 0° offset reference wave. Phase planes were normalized by dividing the velocity by $2\pi/p$, where p is the period of oscillation. This technique maintains a consistent aspect ratio for all similar-shaped non-sinusoidal waves regardless of their period.

RESULTS AND DISCUSSION

Intuitively, the phase relationship across the cycle between the two sine waves, where one is twice as fast as the other, is a monotonically increasing line between 0° and 360° . This intuitive relationship was only observed after normalization. When no normalization was employed the phase relationship oscillated around the known DRP relationship. This oscillation was due to the elliptical shape of the phase plane of the higher frequency signal. Even without attempting to achieve a circular state-space and the intuitive monotonically increasing phase shift, without some form of normalization the CRP between 1 and 2 Hz sinusoids will not be the same as it is in a 2 vs. 4 Hz comparison. A coordination measure should be robust enough to yield an identical output when the relationship between the two inputs is identical regardless of the frequency.

The constant time lag between the non-sinusoidal saw tooth signals did not produce a constant CRP output. Moreover, the shape of the CRP pattern was not consistent between the signals with the 18° and 126° phase shifts. While other state-space normalization techniques typically used (Hamill et al., 2000) produce different CRP trajectories, none provide the constant output expected from a DRP measure. As a result of this difference between the information provided by CRP and DRP it is incorrect to state, for example, that a CRP value near 180° means that the two signals being compared are moving in opposite directions.

SUMMARY

Through simulation, we have shown that normalization is necessary to reduce the effects of frequency when using CRP to compare two signals. Additionally we have stressed that traditional CRP measures provide a relationship between the position-velocity state-spaces of two signals and therefore cannot reliably be used to describe the relationship between the two signals in the temporal domain. Caution should thus be used when interpreting CRP data and presenting its results.

CENTER OF PRESSURE MIGRATION DURING PROLONGED UNCONSTRAINED SITTING

Jason Lusk¹ and Qiong Wu²

Mechanical Engineering Department, University of Manitoba, Winnipeg, Manitoba, Canada

¹M. Sc. Graduate Student

²Associate Professor, cwu@cc.umanitoba.ca

INTRODUCTION

The risk of developing pressure sores arises whenever tissues are exposed to excessive or prolonged mechanical loading. Although healthy, able-bodied individuals are always forewarned of excessive pressures by feelings of local discomfort, and can take the necessary corrective action, this is not the case for some populations, such as people with spinal cord injuries, diabetics and elderly. To prevent pressure sores, the idea of developing closed-loop automated seating systems, which allows for simultaneous adjustment of seating contours and measurement of the resulting pressure, has attracted much attention (Kwiatkowski and Inigo, 1993). Some studies have been carried out on understanding optimal seating (Levine *et al.*, 1990). In this work, the patterns of the pressure center migration of healthy individuals during prolonged unconstrained seating (PUS) will be studied. The main goal is to show that during PUS, specific and consistent patterns of the center of pressure migration exist. Investigations of healthy individual seating can contribute to better understanding of optimal seating.

METHODS

Fifteen healthy subjects, ten males and five females, participated in this study. Each subject was asked to sit on a force plate (Kistler 9286AA) for an interval of 30 minutes. The subjects were asked to sit in the middle of the force plate with their feet on a foot rest. They were not given any instructions on how to sit other than that once on the force plate they were required not to get off and their feet must rest on the foot rest. The subjects were allowed to adjust their posture in order to remain comfortable at all times. Each subject was allowed to converse with someone in the room, read a book, or listen to music during the data acquisition.

The data was collected using the Kistler BioWare software Version 3.21 for COP measurement. Each subject was given a few minutes to get comfortable before the data was recorded. The COP values were given in the X-Y plane, with the X

direction corresponding to the anterior-posterior directions and the Y direction corresponding to the medial-lateral directions. The data was collected in 1½-minute intervals and transferred to an Excel spreadsheet, completing the 30-minute trial. Plots were then produced for both the x (a-p) and y (m-l) directions.

RESULTS AND DISCUSSION

As a result of the data acquisition it has been determined that COP migration patterns during prolonged unconstrained sitting do exist. Three COP migration patterns were found as shown in Figure 1: (1) shifting, a fast displacement of the average position of the COP from one region to another, (2) fidgeting, a fast and large displacement and returning of the COP to approximately the same position, and (3) drifting, a slow continuous displacement of the average position of the COP. Similar patterns were found in a study done on prolonged unconstrained standing (Marcos and Duarte, 2000). The following preliminary results have been obtained for a 30 minute trial PUS: shifting occurred approximately 13.3 ± 8.8 times in the a-p direction (average amplitude of 16.6 ± 12.3 mm) and 5.4 ± 2.5 times in the m-l direction (average amplitude of 13.3 ± 7.3 mm). Fidgeting occurred on average 16.1 ± 4.3 times in the a-p direction (average amplitude of 21.7 ± 13.3 mm) and 17.7 ± 6.6 times in the m-l direction (average amplitude of 19.5 ± 13.3 mm). Drifting occurred on average 1.4 ± 1.4 times in the a-p direction (average amplitude of 13.4 ± 8.0 mm) and 1.0 ± 1.3 times in the m-l direction (average amplitude of 9.4 ± 5.7 mm).

Currently, we are focusing on developing computer software to detect the COP migration patterns automatically.

EFFECT OF FATIGUE ON LEG KINEMATIC IN RUNNING TILL EXOSTION

Ales Dolenc and Branko Skof

Faculty of Sport, University of Ljubljana, Ljubljana, Slovenia

INTRODUCTION

Running is very well described by kinematic parameters. Although kinematic parameters are not so sensitive to fatigue as EMG parameters there are some changes in running kinematic during fatigue. The most noticeable changes in fatigue running compare to unfatigued running are stride frequency and stride length. There are changes in knee angle, too (Mizrahi et al. 2000). The aim of this experiment was to find out which kinematic parameters changed during the fatigue running compared to the unfatigued running.

METHODS

Eight well-trained middle distance runners (age $20.6 \text{ yrs} \pm 4.8$; mass $66.4 \text{ kg} \pm 3.5$) participated in the experiment. Running velocity ($5.8 \text{ m/s} \pm 0.4$) was 3 % lower than the velocity of their season best in 3 km run. Subjects were ordered to run as long as possible at given velocity. During the run the 3D kinematic parameters were obtained with APAS system (Ariel Dynamics Inc., USA). The running was filmed with two synchronized digital cameras, at 50 Hz frequencies. The masses and centre of gravity of the segments and the common center of gravity of the 15-segment model of the body were computed according to the anthropometric model (Dempster, 1955). Paired samples T-test was used to compare the kinematic parameters in non-fatigued and fatigued conditions.

RESULTS AND DISCUSSION

Although the running velocity during the experiment was 3 % lower than the velocity of their season best in 3 km run, only one subject was able to run 4050 m. One subject was running for 2850 m, two subjects were running for 2450 m and four subjects were running for 2050 m. This rather short distance of running is probably caused by weight of the measuring equipment (2 kg) that subjects were wearing during the run and that the experiment was done at the end of the season.

The results of the kinematic parameters are presented in table 1. The subjects were unable to sustain the running velocity constant in the last 400 m. The decrease of running velocity was small but significant. The subjects increased the contact time. This was made by increasing the leg angle at the moment of touch down and by increasing the knee angle amplitude during the contact phase. Increased knee angle amplitude during extension in fatigued conditions compared to the unfatigued conditions probably caused increase in maximal angle velocity during knee extension. Longer contact time in fatigued conditions compared to unfatigued conditions

probably caused smaller maximal angle velocity during hip contraction since this velocity is reached during the ground contact.

Table 1: Kinematic parameters in fatigued and non-fatigued conditions.

Parameters	Rest Mean \pm SD	Tired Mean \pm SD	p
Velocity	$5.8 \pm 0.4 \text{ m/s}$	$5.4 \pm 0.3 \text{ m/s}$	*
Contact time	$168 \pm 14.5 \text{ ms}$	$188 \pm 14.6 \text{ ms}$	*
Angle leg touch down	$110.9 \pm 3 \text{ deg}$	$113.5 \pm 2.7 \text{ deg}$	*
Ankle dorsiflexion amortization	$16.2 \pm 4.6 \text{ deg}$	$19.9 \pm 2.1 \text{ deg}$	**
Knee amplitude amortization	$10.1 \pm 4.2 \text{ deg}$	$14.2 \pm 3.6 \text{ deg}$	*
Knee amplitude extension	$27.1 \pm 4.9 \text{ deg}$	$33.1 \pm 4.5 \text{ deg}$	**
Knee angle velocity extension	$399 \pm 52 \text{ deg/s}$	$440 \pm 42 \text{ deg/s}$	*
Hip angle velocity contraction	$580 \pm 28 \text{ deg/s}$	$554 \pm 49 \text{ deg/s}$	*

* $p < 0.05$; ** $p < 0.01$

SUMMARY

The subjects changed running technique in the fatigued conditions compared to unfatigued conditions. Probably most changes were made to decrease maximal power requirements. McMahon et al. (1989) found that these changes can increase O_2 consumption up to 50 % and so decrease the economy of running.

INTRODUCTION

Falling is a major concern for older adults, resulting in injury, restriction of activity, and even death (Nevitt et al. 1989). Identification of risk factors that predict the risk of falling is crucial to providing effective and efficient therapy that will be specifically targeted at fall reduction in older adults. Wu (2001) hypothesized that increased head movement during a backward platform acceleration may predict the risk for falls in older adults. We tested this hypothesis using a unique set of biomechanical data collected from healthy older adults on whom trips were imposed. We determined if head motion during the first 100 ms following the trip could predict the success or failure of the recovery.

METHODS

Fifty women and 29 men (age: 72 ± 5 years, mass: 76.0 ± 14.0 kg, height: 1.64 ± 0.09 m) gave written informed consent to participate in this study (Pavol et al., 1999). Subjects were screened for the presence of musculoskeletal, neuromuscular and cardiovascular exclusion factors and were required to have bone mineral density of the femoral neck of >0.65 g/cm².

During the protocol, subjects were tripped unexpectedly while walking (Pavol et al., 1999). The trips were induced using a concealed, pneumatically driven, mechanical obstacle. Subjects were protected from contacting the ground by a safety harness that was connected to an overhead rail. Kinematic data was collected using a six-camera motion analysis system (Motion Analysis, Santa Rosa, CA).

Recoveries were visually graded as successful or failed (i.e. falls). A load cell in the safety harness was used to identify and exclude subjects who were assisted by the harness. Sagittal plane head kinematics were determined. Head flexion and extension were quantified by the orientation of the head relative to the trunk (i.e. the neck flexion or extension angle). Five variables were extracted during the first 100 ms post-trip: maximum head flexion and extension, maximum head flexion and extension velocity, and head flexion/extension range of motion. Independent t-tests were used to determine those variables for which differences between successful and failed recovery were significant ($p < 0.05$).

RESULTS

Thirty-seven older adults successfully recovered and eight failed to recover from the induced trip. None of the five variables describing post-trip head kinematics exhibited a significant difference between successful and failed recoveries (Table 1).

Table 1: Sagittal plane head kinematics for 100 ms following trip initiation (mean \pm SD)

	Success	Failure	P Value
Flexion Angle	0.12 ± 0.15 rad	0.19 ± 0.17 rad	0.221
Extension Angle	0.08 ± 0.17 rad	0.16 ± 0.17 rad	0.282
Range of Motion	0.20 ± 0.08 rad	0.35 ± 0.33 rad	0.507
Flexion Velocity	0.23 ± 0.37 rad/s	0.48 ± 0.32 rad/s	0.161
Extension Velocity	0.19 ± 0.33 rad/s	0.02 ± 0.19 rad/s	0.519

DISCUSSION

We found that head motion in this group of healthy older adults was not a sensitive determinant of falling following an induced trip. This finding tends to argue against the hypothesis that head movement may be used as a measure for risks for falls. Previously, we have found that walking speed, step time, and step length could classify falling following an induced trip with a sensitivity of 70% (Pavol et al., 1999). At this time, these variables appear to be better predictors of risks for trip related falls than head movement.

PASSIVE ELASTIC PROPERTIES OF BICEPS; CONTRIBUTION TO LOCOMOTOR ECONOMY IN THE HORSE (*EQUUS CABALLUS*)

Watson J.C., McGuigan M.P., Wilson A.M.

Structure and Motion Lab, The Royal Veterinary College, North Mymms, Hatfield, Herts, AL9 7TA England

INTRODUCTION

Storage of elastic strain energy in the collagenous component of muscle tendon units is important in reducing the mechanical work of locomotion. This mechanism has been demonstrated in the gastrocnemius tendon of the wallaby (Biewener *et al*, 1998), the digital flexor tendons of the horse (Wilson *et al*, 2001; McGuigan *et al* submitted) and the plantaris muscle of the human foot. Such studies have focussed on tendons that are loaded by gravitational and inertial forces during stance phase and which therefore produce a vertical displacement of the centre of mass as a spring mass system. The equine biceps has a substantial collagenous component and is strained by downward movement of the trunk at the shoulder joint. Linked flexion of the elbow joint however has the opposite effect reducing the strain in the muscle-tendon unit. Shortening of the muscle-tendon unit at the end of stance would however extend the shoulder and flex the elbow – the movement required to protract the limb. This led us to propose the hypothesis that energy stored in biceps has a role in initiating limb protraction.

METHODS

1. Biceps force was calculated during trot locomotion from shoulder joint moment and limb force using forceplate (9287BA, Kistler) and video motion analysis (ProReflex, Qualisys). Biceps moment arm was determined by radiography. The extensor contribution of biceps was estimated from measures of physiological cross sectional area (PCSA) and moment arm of the shoulder extensors.
2. Biceps muscles were harvested from horses euthanased for other reasons. Muscles were mounted in a servo hydraulic tensile testing machine (Instron) via bolts placed through the scapula and radius adjacent to muscle attachments. Each muscle was then loaded to a force of 8kN and force and deformation (via an optical system – ProReflex, Qualisys) recorded. Energy stored in the muscle was determined by integration of the force displacement curve.
3. Muscles were dissected and PCSA determined for each muscle.

RESULTS AND DISCUSSION

1. Peak extensor moment on the shoulder joint during stance phase was 8000Nm. Attributing 70% of this to biceps produces a peak muscle force of 17kN. At 85% of stance (when the heel leaves the ground) values were 1600Nm and 4.2kN.

2. Muscle tendon units were about 400mm long. Tendon strains at 8kN force were 10% and muscle tendon unit strain 4 –7%. This is similar to that recorded in other energy storage tendons at peak strain. Energy stored in the muscle at 8kN was 50-57J.
3. Biceps fibre lengths were 6 to 14 mm in the lateral head and 23 to 27mm in the medial head, similar to those reported by Hermanson *et al*, 1990. The mean PCSA was 330cm². Taking an isometric force capacity of 30Ncm⁻² gives an isometric force capacity of 9.9kN.

It is unclear how to relate the passive muscle properties with the potential force generation capacity of the contractile element. The force during locomotion appears to approach or exceed the passive force. Activation of the contractile element is however likely to enhance the force resisting capacity of the muscle, perhaps by as much as the predicted isometric force. This would produce a peak force of 18kN – similar that calculated *in vivo*. The tendon strain data however suggest that a muscle force of 8kN would be a reasonable maximum. It therefore appears that either our estimate of *in vivo* biceps force is too high or that biceps can resist a higher force than determined here. The energy stored in biceps at a force of 4.2kN is 18J. If the entire shoulder moment was provided by biceps at this stage of stance this would rise to 6kN and 32J. This is a significant proportion of the energy required to protract the limb. We are currently extending the data set for this study.

SUMMARY

Biceps resists high forces during locomotion and will store large amounts of elastic strain energy. The muscle fibres are relatively short compared to the length changes that occur during elastic deformation suggesting that most of the muscle's function is related to its passive properties. The energy stored within the muscle appears sufficient to make a useful contribution to initiating limb protraction.

THE EFFECTS OF LIGAMENT AND CARTILAGE PROPERTIES ON THE GLENOHUMERAL JOINT

John E. Novotny, Ph.D., Bruce D. Beynnon*, Ph.D., Claude E. Nichols, III*, M.D

University of Delaware, Dept. of Mechanical Engineering, Spencer Laboratory, Newark, Delaware, USA, novotny@me.udel.edu

*University of Vermont, Dept. of Orthopaedics and Rehab., McClure Musculoskeletal Research Center, Burlington, Vermont, USA

INTRODUCTION

An analytical model of the glenohumeral joint was developed consisting of a 3D representation of the glenohumeral joint, with linear elastic ligament elements that could wrap around the humeral head, and deformable articular contact between the humeral head and glenoid [Novotny, 2000]. Models were generated to simulate individual experimental specimens used during in vitro tests of that simulated the 'cocked phase' of throwing [Novotny 1998a; 1998b]. Experimental loading conditions were inputs. The position and orientation of the humerus relative to the glenoid that resulted in equilibrium was solved. The sensitivity of glenohumeral joint kinematics (model outputs), to the ligament and cartilage material properties (model input parameters) was investigated. This will provide insight into the effect of these structures and their properties on glenohumeral joint function, injury and surgical repairs, such as the Bankart repair.

METHODS

A sensitivity analysis of the model output to variations in its input structural and geometric constants was explored. A model of a single loading condition, with the humerus loaded with 3 Nm abduction, 3 Nm extension and a 2.5 Nm external rotation moments (cocked phase of throwing), was chosen. The model was solved, then an input parameter was changed and the model solved again. The input parameters were increased by 5% of their initial value. For each new model solution, the changes in each of six model output parameters representing the position (X, Y, Z) and Euler angle orientation (RZ, RY, RX) of the humerus relative to the glenoid were calculated [Figure 1]. The sensitivity of the model kinematics was first assessed to changes in the stiffness (K) and initial lengths (L_0) of the five ligament elements (the superior, middle and the anterior band, axillary pouch and posterior band of the inferior glenohumeral ligaments). Secondly, the aggregate modulus (S) and thickness of the articular cartilage layer (b) of the glenoid and humeral head were changed. Finally, the sensitivity of the model output to changes in the position of the glenoid ligament elements insertions was performed.

RESULTS AND DISCUSSION

Anterior-posterior translation was most sensitive to increases in the K and L_0 was. Increases in K resulted in the humeral head translating further posteriorly and inferiorly. Increasing L_0 resulted in more laxity, allowing the humeral head to translate and rotate further in the posterior-inferior direction.

With an increase of b, the higher contact force and area must be balanced by increased ligament tensions, causing the humeral head to translate posteriorly. Loss of b, as typically produced by osteoarthritis, could have pronounced effects on glenohumeral translations. Posterior translation was only moderately sensitive to an increase in S. The model exhibited high sensitivity to the medial movement of the glenoid insertion of the anterior band of the inferior glenohumeral ligament. Unlike the other findings, moving the insertion affected rotations more than translations, resulting in a higher abduction angle, and less external rotation and extension. The sensitivity to rotation may indicate that changes in insertion location could be more important in controlling joint rotations than changes in the material properties of the elements.

SUMMARY

In previous experiments [Novotny, 1998b], rotations were altered after Bankart repair while translations were not, similar to the results found after moving the ligament element insertions in this study. It could be surmised that the Bankart repair may relocate the capsular insertions rather than change the initial lengths of the ligaments. The shortening of the lax capsule is often the stated goal of the Bankart repair, hopefully resulting in a reduction of anterior translation of the humerus. Constraining glenohumeral rotation is to be avoided since it limits arm function. This sensitivity analysis indicates that the maintenance of ligament insertion location during repair may be most important to avoid loss of rotational range of motion.

PREDICTING THE INERTIAL CHARACTERISTICS OF THE HUMAN THIGH USING A GEOMETRIC MODEL

Jennifer L. Durkin¹, Laura Scholtes and James J. Dowling²

Department of Kinesiology, McMaster University, Hamilton, Ontario, Canada

¹PhD Candidate, durkinjl@mcmaster.ca, ²Associate Professor, dowlingj@mcmaster.ca

INTRODUCTION

Accurate body segment parameter (BSP) information is required to calculate the kinetics of motion. Dual energy x-ray absorptiometry (DXA) has been used to measure BSPs and provided errors of less than 3.2% (Durkin, et al. 2002). The method is rapid and safe, allowing the scanning of large numbers of subjects for both subject-specific BSP data and the development of mathematical models. Current mathematical models have been criticized for their assumption of constant density and limited application to different populations. The purposes of this study were to i) determine the mass, centre of mass location (CM) and moment of inertia about the centre of mass (I_{CM}) of the thigh segment from 4 human populations ii) create a geometric model based on the mass distribution (MD) properties of the thigh to accurately predict BSPs, and iii) evaluate the accuracy of BSP predictions from one popular source in the literature.

METHODS

20 human volunteers from 4 populations underwent a frontal plane DXA scan followed by anthropometric measurements of the thigh segment. Custom software was used to section the right and left thigh segments, retrieving mass information in elements of 0.13cm^2 . The digitized mass elements were summed every 1% of segment length (SL) and normalized to 100% segment mass (SM). An ensemble average of the mass distribution plots for each group was calculated to yield the mean (\pm SD) % SM per 1% SL (Fig.1). A geometric solid was developed to predict the BSPs of the thigh segment based on the MD properties observed (Fig. 2). The anthropometric measurements were used in the model to calculate the BSPs. %RMS errors were calculated between the DXA measurements and model predictions and between predictions from Winter (1990) and the DXA measurements.

RESULTS AND DISCUSSION

The present model provided more accurate BSP predictions than Winter (1990), particularly for the younger populations (Table 1). The model accurately reproduced the distal half of

Figure 1. Ensemble average of MD properties of Males 19-30 years (Mean \pm SD).

Figure 2: Geometric thigh model used to calculate BSPs.

the segment, however the proximal measurements underestimated segment mass and I_{CM} in this region. Knowledge of the MD characteristics of body segments enabled evaluation of geometric similarity between populations and allows the development and validation of a geometric model that accurately predicts BSPs for these populations. Further refining of this model and the development of other models for the remaining body segments using the MD characteristics from DXA will enable accurate BSP predictions for different populations.

DEVELOPMENT AND VALIDATION OF A JOYSTICK DYNAMICS MODEL TO PREDICT OPERATOR INPUT TORQUE

Michele Oliver¹, Bob Rogers², Phil Garland², Troy Gallant², and Ed Biden^{2,3}

¹School of Engineering, University of Guelph, Guelph, Ontario, Canada, moliver@uoguelph.ca

²Department of Mechanical Engineering and ³Institute of Biomedical Engineering, University of New Brunswick, Fredericton, New Brunswick, Canada

INTRODUCTION

Over the past thirty years, North American manufacturers of off-road equipment for the construction, forestry and mining industries have gradually made a conversion from the exclusive use of lever, button and steering wheel controls to joysticks. Surprisingly, despite their widespread use, joysticks have not been studied extensively. The purpose of this work was to develop a dynamic model for hydraulic-actuation joysticks that would allow one to study the effects of joystick stiffness and speed on selected dynamic torque characteristics as a first step towards the development of a protocol for joystick design.

METHODS, RESULTS AND DISCUSSION

When an external torque due to contact from an operator's hand is present, according to Figure 1, the governing equation for the joystick becomes:

$$J\ddot{\theta} + C\dot{\theta} + M_s = mgh \sin \theta + T_{ext} \quad (1)$$

By calculating the first four terms, the operator input torque (T_{ext}) can be determined.

Figure 1: Free body diagram of joystick

The polar moment of inertia (J) of the rotating portion of the joystick (cam, shaft, handle, locking and connecting nuts, and one-half of the U joint) (Figure 2) can be determined experimentally by modeling the joystick as a compound pendulum. The moment (M_s) components are determined by disassembling the joystick and placing the actuator portion (Figure 2) in an InstronTM testing jig to determine actuator spring stiffnesses. Other components of M_s are determined through measurements of joystick geometry. The various θ terms (displacement, velocity and acceleration) are determined experimentally using a VICONTM motion analysis system and a pair of uniaxial piezoelectric accelerometers thread mounted

to the top of the joystick. For the $mgh \sin \theta$ term, h is the distance between the U joint pivot and the centre of mass for the rotating portion of the joystick. Given that the joystick actuators contain pairs of preloaded springs, when the joystick is set into free motion, unlike a simple mass-spring-damper system, a reducing period is observed. Consequently, simple logarithmic decrement methods cannot be used to estimate the damping constant C . Therefore, C is estimated using a fourth order Runge Kutta numerical integration method using the model outlined in equation 1 (without T_{ext}) (Rogers et al., 2001). Using known values for the various model constants, and trial and error values for C , the Runge Kutta output for a given joystick is compared with experimentally obtained joystick motion time-histories. In this way, model validation is accomplished at the same time as C is estimated.

THE EFFECT OF LIGAND DENSITY ON TETHER FORMATION BETWEEN ENDOTHELIUM AND MONOCYTES

George A. Truskey and Dora J. Levin

Department of Biomedical Engineering
Duke University, Durham, NC 27708-0281
Corresponding author: george.truskey@duke.edu

INTRODUCTION

Normal forces arising from secondary flows may play an important role in creating adhesive forces that resist detachment of monocytes from endothelium in the relatively high shear stress environment found in the arteries (Rinker et al., 2001). Cell rolling and arrest involves bond (Alon et al., 1995) and membrane tether formation (Shao et al., 1998). Tether formation influences the forces acting on cells (Shao et al., 1998). The objective of this study was to test the hypothesis that the receptor density on endothelium influenced tether formation.

METHODS

Human umbilical vein endothelial cells (HUVEC) were cultivated on microcarriers with endothelial growth media (Levin et al., 2001) and adhesion of Mono Mac 6 (MM6) cells studied using micropipet aspiration (Shao et al., 1998, Levin et al., 2001). Receptor populations were changed by incubation with 100 U/ml TNF- α for 4 h. In some cases, the TNF- α treatment was performed in the presence of cycloheximide to stabilize the number of receptors expressed. Multiple bonds were determined indirectly through observed trends in the adhesion probability, P_a . Previous studies established that adhesion probabilities $> 30\%$ suggest that multiple bonds are a significant percent of adhesive contacts (Chesla et al., 1998).

RESULTS AND DISCUSSION

TNF- α stimulation of HUVEC increased E-selectin, ICAM-1 and VCAM-1 expression. Addition of anti-ICAM-1 significantly inhibited MM6 rolling and adhesion under flow. ICAM-1 levels were zero in control cells, $4.7 \pm 0.8 \times 10^5$ molecules per cell in cells treated with TNF- α in the presence of cycloheximide and $1.6 \pm 0.1 \times 10^6$ molecules per cell in TNF- α treated cells. In micropipet experiments, adhesion was infrequent in unstimulated HUVEC, $P_a = 8 \pm 2\%$, and was significantly higher when HUVEC were stimulated with 100 U/ml TNF- α for 4 hours with ($P_a = 48 \pm 5\%$) or without ($P_a = 51 \pm 18\%$) cycloheximide prior to testing. These results suggest that adhesion in control experiments is predominantly mediated by single bonds while multiple bonds contribute significantly to adhesion in TNF- α -stimulated cells. Multiple tethers were inferred from successive increases in MM6 velocity as it separated from HUVEC. Multiple tethers were observed in $40 \pm 15\%$ of TNF- α -treated cells, while only one multiple tether was detected in four sets of control data ($8 \pm$

17%). Multiple tethers provide direct evidence for more than one initial bond forming.

We observed a lag period prior to tether formation that increased with TNF- α stimulation of HUVEC. The applied contact time between MM6 cells and HUVEC was held constant for all conditions tested. Prior to tether formation, the lag period increased from 0.53 sec for unstimulated HUVEC to 1.33 sec for TNF- α stimulated HUVEC ($p < 0.01$). The tether lifetime was, however, unaffected by ligand density.

SUMMARY

Increasing the receptor density on endothelial cells by TNF- α stimulation caused an increase in the probability of adhesion. Increased adhesion led to a greater frequency of single and multiple tether formation with an increase in the lag time between application of force and formation of tethers. These results indicate that multiple bond formation will produce multiple tethers but may delay the onset of tether formation by hindering the separation of cortical cytoskeleton from the cell membrane. Thus, tether formation is dependent upon both the force applied on the cell (Shao et al., 1998) and the density of receptors bound to ligand on monocytes.

COMPARISON OF 3 MEASURES OF GROUND REACTION FORCE: FORCE PLATE, FSCAN®, AND MULTIPLE FORCE SENSORS

Evelyn L. Morin, Susan A. Reid, J. Mikael Eklund, Joan M. Stevenson and J. Tim Bryant
Ergonomics Research Group, erg@post.queensu.ca
Queen's University, Kingston, Ontario, Canada

INTRODUCTION

The ability to measure instantaneous ground reaction forces (GRFs) generated during free gait forms an integral part of the analysis of human motion. Vertical GRFs and centres of pressure (COPs) during gait are compared when calculated from the in-shoe contact pressure measured with an FScan® to those measured by an AMTI force plate. Further study is done on the error introduced by grouping the FSRs to estimate the COP with a reduced data set size. The FSR groups are chosen based on 10 clinically significant anatomical regions.

METHODS

FScan® sensors are comprised of up to 960 force sensing resistors (FSRs). These were placed in a subject's shoe and calibrated. Data was simultaneously recorded from FScan® and the force plate at a 50 Hz sampling rate in three conditions: during various walking rates, while a stationary subject shifted their body weight, and during barefoot walking on the FScan® and force plate.

Data from the two in-shoe conditions were used to compare the vertical GRF computed by FScan® and the force plate. Data from the barefoot walking were used to compare the COP path computed from FScan® recordings and the force plate. Post hoc alignment of the data sets was necessary and done using heel-strike and toe-off as reference markers.

In-shoe FScan® data were used to develop a hypothetical grouping of FSRs, based on 10 anatomically significant regions proposed by Bhatia et al. (1999). This would reduce the data size by one order of magnitude. The sum of grouped sensor forces was used with their mean position to calculate COP. Reduction in data inputs is desirable for a portable data acquisition system and its impact on accuracy is evaluated.

RESULTS AND DISCUSSION

The Fz GRF was determined from 41 in-shoe trials. FScan® under reported Fz with a mean RMS error of 30.15%.

COP path was computed from FScan® and force plate data for 10 trials. An example of the COP trajectories can be seen in Figure 1. Mean error: 1.44 mm, STD 0.58 mm. This would cause 1–2% error in ankle moment calculations.

Figure 1: Force Plate and FScan® calculated COP position

Grouping FScan® sensor data into 10 regions as described by Bhatia (1999) resulted in a mean error of 2.97 mm medial/laterally and 6.85 mm anterior/posteriorly. This error in the estimate of moment arms will have a limited effect on the magnitude of joint moments. Careful placement of the FSRs can further minimize this.

SUMMARY

The FScan® system under reported the vertical GRF by 30% in this study. Furthermore, error in Fz increased with use.

It is possible to align two independent coordinate systems post hoc by aligning the lines of progression of the COP. When aligned, the FScan® sensor is capable of tracking the trajectory of the COP with a RMS error of 13% (1.44 mm).

Calculating the COP path using 10 discrete areas resulted in an RMS error of 17.26% medial/lateral variation (2.97 mm) and 4.24% anterior/posterior variation (6.85 mm). Further work will be undertaken to determine an optimum FSR size and placement to minimize the error in COP trajectory.

DETERMINATION OF INERTIAL CHARACTERISTICS OF THE HUMAN FOOT USING DUAL ENERGY X-RAY ABSORPTIOMETRY

Mark R.J. Young and James J. Dowling

Department of Kinesiology, McMaster University, Hamilton, Ontario, Canada
youngmr@mcmaster.ca

INTRODUCTION

Linked segment analyses require the input of inertial characteristics to yield estimations of internal forces and moments. Modern methods of medical imaging allow accurate measurements of these characteristics in living subjects. The purpose of this study was to compare dual energy x-ray absorptiometry (DEXA) measurements of the inertial characteristics of the human foot with previous methods using cadavers and geometric shapes. (Winter, 1990; Zatsiorsky et al., 1990a; Zatsiorsky et al. 1990b)

METHODS

Twenty subjects were scanned in the sagittal plane using DEXA. Twenty-one anthropometric measurements were then taken of the foot and leg segments for use in the other predictive models.

Using custom software the DEXA foot image was analyzed for mass, centre of mass, and radius of gyration. Anthropometric data were used to calculate mass, centre of mass, and moments of inertia using the regression equations of Winter (1990). Only mass and moments of inertia were calculated using the regression equations of Zatsiorsky et al. (1990a), and the geometrical models of Zatsiorsky et al (1990b).

Masses and moments of inertia were compared using simple linear regression. The error in the ability of Winter (1990) and Zatsiorsky et al. (1990a; 1990b) to predict the true value was quantified using root mean squared error (RMSE). Differences between the centre of mass predicted by Winter (1990) and DEXA were shown graphically.

RESULTS

The regression for the mass of the foot segment vs. DEXA yielded strong correlations for Winter, Zatsiorsky (Regression), and Zatsiorsky (Geometrical Models). The corresponding r^2 values were 0.82, 0.77, and 0.88 respectively. The RMSE of the three models was 13.2% for Winter, 11.9% for Zatsiorsky's regression equations, and 8.9% for Zatsiorsky's geometrical models.

The centre of mass, as indicated by Winter, was designated by the coordinates (50,0) along a line between the ankle and the metatarsal-phalangeal joint. DEXA showed that the true coordinates of this point could be located at (46.8, -13.7). This would indicate that the centre of mass is located more inferiorly in the foot than predicted.

Comparison of DEXA Centre of Mass Location with Predicted Winter Centre of Mass

For the moment of inertia all three tested models correlated highly with DEXA. Coefficients of determination ranged from 0.81 for Winter to 0.86 for Zatsiorsky's geometrical models. However, the relationship found was not 1 to 1. The error in predicting the true values was 58% for Winter, 34% for Zatsiorsky's regression equations, and 65.2% for Zatsiorsky's geometrical models.

DISCUSSION

The errors in the ability to predict mass show little error. However, errors in prediction of centre of mass and moment of inertia show that current methods of predicting the distribution of this mass are not valid. DEXA values would enable us to more accurately estimate forces and moments at the ankle joint.

NEUROMUSCULAR FUNCTION IN ANTERIOR CRUCIATE LIGAMENT DEFICIENT AND UNINJURED PEOPLE

Glenn N. Williams, Peter J. Barrance, Lynn Snyder-Mackler, Michael J. Axe, Thomas S. Buchanan

Center for Biomedical Engineering Research, University of Delaware, Newark, DE, USA E-mail: glennwms@udel.edu

INTRODUCTION

It is estimated that 250,000 anterior cruciate ligament (ACL) injuries occur in the United States each year (Boden, 2000). Some people can cope with ACL injury and return to sports, but most cannot without surgical intervention. The annual cost of this treatment is over \$1.5 billion per year (Boden, 2000). Longitudinal evidence indicates that people who sustain ACL injuries suffer early knee osteoarthritis despite successful treatment (Daniel, 1994). The inability to cope with ACL injury and the incidence of osteoarthritis following this injury may be related in part, to neuromuscular function. The purpose of this study is to compare the neuromuscular function of people with ACL deficiency (ACL-D) with that of highly active uninjured people using an experimental protocol that requires fine control of force and position.

METHODS

Five non-coping ACL-D subjects (mean age 28 ± 13 years) and 5 uninjured subjects (mean age 27 ± 6 years) have volunteered to participate in this study to date. All subjects were regular participants in high-level sports. The subjects' goal in the experimental protocol was to position a circular cursor over a narrow target that consisted of two concentric circles. The cursor moved in response to loads produced against a 6 degree of freedom (DOF) load cell to which the subjects were rigidly fixed via a cast and clamp at the distal shank. Targets appeared in random order at one of 18 positions (located at every 20° of a circle in the flexion-extension-varus-valgus plane). Seventy-two trials were performed bilaterally at each of three knee flexion angles - 50° , 70° , and 90° . Hip flexion was standardized at 90° . A load of 30% maximum force (collected prior to the trials) was required to move the cursor toward the target. Subjects were required to hold the cursor within the narrow target for 1 second before the trial was considered successful.

Electromyographic (EMG) data were collected from the medial hamstrings, lateral hamstrings, sartorius*, rectus femoris, tensor fascia lata*, gracilis*, vastus medialis, vastus lateralis, and the medial and lateral gastrocnemius during the final second in each target using either surface or indwelling electrodes (* = indwelling electrodes used). The data were later full-wave rectified, averaged, and normalized using maximum EMG data collected earlier in the session.

The specificity of muscle utilization was analyzed by calculating a specificity index for each muscle using the formula: $\sum(EMG_i \cdot \underline{\lambda}) / \sum |EMG_i|$, where EMG_i describes the EMG magnitude in each target direction and $\underline{\lambda}$ is the unit vector in the EMG direction. Besides specificity indices, EMG magnitudes and maximum force production were evaluated. Data were broken into 4 group-limb combinations: control

left, control right, ACL-D involved and ACL-D uninjured. A two factor (group-limb, angle) MANOVA with each muscle as a dependent variable was used to test for significant differences in muscle specificity and magnitude. *Post hoc* Bonferroni-adjusted multiple comparison tests were performed. Regression analysis was used to assess the relationship between specificity and strength (peak force production).

RESULTS AND DISCUSSION

Quadriceps and hamstrings strength were similar between groups. There was a significant group-limb main effect ($p < .05$) for muscle specificity in all muscles except for the lateral hamstrings, sartorius, and gracilis. In general, the ACL-D involved limb had significantly less specificity of muscle action than the other group-limb combinations, which were usually similar. The relationship between muscle specificity and strength was insignificant. Interestingly, the mean EMG magnitude for the ACL-D involved vastus medialis and vastus lateralis were 83-100% greater than the uninjured groups' respective values. In Figure 1, mean EMG vectors at each target are plotted in polar coordinates. This figure demonstrates the decreased specificity of the vastus lateralis in the ACL-D group (note the activity in flexion in the involved limb) and that rather than quadriceps avoidance, there is a greater amount of quadriceps activity. These findings suggest that ACL injury leads to alterations in neuromuscular function and may help to explain the variable disability associated with ACL deficiency, as well as, have implications for the predisposition for early osteoarthritis following ACL injury.

REGISTRATION OF 3D BONE GEOMETRY WITH CINE-PHASE CONTRAST MRI DATA FOR THE DETERMINATION OF IN VIVO JOINT KINEMATICS

Peter J. Barrance, Glenn N. Williams and Thomas S. Buchanan.

Center for Biomedical Engineering Research, University of Delaware, Newark, DE. USA. Email: peteb@udel.edu

INTRODUCTION

Accurate determination of *in vivo* joint kinematics has been the subject of much previous research. These investigations are important for assessing the subtle changes in joint function resulting from injury to passive or dynamic stabilizing structures. In the technique described here, 3D geometries of the articulating bones are modeled, and the motions of each are computed. Optimal trajectories of each bone are modeled to achieve correspondence with cross-sectional images and velocity data acquired in a Cine-Phase Contrast (Cine-PC) MRI study of the joint in motion. This allows accurate calculation of kinematic joint parameters, as well as estimation of areas and velocities of contact between the articular surfaces. Joint kinematics are evaluated during functional movement. This report describes an application of the method to the determination of kinematic parameters in the knee.

METHODS

MRI data is acquired using a protocol similar to that described by Sheehan et al. (1998.) Subjects perform a repetitive knee flexion/extension exercise within an MRI scanner (GE Signa LX) while lying supine. The knee angle varies between approximately 30° flexion and full extension.

Cine-PC data: A sequence of 24 frames of data is collected through the motion cycle on a user-specified sagittal image plane. Each resulting data frame yields four separate images on the selected plane; one is the usual anatomical cross-section (magnitude image), and the others are *encoded with velocity* in three orthogonal directions.

3D static scans: A sequence of high resolution axial plane MR images is acquired, centered at the subject's knee joint.

3D model reconstruction: 3D graphical models of the surfaces of the distal femur and proximal tibia are created. The periphery of each bone is traced on the 3D MR images using a digitizing tablet. Custom developed software is used to reconstruct the polygonal graphical models (Fig. 1a)

Cross-section registration: The sagittal plane MR images show lines of low signal around the edge of each bone's intersection with the image plane. An initial estimate of the location of the bone is made by intersecting the geometric model with a *virtual* cutting plane in various position and orientations. The difference between observed and virtual cross-sections is minimized computationally. Using this procedure, a region of interest (ROI) of each sagittal image is extracted which contains only points lying within the bone of interest (Fig. 1b).

Velocity tracking: Using the ROI velocity data and invoking the relationships between the motions of particles within rigid bodies, the angular and linear velocities of the bone are estimated. An iterative procedure minimizes the error between the apparent velocities produced by a modeled trajectory of the rigid body and those observed in the velocity data set.

Figure 1: (a) 3D geometric models of knee joint bones. (b) Distal femur ROI of sagittal image is determined by cross-section matching.

Kinematic data: In order to quantify joint motion, anatomically based coordinate systems are fixed within each bone, and the relative motion is decomposed into rotation and translation parameters. To locate landmarks away from the joint, the surface of each 3D model is matched to a larger scale, lower resolution geometric model of the whole bone. The parameters shown here follow the convention of the knee joint coordinate system of Grood and Suntay (1983.)

RESULTS AND DISCUSSION

Figure 2: Grood & Suntay's joint coordinate system parameters calculated for a single knee: (a) rotations, (b) translations

Figure 2 shows an example sequence of joint parameters calculated through the knee flexion/extension cycle. As the knee is flexed, coupled internal rotation and posterior translation of the proximal tibia relative to the distal femur are observed. In an ongoing study, the current technique is being applied to quantify differences between the kinematics of normal and anterior cruciate ligament deficient knees.

INTRODUCTION

Three actuation torque characteristics (peak torque, angular impulse, and acceleration at the hard endpoint) were chosen to provide an acute indication of the injury risk associated with using a hydraulic actuation joystick found commonly in North American excavators.

METHODS

The joystick dynamics model derived and validated in the companion WCB paper was used to quantify the actuation torque requirements for nine, untrained operators during the performance of a joystick routine which consisted of six sets, each involving a different experimental condition (slow speed-normal stiffness, fast speed-normal stiffness, slow speed-light stiffness, fast speed-light stiffness, slow speed-heavy stiffness, fast speed-heavy stiffness) of eight right-hand-side joystick motions using the excavator mock-up pictured in Figure 1. The normal stiffness condition was what would be found in an operating excavator. Subjects were instructed to move the joystick from the neutral position to one of four endpoints (forward, back, left or right) and back to neutral again. Angular displacement and acceleration were determined respectively using a three camera VICONTM motion analysis system and a pair of uniaxial piezoelectric accelerometers thread-mounted (to the top of the joystick) orthogonally to one another.

The instantaneous risk to the operator over the course of the joystick motion (not including the hard endpoint) was evaluated using the peak torque value. Peak torque at the hard endpoint of the motion could not be determined since the mathematical model did not include end-condition stiffness. Angular impulse, taken as the area under the torque time curve (not including the hard endpoint), provided an indication of the sustained exposure to torque. The third indicator, acceleration at the hard endpoint, was included to provide an indication of risk as the joystick came to a sudden stop at the hard endpoint.

RESULTS AND DISCUSSION

Based upon significance determined from analysis of variance procedures and post-hoc tests, for peak torque, fast motions to the right or left using the heavy stiffness joystick provide the highest risk to the operator. For angular impulse, slow motions forward and to the right using the heavy stiffness joystick were found to provide the highest risk. For fast speeds, where the angular impulse values were lower, there was greater risk with the forward than the right motions. Based upon the acceleration results, fast motions to the left presented the

highest risk to the operator for sudden palm and/or finger compression.

Figure 1: Excavator mock-up

CONCLUSIONS

From the results obtained from the three indicators, it is safe to conclude that side-to-side motions pose the highest injury risk to an operator. Based upon the angular impulse data, slow motions pose a higher exposure risk to an operator while based upon the acceleration at the hard endpoint values, fast motions pose a higher instantaneous compression risk of the soft tissues of the fingers and palm. Golsse's (1989) finding that skilled forest machine operators make over 20,000 motions with one joystick over the course of nine hours of work indicates that dynamic joystick actuation torque requirements should be considered when designing joysticks.

FUNCTIONAL CHANGES IN KIDNEY CELLS IN RESPONSE TO SUSTAINED HYDROSTATIC PRESSURE

Julie S. Martin¹ (jspoelke@purdue.edu), Hiroki Yokota², and Karen M. Haberstroh¹

¹Department of Biomedical Engineering, Purdue University, West Lafayette, IN 47907-1296

²Department of Biomedical Engineering, Indiana University Purdue University at Indianapolis, Indianapolis, IN

INTRODUCTION

Pathologically elevated hydrostatic pressures have been shown to alter functions in many tissues and organs, including the kidneys (Meldrum, 2001). It is our hypothesis that changes in the cellular mechanotransduction pathway lead to such altered cell/tissue responses following exposure to an increased pressure stimulus. This study will aim to understand these complex signaling pathways by monitoring the cellular and molecular level responses of two important renal cells (specifically, tubular epithelial and inner medullary cells) under a known pathological hydrostatic pressure (60 cmH₂O; McGuire, 1981).

METHODS

Cell Culture. IMCD (cell line CRL-2123; ATCC) and LLC-PK1 (cell line CL-101; ATCC) cells were cultured under standard cell culture conditions (that is a sterile, humidified, 37°C, 5% CO₂/95% air environment) in Ham's F-12 and Medium 199, respectively, supplemented with 10% Fetal Bovine Serum (FBS) and 1% penicillin/streptomycin (P/S). All cells were used between population numbers 4 to 15 for the pressure experiments.

Pressure Experiments. Prior to the experiments, IMCD and LLC-PK1 cells were seeded (3,523 cells/cm²) onto etched glass coverslips. After two days in culture, the standard culture media was removed and replaced with Ham's F-12 or Medium 199 supplemented with 5% FBS and 1% P/S. Kidney cells were then exposed to a sustained pressure of 60 cmH₂O for 6 hours, 12 hours, 24 hours, 3 days, or 7 days using a computer controlled pressure chamber. Control cells were maintained under 0.3 cmH₂O pressure for similar periods of time.

Cell Proliferation. Following pressure exposure, kidney cells were fixed using a 3.7% formaldehyde solution and the nuclei were stained using Hoescht 33258 (Sigma). Cell proliferation data were determined by averaging the number of cells in each of five random fields per substrate. Each experiment was run in duplicate and repeated at least three separate times. Statistical analysis was performed using student t-tests, with $p < 0.05$ considered significant.

Cytoskeletal Staining. Following pressure exposure, kidney cells were fixed in a 3.7% formaldehyde solution. The microtubules were stained using a fluorescently conjugated α -tubulin antibody according to the manufacturer's protocol (Sigma); microfilaments were subsequently counter stained using rhodamine phalloidin and according to the manufacturer's protocol (Molecular Probes). Cytoskeletal elements were then visualized in the same frame using fluorescence microscopy.

RESULTS AND DISCUSSION

Results provided the first evidence that in both medullary and tubular kidney cells, exposure to hydrostatic pressures of 60 cmH₂O altered cell functions. Specifically, cell proliferation of controls (or cells maintained under 0.3 cm H₂O pressure) was increased ($p < 0.05$ at 12 hours and $p < 0.1$ at 24 hours) compared to cells exposed to pressures of 60 cmH₂O at all time points up to 24 hours. In contrast, pressure exposed cell numbers were greater than controls for the remainder of the seven day experiment. The most significant difference was observed at seven days, when, for example, the average cell counts of tubular cells under pressure increased by 25% ($p < 0.01$) compared to controls. These results were intriguing and led us to question the mechanism resulting in altered kidney cell growth following exposure to hydrostatic pressure. In previous studies with other cell types, the cytoskeleton has been implicated in such signal transduction to the nucleus (Numaguchi, 1999). Our fluorescence microscopy studies supported these findings, and provided the first evidence of such time and pressure- dependent cytoskeletal alterations in kidney cells exposed to hydrostatic pressure. Specifically, the microfilaments in control cells remained elongated and in continuous fibers throughout the length of the cell. In contrast, kidney cells under 60 cmH₂O had shorter microfilament fibers that were branched throughout the cell.

Future work in our lab will be focused on understanding the molecular mediators (such as c-fos and c-jun) involved in the signal transduction pathway of renal cells to hydrostatic pressure. This information may help identify a controllable step under pathological conditions, and may aid in the design of novel, targeted drug therapies.

INTRODUCTION

The onset of atherosclerosis is described by the response to injury theory: endothelial cells suffer an injury resulting in altered morphology, metabolism, or other cell functions, which stimulates smooth muscle cell proliferation and migration into the lumen, ultimately causing vascular thickening and hardening (1). The objective of the present study was to determine which soluble and transferable factors, released by endothelial cells in response to laminar fluid flow, induce smooth muscle cell function indicative of atherosclerotic conditions.

MATERIALS AND METHODS

Cell Culture. Rat aortic endothelial cells (RAEC) and rat aortic smooth muscle cells (RASMC) (VEC Technologies) were maintained in MCDB-131 Complete Medium (VEC Technologies) or Dulbecco's Modified Eagle's Medium (DMEM; Hyclone) supplemented with 10% fetal bovine serum (...) and 1% penicillin/streptomycin (...), respectively. Cells were grown under standard cell culture conditions, that is, a humidified, 37°C, 5% CO₂, 95% air environment. All cells were used at population numbers five through fifteen without further characterization.

Exposure of RAEC to Laminar Flow. Prior to fluid flow exposure, endothelial cells were seeded (35,242 cells/cm²) on etched glass cover slides previously coated with fibronectin (10 µL/mL; Sigma). Once confluent, endothelial cells were exposed to laminar fluid flow in a modified version of the parallel plate flow chamber (3) for 6 or 24 hours. The shear stress generated in this system was 11.25 dyne/cm².

RAEC Morphology. At the end of the prescribed time period, endothelial cell morphology was visualized using light and fluorescence microscopy. Briefly, cells were fixed with 4% formalin in a sodium phosphate buffer solution for ten minutes and stained with rhodamin phalloidin following manufacturer's protocol (Molecular Probes). Cell morphology was visualized under the light microscope and F-actin filaments were visualized using fluorescence microscopy.

mRNA Expression by RAEC Exposed to Fluid Flow. Following exposure to fluid flow, mRNA from endothelial cells was digested with Triazol (Gibco), extracted with chloroform, and precipitated with isopropanol. Reverse transcriptase-polymerase chain reaction was performed using sample RNA and the Ambio Retroscript Kit with primers (20 pmol/µL; Gibco) specific to either glyceraldehyde 3-phosphate dehydrogenase (GAPDH), cyclooxygenase-2 (COX-2), platelet derived growth factor (PDGF), or endothelial cell nitric oxide synthase (ecNOS). Electrophoresis of cDNA samples was performed in a gel

casting system (Biorad) with 1X TAE buffer for 1.5 hours at 200V. The amount of cDNA in each lane was determined using a phospho imager (Biorad) and densitometry.

RASMC Proliferation Under Conditioned Medium. RASMC were seeded (3,500 cells/cm²) onto etched borosilicate glass coverslips and incubated under standard cell culture conditions in DMEM for 24 hours. At this time, the standard media was removed and replaced with either fresh MCDB-131 medium (control) or *conditioned MCDB-131 medium* (experimental). *Conditioned medium* was collected from the laminar flow system after a 24-hour experiment; this medium contained any soluble factors released by endothelial cells upon exposure to laminar flow.

All cells were allowed to proliferate in a static environment under standard cell culture conditions for 1, 3, and 5 days. At the end of the prescribed time period, cells were fixed with 4% formalin and stained with Hoechst 33258 (Sigma) and counted.

RESULTS AND DISCUSSION

After shear exposure, endothelial cells realigned in the direction of flow, whereas cells maintained under control conditions demonstrated typical cobblestone morphologies. Furthermore, mRNA studies confirmed previous reports of increased COX-2, PDGF, and ecNOS mRNA expression (2,3) following laminar flow exposure. More importantly, our results have provided the first evidence that smooth muscle cell proliferation was altered (compared to that of cells maintained under control media) as a direct result of the soluble and transferable factors released by endothelial cells in response to fluid flow.

EVALUATING POSSIBLE TECHNIQUES FOR DELAYING THE WRIST RELEASE: A COMPUTER SIMULATION APPROACH

Sasho Mackenzie and Eric Sprigings

College of Kinesiology, University of Saskatchewan
sashomackenzie@hotmail.com

INTRODUCTION

A delayed wrist release during the down swing in golf is a common characteristic of golfers that develop high clubhead velocity at impact (Robinson, 1994). It has been shown that the wrist release can be delayed using a resistive wrist torque with a corresponding increase in clubhead velocity at impact. The optimal length of the delaying wrist torque was approximately 50ms (Sprigings et al., 2001). Adequately performing this technique would require precise timing from the golfer. It is possible that a phenomenon other than a resistive wrist torque is responsible for the delayed release. The purpose of this paper is to evaluate two possible techniques for delaying the wrist release. The first involves increasing the angular acceleration of the segments proximal to the wrist through increased muscular torques. The second involves applying linear accelerations to the origin of the model at the spine.

METHODS

A 2-dimensional, 3-segment mathematical model, consisting of a torso, left arm, and golf club, was developed to simulate the golf swing. Torque actuators, constrained by activation rate and muscle force-velocity properties (Alexander, 1990), were inserted at the proximal end of each of these three segments. The formulation of the equations for the model was similar to that previously published by Sprigings et al. (1998). Two separate sets of trials were conducted using the model. First, systematic increases of the trunk and shoulder torques were applied to the model. The torques were increased by adjusting the main parameters in the activation rate and force-velocity functions. The angular displacement of the arm from the right horizontal (T_A) before the relative wrist angle increased was the measured dependent variable. Second, the model's origin at the spine was accelerated linearly (A_O). The angular displacement of the arm was again used as the dependent variable. The linear displacement of the origin (R_O) was also recorded.

RESULTS & DISCUSSION

The effects of increased trunk and shoulder torques on delaying the release of the wrist are shown below (Table 1). Increasing the trunk torque alone resulted in a later release. Increasing both torques also resulted in a later wrist release. Increasing the shoulder torque alone resulted in an earlier release. A positive vertical acceleration of the model's origin resulted in a later release, while a negative vertical acceleration produced an earlier release (Table 2). The

combination of a positive vertical acceleration and a 50% increase in trunk torque resulted in the greatest delayed release (172.5°), while combining a negative vertical acceleration and a 50% increase in shoulder torque produced the smallest delayed release (164.4°) (Table 3).

Table 1: Angular displacement of the arm ($^\circ$) at release for various trunk and shoulder torque combinations.

Torque Increase	Trunk	Shoulder	Shoulder & Trunk
0 %	166.9	166.9	166.9
30 %	168.4	165.7	169.2
50 %	169.9	165.2	170.7

Table 2: Angular displacement of the arm ($^\circ$) and translation of the origin (cm) at release for various accelerations.

A_O (m/s/s)	0	+5x	-5x	+5y	-5y
T_A ($^\circ$)	166.9	165.1	166.7	168.4	164.0
R_O (cm)	0	9.2x	-11.4x	10.2y	-10.4y

Note: x – horizontal; y – vertical

Table 3: Angular displacement of the wrist ($^\circ$) at release when accelerations and torque increases were applied simultaneously.

A_O (m/s/s)	50% Torque Increase	
	Shoulder	Trunk
5y	168.2	172.5
-5y	164.4	168.9

Note: y – vertical

These results suggest that the position of wrist release can be altered by manipulating the angular accelerations of the segments proximal to the wrist and by accelerating the origin of the model. Whether or not these factors play a role in an experimental setting has yet to be determined.

THE EFFECTS OF STEP UNCERTAINTY ON IMPACTS AND CONTACT KINEMATICS WHILE RUNNING ON A TREADMILL

Joshua M. Thomas and Timothy R. Derrick

Iowa State University, Ames, IA
Corresponding Author: jmt@iastate.edu

INTRODUCTION

Impacts have been implicated in overuse injuries in runners (Messier et al.). They have been studied under normal environmental conditions but have not been looked at during environmental conditions that produce uncertainty in the runner. The popularity of running in society has resulted in a variety of training methods and conditions that would not be considered “ideal.” These conditions are not comparable to controlled laboratory conditions. The purpose of this research was to determine the effects of step uncertainty on impacts and contact kinematics.

METHODS

Twelve experienced middle to long distance runners ran at a self-selected pace (3.30 ± 0.24 m/s) on a treadmill under three light intensities (light ~40 foot candles, medium ~0.4 foot candles, dark ~0.02 foot candles) and two surfaces (smooth and irregular). The irregular surface was achieved by attaching wood slats (0.013 m x 0.051 m x 0.406 m) to the treadmill surface. Approximately 30% of footfalls made contact with a bump. Accelerometers were attached to the head and leg. Electrogoniometers were used to measure knee and subtalar motion. After two minutes of running the data were sampled (1000 Hz) for approximately 11 strides. Heart rate data were also collected during this period. Repeated measures analyses of variance were performed with an alpha level of 0.05.

RESULTS AND DISCUSSION

Heart rate (HR) was significantly higher during the irregular surface conditions but light intensity had no effect. Stride length (SL) did not show a significant effect of either surface or light intensity. Knee angle at contact (KNEEC) showed greater flexion with the irregular surface. Rearfoot angle at contact (RFC) was decreased during the irregular surface but it was non-significant ($p=0.056$). There were no significant differences in the peak head impacts (PH). Peak leg impacts

(PL) increased significantly on the irregular surface but light intensity had no effect. This resulted in a nonsignificant increase in impact attenuation (ATT) during the irregular surface running.

Table 2: Impact variables, means and (SD)

	Smooth	Irregular	Light	Medium	Dark
PH (g)	1.52 (0.47)	1.60 (0.41)	1.55 (0.40)	1.55 (0.46)	1.57 (0.47)
PL (g)	5.85 (1.93)	6.62 (1.39)	6.19 (1.34)	6.14 (1.69)	6.37 (1.79)
ATT (%)	72.4 (7.14)	74.8 (4.42)	73.7 (5.32)	73.4 (5.25)	73.7 (5.77)

Questionnaire results indicated that runners felt more anxious while running on a treadmill with bumps. In response they altered knee joint and possibly subtalar joint kinematics. Despite the small degree of change in KNEEC between surfaces, it was significant. KNEEC has been shown to cause impact forces to decrease up to 65 N per degree of change (Gerritsen et al.), however increased KNEEC also decreases the effective mass (Denoth) and therefore allows a greater acceleration of the leg. The result was greater PL accelerations and greater impact attenuation. Because the increased impacts were, at least in part, the result of a decreased effective mass, they probably did not increase injury potential. In fact, the results of Gerritsen et al. suggest the impact forces may have decreased in response to the increase in KNEEC. This kinematic adjustment may have had an associated metabolic cost. It has been shown that an increased knee contact angle can increase metabolic cost (McMahon et al.) but in this study subjects also had increased levels of anxiety while running on the irregular surface.

The irregular surface had a greater affect than light intensity. Subjects appeared to increase KNEEC to accommodate unexpected changes in terrain. They may have also decreased RFC to minimize the potential for an inversion sprain on the irregular surface. HR increased as a result of increased metabolic cost or increase levels of anxiety.

INTRODUCTION

One major challenge in the development of finite element models of the hip is the modeling of joint contact surfaces and their contact pressure distributions. The complexity of the parameter space and the computational intensity of the finite element analysis (FEA) make them less desirable for the development of models for individual-based functional data. Discrete element analysis (DEA) (also known as rigid-body spring modeling) (Kawai, 1986; An et al. 1990, Li et al., 1997) is a simple, fast technique suitable for such data. The objective of this work was to determine whether the contact pressures on hip joints calculated using this technique could be experimentally validated.

METHODS

The 3D surface geometry of two porcine pelvis and femur bones was digitally scanned using an H40 Laser head with Nvision Faro Arm laser scanner. A computer model of the acetabular cartilage of the hip was generated from the digitized scanned data (Figure 1A). Discrete element analysis (Figures 1A and 1B) was performed for four different pelvis orientations and three sets of loads (890, 1335, and 1780 N). In order to validate the modeling results, Fuji prescale film was used to measure joint contact pressure when a preset axial force was applied from femur to the pelvis using an Instron testing machine (Figure 1C). The pelvis orientation was rotated and tested at 10° adduction, 10° abduction, 20° abduction, and normal standing positions. Each pressure pattern was analyzed for location and magnitude of the maximum pressure and the percentage of joint contact surface registering above 2.5 MPa (lower limit of the film).

RESULTS AND DISCUSSION

The DEA model consistently predicted the location of the maximum contact pressure with an error of less than 10% as compared to experiments. The simulation consistently underestimated the magnitude of the maximum contact pressure. The mean underestimation was 20±6.5%. The congruency assumption for the simulated contact surface led to an overestimation of the contact area, which in turn resulted in the underestimation of the maximum contact pressure. However, the standard deviation of the difference between the model and experimental results was relatively small.

Figure 1. (A) Contact pressure distribution on the surface of the acetabular cartilage. The load of the femur is 1335 N along Z-axis. (B) Projection of the cartilage surface into a plane. The solid lines separate anterior, superior, and posterior portions of the cartilage. The arrow and the + mark represent the polar coordinates of the maximum pressure. (C) The experimental contact pressure distribution on a rosette cut from the Fuji prescale films.

SUMMARY

DEA technique can approximate the pressure distribution within an acceptable range. This technique is at least 2 orders of magnitude faster than FEA for contact analysis. Therefore, it can be used for applications that require dynamic subject-specific models of pressure distribution in articular joints. By validating the DEA technique, this study supports the effort necessary to develop hybrid FEA/DEA techniques for analysis of stress in both bones and articular joints.

DEVELOPMENT OF A HIGH PAYLOAD TESTING SYSTEM TO STUDY JOINT KINEMATICS AND FORCES

Richard E. Debski, Shon Darcy, Jorge E. Gil, Jesse Fisk, Savio L-Y. Woo

Musculoskeletal Research Center Department of Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, USA

INTRODUCTION

Robotic manipulators have been utilized in orthopaedic research to study joint kinematics and forces in ligaments (Livesay, Fujie et al. 1995; Fujie, Livesay et al. 1996; Rudy, Livesay et al. 1996). A new high-payload robotic/universal force-moment sensor (UFS) testing system is being developed to determine the forces in ligaments while simulating *in vivo* activities with high joint contact forces. This testing system will also reproduce joint kinematics, data imported from patients. To accomplish these tasks, the system must accurately reproduce the path of motion. Therefore the objective of this study is to evaluate position repeatability and resulting force variations measured with the high-payload robotic/UFS testing system.

METHODS

A spring model that simulated the stiffness of the knee with four linear springs was used to provide resistance to the motions of the robot (figure 1). The high-payload robotic/UFS testing system (S-900W, FANUC Robotics North America, Inc, Auburn Hills, MI) was moved through six positions in the horizontal and vertical planes. The vertical plane simulated knee flexion-extension. At each position, three points were digitized on the robotic end-effector using a MicroScribe (3DX) to determine position repeatability. The MicroScribe can digitize points with an accuracy of less than .1 mm. Force was recorded directly from the UFS (Theta Model, ATI-Industrial Automation, Garner, NC). The positions in the horizontal and vertical planes were repeated twelve times alternating between clockwise (CW) and counterclockwise (CCW), to investigate position repeatability due to backlash. This protocol causes the manipulator to approach positions different directions.

RESULTS

Transnational (Tran) and rotational (Rot) variability range from .2 to .4 mm and .1 to .4°. Force variability ranges from 1.2 to 10 N, with the average variability for the vertical and horizontal planes being 5.4 and 2.6 N. The variability in positions and forces (Forc) is calculated as the standard deviation of the 12 trials. Resultant force (FMag) measured by the UFS due to deformation of the springs ranged from 148 to 667 N. The highest percent force variability was 2.6% while the average variability for the horizontal and vertical planes was 1.5% and .7% respectively.

DISCUSSION

The high-payload robotic/UFS testing system can precisely reproduce a path of motion as demonstrated by the position repeatability, which resulted in little variation in force.

Position repeatability and force variability is relatively constant for all positions and magnitudes of force examined. Therefore force variability is not affected by force magnitude. High force variability at certain positions was caused by reseating of the spring attachments in the spring model. In the future the high-payload robotic/UFS testing system will be used to evaluate clinical examination, post-operative rehabilitation exercises and provide experimental validation for computational models in response to *in-vivo* kinematics obtained from patients.

Table 1: Position repeatability and force (F) variation [Force (N), Tran (mm), Rot (deg)].

INTRODUCTION

Ankle sprains are one of the most common athletic injuries (Thacker et al., 1999). Stress to the lateral ligament structures occur when the ankle is inverted, plantarflexed, and internally rotated. This mechanism occurs frequently during movement from open to closed chain activities such as landing from a jump (Hume & Gerrard, 1998), coinciding with changes from ligamentous to osseous restraint of the hindfoot (Stormont et al., 1985). A prophylactic ankle brace (PAB) is frequently used to reduce the risk of lateral ankle ligament injuries (Thacker et al.). Research has shown that PABs are beneficial in preventing ankle injuries (Sitler et al., 1994).

During landing from a jump, the body's energy is converted from potential to kinetic energy, and it is through the eccentric tension of muscles that the body begins to absorb these forces (Dufek and Bates, 1990). The greatest risk of injury is at the transitional period between flight and landing. This study examines the effect PABs have on 3-D kinematics and kinetics of the ankle and knee during landing from a lateral jump.

METHODS

Ten healthy males (age 26±4 yr; height 180.3±15.2 cm; mass 85.4±28.7 kg) performed five trials of a lateral drop jump under two conditions (AirCast[®] Sport Stirrup PAB and nonbraced control). A wooden box with a height of 46 cm was used to standardize the landings across subjects. Kinematic and kinetic variables were collected using a five camera, 120 Hz VICON 370[®] Kinematic System and a Kistler[®] force plate. A modified Helen Hayes marker set for the lower extremity was used for data collection. Data were collected for the ankle and knee during the period from the initial forefoot contact on the force plate to the point where the sacrum reached its lowest level.

RESULTS AND DISCUSSION

The ankle and knee kinematic results are presented in Table 1, and the kinetic results are found in Table 2. The total sagittal plane range of motion (ROM) at the ankle was significantly reduced 4.11° with the PAB. The initial rate of dorsiflexion was reduced 21.1% while utilizing the PAB. A combination of a decrease in ROM and rate of loading may aid in protecting the ankle ligaments from excessive stress. The decrease in ankle sagittal plane ROM at contact resulted in an increase of 2.2° in initial knee flexion angle with the PAB. The finding of a decrease in knee internal rotation angle was associated with an increase in internal rotation moment. The

decrease in valgus moment at the knee might reduce the stresses on the intrinsic structures (e.g. meniscus). The reduction in ankle internal rotation moment may be reducing stress on the lateral ligaments, which could protect them from injury. A decrease in the total ankle power absorbed was associated with no significant change in total knee power. The increases in maximum ankle inversion and knee internal rotation moments are not necessarily experienced by the lower limb. Some percentage of these loads may be borne by the PAB. Further research is needed to determine if the PAB is load sharing with the lower extremity, hence further reducing the kinetics experienced by the limb.

SUMMARY

The pilot data indicates that the lateral ankle ligaments are protected by the PAB when landing from a lateral drop jump, without deleteriously effecting the surrounding structures of the lower extremity.

Table 1: Ankle and Knee Kinematic Variables

Max = maximum; PF = plantarflexion; DF = dorsiflexion; Min = minimum;

Variable	PAB	Control
Max PF Angle (deg)	12.4±5.1***	19.7±5.4

IS DAMAGE DEVELOPMENT DIFFERENT IN BONES WITH A SHORTER FATIGUE LIFE?

Winson George and Deepak Vashishth

Department of Biomedical Engineering
Rensselaer Polytechnic Institute
110 8th St. Troy NY 12180, vashid@rpi.edu

INTRODUCTION Progressive damage development in the form of matrix microcracking, delamination and coalescence of microcracks causes the primary, secondary and tertiary loss of bone stiffness (Schaffler et al. 1990). However, it is unknown whether this 3-phase characteristic behavior of bone fatigue is altered with aging and disease, where a marked reduction in the fatigue life of bone is expected without any change in the imposed loading. In the current study we used modulus reduction data from two groups of bovine bone specimens demonstrating significantly different fatigue life under identical loading conditions to test the hypothesis that a reduction in fatigue life of bone is accompanied by a change in the 3-phase characteristic behavior of bone fatigue.

METHODS Twelve bovine bone cylindrical dumbbell specimens (3mm dia) were wet machined from four bovine tibiae (Age:18-24 mo.). Specimens were fatigue tested on an MTS MiniBionix System under identical loading ($\pm 50\%$ UTS @ 2 Hz; Wet). Based on the statistical analysis of the fatigue life data the specimens were separated into long (5933 ± 3314) and short life (643 ± 332) groups of six specimens each. Stress-strain data collected continuously for every specimen until failure was then used to calculate tangent moduli under tension and compression in both the short life (SL) and long life (LL) groups. The reduction in moduli was plotted against fatigue life (Fig. 1) and compared within each group to determine the occurrence of the primary, secondary and tertiary phases of modulus loss (Table 1). Initial moduli and total moduli loss were also compared between the short and long life groups.

RESULTS AND DISCUSSION Although the total moduli loss was the same (*Tension*:SL=26%; LL=25%, $p=0.81$; *Compression*:SL=10%, LL=11%, $p=0.83$), the modulus degradation profiles between the groups were fundamentally different (Fig. 1). Short life group displayed the three phases of tensile modulus loss at 0-10%, 10-80% and 80-100% of the fatigue life (Table 1). In contrast, long fatigue life group showed only two phases of modulus loss at 0-70% and 70-100% of the fatigue life (Table 1). Compressive moduli degradation profiles were different from tensile moduli degradation profiles and varied significantly between the short and long life fatigue groups (not shown).

The results of this study are consistent with the occurrence of different damage mechanisms (Pattin et al., 1996; Boyce et al. 1998) in tension and compression, and demonstrate, for the first time, the role of progressive damage development in

determining the fatigue life of bone. Specifically, our study shows that bones with long fatigue life do not undergo the primary phase of stiffness loss associated with transverse matrix microcracking and spend majority of their lives in the secondary phase where microcracks, parallel to the loading axis are formed (Pidaparti et al. 2002). Longitudinal microcrack formation and growth cause minimal changes in axial moduli and bone maintains its structural integrity. In contrast, bones with shorter fatigue life undergo primary phase of stiffness loss and form transverse matrix microcracks that combine more easily to cause fracture. Consequently, the secondary phase of fatigue behavior and the fatigue life itself is reduced. Thus, these data suggest that factors affecting the morphology and development of damage play a key role in determining the fatigue life of bone.

Figure 1: Average values of tensile modulus loss in short (SL) and long life (LL) groups.

Table 1: Paired t-tests were used in each group to compare the initial moduli with reduced moduli at different % of the fatigue life (10% increments). Once a difference ($p < 0.05$) was detected, the new reduced moduli was chosen for further comparisons. Columns show p-values for selected load cases.

% Fatigue life → ↓Fatigue Groups	10%	40%	70%	80%	100%

⁴Department of Physical Medicine and Rehabilitation, Harvard Medical School, Boston, MA, USA

INTRODUCTION

Diminished balance ability, seen in older adults, poses a serious health risk due to the increased likelihood of falling (Tinetti et al., 1995). Proprioceptive information is critical to balance control and the prevention of falls in older adults (McChesney and Woollacott, 2000). Recently, balance control in humans has been enhanced by applying mechanical noise to the plantar surface of the feet (Priplata et al., Submitted 2001). This noise-based technique operates by improving the detection and transmission of weak sensory signals contributing to balance control. The goal of the present study was to use electrical noise applied at the knee joint to improve proprioception and balance control in older adults.

METHODS

Thirteen healthy elderly adults (age 68-79) volunteered for this IRB approved study. Subjects were asked to perform 16 trials of single-legged stance on a slightly bent knee for up to 30 seconds while standing on a force platform. Surface stimulation electrodes were placed on the medial and lateral aspects of the stance knee, and electrical noise (zero mean, Gaussian white, SD = 0.05 mA) was applied during 8 of 16 trials in a random order. The level of stimulation was below the cutaneous sensation threshold for all subjects, ensuring a blind treatment condition. Balance improvements were measured as reductions in center-of-pressure (COP) displacement parameters when electrical noise was applied to the knee (STIM). The COP variables investigated were the standard deviations (SD) and maximum excursions in the anteroposterior (AP) and mediolateral (ML) directions, the mean radial (R) displacement, and the cumulative path length and swept area of the COP trajectory. Significant changes

were noted between the STIM and non-STIM conditions using paired *t*-tests.

RESULTS AND DISCUSSION

All but one of seven traditional COP displacement parameters decreased with electrical noise, indicating an overall improvement in balance performance when electrical noise was applied to the knee (Table 1). The improvement was statistically significant for three of these measures ($p < 0.05$). Averaged across subjects, there was a 3.8% reduction in the ML COP SD ($p = 0.041$), a 5.4% decrease in the maximum AP COP excursion ($p = 0.031$), and a 3.1% reduction in the COP path length ($p = 0.041$) with application of electrical noise.

SUMMARY

Imperceptible electrical noise, when applied to the knee, can enhance the balance performance of healthy elderly adults. These balance improvements are likely related to an enhanced ability of knee joint proprioceptors to detect sensory stimuli in the presence of noise. These results suggest that noise-based devices may be effective in improving balance control in elderly people.

Positive percent improvements indicate a reduction in COP displacement with electrical noise. *Indicates a significant p-value at the 0.05 level.

WALKING WITH PLATFORM SHOES – NORMAL WALKING PATTERN?

Andreas Kranzl, Nina Seirlehner, Belinda Priester, Julia Wlcek and Franz Grill
Labor für Gang- und Bewegungsanalyse, Orthopedic hospital Speising, Vienna, Austria
andreas.kranzl@aon.at

INTRODUCTION

Nowadays the young people are wearing platform shoes for fashionable reasons. But this shoes were not designed to be comfortable and healthy. They were designed to be trendy. There are some studies about platform shoes dealing with the higher injury risks caused by the increased lever arm. There are no published data's (known to us) reporting on the influence of the platform shoes onto the gait pattern. Some of the platform shoes have a small high heel component. The biomechanical influence of high heeled shoes was the topic of many research papers. So it would be interest to see the effect of this shoes and if there exists one is it compared to high heeled walking.

METHODS

The subjects for this investigation were 16 young female students. All of them had experience in walking with platform shoes and had the same shoe size. A 3-dimensional optoelectronic system (Motion Analysis Cor.) combined with two force platforms (AMTI) were used to acquire the kinematic and kinetic parameters. Physical examination were performed including ROM, force and alignment of the lower extremity. Three conditions were analyzed: walking barefoot (BF), walking with gym shoes (GS) and walking with platform shoes (PS). The analyzed order were chosen randomized. All trials were carried out at self selected speeds. The platform shoe had 10.3 cm heel height and 6 cm toe height. Statistical analysis for the kinematic and kinetic parameters were performed by using the paired t-test.

RESULTS AND DISCUSSION

Some significant differences between the three conditions were found. Table 1 shows the results for the temporal-spatial parameters. The kinematic parameters showed a reduced max knee flexion during the swing phase for the shoe conditions. No differences for the pelvic and hip motion was detected. The significant greater plantar flexion of the PS were caused by the shoe geometry. A reduced ROM of the ankle joint were found for the GS and PS. In the transverse plane a reduced foot

progression angle were found for both shoe types compared to BF walking. The kinetic parameters showed a higher valgus moment for PS during second half of the stance phase compared to BF. The lowest power generation at the ankle joint was found by the PS followed by the GS and BF walking. At the frontal hip moment after loading response BF and GS walking showed a significant higher moment compared to PS.

Figure 1: kinematic and kinetic results of all three conditions.

SUMMARY

The differences we found were not so big as we expected. Not all reported results for high heeled walking (Opila-Correia,K.A. 1990, Kerrigan,D.C.1998, Snow,R.E. 1994) are corresponding with our PS results. Especial the results for the pelvic and hip are not corresponding to high heeled gait pattern. The risk of injury caused by supination or pronation trauma due to the thicker sole (increased lever arm) should not be neglected.

OPTIMIZED JOINT CENTRES AND AXES OF ROTATION IMPROVE REPEATABILITY OF GAIT DATA

Thor Besier, Daina Sturnieks, Jacque Alderson, and David Lloyd

Department of Human Movement & Exercise Science, University of Western Australia, Perth, Australia

Email: tbesier@cyllene.uwa.edu.au

INTRODUCTION

Imprecise location of anatomical landmarks (ALs) has been noted as the greatest source of error during motion analysis compared to instrument error or skin movement artefact (Della Croce et al., 1997). These errors propagate to joint kinematics and kinematic ‘cross-talk’ and are likely to effect the repeatability of kinematic and kinetic gait data. Mathematical optimization offers a way to functionally determine joint centres and define axes of rotation, independent of ALs (OPTIM method).

The purpose of this paper was to compare the repeatability of a marker cluster model utilising either ALs alone, or ALs combined with optimized joint centres and axes of rotation.

METHODS

Gait analyses were performed on three separate occasions for ten subjects. To investigate inter and intra-tester repeatability, two different examiners administered the testing sessions. A six-camera VICON motion analysis system (Oxford Metrics, Oxford, UK) was used in conjunction with two AMTI force-plates (AMTI, Watertown, MA) to collect motion data (50 Hz) and ground reaction force data (2000 Hz), respectively. Data were collected on at least six walking trials for each limb. The kinematic/kinetic model was constructed using BodyBuilder software (Oxford Metrics, Oxford, UK).

Clusters of three retro-reflective markers were attached to lower limb segments of interest. During a series of static trials, ALs were located relative to each segment cluster (cf. Cappozzo et al., 1995). Hip joint centres were defined using either a regression equation for the AL method (Shea et al., 1997) or by using a functional method for the OPTIM marker set (cf. Piazza et al., 2001). Knee joint axes were defined by the transepicondylar line of each femur in the AL method, or by an optimal helical axis for the OPTIM method (cf. Stokdijk et al., 1999).

A Coefficient of Multiple Determination (r^2 , Kadaba et al., 1989) was used to determine the repeatability of the wave form data, normalised to stride. A two-way ANOVA was then used to determine the difference in r^2 values between using the AL and OPTIM method, and to determine any differences in repeatability between and within testers.

RESULTS AND DISCUSSION

The OPTIM method had little effect on the repeatability of sagittal plane data (Table 1). However, the frontal and transverse kinematic data for the knee were more repeatable using the OPTIM method ($p < 0.05$). Furthermore, there appeared to be less cross-talk between knee flexion and knee abduction/adduction using the OPTIM method (based on a

correlation coefficient). The kinetic data were less effected by the method used, due to the repeatability and influence of the ground reaction force.

Table 1: Mean \pm SD Coefficients of Multiple Determination (r^2) for kinematic gait data for the AL and OPTIM methods.

		<i>Flexion Extension</i>	<i>Abduction Adduction</i>	<i>Internal External Rot'</i>
Hip	AL	0.980 \pm 0.009	0.925 \pm 0.036	0.547 \pm 0.204
	OPTIM	0.982 \pm 0.008	0.936 \pm 0.027	0.583 \pm 0.203
Knee	AL	0.981 \pm 0.011	0.736 \pm 0.138	0.809 \pm 0.130
	OPTIM	0.982 \pm 0.011	0.844 \pm 0.129	0.854 \pm 0.116
Ankle	AL	0.947 \pm 0.018	0.651 \pm 0.225	0.795 \pm 0.122
	OPTIM	0.950 \pm 0.016	0.630 \pm 0.204	0.753 \pm 0.159

The between-tester repeatability was expected to improve using the OPTIM method, as the examiner source of error in locating ALs is removed. However, within and between-tester repeatability was similar using both techniques. This was perhaps due to the experience of the examiners performing the tests.

SUMMARY

Repeatability of gait data was slightly improved by optimizing joint centres and axes of rotation. However, given that the optimization technique does not rely on the accurate location of ALs and is faster and easier to implement, the use of optimized joint centres and axes of rotation in a daily clinical setting should be encouraged.

DEVELOPMENT AND VALIDATION OF AN APPROACH TO RECORD AND REPRODUCE KINEMATICS

Jennifer Zeminski, Mary T. Gabriel, Maribeth Thomas, Richard E. Debski, Freddie H. Fu, Savio L-Y. Woo

Musculoskeletal Research Center, Department of Orthopaedic Surgery, University of Pittsburgh
Pittsburgh, PA. 412-648-2000. Fax: 412-648-2001. decenzod@msx.upmc.edu

INTRODUCTION

Understanding knee kinematics and *in situ* force in the anterior cruciate ligament (ACL) and replacement graft during activities of daily living is essential to efficiently diagnose injury and develop effective treatment strategies. Studies have measured these data in response to arbitrary loading conditions [Kanamori, 2000, Markolf, 1995]. However, the *in situ* force in the ACL during more realistic loading conditions needs to be determined. Therefore, the objective of this study was to develop and validate a method of recording and reproducing joint kinematics to measure external loads and the force in ligaments during more realistic activities.

METHODS

A novel method was developed to: 1) record the kinematics of a diarthrodial joint during activities of daily living or a clinical examination, and 2) reproduce the exact kinematics of the same joint using a robotic/universal force-moment sensor (UFS) testing system to determine the external loads applied to the joint and force in ligaments (**Fig 1**). To validate this method a model consisting of two plexiglas plates connected by linear springs was constructed to represent a joint (**Fig 2**). Small plexiglas cubes, or registration blocks, were attached to each plate. Points on the three orthogonal faces of the registration blocks measured by a spatial digitizer (Immersion Corporation, San Jose, CA) were fit to planes and used to define a local coordinate system for each plate [Fischer, 2001]. The top plate of the model was moved, and the relative motion of the registration blocks was determined. The forces in the spring scales were summed and used to independently record the external force applied to the model. The model was then rigidly mounted in a robotic/UFS testing system [Rudy, 1996]. The location of the registration blocks with respect to the robotic manipulator was registered. Using this information, as well as the relative motion of the registration blocks, the path of the robotic manipulator was calculated and reproduced on the model, while the force was measured by the UFS [Zeminski, 2001].

RESULTS AND DISCUSSION

For validation, the external force recorded by the springs during the original motion was compared to the force measured by the UFS when the motion was reproduced and found to be within 3 N. Similarly, the relative motion of the registration blocks that was recorded and reproduced were compared and found to be within 1.5 mm and 0.5°. An error analysis found that 0.1 mm of error in the measurements of joint motion produces over 1 mm of error in the calculated

motion of the robotic manipulator. This finding is due to error propagation throughout the matrix manipulations.

A novel method to record and reproduce kinematics was successfully validated. This new approach has the unique ability to obtain *in situ* force in the ACL in response to more realistic activities rather than subjecting the knee to arbitrary external loads. The accuracy of this method is limited by error propagation throughout matrix manipulation. This method will be used to record and reproduce the kinematics of a cadaveric knee during more realistic activities such as clinical examination. The *in situ* force in the ACL as well as the external forces applied to the knee can then be determined.

COORDINATION OF HIP AND KNEE KINEMATICS DURING REPETITIVE LIFTING

Wayne J. Albert and Cynthia Babineau

Human Performance Laboratory, University of New Brunswick, Fredericton, NB, CANADA

INTRODUCTION

Differences in neuromuscular coordination have been reported during lifting activities when individuals are required to adapt to an increasing load (Scholz, 1995). It has been speculated that differences in coordination contribute to low back pain development, but there has been little research to date that corroborates this theory. Parnianpour et al. (1988) reported an increase in asymmetric trunk rotations due to fatigue during repetitive lifting. Similarly, Sparto et al. (1997) indicated a shift from a coordinated movement of the knees and hips to a lifting motion led by knee extension as the lifting task began to cause fatigue.

The effects of adaptations in lifting technique and changes in lifting motion coordination remain unclear. This preliminary work investigates the changes in coordination during a repetitive lifting task performed by inexperienced lifters.

METHODS

The inclusion criteria for this study were healthy men and women with little manual material handling experience. Participants were instructed to lift a 25-pound box, instrumented with handles, in a freestyle manner from the floor to a table at hip height. The box was lifted and lowered at a fast rate (every 6 seconds), in order to stimulate fatiguing conditions in a short amount of time. To examine the kinematics of the lifting movement, data were collected using standard video techniques and digitised at 30Hz.

Methods outlined by Scholz (1995) were used to calculate the coordination (phase angles) of knee and hip movement during the lifting task. To do this, the phase angle of each joint is calculated as the inverse tangent of the normalized angular velocity (scaled between -1 and 1, indicating maximum flexion and extension, respectively) divided by the normalized angular position (scaled between -1 and 1).

RESULTS AND DISCUSSION

The length of time lifted varied between subjects with the average lifting duration being a half hour. Although the lift posture for initiating the lift and the trajectory of the lift were unchanged over the lifting activity, changes in back and knee motions were observed. As expected most participants demonstrated a decrease in the extension velocity of the hip (Figure 1), indicating fatiguing of the back musculature. This change in velocity was reflected in the coordination pattern between the hip and knee movements. There was no observed change in the lifting posture; a finding reported by others, however as the lifting task progressed the motion of the

extension of the hip lagged behind that of the knees. Others increased the extension velocity of their knees with little change to hip extension (Figure 2). Therefore, it appears that there is individuality in the coordination accommodations in response to lifting in fatiguing conditions. Current investigations are exploring how these changes affect lumbar loading.

Figure 1: Observed change in hip angular velocity from early in the lifting activity (solid line) to a trial near the end of the activity (dotted).

Figure 2: Change in relative phase angles from early lifting trials (solid line) to late lifting trials (dotted line).

VISUAL CONTROL AND LOAD EFFECTS OF FAST ROTATIONAL MOVEMENTS

Juergen Krug, Thomas Muehlbauer and Falk Naundorf

Faculty of Sport Science, University of Leipzig, Germany

INTRODUCTION

In gymnastics, diving, and figure skating rotations around the longitudinal and transversal axis are the basic skills. Airborne movements like twisting somersaults (Yeadon, 1984) are explained by mechanical principles. But there is a lack of studies to fast rotational movement's visual control and load effects. Stangl & Gollhofer (1998) reported on the spatial-dynamic precision of the vestibulo-ocular reflex. Though, the angular velocity in this experiment was relatively slow (100 deg/s). The aim of this paper was to investigate visual control and load effects of fast rotational movements.

METHODS

To analyze visual control and load effects of fast rotational movements a "Somersault Simulator" (figure 1) and a "Longitudinal Rotation Simulator" were used.

Figure 1: Measuring unit "Somersault Simulator"

In the "Somersault Simulator" the athletes were rotated by the coach using the wheel. On the "Longitudinal Rotation Simulator" the athletes rotated in a hanging position. The same measuring unit was used on both simulators.

The number of rotations and the angular velocity were recorded by computer. The diode lamp was used to test the visual control during movements. By means of a force plate (Kistler®, Typ: 9261A), the sway of the COP before and after the rotational load was analyzed. The recording time was 30 s with a sampling rate of 300 Hz.

RESULTS AND DISCUSSION

In the first study the visual control was investigated. In the "Somersault Simulator" 3 female and 3 male divers (13-15 years) trained in a 12 sessions period the visual perception of

the diode lamp. Corresponding to somersaults in diving and gymnastics the angular velocity was approximately 700 deg/s. The recognition rate of the flash was significantly increased. In a replication study with 10 divers (5 female and 5 male, 12-15 years) the results could be confirmed.

In the second study the load effects of fast somersault rotations were investigated. Six divers (3 female and 3 male, 13-15 years) performed 15 somersault rotations. In a pre-post-test design the postural stability before and after these rotations was analyzed. The athletes had to go quickly to the platform for the post-test. There was a significant difference of the sway between the pre- to post-test.

In the third study the load effects of fast longitudinal rotations were analyzed. Five youth figure skaters performed ten longitudinal rotations in both directions. In a pre-post-test design the postural stability before and after rotations was investigate. There were a significant increase of the sway from pre- to post-test and a insignificant difference between the left and the right direction. In a further study to load effects of fast longitudinal rotations the differences between 6 gymnasts and non-athletes (female, 10-14 years) were investigated. There are significant differences in the postural control between both groups. The gymnasts reached a significant lower level of the sway intensity.

SUMMARY

Athletes are able for visual control in fast somersault rotations. This phenomenon could be used by diving coaches for technique training. The posturography is a suitable method to indicate load effects. The higher oscillation of the COP after rotations around the longitudinal and transversal (somersault) axis is comparable to the rotational load.

MATERIAL PROPERTIES OF PORCINE PARIETAL CORTEX

Brittany Coats and Susan S. Margulies, Ph.D.

Department of Bioengineering, University of Pennsylvania,
Philadelphia, Pennsylvania. margulies@seas.upenn.edu

INTRODUCTION

Accurate material property descriptions are crucial to the development of biofidelic computational models of the brain. Previously we reported significant mechanical property differences between gray and white matter, and even between regions of white matter with differing degrees of neural tract alignment (Prange et al, 2002). In this study, we extend our investigation to gray matter, to examine the hypothesis that gray matter (cortex and thalamic nucleus) can be considered homogeneous.

METHODS

Adult porcine brains were collected less than 1 hour post-mortem, and transported in chilled mock-CSF solution. Rectangular samples approximately 1 mm x 5 mm x 10 mm were excised from two lateral parietal cortical locations containing predominantly (~80-99%) gray matter (N=7).

Samples were mounted in a parallel plate shear testing device described previously (Prange et al., 2002). In a humidified environment, each sample was tested using a shear relaxation protocol consisting of a rapid (60msec) ramp to 2.5% strain, and return to rest after a 60sec hold period. The test sequence continued to 5, 10, 20, 30, 40, and then 50% strain. Previously we reported that this test sequence was reproducible, and was not associated with tissue damage (Prange et al., 2001). Measurement at each strain level was preceded by two preconditioning tests at the same magnitude. All tests were completed within 5 hours post-mortem.

ANALYSIS

Data collected were fit to a modified hyperelastic Ogden model with a strain energy density function, W :

$$W = \frac{2\mu(t)}{\alpha^2} (\lambda_1^\alpha + \lambda_2^\alpha + \lambda_3^\alpha - 3)$$

where λ is the principal stretch ratio, α describes the nonlinear strain-magnitude sensitive behavior, and $\mu(t)$ is viscoelastic shear modulus expressed as a first-order Prony series. Data extracted from the hold period at 5 (time = 100, 300, 600, 1800, and 6000 msec) isochrones were used to fit parameters α and $\mu(t)$ (IGOR Pro 3.1.4). An unpaired Student's t-test was performed to determine significant difference between nonlinear shear moduli at each isochrone.

Figure 1: Shear moduli gathered from literature were compared to the average porcine cortical gray measured in this experiment. Significant difference was found between porcine cortical gray and: Human adult cortical gray ($p < .001$) and porcine average thalamic gray ($p < .01$).

RESULTS AND DISCUSSION

The properties of the two cortical regions were not significantly different, and the data was combined for further analysis. The average stiffness of the porcine parietal cortex was found to be significantly lower than that published (Prange et al, 2002) for thalamic gray matter ($p < .01$) at every isochrone. These findings may be explained by the presence of constitutive elements in the thalamus, such as the internal medullary lamina and the intralaminar nuclei, which could contribute to the increased stiffness in this region. Regardless, we must reject our hypothesis of gray matter homogeneity, and conclude that gray matter within the porcine brain is heterogeneous.

Furthermore, the average porcine parietal cortical stiffness was significantly ($p < 0.001$) less stiff (38.2 to 43.9% lower) than previously published adult human temporal cortical gray matter values (Prange, et al 2002), and underscores the need for more data from fresh human brain tissue samples.

KINEMATICS OF THE GLENOHUMERAL JOINT DURING THE ANTERIOR AND POSTERIOR DRAWER TEST

Susan M. Moore, Volker Musahl, Patrick J. McMahon and Richard E. Debski

Musculoskeletal Research Center, Department of Orthopaedic Surgery, University of Pittsburgh
Pittsburgh, PA. 412-648-2000, Fax: 412-648-2001, genesis1@pitt.edu

INTRODUCTION

Clinical exams that translate the humerus with respect to the scapula are utilized to diagnose injury of the glenohumeral (GH) joint. Translations of the humeral head in response to an applied torque, without active muscle forces, have been quantified; (Harryman, 1990) however, this data has not been determined during a clinical exam. Therefore, the objective of this study was to determine the magnitude and repeatability of the translations of the humeral head during the anterior and posterior drawer test at multiple angles of external rotations (ER).

METHODS

Three cadaveric shoulder specimens (53 ± 1 yrs.) were dissected leaving the mid-humerus, scapula, rotator cuff muscles, and the GH capsule (vented at the rotator interval) intact. The scapula and humerus were fixed in epoxy putty. The scapula was mounted vertically in a Plexiglass fixture and 13.4N was applied to the rotator cuff muscles. A 6 degrees-of-freedom magnetic tracking system (The Bird, Ascension Technologies, Inc.) determined the motion of the humerus with respect to the scapula (Debski, 1995). Anatomical landmarks were digitized to define the coordinate system for the joint motion description (Grood, 1983). For standardization, the humerus was placed at 60° of GH abduction, neutral rotation, and neutral horizontal adduction at the beginning of each exam. The clinician maximally translated the humeral head to its limit in the anterior and posterior directions at 0° , 30° , and 60° of ER and then returned the humeral head to its starting position (5 cycles). The translations for each of the 5 cycles were collected by the magnetic tracking system.

RESULTS

The magnitude and repeatability for the anterior and posterior translations are shown in Figure 1. As ER increased from 0° - 60° the total anterior translation decreased by more than 60% for all specimens. During the anterior drawer test, inferior translations (coupled motion) also occurred. In contrast, superior translation occurred during the posterior drawer test and increased with ER (Figure 2). For example, in Specimen 1, during the anterior drawer test at 0° , 30° , and 60° of ER inferior translations of 1.6 ± 1.2 , 11.7 ± 1.4 , and 17.5 ± 0.5 mm occurred, respectively. The posterior drawer test produced superior translations of 3.2 ± 1.0 , 2.2 ± 0.4 , and 9.8 ± 0.7 mm, respectively.

DISCUSSION

The magnitude and repeatability of the translations of the humeral head were determined during the anterior and

posterior drawer test. The translations in each direction were highly repeatable. Coupled motions were found in the superior and inferior directions. These findings provide further insight into the interaction of the capsular components that guide the motion and stabilization of the GH joint. Evidence of excessive coupled motions, or the lack of coupled motions may aide clinicians in diagnosing injury. Furthermore, analytical models can utilize this information to produce a more accurate representation of joint function. Future investigations will include replaying the recorded kinematics using a 6 degree-of-freedom robotic testing system to determine the in situ forces of the capsular components.

Figure 1. Maximum anterior and posterior translations of the humeral head at 0° , 30° , and 60° ER during the anterior and posterior drawer tests of the three specimens.

Figure 2. Representative plot that illustrates the translations of the humeral head for 1 cycle of the anterior and posterior drawer test.

EFFECT OF JOINT COMPRESSION ON THE BIOMECHANICS OF THE INTACT ACROMIOCLAVICULAR JOINT

Ryan S. Costic, Rajesh Jari, Mark W. Rodosky and Richard E. Debski

Musculoskeletal Research Center, Department of Orthopaedic Surgery, University of Pittsburgh
Pittsburgh, PA. 412-648-2000, Fax: 412-648-2001, genesis1@pitt.edu

INTRODUCTION

High loads can be transmitted from the upper extremity across the acromioclavicular (AC) joint to the axial skeleton during activities of daily living and can lead to pain and early joint degeneration [Petersson, 1983]. Therefore the objective of this study was to quantify the effect of joint compression on shoulder biomechanics during application of 70N anterior, posterior and superior loading conditions.

METHODS

Fresh frozen human cadaveric shoulders (n=12) were dissected, fixed in epoxy putty and rigidly fixed to the robotic universal force-moment sensor base and arm [Debski, 2000, 2001]. After determining a joint reference position, specimens were cycled ten times under an anterior, posterior and superior load of 70N with constant 10N or 70N of joint compression. The resultant joint kinematics and *in situ* forces were recorded during the last cycle (3-DOF). The recorded paths of joint motion were repeated after sequential cutting of the inferior and superior AC capsule, conoid and trapezoid ligaments (varied). Using the principle of superposition, the vector difference in forces before and after cutting of a ligament represented the *in situ* force in that structure. Two-factor repeated-measures ANOVA was used to determine the effect of joint compression on the *in situ* forces of the AC capsule and coracoclavicular (CC) ligaments ($p<0.05$).

RESULTS

Joint compression with a 70N anterior, posterior and superior load did not significantly change primary (in the direction of loading) anterior or superior translation but significantly decreased primary posterior translation (6.6mm to 3.7mm, $p<0.05$, Figure 1). Accordingly, only two of six coupled (perpendicular to primary loading direction) translations were significantly affected by joint compression. During posterior and superior loading, coupled proximal translation decreased (2.2mm to 0.6mm) and coupled anterior-posterior translation shifted (0.5mm ant. to 0.6mm post.), respectively ($p<0.05$).

Although joint compression only affected the translation minimally, it significantly affected the *in situ* forces during all loading directions. With an applied 70N in all directions and joint compression, the *in situ* force in the superior AC capsule decreased by 10N while the force in the inferior portion remained unchanged (Figure 2). The CC ligaments were not affected by joint contact except for the 10N force increase in the conoid ligament during posterior loading. However, the joint contact force significantly increased by 20N in all loading directions with joint compression ($p<0.05$).

DISCUSSION

The effect of joint compression on the shoulder biomechanics of the intact AC joint were quantified. The decreased force in the superior AC capsule and increased joint contact force that occurred with joint compression in all loading directions suggests that the high compressive load is primarily transmitted through joint contact rather than the supporting ligaments. Therefore, common surgical techniques such as distal clavicle resection, which initially reduce painful joint contact, may adversely affect the soft tissue components of the shoulder by increasing the force transmitted through these structures. These large forces could contribute to degenerative changes in the joint and therefore the magnitude of the *in vivo* forces that are transmitted across the shoulder should be determined in the future.

Figure 1. Translations during a 70N anterior, posterior and superior load with 10N or 70N of joint compression.

Figure 2. *In situ* force in soft tissue structures along with the joint contact force during the application of a posterior load.

MODELLING THE SOLIDIFICATION OF AQUEOUS SOLUTIONS: A COUPLED-FIELD FINITE ELEMENT APPROACH

Richard Wan¹, Zhihong Liu¹, and Ken Muldrew²

INTRODUCTION

The modelling of aqueous solution freezing with concomitant ice formation is of prime interest in many engineering, physical, biological problems. One of the main challenges lies in the mathematical complexity in solving a fully coupled heat-mass transfer problem. In biological tissues, the coupling results from solute diffusion and freezing processes through the freezing point depression. Any solute concentration would lower the freezing point of water, which in turn controls the growth of ice. The rate at which salt is excluded from the ice front limits its propagation. Thus, both the thermal and solute fields are strongly coupled to each other and have to be solved simultaneously in any numerical modelling endeavour.

METHOD

The mathematical treatment of a sharp discontinuity in both heat flux and solute concentration at the phase-change zone, as well as the ice front tracking in time, are two major problems that arise while solving the coupled heat and solute field equations within a Finite Element (FE) framework. In order to overcome these difficulties, we transformed both the solute concentration and temperature fields into virtual *liquidus temperature* and *freezing index* fields respectively. While these newly introduced field variables are continuous, they also facilitate the writing of a variational principle which leads to a general set of FE equations defined over the entire domain of interest for both phases. Thus, a fixed mesh approach can be used to track the ice front propagation with coupled phase change-solute diffusion. The resulting coupled non-linear FE equations are readily solved via Newton-Raphson method. A staggered iterative procedure is used to optimize the computations.

RESULTS AND DISCUSSION

The FE model was first quantitatively compared with experimental studies of solidification of aqueous solution (Korber et al, 1983). Computed transient positions of the ice front were in excellent agreement with experimental data. The simulation of a piece of cartilage tissue subjected to a cooling rate of 1°C/min from 0°C to -25°C was next attempted. In Fig. 1, the distribution of solute concentration within the tissue identifies two distinct regions: one with low concentration in

which planar ice front forms, and the other with highly concentrated or supercooled solution with propensity to ice lensing. The numerical computations exactly capture the essential physics of the cartilage freezing problem (Muldrew, 1997).

Figure 1: Solute concentration distribution in a 1.5x1.5mm cartilage tissue during freezing at 120 seconds.

SUMMARY

A FE procedure to solve the coupled phase change-mass transfer problem was developed using virtual *liquidus temperature* and *freezing index* as main variables. The effect of microstructure is readily amenable to the current model by introducing freezing point depression due to pore size. The model will be able to estimate cell survival rates under the combined effects of temperature and osmotic environment given a “cell viability criterion”.

DETERMINATION OF PEAK LIMB FORCE FROM DUTY FACTOR

Knill, K., McGuigan, M.P., Witte, T.H. and Wilson, A.M.

Structure and Motion Lab, The Royal Veterinary College, North Mymms, Hatfield, Herts AL9 7TA England

INTRODUCTION

Ground reaction force (GRF) curves are approximately sinusoidal in running animals. Since mean limb force must equal body weight it is possible to estimate peak limb force from duty factor (the proportion of the stride that an individual limb is in contact with the ground) and the proportion of the body mass that is “supported” by that limb. This approach was used by Alexander *et al* (1979) to estimate peak limb force in the elephant and buffalo. The technique was also applied by Kram and Dawson (1998) who validated it using one kangaroo hopping over a forceplate. They found that the technique under estimated peak limb force in kangaroos by 36%. There are several possible explanations for this discrepancy: kinematic data were used for determination of foot on and off which can be inaccurate; the GRF curve may be “fatter” or “thinner” than a cosine wave of equivalent base and in multi-legged animals the weight distribution may not be as assumed. In this study we tested the hypothesis that the technique is more accurate if weight distribution is determined experimentally for similar animals.

METHODS

Accelerometers were attached to the dorsal hoof wall of the front and hind feet of horses with an orientation appropriate to differentiate heel off and toe off. Accuracy of timing of foot on and off and the error in the estimation of peak vertical GRF were determined from simultaneous forceplate recordings (Kistler 9827BA). Six horses were trotted repeatedly over the forceplate and six foot strikes recorded for each limb. Analogue accelerometer data were radio telemetered using a narrow band FM transmitter module mounted on each leg. Telemetered accelerometer data and forceplate data were recorded simultaneously at 2000 samples per second using LabView software. Horses were weighed.

The beginning and end of stance on the forceplate record were defined as the first and last samples respectively that varied from the baseline value. Peak force and vertical impulse were determined for each limb and the fore:hind ratio determined.

Peak limb vertical force (F_z) was predicted from

$$F_z = \pi p m g / 4 \beta$$

duty factor p , body mass m , acceleration due to gravity g and fore:hind leg weight distribution $\beta_f \beta_h$ (0.6/0.4 for the horse, Alexander *et al* 1979).

RESULTS AND DISCUSSION

There was an easily recognizable peak in the accelerometer signal when the foot contacted the ground. The timing of this

peak was within one sample of the beginning of stance determined by the forceplate for 86% of the values and within 2 samples (1 millisecond) for 98% of values. At the end of stance it was possible to determine the time when the heels left the ground and when the toe left the ground from the accelerometer signal. Toe off was detected within 4 samples of the forceplate for 56% of values and 12 samples (6ms) of 80% of values. The error was however evenly distributed around the mean.

Application of the Alexander *et al* (1979) equation gave a mean underestimate of peak limb force of $2.7 \pm 2.7\%$ (\pm standard deviation) for the forelimb and $21.8 \pm 2.0\%$ for the hindlimb. This was assuming a fore:hind weight distribution of 0.6:0.4.

The actual weight distribution at trot for six horses (6 stance phases per horse) was 0.53:0.47 (± 0.02) for peak force and 0.56:0.44 (± 0.02) for vertical impulse. Calculation of the peak force using this vertical impulse distribution resulted in an underestimate by $13.3 \pm 6.9\%$ for the forelimb and $14.1 \pm 2.2\%$ for the hindlimb.

The error in the determination of peak vertical force from duty factor appears to be due to vertical GRF increasing more rapidly than an equivalent cosine wave. Thus peak vertical GRF occurs before the peak of the cosine wave (17 ± 10 ms in this group of horses). This rate of rise is however dependant on surface stiffness.

SUMMARY

The difference between the vertical GRF curve and a cosine wave was consistent across all the limbs of all the horses. The use of the corrected fore:hind weight distribution resulted in a similar error for the estimation of the peak vertical force in the front and hind limbs. It would be possible to apply a correction factor to the equation to partially account for the difference between GRF profile and the cosine wave and hence improve the accuracy of the estimation and its usefulness in the assessment of field locomotion.

INTRODUCTION

Knee kinematics after Total Knee Replacement (TKR) are shown to be affected by, among other things, the design of the prosthesis and the surgical placement of prosthetic components. Based on the ligament-strain energy-minimization principle, a mathematical model of a knee was constructed for studying the passive kinematics of condylar-type total knee prosthesis. The model relied on knowledge of the prosthetic bearing surface and patient-specific ligament data, and determined the quasi-static knee kinematics by finding successive contact points of prosthetic components over a range of flexion angles.

METHODS

The goal of this study was to understand interactions between the geometry of the articular surfaces and the surrounding ligaments, and to see how such interactions affect the overall kinematics of the knee. Passive knee kinematics were computed as a quasi-static solution to energy minimization of a system with ideal single point contact. Potential energy is stored in the ligament filaments. The femoral and tibial components are assumed to be rigid in a passive model. By using patient-specific ligament data and accurate representation of articular surfaces, patient-specific kinematics were derived. Combining the quasi-static solutions from numerous flexion angles provided (a) the contact paths on the bearing surfaces and (b) the roll/slip characteristics of relative motion.

Data were collected intraoperatively from 10 consecutive patients. The neutral lengths of the ligaments were determined physically, by gently distracting the tibia until the relevant ligament were determined to be at neutral length. The articular geometries were virtually implanted to a standard position, as recommended by the manufacturer's description of surgical technique, and later validated by a surgeon, and still later were artificially deviated from that position to simulate various implantation strategies. For each flexion angle, the varus-valgus angle and internal-external rotation angle that jointly had the minimal total strain energy were selected as the orientation of passive motion, producing a total of 63 angulations of passive motion. The contact paths, relative kinematics, and ligament energies were determined for each angulation.

RESULTS AND DISCUSSION

Using previous patient ligament data, the kinematics of the AMK design were derived. This model demonstrated that general knee kinematics are a combination of spinning,

rolling, and further spinning motion as the knee flexes from full extension to deep flexion. Posterior tilting/displacement of the tibia increases the range of motion, while anterior tilting/displacement of the tibia decreases the range of motion.

Figure 1: Knee motion is animated in 3D and demonstrates spinning, rolling, and sliding as flexion increases.

SUMMARY

A patient-specific knee model demonstrates that knee kinematics after TKR are affected by the geometry of the articular surfaces and the surgical placement of the prosthesis. Proper placement of the prosthesis can increase the range of motion with desired knee kinematics, whereas improper placement can lead to decreased range of motion and kinematics that lead to excessive tibial wear. This model provided a unique tool for evaluating the effect of different surgical implantation strategies. The model can also be used to optimize anticipated wear during the design phase of prosthesis.

EVALUATION OF TIBIOFEMORAL COMPRESSIVE AND SHEAR LOADS IN THE MEDIAL AND LATERAL KNEE COMPARTMENTS DURING ISOMETRIC KNEE EXERCISES

Steadman♦Hawkins Sports Medicine Foundation¹ and Clinic², Vail, Colorado, mike.torry@shsmf.org

INTRODUCTION

Multi-angle isometric knee extension and quadriceps sets (Qset) are often the first exercises employed to develop muscular strength in individuals who have sustained or are in recovery from surgical repair of a tibiofemoral (TF) articular cartilage lesion (Irrgang and Pezzullo, 1998; Gillogly et al., 1998). Successful rehabilitation of these injuries are predicated on 1) limiting the range of motion (ROM) to angles that do not engage the lesion, and 2) performing strengthening exercises that minimize shear load across the knee while maximizing quadriceps strength gain (Irrgang and Pezzullo, 1998). To date, clinicians have relied mostly on cadaver mechanical testing to establish ROM guidelines for selecting appropriate joint angles to conduct these exercises. However, these studies are limited as it is difficult to apply the necessary physiologic loads typical of such exercises and, most do not simulate the weakened condition of the knee muscles commonly found after this type of injury or surgery (O'Reilly et al., 1998). Furthermore, few of these studies have attempted to quantify the compressive and shear loads that may be occurring in each compartment throughout 0°-90° of knee range of motion (ROM). The purposes of this study were: 1) to assess the TF compressive and shear loads in the medial and lateral knee compartments during Qset and knee extension exercises, and 2) to determine the ROM over which either of these exercises may be beneficial in reducing compressive or shear forces.

METHODS

Isometric knee extension and Qset exercises were simulated using a 3-D model of the lower extremity. The geometry of the model bones, ligaments, muscles and the mechanics governing the dynamic performance of these tissues has been described in detail (Pandy et al., 1997). In short, the model includes: the three-dimensional geometry of the patella, tibia, and femur, 13 non-linear springs representing the major tibiofemoral ligaments and joint capsule, 13 muscle-tendon units spanning the knee that include the force-length property of muscle, and a model of articular cartilage compression between the bones of the tibia and femur. Isometric knee extension and Qset exercises were simulated at varying joint positions (0°-90° at 15° intervals). Healthy isometric knee extension exercises were simulated utilizing 100% activation of all knee extensors and 0% flexors. These simulations were then repeated altering quadriceps activation -25% to simulate decreased strength conditions (O'Reilly, et al., 1998). Isometric Qsets were simulated by balancing quadriceps activation with hamstring activation (muscular co-contraction) that resulted in zero knee joint motion.

RESULTS AND DISCUSSION

The simulations reveal that shear (Figure 1) and compressive forces in both medial and lateral compartments are highest when conducting the Qset exercises in the ranges of 0° - 45° of knee flexion. After 45°, shear and compressive forces were more pronounced for the isometric knee extension exercise. The effect of varying individual muscles or even the entire quadriceps muscle group (Weak) did not change this trend, although it did reduce the overall load being transmitted across the joint.

Figure 1. Shear load for medial (M) and lateral (L) compartments during knee extension (Ext) and Qsets (Qset) and under 25% decreased quads activation (Weak).

SUMMARY

These results suggest that the use of Qset and knee extension exercises is dependent upon knee angle to selectively reduce shear and compressive loads in the medial and lateral compartments of the knee joint.

RELATIONSHIP BETWEEN LINEAR WRIST VELOCITY AND IMPULSE DURING FASTBALL PITCHING IN COLLEGIATE BASEBALL PITCHERS

Jeremy Smith¹, Jerry Wilkerson², and Brian Umberger¹

¹Exercise & Sport Research Institute, Arizona State University, Tempe, AZ, USA (email: jeremy.d.smith@asu.edu)

²Kinesiology Department, Texas Woman's University, Denton, TX, USA

INTRODUCTION

In the coaching literature there are two conflicting views as to whether a baseball pitcher should actively push off the mound while pitching. House (1983) stated that a pitcher should not “violently drive” towards home plate, but rather fall towards home plate in a controlled manner. Conversely, Ryan and Torre (1977) suggested a pitcher should drive as hard as possible towards home plate. MacWilliams et al. (1998) reported linear wrist velocity was significantly related to both anterior/posterior (AP) ($r^2 = .82$) and vertical ($r^2 = .74$) ground-reaction forces at the time when AP force peaked. These results tend to support a drive by the pitcher rather than a “controlled fall”. Peak forces by themselves, however, do not provide a complete picture of force application by the pitcher. Quantifying impulses associated with the GRF during pitching may provide greater clarity for this issue. A positive relationship between linear wrist velocity at ball release and impulse in the AP direction of the push-off leg, provide further evidence that a pitcher drives off the pitching rubber to deliver a fastball. Therefore, the purpose of this study was to determine the relationship between linear wrist velocity at ball release and the impulses generated by the push-off leg in the three component directions of the GRF, which to date has not been reported in the literature.

METHODS

Participants were ten in-season collegiate baseball pitchers. Pitchers were allowed to warm-up until they felt comfortable enough to pitch in the first inning of a regular baseball game. Each pitcher threw five consecutive fastballs from an indoor pitching mound, which housed two force plates. The push-off force plate was oriented horizontally with the positive medial/lateral (ML) axis pointed towards third base, the positive AP axis pointed towards the catcher, and the positive vertical axis directed upward. Data from the landing plate are not reported in the present study. GRF data were collected at 1200 Hz and electronically synchronized with four 120 Hz video cameras. Video records were used to calculate 3-D resultant linear wrist velocity and identify temporal events in the progression of the pitching cycle (e.g. ball release). Since it has previously been reported that intrasubject variability in GRFs is low (MacWilliams et al., 1998), the trial that produced the highest linear wrist velocity at ball release was used in statistical analyses. GRF data were normalized by body

weight and expressed relative to 100% of the pitching cycle (beginning when the ball left the glove until the ball was released). Pearson product moment correlations were used to test for significant relationships between linear wrist velocity and impulses generated in the AP, ML and vertical directions for the push-off leg.

RESULTS AND DISCUSSION

Table 1 reports the means and standard deviations for impulse and peak force in the AP, ML, and vertical directions on the push-off plate. Peak forces were consistent with previously reported data and demonstrate that substantial forces are produced in the plane of the pitch. Values for impulse in each component direction also support the “drive” theory since the largest impulses are in the AP and vertical directions. A significant relationship ($r = .647$, $p = .043$) existed between linear wrist velocity and AP impulse for the push-off plate, such that pitchers who generated more impulse in the anterior/posterior direction of the push-off plate threw with greater linear wrist velocity.

Table1: Push-off plate means for peak forces and impulses

	ML shear	AP Shear	Vertical
Peak Force	0.16(.08)	0.57(.08)	1.23(.10)
Impulse	0.004(.005)	0.037(.005)	0.100(.014)

Note. Peak forces are normalized to BW and impulses are normalized to $BW * ((\text{height}/\text{gravity})^{.5})$.

SUMMARY

The correlation between the linear wrist velocity at ball release and the AP impulse generated by the push-off leg, combined with the high levels of force generated on the push-off plate are evidence in support of the drive theory. Our results support the hypothesis that pitchers drive towards home plate when delivering a fastball pitch.

MEASUREMENT OF THE ENCEPHALON PHYSICAL PARAMETER WITH MRI SATURATION TRANSFER METHOD

Hideaki Obata¹, Masataka Tokuda, Tadashi Inaba, Shigeru Matsushima² and Yasutomi Kinoshita³

¹Department of Mechanical Engineering, Mie University, Tsu 514-8507, Japan, obata@bio.mach.mie-u.ac.jp

²Department of Radiation Oncology, Aichi Cancer Center, Nagoya, 464-8681, Japan

³Department of Medical informatics, Gifu University, Gifu 500-8705, Japan

INTRODUCTION

Magnetic resonance imaging (MRI) came to be used for many kinds of image diagnosis recently. And it can get more useful biomechanics information by using this MRI, because it is a very effective device to know the physical parameter of biomaterials. The saturation transfer method can show restricted H₂ molecular like some kind of polymer rather than amount of moisture. In this research, it was measured by the saturation transfer method which used MRI for the purpose of knowing the physical parameter of human brain.

METHODS

Nine patients, they have disease except in the head are imaged by Signa model of GE Medical Systems equipped with 1.5 Tesla clinical scanner. First, some MRI pictures to decided location are taken. Then conventional spoiled-gradient recalled acquisition in the steady state (SPGR) and also SPGR under the irradiation of ST-pulse (ST-SPGR) were obtained in the coronal plane. The off-resonance technique was adopted to achieve preferential saturation of the immobile protons and to calculate saturation transfer ratio (STR). The single ST-pulse frequency in an interval was irradiated at the frequency of 19, 5, 2, -2, and -5 ppm apart from that of water resonance. The regions of interest (ROI) for signal intensity were measured at the same site inside of the every sample. The saturation transfer ratio (STR) values were defined as the percentage of signal loss between unsaturated (i.e., SPGR) and saturated (ST-SPGR) images according to the eq.1;

$$\text{STR}(\%) = (\text{Mo} - \text{Ms}) \times 100 / \text{Mo} \quad (1)$$

where Mo and Ms are the signal intensity on the SPGR and on the ST-SPGR image, respectively.

RESULTS AND DISCUSSION

Figure 1 shows instances conventional (a) SPGR image and (b) ST-SPGR at the frequency offset by 5 ppm from water proton. And the calculated STR images are shown in Figure 2, (a) STR 5ppm, (b) STR 2 ppm, (c) STR -5 ppm. The conventional SPGR images were directly resulted from T₁ (longitude relaxation time)-weighted image. In the ST-SPGR

images, the signal intensity was lower than that in the conventional SPGR. The ST-effect is larger, the intensity in the STR image become higher, as is demonstrated by the STR images calculated according to the eq.1.

Figure 1. Conventional MR Images. (a) T₁-weighted SPGR image. (b) ST-SPGR at the frequency offset by 5 ppm from water.

Figure 2. Calculated STR images at frequency offset of (a) 5ppm (b) 2ppm (c) -5ppm

In this worth pointing that the degree of reduction should be dependence upon the frequency of the ST pulse. And especially, the STR values for the human encephalon are correlated with their total water content or physical parameter.

SCREW AND BLADE TYPE HIP IMPLANTS PRODUCE DISTINCT INSERTION FORCES

L. W. Ehmke¹; B. Kam²; M.B. Sommers¹; M. Bottlang¹

¹Legacy Clinical Research & Technology Center, Portland, OR; email: mbottlan@lhs.org

²Oregon Health Sciences University, Portland, OR

INTRODUCTION

Dynamic hip implants are routinely used for fixation of hip fractures (Haynes, 1997; Koval 1994). During insertion, these implants exert considerable torsional and axial forces to the femoral head (Mohan, 2000). With limited intraoperative means to constrain the femoral head during implant insertion, such forces can lead to rotational displacement and subsequent malreduction. Most recently, a novel helical blade-type implant design has been introduced, which may pose less propensity for femoral head rotation as compared to lag screws with a traditional thread design. This cadaveric biomechanical study provides a quantitative comparison of insertion forces between screw and blade-type hip implants.

METHODS

Twenty-four paired proximal femora from 7 female and 5 male fresh-frozen human cadavera with an average donor age of 76 ± 6 years were obtained. The femoral heads were sectioned at the neck and potted into a 50-mm diameter steel shell with low melting alloy. Insertion forces of two cannulated dynamic hip implant designs were tested, one of which had a traditional thread design (DHS, Synthes), and one had a novel helical blade design (DHHS, Synthes) [Fig. 1a].

Fig. 1a) Screw and blade type hip implants, **b)** testing setup

Specimens were mounted on a bi-axial load cell and implants were attached to the bi-axial actuator of a material test system (8874 Instron) [Fig. 1b]. Implants were advanced in concurrent linear and angular displacement to precisely reflect the pitch of the implant's thread or blade. Each implant was inserted over a guide wire to a depth of 40 mm, according to the manufacturer's insertion technique, while the insertion torque and axial load were recorded. Both outcome parameters were evaluated as a function of insertion depth. Finally, the total amount of energy expended during implant insertion was computed as the area under the force-displacement curve (i.e. axial insertion energy), plus the area under the torque-angle curve (i.e. torsional insertion energy) (Heiner, 2001).

RESULTS

For all implants, insertion torque increased with increasing insertion depth [Fig. 2a]. At 40-mm insertion depth the DHHS implant exhibited an insertion torque maximum of 5.7 ± 1.7

Nm, while the DHS implant induced a significantly higher maximal insertion torque of 8.7 ± 3.2 Nm ($p < 0.01$). Axial forces were significantly higher during insertion of the DHHS implant compared to the DHS implant ($p < 0.01$) [Fig. 2b]. At 40-mm insertion depth, axial loads were 1938 ± 906 N and 923 ± 488 N for the DHHS and DHS implants, respectively.

Fig. 2) Insertion forces vs. insertion depth (avg. values, $n=12$)

The overall insertion energy was significantly lower for DHHS implants compared to DHS implants ($p < 0.01$) [Fig. 3]. DHHS implants required 41 ± 13 J total energy with over 90% due to axial forces, while DHS implants necessitated 275 ± 90 J total energy with over 90% due to torsional forces.

Fig. 3) Total insertion energy distribution of DHS and DHHS

DISCUSSION

The results of this study provide a quantitative analysis of the forces and energy of insertion of a novel helical-blade type implant and a traditional screw-type implant. Axial loads during implant insertion are directly supported by the acetabulum and may be well tolerated. The reported insertion torque is likely to correlate to the propensity for femoral head rotation during implant insertion. Therefore, the six fold reduced insertion energy of blade-type implants may pose a lower risk for malreduction.

IN VIVO MOTION OF THE SCAPHOTRAPEZIO-TRAPEZOIDAL (STT) JOINT

Joseph J. Crisco^{1,2}, Lana Kang¹, Sharon Sonenblum², Edward Akelman¹

¹Dept. of Orthopaedics, Brown Medical School/Rhode Island Hospital and ²Div. of Engineering, Brown University Providence, RI
E-mail: joseph_crisco@brown.edu

INTRODUCTION

The majority of cases with wrist arthritis involve the scaphoid bone (Watson and Ryu, 1986), and a large percentage of these involve the STT joint. Altered kinematics is a potential mechanism in the etiology of degenerative joint disease, but the normal kinematics of the STT joint have been difficult to document. Recently, STT kinematics were studied *in vitro* by Moritomo et al (2000), who reported that the STT joint is a single degree of freedom joint; the motion of the trapezium and trapezoid relative to the scaphoid is the same in flexion/extension and radial/ulnar deviation. The purpose of this study was to examine this finding *in vivo*. Specifically, we measured the 3-dimensional (3-D) kinematics of the STT joint *in vivo* and we sought to determine if STT motion was the same in flexion, extension, and ulnar deviation.

METHODS

Using a computed tomography based markerless bone registration algorithm, carpal bone kinematics were determined for both wrists of ten healthy volunteers (5 male, 5 female, avg. age: 26 [range: 21-47]). After IRB approval and informed consent, both wrists were scanned simultaneously in positions of neutral, 30° and 60° of flexion and extension, and 20° and 40° of ulnar deviation. Each carpal bone, radius and ulna were segmented and registered to the neutral position. Due to the difficulty in accurately positioning the wrist, the calculated motion of the capitate was used to define wrist motion. The kinematics of the trapezium and trapezoid were determined relative to the scaphoid and described with respect to a scaphoid coordinate system (SCS) using the helical (screw) motion parameters that completely characterize 3-D kinematics by a rotation angle about and translation along a uniquely orientated and positioned axis.

A single wrist position at 40 degrees in each direction of wrist motion was analyzed and reported here. Due to the variability in defining wrist position precisely, we analyzed positions in a 10 degree bin about 40 degrees, which resulted in a sample size of n = 17, 14, and 22 for extension, flexion, and ulnar deviation, respectively. A one-way ANOVA with a Tukey-Kramer post-hoc test was used to test the difference in rotation with each direction of wrist motion. A paired Student's t test was used to compare the motion of the trapezium with the motion of the trapezoid.

RESULTS

The trapezium and trapezoid rotated more ($P < 0.01$) in ulnar deviation than in extension or in flexion (Table 1). There was no difference in the amount of rotation between extension and

flexion. The trapezium and trapezoid did not move as a single unit. The trapezium rotated less ($P < 0.02$) than the trapezoid in flexion but more ($P < 0.01$) than the trapezoid in ulnar deviation.

Table 1. Rotations of the trapezium and trapezoid, relative to the scaphoid, in various directions of wrist motion. Wrist positions were defined by the capitate positions listed below.

Bone	Ext. (deg)	Flexion (deg)	Ulnar (deg)
Trapezium	20 ± 12	16 ± 6	51 ± 11
Trapezoid	19 ± 12	21 ± 8	44 ± 6
Capitate	-39 ± 6	42 ± 5	40 ± 5

The orientation of the trapezium and trapezoid rotation axes varied with the direction of wrist motion. In extension, the trapezium rotation axis was primarily along the Y-axis and also along the X-axis, whereas for the trapezoid it was nearly equal along the X-axis and the Y-axis (refer to Figure 1). In flexion, both bones rotated primarily about the Z-axis. In ulnar deviation, the trapezium rotation axis was primarily along the Y-axis and also nearly equal along X-axis and Z-axis, and for the trapezoid it was primarily along the Z-axis and also along the Y-axis.

FIGURE 1: A radial view of the distal radius and the scaphoid. The X, Y, and Z axes of the scaphoid coordinate system (SCS) are shown.

SUMMARY

The *in vivo* motions of the trapezium and trapezoid varied when the wrist was

in flexion, in extension, and in ulnar deviation. These findings do not support the hypothesis that the STT joint is a single degree of freedom joint; rather they suggest that the STT joint is a more mobile, complex joint than previously appreciated.

TURBULENCE INDUCED VEIN-WALL VIBRATION MAY PLAY A ROLE IN ARTERIOVENOUS DIALYSIS GRAFT FAILURE

INTRODUCTION

Intimal hyperplasia at the venous anastomosis of hemodialysis arteriovenous (AV) graft is often the cause of graft failure resulting in significant morbidity and cost. The AV circuit represents a unique hemodynamic environment in which transition to turbulence often occurs. Large velocity and pressure fluctuations at the venous anastomosis induce vein-wall vibration. This vibration is thought to be important in the development of intimal hyperplasia. We have established a porcine model to investigate the importance of *in vivo* vein-wall vibration on the level and activity of the ERK1/2 mechanotransduction pathway.

METHODS

Infrarenal aorta to external iliac vein 4-7 mm AV grafts were implanted in 8 male miniature swine using a standard anastomotic geometry. Volumetric flow rate was measured in the distal and proximal outflow tracts by ultrasonography. Using laser Doppler vibrometry (LDV), vein-wall vibration was passively determined at defined anastomotic regions on the vein (A, B, and C) as shown in Figure 1. Turbulence induced vibration intensity (VI) was quantified by computing the root mean squared (RMS) value of the vibration velocity amplitude in the frequency range 40-800 Hz. Western blot analysis was used to quantitate ERK1/2 levels and its activity was determined by measuring Elk1 phosphorylation with a kinase assay. The degree and cellular colocalization of ERK1/2 was assessed at 4 hours and 4 weeks using immunocytochemical analyses. Results were considered significant at the $P < 0.05$ by a two-tailed T-test.

RESULTS AND DISCUSSION

Mean flow rate in the anastomoses was 654 ± 285 ml/min (range 350 – 1000 ml/min). High vibration regions were located just downstream of the graft-to-vein junction in the proximal venous segment (region B) as shown in Figure 2. There was close to 2.5-fold increase in vein-wall VI at region B (4.3 ± 4.94 mm/s, range 1.24 – 8.3) when compared to region A (1.6 ± 0.57 mm/s, range 0.5 – 2.71) ($P = 0.0085$). Correspondingly, the western blot analysis showed a 3-fold increase in ERK1/2 and Elk1 phosphorylation in region B relative to region A after four hours.

Our group has previously reported results that describe the transitional flow field present within the venous anastomosis of an AV graft [1]. Numerical simulations revealed the pressure

and velocity fluctuations within the anastomosis to have frequencies consistent the vein-wall vibration frequencies measured *in vivo* (~300Hz). Thus, transitional flow or weakly turbulence flow is thought to be the cause of the vein-wall vibration. These preliminary results of vibration and ERK1/2 levels implicate vein-wall vibration as a biomechanical stimulus for the activation of ERK1/2 and intimal thickening. Further work is necessary to determine the precise relationship between AV graft failure and fluid-dynamic variables such as velocity fluctuations and wall shear stress, as well as their relative importance.

INTRODUCTION

Over the past two decades, the fluid mechanics of blood flow has been shown to play an important role in arterial adaptation and disease localization (Giddens et al., 1993). For numerical studies, Milner et al. (1998) demonstrated the importance of using the true geometry of the carotid bifurcation as opposed to an idealized geometry that does not accurately represent *in vivo* curvature and variable diameter. Here, we describe a technique to generate high quality, unstructured, hexahedral meshes appropriate for spectral and finite element simulations in bifurcation geometries. This work improves upon our previous bifurcation meshing technique (Lee et al., 2000) by using thermal conduction solutions in the corresponding model domain to generate element cutting planes that are guaranteed to be orthogonal to the domain boundary and nonintersecting. This approach also automatically determines principal cutting planes that previously had to be specified by the user.

METHODS AND RESULTS

Our mesh generation technique has four main steps. First, the medical images must be processed to extract the geometry data, which is converted using Mimics (Materialise, Inc.) to a stereolithography (.stl) surface format consisting of triangles. The surface data is smoothed with a non-shrinking smoothing algorithm (Taubin, 1995). Next, the smoothed data is used to create a preliminary mesh with any meshing code (ICEM-CFD) (Fig 1a). The main objective of the preliminary mesh is to preserve the surface information, whereas the mesh quality is not as important. In the third step, three separate conduction problems are solved within the bifurcation geometry using the preliminary mesh. For each conduction problem, temperatures are specified at two branch tips with the values of one and zero, while the third branch tip is insulated. The three conduction problems are determined by a cyclic permutation of the tip boundary conditions. In all three cases, the remainder of the surface is insulated so that thermal isosurfaces are orthogonal to the domain boundary. The final step is to use these isosurfaces to generate bounding surfaces for “slabs” of hexahedral elements. Candidate isosurfaces are tessellated with quadrilateral elements, such that adjacent pairs of isosurfaces define a slab comprising hexahedral elements. Note that the isosurfaces are guaranteed to be non-intersecting. It is clear from Figs. 1b-d that a single conduction problem suffices to mesh two of the three branches. By using these isosurfaces to mesh only half of each active branch and

combining the result with similarly generated meshes from the complementary problems, a symmetric approach to meshing all of the branches is obtained. The dividing surface that determines which conduction solution to use in each half-branch is taken to be the isosurface that emanates from the branch tip when that tip is insulated. Remarkably, all three of these “principal” cutting surfaces intersect in a single line such that the domain is automatically partitioned into 6 parts. Fig. 1e shows a spectral element mesh generated by this process.

Figure 1: Meshing process of stenosed carotid shown in detail (top left branch is external carotid artery, top right is internal, bottom is common), a) preliminary mesh from commercial software, b) temperature field with ECA = 0, ICA = 1, CCA = Ins, c) ECA = 1, ICA = Ins, CCA = 0, d) ECA = Ins, ICA = 0, CCA = 1, where Ins denotes ‘insulation’, and e) final mesh based on the temperature fields.

CONCLUSION

The solution of simple conduction problems provides a method of generating nonintersecting bounding-surfaces for coarse hexahedral elements that are guaranteed to be orthogonal to the domain boundary.

SWELLING OF ORGANOTYPIC BRAIN CULTURES AS A MODEL FOR TRAUMATIC BRAIN INJURY

Mark B. Sommers¹, Jennifer Miesch², Zhigang Xiong², Michael Bottlang¹

¹Legacy Biomechanics Laboratory, Portland, OR

²Legacy Neurobiology Laboratory, Portland, OR

INTRODUCTION

Traumatic brain injury (TBI) is the leading cause of death and disability below age 45, affecting approximately 1.5 million people in America each year [Thurman, 1994]. TBI is accompanied by diffuse brain swelling, which leads to increased intracranial pressure and reduced blood circulation by vascular congestion. A well-controlled laboratory model is essential to investigate clinically relevant traumatic brain injury and associated swelling behavior. Organotypic brain cultures can provide the basis for an attractive alternative to conventional *in vitro* and *in vivo* brain injury models. They eliminate the complexity of *in vivo* apparent systemic responses, and resemble a heterogeneous cell distribution in a physiologic matrix arrangement, unlike *in vitro* monolayer cultures.

This study quantifies for the first time the swelling behavior of organotypic brain slice cultures in response to the primary insult sustained during brain sectioning. This defined and reproducible mechanical trans-section insult induced brain swelling, which closely resembled *in vivo* apparent injury cascades. It constitutes a valuable model for investigation of TBI and consequential swelling mechanisms.

METHODS

Organotypic brain slices were obtained by a modified method of Adamchick et al. [Adamchick, 2000]. Whole brains were removed from 8-10 day old Swiss mice pups and immersed in chilled dissecting medium. Brains were sectioned coronally into slices of 400 μm thickness on a vibrotome (Leica VT 1000). This sectioning not only yielded organotypic slices of highly accurate thickness, but also induced defined and reproducible trans-section brain injury. Subsequently, each brain slice was transferred to a culture membrane (Millipore, Millicell-CM) and maintained in 1.1 ml of serum-based culture medium in a 37° humidified incubator at 5% CO₂.

Fig. 1: a) organotypic brain culture, b) culture geometry scan.

Brain slice thickness was digitized utilizing a custom-built laser-based surface scanner (Fig. 1b). This scanner was able to scan three-dimensional surface geometries in a non-contact fashion with an accuracy of 35 μm [Sommers, 2001]. Since this scanning technique terminated slice viability, slice thickness could only be measured at one time point per slice.

Thickness measurements were performed by averaging the height over a 4 mm² region on the center of the slice culture. Three brain slices, each from different mice, were measured immediately after sectioning, at 12 h and 24 h post-sectioning, and after 2, 3, 4, 9, 16, and 23 days in culture. Cell death was assessed by measuring the release of lactate dehydrogenase (LDH) into the slice each day from day 1 to day 7, as well as at days 9, 11, 14, 15, 20, and 25.

RESULTS

The trans-section TBI resulted in significant swelling of the organotypic brain slice. Maximum swelling to a slice thickness of 663 \pm 53 μm was detected at 48 hours post insult. The brain slice thickness increase by 70% and 87% at day 1 and day 2, respectively, was highly statistically significant ($p < 0.01$) (Figure 2). After 48 hours, brain swelling declined. At day 9, the initial brain slice thickness of 400 μm was recovered. Cell necrosis, as measured by LDH release, reached its maximum at post sectioning day 3, at which time it had increased by 46% compared to day 1. LDH continuously declined thereafter and became negligible 14 days after the traumatic insult.

Figure 2: time history of brain slice swelling and LDH release

DISCUSSION

The reported brain swelling of organotypic slices correlates closely with clinically observed time-histories of intracranial pressure increase following TBI, and with *in vitro* studies of closed head trauma [Schneider, 1994]. The observed shift between LDH and swelling maxima may be in part caused by the requirement of LDH to diffuse into the culture medium. In conclusion, the consistent and reproducible swelling phenomena of organotypic brain slices constitutes a controlled and clinically relevant *in vitro* model for TBI. As such, it can serve as a powerful tool for the evaluation of pharmacological strategies to reduced brain swelling.

A BIOMECHANICAL MODEL OF THE ELBOW, FOREARM AND WRIST

Rahman Davoodi, David Kleiman, Tomo Murakata and Gerald E. Loeb

A.E. Mann Institute for Biomedical Engineering and Department of Biomedical Engineering

University of Southern California, Los Angeles, CA 90089 USA; [Http://ami.usc.edu](http://ami.usc.edu); Davoodi@usc.edu

INTRODUCTION

Biomechanical models of the human arm provide a convenient and safe environment for studying the control of natural reaching movement and its restoration after paralysis. The model developed here simulates the movement of the elbow, forearm and wrist joints under arbitrary muscle excitations and external forces. It incorporates the most recent experimental data available regarding the moment arms and musculotendinous architecture of the muscles. It has been developed in a popular modeling environment for ease of sharing and future upgrades.

METHODS

The model has four segments (humerus, ulna, radius and hand), three joints (elbow, forearm and wrist), and fifteen muscles (Fig. 1). The skeleton was constructed by averaging the sizes of ten cadaver specimens reported by Murray (1997). Inertial parameters of the segments were estimated by the use of Hanavan's geometric models and experimentally measured segment densities.

Figure 1. Anatomical model of the arm implemented in SIMM® from Musculographics, Inc.

To complete the anatomical model, the muscles were attached to the bony landmarks. Adjustments to cylindrical wrapping surfaces and muscle attachment points were used to reproduce the average experimental moment arms (Murray, 1997; Horii *et al.*, 1993; Lemay and Crago, 1996; Loren *et al.*, 1996) as a function of joint angle. The moment arms about the primary joint, where the muscle is a prime mover, were matched first. Then, additional parameters were modified to match the moment arms about the remaining joints as well as possible. The muscles' architectural parameters were selected from literature (Murray, 1997; Lieber *et al.*, 1990; Lieber *et al.*, 1992). Because the musculotendon lengths were slightly different from that of the model, the lengths of the tendons were adjusted to match the modeled and experimental operating ranges of the muscle fascicles.

Model parameters were fed to Virtual Muscle™ (Cheng *et al.*, 2000), SIMM (Delp and Loan, 2000), and MMS (Davoodi and Loeb, 2001) to build the forward dynamic model of arm that runs in the Simulink® simulation environment of MATLAB.

Figure 2. Biceps Brachii's modeled (thick) and experimental (thin) moment arms (left) and muscle fibers operating ranges superimposed on a normalized force-length curve (right).

RESULTS AND DISCUSSION

As an example of realistic moment arms for multijoint muscles, the modeled and experimental moment arms of the biceps muscle are shown in figure 2. Also shown are the operating ranges of the muscle fibers that are similar to those reported in the literature (Murray, 1997; Loren *et al.*, 1996).

The moment arms about multiple joints and operation of the muscle fibers in the correct region of the force length curve are key features of a realistic arm model. Further validation of the model requires moment arm data about all the joints crossed by each muscle and in different arm configuration. The data from single cadaver specimens should also be as complete as possible because there is no validated methodology for scaling the biomechanical data among specimens.

The model is being used to design neural prostheses for reach and grasp. The MATLAB software environment is slow and simulation of one second of movement requires minutes of computation time on a PC. This modeling environment is suitable for developing and testing highly accurate models that can then be simplified and converted to fully compiled versions for specific requirements.

MATRIX BIOSYNTHESIS DUE TO EXOGENOUS STIMULI DIFFERS FOR CARTILAGE AND FIBROCARTILAGE

Imler SM¹, Hunter CJ², Vanderploeg EJ¹, and Levenston ME¹

Georgia Institute of Technology, Atlanta, Georgia, USA, marc.levenston@me.gatech.edu

¹George W. Woodruff School of Mechanical Engineering

²Wallace H. Coulter Department of Biomedical Engineering

INTRODUCTION

Matrix metabolism in cartilaginous tissues is regulated by a variety of environmental factors, including biomechanical stimulation and soluble growth factors. The effects of such factors on articular cartilage have received much attention in the literature. To date, however, fibrocartilages such as the knee menisci have received less attention. The menisci are critical to maintaining normal knee biomechanics, yet little is known about the role of environmental stimuli in maintaining healthy meniscal tissue. This study compared the effects of exogenous biomechanical and biochemical stimuli on animal-matched explants of articular cartilage and meniscal fibrocartilage.

METHODS

Tissue cores (4mm dia) were obtained from articular cartilage and menisci of immature bovine stifle joints and trimmed to a prescribed thickness. In each experiment, protein and proteoglycan (PG) synthesis rates were measured via radiolabel incorporation (³H and ³⁵S) during the final 21 hours of culture. **Mechanical Stimulation** Explants were pre-cultured in serum supplemented medium for 3 days and then mechanically compressed for 21 hours. Explants (n=8) were placed under static compression (0%, 25%, or 50%) or oscillatory compression (10%±3% at 0.1 Hz or 1.0 Hz). **Biochemical Stimulation** Explants were pre-cultured in serum free medium plus 0.1% BSA for 3 days. Explants (n=8) were then cultured in serum free medium with 0.1% BSA or 0.1% BSA and 200 ng/ml rhIGF-1.

RESULTS AND DISCUSSION

Mechanical Stimulation In cartilage explants, both protein and PG synthesis were inhibited by static compression and stimulated by oscillatory compression (Figures 1 and 2), as previously reported (Sah, 1989). In meniscus explants, protein synthesis was also inhibited by static compression and stimulated by oscillatory compression, with synthesis per cell comparable to that in cartilage. In contrast, PG synthesis was not significantly influenced by either static or oscillatory compression. **Biochemical Stimulation** The responses to biochemical stimulation were less consistent. IGF-1 did not substantially influence protein synthesis in cartilage explants, but it significantly stimulated protein synthesis in meniscus explants (Figure 3). IGF-1 stimulated PG synthesis in both tissues, with a more dramatic effect on meniscus explants.

Figure 1: Static compression results

Figure 2: Oscillatory compression results

Figure 3: IGF-1 time-course results (meniscus and cartilage)

SUMMARY

This study elucidates biosynthetic differences of fibrocartilage and cartilage in response to biomechanical and biochemical stimuli. PG synthesis in meniscus explants was nonresponsive to mechanical stimulation. RT-PCR analysis indicates that the meniscal fibrochondrocytes do express aggrecan mRNA at roughly one-third the level of articular chondrocytes, indicating a potential for PG production. Indeed, IGF-1 induced sustained stimulation of meniscal PG synthesis, although the synthesis rates remained well below levels seen in cartilage. In stark contrast, regulation of protein synthesis by mechanical compression was similar for the two tissues, despite the probable difference in the predominant protein type (collagen I in meniscus and collagen II in cartilage). Effects of sustained loading on meniscal tissue remain undetermined and will give further insights into meniscal physiology.

TREADMILL SPEEDS RELATED TO SPRINTING ABILITY

Derek Kivi¹, Brian Maraj², and Pierre Gervais¹

¹Sports Biomechanics Laboratory and ²Perceptual Motor Behavior Laboratory
University of Alberta, Edmonton, Alberta, Canada, dkivi@ualberta.ca

INTRODUCTION

Treadmill sprinting is a demanding form of speed training, requiring strength and dexterity in order to be an effective training tool. The purpose of this study was to compare the stride characteristics and lower extremity kinematics of sprinters of different abilities on a treadmill, and determine whether or not a sprinter's velocity should be a factor as to how the treadmill is used for speed development.

METHODS

Six national level sprinters (3 males, 3 females) were recruited for the study, all of whom were familiar with sprinting on the treadmill. Each subject performed runs of 70%, 80%, 90%, and 95% of their previous maximum. The treadmill was preset to a specific velocity for each individual prior to the trial; there was no acceleration or deceleration phase. A Canon 8mm video camera recorded the performance in the sagittal plane at 60Hz and a shutter speed of 1/2000. Data processing was completed using the Ariel Performance Analysis System. For each test condition three successive strides were analyzed. Data were smoothed using a low-pass digital filter with a cutoff frequency of 8 Hz. Subjects were categorized in either the highly skilled or less skilled sprint group based on the velocities selected for testing. Descriptive statistics (means (M) and standard deviations (SD)) were calculated for variables selected for analysis based on previous treadmill sprinting research (Kivi *et al.*, In Press).

RESULTS AND DISCUSSION

The results are seen in Table 1 and indicate that there are differences between groups while sprinting on a treadmill, particularly at higher velocities. The highly skilled group showed faster treadmill velocities at all test conditions, however the stride frequency was similar between groups.

This suggests that the differences in velocity were a result of longer stride length, as velocity is the product of stride length and stride rate. Group differences were seen in the positions achieved at the hip and knee. The highly skilled sprinters were better able to limit hip and knee extension at take-off (smaller angle) which helped reduce stance time, and were able to achieve greater angles of hip flexion (larger angle) which made leg recovery more efficient (Mann, 1985). The less skilled sprinters, in order to execute the same movements, required greater angles of knee flexion (smaller angle) through recovery to minimize the rotational inertia. These findings suggest that the differences in treadmill sprinting velocity seen between groups are a result of a lack of strength in the hip flexors, as Mann (1985) stated that excessive extension at take-off is indicative of a lack of leg strength. It is recommended that less skilled sprinters using a treadmill as a speed development tool should not train at near maximum velocities until they have developed sufficient strength through the hip flexors, in order to prevent unwanted breakdown in technique. With the small number of subjects preventing adequate statistical comparison, further investigation is required.

SUMMARY

Stride characteristics and lower extremity kinematics were compared between two groups of sprinters of different abilities on a treadmill. The results suggest there are differences between groups at higher velocities, which may be the result of inadequate hip flexor strength.

INTRODUCTION

Idiopathic scoliosis (IS) is a complex pathology, recognized as a 3-dimensional deformation of the spine. Considerable research has focused on the deformation of the spine and thorax, with little focus on understanding the mechanisms that are responsible for postural control, and how they relate to the progression of spinal curvature. Quiet standing has been understood primarily through the Inverted Pendulum Model, where the horizontal acceleration of the Centre of Mass (COM) is proportional to the difference in amplitude between the Centre of Pressure (COP) and COM. More recently ankle muscle stiffness has been proposed to explain how the CNS controls quiet stance. The objective of this study is to apply the Stiffness model to contribute to the understanding of the mechanisms responsible for postural control in this unique pathology.

METHODOLOGY

There were 4 IS patients (age: 10, sd: 1 year) and 4 control subjects (age: 9, sd: 1years) in this study. Each subject was placed in a quiet standing position with each foot on an AMTI forceplate. One Optotrak Position sensor captured the 3D position of IRED's placed on the base of support, lower and upper extremities. Four quiet standing trials were collected (120 s, 30 Hz) with adequate rest in between each trial. The following equations presented by Winter et al., 2001 were utilized to calculate in reference to the ankle joint the COM sway angle (θ_{sw}), moment (M_a) and stiffness (k_a). (m = mass of the subject above the ankle joint; g = acceleration due to gravity, COP_{net} = net centre of pressure position based on COP of the right and left feet, COM = 12 segment model)

$$M_a = mg * COP_{net} \quad \text{Equation 1}$$

$$\theta_{sw} = COM/h \quad \text{Equation 2}$$

$$K_a = dM/d\theta_{sw} \quad \text{Equation 3}$$

RESULTS AND DISCUSSION

The stiffness, sway angle and R^2 between the sway angle and the ankle moment are presented in Table 1. The R^2 between the sway angle and ankle moment ranged between .87 to .96 for the control subjects and .93 to .97, for the scoliosis patients. This reflects how close the ankle stiffness approaches an ideal spring, and is similar to the values reported by Winter et al., 2001 for adult control subjects.

Table 1: Sway angle (θ_{sw}), stiffness (K_a), and R^2 .

	Sway (θ)	K_a (nm/rad)	R^2
Control	3.1 (.4)	231 (64)	.93 (.04)
IS	3.7 (.3)	159 (54)	.96 (.04)

There was a tendency to have an increased sway, and decreased stiffness for the IS patients. Also, despite an RMS sway angle of less than 1° for all subjects, the sway angle range during the 120 s was from a minimum 1° to maximum 4° across subjects. There was a similar observation for the stiffness with a minimum range of 226 Nm/rad to a maximum range of 1244 Nm/rad across subjects during the same period. The stiffness of a typical subject is presented in Figure 1.

Figure 1: Ankle stiffness (K_a) of a Scoliosis patient.

SUMMARY

The control of AP sway about the ankle joint reflects a spring like mechanism that has different characteristics between IS and control subjects. The range of stiffness and sway angle over the 120 s indicates a more complex process of stiffness control than previously thought.

ACCELERATION TRANSIENTS AND TRANSTIBIAL PROSTHETIC PYLON ATTENUATION DURING GAIT

Jocelyn S. Berge^{1,2}, Glenn K. Klute^{1,3} and Joseph M. Czerniecki^{1,4}

¹Departments of Veterans Affairs, VA Puget Sound Health Care System, Seattle, WA (jberge@u.washington.edu)

INTRODUCTION

Repetitive high frequency transients arising from heel strike during locomotion are thought to be responsible for the deleterious effects observed on the residual limb tissue and other structures of lower limb amputees (Whittle, 1999). To ameliorate this effect, prosthetic manufactures have developed shock absorbing pylons (SAPs) to attenuate shock transients transmitted to the residual limb. To date, the performance and efficacy of SAPs is not well understood. Our focus is measure the accelerations transients transmitted to the residual limb and then access how these transients are altered by an SAP (TT Pylon, Blatchford, UK) as compared to a rigid pylon.

METHODS

Five unilateral transtibial Veteran amputees were recruited to participate, each provided informed consent. Subjects were fit with a standard prosthetic limb able to accommodate either pylon. Pylon order was randomized and after a three-week acclimation period, accelerometry data were collected while subjects walked 3-5 repeated trials at $1.2 \text{ m/s} \pm 10\%$. A lightweight accelerometer (Entran, USA) was rigidly mounted proximally on the pylon. Data were sampled from the axis parallel to the pylon ($f_s = 600 \text{ Hz}$, $f_c = 100 \text{ Hz}$). Subjects were then fit with the other pylon and asked to repeat the protocol sequence. The time series signals were cropped to include only one stance phase and padded, by extending the first and last values, to 512 points in preparation for the analysis. Fourier analysis determines the magnitude of a signal using the entire sample period resulting in an underestimation of damped transient magnitudes. A multilevel stationary wavelet discrete transform using a least asymmetric wavelet (width 8) (LA8) preserves both frequency and time information of the signal. The LA8 was selected to minimize sidelobes outside the pass-band (Percival and Walden, 2000). The analysis included pass-bands from 9-18 Hz (pb1), from 18-38 Hz (pb2), from 38-75 Hz (pb3), and from 75-100 Hz (pb4). Peak acceleration magnitudes within each pass-band were averaged for each pylon. A repeated measures ANOVA was performed with an *a priori* α of $p < 0.05$.

RESULTS AND DISCUSSION

The wavelet analysis of accelerometry data from the rigid pylon and the SAP reveal large accelerations transient magnitudes entering the residual limb (Figure 1). For perspective, with 1 g acceleration and an assumed effective leg mass of 5 kg, a significant shock load of 50 N is transmitted. The mean peak accelerations, for the most part, decrease in magnitude with increasing pass-band frequency (Figure 2). All pass-bands showed reduced magnitude transients for the SAP compared to the rigid pylon but none were statistically

significant. The attenuation could be attributed to the pylon and/or the individual loading characteristics of the amputee.

Figure 1: Illustrative accelerometry data and a multilevel wavelet analysis pass-band pb2 for an amputee wearing a rigid pylon and an SAP.

Figure 2: The means ($n=5$) and standard deviations of peak acceleration transients at each pass-band.

SUMMARY

Large magnitude accelerations transients were present for both pylons with decay occurring within 0.1 seconds. This wavelet approach is able to retain frequency and time information allowing for observation of possible prosthetic component differences. Reduced, but not statistically significant, mean signal magnitudes for all frequency pass-bands were observed when amputees walked on a rigid pylon versus an SAP.

PERTROCHANTERIC FRACTURE FIXATION: EFFECTS OF IMPLANT DESIGN ON CUT-OUT FAILURE UNDER DYNAMIC LOADING

Mark B. Sommers¹, Michael Bottlang¹, Christoph Roth², Harry Hall², James C. Krieg¹
¹Legacy Clinical Research & Technology Center, Portland, OR; email: mbottlan@lhs.org
²Synthes(USA), West Chester, PA

INTRODUCTION

One of the most severe orthopaedic challenges is the rapidly rising number of over 300,000 hip fractures per year in the US [Rubenstein, 2000]. A preferred treatment option for hip fractures is the use of lag-screw implants. Despite widespread use, these implants exhibit a disturbingly high complication rate of up to 23% [Baumgaertner, 1995]. The most common failure mode is cut-out of the implant through the femoral head. The efficacy of implants to resist cut-out has been studied intensively under quasi-static loading conditions. This study investigated the fixation strength of various implants under dynamic loading.

METHODS

Four implant designs from two manufacturers (Synthes (USA), Paoli, PA; Stryker Howmedica Osteonics, Allendale, NJ) were tested (Table 1). Two lag-screws had a conventional thread design (i.e. Dynamic Hip Screw – DHS, Gamma Nail), while the other two implants featured a novel helical blade design (i.e. Dynamic Helical Hip System – DHHS, Titanium Femoral Nail – TFN).

Implant	Company	Fixation type	Implant design	
DHS	Synthes (USA)	Side Plate Fixation	Lag Screw	
DHHS			Helical Blade	
TFN	Howmedica	Intramedullary Nail Fixation	Helical Blade	
Gamma Nail			Lag Screw	

Table 1: Implant Specifications

Implants were tested in a femoral head/neck model, that simulated constraints characteristic of an unstable, fully collapsed pertrochanteric fracture type OTA 31-A2.1 [Fracture compendium, 1996] (Figure 1). Implants were inserted into cancellous bone surrogates (polyurethane foam, 60 MPa compressive modulus, Pacific Research Inc., Vashon, WA) with a defined posterior offset of 7 mm to simulate clinically relevant procedural imprecision of implant insertion. The shaft of the implant was affixed to a rigid base, with the implant's longitudinal axis oriented at 149° toward the horizontal plane. An electro-magnetic motion tracking system was used to record femoral head rotation around the longitudinal implant axis (α_{NECK}), and varus collapse (α_{VARUS}). A material test system (Instron, Canton, MA) was used to exercise specimens cyclically (3 Hz) to cut-out failure or up to 100,000 cycles at six distinct load levels (n=3), ranging from 0.5kN to 1.65kN.

Figure 1: Fracture model and loading scenario.

RESULTS

The number of loading cycles to cut-out failure for all implants is depicted in Figure 2 in terms of fixation life curves. For a median load level of 1.2kN, implant cut-out occurred at 4 ± 1 , 894 ± 430 , 7850 ± 5380 and 28300 ± 4750 load cycles for the DHS, Gamma Nail, DHHS and TFN implant, respectively.

Figure 2: Fixation life curves

Implant cut-out failure was accompanied by femoral head collapse into varus (α_{VARUS}) and femoral head rotation around the implant axis (α_{NECK}) induced by the 7mm posterior offset (Figures 3, 4). After 10 load cycles at 1.0kN load amplitude, α_{VARUS} and α_{NECK} advanced on average to 64% and 89% (DHS), 35% and 58% (Gamma), 16% and 21% (DHHS) and 5% and 7% (TFN) of their maximal values, respectively.

Figure 3: Femoral Head rotation versus loading cycles

Figure 4: Varus collapse versus loading cycles

DISCUSSION

The presented cut-out model allowed reproducible assessment of the implant-specific migration onset and pathway. It closely resembled clinically observed cut-out failure modes, which most frequently occur in unstable pertrochanteric fractures. It also delineated the efficacy of specific design parameters to increase cut-out resistance in a well-controlled laboratory setting. Both helical blade implants provided superior resistance to migration and subsequent cut-out failure. This suggests, that a helical blade design provides increased fixation strength compared to a conventional lag screw design.

INTRODUCTION

The underlying motor control mechanisms of quiet standing have traditionally been characterized by measuring the movement in the frequency and time domains of the centre of pressure (COP) and less often the centre of mass (COM). However, Idiopathic scoliosis (IS) for example, affects spinal alignment, and ultimately the position and orientation of the pelvis, thorax and shoulder girdle during periods of rapid growth and maturation of the neuro-musculo-skeletal system. These changes may be masked by models that use only the COM or the COP. The objective of this study is to compare the segmental posture of adolescent control and IS patients during quiet standing.

METHODOLOGY

There was 5 IS patients (age: 14, sd: 2years) and 5 control subjects (age: 12, sd: 2years) who participated in this study. Each subject was positioned in a quiet standing position and IRED's were placed on the base of support, pelvis, spine, thorax and shoulder girdles and captured by an Optotrak Position Sensor. Four quiet standing trials were collected (120s, 20 Hz) with adequate rest in between each trial. The parameters calculated included the anterior-posterior (A/P), and medial-lateral (M/L) shift of T1 and S1 spinous processes in reference to the base of support, as well as a relative measure between the two vertebra. The angular parameters included rotation and tilt of the pelvis and shoulders in the transverse and frontal planes. The mean and root mean square (RMS) of each trial, for each angular and linear parameter was averaged across the four trials and compared between groups.

RESULTS AND DISCUSSION

There was a significant difference between the IS and control subjects for the mean orientation of the pelvis, thorax and shoulders. (See Table 1)

Table 1: Orientation of pelvis and shoulders.

	IS	Control
Pelvis Tilt	-3±2°	0.5±2° *
Shoulder Tilt	4±1°	-0.1±2° *
Shoulder Rotation	4±2°	-0.3±2° *
Thoracic Rotation	-8±3°	-2±3° *

* $p < 0.05$

The presence of these postural asymmetries may be the consequence, or represent an aggravating factor for the

evolution of IS. The lateral deviation and curvature of the spine will affect the position and orientation of the adjacent pelvis, shoulder girdle, and thorax. The direction of these asymmetries may depend on the side, level and severity of the curvature. However, in consequence this asymmetry may place un-even forces on the vertebral body, which during periods of rapid growth and development may promote vertebral deformation and progression of the spinal curvature.

There was a difference between groups (IS vs Control; $p < 0.05$) for the RMS during the 120 s for the shift of T1 in reference to S1 (A/P: 3±1mm vs. 5±1mm; M/L: 1±1mm vs. 3±1mm). The control subjects demonstrated greater variability in the postural control of the trunk than the IS patients. Factors that must be considered include the phase of growth of the individual where the neuromuscular system is adapting to the changing morphology of the skeletal system, and is making continuous fine motor adjustments until a stable equilibrium is reached. The IS patients also undergo this process of maturation in addition to being challenged by greater postural asymmetries and a lateral deviation of the spine. However, changes to soft tissue (muscle fibre length and composition) and individual vertebral deformation and disorientation may contribute to the decreased mobility, and reflect greater spinal rigidity as the pathology evolves.

SUMMARY

The postural alignment and variation of IS patients does exhibit differences to adolescent control subjects. These differences and the presence of the spinal deformation will implicate unique challenges to the postural control system of the IS patients.

DOES VERTEBROPLASTY ALTER THE MECHANICAL RESPONSE OF OSTEOPENIC VERTEBRAE?

Dietrich von Stechow¹, Zurakowski David², Torres Katherine³, SerhanHassan³, Ron N Alaklay¹

¹Orthopedic Biomechanics laboratory, Beth Israel Deaconess Medical Center, Boston, MA.

INTRODUCTION

Percutaneous vertebroplasty (PVP) using PMMA is rapidly gaining acceptance as an appropriate surgical treatment for age related vertebral fractures and has shown promising results with, at present, few reported complications. Although PVP significantly increases the structural compressive strength of augmented vertebrae, little is known on the efficacy of this procedure in restoring the overall structural response of failed vertebrae under complex loads.

METHODS

Nineteen thoracic and lumbar vertebrae from three spines, aged 65-78 years, were radiographed to estimate the body posterior and anterior height and their Bone Mineral Density assessed by DXA (Hologic 2000+, Hologic, MA). A custom testing jig was employed to test the vertebrae to failure using a hydraulic test system (1331, Instron, Canton, MA) under combined compression-flexion at a rate of 5mm/min. Failure was defined as 50% reduction in the vertebra anterior height or a reduction of 10% in maximum load. A 6DOF load cell (MC5, AMTI, MA) was employed to measure the resulted forces and moments and displacement to failure, measured via the material testing system, with the data acquired using LabView (National Instruments, TX) at the rate of 10Hz. The failed vertebrae were allowed to recover for 30 min, the vertebral body heights re-measured and the vertebrae re-tested. A bilateral transpedicular approach was employed to augment each fractured vertebral body using PMMA cement (Vertebroplastic, Codman&Shurtleff, MA). Augmentation was performed under fluoroscopic imaging with the procedure terminated when a complete body fill was obtained or leakage of the material was observed. The augmented vertebra was allowed to rest for two hours, vertebral body heights re-measured and the vertebrae re-tested to failure. Repeated measure ANOVA was used to test for differences in maximal failure load and stiffness estimated from the linear portion of the load-displacement curve, for each of the forces and moments (JMP, SAS, NC).

RESULTS AND DISCUSSION

For L1 levels of the specimen the mean bone mineral density ($0.54 \pm 0.06 \text{g/cm}^2$) suggested the spines to be osteoporotic. All of the vertebrae tested exhibited a typical anterior-flexion compressive failure. The augmented vertebrae showed a highly significant increase in compressive strength, $3552 \pm 961 \text{N}$, and stiffness $-741 \pm 288 \text{Nm/mm}$, compared to that of the failed

vertebrae $1082 \pm 313 \text{N}$ and $-262 \pm 186 \text{Nm/mm}$, respectively ($p < 0.001$). Similarly, the augmented vertebrae showed significant increases in flexion strength and both strength and stiffness parameters under anterior-posterior shear, Table 1. However, out of plane forces and moments remained relatively constant throughout the test, (Table 1).

Table 1: Mechanical parameter for fractured and augmented vertebrae

Mean \pm S.D, N.S: Not significant.

This study investigated the effect of cement augmentation on the structural response of augmented thoracolumbar vertebrae under compression-flexion loads. Compared to the failed vertebrae, the augmented vertebrae exhibited a significant increase in structural load carrying ability and decreased deformation, particularly in the plane of loading (Table 1). However, from the out of plane response of the augmented vertebrae, it is evident that its structural behavior was markedly different than that of the failed vertebrae. Although the desired outcome of vertebroplasty is to restore the stiffness and the strength of the vertebra to the level of non-fractured vertebrae, the observed increases in compression force (+228%) and lateral bending (+489%), may pose a risk to adjacent segments due to altered load transference.

SUMMARY

The effect of cement augmentation on the structural response of failed vertebrae was investigated. Augmentation produced a significant increase in the structural competence of the failed vertebrae whilst, at the same time, causing a significant change in the overall structural response of the failed vertebrae.

ASSESSMENT OF POSTURAL RESPONSE TO AN INTERNAL PERTURBATION

Nicolas Termoz^{1,2}, François Prince¹ and Luc Martin²

¹L.P.L., Centre de réadaptation Marie Enfant, Hôpital Sainte Justine, Montréal, Québec, Canada

INTRODUCTION

Two variables are generally used for postural studies: the Center of Pressure (COP) and the Centre of Mass (COM). Brenière et al., (1987) highlighted the existence of a linear relation between the COP-COM signal and the linear acceleration of the COM during gait initiation. Later, Winter et al., (1998) used this relation to validate the inverted pendulum model, and Rietdyk et al., (1999) expanded it to balance perturbation tasks. On the basis of this research, the objective of this study is to use this relation to quantify the efficiency of the body to respond to a self-initiated postural perturbation and returns to quiet standing.

METHODS

Eight young subjects took part in this study. An anthropometric model composed of three segments (legs, trunk, arm) was defined. A kinematic analysis was coupled to a kinetic analysis to calculate the COP and the COM for the whole body. From an initial standing position, the subjects were asked to perform an upward and downward symmetrical arm swings at three different speeds (slow (V_s), natural (V_n) and fast (V_f)). Five trials of 30 s per conditions were carried out and analysed.

The relationship linking the two variables for the sagittal plane for example, is expressed as follow:

$$\ddot{x}_{COM} = -k(x_{COP} - x_{COM})$$

where \ddot{x}_{COM} is the linear acceleration of the COM, k is an inertial constant and x_{COP} and x_{COM} are the COP and COM position to the ankle joint in this plane, respectively.

To quantify this relation, the coefficient of determination (R^2) was calculated between the “error signal” (COP-COM) and the horizontal acceleration of the COM on various ranges of time: before, during and after the movement. Moreover, a mobile R^2 was calculated and compared to the R^2 measured before the movement in order to determine the instant from which the disturbance does not affect the system anymore. The R^2 was examined in a one-way ANOVA to determine the effect of the period of analysis (before, during and after the movement).

RESULTS AND DISCUSSION

The average angular velocities are $V_s=1.68$ rad/s (sd=0.23), $V_n=2.85$ rad/s (sd=0.64), $V_f=6.71$ rad/s (sd=0.42) for the slow, natural and fast movements, respectively. The relationship between COM and COP does not seem to be affected during the movements with a slow velocity (figure1).

Figure1: R^2 before, during and after the movement, *significant difference at $P < 0.05$)

However, as the speed increases, the inter subject variability of the R^2 during the movement increases. This could be partly explained by the inter subject speed variability for the fast movements. Finally, in spite of a significative reduction of the R^2 for the natural and fast speed, probably explained by the intervention of another joint to counterbalance the perturbation, the relationship is always greater than .80.

Therefore, the COP remains the control variable and still maintains the COM within the base of support as suggested by the inverted pendulum model. Rietdyk et al., (1999) also found that the body controls its balance using this model for medial-lateral perturbations of the upper body during standing even though the body does not behave as a single pendulum.

The average time to recover steady state was variable from one subject to another and between the three conditions. For 80 % of the trials (slow, natural, fast) the time when the posture stops to be affected by the movement was determined to be slow= 5.78 ± 2.64 s; natural= 5.46 ± 2.24 s; fast= 5.80 ± 1.52 s. For 20% of the trials, the subjects did not return to a stable period within the data collection time. A study over a longer period should be made to evaluate this stabilization period.

SUMMARY

On the basis of the inverted pendulum model, the objective of this study was to quantify the efficiency of the body to respond to an internal perturbation such as an arm movement. Results show that the linear relation linking the COP and the COM signals to the acceleration of the COM is a valuable variable to study the control of posture following a self initiated perturbation.

A NOVEL ALGORITHM FOR GENERATING A FORWARD DYNAMICS SOLUTION TO THE TRADITIONAL INVERSE DYNAMICS PROBLEM

Behzad Dariush

Honda R&D, Fundamental Research Labs, Mountain View, California, U.S.A. bdariush@hrra.com

INTRODUCTION

In human motion analysis, the recursive “ground up” inverse dynamics analysis is a commonly used technique to estimate joint moments. The method assumes knowledge of the kinematics and ground reaction forces to recursively determine the applied moments at the joints. In an alternative approach, forward dynamics solutions using linear optimal control (Runge et al., 1995), and nonlinear optimization (Chao and Rim, 1973) have also been used for estimating joint moments. Unlike inverse dynamics analysis, optimization based methods do not require estimation of accelerations by numerically differentiating kinematic data: a notoriously difficult and ill-posed problem. However, widespread application of optimization and optimal control solutions are limited because the methods are computationally expensive, are not guaranteed to converge, and are in general too complex to implement. In this abstract, a novel recursive algorithm is developed that represents a robust ‘ground up’ forward dynamics solution to the inverse dynamics problem. The solution is simple to implement, fast (real time), stable, guaranteed to converge, and does not require accelerations.

METHODS

The underlying theory of the recursive algorithm is derived from concepts in tracking control and feedback linearization. The objective of trajectory tracking control is to compute a set of forces and moments that when applied to a forward simulation would result in a trajectory sequence that track (or reproduce) the measured kinematic data. The tracking proposed here is based on a feedback linearization procedure implemented at each isolated body segment of a multi-body system (see Figure 1). The required inputs to initiate the recursion equations at joint i include the measured kinematics (q_{i_m}), estimates of their velocities (\hat{q}_{i_m}), and the joint torque and joint reaction force vector (concatenated in vector U_i). The estimated accelerations ($\hat{\ddot{q}}_{i_m}$) may also be used in noise free applications, but are not required. The output is the estimated reaction force and torque vector at joint $i+1$ (U_{i+1}), which is used as the input for the next iteration. The matrices K_p and K_v represent the proportional and derivative feedback gains, respectively. They are constant, diagonal matrices whose values are selected to yield a critically damped response (Craig, 1989). The simulated states are described by (q_i, \dot{q}_i) and the error between the simulated and measured kinematics is represented by the vector $e_i = q_{i_m} - q_i$. If the measurements are noise free, the parameter a is set to 1. In dealing with real measurements, it is suggested to exclude accelerations ($\hat{\ddot{q}}_{i_m}$) by setting the parameter a to zero. In

both cases, the tracking error can be forced to approach zero by increasing the feedback gains.

Figure 1: Recursive, feedback linearization block diagram.

RESULTS AND DISCUSSION

Extensive simulations were conducted with real motion data as well as with synthetically generated data injected with random noise. Simulations of the tracking performance for a synthetically generated rhythmic motion injected with noise is shown in Figure 2. For this motion, simulations for different values of K_p were carried out and the absolute mean tracking error was plotted for the case $a=0$ and $a=1$. The simulation results of this motion, and other motions, support the theory that the tracking error using the feedback structure in Figure 1 can be forced to approach zero by increasing K_p .

Figure 2: Tracking error is reduced by increasing K_p .

SUMMARY

A feedback linearization approach has been presented to recursively estimate the joint forces and joint moments from kinematic and ground reaction measurements. The proposed method does not require accelerations, is predictive, and represents a forward dynamics solution to the traditional ‘ground up’ inverse dynamics problem.

BUFFY COAT CONCENTRATE (AGF™) WITH ALLOGRAFT IMPROVES IMPLANT FIXATION

Joan E Bechtold¹, Thomas B Jensen^{1,2}, Pascal Swider³, Olivier Mouzin^{1,3}, Kjeld Søballe²

¹Orthopaedic Biomechanics Laboratory, Minneapolis Medical Research Foundation, MN, ²Aarhus University, Dept. of Orthopaedic Surgery, Denmark, ³CHU Purpan, Toulouse, France. Email: becht002@tc.umn.edu

INTRODUCTION: Platelet rich plasma increases incorporation of bone *autograft* (Marx, 1998). AGF™ is a commercially available autologous platelet and white cell ultra-concentrate. We hypothesized that AGF™ mixed with morzelized bone *allograft* would increase bone formation and implant fixation.

METHODS: Eight dogs (16 implants) were followed for 4 weeks, with all animal handling and AGF™ processing approved by Institutional IACUC.

Implants: Plasma sprayed cylindrical titanium implants (6x10mm) were inserted extraarticularly in each proximal tibia, surrounded by a 2 mm gap (Jensen et al., 2002b). One gap was packed with fresh frozen bone allograft alone, and the contralateral gap was packed with allograft+AGF™.

AGF™ preparation: Under anaesthesia, immediately prior to surgery, 450 ml of blood was drawn. A cell separator divided blood into platelet poor plasma, platelet rich buffy coat, and erythrocytes. The buffy coat (~60 ml) was isolated and further concentrated (UltraConcentrator™ Interpore-Cross) to 20 ml.

Statistics: Mean±SD are shown. With paired t-test, p-values < 0.05 (two-tailed) were considered significant.

Mechanical test: Under axial pushout, shear strength, apparent shear stiffness, and energy absorption were determined. **Histomorphometry:** Volume fractions of woven bone, allograft and non-mineralized tissue were determined using point grids: 0-900 µm (Zone 1) and 1000-1800 µm (Zone 2) from implant surface. Bone, fibrous and other tissue in contact with implant surface was estimated as % of total implant surface.

RESULTS: Mean platelet count increased from 169±58*10⁹/l to 1212±466*10⁹/l (AGF). Adding AGF to graft increased mechanical parameters (Table I; reported previously (Jensen et al., 2002a) and bone ongrowth, and decreased fibrous membrane in contact with implant surface (Table II) (p<0.05). Volume fractions of bone & graft in gap were unchanged with AGF (Table III); all measurements were blinded.

Table I: Mechanical parameters (mean (SD))

Group	Shear strength (MPa)	Energy abs. (J/m ²)	Stiffness (MPa/mm)
Graft	1.24 (0.83)	322 (252)	5.27 (3.66)
Graft+AGF	1.88 (1.18)*	453 (265)	7.32 (5.13)

*: p<0.05 compared to allograft without AGF

Table II Contact (mean (SD)): in % of total surface

Group	Bone	Fibrous	Other tissue
Graft	7 (5)	25 (35)	68 (37)
Graft+AGF	11 (7)*	17 (29)*	72 (25)

*: p<0.05 compared to allograft without AGF

Table III Volume fractions of woven bone, bone graft and non-mineralised tissue, % (mean (SD))

Zone	Woven bone		Graft		Non-mineral.	
	1	2	1	2	1	2
Graft	20(7)	19(5)	6(4)	3(2)	74(10)	78(5)
Graft+AGF	20 (4)	18 (5)	5 (2)	3 (1)	75 (4)	79 (5)

No sig. diff. between AGF treated vs. non treated.

DISCUSSION: The increase seen with AGF in strength, stiffness and energy (52%, 39%, 41%, respectively) was reflected by a similar increase in the amount of bone/implant contact (57%). In contrast, there was no significant increase in bone in Zones 1 (0%) and 2 (-5%) with the addition of AGF to graft (Table III). Hence, the increase in mechanical parameters with AGF can be attributed to the increased bone found in direct implant contact. This agrees with companion theoretical mechanical studies demonstrating that the highest shear stresses are found at the implant surface, and previous experimental studies showing a similar relationship between mechanical parameters and bone in the region immediately at the implant surface (Mouzin, 2001).

SUMMARY: These results suggest that a buffy coat concentrate mixed with bone allograft may enhance early fixation and bony incorporation of implants, and suggest that this improvement is achieved by increased bone growth on the implant surface. Since bone grafting is often required in the revision of failed joint replacements (which have an inherently poor healing prognosis), application of bone stimulating agents such as AGF to the graft is of great clinical interest.

OSCILLATORY COMPRESSION OF ARTICULAR CARTILAGE: RELEASE OF CELL SIGNALING MOLECULES AND THE EFFECT OF CONDITIONED MEDIUM ON CHONDROCYTES IN AGAROSE GEL CULTURE

Christopher J. Hunter¹ and Marc E. Levenston²

Georgia Institute of Technology, Atlanta, Georgia, USA

¹Wallace H. Coulter Department of Biomedical Engineering

²George W. Woodruff School of Mechanical Engineering, marc.levenston@me.gatech.edu

INTRODUCTION

We previously reported the response to mechanical compression of tissue engineered cartilage in an *in vitro* repair model. Chondrocyte-seeded agarose gels were cast inside annuli of articular cartilage and cultured under mechanical compression. Both protein and proteoglycan synthesis rates were inhibited by static compression and stimulated by oscillatory compression (Fig. 1; Hunter and Levenston, 2002). We proposed that this response was due to local mechanical signals induced by compression. An alternate explanation, however, is that the repair tissue was indirectly stimulated by factors released from the tissue in response to compression. To address this hypothesis, the current study examined the influence of compression on release of TGF- β , IGF-1 and nitric oxide by articular cartilage explants and the effect of conditioned media on matrix synthesis in engineered cartilage.

Figure 1. Radiolabel incorporation by agarose gels inside cartilage annuli. Stars: $p < 0.05$ vs. free-swell. Daggers: $p < 0.05$ vs. static (mean \pm s.e.m., $n = 8$).

METHODS

Cartilage discs were isolated from calf femoral condyles and pre-cultured in serum-free medium for two days. Discs were then assigned to one of three compression conditions ($n = 5$): free-swelling, static (10% of cut thickness), and oscillatory ($10 \pm 4\%$) at 1 Hz. After 24 hours, the culture media were analyzed for TGF- β and IGF-1 via ELISA and nitrite via the Greiss assay. Chondrocytes isolated via collagenase digestion from the remaining cartilage were cast into 2% agarose gels at 10^7 cells/ml and pre-cultured in serum-free medium for two days. Gels were then cultured in 500 μ l of conditioned medium from each compression condition mixed with 500 μ l of radiolabeled medium (10 μ Ci/ml 3 H-proline, 5 μ Ci/ml 35 S-sulfate). After 24 hours, the gels were assayed for DNA, 3 H, and 35 S content. Data were analyzed with GLM (significance at $p < 0.05$) and Tukey's test for post-hoc analyses.

RESULTS

Static compression of cartilage explants significantly decreased TGF- β release and increased nitrite in the medium, but did not significantly affect IGF-1 release. Oscillatory

compression did not significantly change either TGF- β or IGF-1 release, but did increase nitrite content (Fig. 2). Levels of all three factors were higher than those in unconditioned medium containing 10% FBS. Conditioned media had no detectable effects on matrix synthesis rates by chondrocytes in free agarose gels (Fig. 3).

Figure 2. Analysis of conditioned culture media. Dashed lines show level in unconditioned 10% FBS medium. Stars: $p < 0.05$ vs. free-swell. Daggers: $p < 0.05$ vs. static (mean \pm s.e.m., $n = 8$).

Figure 3. Radiolabel incorporation by uncompressed agarose gels treated with conditioned media (mean \pm s.e.m., $n = 5$).

DISCUSSION

We previously demonstrated that mechanical compression significantly influenced matrix synthesis by engineered cartilage in a defect repair model. Compression induced changes in local mechanical stimuli, but may also have induced release of soluble biochemical factors. In the present study, we found that oscillatory compression of cartilage explants did not produce an increase in TGF- β or IGF-1 release, and that conditioned media from compressed cartilage did not stimulate synthesis by chondrocytes in agarose gels. Therefore we conclude that stimulation of matrix synthesis in the defect repair model was largely due to mechanical stimuli. These results suggest that indirect stimulation of repair tissue through soluble factors released by native tissue is minimal in comparison to stimulation by local biomechanical phenomena.

SHRINKAGE OF VACUUM MIXED CEMENT CAUSES INTERFACE GAPS AND STRESS CONCENTRATIONS IN CEMENT MANTLES SURROUNDING FEMORAL STEMS

Amos Race, Mark Miller, David Ayers and Kenneth Mann

Musculoskeletal Science Research Center, Upstate Medical University, Syracuse, New York, USA
racea@mail.upstate.edu

INTRODUCTION

Polymerization shrinkage of bone-cement has been known of for some time but has never been quantified in a stem/cement/femur construct. Gaps around femoral stems have been observed in transverse sections of stem/cement/femur constructs (Race, 2001). A greater proportion of stem/cement (s/c) interface gaps were found around grit blasted sections of stems than satin finished sections. It was not clear whether the gaps were due to air inclusion or cement shrinkage. If s/c gap formation were a shrinkage artifact then the mantles with few s/c interface gaps must manifest shrinkage elsewhere, at the c/b interface or voids. 'Mould-gaps' at a c/b interface have been described previously (Miller, 1978) but not quantified. The present study analyzed the cross-sectional area of gaps at both interfaces. We *hypothesized* 1) Total gap area was the same for all transverse sections. 2) Satin sections had greater c/b gap areas than grit sections.

METHODS

Transverse sections of 10 Charnley stem/cement/femur constructs from our previous study were processed to highlight gap areas. 5 of the stems had the standard satin finish (Ra 0.75um) and 5 were grit-blasted over their proximal 40mm (Ra 5.3um). Large gaps were filled with black modeling clay and then the sections were coated with matt black spray paint. Sections were then polished using 280 grit emery paper to remove the paint from the surface. This process left all interface gaps and voids filled with black paint, which could be conveniently digitally imaged. Gaps were visually identified and measured using Image-Pro. Gap areas for each transverse section were normalized by the area of cement in that section.

RESULTS AND DISCUSSION

There was no difference in total gap area between surface finishes (Table 1), which supports our first hypothesis. S/c gap areas were significantly greater around grit blasted sections, which was consistent with our previous finding. C/b gap areas were significantly greater around satin finished sections, which supports our second hypothesis.

Table 1: Mean gap fraction for transverse sections grouped by the local surface finish of the stem (% of cement area \pm sd)

	TOTAL	S/C	C/B	Voids
Satin	3.1 \pm 1.4	0.1 \pm 0.4	2.3 \pm 1.3	0.6 \pm 1.0
Grit	3.4 \pm 1.5	1.9 \pm 1.7	1.0 \pm 0.9	0.5 \pm 0.9
	N/S	p<0.0001	p=0.0001	N/S

Identifying gaps at the s/c interface was straightforward, the c/b interface gaps were subjective but there were generally obvious 'mold gaps' between cement and bone (Fig. 1). The dramatic shift in gap location with a change in surface finish is illustrated in Figure 2. The total gap areas were less than the 4.8% shrinkage that is theoretically expected, it is likely that narrow but extensive c/b gaps were missed.

Figure 1: Transverse section of a stem/cement/femur construct showing detail of 'mould-gap' at the cement/bone interface.

Figure 2: Graph of s/c and c/b gaps as a function of axial position for the 'grit' stems. Note that the grit blasting ended at 40mm.

It has been generally assumed that cement shrinkage manifests in a very narrow gap around the whole of the c/b interface. This study has demonstrated that cement shrinkage tends to localize into larger interface gaps. These large gaps must lead to stress concentrations, be they at the s/c or c/b interfaces. C/b gaps are potentially benign as they can fill with bone. However, it is also possible that cement will fail at the points of contact and generate debris which will hinder bone formation.

Cement shrinkage has been overlooked in recent years but is still a cause for concern.

MECHANICAL AND METABOLIC REQUIREMENTS OF LATERAL STABILIZATION IN HUMAN WALKING

J. Maxwell Donelan¹, David W. Shipman² and Arthur D. Kuo³

¹ Centre for Neuroscience, Dept. of Physiology, Univ. of Alberta, Edmonton, mdonlean@ualberta.ca;

² Dept. of Integrative Biology, Univ. of California, Berkeley; ³ Dept. of Mechanical Engineering, Univ. of Michigan, Ann Arbor

INTRODUCTION

Human walking is passively unstable in the lateral direction (Kuo, 1999). Humans appear to actively stabilize lateral motion using medio-lateral foot placement (Bauby & Kuo, 1998). While this stabilization mechanism is effective, it is not without cost—precise control of the swing leg is required and variability in foot placement increases mechanical work (Donelan et al., 2001). Our purpose was to study the mechanical and metabolic requirements of active lateral stabilization in human walking. We hypothesized that external lateral stabilization would reduce the amount of active stabilization required to walk, resulting in less variability of medio-lateral foot placement and a lower metabolic cost.

METHODS

Ten healthy adults (6 male, 4 female) participated in the study after providing informed consent. They walked on a treadmill at 1.25 m/s, both with and without external stabilization (Fig. 1). To control for the effects of average step width, we instructed subjects to walk on a single line marked on the treadmill belt. We chose to enforce zero step width because our device stabilized the body about a trajectory with zero lateral movement. Subjects walked with arms crossed to prevent differences in use of arms to stabilize balance. Subjects practiced the experimental protocol prior to data collection.

The external lateral stabilizer consisted of lightweight elastic cords attached to a padded waist belt pulling in both lateral directions. The relatively long (8 m) cords insured that any non-lateral forces exerted by the apparatus were negligible. The device exhibited an effective spring constant of 1700 N/m and negligible damping (14 N-s/m).

Figure 1.

We developed a mathematical model, based on passive dynamic walking, to characterize the effect of the external stabilizer. The model predicted that the cords were sufficient to passively stabilize the body laterally, suggesting that the subject need not actively adjust medio-lateral foot placement with each step, as is normally necessary. The model therefore predicts lowered medio-lateral foot placement variability, as well as lowered metabolic cost due to the decreased active foot placement.

We measured center of pressure under the feet using a force treadmill (Kram, et al., 1998). We analyzed the first 200 steps after the subject had been walking for 150s. Step width for each step was defined as the lateral distance between consecutive centers of pressure, averaged over the single stance phase.

We calculated variability in step width and length as a function of external stabilization. We also measured net metabolic power using standard methods of indirect calorimetry (Donelan et al., 2001).

RESULTS AND DISCUSSION

When stabilized, variability in step width decreased by 35% while metabolic cost decreased by 6% when compared to unstabilized walking ($p=0.0003$ and 0.025 , respectively). For comparison, step length variability decreased by a smaller amount (14%, $p=0.01$) than step width variability. Mathematical models predict this slight coupling between lateral and fore-aft dynamics. Average step width and length were not affected by stabilization ($p=0.80$ and 0.69 , respectively).

These results support our hypotheses that (a) lateral foot placement is used to actively stabilize walking, (b) external lateral stabilization reduces the need for this active stabilization, and (c) the reduced active stabilization results in slightly lower metabolic demand. Stability and energy consumption are concerns for groups such as amputees and the elderly. Mathematical modeling and empirical testing may lend insight into possible interventions for these groups.

Figure 2. a) Metabolic cost, step width variability and step length variability decreased with stabilization.

KINEMATICS OF 90° RUNNING TURNS IN WILD MICE

Rebecca Walter

Biology Department, University of Utah, Salt Lake City, Utah, USA

walter@biology.utah.edu

INTRODUCTION

Turning is an important component of locomotion on the variable terrain which most terrestrial animals inhabit and a deciding factor in many predator prey interactions. Despite this, the kinematics and mechanics of quadrupedal turns are not well understood. This study describes the kinematics of 90° running turns in wild mice, and compares them to running turns in humans and cockroaches.

METHODS

Six adult wild mice were videotaped from below at 250 Hz as they performed ninety-degree running turns. Five markings placed along the sagittal axis were digitized to allow observation of lateral bending and body rotation throughout the turn. Ground contact periods of the fore and hindlimbs were also noted for each frame. Similar control runs were done along a straight trackway for comparison of maximum velocity and other gait parameters.

RESULTS AND DISCUSSION

During turning, mice increased their ground contact time, but did not change their stride frequency relative to straight running at maximum speed. Compared with humans running along curved trajectories (Greene, 1985), mice maintained relatively higher velocities at proportionately smaller radii (Figure 1a). One possible explanation is that being quadrupedal rather than bipedal may be advantageous for turning. Chang and colleagues (2001) found that humans are limited in their abilities to apply ground forces with the inside leg during turns. In contrast, a bounding quadruped would be simultaneously be applying forces with both inside and outside limbs and thus be less hindered by such a constraint. A second explanation for this difference lies in the more crouched limb posture of mice, which increases the mechanical advantage in horizontal relative to vertical ground force production (Figure 1b).

Figure 1. a) Curve shows the predicted relation between maximum speed over a curve divided by maximum speed

along a straightaway (V/V_0) and dimensionless curve radius (Rg/V_0^2) (Greene, 1985). Filled circles and open triangles show mouse and human data respectively superimposed onto the curve. b) Comparison of the effective mechanical advantage for horizontal versus vertical force production in crouched and upright postures. Effective mechanical advantage equals r/R (Biewener, 1989) and is greater for a crouched posture in horizontal force production.

Postcranial body rotation did not occur in one continuous motion, but rather in bouts of 15-53°. These bouts were synchronized with the stride cycle, with the majority of rotation occurring during the second half of forelimb support and the first half of hindlimb support. In this phase of the stride cycle, the postcranial bodies of the mice were sagittally flexed and rotational inertia was 68% of that during maximal extension. By synchronizing body rotation with the stride cycle, mice can achieve a given angular acceleration with much lower applied torque. Head and neck rotation was smoother and less phasic than that of trunk. This may aid in visual and vestibular orientation.

Figure 2: Percent of total head/neck (open) and body (filled) rotation occurring in each phase of the stride cycle.

Unlike in cockroaches (Jindrich and Full, 1999) postcranial body rotation preceded deflection in heading. The more sprawled limb posture of cockroaches may facilitate application of lateral ground forces, whereas the parasagittal limb posture of mice may favor production of fore-aft ground forces.

DIRECT AUGMENTATION RESTORES THE STRUCTURAL RESPONSE OF FAILED METASTATIC DEFECT VERTEBRAE

Ron N Alaklay¹, Dietrich von Stechow¹, Torres Katherine², Serhan Hassan²

¹Orthopedic Biomechanics laboratory, Beth Israel Deaconess Medical Center, Boston, MA.

²DePuy Acromed, Raynham, MA

INTRODUCTION

The spine is the most common site for skeletal metastasis with approximately 30% of bone metastasis related vertebral fractures requiring surgical intervention due to progressive spinal deformity and neurological compromise. The efficacy of Polymethylmethacrylate cement, advocated for the augmentation of vertebral bodies, in restoring the structural competence of vertebrae having a critical defect via a minimally invasive direct approach, is currently unknown.

METHODS

Twenty thoracic and lumbar vertebrae from three spines, aged 65-78 years, were radiographed to estimate the body posterior and anterior height and their Bone Mineral Density assessed by DXA (Hologic 2000+, Hologic, MA). A high-speed bur was used to create a critical defect involving 50% of the vertebral body and the vertebrae re-radiographed to verify the extent of the defect. A custom testing jig was employed to test the vertebrae to failure using a hydraulic test system (1331, Instron, Canton, MA) under combined compression-flexion at a rate of 5mm/min. Failure was defined as 50% reduction in the vertebra anterior height or a reduction of 10% in maximum load. A 6DOF load cell (MC5, AMTI, MA) was employed to measure the resulted forces and moments and displacement to failure, measured via the material testing system, with the data acquired using LabView (National Instruments, TX) at the rate of 10Hz. The failed vertebrae were allowed to recover for 30 min, the vertebral body heights re-measured and the vertebrae re-tested. A direct approach through the defect in the vertebral body cortical shell was employed to augment the failed vertebrae using 4.0-7.0cc of PMMA (Vertebroplastic, Codman & Shurtleff, Rynham, MA). The augmented vertebra was allowed to rest for two hours, the height of the vertebral body re-measured and the vertebra re-tested to failure. Repeated measure ANOVA was used to test for differences in maximal failure load and stiffness estimated from the linear portion of the load-displacement curve, for each of the forces and moments (JMP, SAS, NC).

RESULTS AND DISCUSSION

For L1 levels of the specimen the mean bone mineral density was measured at $(0.32 \pm 0.10 \text{ g/cm}^2)$. All of the vertebrae tested exhibited an anterior-flexion compressive failure preceded by buckling of the cortical shell. Compared to intact vertebrae, the failed vertebrae showed a highly significant reduction in ultimate compressive load, $1409 \pm 603 \text{ N}$ versus $2246 \pm 897 \text{ N}$,

($P < 0.001$), and a significant reduction in compressive stiffness, $-250 \pm 130 \text{ Nm.mm}^{-1}$ compared to $-382 \pm 194 \text{ Nm.mm}^{-1}$ ($P < 0.05$). Similarly flexion strength and stiffness ($58 \pm 90 \text{ Nm}$ and $9 \pm 10 \text{ Nm.mm}^{-1}$), were significantly reduced, $62 \pm 26 \text{ Nm}$ and $-11 \pm 5 \text{ Nm.mm}^{-1}$, compared to the intact vertebrae $P > 0.05$. Augmentation significantly increased vertebral ultimate compressive load and stiffness to $2606 \pm 813 \text{ N}$, $P < 0.01$, and $-340 \pm 203 \text{ Nm.mm}^{-1}$ respectively. Similarly, flexion strength, $66 \pm 26 \text{ Nm}$, and stiffness, $10 \pm 4 \text{ Nm.mm}^{-1}$, showed a significant increase compared to that of the failed vertebrae. However, compared to the intact vertebrae, these increases were not significant. The remaining loads and moments remained relatively constant throughout the test.

This study investigated the ability of PMMA cement augmentation to restore the structural competence of failed vertebrae having a simulated critical metastatic defect under anterior flexion-compression load. The model was successful in producing both clinically relevant defects and a repeatable combined flexion-compression fracture pattern. Compared to the intact vertebrae, the failed vertebrae exhibited a highly significant reduction in structural load carrying ability, particularly in the plane of loading. The load displacement curves, although revealing vertebral loads to exist mainly in the plane of loading, showed out of plane loads to develop on the vertebral body during the failure process. These responses combined with the complex pattern of vertebral body collapse may suggest the response to be dependent on the extent of the defect. Vertebral augmentation using PMMA was highly effective in restoring the overall mechanical competence of the vertebrae with the PMMA, in effect, masking the load response of the vertebrae. This procedure thus holds promise as an alternative for full resection of the vertebral body. Further research is needed to quantify the possible effect of the significant changes in vertebral body structural response on adjacent vertebrae and to develop predictive methods to assess its applicability.

SUMMARY

The effect of a critical (50%) metastatic defect and consequent cement augmentation on the structural response of failed vertebrae was investigated. The metastatic defect vertebrae showed a both a significant reduction in structural competence and a complex load-deformation response under combined compression-flexion loads. Augmentation was highly effective in restoring the structural competence of the failed metastatic vertebrae.

INFLUENCE OF LOADING AND LOCAL DENSITY ON BONE FRACTURE TOUGHNESS PARAMETERS

Christina L. Beardsley¹, Helen G. Fuller¹, Yasser M. Dahab¹, and Thomas D. Brown^{2,1}

Departments of ¹Biomedical Engineering and ²Orthopaedic Surgery, University of Iowa, Iowa City, IA, USA

email: tom-brown@uiowa.edu, web: <http://poppy.obrl.uiowa.edu/>

INTRODUCTION

Fracture mechanics has been applied to scrutinize bone failure processes, but primarily for quasi-static loading. Dynamic fracture behavior of bone is less well understood, especially since fracture toughness (K_{Ic}) is very sensitive to loading rate. However, another fracture toughness parameter, the critical strain energy release rate (G_c), is reportedly relatively rate-independent in other viscoelastic materials (Williams, 2001). We hypothesized that, in cortical bone, dynamic G_c is less than one order of magnitude higher than quasi-static G_c , and that, furthermore, the surface produced per joule absorbed in impact tests would correlate strongly with quasi-static G_c . For brittle solids such as bone, fracture toughness parameters depend on relative material density. Various researchers have invoked power law relationships to regress fracture toughness from physical density (Gibson, 1988); we incorporated these as well.

METHODS

Segments measuring 80-mm were harvested from the mid-diaphyses of fresh frozen bovine tibiae (Fig. 1). These were subjected to a drop tower test with an impact velocity of 5.5 m/s. Helical CT data were collected from both intact specimens and fracture fragments. Using digital image analysis, the area of *de novo* fracture surface was extracted from each fractured specimen for G_c computation. The number of square millimeters of surface realized per absorbed joule was computed, and then multiplied by the normalized average Hounsfield density (H^*) of the fractured specimen raised to the 1.5 power.

The H^* was measured in the proximal-most 5mm of the intact segments. With this data, the dependence of the quasi-static G_c on Hounsfield density was explored. Bone in the region immediately superior to the proximal end of the impact segment was milled into three thin, ring-like (Fig. 1) specimens (one 4.5 ID/20.0 mm OD, two 1.5 ID/5.0 mm OD). Quasi-static fracture mechanics testing was conducted with a Bionix 858 servohydraulic load frame. Following pre-cycling to determine tangential and longitudinal moduli, rings were then loaded to failure in diametral compression at a rate of 0.02 cm/min. G_c was computed from the loading curves using an established protocol (Beardsley, 2002).

RESULTS AND DISCUSSION

Pre-fracture Hounsfield density, raised to the 1.5 power as suggested by Gibson (1988), was directly proportional to quasi-static G_c ($R^2 > 0.99$) (Fig. 2).

The average G_c computed from the impact test was 4406 N/m, as compared to 939.7 N/m for the quasi-static test. The pairing between quasi-static and (Hounsfield-normalized) dynamic tests showed reasonable correlation ($r=0.57$). In drop tower testing, fragment free surface energy resulting from an impaction event correlates strongly with absorbed kinetic energy, but demonstrates appreciable variability. The present data demonstrate that a substantial fraction of that variability is attributable to the variability of bone fracture toughness, which can be precisely accounted for in terms of Hounsfield number.

Figure 1: Specimen geometry used for (l) impact and (r) quasi-static fracture toughness testing (not to scale).

Figure 2. G_c was closely linked to a power of H^* ($n=12$).

INTRODUCTION

Vertebral damage occurs when the loads applied exceed the vertebral structural capacity (force at failure). Characterization of trabecular bone tissue stresses and strains is important in understanding basic skeletal mechanics, fracture risk, damage, and fracture repair. More explicit mechanical stress-strain behavior is obtained using numerical techniques such as the finite element analysis (FEA) method. The objective of this study was to develop a structural FEA model that could be used to simulate various levels of structural damage, and show the effects of various polymethylmethacrylate (PMMA) volumes on the apparent stiffness of vertebral bodies during repair (vertebroplasty).

METHODS

A two-dimensional (2D) osteopenic FEA model was developed from sagittal μ CT scan images (83 μ m/element resolution) of a T10 vertebral segment. This model was coupled with a modulus reduction algorithm derived from perfect plasticity theory [Betten, 1989]. Trabecular bone, intervertebral disc, and bone marrow tissues, are assumed to be isotropic, linear elastic materials with elastic modulus values of 10 GPa, 2.16 MPa, and 10 kPa, respectively. A Poisson's value of 0.3 is assumed and the 299 x 235 (70,265 elements) model having 4-node isoparametric elements is loaded using a uniform compressive load ranging from 50-500 N in 50 N increments. After each increment of load, the element stresses and strains were used to determine the modulus reduction (if any) for each bone element. This model was used to simulate vertebroplasty studying the effects of 6 cement ($E = 2.16$ GPa) volumes on apparent stiffness, and tissue stress intensity for 2 vertebral damage levels (18.7% and 91% reduction in apparent modulus).

RESULTS AND DISCUSSION

The model resulted in a non-linear stress-strain curve with a yield stress of 4.5 MPa and yield strain of 0.41%. The yield stress corresponded closely with experimental estimates of the intact strength of human lumbar vertebra [Hansson, 1977]. Trabecular bone tissue stress intensity (element stress/apparent stress) ranged from -5 to 26 for the undamaged vertebral segment. Replacement of all the bone marrow elements with PMMA cement elements ($A_f = 0.35$) resulted in an increase of apparent modulus for both damage levels (18.7% and 91%) that were well beyond the undamaged vertebral body apparent modulus (Figure 1). The 18.7% damage model reached the undamaged modulus using only a 0.25 A_f of PMMA whereas

the 91% damage model required the vertebral body to be completely filled with cement (0.35 A_f).

Figure 1. Change in apparent modulus with increasing PMMA following vertebroplasty for 2 damage models.

A reduction in highly stressed elements (stress intensity > 3) was found for both damage models over the range of cement A_f examined (Figure 2). The PMMA filled 18.7% damage model resulted in only 1% of the total elements having a stress intensity greater than 3 compared to a 2.7% of total elements for the 91% PMMA filled damage model.

Figure 2. Stress intensity variations of the 2 damage models with increasing PMMA.

SUMMARY

In summary, the non-linear stress-strain behavior of an anatomically accurate 2D structural FEA model results reproduced experimental findings of damage in intact vertebra, and corroborates recent experimental and numerical simulations of vertebroplasty.

THE EFFECT OF BRACING ON PATELLOFEMORAL JOINT STRESS DURING FREE AND FAST WALKING

Yu-jen Chen¹, Samuel R. Ward¹, Li-der Chan¹, Michael S. Terk², Christopher M. Powers^{1,2}

¹Musculoskeletal Biomechanics Research Laboratory, University of Southern Calif., Los Angeles, CA. yujensch@usc.edu

²LAC/USC Imaging Science Center, Dept. of Radiology, Keck School of Medicine, University of Southern Calif., Los Angeles, CA.

INTRODUCTION

The etiology of patellofemoral pain (PFP) is not entirely clear, however, the most accepted hypothesis is related to abnormal patellar tracking, which increases patellofemoral stress and subsequent cartilage wear. Patellar bracing is commonly used in the conservative management of PFP. Although, it has been suggested that bracing reduces patellofemoral stress, this hypothesis has not been tested. The purpose of this study was to quantify the effects of bracing on patellofemoral stress in persons with PFP during free and fast walking.

METHODS

Ten subjects with a diagnosis of PFP took part in this study (mean age 30.6 ± 6.8 , height 163.6 ± 5.1 cm, weight 56.0 ± 5.0 kg). Subjects were included if they reported at least 50% pain reduction following application of an elastic sleeve brace (Don Joy Inc.). Initially, individualized patellofemoral contact area was obtained at 0, 20, 40 and 60 degrees of knee flexion using a previously described MRI method (Ward et al., 2001). Lower extremity kinematics (Vicon[®] motion analysis system) and kinetics (AMTI forceplates) were then obtained as subjects walked at self-selected free and fast walking velocities over a 10-meter walkway. Three trials were obtained under each gait condition. MRI and gait assessment was repeated following the application of the brace. Patellofemoral joint contact area, knee joint angle and the knee extensor moment were used as input variables into a previously described biomechanical model of the patellofemoral joint (Salem G.J., 2001), which was used to derive patellofemoral joint reaction force and stress. Data from the three trials were averaged for analysis. To compare peak patellofemoral joint reaction force, average utilized contact area, and peak stress between brace conditions, separate two-way ANOVA's with repeated measures (brace condition x walking speed) were used.

RESULTS AND DISCUSSION

Compared to the no-brace trials, peak PFJRF was greater in braced condition during both free gait (8.9 ± 5.5 vs. 7.2 ± 4.0 N/kg, $p=0.048$) and fast gait (13.3 ± 6.2 vs. 10.8 ± 4.8 N/kg, $p=0.023$). There was a significant decrease in peak PFJ stress in braced condition during fast gait (2.7 ± 0.9 vs. 3.4 ± 1.0 N/mm², $p=0.011$), however there was only a trend towards significance during the free gait condition ($p=0.10$). The utilized contact area was significantly greater with the brace compared to non-braced condition during both free (251.5 ± 114.4 vs. 171.0 ± 47.1 mm², $p=0.046$) and fast walking speeds (277.9 ± 104.5 vs. 173.2 ± 54.0 mm², $p=0.003$).

SUMMARY

Following the application of an elastic sleeve patellofemoral brace, subjects reported a 53% decrease in pain. This decrease in pain was accompanied by a 20% decrease in peak patellofemoral stress during fast walking. Decreases in peak stress were the result of increased contact area as patellofemoral joint reaction forces were significantly greater under the braced conditions. These results suggest that the mechanism by which bracing influences symptoms may be related to changes in joint stress.

A COMPARISON OF ISOKINETIC STRENGTH BETWEEN SINGLE- AND MULTI-KNEE FLEXION AXIS TOTAL KNEE ARTHROPLASTY LIMBS

Kathy Simpson (ksimpson@coe.uga.edu)

University of Georgia, Department of Exercise Science, 300 River Road, Athens, GA, USA, 30602

INTRODUCTION

As many individuals who have undergone a total knee arthroplasty (TKA) had painful, compromised physical function prior to the arthroplasty, older individuals, in particular, may have less than desired quadriceps strength and/or balance. Therefore, TKA designs should provide optimal knee functioning and stability.

Some TKA patients complain of AB/ADD knee instability that occurs during the midrange of knee flexion (KF) or extension (KE) while performing daily (personal observation, O.M.M.). Most TKA designs have multiple KF/KE axes (M-AX), thus also have varying lengths of radii of rotation (ROR) that likely influence collateral ligament tension at different knee angles.

If a TKA design only has a single KF/KE axis (S-AX) and ROR, then less co-contraction muscular activity should be required to maintain frontal plane stability compared to a M-AX design. In addition, for the S-AX (Scorpio) compared to an M-AX design (Osteonics 7000®), the S-AX TKA axis is located such that its quadriceps patellar ligament moment arm is surmised to be longer, according to the manufacturer of both implants (Stryker-Howmedica-Osteonics, Inc., personal communication). Therefore, all else equal, a limb with an S-AX implant should be able to generate greater knee extensor moment than an M-AX limb.

METHOD

Bilateral implant participants (n = 9; $\bar{X} \pm \text{SD}$: age = 73.0 ± 9.1 yr; mass = 88.13 ± 0.80 kg; min. time since last TKA = 60.4 ± 33.0 mo.) who had both arthroplasties performed by the same surgeon were recruited and medically screened. KS SF-12 scores (Insoll, et al., 1989) and morphological data, including KF ROM were obtained. Participants practiced performing the isokinetic tests during two accommodation sessions. During the actual isokinetic strength tests, EMG signals also were obtained ($1080 \text{ samples} \cdot \text{s}^{-1}$) for rectus femoris, vastus medialis and lateralis, biceps femoris and semi-tendinosis. For concentric EMG, values were scaled to isometric MVC; for eccentric co-contraction data, values were scaled relative to the maximum eccentric strength values for the same knee angles (Snow, et al., 1995). Root-mean square RMS EMG data (window size equivalent to 6.6 Hz cut-off frequency) were generated. Then the RMS EMG values were averaged for each knee angle interval of 15° between 15° and 75° knee flexion angle. RM MANOVAs ($p < 0.05$) were used for the strength (LIMB) and EMG data (LIMB x KNEE ANGLE INTERVAL).

RESULTS AND DISCUSSION

As shown in Table 1, compared to the M-AX limbs, the S-AX limbs demonstrated greater ($p < 0.05$) concentric KE peak moment and total work with similar KE RMS EMG and less concomitant KF co-contraction EMG during the $15^\circ - 29^\circ$ knee angle interval. No differences were detected for hamstrings: quadriceps ratio (0.48 and 0.55, respectively) or the angle that peak KF or KE moment occurred.

As anticipated, the S-AX versus the M-AX limbs produced greater quadriceps moment and work, but displayed similar REMG, suggesting that the S-AX's longer moment arm may have influenced the knee extensor moment. The biceps femoris activation displayed by the M-AX limbs increased for the KF angle interval of 15° to 29° during the KF concentric test. This may be due to the shift from the longer ROR to one that is more infero-posterior. Consequently, the new ROR has a reduced KF moment arm and/or creates knee instability that is compensated by increasing the BF activation.

Table 1. Means and Standard Deviations (SD) of Strength Variables.

	Peak Moment (Nm)		Angle to Peak Moment (deg)		Total Work (J)	
Limb	Mean	SD	Mean	SD	Mean	SD
Knee Extensors						
S-AX	103.15	44.14	66	3	98.2	39.2
M-AX	88.44	37.30	64	4	89.1	34.3
Knee Flexors						
S-AX	51.18	27.81	31	12	58.0	27.4
M-AX	48.33	24.42	35	16	46.4	22.5

SLIP ANTICIPATION EFFECTS ON GROUND REACTION FORCES

Brian Moyer¹, Rakié Cham¹, and Mark S. Redfern^{1,2}

¹Department of Bioengineering and ²Department of Otolaryngology
University of Pittsburgh, Pittsburgh, PA, USA

INTRODUCTION

Accidental injuries and deaths are often the result of slips/falls. Researchers have used laboratory gait analysis tools both to characterize potential slip risk (Grönqvist et al., 2002) and to gain insight into the relationships between people and their environment. One of the many assumptions that such laboratory analysis requires is that when subjects do slip in the lab, their gait is not sufficiently altered from their normal walking style up to the point of the slip nor for subsequent trials after that slip. The goal of this paper is to investigate anticipatory effects that an initial laboratory induced slip may have on subject gait parameters for subsequent trials. In other words, once subjects experience an induced slip, do they change the way that they walk, even when instructed to walk normally for all trials?

METHODS

Five healthy male subjects, aged 35 years or less, were screened for neurological, vestibular and orthopedic abnormalities prior to their recruitment in the study. Subjects were equipped with a safety harness and motion measurement LEDs, and instructed to walk naturally across a vinyl tile walkway instrumented with two Bertec force plates (FP) in a laboratory with dimmed lights. Ground reaction forces and whole body motion (2 Optotrak-3020 motion measurement systems) were recorded bilaterally at 60 Hz for all trials. After several practice trials to ensure that subjects were walking comfortably, subjects were informed that the first few trials would be non-slippery to ensure natural gait. Then, while the subject still expected dry trials, a soap solution was applied to the left (second foot) FP without the subject's knowledge. After the resulting, unanticipated slippery trial, the soap contaminant was removed from the floor, subjects were given fresh shoes and were told that any of the subsequent trials could be slippery. Several additional dry trials were then conducted for comparison. Data processing included the derivation of foot kinematics (linear/angular position, velocity and acceleration), whole body joint angles, joint moments, and several ground reaction force related measures. Ground reaction force related measures are reported here.

Ground reaction force data were normalized to subject body weight and with respect to foot contact time from heel-strike (HS) to toe-off (TO). For both the lead foot (right) and the slip foot (left) parameters were calculated for trials before and after the first slip, including: 1) the loading rate, i.e. the slope of the normal force from heel strike (HS) to the peak normal force, 2) the magnitude of the highest peak after heel strike, and 3) the peak of the ratio of shear/normal forces. In addition, double support time, contact time and differences between the two feet were investigated.

RESULTS AND DISCUSSION

T-test analyses indicated significant differences ($p < 0.05$) for parameters measured before and after the first slip. The amount of time spent in double support increased by 1.5% and the left foot had a higher peak shear/normal ratio than the right foot after the initial slip. In addition, the slip-foot (left) total contact time decreased by about 5% and the difference between lead foot and slip foot peak normal force magnitude increased by 6.8%. Although anticipated, results did not indicate significant differences for the loading rates of normal force pre- to post- slip.

SUMMARY

Based on this pilot study, slip anticipation affects subsequent gait, even though subjects attempt to walk naturally and do not know that a contaminant is placed on the floor. The subjects in this study did change their gait in anticipation of future slips once they had experienced an initial slip. This conclusion should influence data collection protocols where multiple coerced slips are expected and should shape conclusions regarding required coefficient of friction specifications based on subjective measures. As most slips leading to injuries are likely unanticipated, measurements of gait parameters that do not take slip anticipation effects into consideration may underestimate genuine slip risks.

FACTORS THAT CONTRIBUTE TO PEAK KNEE FLEXION IN NORMAL SWING: IMPLICATIONS FOR STIFF-KNEE GAIT

Saryn R. Goldberg^{1,2}, Frank C. Anderson¹, Marcus G. Pandy³, and Scott L. Delp¹

¹Department of Mechanical Engineering, Stanford University, Stanford, California, USA, ²saryn@stanford.edu

INTRODUCTION

Swing-phase knee flexion is necessary to achieve the toe-clearance required for limb advancement. In stiff-knee gait, a movement abnormality observed in persons with cerebral palsy, knee flexion during swing is diminished. This is commonly attributed to abnormal swing-phase quadriceps muscle activity. However, treatments aimed at altering the function of this muscle group only benefit some patients. Outcomes may be variable because other factors, such as low knee flexion velocity at toe-off or weak hip flexors, may limit knee flexion in some patients. To understand the relative importance of factors that could contribute to stiff-knee gait, we used a new methodology, an induced-position analysis, to quantify the contributions of individual muscles and knee flexion velocity at toe-off to peak knee flexion during the swing phase of normal gait.

METHODS

Induced accelerations describe the contribution of each force component in the equations of motion to the angular accelerations of the joints in a system (Zajac and Gordon, 1989). These components typically include forces due to muscles, gravity, Coriolis, and centripetal effects. Double integration of the induced accelerations over time yields induced positions, which quantify how accelerations due to each force component contribute to the change in position of the joint of interest during the integration time period.

Muscle forces and model kinematics for our analysis were based on the dynamic optimization solution for normal gait computed by Anderson and Pandy (2001). The induced accelerations were computed by assuming rigid contact with the ground (Anderson and Pandy, *in review*). We calculated the induced knee flexion angle from the time of toe-off to the time of peak knee flexion in swing due to each force component in the equations of motion, including all 54 muscles represented in the model. The change in knee angle due to the knee flexion velocity at toe-off was found by integrating this constant over time. The largest contributors to peak knee flexion were those factors that induced the largest change in knee angle during the time of interest.

RESULTS AND DISCUSSION

Because superposition holds for this analysis, the simulated knee kinematics can be reconstructed by summing the induced knee angle due to each factor (Fig. 1). Changes in the knee flexion angle due to gravity, Coriolis, and centripetal forces were small compared to the changes due to the initial knee

flexion velocity and actuators (muscles and ligaments). The initial knee flexion velocity of the swing limb ($375^\circ/\text{s}$) was the largest contributor to the peak knee flexion angle; its effect was more than double the net effect of all the actuators combined. The largest contributions to peak knee flexion made by swing-limb muscles were from the active forces in iliopsoas and the ankle dorsiflexors and from the passive forces in vasti (Fig. 2). The stance-limb gluteal muscles also made large contributions to peak knee flexion (Fig. 2).

Figure 1: Induced knee angle up to time of peak knee flexion.

Figure 2: Largest contributors to peak knee flexion in swing.

CONCLUSIONS

These results suggest that the muscle activity that gives rise to swing-phase initial conditions may be more important than the muscle activity that occurs after toe-off in determining peak knee flexion in normal swing. This supports the possibility that low knee flexion velocity at toe-off contributes to stiff-knee gait in some patients.

COMPARING MOVEMENTS ACROSS THREE VISUAL CONDITIONS IN A STEP AND REACH TASK

Jan M. Hondzinski, Ph.D.,

Louisiana State University, Baton Rouge, Louisiana, USA, Email: jhondz1@lsu.edu

INTRODUCTION

The effect of vision in movement control is not well understood. There is evidence to suggest that reaching errors are biased toward step and gaze directions when stepping and reaching to remembered targets (Flanders et al., 1999; Medendorp et al., 1999). This study was designed to gain a better understanding of the role of vision in whole body movement control. Thus, the purpose was to examine the relationship between final reach position and variables associated with gaze and step direction in a whole body reaching task requiring a step.

METHODS

Six healthy subjects were asked to step and reach to 9 targets. Figure 1 shows 3 target location heights approximating the shoulder, hip and knee joints (45 cm, 90 cm and 147 cm). At each height targets were located in 3 positions: central; 30 degrees right; and 20 degrees left. Radial target distance was 95 cm from the trunk. During reaches markers on head and body segments were monitored (60 Hz) using a passive marker video system (Motion Analyses Co.).

Figure 1: Experimental setup. Target location is shown from a lateral view with the subject in start position.

Reaches occurred under three visual conditions: NORMAL, where there are no alterations in the visual field and subjects gaze at the target; VIRTUAL, where the target location is remembered and subjects gaze at the remembered target position; and GAZE where an eccentric target location is noted in the subject's peripheral visual field, while gaze position is anchored elsewhere (see *gaze target*, Fig. 1).

Lateral, vertical and anterior/posterior (a/p) reaching errors (relative to an imaginary horizontal line through the midpoint between subjects toes at start and target positions) were computed. In addition, step length (length), horizontal step angle (angle) and horizontal and sagittal plane head angles (horz and sag, respectively) were calculated as movement variables. Five trials were used to compare changes in a given variable across the visual conditions and target locations for each subject using a repeated measures ANOVA (Tukey HSD post-hoc).

RESULTS AND DISCUSSION

The analyses revealed that reaching errors varied across visual conditions and target locations ($p < 0.05$). The reaching

error type (lateral, vertical or A/P) was different across subjects. For example, in some subjects there was a difference found between lateral errors for the VIRTUAL and NORMAL conditions, whereas others had different vertical errors. To better understand the role of gaze and step direction contributions for whole body reaches, differences in reaching errors across visual conditions were matched to movement variables. Cases where no match was found for the given variables were identified as *none*. Each number in the table represents the number of matches identified for the given error and variable for the visual conditions. These numbers were highest (see bold, high-lighted box in Table 1) for reach error and horz, sag or none matches. Although the eyes and head are not required to move together, it is well known that head and eye movements are coupled to some degree. Thus, these data provide some evidence to suggest that people rely more heavily on gaze than step direction when reaching to targets, which require a step.

Table 1: Number of Significant Comparisons

Lateral Reach Error	length	angle	horz	sag	none	Total
NORMAL/VIRTUAL	0	0	3	1	3	6
VIRTUAL/GAZE	1	8	16	13	1	17
NORMAL/GAZE	3	7	15	13	0	15
Vertical Reach Error	length	angle	horz	sag	none	Total
NORMAL/VIRTUAL	1	0	2	4	7	11
VIRTUAL/GAZE	0	6	7	9	3	13
NORMAL/GAZE	4	10	15	21	0	22
A/P Reach Error	length	angle	horz	sag	none	Total
NORMAL/VIRTUAL	2	0	4	6	7	15
VIRTUAL/GAZE	1	4	9	7	0	10
NORMAL/GAZE	5	5	10	14	1	17

SUMMARY

Subjects were asked to step and reach to targets in three visual conditions. There were a greater number of matched changes across reaching errors and head directional variables than for reaching errors and step direction variables. It is suggested that gaze direction has a greater influence than step direction when stepping and reaching to a target.

SIMULATION OF SCLERAL BUCKLING OPERATION ON AN EYEBALL BY USING FEM PROGRAM FOR COUPLING ANALYSIS OF HYPERELASTIC SOLID AND STATIC LIQUID

Zhi-Gang Sun¹, Akitake Makinouchi² and Hiroo Yabe³

The Institute of Physical and Chemical Research, 2-1, Hirosawa, Wako-shi, Saitama 351-0198, Japan

¹Advanced Computer Center, zgsun@postmann.riken.go.jp, ²Integrated V-CAD System

Toho University School of Medicine, 2-17-6, Ohashi, Meguro-Ku, Tokyo 153-8513, Japan

³2nd Department of Ophthalmology

INTRODUCTION

Scleral buckling operation is frequently performed in clinic to treat the eyeball retinal detachment. However, the effect of the operation heavily depends on surgical experiences and it is usually difficult to obtain a desired operation effect. So the computer-added operation planning is at present greatly desired. Biomechanical simulation is a useful means to provide information for this purpose. In this study, the segmental buckling operations under different conditions were numerically simulated by employing a 2-D FEM program to qualitatively investigate the influence of factors such as buckle shape, suture width and intraocular pressure on the operation.

METHODS

To enable the simulation of the scleral buckling operation on an eyeball, a 2-D FEM program for coupling analysis of hyperelastic solid and static liquid in which the functions of the contact treatment and suture treatment are implemented was developed based on an incompressible hyperelastic program¹ which has been developed by the authors.

Total four cases of simulations were performed under the different buckle shapes, suture widths and intraocular pressures as shown in Table 1. The analysis model is shown in Fig.1. The neo-Hooke hyperelastic material model, in which the stored energy function is expressed as $W = c(I_1 - 3)$, was used for all the soft tissues except zinn's zonules, and the material constants are given in Table 2. The bulk modulus of 2083.3MPa was used for the liquid tissues.

As shown in Fig.2, the simulations were performed in two steps: in the first step, pressure was applied to the eyeball internal surface as a pressure boundary condition to generate its initial intraocular pressure; in the second step, a coupling analysis was performed to simulate the suture process.

Fig.1 Analysis model for segmental buckling operation.

RESULTS AND DISCUSSION

The simulation results are shown in Fig.3. These results demonstrate that the ellipse-like buckle shape, wider suture width and lower intraocular pressure produce higher scleral buckling effects and the ellipse-like buckle shapes give relatively uniform stress distributions in the buckling sections compared to the

Table 1: Material constants for the soft tissues

	cornea-1	sclera-2	choroids-3	retina-4	optic nerve-5	lens-6
c	0.0333	0.0833	0.0083	0.0008	0.0083	16.67

Table 2: Buckling conditions in each analysis case

	buckle shape	suture width	Intraocular pressure
Case1	quadrilateral-like	8.8mm	3.75 mmHg
case2	ellipse-like	8.8mm	3.75 mmHg
case3	quadrilateral-like	8.8mm	1.50 mmHg
case4	ellipse-like	6.4mm	3.75 mmHg

quadrilateral-like ones. This implies that different factors would result in different operation effects, and therefore it is important to adopt suitable factors for getting the desired operation effect in the clinic. Through these results, some useful conclusions could be made. For example, in the case that an inexperienced surgery want to avoid an unexpected high buckling effect which is due to an overly strong buckling, a buckle shape with a flat bottom would be preferred, as well as a buckle shape with curved bottom can be expected to avoid the so-called fish mouth opening phenomenon that is considered to be caused by the nonuniform stress distribution of the retina in the buckling section.

SUMMARY

In this study, some useful results were obtained. It is expected that desired buckling effect would be available in the clinical operation with the aid of these results.

BONE MORPHOLOGY CHANGES IN DDH HIPS

Douglas R Pedersen, Heather Ralston, Colleen A Lamb, Stuart L Weinstein
Orthopaedic Biomechanics Laboratory, University of Iowa, Iowa City, Iowa, United States of America
poppy.obrl.uiowa.edu

INTRODUCTION

Developmental dysplasia of the hip (DDH) is a disease that leads to osteoarthritis much earlier than the population norm. After treatment, pelvis-centered anteroposterior radiographs are used to follow the progression of spherical femoral head growth and acetabular coverage that will provide natural ball-and-socket function of the hip. A group of patients with DDH, who have been treated conservatively since early infancy, are now in their fifth decade of radiographic and clinical follow-up. This combination of conservative treatment and long-term follow-up of patients afflicted with unilateral DDH constitute a unique resource to quantify the natural history of bone growth in hips with DDH. Digital methods were used to quantify radiographic changes in bone morphology, over a ten-year period, and between affected and unaffected hips.

METHODS

The thirty and forty-year follow-ups of forty-six patients with unilateral DDH are the source of clinical and radiographic data. In a recent study, a program was shown to objectively and reliably quantify hip morphology measurements on standard antero-posterior (AP) pelvic radiographs. [Lamb, 2002] The measured variables include: Sharp's angle, the center-edge of Wilberg; the articulo-trochanteric distance; the acetabular depth, width and quotient; the percentage coverage of the femoral head; the femoral head-to-head ratio; and the tear drop width. Ninety-two clinical radiographs were scanned at 300 dots per inch and 8-bit (256) gray scale. A digitizing program (written in PV-WAVE Version 6.1, Visual Numerics Inc.) prompted the user to mouse-select 32 points on each digital image. A line through the distal teardrops defined the horizontal axis of the pelvis. Trigonometric and algebraic algorithms were used to exactly mimic the defined measurements of the variables by hand on clinical films.

RESULTS AND DISCUSSION

The average of 46 measured values (± 1 Standard Deviation) of eight bone morphology variables are shown for both the DDH diagnosed hips and the unaffected hips at their 30-year and 40-year follow-ups (Figure 1). The DDH hips had a greater Sharp's angle than their asymptomatic contralateral hips. This is consistent with a more vertically inclined acetabular opening in dysplastic hips. The acetabulum in dysplastic hips is also wider and not as deep as in the non-affected hips. These abnormal acetabular features combine to cover only 70% of the femoral head, on average. This is an appreciable reduction from the average 85% femoral head coverage in non-affected hips. Another notable characteristic of dysplastic hips is the reduced vertical distance (ATD) from the top of the greater trochanter to the lateral margin of the articular surface. All bone morphology parameters were more consistent (smaller S.D.) for the non-affected hips than for the more irregular dysplastic hips.

Figure 1 Digitized measurements (°, %, mm) on 30-year and 40-year films of 46 unilateral DDH patients

The non-affected hips showed almost no change during the decade between the 30 and 40-year follow-ups. Morphologic measures of the dysplastic hips quantified the erosion of the acetabulum over time (greater width, decreased depth). Combined with supero-lateral migration of the femoral head, one dysplastic hip had center-edge angle change of -35° over the 10 years between follow-ups (Figure 2).

Figure 1 Radiographs of the hip at 30-year (left) and 40-year (right) follow-ups.

SUMMARY

This study demonstrates that there are measurable differences between asymptomatic hips and hips that are afflicted with DDH. Asymptomatic hips showed little change over time. However, for DDH affected hips, some measurements displayed substantial differences a decade later.

DYNAMIC LATERAL ARTICULATION OF THE RIGID TRUNK PRODUCES FOOT CLEARANCE IN MLKAFO GAIT

T. Adam Thrasher¹ and Brian J. Andrews²

¹ University of Alberta, Department of Biomedical Engineering, Edmonton, Canada

² University of Reading, Department of Cybernetics, U.K.

INTRODUCTION

Having no components above the waist, the medially linked knee-ankle-foot orthosis (MLKAFO) [1] allows for a unique form of gait involving unconstrained movements of the trunk. The objective of this study was to assess the feasibility of a method of lifting the feet during paraplegic gait by laterally articulating the upper body, a process that has been demonstrated in some anthropometric robots [2].

METHODS

This study consisted of human experiments and computer simulations. MLKAFO braces were custom fitted to each of three human subjects: one paraplegic with a complete spinal cord lesion at T12, and two able-bodied subjects (all adult males). While standing in the braces with knees locked in full extension, the subjects were asked to alternately lift their feet by flexing their trunks laterally. They were also asked to walk. Motion was recorded using a 4-camera Vicon 140 motion analysis system. The rocking motion was also simulated using a two-segment, two degree-of-freedom rigid body model consisting of an upper body segment and a lower body segment connected via the lumbosacral joint, which was treated as a simple pin joint spanned by abdominal oblique muscles on either side. Periodic activation signals were applied to the muscles to produce the rocking motion.

RESULTS AND DISCUSSION

The paraplegic subject was able to perform the rocking motion with and without handrails, but he could not walk. A typical trial is shown in Figure 1. The able bodied subjects performed the rocking with ease and were able to walk at speeds of 0.19 to 0.73 m/s. Two different modes of rocking were observed. In "Mode I," the upper and lower bodies rotate in opposite directions, while in "Mode II," they rotate in the same direction (relative to the frontal plane). The paraplegic subject used Mode I when using handrails and Mode II when not. The able-bodied subjects used mode I in all of the rocking trials, and in 80% of the walking trials.

The computer model was able to produce successful rocking

cycles in both rocking modes. A stability criterion was found: the effective stiffness of the lumbosacral joint must be greater than approximately 120 Nm/rad.

Figure 1: Paraplegic subject rocking while holding handrails (mode I). By convention, (+)ve trunk flexion is to the left. Grey rectangles indicate periods when a foot is raised: above zero indicates left foot, below zero indicates the right.

SUMMARY

This study serves as a basis for stiff-legged MLKAFO gait involving dynamic lateral trunk articulation. We demonstrated that a rocking strategy is capable of producing lower body movements that alternately lift the feet, however some additional assistance is required for paraplegic gait.

FINITE ELEMENT ANALYSIS OF MEDIAN NERVE INSULT IN THE CARPAL TUNNEL

Christopher P. Petrie¹, Thomas D. Brown^{1,2}, Curtis M. Steyers²

Departments of Biomedical Engineering¹ and Orthopaedic Surgery², University of Iowa, Iowa City, Iowa, United States

INTRODUCTION

Despite its prevalence (over 600,000 new cases each year (Tanaka 1998)) and multi-billion dollar annual societal costs, Carpal Tunnel Syndrome (CTS) has received disproportionately little attention from the biomechanics research community. To date, for example, there have been no finite element (FE) analyses of the biomechanical interactions that likely lead to the development of CTS. Biomechanical research on CTS has been mostly limited to measuring 'pressure' in the tunnel. The data reported have varied widely both within and between studies (Rempel 1994, Seradge 1995). This may be due to experimental limitations or variable interpretation of terminology, or both.

METHODS

Our approach is to utilize an FE model of the wrist, including the interstitial fluid space, to conduct parametric studies of median nerve insult as a result of varying load conditions. A plane strain model currently is serving as a proof-of-concept, and as a stepping-stone on which to base the full 3-D model.

Figure 1: a) Transverse slice through wrist, b) Image in 1a with all tunnel contents and tunnel boundary sectioned, c) FE mesh of sectioned areas from 1b (includes solid and fluid mesh), d) 3-D surface model (cutaway view) of tunnel and its contents (FDS-L, FDS-R, FDS-S removed for clarity.)

The geometry for the FE model is derived from segmented high-resolution images of serial sections of a fresh-frozen

cadaver. The sections are resampled into a voxel set with a voxel size of 0.247 x 0.247 x 0.247 mm. The images are segmented manually, and the segmentation data are run through a custom program that outputs the FE geometry definitions. These data are brought into ADINA v7.5 (an FE program with fluid-solid interaction capabilities), and the geometry is meshed appropriately. Figure 1a-c shows the sequence of moving from a single slice to solid/fluid mesh. Figure 1d shows a full 3-D surface model (cutaway view) of the carpal tunnel and its contents. Experimental work is ongoing concurrently, to improve on limited material property data currently existing for the flexor tendons, median nerve and the transverse carpal ligament.

RESULTS AND DISCUSSION

Figure 2 shows the computed stress distributions in the median nerve during a simulated keystroke maneuver. The dilatational stress, a reflection of the tendency

Nerve Insult During Keystroke Maneuver

Figure 3: Nerve insult due to FDS-I excursion

for volumetric compression (presumably correlating with compromised microvascular perfusion), is shown for the nerve as the tendons approach, contact and eventually entrap the nerve against the tunnel boundary. Another insult measure is deviatoric stress, a potential correlate of shear-induced nerve tissue disruption at the cell or axonal level. These local stress measures, integrated over the tunnel-enclosed nerve, provide a basis to link median nerve insult with global limb motions or postures (Figure 3). This potentially provides a means to identify, and avoid, problematic workplace activities.

IS SENSORY CONTROL OF THE LOCOMOTOR SYSTEM CRUCIAL OR NOT?

Sergiy Yakovenko and Arthur Prochazka

Centre for Neuroscience, University of Alberta, Edmonton, Alberta, Canada
sergiy.yakovenko@ualberta.ca

INTRODUCTION

It has been shown that isolated neural networks in the central nervous system can generate the basic locomotor rhythm even in the absence of sensory feedback. Furthermore, the spring-like properties of muscles provide automatic load-compensation during weight-bearing. How crucial is sensory control of the motor output, given these basic properties of the locomotor system? A biomechanical model was used to test two hypotheses. 1) Stretch reflexes are too weak and too delayed to contribute significantly to weight-bearing. 2) The important contributions of sensory input involve state-dependent processing.

METHODS

We constructed a two-legged planar locomotor model with 9 segments, driven by 12 musculo-tendon actuators with Hill-type force-velocity and monotonic force-length properties. Electromyographic (EMG) profiles of the simulated muscle groups during slow level walking served as actuator activation functions. Stability was compared in the open-loop “de-afferented” model and in models with feedback control based on either sensory-evoked stretch reflexes or finite-state rules. Spindle Ia and tendon organ Ib sensory inputs were represented by transfer functions with a latency of 35 ms and gated to be active only when the receptor-bearing muscles were contracting (Prochazka 1999). In each case, the reflex was set to contribute 15% to the net EMG profile. Together the sensory-evoked responses therefore contributed 30% of the net EMG. Finite-state rules identified in different animal species (Prochazka 1996) were used to switch between step cycle phases. Locomotor stability was assessed by parametric variations of actuator maximum forces and by mechanical perturbations during locomotion.

RESULTS

Without sensory control, the intrinsic stiffness of the muscles could provide enough weight support and flexibility to make continuous adjustments to compensate for small variations in body speed, height, and the relative positions of the limb segments (see first 2 steps in Fig. 2). However, stability was easily abolished by parametric variations such as changes in peak muscle force or cycle frequency of the CPG. When the underlying activation levels were low, stretch reflexes could provide enough additional drive to prevent a collapse (Fig. 1). However, if the underlying activation levels were sufficient to support body weight, stretch reflexes caused only a modest increase in the velocity of gait (Fig. 2). Finite-state logic considerably increased the range of kinematic and terrain variations over which gait remained stable.

Figure 1: Model of control of locomotion with and without stretch reflexes mediated by muscle spindle Ia and tendon organ Ib afferents, when centrally generated activation levels are low. The net reflexive components of EMG are shown as black caps on top of ankle extensor (AE) EMG profile.

Figure 2: Contribution of stretch reflexes when actuators have high activation levels.

SUMMARY

- 1) In the absence of sensory control, the intrinsic stiffness of limb muscles driven by a stereotyped rhythmical pattern can produce surprisingly stable gait.
- 2) Contrary to hypothesis 1, the contribution of stretch reflexes can range from being modest to crucial, depending on the circumstances.
- 3) Finite-state control can greatly extend the adaptive capability of the locomotor system.

EFFECTS OF VIBRATION INDUCED BY INLINE SKATING ON NEUROMOTOR FUNCTIONS COMPARISON BETWEEN VIBRATION ABSORPTION CONDITIONS

Richard Lefebvre¹, Cynthia Thompson², Frédéric Morin², Mohamed Iken², Marc Bélanger²

¹ Department of Kinesiology and Physical Education, McGill University, Montreal, Quebec, Canada, richard_lefebvre@uqtr.ca

² Département de Kinanthropologie, Université du Québec à Montréal, Montreal, Quebec, Canada

INTRODUCTION

Unusual sensations in the lower limbs, such as, numbness, weakness and increased difficulty in controlling the movements have been experienced after doffing the skate by people who practice inline skating. These sensations may be the results of vibration which is known to be produced by this activity (Mahar et al. 1997, Burström et al. 1999). Vibration has also been shown to alter several neuromotor functions, such as monosynaptic reflexes (Hoffmann reflex or H-reflex) (Matthews et al. 1964, Martin et al. 1986). The purpose of this study was therefore to verify the effects of vibration induced by inline skating on the Soleus (Sol) H-reflex, and to compare different vibration absorption devices on inline skates.

MATERIAL AND METHODS

Eighteen volunteer subjects (14 males, 4 females, mean age=27 years) participated in this study. In the pre-skating procedure, a minimum of 10 H-reflex responses in which the stimulus intensity was set to elicit a Motor (M) response of $10 \pm 1\%$ of the maximal M response (Mmax) were recorded from the right Sol. The subjects were then asked to skate back and forth, at their own cruise speed, on a 200 metre section of a paved cycling path for 30 min. All subjects were recreational skaters and they all used the same four skate models (provided by a local supplier), in a randomized order. Skate 1 is a prototype inline skate, Skate 2 and Skate 3 are market available inline skates, whereas Skate 4 is a market available roller hockey skate. The four skating sessions were separated by a resting period of at least 24 hours. The frequency and amplitude of vibration were measured for the first 2 return excursions (4 lengths) using a set of 2 accelerometers positioned in different combinations; right front skate's chassis (FSC) and the middle of the medial surface of the tibia (MT); right front skate's chassis (FSC) and right front skate's boot (FSB); right rear skate's chassis (RSC) and right rear skate's boot (RSB); right front skate's chassis (FSC) and right Achilles tendon (AT). Each length of skating was timed and the subjects were asked to give the experimenter the level of numbness and fatigue felt in the lower limbs every other length, based on the 10 points Borg scale. After the skating period, the subjects returned to the lab where the H-reflex being recorded for 30 min. at a rate of one every 5 to 8 sec.

RESULTS

As a comparison base, the vibration frequencies were found to be between 105-190 Hz and 15-115 Hz. at FSC and MT levels, respectively. The vibration amplitude recorded at FSC could reach up to 5 g while that at MT went up to 2 g. Fig. 1 reveals that the H-reflex amplitude decreased significantly ($p < 0.05$) after skating and this H-reflex inhibition had not recovered to the pre-skating level in all of the vibration absorption conditions. This could not be attributed to muscle fatigue since the spectral analyses of the Sol and MG EMG during the MVC, obtained from a former pilot session, showed

no change between pre and post skating evaluations. The H-reflex changes were not correlated with either psychophysical test of numbness or fatigue, meaning that, the H-reflex was still inhibited while the subjects normal perception with respect to numbness or fatigue. However, Skates 1 and 2 were providing a significant faster neuromuscular recovery ($p < 0.05$) when compared to the two other vibration absorption conditions (Skates 3 and 4), as shown in Fig. 2.

Figure 1: M-response and H-reflex (mV) in Pre-skating (PrS), Post-Skating after 8 min (PoS 8) and 35 min (PoS 35).

Figure 2: H-reflex (% pre-skating value) amplitude comparison between the 4 vibration absorption conditions.

DISCUSSION AND CONCLUSION

Inline skating produces vibrations that are transmitted to the lower limbs and that have some effects on the neuromuscular functions, in particular, the monosynaptic reflex. These changes will undoubtedly affect activities following skating since the effects are relatively long lasting (>30 min). It may also be attributed to a greater reliance on the skin and joint afferent information. This is supported by the relatively quick return to normal on the numbness scale.

IN VIVO MUSCLE FORCE-LENGTH BEHAVIOR DURING INCLINED HOPPING IN TAMMAR WALLABIES

Craig McGowan^{1*}, Russell Baudinette², and Andrew Biewener¹.

¹Concord Field Station, Harvard University, Bedford, Massachusetts, USA

²Department of Zoology, University of Adelaide, Adelaide, South Australia, AU

*e-mail: cmcgowan@oeb.harvard.edu

INTRODUCTION

Unlike most terrestrial mammals, Tammar wallabies and other larger macropods do not experience an increase in oxygen consumption with increased locomotor speed (Baudinette *et al.*, 1992). This locomotor economy has been linked to high force production with limited muscle shortening in the ankle extensor muscles, which facilitates elastic energy recovery in the large 'Achilles' tendon during steady, level hopping (Biewener *et al.*, 1998). In the wild, these animals are often faced with maneuvering through more variable conditions. The goal of this study was to determine the role that the ankle extensor muscles play when the animals hop up an incline.

METHODS

Four adult tammar wallabies *Macropus eugenii* (two male and two female, ranging from 5.77-7.15kg in body mass) were trained to hop over a range of speeds on a treadmill set at 0 and 10 degrees. *In vivo* measurements were recorded from each animal at two-three speeds on the level and incline. These measurements included muscle strain and activity patterns in the Plantaris (PL) and Lateral Gastrocnemius (LG) muscles as well as forces from the Plantaris and common Gastrocnemius tendons. All trials were recorded using high-speed video (Redlake PCI-500).

Muscle strain was measured via sonomicrometry, with one pair of crystals implanted in each muscle belly aligned with the fiber trajectory. Electromyography electrodes were inserted into the muscle adjacent to crystals in to monitor electrical activity. Muscle-tendon forces were recorded by means of an 'E'-shaped buckle transducer secured to each tendon. The buckles were calibrated *in situ* post-mortem.

RESULTS AND DISCUSSION

The results of the *in vivo* strain measurements showed that in level hopping, both the LG and PL undergo little length change while producing force (LG -2.7 %; PL -4.2%; Figure 1), and therefore produce little or no net work (LG -0.03J; PL -0.01J).

Figure 1: Average muscle strain (dL/L) in the LG and PL for steady state hopping at 4.2 m/s on level and incline.

Preliminary data suggests that there may be shift in the LG towards active shortening during inclined hopping (Figure 1), but the values for muscle strain and net work are quite small (.5% and 0.01J, respectively). The PL shows no difference in muscle strain or net work (-4.3% and -0.01J, respectively) during inclined hopping.

SUMMARY

Our data suggests that during inclined hopping, at least up to 10 degrees, there is no change in the mechanical role of the ankle extensor muscles. Such findings lead us to believe that the additional power necessary to move up a hill must be being supplied by more proximal limb muscles. Future work will explore the function of proximal muscles both in level and inclined hopping to help gain a better understanding of the mechanics of hopping.

DESIGN FACTORS AFFECTING THE CONTACT STRESS PATTERNS IN A CONTEMPORARY MOBILE BEARING TOTAL ANKLE REPLACEMENT

Terence E. McIff

Orthopedic Research Laboratory, University of Kansas Medical Center,
Kansas City, Kansas, USA
tmciff@kumc.edu

INTRODUCTION

Most total ankle implants were originally developed without the aid of concerted engineering design efforts. Increasing interest in ankle arthroplasty has led to a closer examination of current ankle replacement designs in the hopes of predicting and averting any potential failure. Because of the high loads predicted at the ankle joint during normal activity (5-10X BW), there is concern that ankle implants might experience higher polyethylene wear rates than other joints. Low-constraint joint replacement prostheses, such as mobile bearing devices, are seemingly effective in reducing the shear and rotational loading believed to contribute to implant loosening. Unlike mobile bearing total knee prostheses, however, mobile bearing ankle replacements (Figure 1) have the additional advantage of maintaining complete congruency between bearing interfaces, hypothetically distributing loads more evenly and avoiding high stress concentrations implicated for higher wear rates. In previous studies, it was found that under quasi-static loading conditions uneven and unexpected contact stress distributions were observed for one of the congruent mobile-bearing total ankle devices evaluated (Figure 2), in particular, very high anterior and posterior-edge contact stresses were observed on the inferior contact surface. In this current study, design features of the polyethylene bearing were hypothesized to influence these stress patterns. This study examined the influence of several design features on the contact stress between bearing interfaces.

METHODS

A dual-contact-surface finite element model (Fig 1) was formulated for the mobile bearing device using Patran 9.0 and executed in Abaqus 5.8. The polyethylene bearing was modeled using a finite element mesh comprised of reduced-integration, 8-node Hex elements and used an elasto-plastic constitutive model. The tibial and talar components were modeled as rigid bodies. Finite sliding contact formulation was used. The FEM models were loaded with 3650 N axial force representing 5 times body weight of a 75 kg person. Once loaded, the polyethylene was constrained solely by friction and the topography of the contact surfaces. Multiple models were created wherein design features of the polyethylene bearing only were varied. A parametric study was undertaken to determine the influence of changes in these features on the contact stress distribution (both inferior and superior bearing surfaces) under static and quasi-static conditions. The independent parameters included: ant/post

bevel angle, contact surface area, radius of curvature of the talar component, and mating surface conformity. Different angles of anterior and posterior bevel were modeled without altering the contact interface areas.

Figure 1: FE model of STAR total ankle replacement.

Figure 2: Inferior surface of the mobile bearing showing areas of high contact stress.

RESULTS AND DISCUSSION

The high stresses observed in the original design (approx. 18MPa) near the interior of the inferior bearing surface were found to result from a non-uniform curvature of the talar component. The anterior and posterior bevel angle was found to substantially influence the magnitude of the contact stress at the anterior and posterior edges. Altering of this bevel angle so that a tangent to the beveled surface is perpendicular to the surface of the talar component (Figure 3) was found to reduce the magnitude of edge stresses to the level observed over the rest of the contact area (from over 30MPa to approx. 10MPa).

Figure 3: Medial-lateral view of the mobile bearing ankle replacement with bevel angle at a perpendicular to the surface of the talar component.

SUMMARY

Congruency of contact surfaces does not imply uniform stress distribution.

Seemingly insignificant design features can substantially affect the contact mechanics of joint replacement devices. Here, the mechanisms by which a few alterable design features contribute to the disparate contact stress distributions were identified and quantified.

A NOVEL APPROACH TO MEASUREMENT OF HOOP STRAIN IN THE HUMAN MENISCUS

Cristy Richards¹, Charles J. Gatt Jr. M.D.², and Noshir Langrana Ph.D.¹

¹Rutgers University, Department of Mechanical and Aerospace Engineering, Piscataway, New Jersey, USA,
crich@eden.rutgers.edu

²UMDNJ University Hospital, Department of Orthopaedic Surgery, New Brunswick, New Jersey, USA

INTRODUCTION

Treatment of a torn meniscus is the most common reason for knee surgery in the United States today. With a variety of treatment options, there is need for a competent means to evaluate each method to determine which serves best to restore or maintain meniscal function with the least amount of trauma to the patient. At present, however, methods for the assessment of human meniscal function involve only indirect techniques. Procedures such as casting (Walker et al 1975), and the use of micro-transducers (Walker et al 1975), Fuji Film (Baratz et al 1986), or staining (Krause et al 1976) ignore the functional means by which the meniscus bears a load. The hoop stress theory of meniscal function proposes that axial loads across the knee joint are distributed through the menisci as tension in circumferentially arranged fibers (Mow et al 1992, 1997). Therefore, only measurement of the longitudinal deformation of these circumferential fibers in response to knee joint load will allow for a direct determination of meniscal load bearing function.

METHODS

A multiple-degrees-of-freedom comprehensive testing apparatus has been designed and fabricated to simulate knee joint function under load. An Instron® mechanical testing machine is used to produce loading on the knee. Static and quasi-dynamic motion analyses are performed to assess the function of the human meniscus in response to knee joint loads, translations, and rotations. Quadriceps forces are simulated and measured by attachment of a slackening mechanism in series with a tensiometer to the patella tendon. A differential variable reluctance transducer (Microstrain® DVRT) is used for direct measurement of meniscus fiber deformation in response to axial loads across the knee joint. In addition, pressure sensitive film is used to obtain calibrated contact areas from which meniscal loading is calculated.

RESULTS AND DISCUSSION

The focus has been on the development and implementation of a new experimental protocol to evaluate meniscus strain. This

involves the correlation of DVRT data with an accepted method of meniscal evaluation. Fuji film was chosen for its apparent ease and accessibility.

Three knees have thus far been tested for hoop strain with respect to external loading as given by the Instron machine and compared with coincident measurements taken with Fuji pressure sensitive film. At 1200N, result indicate strains in the mid-section of the medial meniscus of about 4.9% +/- 0.12% and Fuji film pressures of 1.5 MPa +/- 0.087 Mpa. Measurements were also taken at 800 N and 1600 N for the straight leg case. Additional data was collected for the quasi-static loading of the bent knee.

SUMMARY

Evaluation of meniscus function by means of the DVRT has been explored and compared to the widely accepted use of Fuji film. The DVRT has proven to perform with intuitive clarity over both straight and bent leg scenarios, which methods such as the use of Fuji film cannot accommodate due to the development of shear components.

By providing quantitative data combined with engineering analysis on the function of an intact, torn, partially resected, and repaired meniscus in different articular configurations, this study will allow orthopaedic surgeons to make better informed decisions regarding this common diagnosis.

WALKING AROUND STATIC AND MOBILE UPRIGHT OBSTACLES

Martin G  rin-Lajoie^{1,2}, Bradford J. McFadyen^{1,2}, Carol C. Richards^{1,2} and Lori Ann Vallis^{1,2}

¹Center for Interdisciplinary Research in Rehabilitation and Social Integration (CIRRS), Qu  bec, Canada

²Faculty of Medicine, Laval University, Qu  bec, Canada G1K 7P4

INTRODUCTION

The ability to avoid obstacles is crucial for safe locomotion and requires pre-planned motor adaptations. Our daily activities often require that we navigate around upright static and mobile obstacles such as people standing or moving on the street or in a mall. Strategies to avoid upright static and mobile obstacles have received little attention in the literature. Studying such anticipatory locomotor strategies will provide a better understanding and assessment of locomotor ability within real world environments. The present study investigates the anticipatory strategies used to avoid static and mobile upright obstacles both with and without prior knowledge of the obstacle's movement.

METHODS

At this stage, five healthy subjects (2 females and 3 males; age 26.0 ± 3.2 years, height 1.74 ± 0.11 m, weight 64.44 ± 8.56 kg, gait speed 1.45 ± 0.23 m/s) have volunteered for the study. The experimental protocol was approved by the ethics committee of the Qu  bec Rehabilitation Institute and informed consent was given by all participants. Exclusion criteria included any self-reported neurological or musculoskeletal impairments. A score of 20/20 on the Snell vision test was also required.

Three non-colinear infrared markers placed on the feet, legs, thighs, pelvis, trunk, left arm, left forearm and head, were tracked using the Optotrak 3020 motion analysis system (60 Hz; Northern Digital Inc, Canada). Certain anatomical points were also probed in relation to these markers to allow the calculation of principle axes and the creation of virtual marker trajectories (e.g., the heels). The obstacle used was a full-size department store mannequin mounted on an overhanging rail that crossed the walkway at a 45 degree angle. Using a remote controlled electrical motor, the mannequin could be moved at predetermined speeds, or simply placed in a set position, along the rail. Mannequin movement was also tracked using three additional infrared markers.

Subjects were asked to walk naturally, without stopping, up to a table located at the end of the walkway and to avoid the mannequin when it obstructed their path. No information was given about the direction to avoid the mannequin, but the laboratory set-up encouraged deviations to the right. For half of the trials, the action of the mannequin was revealed prior to

executing the task (known), while it was unknown for the other half (uncertainty factor). Trials related to no, static and mobile obstacles, as well as to either prior or no knowledge of the obstacle's movement were randomly presented.

Dependent variables include average gait speed, lateral centre of mass displacement, forward centre of mass momentum, yaw (transverse plane) angles of the head and trunk, roll (frontal plane) angle of the trunk, and clearance of the left elbow of subject from the left elbow of the mannequin. Onsets of deviation in the variables for obstructed walking were recorded when the data began to deviate from the average control profiles and continued beyond one standard deviation of this control data. Onset times were calculated in reference to time of obstacle crossing.

RESULTS AND DISCUSSION

Preliminary analyses indicated that subjects planned their avoidance strategy in two distinct stages: 1) an early lateral deviation of the centre of mass at about 5 to 6 steps before obstacle crossing; and 2) a later more drastic lateral deviation within one stride of the mannequin. There was also a break in the forward progression of centre of mass momentum associated with the second, later, path deviation. Obstacle mobility had no effect on the centre of mass deviations, but subjects tended to reduce their average gait speed when the obstacle was mobile and when the action of the mannequin was unknown.

There was no clear upper body strategy related to head or trunk yaw movements for any condition, and head yaw was even absent for some subjects perhaps indicating a level of attention the subjects gave to the obstacle during the approach. In addition, trunk roll was non-existent for all subjects. Therefore, the data would appear to support more of a lower limb strategy to initiate changes in the lateral CM trajectories for the environmental context used here. Finally, obstacle mobility and uncertainty did not appear to affect the distance with which subjects cleared the mannequin, suggesting that subjects are not planning actual clearance distance.

NEUROMUSCULAR ADJUSTMENTS FOR HOPPING ON A HEAVILY DAMPED SURFACE

Chet T. Moritz¹, Spencer M. Greene² and Claire T. Farley²

¹Department of Integrative Biology, Univ. of California, Berkeley, California, USA, ctmoritz@socrates.berkeley.edu

²Locomotion Laboratory, Dept. of Kinesiology and Applied Physiology, Univ. of Colorado, Boulder, Colorado, USA

INTRODUCTION

In the natural world, animals move over a variety of energy dissipating surfaces. Unlike running on a hard surface, to maintain a steady speed on an energy-dissipating surface, animals must produce more work than they absorb to replace the mechanical energy lost with each step. Indeed, during running on sand, humans must produce extra mechanical work and they consume more metabolic energy than on a hard surface (Lejeune et al., 1998). We hypothesized that humans hopping in place will adjust the timing of leg compression and extension and will produce extra work as surface damping increases, thereby maintaining similar center of mass dynamics regardless of surface damping. Previous work has shown that human hoppers conserve center of mass (COM) dynamics by adjusting leg stiffness on *elastic* surfaces of different stiffness (Farley et al., 1998).

METHODS

Five subjects hopped in place at 2.2 Hz on a surface supported by springs and dampers, and mounted on a force platform. For five trials, we increased surface damping from 0 to 3200 Ns/m and simultaneously decreased the spring stiffness from 30.3 to 13.3 kN/m to maintain a 6cm surface compression. We controlled for surface compression because it has a large effect on leg compression. We recorded ground reaction forces, surface compression, and sagittal plane video to determine leg compression, COM vertical displacement, and mechanical work. We determined significance ($p < 0.05$) with a repeated measures ANOVA. All values are Mean \pm SEM.

RESULTS AND DISCUSSION

Hoppers maintained similar COM dynamics regardless of surface damping by altering leg mechanical work output, leg compression timing, and leg length at takeoff. The most damped surface dissipated $67 \pm 1\%$ more of the hopper's COM mechanical energy than the elastic surface. Thus, the hopper would not have left the ground at the end of stance if the legs had behaved like springs, as they do on undamped surfaces. The legs performed increased work while maintaining similar COM dynamics by shifting the timing of maximum leg compression to offset changes in the timing of surface compression. On the most damped surface, the legs reached peak compression 33.3 ± 3 ms earlier ($p < 0.05$), and the surface reached maximum compression 46 ± 3 ms later ($p < 0.05$) than on the undamped surface. As a result, the minimum vertical position of the COM occurred at nearly the same time on all surfaces (see Figure 1).

Figure 1: Surface damping vs. the time from foot contact to: (1) the minimum vertical position of the center of mass (solid), (2) the maximum surface compression (dotted), and (3) the maximum leg compression (dashed). Values are mean \pm SEM and a * denotes $p < 0.05$.

The legs reached peak compression earlier and absorbed $9 \pm 2\%$ less energy ($p < 0.05$) on the most damped surface compared to the undamped surface. Work output during takeoff increased by $125 \pm 2\%$ ($p < 0.05$) because the legs extended by $71 \pm 4\%$ ($p < 0.05$) more, reaching a 3.1 ± 0.1 cm ($p < 0.05$) longer length at takeoff on the most damped surface compared to the undamped surface. The remainder of the increased work was due to an increased average force during leg extension. The most damped surface was still compressed at takeoff, nearly offsetting the longer leg length and maintaining similar COM dynamics.

SUMMARY

Hoppers altered the timing of leg compression to offset differences in the timing of surface compression, thus maintaining similar COM dynamics regardless of surface damping. The legs performed net positive work to replace the energy dissipated by the damped surfaces by beginning extension earlier, and extending to a longer length at takeoff. These results show that animals can precisely adjust the timing and magnitude of leg compression and extension to maintain steady state locomotion on natural energy dissipating surfaces.

ASYMMETRIES IN THE DYNAMIC STRUCTURE OF THE CENTER-OF-PRESSURE TIME SERIES

Mark Musolino and Mark Redfern

Human Movement and Balance Laboratory, Departments of Bioengineering and Otolaryngology
University of Pittsburgh, Pittsburgh, PA, USA (markmuso@pitt.edu)

INTRODUCTION

Investigation of the center-of-pressure (COP) during quiet stance has traditionally involved the use of summary statistics (RMS, velocity, range) to quantitatively describe the COP time series collected via a single force plate. Limitations of this approach are (1) the failure of summary statistics to reflect dynamic aspects of the COP, and (2) the inability of a single force-plate to uncover any left/right asymmetries. While various metrics have recently been developed to examine COP dynamics, the issue of asymmetries in spontaneous sway remains seldom reported (Mizrahi and Susak, 1989). In light of this, *the objective of the current study was to compare dynamic measures of COP between left (L) and right (R) feet.*

METHODS

Postural steadiness was examined in five healthy adult males with no evidence or history of neurological disease or postural disorders. All subjects provided informed consent prior to testing. Each subject was asked to “stand as still as possible”, in a comfortable upright posture, looking forward, with arms hanging freely at the sides, and with bare-feet placed side-by-side on adjacent, identical force plates (Model 4060, Bertec, Inc., Columbus, OH). Data were collected at 100Hz, and post-processed in Matlab (The Math Works, Inc.). Each subject performed 20 30-second trials – 10 w/ eyes open (EO), 10 w/ eyes closed (EC). EO/EC order was randomized. Numerous techniques were available to parameterize COP (Chiari et al, 2000; Newell et al.,1997; Riley et al.,1999). The stabilogram-diffusion approach of Collins and DeLuca (1993) was used because of its suitability in providing dynamic COP metrics, and because of its relative ease of application. Diffusion coefficients (D_S , D_L) and scaling exponents (H_S , H_L) were calculated for each 30 second COP time series.

RESULTS AND DISCUSSION

Visual inspection of the data and cross-correlation analysis revealed that corresponding L and R COP time series were in-phase (maximum correlation occurring at zero lag). However, L-R differences were observed in the stabilogram-diffusion parameters (Figure 1, Table 1). L values were consistently

lower than R values, for all parameters – perhaps due to a R leg dominance effect. An eye condition effect was not apparent. Values for D and H were comparable to those reported by Collins and DeLuca, and indicate the existence of two distinct regions in the stabilogram-diffusion plot (Figure 1). Values for Tcrit, the transition point between “short” and “long” time interval regions, were in most cases similar for R and L; however, differences of up to 0.5 seconds were seen.

Figure 1: Stabilogram-diffusion plot shows L-R differences

SUMMARY

Noticeable differences were observed between L and R COP time series. Such asymmetries don't necessarily implicate a particular form of postural controller, but rather just indicate that R and L sides are differentially affected by the processes that are involved in spontaneous sway.

THE CONTRIBUTION OF THE ARM SWING TO MAXIMUM VERTICAL JUMPS

Zachary J. Domire and John H. Challis

Biomechanics Laboratory, Department of Kinesiology, The Pennsylvania State University, University Park, Pennsylvania, USA
Email: zjd100@psu.edu, jhc10@psu.edu

INTRODUCTION

When studying vertical jumping, it is common to ask subjects to perform jumps without arm swing. This simplifies analysis and reduces the amount of marker loss when performing motion analysis. It is generally accepted that not using the arms decreases jump performance. Clearly by swinging the arms the center of mass can be higher at take-off than if the arms are simply held by the side, but the motion of the arms can have other contributions to performance. The mechanisms via which arm swing can improve performance in these jumps are not fully understood. Feltner et al. (1999) proposed that a moment produced at the shoulders could oppose extension of the legs and allow for a longer period of force development and therefore an increase in jump height, others have referred to increase vertical momentum generated by arm swing (Lees et al., 2000). It is the purpose of this study to determine what effect arm swing has on the performance of a maximum jump.

METHODS

Seven healthy male subjects (age: 24 ± 2.45 years; height: 181 ± 0.075 cm; body mass: 75.1 ± 5.6 kg) each performed six maximum squat jumps. Three were performed with arm swing and three without. Force plate and motion analysis data were collected for all these jumps. Jump height was computed by computing take-off velocity from the impulse obtained by integrating the vertical force-time curve. Jump height was assumed to be the maximum vertical displacement of the center of mass once contact was lost with the ground. Time histories of the joint angles, angular velocities, and resultant moments were computed.

A direct dynamics simulation model was developed, designed to represent a typical subject. A five-link (foot, shank, thigh, trunk, arm) rigid segment model was constructed. Links were connected by frictionless hinge joints. The foot was connected to the ground by a hinge joint at the metatarsal-phalangeal joint. It had a rotational spring-damper at the heel. Inertial properties were determined from a geometric solids model of one of the subjects (1.80m and 75.2kg).

Using the model, and given for each instant throughout the jump the segment angles and angular velocities, the moments at the shoulder joint were used to estimate the accelerations these moments generate at the other joints in the model. This is referred to as induced acceleration.

RESULTS AND DISCUSSION

Jump height was $19 \pm 10\%$ higher for the jumps with an arm swing than without. This compares favorably with the results

of Feltner. The kinematics and the kinetics of the tasks were similar to data presented in the literature (e.g. Challis, 1998).

The induced acceleration analysis showed arm swing causes joint accelerations away from the desired direction of motion at the knee and ankle throughout the jump, allowing the musculature at these joints longer to generate force. At the hip there is little effect until the end of the movement, when arm swing extends the hip. Figure one shows the induced acceleration at the hip, knee, and ankle throughout the jump.

Figure (1). Induced acceleration. Extension is negative.

Bobbert et al. (1996) suggested that vertical jumps with a counter movement are higher than those with a static start because in the former there is increased time for muscle activation. The induced acceleration analysis performed here shows that a similar mechanism is at play when an arm swing is employed during a jump. It would be interesting to use this approach to analyze the influence of arm swing when subjects perform sit-to-stand, where for a phase of the movement accelerations at the knee cannot be induced as the subject is still in contact with the chair.

CONTROL OBJECTIVES CHANGE BETWEEN PHASES OF JUMPING AND LANDING TASKS

K. E. Costa and J. L. McNitt-Gray

Biomechanics Research Laboratory, Department of Kinesiology, University of Southern California, Los Angeles, California, USA

Communicating author: kcosta@usc.edu

INTRODUCTION

Previous investigations have shown foot position at contact and TBCM position at the time of the explosive extension during ground contact influence the redirection of total body momentum (Hodgins & Raibert, 1990; Ridderikhoff et al., 1999). The purpose of this investigation was to compare the control objectives of the trunk and leg subsystems during the landing and jumping phases of a practiced, goal-directed task.

METHODS

Sagittal plane kinematics (200Hz, NAC) were recorded while female collegiate basketball players (n=6) performed a series of rebound-like jumping and landing tasks. Subjects were asked to jump, reach a ball suspended overhead (0.4m above individual's stand and reach height), land, and jump again to reach a second ball suspended overhead (90% of max vertical jump). Ground reaction forces were recorded from the time of landing from the first jump to take-off of the second jump (Kistler, 800Hz). Subjects were asked to use their normal jumping and landing techniques. Body landmarks (DeLeva, 1996) were manually digitized (Peak Performance). Leg angle (ankle to hip), trunk segment angle (hip to C7), and TBCM position vector from ankle to TBCM position (r angle) were calculated from touch-down to take-off relative to the right horizontal

RESULTS AND DISCUSSION

Control of the lower extremity appeared to take precedence over the need to position the TBCM at contact. Within-subject, leg segment orientation at contact varied 1-2°. Whereas, r angle at contact varied on average by 11°. These results highlight the need to control the lower extremity position so that the neural system can anticipate and prepare for the mechanical demand imposed upon the lower extremity during impact. Whereas, the positioning of the TBCM appeared to determine the initiation of the explosive extension phase (figure 1). These results support the findings of Ridderikhoff et al. (1999), which identified a rotation phase preceding the explosive extension phase of maximum squat jumps. Similarly Hodgins & Raibert (1996) altered

biped robot gait by adjusting the timing of the thrust according to leg position during stance. Trunk-leg subsystem control used to position the TBCM during ground contact varied across subjects. Subjects who utilized greater trunk segment motion to achieve the TBCM position prior to explosive extension utilized longer ground contact time than those using leg motion.

Figure 1: Angle-angle diagram of TBCM position vector (R angle) vs. knee joint angular position during ground contact. Diamonds indicate ground contact. Turning point synchronization of the variables suggests the initiation of the secondary jump task is coupled with the position of the TBCM, such that the explosive extension occurs after the preferred angular rotation of the TBCM vector.

INFLUENCE OF INCREASED ROTATIONAL INERTIA ON HUMAN TURNING PERFORMANCE

David V. Lee, Rebecca M. Walter, Stephen M. Deban (sdeban@usa.net) and David R. Carrier

Department of Biology, University of Utah, Salt Lake City, Utah, USA.

INTRODUCTION

Organismal biologists have focused considerable attention on the many ways in which body size and shape influence animal locomotion, but few studies have considered the impact of rotational inertia on turning performance (Thollessen and Norberg, 1991; Evans and Thomas, 1992; Eilam, 1994; Van Den Berg and Rayner, 1995; Jindrich and Full, 1999). Given the importance of turning agility in competitive sports and athletic activities, the influence of rotational inertia on locomotor performance warrants investigation. We became interested in the effect of rotational inertia on turning performance because we were curious about the extent to which body configuration influenced the agility of theropod dinosaurs (Carrier et al. 2001). Results from that study led us to suspect that the relationship between rotational inertia and turning performance is not as simple as one might initially expect. Elevation of rotational inertia in human subjects decreased turning performance, but the effect appeared not to be in proportion to the change in rotational inertia. Thus, we quantified the effect of an elevation of rotational inertia on the turning performance of human subjects (Lee et al., 2001).

METHODS

To determine the effect of rotational inertia (I) on turning performance, we elevated I of human subjects an average of 9.2-fold above natural values and had the subjects execute maximum effort turns during vertical leaps from a Kistler 9281B SN force plate (i.e., "jump turns"). The subjects began each jump with their feet at shoulder width and their arms at their sides throughout the jump. Force plate records allowed us to measure the mean and maximum torque (T), period of torque application, total angular impulse, maximum and mean angular power (P) and angular work during the turn (Lee et al., 2001). Forces applied to the force plate were sampled at 200Hz with a BioPac Systems, Inc. (MP 100) A-D converter and a Macintosh computer. Free moments generated by the subjects during maximal jump turns were calculated from the horizontal forces and the position of the center of pressure using the methods of Holden and Cavanagh (1991).

RESULTS AND DISCUSSION

Maximum and mean T increased significantly in jumps with increased I ($P < 0.001$), as did angular impulse and push-off period (Table 1). The increase in T, period, and impulse partially compensated for the increased I, and resulted in less decrease in angle turned than expected in jumps with increased I. Maximum and mean angular power were lowest in jumps with increased I, but angular work did not vary significantly among conditions. Maximum T during jumps with increased I approached isometric maximum torques (mean: 92.5 ± 8 Nm), suggesting that turning performance may ultimately have been limited by the ability to produce torque. We suggest that there are at least two factors that contribute to the greater torque production when the subjects turned with increased rotational inertia: (1) adjustments in the pattern of

muscle recruitment and (2) a reduction in muscle shortening velocity that resulted in increased muscle forces.

CONFLICT BETWEEN MOMENTUM AND BALANCE CONTROL DURING LANDING

J.L. McNitt-Gray#, Philip Requejo#, and Henryk Flashner*

Biomechanics Research Laboratory, Department of Kinesiology#, Department of Mechanical Engineering*,
University of Southern California, Los Angeles, CA 90089, USA

Communicating author: mcnitt@usc.edu

INTRODUCTION

Multijoint control of moments induced by large reaction and intersegmental forces experienced during landing presents a significant challenge to the neuromuscular system prior to and during contact with the supporting surface. The set of muscles an individual chooses to control the reaction force will likely influence the mechanical loading experienced during the landing as well as their ability to position and control the momentum of the total body center of mass. The purpose of this study was to determine the source potential conflicts between momentum and balance control strategies used by individuals during landings requiring both momentum and balance control with a single placement of the feet.

METHODS

Successful landings (S: balanced without steps, $n=11$) and under rotated landings (UR: requiring a step forward to control balance, $n=4$) of flyaway layout salto dismounts performed by female gymnasts (mean height: 1.45m (.07±m); weight: 420N (62±N)) participating in the Artistic Gymnastics Competition during the 2000 Olympic Games were selected for analysis. During competition, flight and landing phase kinematics were simultaneously collected using two stationary digital cameras (200 Hz; C²S NAC Visual Systems, Burbank, CA, U.S.A.). 3-D coordinates were derived from manually digitized 2-D coordinates using direct linear transformation (Abdel-Aziz & Karara, 1971) and filtered (15Hz, Woltring, 1986). A 2-dimensional human body model consisting of five rigid segments interconnected by frictionless revolute joints actuated by moments about the joint centers (Figure 1). The equations of motion representing the human system flight dynamics were expressed as a set of N -second-order differential equations of the form:

$$\mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{V}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{G}(\mathbf{q}) = \mathbf{Q}$$

Mechanical variables at initial contact and during the landing phase were computed and compared between successful (S) and under rotated (UR) landings.

RESULTS AND DISCUSSION

Gymnasts, able to achieve both momentum and balance control objectives (S), used multijoint strategies that allowed the CM position to come rest within their functional base of support. In contrast, gymnasts performing under rotated

landings satisfied the momentum control objective using a multijoint strategy that resulted in a CM position beyond the functional base of support (Figure 1). No significant differences in CM position or velocity at contact were observed between the S and OR landings.

Figure 1:

Phase plane relationship between R angle and R angular velocity during the landing phase of S and UR landings. Note that the multijoint control strategy used by the individual performing the UR landing was unsuccessful in positioning their CM over the base of support.

SUMMARY

Successful landing performance requires the use of momentum control strategies that simultaneously achieve balance control objectives.

EFFECTS OF TARGET DISTANCE AND SIZE ON REACHING KINEMATICS IN INDIVIDUALS WITH HEMIPARESIS

Patrick H McCrea^{1,3} and Janice J Eng^{2,3}

Dept. of Mechanical Engineering¹ and School of Rehabilitation Sciences², University of BC
Rehabilitation Research Lab³, GF Strong Rehab Centre, Vancouver, Canada
www.rehab.ubc.ca/jeng

INTRODUCTION

The ability to reach with the upper extremity is critical for activities of daily living. Acute and chronic upper extremity impairment is experienced by 85% and 40% of individuals with brain injury, respectively (Parker et al., 1986).

Few formal rules in neuromotor control have the same status as Fitts' law (Fitts, 1954) with regards to its robustness and to its mathematical simplicity. The purpose of this study was to determine if the Fitts' tradeoff between speed and accuracy describes aimed reaching movements in persons with brain injury due to stroke. Secondly, we evaluated the kinematic properties of reaching to determine characteristics of reaching which may contribute to reaching performance.

METHODS

Twenty individuals with stroke (mean age=60.9±6.1 years, duration of injury=4.3±2.6 years, Fugl-Meyer upper extremity score=38±19 Ashworth=1.2±1.0) and 10 healthy age-matched controls (mean age=61±9.0 years) participated in the study. Individuals with stroke had a minimum of one year post-stroke and were able to voluntarily flex/abduct their shoulder 45° and extend their elbow 30°. Subjects were seated at a table and were instructed: "At the sound of the tone, reach to the target as fast as you can. Make sure that you touch the target." We randomized combinations of target distance (10, 20, and 40 cm) and width (2, 4, 8, 16 cm). Movements were recorded at 60 Hz with an infrared emitting diode (attached to the tip of the pointing finger) using a 3D optoelectronic system (Northern Digital) and then low pass filtered at 10 Hz.

The index of difficulty (Fitts, 1954) was determined as the logarithmic term where A is its amplitude (i.e., distance), W is the width of the target in the direction of movement, and constants a and b are experimentally determined:

$$\text{MovementTime} = a + b \log_2 \left(\frac{2A}{W} \right)$$

Linear regressions were performed between movement time (representing speed) and the index of difficulty (representing accuracy) for four groups: 1) dominant arm-control, 2) non-dominant arm-control, 3) less affected arm-stroke, 4) more affected arm-stroke. MANOVAs quantified differences in kinematics (movement time, time to peak velocity, skewness, kurtosis, segmentation, and directness) among the groups. Kinematic measures were then correlated with movement time to determine factors underlying reaching performance.

RESULTS AND DISCUSSION

The relationship between movement time and index of difficulty was significant for all groups except for the more

affected arm-stroke. A sub-analysis of the more affected arm-stroke group showed definitive trends towards linearity between movement time and index of difficulty for all these subjects, however, only half reached significance, suggesting that Fitts' Law was not as robust in this group.

Figure 1. Typical velocity profiles normalized to movement time of the more (thick line) and less (thin line) affected arms in stroke. Plots are titled by target distance and width (in cm). MT_l=movement time, less affected arm-stroke (sec). MT_m=movement time, more affected arm-stroke (sec).

All kinematic measures were significantly different between the more and less-affected arm of the stroke subjects and surprisingly, between the non-dominant arm-control and the less affected arm-stroke for all measures except directness. In the more-affected arm, movement time was strongly correlated with segmentation ($r=.92$), skewness ($r=.76$), and time to peak speed ($r=.89$) while correlations between movement time and kinematic measures in the other 3 groups were more modest ($<.50$) or not significant.

SUMMARY

We suggest that the altered kinematics in the more affected arm-stroke group contributed to the weaker speed-accuracy relationship during a reaching task compared to the less affected arm-stroke group and healthy controls.

MEASUREMENT OF THREE-DIMENSIONAL KINEMATICS OF THE GLENOHUMERAL JOINT DURING MANUAL WHEELCHAIR PROPULSION USING SKELETAL MARKERS

Tung-Wu Lu¹, Gen-Jia Li¹, Mei-Ying Kuo^{1,2}, Ling-Ying Chang², Horng-Chaung Hsu^{2,3}

³Department of Orthopedics, China Medical College Hospital, Taichung, Taiwan

INTRODUCTION

Manual wheelchair propulsion (MWP) is an important form of mobility for people with locomotor system impairments, placing a huge mechanical demand on the glenohumeral (GH) joint. A complete understanding of the mechanics of the joint during MWP is essential for the prevention and treatment of relevant injuries. Due to the big relative movement between the scapula and the overlying skin, the motion of the GH joint has been approximated by that of the humerus relative to the trunk [1], providing only limited information of the GH motion. No study on the actual motion of the GH joint during MWP exists. The purpose of the study was to bridge the gap by measuring the 3-D kinematics of the scapula using skeletal pins.

MATERIALS AND METHODS

Five healthy male volunteers (age: 20-25 yr) participated in the study with informed consents. The experiment was approved by the Ethics Committee of the CMC Hospital. Each subject performed wheelchair propulsion in a gait lab equipped with a 7-camera motion analysis system (Vicon 370, Oxford Metrics, U.K.). The trunk and humerus were each attached with 4 retroreflective markers. Four markers attached to scapular bone-pins inserted into the acromion were used to provide the true positions of the scapula. Positions of the bony landmarks of the scapula relative to the bone-pin markers and those of the lateral and medial epicondyles relative to the humeral markers were defined using a pointer during a subject calibration trial.

Movements of the scapula were described relative to the trunk and those of the humerus relative to the scapula, giving the motion of the GH joint. The rotational movements of the humerus were defined using an Euler angle sequence consisting of the plane of elevation, amount of elevation and internal/external rotation (y-z'-y''). Rotation sequence for the scapula was internal/external rotation, upward/downward rotation and posterior/anterior tilting (y-z'-x'').

RESULTS AND DISCUSSION

The scapula moved significantly during MWP. Patterns of the scapula and GH joint motion are shown in Fig. 1. The scapula moved from 12° in protraction at initial contact to a maximum of 29° at the end of push phase and then retracted back to 12° during recovery. During the cycle, the scapula rotated downward followed by upward rotation with a range of approximately 8° and tilted anteriorly from 16° to 8° in posterior tilt and then back to 16°.

The GH joint moved from 43° in the posterior plane at initial contact and then moved progressively forward throughout the push phase and gradually reached a maximum of 9° in the anterior plane. The GH joint remained at about 40° of elevation throughout the propulsion cycle and rotated externally from 45° in internal rotation at initial contact to about 0° at the beginning of the recovery phase. These observed movement patterns differed significantly from those of the humerus relative to the trunk (Fig. 2), suggesting that traditional method of approximating GH motion by that of the humerus relative to the trunk is misleading.

The present study provided the first data on the 3D kinematics of the scapula and GH joint during MWP, which will be helpful for the improvement of the design of wheelchairs as well as the prevention and treatment of relevant injuries.

Fig. 1: Movement patterns of the scapula (a) and GH joint (b).

Fig. 2: Movement patterns of the GH joint from traditional method (thin curve) and the present study (thick curve).

INTRODUCTION

Finite Element Modeling (FEM) is a powerful method to investigate musculoskeletal structures. However, models of complex structures require validation by means of direct measurements [1]. We hypothesize, that a novel three-dimensional Electronic Speckle Pattern Interferometry system (3-D ESPI) is able to acquire full-field deformation measurements for validation of FEM models.

In this study, a 3-D ESPI system has been applied to measure tibial plateau deformation under compressive loading. This laser-based measurement technology enables acquisition of three-directional surface deformation maps in sub-micrometer resolution. For direct comparison, tibial plateau deformation was analyzed in a FEM of the proximal tibia under identical loading conditions. The results of this study demonstrate the merit of 3-D ESPI to deliver full-field experimental measurements that are directly comparable to FEM analyses of musculoskeletal structures.

METHODS

3-D ESPI Measurement: A tibia was harvested from a 78 years old non-embalmed female cadaver and transected 50 mm below the plateau. The proximal tibia section was potted with polymethylmethacrylate in a custom-made pressure chamber in a manner, that only the tibial plateau remained visible (Fig. 1a). Within this chamber, the tibial plateau was subjected to uniform pneumatic pressurization up to 200 KPa in 8 increments. The sensor of a 3-D ESPI system (Q100, Ettemeyer AG, Nersingen, Germany) was mounted over a glass cover on the chamber to record surface deformation on the tibial plateau in response to incremental pressurization.

Figure 1: a) setup for 3-D ESPI measurement; b) FEM

The 3-D ESPI system generated laser speckle images on the plateau before and after pressurization. Subsequent subtraction and analysis of speckle images yielded the three-directional surface displacement over a 25 x 25 mm region of interest (ROI), which was centered over the medial tibial plateau. Three repeat measurements of the tibial plateau deformation in response to 200 KPa pressurization were obtained. Measurements were repeated after introduction of a 10 mm diameter cylindrical subchondral bone defect, centered underneath the medial plateau at 5 mm distance to the plateau.

FEM Simulation: A proximal tibia FEM was created in ANSYS (ASA IP, Canonsburg, PA) (Fig 1b). Model geometry was generated by milling the proximal tibia specimen in 1 mm coronal planes. Images of each coronal section were obtained, and the tibial surface geometry was digitized and imported to ANSYS. The FEM contained over 5,000 tetrahedral 4-node elements. Trabecular bone was modeled with linear elastic material properties, where the E-modulus of 554 MPa was estimated from DEXA bone density scanning of the specimen [2]. Equally distributed pressure of 200 KPa was applied, first to the intact FEM, and subsequently after introduction of the 10 mm diameter subchondral bone defect.

RESULTS

3-D ESPI was able to acquire full-field three-directional surface deformation reports on the medial plateau with high reproducibility. Extraction of the out-of-plane deformation component yielded a plateau center deflection of $4.05 \pm 0.45 \mu\text{m}$ in the intact specimen. After introduction of the subchondral defect, the maximum deflection increased significantly to $6.16 \pm 0.22 \mu\text{m}$ (Fig.2a). The FEM delivered center deflections of $6.34 \mu\text{m}$ and $8.45 \mu\text{m}$ for the intact and subchondral defect model, respectively.

Fig. 2. Tibial plateau deflection: a) FEM, b) 3-D ESPI

DISCUSSION

This study demonstrated that the high sensitivity of 3-D ESPI allows for non-destructive evaluation of bone structure, while its three-directional displacement records are directly compatible with typical FEM output data. Since the sensitivity of 3-D ESPI is well below $0.5 \mu\text{m}$ [3], differences in outcome parameters can be attributed to the limited detail and accuracy of the FEM.

IN VIVO FUNCTION OF FASCICLES AND TENDINOUS STRUCTURES OF HUMAN GASTROCNEMIUS DURING STRETCH-SHORTENING CYCLE MOVEMENT

Sadao Kurokawa¹, Senshi Fukashiro², Tetsuo Fukunaga²

¹Joshobi University of Art and Design, Tokyo, Japan, sadao.kurokawa@nifty.ne.jp

²Department of Life Sciences, University of Tokyo, Tokyo, Japan

INTRODUCTION

The purpose of this study was to investigate the *in vivo* function of human fascicle and tendinous structures during the stretch-shortening cycle (SSC) movement by observing the behavior of the muscle-tendon complex (MTC) using real time B-mode ultrasonography.

METHODS

Eight male subjects were requested to perform drop jumping (one of the typical SSC movement) from height of 0.2m (DJ). Simultaneously, ultrasonographic, kinematic, kinetic and electromyographic data were recorded during the movement.

A real-time B-mode computerized ultrasonic apparatus (SSD-2000, Aloka, Japan) was used with an electronic linear array probe of 7.5 MHz wave frequency to obtain longitudinal ultrasonic images of the gastrocnemius medialis (MG) during DJ. The probe was carefully fixed onto the tissue surface with a specially designed tool and elastic tape. During DJ, the longitudinal ultrasonic images of the MG were stored consecutively in the cine-memory of the ultrasonic apparatus set to operate at 40 frames·s⁻¹. Fascicle lengths (L_{fascicle}) and Fascicle angles (α) were measured using NIH-image software.

The movements were filmed at 200Hz with a high speed digital video camera. Ground reaction force was recorded using a force platform. After synchronization of kinematic and kinetic data, instantaneous net joint moments about the ankle and knee were calculated using inverse-dynamics.

MTC length (L_{MTC}) of MG was estimated from knee and ankle joint angles (θ_k and θ_a , respectively) using the equation proposed by Grieve et al. (1978). Tendinous structure's length (L_{TS}), moment arm length (d), MG tendon force ($F_{\text{tendon MG}}$), MG fascicles force ($F_{\text{fascicles MG}}$) were calculated as follows;

$$L_{\text{TS}} = L_{\text{MTC}} - (L_{\text{fascicle}} \cdot \cos \alpha)$$

$$d = \Delta L_{\text{MTC}} / \Delta \theta_a$$

$$F_{\text{tendon MG}} = k_{\text{MG}} \cdot (M_{\text{ankle}} \cdot d^{-1})$$

$$F_{\text{fascicles MG}} = F_{\text{tendon MG}} \cdot \cos \alpha^{-1}$$

, where k_{MG} and M_{ankle} indicate the ratio of physiological cross sectional area of MG among plantar flexors and, the plantar flexing moments produced by single leg, respectively (see Kurokawa et al, 2001).

RESULTS AND DISCUSSION

During the down phase, MTC of MG was stretched by 4.0% relative to the length in the erect standing position. Fascicle, however, shortened by 10.6%. Consequently, the tendinous structures were stretched by 6.8%. During the following up

Fig. 1 Mean time histories of the displacement of mass center of body, muscle-tendon complex length, fascicle length and tendinous structures length during drop jumping. Time is expressed relative to instant of toe-off. Thin vertical bars indicate S.E.M., n=8 subjects.

phase, the fascicles continued to shorten only by 4.7% at relatively slow velocity (*i.e.*, quasi-isometric contraction of fascicle) while the MTC abruptly shortened by 6.5%. The work done by the fascicles was only 1.9 J in this phase. Elastic energy stored in the tendinous structures ($7.6 \pm 0.45 \text{ J}$) during down phase was derived from the work done by the fascicles ($5.0 \pm 0.49 \text{ J}$) and a part of mechanical energy change of subject between in the onset of down phase and in the end of up phase ($2.6 \pm 0.39 \text{ J}$). 76% of the amount of elastic energy stored in the tendinous structures ($5.8 \pm 0.6 \text{ J}$) was reutilized, and it account for 75% of the amount of mechanical work done by the MTC during up phase. It is highly probable that rapid recoil of tendinous structures allows the muscle fibers to behave quasi-isometrically during the up phase. It could be concluded that the fascicles function as a force generator operating high force region of force-length-velocity relationship, and the tendinous structures play the role of velocity generator during concentric phase, which was preceded by eccentric phase (pre-stretch) in SSC movement. And so, high power out put may be realized during this phase.

GENETIC VARIATIONS INFLUENCE BONE'S SENSITIVITY TO THE LOSS OF FUNCTIONAL WEIGHTBEARING

Stefan Judex, Russell Garman, Maria Squire, Clinton Rubin
Department of Biomedical Engineering
State University of New York, Stony Brook, NY

INTRODUCTION

The structure of the adult skeleton is determined, in large part, by its genome. Whether genetic variations also influence the degree of bone loss induced by bedrest, spaceflight, or aging is unknown. Using genetically distinct strains of inbred mice displaying greatly different bone mass and architecture (**Fig. 1**), we have recently demonstrated that the loss of functional weightbearing reduced osteoblastic activity in only one of three mouse strains considered while bone formation was unaffected in the other two strains. Here, we focused on the balance between bone formation and resorption and investigated whether genetic variations also control the effectiveness of mechanical disuse to alter bone quantity and quality.

METHODS

Adult (16wk) C57BL/6J (B6), BALB/cByJ (BALB), and C3H/HeJ (C3H) mice were subjected to either hindlimb suspension or free cage activity ($n \sim 10$ per group) in protocols up to 3wk. Upon sacrifice, distal femurs were scanned in a micro-computed tomography (μ CT) scanner (Scanco Medical AG, Switzerland) at a resolution of $11 \mu\text{m}$ and fractional bone volume (BV/TV), trabecular number (Tb.N), trabecular spacing (Tb.Sp), trabecular thickness (Tb.Th), degree of anisotropy (DA), and structural model index (SMI, a measure of whether trabeculi are more plate-like or more rod-like shaped) was determined for the trabecular bone fraction.

Figure 1. Micro-computed tomography images of the distal femur, volumetrically rendered longitudinally between the femoral condyles from a 4 month old (a.) B6, (b.) BALB, and (c.) C3H mouse depicting the differences in trabecular and cortical bone structure associated with the differential genotype.

RESULTS AND DISCUSSION

Fractional trabecular bone volume (BV/TV) of the distal femur was five-fold greater in BALB than in B6 mice (**Fig. 2**). Trabecular bone volume was similar between BALB and C3H mice despite the approximately 25% higher femoral bone mineral density (BMD) in C3H mice when BMD is averaged over the entire femur including both cortical and trabecular

bone. The effect of hindlimb suspension on trabecular bone quantity and quality was greatly different in the three strains of mice. The loss of functional weightbearing caused a 60% reduction ($p < 0.001$) in the amount of trabecular bone in BALB mice while no bone tissue was lost in C3H or B6 mice (**Fig. 2**). This large decrease in bone quantity was accompanied by compromised bone architecture in the BALB mice: connectivity density was decreased by 35% ($p < 0.03$), trabecular number was decreased by 20% ($p < 0.003$), and mean intercept length in the longitudinal direction was increased by 70% ($p < 0.007$). The SMI increased by 80% ($p < 0.0004$). In contrast, bone quality was not significantly

reduced in BALB but not in C3H mice (mean \pm SD, $n \sim 10$).

These data reveal the rapidity and severity by which mechanical unloading selectively reduces trabecular bone volume in BALB mice, but not in the similarly dense C3H strain or low bone density B6 strain. The current data are also consistent with our earlier studies in these three strains of mice which demonstrated that only osteoblasts from BALB mice responded to the loss of mechanical stimuli.

SUMMARY

We demonstrated that the efficacy of a strongly catabolic stimulus heavily relies on genetic makeup. Extrapolated to humans these data may explain the large individual variability in bone loss during bedrest, spaceflight, or aging. Our data also indicate that genetic variations may influence the effectiveness of therapeutic interventions of bone diseases. We are currently exploiting this large difference in mechanosensitivity between these three strains of mice to identify the genetic basis for this quantitative trait as well as to search for regulatory genes involved in the process by which mechanical stimuli (or lack of them) alter bone formation.

ACTIVE MYOFIBER STRESS DISTRIBUTION IN PATIENT SPECIFIC MODELS OF CARDIAC MECHANICS

Liesbeth Geerts¹, Peter Bovendeerd², Roy Kerckhoffs^{1,3}, Theo Arts^{1,4}

Departments of ³Physiology and ⁴Biophysics, Maastricht University, Maastricht, The Netherlands

p.h.m.bovendeerd@tue.nl

INTRODUCTION

Mathematical models of cardiac mechanics are developing into a stage where patient specific modeling will be possible. Simultaneously, Magnetic Resonance Tagging offers the possibility of non-invasive assessment of cardiac tissue deformation. The combination of mathematical modeling and tagging may lead to a diagnostic tool, with which abnormalities in the cardiac deformation pattern can be deduced to the underlying tissue pathology. However, while some model parameters, e.g. geometry, can be assessed for each patient individually, for several model parameters, e.g. myofiber orientation, default model parameters must be used. In this study, we assess the effect of incorporating a default myofiber orientation field in a patient specific geometry, on the model estimated active myofiber stress distribution.

METHODS

A finite element model of left ventricular (LV) mechanics (Bovendeerd et al., 1992) was used. Inner and outer LV surfaces were approximated by confocal ellipsoids. Variation between patient geometries was modeled by variation of the ellipsoid short axis/long axis ratio from 0.2 (GeoCYL) through 0.35 (GeoREF) to 0.99 (GeoSPHERE) (see Figure 1). Myofiber orientation was quantified by helix and transverse angles. Reference angle values (FibREF) were chosen to yield a practically homogeneous stress distribution in the reference geometry (Rijcken et al, 1999). Passive material was modeled nonlinearly elastic, transversely isotropic, and virtually incompressible. Active stress development was uniaxial, depending on myofiber strain, strain rate and time. LV afterload was simulated using a 3 element Windkessel model.

Figure 1: Geometries and helix angles in the model LV.

A complete cardiac cycle was simulated. Model predicted active stress was averaged in time over the ejection phase. Sensitivity of the equatorial transmural active myofiber stress distribution to geometry variation was assessed. For

comparison, sensitivity to changes in transmural course of the helix fiber angle was determined, by changing, in the GeoREF geometry, either the slope by 10% (Fib*0.9 and Fib*1.1) or the offset by 5 degrees (Fib+5 and Fib-5) (see Figure 1).

RESULTS

Transmural stress distribution was virtually homogeneous in the GeoREF (48.1±1.5 kPa; mean±SD) geometry. Midwall stress was relatively low in the GeoCYL geometry, and high in the GeoSPHERE geometry and inhomogeneity in stress increased (GeoCYL: 45.9±5.2 kPa; GeoSPHERE: 43.2±5.5 kPa). A change in slope of the helix angle course (Fib*0.9, Fib*1.1) resulted in a redistribution of stress between midwall and superficial layers; a change in offset (Fib-5, Fib+5) gave a redistribution of stress between the subendocardial and subepicardial layers (Figure 2). For all helix angle variations SD in stress increased to about 5 kPa.

Figure 2: Equatorial time-averaged active myofiber stress, for varying geometry (left) and fiber orientation (right).

DISCUSSION AND CONCLUSIONS

Model geometry was varied over a wide range, expected to cover the majority of patient LV geometries. With the default fiber field, these geometry variations change active myofiber stress by about 10%. A similar change in stress is induced by a 10% change in slope or a 5 degree change in offset of the transmural course of the helix angle. The latter angle changes correspond to the accuracy of experimental angle data which makes the benefit of accounting for patient specific geometry questionable when using experimental fiber data. However, if fiber orientation is chosen for homogeneous distribution of active myofiber stress (Bovendeerd, 1992) or myofiber shortening (Rijcken, 1999), the optimal transmural range of the helix angle is expected to increase with decreasing short axis/long axis ratio of the ventricle.

MULTIJOINT CONTROL DURING SHORT DURATION MOVEMENTS IS SCALED USING BIARTICULAR MUSCLES

Witaya Mathiyakom, J.L. McNitt-Gray, K.E. Costa and P.S. Requejo
Biomechanics Research Laboratory, Department of Kinesiology, University of Southern California
Los Angeles, CA 90089, USA mathiyak@usc.edu

INTRODUCTION

Control and generation of large reaction forces during short duration movements presents a significant challenge to the neuromuscular system prior to and during contact with the supporting surface. In this paper, we tested the hypothesis that the multijoint control strategy used to generate impulse during short duration multijoint tasks ($<0.2s$) would be regulated by impedance like control as exhibited during the impact phase of landing tasks (McNitt-Gray et al., 2001). The take-off phase of Forward (forward translating, forward rotating) and Inward (backward translating, forward rotating) dives provided a set of practiced, goal directed multijoint movements to test this hypothesis. We expected that a) the set of muscles used to generate the impulse during the take-off phase of the dives would correspond with the net joint moments (NJMs) required by each task (**FW**: hip flexor and knee extensor NJM (Mathiyakom et al., 1998), **IN**: hip and knee extensor NJM (Mathiyakom et al., 1999) and b) the activation of biarticular muscles would be used to scale the impedance-like control between tasks.

METHODS

Eight US National Level divers (male = 5, female = 3) performed FW and IN dive take-offs ($n=2$) from a force platform onto a landing pit, using their competitive style. Two trials of the forward (FW) and inward (IN) rotating dive take-offs were analyzed. Sagittal plane kinematics (60 Hz), reaction force (1200 Hz) and muscle activation (surface EMG; 1200 Hz) of eight lower extremity muscles were simultaneously recorded and synchronized at plate departure. Significant between task differences in normalized EMG (20 ms bins) were tested using paired t-test ($p < 0.05$).

RESULTS AND DISCUSSION

Coactivation of muscles crossing both sides of the joints suggests that impedance-like control strategy (Hogan, 1984) was used to stabilize the joints when generating large (4-6 times body weight) impulsive forces ($<0.2s$) of both dives. As hypothesized, between-task differences in the activation patterns of biarticular knee-hip muscles were observed and corresponded with the specific NJM requirements of each task (Figure 1). Activation of the rectus femoris was significantly larger during the FW, whereas, activation of the hamstrings was significantly greater during the IN dive take-off. Regulation of multijoint joint control through the scaling of biarticular muscle activation may serve as a coordinative

structure for short duration movements (Tuller et al., 1982). These results are consistent with rules of muscle coordination observed in other multijoint tasks (Yamashita, 1975; Wells & Evans, 1987; Prilutsky, 2000).

Figure 1: Activation of the primary knee and hip bi-articular muscles was scaled according to the mechanical demand imposed on the lower extremity during the take-off phase. No significant differences in trunk angular positions nor GM activation were observed between dives.

SUMMARY

Multijoint control during these short duration movements was scaled by modulating the activation of biarticular muscles. Activation of the bi-articular muscle was scaled according to the mechanical demands imposed on the lower extremity during contact. No significant differences in uniarticular hip extensor muscles, however, was observed between tasks.

INTRODUCTION

Idiopathic scoliosis develops during a rapid growth period. This suggests the growth of spinal column is one of primary causes of the idiopathic scoliosis. The etiology of idiopathic scoliosis remains to be elucidated [Lowe et al., 2000], although the spinal scoliosis simulation has been reported with local and/or asymmetric bone growth [e.g. Kawabata et al., 1988; Stokes et al., 1990]. The purpose of this study is to examine the spinal scoliotic curve from the viewpoint of imbalanced growth between the bone and surrounding ligament subsystems by computational biomechanics approach.

METHODS

A spinal column with rib cage was developed in three-dimensional finite elements by referring normal geometry and anatomy. The vertebrae were inter-connected by anterior and posterior longitudinal, intertransverse, supraspinous and interspinous, capsular ligaments and ligamentum flavum. This spine comprised of 8-node brick elements for bone and disc and the tension-only spar elements for spinal ligaments. The resultant spinal system was of 5,320 nodes and 4,646 elements.

The growth strain was applied to the bone elements of the spine model, while no growth was assumed for the ligaments, as an extreme situation. All the degree of freedom was constrained at the lower surface of L5 vertebra. The lateral translation and the rotation in sagittal plane were prescribed at C2 vertebra. The lack of symmetry with respect to the sagittal plane was considered for the asymmetric arrangement of the cardiac and arterial system, and a small disturbance was introduced at T8 level as the aortic force [Williams et al., 1989]. In this simulation, the effect of high growth rates introduced locally was also examined on the scoliotic curve pattern. The spinal deformation was simulated using ANSYS5.6 package (Ansys Inc., Houston, PA, USA).

RESULTS AND DISCUSSION

Figure 1 shows the frontal and sagittal vertebral alignments and vertebral axial rotation. Scoliotic curve was resulted by imbalanced growth between bone and surrounding ligament

subsystems. The curve was of rightward convex thoracic pattern with apex at level T9. It showed the vertebral axial rotation toward the convex side of the scoliotic deflection. The scoliotic simulations with locally high growth rates represented significant influence on scoliotic deflection and rotation.

SUMMARY

The scoliosis and rotation were investigated based on the accumulation of internal stress/strain caused by the imbalanced growth between the bone and surrounding ligament subsystems. The results suggested that the imbalanced growth between bone and spinal ligaments plays a potential role in idiopathic scoliosis as a biomechanical etiology.

FULL-FIELD STRAIN MEASUREMENT OVER ARTICULAR CARTILAGE CROSS-SECTIONS WITH ELECTRONIC SPECKLE PATTERN INTERFEROMETRY

O. K. Erne¹, L. Ehmke¹, J. Reid², M. Bottlang¹

¹Legacy Clinical Research & Technology Center, Portland, OR. 503-413-5489, mbottlan@lhs.org

²Oregon Health & Science University, Portland, OR

INTRODUCTION

Quantitative assessment of strain distributions in articular cartilage is key to understand its normal function and disease mechanisms. Over the past decades, a multitude of tests were introduced to measure static and dynamic constitutive properties of articular cartilage. Within the distinct layers of articular cartilage, pronounced variations in material properties were observed and modeled (Mow, 1997; Flachsman, 2001). Despite widespread efforts to quantify these non-linear strain distributions, no continuous full-field strain map across articular cartilage has been acquired to date. We hypothesize, that an advanced Electronic Speckle Pattern Interferometry technique (3D-ESPI) can be used to measure the strain distributions across diarthrodial joints. In this study, we employed a 3-D ESPI system to measure strain distributions on confined articular cartilage *in situ*, loaded in quasi-static compression. For comparison, we additionally obtained the strain profile across a homogeneous specimen.

METHODS

A novel 3-D ESPI system was used to measure surface strain fields on two specimens, a homogeneous fiber composite, and articular cartilage of a diarthrodial joint.

A paper based fiber composite with a width of 6 mm was confined between two aluminum brackets, in a manner that the surface of the brackets and the composite were in the same plane. The cartilage specimen was harvested from a fresh frozen bovine femoral-tibial joint. The joint was sectioned in para-coronal planes using a diamond saw to obtain a 3 mm thick joint cross-section. The articular cartilage remained attached to the underlying epiphysal bone of the tibia and femur. Each specimen was loaded in uniaxial compression in displacement control to a nominal strain amplitude of 1.65% in a custom-built setup. While the composite specimen was only confined by the compression brackets, the surface of the cartilage specimen was additionally confined underneath a glass-plate to simulate apposition of the neighboring joint cross-sections. In addition, the surface of the cartilage specimen was stained with gold chloride to obtain adequate reflective properties for 3-D ESPI measurements. Compression was applied incrementally with a precision micrometer, and the resulting total displacement over each specimen was measured with a displacement transducer (LVDT LD 400-5, Omega, Stamford, CT). A laser-based quantitative 3D-ESPI system (Q100, Ettemeyer AG, Nersingen, Germany) was employed to measure the full-field surface deformation and strain on the specimen surface after each incremental load step. ISTR software (Ettemeyer AG, Nersingen, Germany) was used for speckle pattern image analysis.

Fig. 1: Side view of test setup with cartilage specimen.

RESULTS

The 3D-ESPI system acquired continuous full-field strain maps on both specimens. The specimens demonstrated highly distinct strain distributions. The strain profile over the aluminum brackets and the composite specimen approximated a step function (Fig.2a). The average compressive strain across the 6 mm wide composite was 1.44%, and approximated the total applied compression of 1.65%. The strain profile across the joint specimen exhibited two compressive strain peaks of up to 2.23% strain. The strain peaks exceeded the predicted strain by up to 35% and were observed at the middle layers of each cartilage. Strain at the cartilage surface layer was 86% smaller as the total applied compressive strain of 1.65% (Fig.2b).

Fig.2: Strain distributions and strain profiles on a) composite specimen; and b) joint cross-section.

DISCUSSION

The results of this study demonstrate that 3D-ESPI is a powerful tool to elucidate non-linear strain distributions across diarthrodial joints. Further refinement of the experimental approach is likely to provide a unique approach to quantitative delineate normal and degenerative joint properties.

³Graduate Student

INTRODUCTION

Ankle Foot Orthoses (AFOs) have been considered useful aid for the disabled patients with gait disorder to assist standing and walking activities. Such aids primarily support and keep the ankle joint at an appreciate position by constraining the movement of ankle joint. Although the constraint of the joint movement brings some restriction in daily life activities at the same time, few studies have been reported on the effect of joint constraint. In this study, the effect of ankle joint constraints is examined in terms of different ranges of motion at ankle joint for the maintenance of standing posture under the forward translation of foot floor.

METHODS

In this investigation, six healthy male subjects participated voluntarily. The experimental set-up is shown in Figure 1. Subjects are requested to stand on the motion platform (MMS-612E2, Mitsubishi Precision) at horizontal position wearing metal column AFOs on their both limbs. The motion platform is translated in forward direction simulating the departure of vehicle such as trains or buses, in four different patterns by the combination of high and low maximal acceleration (800mm/s^2 , 250mm/s^2) and short and long translation (53mm, 150mm). The metal column AFO enables us to adjust the ankle joint range of motion (ROM). By using this mechanism, five ROM conditions are employed of the experiment (Table 1).

The angular displacements of lower limb joints are recorded by the goniometers (M110/M180, P&G) mounted on the joints of right limb. The center of pressure and resultant force of foot pressure are recorded by the foot pressure sensor (Pedar standard/expert, Novel). The joint moments are calculated based on two-dimensional four-link model of human body consisting of foot, shank, thigh, and trunk. The joint stiffness is calculated for each time interval of 0.2 second as the slope of joint moment against the angular displacement.

RESULTS AND DISCUSSION

In the cases with dorsal ROM constraint (case3, case4), the angular displacements at joints were smaller than those in the cases without dorsal ROM constraint (case0, case1, case2), exhibiting the smaller body motion. It suggested us the large influence of the dorsal flexion for the maintenance of standing posture, and supported the importance of the dorsal flexion in maintenance of standing posture in sagittal plane reported [Mihelj et al. 2000]. When the dorsal ROM was constrained,

Figure 1 : Experimental system

Table 1 : Ankle joint constraint cases

	case0	case1	case2	case3	case4
dorsal	B	U	U	C	C
plantar	B	U	C	U	C

B: bare foot C: constrained U: unconstrained

Figure 2 : Knee joint stiffness (800mm/s^2 , 150mm)

the maxima of the joint moments decreased, but the joint stiffness increased (Figure 2). This showed that the smaller body motion under the dorsal ROM constraint was understood by active stiffness adjustment, by using the muscle function.

INTRODUCTION

Hemiplegia is a typical and serious pathology by cerebral stroke. Following to the initial recovery stage, locomotion is frequently disordered due to involuntary plantar flexion of ankle joint by spasticity. Ankle Foot Orthosis (AFO) is prescribed to assist such subjects keeping ankle joints at neutral or slightly dorsal position. In this context, the mechanical function of AFO closely related to spasticity in hemiplegic patients. This study examines characteristics of hemiplegic ankle joint with spasticity from the viewpoint of biomechanical ankle joint moment.

METHODS

AFOs are requested to secure the toe clearance in swing phase by resisting to the involuntary plantar flexion of ankle joint. Thus, it is the first step of AFO prescription and design to measure the plantar flexion moment at ankle joint caused by spasticity. Figure 1 shows the experimental set-up used to investigate the relation between ankle joint moment and ankle joint angle.

Simulating the manual treatment by physical therapist, subjects' ankle joints were flexed in dorsal/plantar direction passively through the operation lever. Subjects were instructed to keep upright sitting posture during the experiment. Six hemiplegia (45-77 years old) and six normal subjects (22-24 years old) participated voluntarily in the experimental measurement. All hemiplegic subjects have a capability to walk with AFO independently.

RESULTS AND DISCUSSION

Figure 2 shows typical examples of ankle joint angle and moment relationship of a normal subject and a hemiplegic subject. Lance et al. (1980) defined the spasticity as a motor disorder characterized by velocity-dependent increase in tonic stretch reflex. The observed relationship between ankle motion and resistant moment were dependent on the angular velocity and were larger than those of normal subjects. Under the high angular velocity over 100 deg/sec, most hemiplegic subjects exhibited moment oscillation i.e. clonus. This oscillation might be caused by hyperexcitability of a kind of the stretch reflex.

Figure 1 : Measurement set-up for ankle joint angle and moment

Figure 2 : Typical of ankle joint angle-moment relationship of hemiplegia and normal subjects

The joint moment deviation of hemiplegic subjects increased rapidly around the angular velocity of 80-120 deg/sec. During the gait motion, the range of angular velocity of hemiplegic subjects may be slower than this threshold in general. It is possible to estimate an appropriate stiffness of an AFO suitable for each patient by referring to resistant moment in this study, although these remains some possibility that factors such as mental intention happen to bring some excess joint moment over the estimated in swing phase.

EFFECT OF PHYSICAL THERAPY AND AFFERENT STIMULATING INSOLES ON MOTOR ABILITIES IN PARKINSON PATIENTS

S. Kimmeskamp, E.M. Hennig and T.L. Milani

University of Essen, Department of Human Locomotion; 45131 Essen, Germany; stefan.kimmeskamp@uni-essen.de

INTRODUCTION

Parkinson's disease (PD) is caused by a deficiency in the neurotransmitter dopamine in the region of the basal ganglia of the brain. Parkinson patients show combined clinical symptoms of rigidity, bradykinesia or even akinesia, as well as resting tremor. They also experience disorders of posture, balance, and gait. Although there are indications of the benefit of physical therapy in PD, there is still need to identify the core elements in PD rehabilitation (1,2). In this study we compared the effects of balance training and trunk flexibility exercises on motor abilities in Parkinson patients. Parkinson patients use external cues (visual or auditory) to improve motor performance. Therefore, a second purpose of this study was to test the therapeutic effect of additional sensory input, provided by foot afferent stimulating insoles. The hypothesis behind this approach is that PD patients use the additional external information (cues) to partially compensate the basal ganglia pathology (2). It is suspected that foot sensation has a considerable influence on locomotion and posture control.

METHODS

96 Parkinson patients were randomly assigned to four different intervention groups. The first group (BN) performed balance training and wore an insole with 4 mm high nubs, evenly distributed across its surface. This insole stimulates skin receptors of the foot. The second group (BB) also trained balance, but wore a "placebo" insole with a formed foot bed (hardness: shore 36 A) and an even surface. The third group (TN) carried out trunk flexibility exercises. They also wore the stimulating insole. The fourth group (TB) also performed trunk flexibility exercises, but wore the smooth insole. The duration of the intervention period was 4 weeks. During this period the physical therapy exercises were performed daily, for 30 minutes. Additionally, the patients were asked to wear the insoles every day as long as possible. Patients with a change of medication were excluded from the study. 22 patients who were not involved in any intervention served as a control group (Co). Gait and balance analyses were performed before and after the intervention period, using a mobile pressure insole system (NOVEL GmbH, Munich). For gait and balance measurements all patients wore a simple canvas shoe. The intervention insoles were not worn during the measurements. The balance task included parallel stance, tandem stance, single limb stance and functional lean forward. Center of Pressure (COP) data were collected over a maximum period of 30 seconds for all balance tasks. Prior to the measurements a neurological examination was undertaken to classify the motor impairment according to the UPDRS-Score. Pre- and post measurements were undertaken during best medication status of the patients and at the same time of the day. The COP_{net} displacement as well as the characteristics of sway in anterior-posterior (A/P) and medial-

lateral (M/L) directions were calculated for all balance tasks. A two way ANOVA analysis was performed to examine differences between the intervention groups.

RESULTS & DISCUSSION

For the parallel stance condition the two way ANOVA revealed a significant reduction of the COP displacement in A/P direction for the balance training group ($p < 0.01$). A similar result was observed for the COP_{net} excursion ($p < 0.05$). However, neither the trunk flexibility exercises nor any insole led to significant changes in parallel stance performance. The parallel stance results indicated that a daily performed balance training helps PD patients to achieve a greater safety during standing.

Figure 1) Changes in functional lean forward (Post – Pre)

Figure 1 shows the changes in the functional lean task. This task tests the ability of PD patients to shift the COP in a parallel stance position as far forward as possible without lifting the heel from the ground. The nub insole has a highly significant ($p < 0.01$) positive effect on the ability of PD patients to lean forward (figure 1). This indicates a therapeutic effect of the nub sole, resulting in an increase of the functional base of support in PD patients

RADIOGRAPHIC LANDMARKS OF THE KNEE FLEXION-EXTENSION AXIS

Martin, K¹; Callahan, E¹; Sommers, MB¹; Marsh, J²; Bottlang, M¹

¹Legacy Clinical Research & Technology Center, Portland, OR; email: mbottlan@lhs.org

INTRODUCTION

Articulated external fixation can be utilized to restore joint function of severely injured knee joints (Simonian, 1998). However, in a clinical scenario it is crucial to closely approximate the flexion-extension axis of the knee to maximize the attainable joint motion. No intra-operative radiographic axis detection technique has been introduced to date, which would allow for proper alignment of an external hinge to the knee. In this study, we identified landmarks to indicate the predominant flexion-extension axis of the knee on lateral radiographs. We furthermore quantified the effect of reversing the radiographic exposure direction on radiographic projections. Both of these aspects are directly applicable to increase the accuracy of hinged fixator application to the knee joint.

METHODS

Eight fresh frozen human cadaveric legs were amputated 130 mm proximal and distal to the knee joint line and mounted in a Plexiglas frame at 30° of knee flexion. Each specimen was aligned and secured such that the predominant flexion extension axis of the knee joint was oriented along the radiographic axis of a standard C-arm fluoroscope (9600 OCEM, Salt Lake City, UA). This alignment position was determined by the centers of two concentric circles fitted to the posterior 140° aspects of the medial and lateral condyles [Hollister, 1993]. Radiographic images were obtained for this 'on-axis' position as well as for 8 distinct 'off-axis' orientations: 5° and 10° each of internal and external, varus and valgus rotation. Two sets of images were recorded with (1) the radiographic source being located lateral to the specimen and (2) the source being located medial to the specimen. At all times specimens were centered between the C-arm source and receiver. All radiographs were comparatively analyzed to extract the indices which most sensitively and reliably depicted femoral on-axis alignment. Indices were quantified on each pertinent radiograph using quantitative image analysis software (PV Wave, Visual Numerics, Inc., Houston, TX) after use of gray-scale equalization and edge enhancement algorithms on the digital radiographs.

RESULTS

The accuracy of on-axis alignment on lateral radiographs (x-ray source lateral to specimen) was documented in terms of the center disparity **CD** of circles fitted to a 140° arc on the posterior condyles. The average center disparities in anteroposterior (**CD_{AP}**) and proximodistal (**CD_{PD}**) directions were 0.6 ± 1.7 mm and -1.1 ± 1.4 mm, respectively (Fig. 1a). The corresponding radii of the circles fitted to the medial and lateral condyles were 17.9 ± 1.7 mm and 19.4 ± 1.4 mm, respectively. The posterior arc of the medial condyle was projected inside the lateral condylar arc. Radiographs obtained with 5° and 10° internal/external femur rotations significantly increased the center disparity in anteroposterior direction

(**CD_{AP}**), while 5° and 10° varus/ valgus exposures significantly altered the center disparity in proximodistal direction (**CD_{PD}**).

Figure 1a) Center disparity index; **b)** on-axis femur alignment

In addition to **CD**, two further radiographic indices were determined: The **RB** index for internal/external rotational alignment, expressed in terms of the width of a radiodense band with respect to the femoral shaft diameter (**RB**=d/f). And the **DR** index for varus/valgus directional alignment, expressed in terms of the radius difference between the circles fitted to the medial and lateral condyles (Fig. 1b). On-axis radiographs were characterized by **RB** = $14 \pm 3\%$ and **DR** = 0.9 ± 1.9 mm (Fig. 2a, 2b).

Figure 2: a) Rotation index; **b)** Varus/Valgus index

Shifting the radiographic source from the lateral to the medial side altered the appearance of the medial condylar arc relative to the lateral condylar arc, with the radii of circles changing to 18.1 ± 1.2 mm and 17.9 ± 1.6 mm, respectively.

DISCUSSION

While the reported **CD** index requires implementation of a circle-fitting algorithm, the **RB**, and **DR** indices can easily be assessed intra-operatively by linear measurement, and provide distinct sensitivity to systematically adjust femoral internal/external, and varus/valgus rotation. Also important was the finding that if a radiograph of the knee is obtained with the x-ray source located lateral, the anatomically larger medial condylar arc is projected inside the smaller lateral arc. This is especially important since radiograph exposure with the source located laterally is routinely used in knee fluoroscopy.

TRAUMATIC BRAIN INJURY IN AN ACCELERATION-DECELERATION SCENARIO

Yung-Hua Chu¹ and Michael Bottlang¹

¹Legacy Clinical Research & Technology Center, Portland, OR. 503-413-5489, mbottlan@lhs.org

INTRODUCTION

In the United States, traumatic brain injury (TBI) is the leading causes of death and long-term disability among people below the age of 45. Evidence of diffuse axonal injury (DAI) is observed in over 35% of all TBI injuries. The objective of the present study is to model a sequence of acceleration-deceleration to the head that will induce shear strain concentrations which closely reflect clinically observed DAI. In 1989, Adams introduced a grading system for DAI, indicating *Grade 1* DAI as axonal damage limited to white matter; *Grade 2* DAI as focal lesions in the corpus callosum in addition to *Grade 1*; and *Grade 3* DAI as focal lesions in the brain stem in addition to *Grade 2*. In addition, we hypothesize that cerebrospinal fluid (CSF) can significantly reduce shear damage to the brain. Therefore, we created a finite element model (FEM) which accounts not only for distinct material properties for specific brain compartments, but which also explicitly models CSF.

MATERIAL AND METHODS

The geometry of a para-sagittal plane of the head was reconstructed from the Visible Human Male data set, and the finite element analysis was proceeded with ANSYSTM (Fig. 1). The nonlinear viscoelastic material properties of the cerebral and cerebellar white matter were assigned with exponential decay shear modulus $G_0=39.47\text{KPa}$, $G_\infty=17.24\text{KPa}$ and a decay constant $t=0.01\text{s}$ (Bandak, 1995). A constant high bulk stiffness of $K=1.86\text{GPa}$ was implemented to simulate near incompressibility of brain tissue (Bandak, 1995). The material properties of white matter were assumed four times stiffer than those of the cerebral and cerebellar cortex and thalamus (gray matter) to account for their fibrous structure (Cotter et al., 2001). CSF was modeled as a viscoelastic solid that was assumed 10 times softer than the cerebral white matter. The skull and the cervical vertebrae were modeled as homogeneous linear elastic solids with $E=6.5\text{GPa}$ and $\nu=0.2$ (Bandak, 1995).

Figure 1: Finite element geometry and distinct compartments of the brain.

To simulate a moderate to severe brain injury over an acceleration-deceleration sequence of 30 ms, a 5,000N frontal step load was applied to the forehead for 15 ms, followed by a dorsal step load of $-5,000\text{N}$ for 15 ms to the hind head. Boundary conditions enforced angular rotation of the skull around a hinge joint at the second cervical vertebra (C2). Nonlinear time-dependent transient dynamic analysis was performed to allow for large deformation, while accounting for inertial effects.

RESULTS

CSF absorbed more than 9 times the shear strain energy than any other brain compartment. During backward acceleration of the head, the interface between gray and white matter of the cerebellum observed shear strain concentrations indicative of *Grade 1* mild brain injury. *Grade 2* moderate DAI was initiated in the distal side of the corpus callosum. During backward deceleration (i.e., after application of the dorsal load step) of the head, the shear strain rate in brain compartments increased rapidly to its maximal values due the large inertial effect during load reversal (Fig.2). *Grade 3* severe DAI was predicted close to distal site of the brain stem.

Fig. 2: Shear strain distribution during deceleration at 25 ms.

DISCUSSION

The results of this study demonstrated that CSF reduced the shear strain to brain compartments by absorbing shear strain energy. The 5,000 N focal impact load and time history realistically resembled acceleration and deceleration conditions, which are associated with *Grade 1* mild DAI, *Grade 2* moderate DAI to *Grade 3* severe DAI. The results of this study closely correlate with clinically observed diffuse axonal injury of the brain during an angular acceleration-deceleration sequence.

REACTION FORCES INDUCED BY MUSCLES IN THE PRESENCE OF COMPLIANT CONTACT

Frank C. Anderson, Allison S. Arnold, and Scott L. Delp

Biomechanical Engineering Division, Mechanical Engineering Department, Stanford University, Stanford, CA, USA

E-mail: fca@stanford.edu

Web: <http://www.stanford.edu/group/nmb1>

INTRODUCTION

Musculoskeletal simulations have tremendous potential to clarify the dynamical actions of muscles during movement (Zajac and Gordon, 1989). However, determining the actions of muscles during tasks that involve compliant interactions with the environment remains a challenge. Reaction forces are generated in response to muscle forces and must be taken into account to understand how individual muscles contribute to the motions of the body. In the presence of compliant contact, it is difficult to know what portion of a reaction force to attribute to an individual muscle because reaction forces are position- and velocity-dependent and do not respond to muscle forces instantaneously. We have developed a method to calculate the reaction forces induced by muscles during movement when interactions between the body and the environment are modeled using viscoelastic elements.

METHOD

Our method is applicable to forward dynamic simulations in which interactions between the body and the environment (e.g., the foot and the ground) are modeled by a set of damped springs distributed over the contact area. The objective of the method is to decompose the reaction force (F_s) of each spring into component forces that are attributable to active forces within the body:

$$F_s = F_s^G + F_s^C + \sum F_s^m, \quad (1)$$

where F_s^G , F_s^C , and $\sum F_s^m$ represent the contributions to the reaction force of the forces due to gravity, Coriolis-centripetal effects, and muscles, respectively.

The force response of a damped spring results from changes in its displacement (x) and velocity (v). This force response can be expressed as a Taylor series expansion of the equations used to model the spring:

$$dF_s = F_s(x+dx, v+dv) - F_s(x, v) = \frac{\partial F_s}{\partial x} dx + \frac{\partial F_s}{\partial v} dv + O(2), \quad (2)$$

where dx and dv are changes in the displacement and velocity of the spring, respectively, and $\partial F_s / \partial x$ and $\partial F_s / \partial v$ are the instantaneous stiffness and viscosity of the spring, respectively. When $|dx| \ll 1$ and $|dv| \ll 1$, the second order and higher terms, $O(2)$ in Eq. (2), are small and dF_s can be expressed in terms of linear decompositions of dx and dv :

$$dF_s \approx \frac{\partial F_s}{\partial x} \{dx_G + dx_C + \sum dx_m\} + \frac{\partial F_s}{\partial v} \{dv_G + dv_C + \sum dv_m\} \quad (3)$$

Hence, to decompose F_s it is necessary to determine how each force in the body contributes to changes in the displacement and velocity of the spring.

Using a Taylor series expansion in time, dx_m and dv_m can be expressed as functions of the accelerations induced by each muscle:

$$dx_m(t+dt) = v_m \cdot dt + \frac{1}{2} a_m \cdot dt^2 \quad (4)$$

$$dv_m(t+dt) = a_m \cdot dt, \quad (5)$$

where a_m and v_m are the acceleration and velocity of the spring induced by the muscle and dt is a small time step analogous to the integration time step used during a forward simulation. The acceleration of the spring induced by the muscle is computed from the inverse of the system mass matrix (I^{-1}), the force in the muscle (F_m), and the corresponding reaction component (F_s^m):

$$a_m = \Psi(I^{-1}\{F_m + F_s^m\}), \quad (6)$$

where Ψ is a transformation between the accelerations of the generalized coordinates of the model and the acceleration of the spring. Eqs. (2)-(5) can be combined to obtain an expression for the change in spring force that occurs during a time step due to F_m :

$$dF_s^m(t+dt) \approx \frac{\partial F_s}{\partial x} (v_m \cdot dt + \frac{1}{2} a_m \cdot dt^2) + \frac{\partial F_s}{\partial v} (a_m \cdot dt). \quad (7)$$

The decomposition is performed by integrating Eqs. (5) and (7) concurrent with the forward dynamic simulation:

$$F_s^m(t) = F_s^m(t_o) + \int_{t_o}^t dF_s^m dt, \quad v_m(t) = v_m(t_o) + \int_{t_o}^t dv_m dt, \quad (8)$$

where $v_m(t_o)$ and $F_s^m(t_o)$ are initial values for the spring velocity and force induced by the muscle and t_o is the initial time of the simulation. Analogous integrations are performed for each force term.

RESULTS AND DISCUSSION

Several investigators have used musculoskeletal simulations to examine the actions of muscles during movement. In these studies, the reaction forces induced by muscles were either ignored, or were estimated using perturbed forward integrations (Neptune et al., 2001) or hard constraint techniques (Anderson and Pandy, 2001a). These approaches have important limitations. The perturbed integration method is imprecise, and it does not allow superposition of the reaction components (Eq. (1)) to be verified. Hard constraint techniques assume rigid contact between the body and the environment. To the extent that contact is not rigid, a portion of the reaction force cannot be explained. This portion can be substantial during impacts, which occur during walking and other activities. Our new decomposition method overcomes these limitations and is applicable to a wide range of biomechanical simulations. We have successfully used this method to decompose the ground reaction force for a 3D simulation of gait (Anderson and Pandy, 2001b) in which contact was modeled using damped exponential springs.

VENOUS RETURN IN LOWER LIMB DURING MUSCULAR CONTRACTION

Jean-Thomas Aubert¹, Ethelle Chabran¹, Philippe Arbeille², Bernard Maton³ and Christian Ribreau⁴

INTRODUCTION

It is well known that in the lower limb, venous flow rate is highly affected by its environment. Indeed, movements, either body force variations or muscular contractions, act on vein and blood. The effects of such actions are not precisely quantified yet. This paper deals with the quantification of flow rate variations in the Common Femoral Vein (CFV) during muscular contractions.

MATERIAL AND METHODS

Venous flow rate was deducted from Doppler echo-velocimeter (ATL HDI 5000). The CFV cross section was measured by transverse scan, in opposition with red cells velocity measurements. Flow rate through the CFV stands for the output boundary condition of the venous network in the lower limb whereas the Popliteal Vein (usual measurement spot) drains only the shank blood (Winter et al, 2000).

The recordings were performed on 11 healthy subjects at rest and during specified movements.

The biomechanical parameters of movements that made explicit the activities of muscles were controlled by means of goniometers (Biometrics), accelerometers (Entran) and a force plate (Satel) for making sure of the repeatability of situations as well as possible and to deduce the body force distribution in blood. Moreover, 6 muscles activities were investigated by superficial EMG: 3 for thigh (Rectus Femoris, Vastus Lateralis and Biceps Femoris) and 3 for shank (Gastrocnemius, Soleus and Tibialis Anterior).

For specified movements of the lower limb, the activation of the muscles gave rise to the filling and emptying of veins. Two postures were defined for differentiating two conditions of the venous network compliance: subjects were standing or lying supine. Furthermore, loaded and unloaded limbs, with or without foot support, were investigated.

The movements involving loaded limbs in standing position were: (i) a so-called voluntary contraction of the femoral quadriceps; (ii) leaning forward with straight legs (the only ankle angle was changing); (iii) loading of the free lower limb from a monopodal position to the bipodal position; (iv) tiptoe; (v) dorsal flexion of feet in standing position.

The movements involving unloaded limbs were: (i) a so-called voluntary contraction of the femoral quadriceps and (ii) dorsal

flexion of feet in lying supine position; (iii) flexion/extension of the leg on the thigh in the standing position, for a constant angle of flexion of about 45° of the thigh on the trunk.

RESULTS

Primary results (Aubert et al. 2001) show large flow rate variations due to muscular activation: from 100 mL/min to 5000 mL/min. Table 1 shows the results of this primary study realised on one healthy subject only. The communication will present the results obtained from the 11 subjects.

	Unloaded limb	Loaded limb
Knee flexion/extension	2.4	
Voluntary contraction	4.5	32
Leaning forward		13.3
Lower limb loading		13.7
Tiptoe		7.9

Table 1: Relative venous flow rate variations in the CFV due to muscular activation in standing position*100 % (Venous flow rate in the CFV in orthostatic position: 150 mL.min⁻¹)

DISCUSSION AND CONCLUSION

This communication presents the variations of the mean flow rate (mean-time average) in relation to the flow rate at rest for each specified movement. It shows the huge effects due to the activation of the muscles in the whole lower limb and not only the calf muscles.

Consequences on wall shear stresses may be expected. Endothelial cell physiology and endothelial cell functions should be concerned by such a study (Haond et al. 1999).

BODY FORCE DISTRIBUTION IN VEINS OF THE LOWER LIMB DURING STATIONNARY GAIT

Jean-Thomas Aubert¹ and Christian Ribreau²

¹ Laboratoires Innothera, Arcueil, France, jean-thomas.aubert@innothera.com

² Laboratoire de Génie Mécanique Productique et Biomécanique, IUT de Cachan, France

INTRODUCTION

Blood flows towards the heart through collapsible vessels: the veins. The flow equations in collapsible tubes show a strong dependence on body forces. The kinematic analysis of the stationary gait had been performed in sagittal plane in order to calculate the acceleration and its variations on every point of the 3D venous network.

BACKGROUND

Flow in collapsible tubes is governed by Equation 1:

$$\rho \left(\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} \right) = \rho (G_x - M_x) - \frac{\partial p_e}{\partial x} - \frac{\partial (p_i - p_e)}{\partial x} - f_v \quad (1)$$

U	axial flow velocity
p	internal and external pressures
G _x	axial component of gravity
M _x	axial component of movement acceleration
x	flow axis
f _v	viscous force
ρ	fluid density

MATERIAL AND METHODS

In order to calculate the absolute acceleration and its variations on any point of the lower limb, the walking limb was considered as a triple pendulum in the sagittal plane (Figure 1a). The kinematic data of the stationary gait have been recorded by eight infrared cameras on one healthy subject (Aubert et al. 2001).

Absolute acceleration of each point of the venous network (in reference to the galilean referential) were computed from the data, and then expressed in the local coordinate frame of each venous trunk of the 3D venous network (Figure 1b).

Figure 1a

Figure 1b

Figure 1: Models

a/ the lower limb; b/ a 3D venous network

RESULTS

As an example, Figure 2 shows the evolution of $\frac{\partial}{\partial t} \left(\frac{G_x}{G} - \frac{M_x}{G} \right)$ at a given node of the network.

Figure 2: Variation of the normalized body forces on a distal point of the Internal Saphenous Vein for over one stride

The different results which are presented in this communication show that component peaks $[M_x]_{\max}$ and $[G_x]_{\max}$ can vary from $[0 - 1,5 \text{ G}]$ and $[0 - 1 \text{ G}]$ respectively. These results agree with Wu's study (Wu et al. 1996). Moreover, results present possible huge variations from 0 to 30 G.s^{-1} of the body forces.

DISCUSSION AND CONCLUSION

Venous trunks are affected with large acceleration peaks M_x (greater than the gravity) and variable orientation of gravity by respect to the vessel axis. Moreover, body force variations undergone by venous trunks are not only large, but also very fast. These points, often forgotten in the modelisation of flow in collapsible tubes open a new field for future theoretical investigations.

BIOMECHANICAL ANALYSIS OF THE UPPER EXTREMITY BETWEEN BADMINTON SMASH AND TENNIS SERVE

Chien-Lu Tsai, Chenfu Huang*, Der Chia Lin*, Shaw Shiun Chang,

National Taiwan Ocean University, Keelung, Taiwan

*National Taiwan Normal University, Taipei, Taiwan

INTRODUCTION

The motions of the tennis service and the badminton smash are quite similar. They are the typical techniques and the most powerful skills in the racket sports. Previous studies related to badminton, Tang, et al, 1994 he used 3D model to measure the rotation of the forearm and the wrist. And had been described the smash strokes. Elliott (1986, 1988) described the motions of the tennis serve. The purpose of this study is going to compare the kinetics variables (the net joint forces, moments and powers) on the upper extremities between tennis serve and badminton smash. In this study, we are interested in analyzing from the phase of the period before and after the point of making contact with the ball or the shuttle.

METHODS

An international world Champion elite badminton player (182cm, 74kg) in Taiwan was served as subject to perform the badminton smash technique. An elite tennis player (top 10 ranking in Taiwan, 192cm, 89kg) was served as the subject to perform the tennis serve in this study. The body segment parameters of each subject were calculated by the model of Dempster(1955). The upper extremity of the subject was separated into three segments, upper arm, forearm and racket (with fist included). A Kodak Ekta-Pro 1000 high-speed video camera (500Hz) was used to record the 2D data. The inverse dynamics solution was employed to calculate the forces, moments and powers of the upper segment joints.

RESULTS AND DISCUSSION

Table 1 shows that the initial velocity of the badminton smash (68.4m/s) is faster than the initial velocity of the tennis serve (61.4m/s). The angular velocity of tennis serve was greater than badminton smash on the wrist joint. The results showed the angular velocity of the wrist joint of the tennis serve is greater than the badminton smash. In figure 1 shows that the peak force of the upper limb joints in tennis serve were occur earlier than the peak force occur in badminton smash. The figure 2 shows the power of the upper limb joints at the contact. The joint power of the tennis serve was greater than the value in the badminton smash. We recommend that the regular training on the elbow flexor will reduce likelihood of injury due to stress the flexor through eccentric contraction during acceleration phase of the badminton smash and the tennis serve.

Table 1: The Variables Comparison Between 2 Movements

Variables	Badminton Smash	Tennis Serve
Initial Velocity	68.4m/s	61.4m/s
Wrist Contact Force	234N	227N
Wrist Contac Torque	44Nm	295Nm

Figure 1: The Joint Resultant Force Pattern of Tennis Serve and Badminton Smash

Figure 2: The Dynamical Pattern of Tennis Serve and Badminton Smash — Tennis ▲ Badminton

SUMMARY

The purpose of this study is going to compare the biomechanical variables on the upper extremities between elite badminton player and elite tennis player when they were performing badminton smash and tennis serve movements. In this study, we found that the value of the joint force, moment and power of the tennis serve were greater than the badminton smash. The results showed that dynamical pattern of the three overhead strokes were different. The regular training on the wrist extensors will be necessary for reduce the risk of the injury of wrist extensors.

RESISTANCE TRAINING RESULTS IN AN INCREASED H-REFLEX EXCITABILITY DURING MAXIMAL MUSCLE CONTRACTION BUT NOT AT REST

Per Aagaard^{1,4}, Erik B. Simonsen², Jesper L. Andersen³, S. Peter Magnusson⁴, Poul Dyhre-Poulsen¹
¹Dept of Neurophysiology, ²Anatomy Dept C, Panum Institute; ³Copenhagen Muscle Research Centre, Rigshospitalet; ⁴Team Danmark Test Centre, Sports Medicine Research Unit, Bispebjerg Hospital. University of Copenhagen, Denmark. E-mail: p.aagaard@mfi.ku.dk

INTRODUCTION

The Hoffmann (H) reflex can be used to assess the excitability of spinal α -motoneurons, while also reflecting the transmission efficiency (i.e. presynaptic inhibition) in Ia afferent synapses (Schieppati 1987).

In the present study H-reflex measurements were performed during maximal muscle contraction and at rest to examine the effect of resistance training on spinal motoneuron function.

METHODS

Fourteen male subjects (age 25.3 ± 4.7 yrs) participated in 14 wks (38 sessions) of heavy resistance training (4-10 RM loads) for the leg muscles. Evoked H-reflex and M-wave responses were recorded pre and post training in the soleus muscle during maximal isometric ramp contractions and at rest.

During maximal muscle contraction (2-s isometric ramps) an electrical stimulus (1 ms square pulse) was applied to the tibial nerve (popliteal fossa) at the instant the ankle plantar flexor moment exceeded 90% MVC. Stimulus intensity was adjusted to yield an M response of $20 \pm 2.5\%$ of the maximal M-wave (M_{\max}) (Dyhre-Poulsen et al. 1991, Simonsen et al. 1999, Ferris et al. 2001). In the resting muscle, the maximal H-reflex response expressed relative to M_{\max} (i.e. H_{\max}/M_{\max}) was obtained as a measure of H-reflex excitability at rest (Voigt et al. 1998, Maffiuletti et al. 2001).

Maximal concentric, eccentric and isometric muscle strength were measured by use of isokinetic dynamometry (KinCom).

RESULTS

During maximal isometric ramp contractions, peak-to-peak H-reflex amplitude increased ($P < 0.05$) from 5.37 ± 0.41 to 6.24 ± 0.49 mV with training (\pm SEM). When expressed relative to M_{\max} , the H-reflex amplitude increased from 0.514 ± 0.032 to 0.609 ± 0.025 ($P < 0.05$).

In contrast, H_{\max}/M_{\max} recorded at rest remained unchanged with training (0.503 ± 0.059 vs 0.499 ± 0.063). Also, during rest the direct M response at H_{\max} did not change (0.103 ± 0.024 and 0.116 ± 0.021 , expressed relative to M_{\max}).

No change was observed in M_{\max} with training (10.78 ± 0.86 vs 10.21 ± 0.66 mV).

Maximal muscle strength increased 23-30% ($P < 0.05$).

DISCUSSION

In the present study an increased H-reflex excitability was observed during maximal voluntary muscle contraction in response to 14 wks of heavy-resistance strength training. Consequently, the neural adaptation to resistance training appears to include increases in spinal motoneurone excitability (and/or reduced presynaptic Ia afferent inhibition). It could be speculated that the increase in H-reflex excitability was caused by reduced presynaptic inhibition of Ia afferent terminals. However, in young subjects it has been demonstrated that the amount of presynaptic inhibition is low or even fully abolished during forceful plantarflexor contraction (Butchart et al. 1993).

Lower resting H_{\max}/M_{\max} has been reported for endurance athletes compared to athletes trained for explosive sports (see Maffiuletti et al. 2001). It cannot be excluded, however, that these findings were the result of subject differences in muscle fibre composition, since at low stimulation intensity the evoked EPSPs will exert a stronger excitatory influence on the smallest spinal motoneurons that innervate the population of slow type I muscle fibres.

In the present study, the H-reflex response measured at rest (H_{\max}/M_{\max}) remained unchanged with training. In contrast, H-reflex excitability increased during active muscle contraction. Identical findings were recently reported in response to 4 wks of hopping training (Voigt et al. 1998).

Based on these findings, it is strongly suggested that training induced changes in neural motor function should be evaluated by recording of the H-reflex during actual contraction, and not rely solely on measurements obtained at rest.

INTRODUCTION

It is important to know the mechanical properties of human aortic aneurysm tissues to investigate the mechanism of their rupture. Aneurysmal walls might be stretched equibiaxially in vivo, because the radius of curvature is almost similar between the circumferential and axial directions of the aorta. Thus, it is crucial to obtain their biaxial tensile properties. While it is important to consider these properties in a physiological state, it is difficult to estimate the strain levels of each subject. It has been reported that hoop stress in a physiological state is kept constant among the aortas of various subjects (Matsumoto, 1994). Thus, mechanical properties under a physiological equibiaxial stress would be a good estimate of those in vivo. In this study, mechanical properties of aortic aneurysms and their adjacent normal tissues were measured under equibiaxial stress with a biaxial tensile tester developed in our laboratory (Tanaka, 2000).

METHODS

Fourteen 15mm square specimens were obtained from 10 thoracic aortic aneurysms of various origins and their adjacent aortas with edges aligned to the circumferential and axial directions of the aorta during aortic replacement surgery. The biaxial tensile tester has two orthogonally-arranged pairs of arms, which are pulled apart by a computer-controlled stepping motor. Each edge of the specimen was hooked with four or five clamps. They were then connected to each arm with a silk thread. A 5mm square bench mark was drawn in the middle of the specimen with black shoe polish. The specimen was stretched biaxially in the physiological saline at room temperature by widening the distance between the opposite arms at the rate of 0.2mm/sec. The tensile test was started at the point where the specimen had 0.1 to 0.2N tension in each direction. Specimens were not preconditioned because some of the specimens were very fragile. The circumferential direction of the specimen was taken as x direction as far as its directions were known clearly.

Cauchy stress in the x and y directions (σ_x , σ_y), and infinitesimal strain in these directions (ε_x , ε_y) were calculated assuming that the specimen was incompressible. Although the displacement of the arms was set equal for both directions, neither strain nor stress applied to the specimen was equibiaxial. The stress-strain curves under equibiaxial stretch were obtained by fitting measured curves with an exponential type two-dimensional strain energy function considering material anisotropy (Fung, 1979):

$$W = C \exp(aE_x^2 + bE_y^2 + 2cE_xE_y),$$

where E_x and E_y are the Green's strains, and C , a , b , and c are material constants. Incremental elastic modulus in an in vivo state was obtained as the slope of the stress-strain curves under equibiaxial stress. The modulus averaged for both directions $H_m = (H_x + H_y)/2$ was used as an index of tissue stiffness. As an anisotropy index, $K_\varepsilon = |\varepsilon_x - \varepsilon_y|/\varepsilon_m$ was used.

RESULTS AND DISCUSSION

Figure 1 shows a relationship between H_m and K_ε at $\sigma_x = \sigma_y = 200\text{kPa}$. In case that multiple specimens were obtained from a patient, each parameter was averaged. There was a significant correlation between the two parameters ($R=0.699$, $P<0.03$, $n=10$). With the progression of the aneurysm, the wall tissue may not only get stiffer but also become more anisotropic.

In this study, we evaluated the mechanical properties of aneurysm tissues in the same stress level. However, the physiological stress level might differ among aneurysms. It is necessary for the future study to estimate stress level of each aneurysm from its shape and blood pressure of each patient.

MEASUREMENT OF INVERSION AND EVERSION MOVEMENTS OF THE FOOT BY USING A POSITION TRANSDUCER

Thorsten Sterzing¹, Ewald Hennig¹, David Pearsall²

¹Faculty of Sport & Movement Sciences, University of Essen, Germany, thorsten.sterzing@uni-essen.de

²Faculty of Kinesiology, McGill University Montreal, Quebec, Canada

INTRODUCTION

Cinematography or electrogoniometers are typically used to estimate subtalar joint motion during different kinds of movement activities, e.g. walking or running. Most pieces of work focus on the relative motion between the posterior lower leg and the heel counter of the shoe. As the foot is likely to move inside the shoe no real representation of foot vs. lower leg motion can be achieved by using the traditional techniques. Previous attempts of in-shoe measurements require a modification of the footwear (Stacoff et al, 1992) or may influence subjects' movement pattern (Hennig et al, 1998). A new in-shoe electrogoniometer technique is proposed to determine the relative motion of the foot vs. the lower leg for an estimation of subtalar joint motion during different kinds of movement activities.

METHODS

A small spring loaded cable displacement position transducer was used for measuring inversion and eversion movements of the ankle during running. (*size*: 19x19x9 mm, *maximum cable displacement*: 38 mm, *weight*: 15 g). The case of the transducer was applied to the subjects' medial part of the tibia above the medial malleolus. The displacement cable was guided straight; going down across the medial malleolus, underneath the foot and then fixed to the lateral aspect of the foot. This alignment was used to avoid an influence of plantar and dorsiflexion on the inversion and eversion measurements. Prestretching of the skin was necessary to decrease skin movement disturbances of the signal. An individual calibration was taken according to each subject's anatomical range of maximum voluntary from inversion to eversion (maximum voluntary range of rearfoot motion).

Simultaneously, an external electrogoniometer was used to determine the relative motion of the lower leg vs. the heel counter of the shoe (Milani and Hennig 2000).

In the present study 10 subjects performed 5 shod heel-to-toe runs on a laboratory runway at a speed of 3.3 m/s.

RESULTS

The external measurement technique provides degree values describing the total range of rearfoot motion. The in-shoe measurement technique provides percentage values of the total rearfoot range of motion based on the maximum voluntary range of rearfoot motion.

Regression Plot: In-Shoe vs. External

Figure 1: x-axis shows in-shoe electrogoniometer values, y-axis shows external electrogoniometer values (mean values of 5 trials per subject)

SUMMARY

The present in-shoe electrogoniometer technique provides useful values for measuring inversion and eversion movement of the foot. As it is attached on the skin directly to the lower leg and the foot, it allows a more accurate representation of rearfoot motion than traditional devices. Measurements of highly dynamic movements are possible to perform. Being independent of high-speed video cameras provides the possibility of taking laboratory experiments back to the field.

STANCE LIMB CONTRIBUTES TO PREVENTION OF FALLING AFTER TRIPPING

Mirjam Pijnappels, Maarten F. Bobbert and Jaap H. van Dieën

Institute of Fundamental and Clinical Human Movement Sciences
Faculty of Human Movement Sciences, Vrije Universiteit Amsterdam, The Netherlands
m.pijnappels@fbw.vu.nl

INTRODUCTION

To prevent falling after tripping, it is essential to rapidly arrest the forward rotation, which the body gets from impact of the swing leg with the obstacle. The present study investigated whether and how push-off of the contralateral stance limb is used to reduce the forward rotation of the body after tripping.

METHODS

Twelve subjects walked over a platform of 10 meters at a comfortable walking speed. Kinematic data and ground reaction forces were measured at 100 Hz, and EMG of lower limb muscles at 1000 Hz. Based on online kinematic data, one of 21 obstacles, hidden in the platform, could be triggered to appear unexpectedly and catch the swing leg at a specific instant in mid-swing. In about 10 of 60 trials, subjects were actually tripped over an obstacle on either left or right side. A harness, attached to a ceiling-mounted rail, ensured safety.

RESULTS AND DISCUSSION

Recovery reactions appeared to be reproducible within subjects; immediately after collision the obstructed swing leg was elevated over the obstacle, while the stance limb provided prolonged push-off. After impact with the obstacle, the body rotated forward. The trunk is the main segment that contributes to body rotation. Figure 1 shows trunk rotation and angular velocity for a typical subject over the stance-phase.

Figure 1: Trunk rotation and trunk angular velocity of one subject, averages over 5 trials of normal walking (—) and of tripping (---). Trip initiation at 0 ms.

The trunk rotated forward rapidly after tripping, but its angular velocity was almost completely arrested within the push-off duration. A strategy to achieve this is reflected in an increase of the moment effect of the ground reaction forces about the body centre of mass, brought about by an increase in ground reaction forces in vertical as well as forward direction (figure 2). This results in a major contribution in the reduction of the body's forward rotation. The required push-off force magnitude and direction was generated by hamstring and gastrocnemius muscles that showed increased activity.

Figure 2: Ground reaction forces and external moment of one subject, averages over 5 trials of normal walking (—) and of tripping (---). Trip in contralateral swing limb at 0 ms.

SUMMARY

After tripping, the body starts to rotate forward. The stance limb contributes in decreasing this forward rotation during push-off, by generating a ground reaction force that brings about a counteracting external moment.

SENSITIVITY ANALYSIS ON DISC BEHAVIOR IN TEMPOROMANDIBULAR JOINT

INTRODUCTION

Temporomandibular joint (TMJ) disorder is deeply related to the biomechanical condition among TMJ components. Permanent anterior disc displacement and disc derangement are typical finding in TMJ disorder. The mouth opening motion naturally induces the anterior disc displacement even in normal TMJ, and the condyle motion and disc properties are considered as the key to understand the disc displacement and stress in the disc [e.g. Solberg et al. 1979]. This study focuses the attention on the effect of disc property and condyle motion on the disc displacement and disc stress in the context of sensitivity analysis with finite element analysis.

METHODS

The biplane magnetic resonance images augmented by anatomical knowledge were used for the finite element (FE) TMJ modeling. The procedure to establish the FE model and the material property of TMJ components are the same as those in the previous work [Tanaka et al. 2001]. The major condyle movement is found in the sagittal plane, and the inferior condyle displacement is represented by a quadratic function of anterior condyle displacement. Such condyle trajectory was determined by referring to the MR images obtained at different mouth opening positions. The elastic modulus reported in the literatures scatters widely and the in vivo-experiment is impossible. The condyle positions used for the condyle path determination were not natural but artificial one for MR imaging. Thus, the anterior disc displacement and stress distribution in the disc were examined in the context of parametric study with the disc modulus ranging 1 and 100 MPa and the condyle path with variations up to 2mm at the fully open position.

RESULTS AND DISCUSSION

Figure 1 illustrates the effect of the disc modulus on the disc displacement and on von Mises stress of a normal subject. Increase in disc modulus accompanied the increase of disc displacement and the elevation of stress averaged over the disc. The image analysis of MR slices resulted the disc displacement marked by the arrow in Figure 1(a). Among the disc modulus examined, the disc modulus of 50 MPa gave the most reasonable disc displacement (Figure 1).

Figure 1: Parametric study on disc elastic modulus

[●:E=1, ○:E=10, ■:E=50, □:E=100MPa]

Figure 2: Parametric study on condyle path

[●:path1, ■:path2, ○:path3]

Figure 2 shows the effect of the condyle path on the disc displacement and von Mises stress. At the fully open position, the inferior displacement in path 2 is 1mm smaller than that of normal path1, and that in path3 is 2mm smaller than the normal. The von Mises stress was very sensitive to the condyle path, although the anterior disc displacement was not. These suggests us the possibility to estimate the disc modulus with the combination of MR image analysis and FE analysis based on it. However, we need some additional information to validate the condyle path that affects the stress in the disc significantly.

ALCOHOL AND OVARECTOMY EFFECTS ON TRABECULAR BONE IN FEMALE RATS

Harry A. Hogan^{1,2}, Kristin L. Luthringer¹, Susan D. Bankston¹, and H. Wayne Sampson²

¹Dept. of Mechanical Engineering, Texas A&M University, College Station, TX, hhogan@mengr.tamu.edu

²Dept. of Medical Anatomy & Neurobiology, Texas A&M University System Health Sciences Center, College Station, TX

INTRODUCTION

Alcohol consumption is a known risk factor exacerbating postmenopausal osteoporosis. The current study was undertaken to investigate these effects using the rat animal model. Recent studies with rats have shown deleterious effects due to alcohol (Turner et al., 2001; Hogan et al., 2001), but no significant effects when combined with ovariectomy (OVX) induced estrogen deficiency (Kidder and Turner, 1998). This last study did not report mechanical properties, however. The main purpose of the current study was to investigate the effects of alcohol and OVX on trabecular bone mechanical properties in adult female rats. Another important clinical issue is the relation between bone mineral density (BMD) and fracture risk or incidence. Thus, changes in BMD have also been studied and compared to corresponding changes in mechanical properties.

METHODS

Female Sprague-Dawley rats were divided into 6 groups at 9 mo. of age. Two groups were fed alcohol for 10 weeks. For each of these two groups there were two types of controls: pair-fed (which were isocaloric to the alcohol animals), and chow-fed (which received standard rat chow and water). After 10 weeks 3 of the groups were terminated and 3 were ovariectomized and then maintained on the same diets for 2.5 more weeks. The OVX groups were designated: OA (alcohol, N=12), OP (pair-fed, N=12), and OC (chow, N=8), and the other groups: A (N=8), P (N=8), C (N=8). The left femur was removed after euthanasia and 2mm long specimens were cut from the distal femoral metaphysis. The specimens were tested by reduced-platen compression (RPC), which directly loads only the trabecular bone portion (Hogan et al., 2000). Before testing, contact radiographs were made of each specimen and digitized for BMD determination. The trabecular bone compartment was isolated and density quantified through a series of aluminum step-wedges that were included in each x-ray.

RESULTS AND DISCUSSION

Alcohol generally reduced mechanical properties and BMD compared to either control group (Table 1). The combination of alcohol and OVX further reduced values of both. None of the differences were statistically significant, however. The % by which the alcohol groups were lower than controls are indicated (as %Δ), and it is clear that mechanical properties were affected more severely than BMD. Ultimate stress correlates well with BMD (Fig. 1), with R^2 values similar to those reported for rat vertebra tests (Nishikawa et al., 2000). The current study suggests, however, that BMD does not capture completely the changes in mechanical properties.

Figure 1: Correlation between ultimate stress and BMD.

INTRODUCTION

Stroke ranks as one of the leading causes of morbidity and mortality in the western world. Atherosclerotic deposits and stenoses are among the contributing factors for catastrophic stroke. These are found in the transcerebral arteries, such as the carotid bifurcation. High- degree stenoses may be surgically approached by endarterectomy or implanted patch-plastics. In addition to these surgical procedures, stents are used for patients with high risk factors, who cannot be treated with open surgery. This procedure is not without risk as clots can be transported into the brain. We studied the influence of such stents on the flow behavior. We positioned three types of stents from the common carotid artery into the internal carotid artery and compared the flow patterns with that found in a model without stent. All three stents influenced the flow behavior significantly.

METHODS.

We studied a wall stent, a self-expanding stent (SelfX) and a covered stent. Each stent was positioned within an elastic 1:1 true-to-scale silicone rubber model of a carotid bifurcation. These models have a compliance similar to that of a real artery. The local velocity was measured at different cross sections using a laser-Doppler-anemometer (LDA). Figure 1 shows the different cross sections and measuring points. The physiological pulsatile blood flow curve was simulated with a piston pump (heart pump) which superimposed a physiological waveform on the steady flow. The flow rate ratio of the internal to the external carotid artery was 70% to 30%.

RESULTS AND DISCUSSION

The flow rate ratio is slightly changing after stent implantation.,
The flow rate ratio was:

70.7 : 29.3 for the self expanding stent

70.64 : 29.36 for the wall stent

73.9 : 26.1 for the covered stent.

The flow rate change of the first two stents can almost be neglected. The covered stent showed a higher resistance towards the external carotid artery. This is caused by the design. The covered stent, however, produced a very smooth flow and formed no vortices. Some small velocity disturbances were created at the inlet and outlet only. Figure 3 shows the velocity distribution at the cross section 2.5 mm distal to the bifurcation in the external carotid artery. The empty model without a stent is compared with the three stent models during the systolic phase $\omega t=30^\circ$. The flow behavior in the external carotid artery is completely altered by the covered stent. At times, peak velocities are created by the stent wire.

ACI

MICRO-TENSILE TESTING OF INDIVIDUAL TRABECULAE FROM NORMAL, AGEING, AND OVARECTOMISED RAT BONES

Laoise McNamara, Patrick J. Prendergast, Kevin O' Kelly and Garrett Lyons

The Bioengineering Group, Department of Mechanical Engineering, Trinity College, Dublin 2, Ireland. mcnamalm@tcd.ie

INTRODUCTION

Cancellous bone is a porous network of interconnected rods and plates called trabeculae. Bone remodeling constantly adapts their structure so that cancellous bone is sufficiently strong to fulfil its load bearing function. Osteoporosis is a disease caused by altered bone remodelling due to a mismatch between bone formation and bone removal. The trabecular struts become thin and eventually fail.

A number of researchers have sought to determine the mechanical properties of the individual trabecula using 3-point bending studies (Choi et al, 1990) and micro-tensile testing (Ryan and Williams, 1989). Due to the size and shape of trabeculae a number of issues arise with respect to the accuracy of testing and reported values for the elastic modulus of an individual trabecula have conflicted, with values ranging from 0.75GPa – 20GPa.

The overall objective of this research is to measure the changes in trabecular strength from normal, aged, and osteoporotic (ovarectomised) rats. Questions arise as to whether or not a micro-tensile testing apparatus can be designed to eliminate errors due to misalignment and stress concentrations at the grips. If this can be done successfully then both tensile and fatigue tests of trabeculae after disease and drug treatments will be possible.

METHODS

Sections of cancellous bone were cut from the tibiae of 6 and 16-month Whistar rats and from 6 month old ovariectomised (OVX) Whistar rats. The sections were cleaned of marrow using a water jet. Using a scalpel blade and forceps individual rod-like trabeculae were excised under a stereomicroscope and stored in saline before testing.

The base test system is an MTS Tytron 250, which operates using a linear DC servomotor, and is capable of applying loads at a resolution of 0.001 N. This system has been modified, through the addition of a microscope assembly and a grip system, for use in micro-tensile testing of individual trabeculae. The main problem faced in testing of trabeculae is that of gripping them during a test. The system developed involves the use of the shafts of hypodermic needles as the grip rods. These rods were attached to the actuator and load cell of the machine. An alignment sleeve, with close tolerance fit was used to align and ensure co-axiality of the grip rods. The ends of the trabecular specimens were inserted into the hypodermic needles and affixed using a cyanoacrylate adhesive. The trabecula was aligned under the microscope, at 30X magnification, using a graticule lens as a reference for alignment. Two specimens from 6-month-old normal and

osteoporotic rat bones were tested, along with 4 specimens from 16-month-old tibia. A constant displacement rate of 1 $\mu\text{m}/\text{sec}$ was applied until failure. The test system software automatically recorded the force and displacement values. The cross-sectional diameter was taken under microscopy.

RESULTS AND DISCUSSION

The stress/strain relationship for seven samples of trabecular tissue have been determined, see Fig. 1. The average elastic modulus calculated for individual trabeculae excised from normal 6-month old tibia was 1.79 GPa whereas that from the normal 16-month old tibia was 1.33 GPa. The elastic modulus calculated for the OVX specimen was 4.01 GPa, but it failed at low strain. The 6 mo old normal samples sustained the highest strain before failure (Fig. 1)

Fig 1: Stress/strain curves for individual trabeculae

SUMMARY

A method has been developed for tensile testing of individual trabeculae that ensures alignment of trabecular specimens that eliminates bending. It has proved capable of discriminating the stress/strain behaviour of trabeculae. It can now be used to compare trabecular bone tissue from both normal and osteoporotic rats. These initial results indicate that ageing of the bones results in a decrease in the stiffness of the tissue.

NEURAL AND BIOMECHANICAL ORGANIZATION OF ANTICIPATORY POSTURAL ADJUSTEMENTS IN FAST SYNCHRONIZED STEPPING AND ARM RISING

Yiou E. and Schneider C.

CIRRIS-Rehabilitation Research Center, IRDPQ, Quebec City, G1M 2S8 Canada, Cyril.Schneider@rea.ulaval.ca

INTRODUCTION

Many of our daily activities require combination of goal-directed arm rising task with postural support displacement. The latter requires the anticipatory postural adjustments (APAs) generating the dynamic conditions for stepping (Brenière et al. 1987). These APAs could be affected by upper limb movements (Yiou & Do 2001), since rising the arm induces an endogenous postural perturbation (Bouisset & Zattara 1988). The question is whether synchronization of arm rising with fast stepping affects the organization of APAs preceding fast stepping or highlights CNS potential for neural and biomechanical adaptation.

METHODS

Five subjects were tested 'stepping', 'arm rising' and synchronized 'stepping / arm rising'. The swing leg in stepping was the *preferential* leg. 'Arm rising' was a 90° flexion of the *contralateral* shoulder (elbow in full extension). In response to an auditory cue, subjects in quiet standing (QS) performed the tasks at maximal velocity. Biomechanical and motor features of APAs were analyzed by means of recordings from force plates (one per stance) and surface electromyographic activity (EMG) of the Deltoideus anterior (DA, shoulder flexors), the soleus (SOL) and Tibialis anterior (TA) (ankle plantar and dorsiflexors) of both legs. The spinal synaptic efficacy was tested by eliciting H-reflexes of swing SOL from the auditory cue to the swing foot-off (for methods, see Schneider et al. 2000).

RESULTS AND DISCUSSION

1- In both stepping tasks (Figure 1), kinetics of APAs was characterized by backward displacement of the center of foot pressure (xP) and forward acceleration of the center of mass (X''_G). These APAs were generated by cessation of SOL EMG prior to TA activation. APAs lasted from the onset of deviation in kinetic traces to the swing foot-off. Their amplitudes corresponded to the values of these deviations.

2- Duration of APAs and integrated EMG (iEMG) of the swing leg were comparable in stepping tasks. However, amplitudes of APAs and iEMG of stance TA were significantly higher in the synchronized task. **3-** Surprisingly, whilst SOL early ceased in stepping, the H-reflex reached amplitudes as high as in QS. H-reflex was then inhibited by reciprocal inhibition from TA burst and remained at minimum values throughout APAs. Conversely, the H-reflex was facilitated during APAs in arm rising. In the synchronized task, the pattern of H-modulation was the same as in the single stepping, without any significant difference in timing and amplitudes. **4-** The whole work reflects that the

Figure 1: EMG, kinetic traces (mean, N=10) and SOL H-reflex (N=4 per symbol) of APAs in synchronized and stepping tasks.

neural and biomechanical organization of APAs in stepping was adapted to the perturbation elicited by the upper limb task, for unloading the swing leg and propelling the body forward.

SUMMARY

Biomechanical and neural techniques revealed the adaptation of the APAs of the stepping synchronized with the contralateral arm rising. Impairments of these central mechanisms may explain part of the pathophysiology of postural control.

BEHAVIOURS OF MUSCLE-TENDON COMPLEX DURING ELECTRICAL STIMULATION WITH TRAINS OF LINEARLY VARYING FREQUENCY IN HUMANS.

Yasuhide Yoshitake, Yasuo Kawakami, Hiroaki Kanehisa, Tetsuo Fukunaga
Department of Life Sciences, University of Tokyo, Tokyo, Japan. ytake@idaten.c.u-tokyo.ac.jp

INTRODUCTION

The force-frequency relation frequently does not show a unique response, but appears to depend heavily on the muscle activation history. From the findings of a prior study (Binder-Macleod and Clamann 1989), stimulus trains in which the frequency varied linearly produce a tension hysteresis with a greater force production when the frequency was decreasing than when it was increasing. The exact physiological mechanisms governing such hysteresis phenomenon have not been clearly identified, but it might involve the interaction with the length changes in muscle-tendon complex throughout the muscle contractions.

Recent development in technology has made it possible to determine the kinetics of muscle-tendon complex in humans by means of real-time ultrasonography (Fukunaga et al. 1997). Using this tool we have shown that tendon elasticity plays an important role during voluntary muscle actions (Kawakami et al. 1998). The aim of this study is to quantify the length changes in the muscle-tendon complex during electrical stimulation with trains of linearly varying frequency and to investigate their effect on force production in vivo.

METHODS

Experiments were conducted on the triceps surae muscle of six male subjects with no history of neuromuscular disorders. Each subject was seated on an insulated, straight-back chair with wide belts crossing his chest and abdomen to immobilize his body and to isolate the planter flexion movement of the ankle at 90°.

The posterior tibial nerve was stimulated supramaximally (100- μ s duration) to induce maximal isometric contractions of triceps surae muscle with a small surface electrode in accordance with the method described in a prior study (Yoshitake and Moritani 1999). We made a stimulation pattern on a DOS/V computer with a digital-to-analogue (D/A) converter which could control the electro-stimulator for inducing contractions. Muscles were tested with a stimulus pattern in which the frequency rose up to 20Hz (increasing frequency) and then fell (decreasing frequency) linearly (see Fig 1A-bottom). The force signals were recorded by an on-line computer system with a 13-bit analogue-to-digital converter (MacLab/16).

A real-time ultrasonic apparatus (SSD-5000, Aloka, Japan) was used to record at 30Hz continuously and simultaneously longitudinal ultrasonic images of the medial gastrocnemius muscle during stimulation. The distance which cross point of two echoes from deep aponeurosis and fascicle moved during electrically induced contractions was determined as the lengthening of tendon structures (L) as described in our previous studies (Fukunaga et al. 1997, Kawakami et al. 1998).

RESULTS and DISCUSSION

Figure 1A shows typical sets of computer outputs indicating torque curves (top) and stimulation patterns (bottom)

Stimulus trains in which the frequency varied linearly show a tension hysteresis

Figure1: Relation between output torque and stimulus rate.

as a function of time during stimulations. The group data of torque-frequency relation showed a marked hysteresis, in which the force enhancement occurred during decreasing frequency of stimulation (Figure 1B). The last twitch was markedly greater than the first twitch in the phase of increasing frequency of stimulation (see Fig.1A), suggesting that post-tetanic potentiation (Vandervoort et al. 1983) contributes to the appearance of hysteresis.

Figure 2 represents the changes in torque and L during stimulation recorded in the same subject presented in Figure 1A. The enhanced torque and elongated tendon structure by increasing stimulation rate were “hold” even when the frequency of stimulation decreased. This indicates that alteration of muscle-tendon length may also contribute to the appearance of the force hysteresis.

Tension hysteresis might be due to resulting in an upward shift of tendon structure

Figure 2: Torque (top) and tendon elongation (bottom) during increasing (solid) and decreasing (dot) stimulations.

DIRECTIONAL DEPENDENCY OF SENSING CHARACTERISTICS TO MECHANICAL STIMULUS IN OSTEOBLASTIC CELL

INTRODUCTION

It is believed that osteoblastic activities are affected by local mechanical environment in adaptive bone remodeling process (Duncan, R. L. et al., C. H., 1995). Investigation on the characteristics of sensing mechanical stimulus in osteoblasts is essential to clarify the cellular level mechanism of bone remodeling. In this study, quantitative deformation was applied to a single osteoblastic cell using a tip of glass microneedle with controlled magnitude and direction, and change in intracellular calcium ion concentration was observed as cellular response to the mechanical stimulation.

MATERIALS AND METHODS

Osteoblastic cell lines MC3T3-E1 (from RIKEN Cell Bank) were cultured in α -MEM supplemented with 10% FBS. Cells were seeded onto the glass bottom dishes at 10^5 cells per dish. After pre-culture for 3 hours, Ca^{2+} fluorescent indicator Fluo-3 was loaded for 60 min.

As a mechanical stimulus, indentation to a single cell was performed using a microneedle with a roundish tip of 10 μm in diameter (Xia, S. L. et al., J., 1992). Angle between microneedle and dish bottom was set at 40 deg. Microneedle was moved down vertically to the height of 2.0 μm from the dish bottom and held for a few seconds, and slid horizontally to apply deformation to the cell. Displacement of the tip was defined as δ (Figure 1a). The angle between micropipette and the major axis of the cell shape was defined as θ (Figure 1b), in which the major axis of the cell was determined from the ellipse fitted with the cell shape.

Change in the intracellular calcium ion concentration $[\text{Ca}^{2+}]_i$ was observed by measuring increase in fluorescent intensity using a confocal laser scanning microscope (MRC-1024/MP, Bio-Rad) in the plane at height of 2 μm from the dish bottom.

RESULTS AND DISCUSSION

By measuring change in $[\text{Ca}^{2+}]_i$, we confirmed that the cell responded to the applied deformation. At relatively small magnitude of applied deformation, $\delta = 2.0$ to 6.0 μm , cells did not show the change in $[\text{Ca}^{2+}]_i$ as response to the stimulus. On the other hand, at $\delta = 8.0$ to 12.0 μm , cells responded. This result suggests that there might be a threshold in magnitude of stimulus that osteoblastic cells could sense and respond. In

Figure 1: Definition of quantitative stimulus, (a) magnitude of deformation δ , (b) angle of applied deformation θ

Figure 2: Directional dependency on probability of responded cells to applied deformation of $\delta = 10 \text{ mm}$

addition, the probability of responded cells increased as the magnitude of deformation δ increased.

In Figure 2, dependency of the probability of responded cells on the angle of applied deformation are plotted for the case of $\delta = 10 \mu\text{m}$, which was obtained by moving average within ± 10 deg. at interval of 5 deg. Thus, the culculated points were 15 from 25 experimental data. The result shows that the probability of responded cells increased as the angle of applied deformation increased. The probability of responded cells are significantly corelated with the angle of applied deformation ($p < 0.05$). Cells are more sensitive to applied deformation with larger angele to cell major axis. This result suggests that there is directinal dependency in sensing mechanical stimulus in osteoblstic cells.

NATURAL FREQUENCIES OF FEMUR BONE AND BONEPIN

Wolfgang Potthast¹, Anton Arndt², G.-P.Brüggemann¹

¹Institute for Biomechanics, German Sport University Cologne, Cologne, Germany

²Karolinska Institute, Dept. Orthopedic Surgery, Huddinge University Hospital, Sweden

INTRODUCTION

Several in vivo studies exist regarding bone acceleration during different movements (Hennig & Lafortune 1991; Whittle 1999). However, the mechanics of the transition of vibrations along the bone are not yet well understood. Therefore, the purpose of this study was twofold: first to estimate the natural frequency of an instrumental setup typically used in in vivo studies (bonepin with marker array) and secondly to identify the frequencies of a vibrating femur bone by means of an accelerometer mounted to a bonepin.

METHODS

A: To identify the natural frequency of the instrumental setup (bonepin, marker array) independent of the bone, a 8 cm long steel bonepin was screwed 2.5 cm into a 9.5x6x5cm rigid plastic block. A triaxial piezoresistive accelerometer (2.5 grams, 2500 Hz) was firmly mounted at the end of the pin. An aluminium marker array with three reflecting markers was mounted on the pin 1.5 cm below its end (Fig1). A pendulum was used to initiate vibration of the system (Fig1).

Fig1: Bonepin with marker array

B: To investigate vibrations of the femur the bone hung free with the bonepin screwed 2.5 cm into the lateral condyle (Fig2). The z-axis of the accelerometer was orientated parallel to the longitudinal axis of the femur. The vibration of this system was initiated by a manual stroke with a metal rod. The stroke was orientated approximately parallel to the longitudinal femur axis and applied centrally in the fossa intercondylaris. The direction and location of the force application was controlled by two video cameras (250 Hz).

In order to identify the occurring and superimposed frequencies in A and B the frequency spectrum was calculated using a fast fourier transformation (FFT). Due to the limitation of the sampling frequency of 2500 Hz no frequencies over 500 Hz were considered.

Fig2: Bonepin inserted in lateral femoral condyle

RESULTS AND DISCUSSION

Fig3 shows a typical FFT of the z-acceleration of both the bonepin in the plastic block and the bonepin mounted in the lateral femoral condyle.

The isolated bonepin shows a single sharp frequency peak located at 120 Hz which could be associated with the natural frequency of the instrumentation. A similar peak (115 Hz) can be identified in the curve for the pin mounted to the bone. An additional peak at 300 Hz occurred when the bone was activated to vibrate by a stroke located at the fossa intercondylaris. This frequency is assumed to be associated with the natural frequency of the isolated femur bone.

Fig3: FFT of isolated bonepin (left) and bonepin inserted in the femur (right)

INTRODUCTION

Our long-term goal is to build robotic exoskeletons for human locomotion. One method for controlling the exoskeletons is to use simple models of biological central pattern generators (i.e. artificial neural oscillators). Several researchers have used artificial neural oscillators to control computer simulations of human locomotion (Taga et al. 1991; Zielinska 1996), but each simulation has been specific to one type of artificial neural oscillator and one biomechanical model. Although this approach has demonstrated the feasibility of artificial neural oscillators as legged locomotion controllers, it is unclear if the findings can be generalized to other artificial neural oscillators and other biomechanical models.

We constructed computer simulations of artificial neural oscillators coupled to simple mechanical models for two purposes. First, we directly compared two artificial neural oscillators to provide a rationale for selecting one oscillator over the other in biological simulation or robotic control. Second, we tested the hypothesis that independent neural oscillators can entrain multi-body systems in the absence of inter-oscillator connections. Countless studies have focused on the feedforward nature of biological neural oscillators, proposing complex inter-oscillator connections sufficient to generate coordinated movement. However, afferent feedback is a powerful mechanism for entraining neural oscillators to the mechanics of a system. Biological neural oscillators and artificial neural oscillators use afferent feedback to tune their neural output to the resonant frequency of the mechanical system even when the oscillator natural frequency is much lower than the mechanical resonant frequency (Hatsopoulos 1996). Thus, it seems possible that afferent feedback may also be used to coordinate the timing of muscle activity about multiple joints. To test this possibility, we built simple neuromechanical models with distributed afferent feedback and no inter-oscillator connections.

METHODS

We examined two artificial neural oscillators, van der Pol (1922) and Matsuoka (1985), and three simple models of a swinging leg: single, double, and triple pendulums. Each pendulum joint was coupled to an artificial neural oscillator via a muscle torque generator and angular position feedback.

RESULTS AND DISCUSSION

Both artificial neural oscillators were able to entrain single and double pendulums to stable limit cycles close to the primary resonant frequencies of the mechanical models. Matsuoka oscillators were also able to entrain the triple pendulum at its primary resonant frequency and the double pendulum close to its secondary resonant frequency (i.e. anti-phase) when given appropriate initial conditions. Furthermore, the Matsuoka oscillator entrained the single pendulum over a much greater range of feedback gains than the van der Pol oscillator (range: 300-fold compared to range: < 10%, respectively). The Matsuoka oscillator also displayed the unique characteristic of reducing its duty factor from 38% to 8% of the cycle period as muscle gain was raised from 2 to 100. This kept muscular impulse from rising beyond a factor of two even though muscle gain increased by 50-fold. The adjustment in duty factor kept the angular displacement steady in spite of the changes in muscle gain.

SUMMARY

A direct comparison of artificial neural oscillators revealed that Matsuoka oscillators are much more robust to changes in feedback gains and muscle gains than van der Pol oscillators. In addition, results also indicate that distributed sensory feedback is sufficient to coordinate inter-joint muscle activation patterns. Although these conclusions are based on simple neuromechanical models, the generality of the results to different mechanical systems and artificial neural oscillators supports the findings. Neural tuning to biomechanical properties is likely more important for biological neural oscillators than generating feedforward commands in the absence of sensory feedback.

DO LOWER SPINE TWISTING MOMENTS AT THE COMPLETION OF LIFT TRAINING REDUCE THE LIKELIHOOD OF BACK INJURY?

Steven A. Lavender, Eric P. Lorenz, Susan Shott and Gunnar B.J. Andersson¹

¹Orthopedic Surgery Ergonomics Laboratory

Rush Presbyterian St.Luke's Medical Center, Chicago, Illinois, U.S.A.

slavende@rush.edu

INTRODUCTION

Previous studies found no change in back injury incidence following training programs that have taught lifting techniques (Daltroy et al., 1997; van Poppel et al., 1998). Daltroy et al. (1997) reported that while employees conceptually understood the desirable lifting techniques, they did not use them. The purpose of this study was to evaluate a new behaviorally oriented training process that was designed to facilitate the adoption of improved lifting techniques. Our hypothesis was that those who complete the initial training with smaller spine twisting (axial rotation) moments would have a reduced likelihood of subsequent back injury relative to those with larger twisting moments or those who did not experience this training process (controls).

METHODS

Sample. Experienced employees were recruited from 17 distribution centers. These workers normally move boxes weighing between 2 and 36 kg at a rate of 160 to 180 boxes per hour. The 1,978 participants were randomized into either the "LiftTrainer" group (n=957) or the "video" control group (n=1021). The control group's participation consisted of viewing a short videotape demonstrating lifting techniques. Participants in the LiftTrainer group had the opportunity to attend 5 half-hour individualized training sessions distributed over a 10-month period. The participants in the LiftTrainer group were, on average, 33.5 years old (s.d.=9.6 yrs.), had 5.9 years of experience in the current job (s.d.=6.8 yrs). All participants were followed for up to 12 months following the completion of the initial training session.

LiftTrainer Training. A magnetic motion measurement system was used to track body movements as lifts were performed. The *LiftTrainer*TM software used the movement and box weight data in a dynamic 3-D linked segment model to instantaneously calculate the 3-D moment vector acting on the spine (L5/S1). The data were sampled and the moment vector calculated at 103 Hz. The magnitude of the resultant moment vector was used as a biofeedback signal in that it controlled the pitch of a tone heard by the trainee. In addition to the continuous time-varying biofeedback, at the completion of each series of lifts the peak 3-dimensional moment components (forward bending, twisting, lateral bending) were displayed graphically.

The lifting task required the employees move four boxes at their normal pace from one pallet to another. The box weights varied across training sites between 11 and 14 kg. The training sessions started by having the employees demonstrate how they would normally complete the lifting task. At the

conclusion of the half-hour session, the tone was turned off and the employee repeated the task one more time. These final lifts provided the final performance data.

Analysis. Back injury data were analyzed using survival analysis techniques in SPSS. The Kaplan-Meier procedure was used to analyze across groups based upon the value of the mean twisting moment from the final set of lifts.

RESULTS

The Kaplan-Meier tests indicated that the likelihood of back injury for those who had a final mean twisting moment less than or equal to 30 Nm was significantly lower than the video controls (p=.016) and those participating in the LiftTrainer training but had a mean twisting moment over 30 Nm (p=.001). This latter group was not significantly different from the controls (p=.10) (Figure 1).

Figure 1. Survival curves for control and the two subdivided LiftTrainer groups.

CONCLUSIONS

Those that completed the initial training session with smaller twisting moments (≤ 30 Nm) were less likely to report a back injury in the following 12 months than LiftTrainer participants who did not achieve the same level of performance or participants who only viewed a video on lifting techniques.

A COMPARISON OF EMG CONTROL BETWEEN DISTAL AND PROXIMAL MUSCLES OF THE UPPER LIMB

Keith Gordon^{1*} and Daniel P. Ferris^{1,2}

¹ Movement Science and ² Biomedical Engineering, The University of Michigan, Ann Arbor MI, USA, *kegordon@umich.edu

INTRODUCTION

Much of the research that has focused on myoelectrical control for assistive devices has targeted computer processing of the EMG signal. Relatively little is understood about the human motor adaptation side of myoelectrical control. Several studies have shown that humans can learn to modify their EMG patterns with audio/visual biofeedback for purposes of rehabilitation. These findings suggest that myoelectric signals will also undergo substantial adaptation when controlling prostheses and orthoses. In addition, it seems reasonable to expect differences in control accuracy and adaptation depending on which muscles are used for the EMG control signal. Muscles that control the hand are used for fine control tasks while more proximal muscles are used more for more gross motor tasks. Thus an important human factor to consider when building a proportional myoelectrical device is the muscular origin of the EMG control signal.

The purpose of this study was to compare the ability of humans to control EMG signals derived from proximal and distal muscles of the upper limb. Because of the superior motor control ability of the distal muscles, it is hypothesized that humans will have greater control over EMG signals derived from the forearm then from the upper arm.

METHODS

We created a software program to operate in real-time on dSPACE robotics hardware. The program inputs EMG signals originating from two muscle groups to control one-dimensional motion of a virtual object. The software controls the virtual object movement by applying a force proportional to EMG amplitude. One EMG signal acted as a positive force and the other as a negative force. An inertial load on the object and a viscous damping constant were set to make the positioning tasks challenging but feasible. Five male subjects, 20–27 years of age, participated in this study.

During the experiment the subjects controlled the movement of the virtual object with paired sets of EMG activity from distal musculature (forearm flexors and extensors) or proximal musculature (side biceps and triceps) on the dominant side. All EMG signals were normalized to EMG amplitude recorded during maximum voluntary contraction. Subjects performed two different positioning control tasks, a static and dynamic task, with both distal and proximal musculature. The static task consisted of the subject moving the virtual object from the 0 position to the 5 position and holding the object consistently and accurately at the target position for the remainder of the trial. For the dynamic trial the subjects were instructed to oscillate the object between two targets, 5 and –5, as fast and as accurately as possible. All trials lasted 30 seconds.

Subjects performed nine sets each of the static and dynamic task while using proximal musculature and another nine sets each while using distal musculature. We analyzed data for the first and ninth trials for each task.

RESULTS AND DISCUSSION

For the static trials, subjects were able to successfully hold the virtual object at the mean target position, 5, using both the distal and proximal musculature. There were no significant differences between muscles groups to position the object during the static task. After practice, the subjects positioned the virtual object at a mean position of 5.016 ± 0.057 using the distal musculature and at 5.068 ± 0.261 when using the proximal muscles.

For the dynamic trials, subjects did not show significant differences in their ability to move the object between the two target positions using either distal or proximal musculature. After practice, subjects had mean error scores (difference between target oscillation end points 5 and –5 and the position where the subject actually changed direction) of distal: 0.025 ± 0.057 . and proximal: 0.080 ± 0.261 .

It was surprising that there were no differences found in the ability of the subjects to control EMG with different musculature. We hypothesized that there would be differences because the relative use to control fine motor tasks. One explanation for the lack of difference is the normalization to maximum voluntary contraction EMG amplitude. When normalized to the maximal flexion force of a muscle, there appears to be no significant difference in force control for the distal and proximal muscles of the arm (Jones 2000).

SUMMARY

Results showed that when subjects controlled movement of a virtual object with proportional myoelectrical control, there was no difference between using forearm muscles and using upper arm muscles for the control EMG signal. If this observation reflects a more general conclusion regarding proximal vs. distal musculature, then humans should be able to use EMG signals from any part of the upper or lower limb to provide accurate proportional myoelectrical devices. Our future studies will examine a greater range of musculature as potential controllers for myoelectrically controlled orthoses.

A NON-INVASIVE METHOD FOR THE BLOOD VISCOSITY DETERMINATION

Patrice Fourgeau¹, José-Maria Fullana¹ and Patrice Flaud²

¹Laboratoires Innothera, Arcueil, France, Patrice.Fourgeau@innothera.com

²Laboratoire de Biorhéologie et d'Hydrodynamique Physico-chimique, CNRS, Université Paris 7, Paris, France

INTRODUCTION

We present a method for the non-invasive determination of the blood viscosity, valid for periodic as well as non-periodic flows. This method is based on the integral method of data inversion (Bruni, 1998). Before application, data are treated using a smoothing technique. We show on numerical data that the coupled system (smoothing plus integral method) works even for large values of noise.

METHODS

The aim of this work consists in computing the hemodynamic parameters of a stasis followed to a starting flow in a rigid cylindrical pipe. We present an inverse method to give a numerical estimation of the viscosity.

We consider a Newtonian fluid. From the Navier-Stokes equations and assuming the axial velocity profiles $w(r,t)$ are known, we can eliminate the pressure gradient and finally find an expression of the viscosity only as a function of the axial velocity profiles. The viscosity expression allows us to compute the viscosity on an optimal spatial region $[R_1; R_2]$ on the radius at each time t :

$$\nu(t) = \frac{R_2^2 \int_0^{R_1} \left(\frac{1}{r} \int_0^r \frac{\partial w}{\partial t} dr \right) dr - R_1^2 \int_0^{R_2} \left(\frac{1}{r} \int_0^r \frac{\partial w}{\partial t} dr \right) dr}{R_2^2 w(R_1) - R_1^2 w(R_2) + (R_1^2 - R_2^2) w(0)} \quad (1)$$

and on an optimal temporal range $T=[t_1; t_2]$ by integration between t_1 and t_2 of the numerator and denominator of (1).

When we applied numerical inversion on experimental data we expect large variations on the solutions because inverse methods are generally ill-conditioned. Moreover in medical research the signal-noise ratio is large and in this particular application the viscosity results from a quotient of integrals. It is thus necessary to smooth the data before computing the inverse problem.

We present also a smoothing technique based on the regularization theory (Poggio et al, 1990, Hertz et al, 1991).

RESULTS

In order to evaluate the noise sensibility on the viscosity results before and after smoothing, the velocity profiles are numerically generated by integration of 2D Navier-Stokes equations. Next, we simulate the experimental data by adding a random noise to the velocity profiles. Thus, we compute the viscosity parameter for different noise values.

The first result is obtained for free-noise set to evaluate the influence of the different viscosity value, the acceleration time t_A (0.08 to 1 s), the optimal spatial region and the time range frequency f_i .

The determination of the optimal parameters and their application on numerical data allows us to test the robustness of the coupled system before experimental applications.

DISCUSSION AND CONCLUSION

Once the optimal spatial region determined, the model gives a very accurate viscosity value (Figure 1): $< 3\%$ for exact profiles, and for noised profiles $< 8\%$ at each time and $< 5\%$ for an optimal temporal region (percentage value related to the viscosity inputs ν_{input}). The highest percentages are obtained for the briefest acceleration times. For exact profiles, the optimal spatial region is confined near the wall, within the viscous boundary layer. The optimal temporal range corresponds to the time to reach a full-developed flow. If noise is present, this optimal temporal range is inferior to the acceleration time. Indeed, the level noise hides the slight differences of profile shapes when the flow is not yet full-developed. Therefore, due to the convolution effects during experimental ultrasonic acquisitions, the velocities near the wall are poorly determined (Flaud et al, 1997). So, it will be necessary to take an optimal spatial region with the radial position R_2 fixed to $(1-n)\%$ of the radius if the convolution size zone is less than $n\%$ of the radius.

Figure 1. Viscosity determination for the optimal spatial region $[0.8; 0.97]$ for a starting flow with $t_A = 0.95$ s, $f_i = 100$ Hz, $\nu_{input} = 4 \cdot 10^{-6} \text{ m}^2 \cdot \text{s}^{-1}$.

It is important to note that, contrary to viscometers, this approach represents a viscosity measurement method in blood vessels without modifying the rheology. Moreover the coupled system presented here is very robust and can be applied directly from instantaneous velocity profiles obtained by Doppler ultrasonic measurements.

INTRODUCTION

Because of the complexity and sophistication of the in vivo environment, to systematically study the behavior of cellular response to mechanical forces has mainly relied on the use of in vitro preparations. The parallel plate flow chamber is the most common used for applying fluid shear stress to cultured cells. Most studies used parallel plate flow chambers under steady flow, and only a limited number of in vitro studies concerned with the influence of pulsatile flow. Several kinds of flow chamber were developed which can provide pulsatile flow to cells (Helmilinger et al, 1991; Ruel et al., 1995; Tacobes et al., 1998). If the flow in flow chamber similar to the in vivo arterial pulsatile flow can be applied to cultured cells, then more useful information may be achieved.

METHODS

A parallel plate flow chamber system which can simulate physiological pulsatile flow in artery was devised. The three dimensional flow field and shear stress distribution were analyzed by numerical calculation under conditions the recorded flow input/output in experiments were applied.

Calf pulmonary endothelial cells (CPECs) were cultured using the apparatus.

RESULTS AND DISCUSSION

Phenomena of CPECs was studied when cultured under steady and pulsatile flow, under different heart rates, different flow rates and different pressure levels.

Figure 1: The flow chamber system (left), and the sketch of the flow chamber (right).

Figure 2: Wall shear stress distribution under pulsatile flow.

Figure 3: CPECs under pulsatile flow for 12 hours.

SUMMARY

The parallel plate physiological pulsatile flow chamber system can be used to study vascular cellular mechanical behaviors, especially combining with the computational fluid dynamics.

THREE-DIMENSIONAL KINEMATICS OF RIGHT VENTRICULAR SYSTOLIC CONTRACTION

Idith Haber^{1,2}, Dimitris N. Metaxas³, and Leon Axel⁴

INTRODUCTION

The right ventricle (RV) receives blood from the right atrium and pumps it out to the lungs. Due to its thin wall (~3-5mm), complex geometry, and large deformation, RV motion has been difficult to capture. Only recently, tagged MRI imaging combined with 3D motion reconstruction has allowed for a detailed capture of 3D motion. We present a quantitative analysis of normal RV motion, with a view towards using such data as a baseline for detecting wall motion abnormalities in diseases affecting the RV.

METHODS

ECG-gated tagged MRI cine-images of 5 normal volunteers are acquired on a 1.5T GE magnet. These images are used to reconstruct the 3D motion of the biventricular unit using a method described in (Haber, 00). The resulting dynamic finite element model of the ventricular motion is used to analyze the kinematics of RV contraction. We quantify the global motion of the RV and septum is relative to the left ventricular (LV) long axis. The finite elements also allow for calculation of the 3D strain tensor. We consider the minimum principal strain (E3), to be a measure of the greatest muscle contraction between end-diastole and end-systole. The angle (α_3) between the E3 direction and the local circumferential direction is also considered. We define regions of the heart using anatomical landmarks: the RV outflow tract; the rest of the RV and septum are sectioned along the long axis into basal, middle and apical regions.

RESULTS AND DISCUSSION

Figure 1: Color plot of E3 on RVFW (scaled is 0 (white) to -.32). Lines indicate E3 directions in midwall. LV is shown darkly shaded

We first quantified the global displacement of the right ventricular free wall (RVFW) and found that the right ventricle exhibits the same twisting motion as the left ventricle: the base rotates counterclockwise while the apex rotates in the clockwise direction. A decreasing base-to-apex gradient (linear regression) in the axial displacement was found in the RVFW ($R=0.931$) and septum ($R = .918$). This indicates that

the base of the ventricle is pulled down towards the apex during contraction. Corresponding (basal, mid, and apical) regions in the free wall showed greater axial displacement ($p<.001$) than the septum.

We calculated the principal strain directions and present the results for E3, which agreed with previous studies (Waldman, 86; Young, 94). Fig. 1 shows a typical result. Within both the free wall and septum, E3 and α_3 were significantly smaller at the base than in other regions ($p<.005$ and $p<.05$, respectively). For the current number of subjects, no significant differences in E3 were found in corresponding regions of the RVFW and septum. However, differences in α_3 were found (Fig. 2). These results are consistent with the fact that the muscle fiber orientations are more longitudinal in the free wall than in the septum (on average).

Figure 2: Angle α_3 : E3 direction vs. the circumference of RV and septum. Freewall: α_3 was smaller (more circumferential) in the base vs. mid, apex ($^*p <.005$), and outflow tract($^{+++}p <.05$). Septum: smaller α_3 in base vs. mid-ventricular and apical regions ($^{++}p <.03$). Paired t-tests between walls showed that α_3 was significantly smaller in the base and mid-ventricle ($^*p <.005$). Multiple comparisons within walls were performed by Scheffe' subtesting. Values are mean \pm SD.

CONCLUSIONS

The 3D motion reconstruction allowed us to find consistent trends among 5 normal cases. We plan to perform more complex analyses of RV motion on more cases in the future.

INCREASES IN KINETIC DEMANDS OF THE SUPPORTING LIMB DURING OBSTACLE CROSSING

Shing-Jye Chen and Li-Shan Chou

Department of Exercise and Movement Science, University of Oregon, Eugene, Oregon, USA

E-Mail: chou@oregon.uotegon.edu

INTRODUCTION

Skeletal muscle strength involved in postural control and locomotion declines with age and disease. The knee extensor and the ankle plantar flexor strength of nursing home fallers were only 37 and 10%, respectively, of those of elderly community dwellers (Whipple et al., 1987). As the available strength reduced, a greater challenge will be imposed on a muscle group when performing activities of daily living. Understanding the change in joint kinetics in reaction to different perturbations during walking may provide us information to better reveal mechanisms underlying increased incidence of falling in the frail elderly. Previous studies demonstrated that significantly greater external knee flexion, hip adduction, and ankle dorsiflexion moments were generated in the trailing limb when supporting the leading limb to step over a higher obstacle (Chou and Draganich, 1997). However, limited information is available to document how the obstacle height affects the joint kinetics when the leading limb is supporting immediately after crossing the obstacle (Chou et al., 2000). Therefore, the purpose of the study was to identify any increases in joint kinetics during both supporting periods when stepping over an obstacle in healthy young adults.

METHODS

Fourteen young healthy subjects, including ten male (mean age, 25.1 years) and four female adults (mean age, 24.6 years) were recruited for this study. Subjects were instructed to walk along an 8m walkway at a comfortable self-selected speed while barefoot. Whole body kinematic data were collected from each subject using a six-camera HiRes™ system (Motion Analysis Corp., Santa Rosa, California) during unobstructed level walking and when stepping over an obstacle of height corresponding to 2.5%, 5%, 10%, or 15% of the subject's height. The order of obstacle height was randomly selected. Joint kinetics was computed using the OrthTrack™ software. Effects of the obstacle height on the joint moments of both limbs were tested with one-way ANOVA with repeated measures at $\alpha = 0.05$ level of significance.

RESULTS AND DISCUSSION

During the support of the trailing limb, the peak external hip and knee flexion moments in the early stance and the peak external ankle dorsiflexion moment in the late stance were found to increase significantly as the obstacle height increased ($p \leq 0.013$; Table 1). During the support of the leading limb, the peak external hip flexion moment in the early stance and ankle dorsiflexion moment in the late stance were found to increase significantly as the obstacle height increased ($p = 0.004$ and $p < 0.001$, respectively).

Effects of the obstacle height on joint moments of the trailing limb identified in this study were in agreement with those reported previously (Chou and Draganich, 1997). Greater muscular demands on extensors of the hip, knee and ankle joints of the trailing limb are required to support and elevate the whole body over the obstacle. Similarly, the hip extensor of leading limb is then challenged to accommodate a greater and faster downward movement of the whole body after crossing the obstacle during early stance. Furthermore, a greater effort from the ankle plantar flexor of leading limb is needed at the end support to regain the normal walking speed.

SUMMARY

Results of this study indicated that greater external flexion moment are generated at the hip and ankle joints of the leading limb when stepping over a higher obstacle. Greater muscular demands on the hip extensor and ankle plantar flexor during early and late stance, respectively, are required to maintain a smooth motion of the whole center of mass and to resume a normal walking speed after successfully crossing the obstacle.

THE USE OF SKIN PRE-TENSION TO MODIFY TIBIAL BONE ACCELERATION ESTIMATES

David J Pearsall¹, Ewald M. Hennig² Thorsten Sterzing²

¹. Department of Kinesiology and Physical Education, McGill University, Montréal, QC, Canada

². Biomechanik Labor, Universität Essen, Essen, Germany

INTRODUCTION

Previous studies have demonstrated that measures taken from tibial bone-mounted accelerometers are closely related to vertical force peak loading rate (Hennig & Lafortune, 1988, 1991). Though surface-mounted accelerometers would be more practical for testing (i.e. non-invasive) the relative skin-to-bone movement has confounded their use for accurately estimating ground reaction force parameters.

METHODS

Fifteen adult subjects (mass=71.3 kg±12.7) participated in the study. A uni-axial accelerometer (Entran), oriented in the longitudinal direction, was mounted on the skin surface of distal anterior tibial shaft of each subject. To apply a constant pre-tension to the skin immediately superior to the accelerometer, two Velcro tapes strips were glued to the skin surface. A band of rubber could be adhered to these Velcro surfaces. By varying the amount of band stretch, skin tension could be induced (Figure 1). Four stretch conditions were evaluated: 0, 1-3, 4-8, 10-15 mm. The tensions needed to induce these changes ranged from 4 to 15 N based on the displacement of the linear elastic rubber band. With the greatest tension, subjects expressed no great discomfort during or after testing. Subjects were evaluated while running at 3.3 m/s with running shoes within the gait lab. From a force plate (Kistler), foot strike ground reaction force measures were collected from the limb mounted with the accelerometer. Five trials of each condition per subject were collected.

Figure 1. Anterior view of tibial shaft with skin deformations of 0, 1-3, 4-8, 10-15 mm induced (a-d, respectively).

RESULTS AND DISCUSSION

As reported previously (Hennig & Lafortune, 1988), elastic rebound of the skin overrepresents the acceleration of the underlying bone. In the present study the measured peak acceleration was lowered from the no stretch to the maximum

stretch condition (14.0, 11.9, 8.6, 7.4 g). Bone mounted accelerometer shock measurements have a very close relationship to the peak force rate of the vertical ground reaction force (Hennig & Lafortune, 1991). With increasing skin tension an improved relationship was found between the peak force rate at ground contact (normalized to body weight) with respect to peak acceleration measures of the tibia. With no pre-tension the relation was poor ($r^2=0.28$) but improved incrementally with applied tension ($r^2=0.47, 0.68, 0.71$).

Figure 2. Peak tibial acceleration (g) vs. peak ground reaction force rate (bw/s) at maximal skin pre-tension.

SUMMARY

The skin pre-tension approach may permit the use of surface mounted accelerometers to estimate tibial bone accelerations and, in turn, ground reaction force variables. Thus, this technique creates the opportunity to explore running dynamics in number of situations where force plates cannot be utilized.

TORSIONAL STABILITY OF TOTAL ELBOW ARTHROPLASTY

Jufang He¹, Mark E. Baratz¹, Felix Riano¹, James Rudert³, Mark C. Miller^{1,2}.

¹Biomechanics Research Laboratory, Allegheny General Hospital, Pittsburgh PA, jhe@wpahs.org

INTRODUCTION

As Total Elbow Arthroplasty is introduced to younger generations, the post-operative stability of the humeral construct is a major concern. In particular, the importance of the humeral condyles is uncertain. The presence of the condyles may increase the stability, but many surgeons remove them to reduce the duration of the procedure. Furthermore, some designs incorporate a flange and the use of a bone block that may add to the stability. This study tests the hypothesis that either condyles or bone block will increase the stiffness of the humeral construct.

METHODS

Eleven frozen cadaveric distal humerus, cut 20 cm proximal to the trochlea were defrosted at room temperature and cleaned off all soft tissue. The humeral canal was broached and the stem cemented. Specimens were mounted into a custom-made jig in a bi-axial testing machine (Bionix, MTS Inc.). Given that the torsional strength of the humerus is approximately 53N-m (Schopfer et al), loads of 10N-m and 20N-m were chosen to test the torsional stability. To avoid hysteresis effects in the structure, every specimen was pre-conditioned 10 times at both load levels. Loads were applied linearly over 10 seconds. Angular displacement and loads were recorded at 12Hz. Each specimen was tested with both condyles and bone block, then with condyles but without bone block, then without condyles and bone block, and finally with bone block but without condyles. Lastly, the specimen was loaded to failure in torsion with the bone block in place. Figure 1 shows the load and displacement curve of a typical specimen. The stiffness was defined as the slope of the best-fit line of the data points through the origin. Stiffnesses were normalized using the first test condition for purposes of comparing and repeated measures Anova was used to statistically compare the stiffnesses under different test conditions.

RESULTS

The relative stiffnesses are shown in Figure 2, in which all values are normalized by the stiffness in the first test condition. The structure with both condyles and bone block had the greatest stiffness. Although Figure 2 shows only the results for 10 N-m, the same trend was found for a 20 N-m load. Stiffnesses decreased with each test, however, statistical analysis showed no significance ($p>0.05$). The average failure load was 37.41 (± 12.51) N-m. All failures were spiral fractures of the humerus.

Figure 1: Load and displacement curve of a specimen at 10 N-m load.

Figure 2: Normalized torsional stiffness (\pm S.D.) of humeral construct under different test conditions at 10 N-m load.

DISCUSSION AND CONCLUSIONS

When no condyles were present, stiffnesses with or without a bone block remained essentially the same. The largest difference appeared between the first and fourth tests ($p=0.062$), however, no significance was found. Although the sequence of test conditions was not varied, the average failure load was substantially larger than the test load. That is, the load levels were well below the failure load and no damage was believed to have affected the relative stiffnesses. This average failure load was somewhat below the results found by Schopfer et al for intact humerus, but a good cement mantle was found in all specimens.

The stability of the humeral construct was represented by the amount of torque required per unit of angular movement. A statistical analysis was performed on the tests. Results showed that the presence of either condyles or a bone block does not increase the torsional stability of the humeral construct. In conclusion, sacrifice of the condyles appears to be a viable surgical option.

THE ROLE OF TORSO MUSCLES IN TRUNK TWISTING

Shrawan Kumar and Yogesh Narayan

Ergonomics Research Laboratory, University of Alberta
Edmonton, AB T6G 2G4, Canada

INTRODUCTION

Kumar (1993) and Kumar et al (1996) reported the phasic and the magnitude relationship of the external and internal obliques, rectus abdominis, pectoralis major, latissimus dorsi and erectors spinae at T₁₀ and L₃ levels in an unrestricted trunk twisting at a normal velocity. These authors reported a differential in onset timing of different muscles. They found that the twisting was initiated and sustained by the contralateral external oblique, the ipsilateral latissimus dorsi. However, it is unclear if the twisting has the same (or similar) phasic and magnitude relationship in isometric and isokinetic modes. The current study reports the results of this investigation.

METHOD

Fifty normal young adults (27 male and 23 female) were placed in upright neutral seated posture in a specially designed and fabricated Axial Rotation Tester (AROT). The subjects were stabilized in the device such that only thoracolumbar region could be rotated. From the upright neutral seated posture the subjects were required to exert their 25%, 50% and 75% of previously measured maximal voluntary contraction (MVC) in bilateral twisting with visual feedback to maintain the force level. A block randomized experimental design was used. The force and EMG from erector spinae at T₁₀ and L₃, external and internal oblique, rectus abdominis, latissimus dorsi and pectoralis major were recorded bilaterally at 1 kHz. The task cycle was referenced to the onset of the torque. The timings of RMS and smoothed EMG were referenced to the torque onset. The slope, normalized EMG amplitude, EMG per unit time and EMG area under the curve were calculated. An analysis of variance, Pearson's product moment correlation between the torque and EMG and the regression analysis was carried out using SPSS statistical software package.

RESULTS AND DISCUSSION

There were no significant differences between male and female subjects in EMG variables. The phasic interrelationships of external obliques, the latissimus dorsi and the erector spinae were different from other muscles ($p < 0.01$). With increasing grades of contraction the latissimus dorsi and the external obliques increased their magnitude significantly ($p < 0.01$) whereas that of erector spinae underwent a decrease in proportionate terms (but not in absolute magnitude) suggesting a stabilizer role for

Figure 1: The magnitude contribution of different muscles in graded contractions in male samples in percent area.

them in trunk twisting. The relative timing and pattern of EMG in graded isometric contractions were significantly different from those of unresisted dynamic twisting ($p < 0.01$). These variables between different grades of isometric contraction did not differ significantly. However, within the isometric graded conditions timing of different muscles were variable due to lack of any motion.

SUMMARY

The twisting of the trunk is initiated by the contralateral external oblique and ipsilateral latissimus dorsi. The erector spinae acts as a stabilizer. The phasic relationship of torso muscles in dynamic conditions is set and repeatable whereas in static condition is variable

AN EFFICIENT AND ROBUST ICP TECHNIQUE FOR SURFACE REGISTRATION

Andrea G. Cutti¹, Angelo Cappello¹, Alberto Leardini²

¹ DEIS – Università di Bologna, Italy, andrea.cutti@ior.it

² Movement Analysis Laboratory, Istituti Ortopedici Rizzoli, Bologna, Italy

INTRODUCTION

In computer-assisted surgery, a robust method for spatial registration is necessary. The Iterative Closest Point (ICP) (Besl et al., 1992) is probably the most widely used algorithm for surface rigid registration, defined as the spatial alignment between a Data Shape (DS) and a Model Shape (MS). This procedure is limited by the monotonical convergence also to local minima of the cost function, and by the computational complexity of the closest point searching when performed extensively. For the former, authors have proposed to perform the registration starting from different initial states (Besl et al., 1992). The present study is aimed at reducing the number of these states. Many solutions have been proposed also for the complexity, but these are not easy to be implemented and require extensive pre-computation (Audette et al., 2000).

METHODS

The local minimum problem was addressed in eight steps: 1) the centroid of DS and MS are initially taken to the origin of the reference system; 2) the index to discriminate global to local minima is taken as the residual distance variance at the end of the registration process; 3) a threshold for this index is empirically defined according to the specific shape of the objects and to the expected noise; 4) a preliminary registration is performed; 5) if the index value at the end of 4) is above the threshold, a set of DS initial states is obtained by uniformly sampling the rotation angle domain and applying these rotations to DS; 7) the set of these states is classified assuming that the best rotation is the one which, after only one iteration of ICP, leads to the smallest residual distance variance; 8) the registration process changes the initial state of the DS at every registration until the index is above the defined threshold. The computational complexity of the closest point searching is reduced using pre-processing based on the Delaunay Tessellation (DT) of the MS (Fortune, 1992). The DT, as dual of the Voronoi Diagram (VD), is intrinsically related to closest point problems, and it has a data structure more manageable than the one associated to VD since DT is made of simplexes. Tests were conducted using a free-form version of the Standardised Femur (Viceconti et al., 1996). For the local minimum problem, MS was set to 5000 points. 300 DS points were randomly extracted from MS, and a Gaussian noise with zero mean value and 2mm standard deviation was added. For the three erroneous local minima (Fig.1), the smallest value of the residual distance variance was found to be 19 mm², independently from the number of points in DS. Having also observed a 2 mm² residual distance variance of the registration around the global minimum, the threshold was set at 3 mm². The sampling rate of the rotation domain was set at 45° for all the rotations. For the closest point tests, different combinations of points for DS and MS have been tested, starting from different positions of DS with respect to MS. The DT and

closest point searching implementation was taken from Matlab (The MathWorks). A highly vectorised function of the exhaustive closest point searching was implemented in Matlab.

RESULTS AND DISCUSSION

From every imposed starting state, the novel algorithm reached a registration around the global minimum. In the worst case (initial pose of 160°, 110°, 0° cardanic rotations), the algorithm imposed 40 guessing rotations to DS. Results for the closest point problem are summarised in Table 1. The starting position proved to have no influence on time performance. The pre-processing of the DT was found to have negligible computational costs (Time_{DT}). The data reported for the closest point searching are the mean values over 60 iterations for every combination of DS and MS points. A reduction in time from 7 to 80 times was obtained.

Figure 1: Opposing local minima for a femur bone.

	Time _{DT}	0.43	0.88	1.43	1.92	2.47
	DS \ MS	1000	2000	3000	4000	5000
DT	500	0.054	0.10	0.16	0.21	0.28
	3000			0.19	0.24	0.31
	5000					0.34
	5000					0.34
Exh.	500	0.41	0.85	1.44	2.12	2.86
	3000			8.55	12.32	16.57
	5000					27.26

Table 1: Computational performance [s] with different DS and MS points. Closest point searching using the proposed DT and the traditional Exhaustive searching are compared. Analysis was performed with an AMD 1000Mhz processor.

SUMMARY

This study enhances the convergence to the global minimum of the ICP algorithm. The proposed solution for the computational complexity of the closest point searching is simple, efficient and with negligible pre-computational costs.

GLENOHUMERAL JOINT LAXITY WITH AND WITHOUT ROTATOR CUFF CONTRACTION

Kevin McQuade^{1,2}, Anand Murthi², Margaret Finley^{1,2}

¹University of Maryland School of Medicine, Baltimore, MD USA

²Baltimore Veterans Administration Medical Health Care System, Baltimore, MD, USA

³Communicating Author: Kmcquade@som.umaryland.edu

INTRODUCTION

Examination of the shoulder routinely involves testing for joint laxity and stability. There have been several obstacles in developing quantitative testing for the shoulder joint under passive and dynamic conditions. These include stabilization of the scapula, appropriate location of translation points, and ability to perform tests with multiple arm configurations. McQuade et al (1999) has developed a method for quantitative assessment of the glenohumeral joint using magnetic tracking and examiner instrumented applied force measurements. This study begins to extend previous work by using a scapular reference frame, using a humeral head center finding algorithm and including an assessment of muscular contraction effects of the rotator cuff. This pilot work presents the first three subjects using this approach.

METHODS

Three athletic female subjects between the ages of 25-30, were tested. Subject 'A' had no history of shoulder problems, Subject 'C' was previously a competitive swimmer and had a long history of shoulder problems including subluxations. Subject 'S' was a squash player with no history of shoulder problems. Subjects were instrumented with electromagnetic tracking sensors (Flock of BirdsTM) for the scapula and humerus of their dominant arm. A third sensor was attached to a small hand held plastic base that was also fixed to a small load cell. This device was held in the palm of the examiners hand and provided information as to the orientation of forces applied to the subject. The Scapula and humerus were digitized using MotionMonitortm software (Innsport Inc, Chicago Ill). Local coordinate frames were determined for the scapula with orthogonal axes perpendicular and parallel to the body of the scapula. Humeral head sensor data was transformed with respect to the scapular reference frame. Humeral head center location was determined by using a least squares method, collecting the orientation of the humerus in ten random different configurations and predicting the zero velocity point. The RMS error (within 4mm) and the positions of the humeral center relative to the humeral sensor and the scapular sensor were used to assess the accuracy of the method. Subject's arm was placed in abduction and external rotation, clinical anterior drawer tests were performed with the subject relaxed and with the subject performing an isometric internal rotation contraction with mild resistance (5lbs).

RESULTS AND DISCUSSION

The anterior translation of the glenohumeral joint during directly applied loads under conditions of relaxation and rotator cuff contraction are shown for the three subjects in Fig 1a, 1b and 1c.

Figure 1abc

Figure 1b

Figure 1c

SUMMARY

Results show how stiffness of the glenohumeral joint changes with contraction primarily of the subscapularis to constrain the humeral head from anterior translation. In subjects 'A' and 'S' the stiffness increased significantly indicating an effective cuff. Subject 'C' demonstrated very little difference, indicating a dysfunctional cuff. This was consistent with her history of shoulder problems. We are continuing this study with a larger sample size and use of EMG for muscle verification and with patient populations to assess the effects of cuff surgery and rehabilitation.

INFLUENCES ON EYE LOCATION AND POSTURE OF DRIVERS

Marion Fehren^{1,2}, Jan Thunnissen¹ and Klaus Nicol²

¹ Johnson Controls GmbH, Burscheid, Germany, marion.fehren@jci.com

² Laboratory of Applied Biomechanics, University of Muenster, Germany

INTRODUCTION

An accurate prediction of the driver's posture is important for comfort and safety. Thus, there are several models available concerning the preferred horizontal seat adjustment and eye location (e. g. Flannagan et al. 1998, Kolich 2000, Manary et al. 1998, SAE J941). Since factors such as visibility and head clearance are not considered in the models, the question was, how far they affect the drivers' joint and eye locations. Thus, posture measurements were made in a real car environment to detect the relationships indicated above.

METHODS

In a middle class car a posture study was performed with 9 volunteers (5th percentile (5th p.) females, 50th p. and 95th p. males). Backrest angle, cushion height, and horizontal seat position were adjusted by the subjects to their preference. After 5 min. of sitting, the coordinates of several palpable landmarks at head, trunk, arms and legs were recorded with a FARO arm. Seat adjusting and posture recording were performed twice for each subject. Subsequently a comfort questionnaire was applied. Then the joint coordinates were calculated according to Reed et al. (1999) and t-tests were applied to detect differences between the subgroups.

RESULTS AND DISCUSSION

The eye locations of the subgroups are shown in Fig. 1. Consistent with results of Manary et al. (1998) the locations are more rearward and upward than the SAE J941 eyellipses (a technical standard for eye location). This indicates that the SAE model is less suitable for realistic driving conditions.

Concerning the z-coordinates, in both male subgroups the eye location is significantly more upward than in the female subgroup ($p < 0,05$), but between the 50th and 95th p. males there is no significant difference in both measurements.

Surprisingly, the x-coordinates of the eye location of the 95th p. males is more forward than the ones of the 50th p. males ($p < 0,05$ in both measurements). However, analysis of the joint locations in side view do not reveal significant differences between the 50th and 95th p. males concerning torso location. Obviously, there occurs a more forward movement of the head relative to the torso for the 95th p. males compared to the 50th p. males. Concerning the reasons for this relative movement the questionnaires reveal limited head clearance and visibility (too low upper edge of windscreen). Further, questionnaires indicate restricted visibility for the 5th p. females caused by the height of the instrument panel.

Substantial differences between model and empirical data (up to 128 mm) are seen in the horizontal seat adjustment too. Inconsistencies certainly can be reduced, if visibility and head clearances are included in the models. It can be concluded that

- visibility and head clearances affect eye location and posture, so eye location and posture studies should not be performed in seat mock-ups only, but in real cars too,
- posture models should consider both, anthropometric and package variables including visibility and head clearances.

Figure 1: SAE eyellipses (for torso angle = 24°) and actually measured eye locations of volunteer drivers

SUMMARY

A posture study in a real car was performed to investigate the effect of certain package factors on joint and eye location. The results indicate substantial differences between model prediction and empirical data and lead to the conclusion that boundary conditions such as visibility and head clearance have to be considered in posture prediction models.

SIZE EFFECTS IN NONLINEAR VISCOELASTICITY

Anthony Escarcega, Paolo P. Provenzano, Rittu Hingorani, Roderick Lakes, Ray Vanderby Jr.

Orthopedic Research Laboratory, University of Wisconsin, Madison, WI. University of Wisconsin Hospital, Division of Orthopedic Research, 600 Highland Ave, Madison, WI 53792. vanderby@surgery.wisc.edu

INTRODUCTION

Ligaments are viscoelastic and thus, display time-dependent and load history-dependent mechanical behavior (Woo, 1982). In this study two viscoelastic properties are considered: stress relaxation and creep. In a recent study (Provenzano et al, 2001) showed nonlinear behavior in the rat MCL in which the rate of creep and relaxation is dependant upon the level of stress and strain, respectively. Since this had never been reported before in the literature, it is the goal of this study to determine if this phenomenon holds true for larger animals. This study examines rates of stress relaxation and creep at multiple levels within the physiologic range using two different sized animal models.

METHODS

Medial collateral ligaments (MCLs) from ten pairs of pig knees and six pairs of rabbit knees were used for this study. The testing for all pairs of ligaments followed the same protocol; multiple stress relaxation tests were performed on each MCL and multiple creep tests on the contralateral MCL. Between each test, the ligament was allowed to recover for at least 10 times the length of the test while remaining hydrated. The order of the tests started with the smallest strain and increased. Stress relaxation for each test lasted 100 s and had a rise time of 10 percent strain per second. The contralateral MCL was tested next in creep for 100 s and the applied load corresponded to the maximum load for stress relaxation. All tests were performed below the suspected structural damage threshold for these tissues (Provenzano, et al., 2002). Data was plotted on a log-log scale and a power law, t^n , was used to determine slopes (rate of relaxation or creep).

RESULTS AND DISCUSSION

The rates for both creep and stress relaxation were dependant upon the level of stress or strain for both the sizes of MCLs. The amount of strain varied from 0.46-5.44% for pig and 0.53-5.00% for rabbit as measured by video analysis. The rate of relaxation varied by nearly 2 times for the pig MCL with the rate being -0.0891 for 0.46% and -0.0451 for 5.06% and four times for the rabbit MCL with the rate being -0.275 for 0.87% and -0.067 for 5.00% (Fig 1). In creep, the results were similar, the pig MCL rate and the rabbit MCL rate had differences of

near 2 times and 4 times, respectively (Fig 2).

Figure 1: Change in the rate of stress relaxation for the rabbit MCL showing a decrease in rate with increasing strain.

Figure 2: Change in the rate of creep for the Pig MCL showing a decrease in rate with increasing stress.

SUMMARY

The magnitudes of the values of the change in rate suggest that there is a size effect in the way the ligaments behave in stress relaxation and creep. The previous experiment in rats has shown an order of magnitude change in rate over the physiologic range, where we have shown the change to be less as the size of the ligaments increases. The mechanism behind this is not understood, but could possibly be related transport of water within the ligament.

BIOMECHANICAL MODELING OF THE SCOLIOTIC SPINE REDUCIBILITY

Yvan Petit^{1,2}, Carl-Éric Aubin^{1,2} and Hubert Labelle²

¹Biomedical Engineering, École Polytechnique, yvan.petit@polymtl.ca

²Research Centre, Sainte-Justine Hospital
Montréal, Québec, Canada

INTRODUCTION

The flexibility of the scoliotic spine is well recognized as an important biomechanical factor in the planning of surgical instrumentation (Kleps et al 2001). Clinical tests like the side bending or the traction tests are commonly used to estimate the possible correction and to define the spinal segment to instrument. However, none evaluate the flexibility of the spine since the forces are not known. Also, there is no consensus on the optimal test to assess the scoliotic spine reducibility. Therefore, the objective is to develop a personalized biomechanical model of the spine that will allow the design of a clinical test providing optimal estimation the reducibility.

METHODS

A flexible multi-body model of the spine (figure 1) was developed to simulate several mobility tests. Vertebrae were represented using rigid bodies. Spherical joints and generalized spring elements were used to represent the intervertebral articulations according to reported experimental data (Oxland et al 1992, Panjabi et al 1976, 1994). Postero-anterior (PA) and lateral (LAT) radiographs of a scoliotic patient taken pre- and post-operatively were used to obtain the 3-D geometry of the spine using a 3D reconstruction and modeling technique (Aubin et al, 1995). Initial conditions of the model were defined from the pre-operative geometry.

Four tests (lateral bending, fulcrum bending, traction and axial rotation of the trunk) were simulated and compared to the reducibility obtained

Figure 1: Flexible multi-body of the spine: a) PA and b) LAT views.

from the pre- to post-op geometry. The reducibility of the spine was analyzed in 5 segments: 2 apical (T8-T10 and L1-L3) and 3 neutral (T4-T8, T10-L1, L3-L5). The reducibility

has been defined as the rotation of the superior vertebra relative to the inferior vertebra and the metric used was the norm of the axial vector of the rotation matrix.

RESULTS AND DISCUSSION

Figure 2 shows the reducibility of the scoliotic segments measured from the 4 simulations and from the surgery. It shows that reducibility is almost uniformly distributed along scoliotic segments and also that lateral bending and axial rotation tests are the closest to surgery. However, simplifying assumptions particularly concerning mechanical properties obtained from the literature and boundary conditions may have influence the results.

Figure 2: Simulated and measured reducibility of segments

CONCLUSION

Preliminary results show that lateral bending and axial rotation demonstrate more reducibility than other tests. Overall, these tests are the closest to that of surgery. Such results can be used to design an optimal clinical test and to define patient-specific mechanical properties for biomechanical models of the spine.

CHONDROCYTES AND FIBROCHONDROCYTES RESPOND DIFFERENTLY TO OSCILLATORY TENSION

Vanderploeg EJ, Collier KR, Imler SM, Levenston ME
Georgia Institute of Technology, Atlanta, GA marc.levenston@me.gatech.edu

INTRODUCTION

Tissue engineering offers potential therapies for patients suffering from degenerative joint disease and complications resulting from traumatic injury. *In vivo*, articular cartilage experiences predominantly compression, while fibrocartilage tissues experience both compression and tension. Understanding cellular responses to tissue-appropriate loading regimes is crucial to developing functional bioartificial tissue replacements. Both articular chondrocytes and fibrochondrocytes are possible cell sources for tissue engineered cartilage, but limited data exist comparing their responses to mechanical stimuli. This study compared the responses of chondrocytes and mensical fibrochondrocytes (MFCs) to oscillatory tension in 3-D culture.

METHODS

Chondrocytes and MFCs were isolated from immature bovine stifile joints and seeded into fibrin constructs at 5e6 cells/mL. Constructs (n=8) were pre-cultured for 1, 7, or 14 days and then cultured for an additional 68 hours either unloaded or with an oscillatory tensile stretch (1Hz, 10% p-p). During the final 20 hours, ³H-proline and ³⁵S-sulfate were added to the culture media. Six constructs were analyzed for ³H and ³⁵S incorporation and total DNA content. The remaining constructs were imaged using confocal microscopy for cell viability and morphology (calcein/ethidium homodimer). Additional constructs were cultured for 1 or 7 days and imaged for F-actin filaments (Alexa Fluor® 546 phalloidin).

RESULTS

MFC Constructs Oscillatory tension had no effect on MFC protein synthesis (³H) but significantly inhibited proteoglycan synthesis (³⁵S) in the 1 day pre-culture group. No effect was seen on MFC construct total DNA content. **Chondrocyte Constructs** Oscillatory tension inhibited protein synthesis (³H) only in the 7 day pre-culture group but significantly inhibited proteoglycan synthesis (³⁵S) at all three time points. Tensile stretch significantly increased total DNA content; this effect was more pronounced at later time points. **Cell Morphology** Cell viability was high in all samples imaged. At all time points, unloaded chondrocytes maintained a rounded morphology (Fig.1b). Although unloaded MFCs exhibited a round morphology in the 1 day pre-culture group, by day 7 the cells had developed fine cellular projections (Fig.1a). Tensile stretch had no apparent effect on MFC morphology. In contrast, oscillatory tension induced a morphological change in a sizeable number of chondrocytes in the 7 and 14 day pre-culture groups. These cells resembled those of the 7 day MFC constructs (Fig.1a,c). Additional images of unloaded

constructs revealed F-actin filaments in the cellular projections of the MFCs and showed clear cytoskeletal organization in the chondrocytes (Fig.2a,b).

a: MFCs unloaded b: Chondrocytes unloaded c: Chondrocytes tension
Figure 1: Tension induces MFC-like morphology in chondrocytes (7 day preculture)

a: MFCs unloaded b: Chondrocytes unloaded
Figure 2: F-actin filaments after 7 days of preculture

DISCUSSION

The results of this study suggest that oscillatory tension causes chondrocytes to transition away from matrix synthesis and towards proliferation. In addition, the confocal microscopy images indicate that chondrocytes take on a more fibrochondrocytic morphology in response to oscillatory tension. These observations support the hypothesis that similar morphologies seen in the tensile regions of native fibrocartilage are functional adaptations to loading (Hellio Le Graverand, 2001, Errington, 1998). The spontaneous development of cellular projections by the MFCs in 3D culture raises questions regarding the stability of the adapted morphology of the chondrocytes. On-going studies are examining kinetics of cytoskeletal reorganization via confocal microscopy and specific changes in phenotype (RT-PCR) in response to tension and after its removal.

DO CONSTANT-RATE RAMP TESTS REPRESENT EQUILIBRIUM BEHAVIORS IN TENDON? DETERMINATION OF TENSILE MODULUS AND POISSON'S RATIO IN TWO DIMENSIONS

Heather Anne Lynch, Jeffrey P. Wu, Andrew Jawa, and Dawn M. Elliott¹
McKay Orthopaedic Research Laboratory, University of Pennsylvania
¹delliott@mail.med.upenn.edu

INTRODUCTION

Tendon modulus is not highly sensitive to strain-rate under constant-rate uniaxial tensile loading (Woo, 1990). However, it is not clear that the tissue is at equilibrium even when very slow rates are used. Equilibrium behaviors, where viscoelastic effects have dissipated, represent elastic tissue properties. These properties are important for elastic modeling and for comparing tissue properties across different studies. Incremental stress-relaxation experiments have not yet been used to measure equilibrium behaviors of tendon. The purpose of this study was to determine if slow constant-rate tensile tests represent equilibrium behaviors in tendon. We hypothesize that the properties of modulus and Poisson's ratio will not be different when measured using incremental stress-relaxation compared to constant-rate ramp tests. Because three-dimensional elastic modeling is needed for tendon, we tested this hypothesis for tendon samples aligned along the fiber direction and transverse to the fiber direction.

METHODS

Sheep flexor tendons were cut into rectangular specimens ($L \times W \times T = 9.16 \pm 1.90 \times 2.41 \pm 0.29 \times 1.87 \pm 0.35 \text{ mm}$) with the long axis either parallel (x_1 ; longitudinal) or perpendicular to the fibers (x_3 ; transverse). Uniaxial tensile loading was applied along the long axis of the specimen. Incremental stress relaxation (σ -RLX) testing of longitudinal specimens included 0.5N preload, preconditioning, and 1% strain increments with a 10-minute relaxation. For transverse specimens, a 0.005N preload and 4% strain increments were used; preconditioning was omitted. Ramp testing used the same preload and preconditioning as above, followed by a 0.01%/s, 1%/s, or 10%/s ramp to failure. Specimen images were acquired and 2-dimensional surface strain was calculated using custom Matlab and ABAQUS programs. Modulus was calculated as the slope of the linear region of the stress vs. strain curve. Poisson's ratio was calculated as $\nu_{13} = -\epsilon_{33}/\epsilon_{11}$.

RESULTS

There was no apparent difference between moduli for σ -RLX and constant ramp tests (FIG 1A,B) for either the longitudinal (E_1) or transverse (E_3) directions. Longitudinal moduli were approximately 2 orders of magnitude greater than transverse, consistent with previous studies (Yamamoto, 1990; Lynch, 2002; Quapp, 1998). Longitudinal Poisson's ratios (ν_{13}) were apparently strain-rate dependent (FIG 1C). The Poisson's ratios for the 1% and 10%/s ramp tests were much lower than those of σ -RLX or ramp testing. Transverse Poisson's ratio (ν_{31}) did not demonstrate strain-rate dependence for the 0.01%/s rate (FIG 1D). Poisson's ratio for the longitudinal orientation was much larger than for the transverse orientation.

DISCUSSION

In this study we measured the equilibrium anisotropic tensile properties of tendon and compared these 'elastic' properties to those of constant-rate tests. Consistent with our hypothesis, the equilibrium tensile modulus was not different from the constant ramp moduli for samples aligned parallel or perpendicular to the tendon fiber direction. Therefore, constant-rate ramp tests may represent the equilibrium elastic modulus of tendon for loading in both the longitudinal and transverse directions. However, contrary to our hypothesis, the Poisson's ratio did demonstrate strain-rate sensitivity. Poisson's ratio ν_{13} decreased as the strain-rate increased (FIG 1C), suggesting that the equilibrium volumetric loss did not have sufficient time to occur for the faster rates. We observed a loss of volume (assuming transverse isotropy of the tissue) for both the incremental stress-relaxation and for the slowest 0.01%/s constant rate tests. Volume loss may occur by fluid exudation. Thus, the values for Poisson's ratio reported here suggest that constant rate ramp tests may not represent equilibrium elastic behaviors. Additional testing is needed to show statistically significant similarities or differences between mechanical properties calculated from stress-relaxation testing and constant rate ramp testing.

STRENGTH PROFILE AND SWING PATTERN IN MALE AND FEMALE ELITE GOLFERS

Wen-Tzu Tang and Lawrence D. Abraham

Kinesiology and Health Education Department, University of Texas at Austin, USA

INTRODUCTION

The purpose of this study was to examine the strength profile and swing pattern of female and male golfers. The delay of the wrist uncocking action during the downswing is known to be one critical factor influencing maximum clubhead velocity at ball impact. Studies to date, however, have not compared male and female elite golfers relative to relationships among release time for uncocking, swing performance, and arm strength. Therefore, the purposes of this study are to compare male and female elite golfers in: (1) strength profile at different clubhead speeds, (2) the relationship between wrist uncocking release time and clubhead speed at ball impact (analyzed from kinematic and kinetic data), and (3) the relationship between wrist uncocking release time and the arm strength necessary to produce maximum clubhead speed.

Kinematic and kinetic data provide the basis for examining the relationship between uncocking release time, clubhead speed, and arm strength in elite male and female golfers. Strength data and kinetic data allow evaluation of the importance of joint torque limits. We hypothesize that different strength profiles in male and female elite golfers may be related to differences in the dynamic swing pattern to optimise performance and prevent injuries.

METHODS

Isokinetic testing was carried out to determine wrist, elbow, shoulder, forearm, and shoulder joint strengths at angular velocities of 30, 120, and 180 degrees/sec in male and female elite golfer groups. A 3-D motion analysis system was arranged to collect accurate swing data for both groups. A dynamic system model of a human swinging a golf club was developed using anthropometric measurements and calculated kinematic data. An inverse dynamics analysis was then performed to estimate torque history during the model swing.

RESULTS AND DISCUSSION

Measurements of average peak isokinetic wrist, elbow, and shoulder torques (defined here as strength) showed that distal joints (i.e., the wrist and elbow) exhibit reduced gender differences when compared with the proximal shoulder joint. Shoulder joint strength in male subjects averaged 40 - 50%

more than that of female subjects. For the wrist, elbow, and forearm, strengths were about 30% greater in males. The clubhead speed at impact for male subjects was 10% - 15% more than for females, a relative reduction which was significantly less than the strength differences between genders. Duration of the wrist uncocking release time before impact was very close (0.13 - 0.14 sec) for both males and females. At the time of ball impact, female golfers exhibited maximum clubhead speed, but male golfers demonstrated the highest clubhead speed following after ball impact. Overall, female subjects had a more efficient swing, considering their strength and the timing necessary to achieve maximum clubhead speed at ball impact.

SUMMARY

Relative to male golfers, female golfers were better able to reach maximum clubhead speed at the time of ball impact. Clubhead speed is relatively higher in female subjects compared with strength differences between the genders. However, torque application in actual swings should also be compared in males and females. For further studies, dynamic analysis of actual swings and application of an optimal control model can lead to understanding of the relationships between joint strength and optimal swing patterns in different individuals and between the two genders.

INTRODUCTION

Most total knee arthroplasty (TKA) designs are based on the classic theory that there are multiple instantaneous centers of rotation (ICR) (Frankel, et al., 1971) for knee flexion/extension (KF/KE) movements. Therefore, a traditional TKA has multiple radii (M-RAD) in the femoral component. Recently, investigators (Hollister, et al., 1993; Churchill, et al., 1998) have shown that the knee joint has only one KF/KE axis, which is fixed at approximately the femoral transepicondylar line. One TKA has been designed to have a single radius (S-RAD) in the femoral component (ScorpioTM, Howmedica-Osteonics, Inc.). There are two major mechanical differences between the S-RAD and the M-RAD TKAs examined in this study. First, the KF/KE axis of the S-RAD TKA is more posterior than that of the M-RAD TKAs. As a result, the quadriceps moment arm of the S-RAD TKA is longer than that of the M-RAD TKA. Second, for an M-RAD TKA, the manufacturer of both TKAs used in this study (www.scorpioknee.com) claims that the collateral ligaments lose tension when the radius of rotation becomes shorter. This may explain why M-RAD patients experience knee joint instability during the mid-range of KF/KE (O.M.M.). The purpose of the study is to investigate the differences between the S-RAD TKA and two M-RAD TKAs for knee kinematics and electromyography (EMG) occurring during the stand-to-sit (SIT) movement. We predicted that, the S-RAD compared to the M-RAD implant would demonstrate less quadriceps activation due to less quadriceps force required, and less hamstrings muscle activation and abduction/adduction (ABD/ADD) displacement due to increased frontal plane knee stability.

METHODS

Nine healthy participants, each with an S-RAD and an M-RAD (S-7000TM, Howmedica-Osteonics Inc.; and P.F.C.TM, Johnson & Johnson Inc.) TKA took part in this study. Three video cameras (120 field-s⁻¹) were used to capture marker locations while the EMG signals (1080 sample-s⁻¹) were collected from vastus medialis (VM), vastus lateralis (VL), rectus femoris (RF), biceps femoris (BF), and semitendinosus (ST). Four SIT trials were conducted. Knee kinematics (Grood & Suntay, 1983) were calculated. The RMS EMG (REMG) were calculated, then averaged for each of 4 equal size angle intervals from 75° to 15° of KF (0° = KE). Doubly multivariable repeated measures with SIT time as a covariate ($\alpha = 0.05$) were used to determine the REMG and kinematics differences between the TKA limbs.

RESULTS

Compared to the M-RAD TKA limb, the S-RAD TKA limb exhibited less VM (30° to 45° KF angle interval), VL (30° to 45° and 60° to 75°), and RF (15° to 75°), but more ST (15° to 60°) REMG. The S-RAD TKA limb showed a trend to have less ABD/ADD displacement than M-RAD TKA limb ($P = 0.092$).

DISCUSSION

We first hypothesized that the S-RAD TKA limb would have less quadriceps effort than the M-RAD TKA limb. This hypothesis was supported by the current study, which showed that the quadriceps muscle groups of the S-RAD TKA limb exhibited less REMG than those of the M-RAD TKA limb. We cautiously interpret this finding to indicate that the longer quadriceps moment arm in the S-RAD TKA may have decreased the needed to produce the knee moments created to decelerate the body's downward velocity.

Our second hypothesis related to the knee joint stability was partially supported. As small sample size reduced our statistical power, we only found a tendency for greater ABD/ADD displacement for the M-RAD than the S-RAD TKA limb. However, the ST of S-RAD TKA revealed greater REMG than the ST of M-RAD TKA, which was not expected. We suggest that the role of ST is serving biarticular functions rather than a primary knee stabilizer.

TIME-DOMAIN REPRESENTATION OF VENTRICULAR-ARTERIAL COUPLING AS A WINDKESSEL AND WAVE SYSTEM

Jiun-Jr Wang,¹ Aoife O'Brien,³ Nigel G. Shrive,² Kim H. Parker³ and John V. Tyberg,¹

¹Departments of Medicine and Physiology & Biophysics (jjwang@ucalgary.ca) and

²Department of Civil Engineering, University of Calgary, Calgary, Alberta, Canada

³Physiological Flow Studies Unit, Imperial College of Science, Technology and Medicine, London, United Kingdom

INTRODUCTION

Shape differences between central aortic pressure (P_{Ao}) and flow waveforms have never been explained satisfactorily in that the assumed explanation — substantial reflected waves during diastole — has never been demonstrated. We propose a functional, time-domain, arterial model that combines a blood conducting system and a reservoir (i.e., Frank's hydraulic integrator, the Windkessel).

METHODS

Aortic pressures, flows, and blood vessel diameters were measured in 16 anesthetized dogs (paced at ~70 bpm), so we can calculate its Windkessel pressure (P_{Wk}) and thoracic blood volume (V_{Wk}). The Windkessel pressure is determined by the inflow and outflow differences: $\frac{dP_{Wk}(t)}{dt} = \frac{dP_{Wk}}{dV_{Wk}} \frac{dV_{Wk}(t)}{dt} = \frac{Q_{in}(t) - Q_{out}(t)}{C}$,

where $C = \frac{dV_{Wk}}{dP_{Wk}}$ is the compliance. The outflow is assumed to be driven by the difference between the Windkessel pressure and the asymptotic pressure of the diastolic exponential decay (P_{∞}), $Q_{out}(t) = (P_{Wk}(t) - P_{\infty})/R$. R is the effective resistance of the peripheral systemic circulation. Total work performed by the LV is the area of the P-V loop. We calculated the total work performed by the LV during systole and then determined the portion of this work that was done in charging the Windkessel. The remainder, the pulsatile work, was considered to be the

Figure 1: A 3-D plot of aortic pressure versus time and distance (by 2-cm increments), from the aortic root to the femoral artery in a single dog. The sum of the work done overcoming the proximal resistance and that done overcoming inductance.

To confirm that the aortic pressure is the combination of waves and the Windkessel mechanism, a 3-D pressure-distance plot was constructed by measuring the pressure at the aortic root with 2 cm increment to the femoral artery (Fig 1).

RESULTS AND DISCUSSION

We find that P_{Wk} is proportional to thoracic aortic volume and that the volume of the thoracic aorta comprises $45.0 \pm 1.8\%$ (SE) of total V_{Wk} . We calculated the fraction of the total LV work that is expended in charging the Windkessel (recoverable) and found it to be $86.8 \pm 1.1\%$, the remainder due to “pulsatile work.” When we subtracted P_{Wk} from P_{Ao} , we found that the difference (excess pressure, P_{ex}) was proportional to aortic flow, thus resolving the differences between P_{Ao} and flow waveforms and implying that reflected waves were minimal (Fig 2). The ratio of P_{ex} to aortic flow is equal to characteristic impedance (from Fourier analysis), consistent with there being a resistive loss in ejecting blood into the Windkessel.

SUMMARY

We suggest that P_{Ao} is the summation of a time-varying reservoir pressure (i.e., P_{Wk}) and (primarily) forward-going waves. The majority of the total energy (~87%) was to charge the Windkessel and that would be discharged to the venous system. The waves were accounted for 13% of total energy, which used to overcome the resistance and inductance.

Figure 2: A. Typical aortic root pressure and calculated Windkessel pressure (red line). B. Excess pressure calculated by subtracting the Windkessel pressure from the aortic pressure (the hatched area of Fig 1A) and aortic flow (black line) plotted against time with the scales adjusted so that their peak values coincide. They appear almost identical in contour.

DETERMINATION OF THE PARAMETERS FOR THE FINITE ELEMENT MODEL OF A DEBONDED STEM-CEMENT INTERFACE PERTINENT TO HIP IMPLANTS

Natalia Nuño

Département de génie mécanique, ETS, Université du Québec, Montréal, Canada
nnuno@mec.etsmtl.ca

INTRODUCTION

During Total Hip Arthroplasty, residual stresses are generated in the bulk cement due to the cement expansion during curing. Mann et al. (1991) found that the behaviour of the push-through-stem tests and the simulated FE analysis gave the best agreement when friction as well as residual stresses was included in the numerical analysis. However, recent investigations still do not include the residual stresses (i.e., Lu and McKellop, 1997; Norman et al., 1996). In this study, at first two parameters, the residual stresses and coefficient of friction, characterizing the debonded stem-cement interface needed in the finite element (FE) model were experimentally determined. Then, the load transfer of a cemented hip implant subjected to bending for an early post-operative situation was numerically investigated.

METHOD

Residual stresses. The residual stresses generated at the stem-cement interface after the cement curing process of an idealized stem surrounded by a PMMA mantle were experimentally determined. The normal residual stresses varied between 2.3 and 3.3 MPa.

Coefficient of friction. The static coefficient of friction between titanium alloy and PMMA was determined experimentally (Nuño et al., 2002) using a standard inclined plane (ASTM 4516-91) and a prototype computerized sliding friction tester. The influence of the contact pressures, temperature, and bovine serum was investigated.

FE Model. Figure 1 shows the idealized cemented hip stem (tapered Ti-6Al-4V stem diameter: min=10 mm, max=18 mm,

5-mm thick PMMA and 7-mm thick bone mantles). The stem-cement interface was debonded, the cement-bone interface was completely bonded and all materials were assumed to be linearly isotropic and homogeneous. The 3D FE model was solved using *Ansys 5.4*. The compressive radial residual stresses generated at the interface, due to the cement expansion during curing, were treated similar to a press-fit problem simulated by assigning an interference to the contact elements. The bending of the system was simulated by a transverse load of 600 N for the full model. The cement stress distributions were determined at the stem-cement interface.

RESULTS AND DISCUSSION

The magnitude of the residual stresses affected the cement stresses at the interface. For the case of 2.4 MPa residual stresses the maximum principal stresses, i.e. von Mises, had up to 3-fold increase compared with the stresses for the case of no residual stresses. Because there is no chemical bond at the interface between the stem and cement, the interface resistance depends on friction thus radial compressive stresses developed by the cement curing play a direct role.

INTRODUCTION

The role of collagen in providing a binding matrix in biomaterials and in interfacing with mineral particles is of great importance in understanding the strength, aging properties, and resilience of calcified tissues. The main objective of this study is to study the relationship between the mechanical, chemical, and electromagnetic properties of dentin collagen using three different scanning techniques on the same sample.

METHODS

Sample Preparation: Several samples of demineralized dentin collagen prepared from unerupted human third molars were used. Dentin slabs approximately 10 x 2 x 1.5 mm were demineralized using the following protocol. Each slab was placed in a vial containing 10 ml of 0.5 EDTA (pH 7.3) for one week. A Raman spectrum of each specimen then was acquired. The absence of spectral features associated with the mineral (P-O band at 960 cm⁻¹) indicated that the demineralization process was complete. Half of the samples were maintained as is, half were infused with Single Bond adhesive.

Experimental Techniques: Micro-Raman spectroscopy (μ RS), scanning acoustic microscopy (SAM), and a GHz scanning evanescent microwave probe (SEMP) were used to study the micro-chemical, material, and electrical properties respectively of collagen both with and without Bis GMA-based polymeric adhesive-infiltration. Samples first were analyzed using μ RS which determined the degree of Bis GMA polymerization as well as defining the regions of infiltration. SAM (400 MHz, nominal lateral resolution 2.5 μ m) was performed over the same area studied by μ RS to study the micromechanical properties. Finally, SEMP at 1 to 10 GHz has been used to measure the complex permittivity over the same area. Typical lateral resolution of the SEMP is on the order of 10 nm.

RESULTS AND DISCUSSION

Figure 1 is the SAM micrograph for the demineralized dentin collagen without adhesive infiltration. Note the uniform gray level of the collagen fibers. In Figure 2, the SAM micrograph of the demineralized dentin collagen infiltrated with Single Bond, a significant number of uniform brighter images indicate

the locations where the Single Bond material has infiltrated the pores in the collagen network; this is identified by the higher acoustic impedance and correspondingly the higher elastic modulus of the Single Bond. A system of calibration curves based on a set of 13 materials including polymers, ceramics, and metals provided the following elastic moduli for the set of samples depicted below: E=1.76 GPa for the collagen alone; E=1.84 GPa for the collagen infiltrated with adhesive; E=3.4 GPa for the adhesive infiltrate.

Figure 1: Demineralized dentin collagen without adhesive infiltration

Figure 2: Demineralized dentin collagen with adhesive infiltration

SUMMARY

By combining the unique capabilities of μ RS, SAM, and SEMP we can perform chemical, mechanical, and electrical characterization over the same small region of tissue-biomaterial interfaces. These complementary technologies provide direct nondestructive in situ detection of the interfacial molecular structure, micromechanics, electrical, and morphologic features of the bonded assembly. The data collected from these synergistic techniques provide added insight into the potential problems at weak interfaces, problems that may be avoided by altering the materials and/or the method of application.

IDENTIFYING THE TEMPORAL LIMITS OF VOLITIONAL GAIT ASYMMETRY

Todd D. Royer and Carolyn A. Wasilewski

Department of Health and Exercise Sciences, University of Delaware, Newark, Delaware, USA
www.udel.edu/HESC/

INTRODUCTION

Persons with a unilateral leg injury or disorder that predisposes one side to pain or instability commonly exhibit an asymmetrical gait pattern. These asymmetrical gait patterns typically result in abnormal loading of the non-affected limb. This is problematic because the non-affected limb is concomitantly made more susceptible to degenerative joint disease, specifically, osteoarthritis (Hurwitz et al., 2001). In assessing temporal gait symmetry of special populations, it is difficult to determine the severity of their asymmetry...are the between limb differences similar to the intralimb variability of healthy individuals or are they more similar to the maximum intralimb differences that can be voluntarily achieved. It is unreasonable to ask persons with unilateral leg pain to walk as asymmetrically as possible. Therefore, the purpose of this study is to assess temporal gait symmetry in healthy individuals and determine how asymmetrically they can walk by volitionally spending as little time as possible on one limb (defined as the affected limb) during stance.

METHODS

Fourteen healthy adults (4 males, 10 females; age = 22 ± 4 yrs; height = 170.9 ± 7.6 cm; mass = 69.9 ± 11.3 kg), free of neurological, cardiovascular, and lower-extremity musculo-skeletal impairments, walked overground at a self-selected walking pace to determine preferred walking speed. Footswitches were placed beneath the heel and big toe under the soles of both shoes. Footswitches of one foot (randomly assigned) were connected to an audio box that emitted a sound when either footswitch from that foot was in contact with the treadmill belt. This audio tone was used in the asymmetrical walking condition described below. Subjects walked under two randomized conditions: normal walking and asymmetrical walking. Instructions to the subject for normal walking were "walk normally and comfortably". Instructions for asymmetrical walking were "spend as little time as possible on the affected limb. When that foot is in contact with the ground an audio tone will be emitted to remind and encourage you to step onto the opposite foot as soon as possible". The treadmill operated at each subject's preferred walking speed. Subjects walked for five minutes under each condition. Footswitch data were sampled at 1000 Hz during the last minute of each condition. Stance and swing times were calculated from footswitch data. Symmetry indices (SI) were calculated to describe the relative similarity between the non-affected (N) and affected (A) limbs:

$$SI = \frac{(A - N)}{0.5(A + N)} \times 100 \quad (\text{Herzog et al., 1989})$$

RESULTS AND DISCUSSION

Stance and swing times are reported in Table 1. The normal walking trial resulted in stance and swing time symmetry indices of 0.9% and -1.5% respectively, indicating similar between limb temporal characteristics. Symmetry indices for the asymmetrical walking trial and results from other studies are reported in Table 2. Data from persons with a trans-tibial amputation (Mattes et al., 2000) suggest their swing time asymmetry falls substantially below the volitional asymmetry of asymptomatic adults. The addition of a 2 kg load to one foot of able-bodied adults also produced a swing time asymmetry that was much smaller than their predicted maximal asymmetry (Royer et al., 1997).

Table 1. Temporal gait characteristics.

Walking Condition	Stance time (s)	Swing time (s)
normal condition		
non-affected limb	0.64 ± 0.05	0.40 ± 0.02
affected limb	0.64 ± 0.05	0.40 ± 0.03
asymmetrical condition		
non-affected	0.66 ± 0.10	0.37 ± 0.05
affected	0.57 ± 0.08	0.46 ± 0.10

Table 2. Symmetry indices for the asymmetrical walking condition of this study and published studies.

Study	Condition	Stance SI	Swing SI
present	volitional asymmetry	$-14.7 \pm 7.9\%$	$20.5 \pm 9.9\%$
Mattes et al (2000)	unilateral trans-tibial amputation	-1.5%	8%
Royer et al (1997)	2 kg asymmetrical foot load	-6%	8%

note: negative stance SI values indicate the intact or non-affected limb was greater; positive swing SI values indicate the prosthetic or affected limb was greater

SUMMARY

Symmetry indices derived from this study represent the maximal voluntary between-limb asymmetries for asymptomatic adults. These values may be used when assessing gait asymmetries of special populations to determine whether their temporal gait pattern may be severe or mild.

A METHOD FOR ASSESSING THE OVERALL IMPACT PERFORMANCE OF HELMETS USED IN CROWD MANAGEMENT INTERVENTIONS

Jean-Philippe Dionne, Ismail El Maach, Aris Makris
Med-Eng Systems, Ottawa, Ontario, Canada
Communicating author: jp.dionne@med-eng.com

INTRODUCTION

Blunt impacts to the head cause differential movement of the brain relative to the skull, disrupting the neural tissue and producing concussive and other traumatic brain injuries (Ryan, 1992). To mitigate those types of injuries, riot helmets have to meet standards with specific impact energy acceptance criteria for the helmet shell and visor. The objective of this study is to introduce a comparative tool that permits the assessment of the impact performance of riot helmets.

METHODS

Riot helmets from 6 manufacturers (referred to as A, B, C, D, E and Med-Eng) were impact tested at an authorized laboratory (5 samples each). Three types of tests were carried out: the resistance of the helmet shell to frontal impact, the resistance of the helmet shell to side impacts, and face-shield deflection tests. The experimental apparatus and test protocols conformed to the NIJ standard (1984). An iterative method was used to determine what impact energy caused an acceleration of 300 g's (E_{300}). For the face-shield deflection test, the energy level of an impactor dropped from a given height was determined that would cause the face-shield to come in contact with the "nose" of the headform (E_c).

RESULTS AND DISCUSSION

The detailed results are listed on Table 1. For frontal impacts, E_{300} values ranging between 69 J and 171 J were obtained, whereas E_{300} values ranging from 102 J to 231 J were obtained for the side. The NIJ standard requirement is 111 J.

Table 1: Summary of the impact results

Helmet	E_{300} Front (g's)	E_{300} Side (g's)	E_c (J)	Frontal Area (%)
Med-Eng	152	190	95	78
Helmet A	162	176	10	68
Helmet B	69	102	18	71
Helmet C	144	165	19	75
Helmet D	171	194	46	67
Helmet E	140	231	58	73

E_c values for the various helmets were found to vary between 10 J and 95 J. For the faceshield deflection, the NIJ standard has an impact energy requirement of only 7.85 J, whereas the CSA requirement is 70 J, almost a 10-fold difference.

Figure 1: Global score assessed to each helmet based on the weighted balance for the three types of experiments

In order to determine a performance criterion, taking the three impact tests into account, a global score system was proposed. All impact results were first normalized with respect to the Med-Eng helmet values, used as a reference. Since it was estimated, through interaction with end users, that about 85% of the threats in a crowd management environment are frontal, a combined weight of 85% was given to the frontal impact and face-shield deflection tests, and the remaining 15% was given to the side impact tests. The 85% was then subdivided according to the percentage of frontal area occupied by the visor relative to the total frontal area. This percentage is shown in Table 1 for all helmets. The global score is thus obtained by the following formula:

$$Score = \left(\frac{E_{300}}{E_{300 \text{ Med-Eng}}} \right)_{Side} \times 15\% + \left[\left(\frac{E_{300}}{E_{300 \text{ Med-Eng}}} \right)_{Front} \left(\frac{A_{shell}}{A_{frontal}} \right) + \left(\frac{E_c}{E_{c \text{ Med-Eng}}} \right) \left(\frac{A_{visor}}{A_{frontal}} \right) \right] \times 85\%$$

where $E_{300 \text{ Med-Eng}}$ and $E_{c \text{ Med-Eng}}$ correspond to the E_{300} and E_c values obtained with the Med-Eng helmet respectively, A_{shell} is the frontal area occupied by the helmet shell, A_{visor} is the frontal area of the visor, and $A_{frontal}$ is the total frontal area of the helmet. The global scores obtained by each helmet are illustrated on Fig. 1.

SUMMARY

Based on this global scoring scheme, the best overall performer is the Med-Eng helmet with a score of 100.

PREDICTION OF OPTIMIZED DIAMETER OF OSTEOCHONDRAL PLUGS IN CARTILAGE REPAIRS

John Z Wu¹, Walter Herzog², Evelyn M Hasler³

¹National Institute for Occupational Safety & Health, Morgantown, WV, USA., E-mail: jwu@cdc.gov; ²Faculty of Kinesiology, The University of Calgary, Calgary, Alberta, Canada; ³Sulzer Orthopedics Ltd, Baar, Switzerland

INTRODUCTION

The transplantation of autologous cartilage/bone (osteocondral) grafts offers a treatment for full thickness cartilage defects on the femoral condyle of the knee. One technical difficulty is to determine the amount of the press fit tolerance between the OC plug and the femur. If the fitting tolerance is too small, the OC plug will slide relative to the recipient hole, whereas if it is too large, the plug will induce excessive stress on the bone surrounding the plug. Further, the risk that the damage of the bone during the procedure inserting the OC plug into the recipient hole will be increased. The purpose of the present study was to predict, theoretically, the optimized diameter of OC plugs.

METHODS

The joint was assumed to be axi-symmetric with a spherical femur and tibia and a cylindrical OC graft (Fig. 1). The coefficient of friction between the plug and the recipient hole walls was assumed to vary from 0.1 to 0.5. The recipient hole was taken to be approximately 1.2 mm deeper than the height of the OC plug, so the plug was not resting on the femoral bone. The cartilage was assumed to have a constant thickness of 2 mm and biphasic material properties (Mow et al. 1980). Subchondral bone was assumed to be elastic with a much higher elastic modulus than that used for the cartilage. The press fitting was simulated using a thermal analogue. The plug was assumed to have an anisotropic thermal expansion coefficient. Expansion was assumed to only occur in the radial direction. Fitting of the plug into the recipient site on the femur was simulated numerically by increasing the temperature of the plug. The calculations of the lateral contact stress were performed assuming that the OC plug was perfectly aligned in the recipient hole (i.e., $\Delta=0$, as shown in Fig. 1).

Figure 1: Finite Element Model of Cylindrical OC Plug. ($h=15$ mm, $R1=50$ mm, $R2=100$ mm)

RESULTS AND DISCUSSION

The lateral contact stresses between the OC plug and the recipient hole as a function of fitting tolerance were predicted. The sliding force of the OC plug was calculated by integration of the contact stress on the lateral contact area. Typical simulation results are depicted in Fig. 2. For a fixed size of the OC plug, the contact stress between plug and recipient hole

increased approximately linearly with the press fit tolerance (Fig.2A).

Our simulations indicate that, for a fixed coefficient of friction and a fixed fit tolerance, the maximal sliding force varies with the size of the plug and reaches its maximum for a plug diameter of 5.5 mm (Fig.3). The sliding force is attributed to two factors, the fitting stress, which is associated with the frictional stress, and the contact area between the plug and the recipient hole. For a given fit tolerance, the fitting stress decreases with increasing diameter of the plug; whereas the contact area between femur and plug increases with increasing diameter of the plug. Consequently, the maximal sliding force is a nonlinear function of the diameter of the plug.

Figure 2: (A) Typical lateral contact stress between the OC plug and the recipient wall as a function of the plug depth. (B): Typical sliding force as a function of press fit tolerance.

Figure 3: Sliding force as a function of diameter of OC plug.

SUMMARY

Because of the large difference in the elastic modulus between articular cartilage and subchondral bone (2.5 MPa for cartilage vs. 2.3 GPa for subchondral bone), the primary force that keeps the plug in place comes from the frictional contact between the lateral surface of the plug and the recipient hole. The stresses in the bone are sensitive to the fit tolerance. Small variations in the fit tolerance induce great changes in bone stress. Therefore, the fit tolerance must be carefully controlled to prevent over-stressing or damaging of the bone. If the diameter of the OC plug is optimized, it would be possible to reach the maximal sliding force at a given fit tolerance, thus it would be possible to use a smaller fit tolerance and the stress in the bone surrounding the OC plug could be minimized.

THE MATERIAL PROPERTIES OF THE SUBCALCANEAL TISSUE IN COMPRESSION

William R. Ledoux, Ph.D.^{1,2}, Glenn K. Klute, Ph.D.¹, Randal P. Ching, Ph.D.^{1,2}, Bruce J. Sangeorzan, M.D.^{1,2}

INTRODUCTION

Computational models of the foot are becoming increasingly anatomically detailed (Thompson et al 1999; Ledoux et al 2000). The accuracy of these simulations depends on the material models of components such as the plantar soft tissue. The *structural* properties of *in vivo* subcalcaneal tissue have been studied via impact tests (e.g., Kinoshita et al 1993), while others explored *in vitro* subcalcaneal tissue with materials testing machines (Aerts et al 1995; Ledoux et al. 1999). However, *material* property data on the plantar soft tissue has not been reported. The purpose of this research was to determine the material properties of the subcalcaneal tissue.

METHODS

Subcalcaneal tissue specimens were obtained from three fresh-frozen cadaveric feet. The tissue was dissected from the calcaneus by sectioning the Achilles tendon and proceeding inferiorly and anteriorly. The soft tissue was placed on a plastic sheet and a 2cm x 2cm specimen was cut using a razor-blade punch. Each specimen was placed on a platen in an ElectroForce 3400 materials testing machine (Enduractec; Minnetonka, MN). The top platen, in series with a load cell, was lowered manually until a force of approximately 1 N was registered. The distance between the platens was measured as the initial thickness of the specimen (Table 1). An environmental chamber enclosed the specimen and platens. To simulate *in vivo* conditions, hot, moist air was circulated to keep the specimen at 37° C and near 100% humidity.

The target loading level for the tissue was based on normative ground reaction force data (Ledoux and Hillstrom 2002); a scale factor of 0.051 %BW/cm² was employed. In load control, the specimen underwent 30 sine waves from 10 N to the target load. The displacement at which the target load was reached at steady state was noted and used for the rest of the experiment. In displacement control, the tissue was preconditioned with 30 1 Hz sine waves followed with 2 quasi-static triangle waves with ramp rates of 0.5 %strain/second.

Table 1: The testing parameters for the subcalcaneal tissue.

specimen	BW (N)	target load (N)	thickness (mm)	displ. (mm)	strain (%)
foot 1	890	181	15.6	9.1	58
foot 2	623	127	10.4	5.5	53
foot 3	979	200	12.5	5.9	47

RESULTS AND DISCUSSION

The force-deformation data were normalized by the specimen area and initial thickness, resulting in a stress-strain plot (Figure 1a). To account for the difference in subject weight, we also plotted the force in %BW versus strain (Figure 1b). These data indicate a long toe region followed by a rapid increase in stress (force) with strain. Although difficult to visualize with this scale, the force increased immediately after the actuator began to move, indicating that despite the small slope in the toe region, the tissue was being loaded.

Figure 1a and b: The stress-strain and force-strain data.

SUMMARY

The data presented here represent material characteristics of the subcalcaneal tissue. We have shown that the tissue is nonlinear and viscoelastic (note the hysteresis). Furthermore, the tissue has a long toe region, after which it becomes stiff very rapidly. Also of interest are the large strains required to generate physiological loads. These properties are indicative of a material that must undergo large deformations, but still protects the underlying osseous structures.

MUSCLE WORK VERSUS MUSCLE FORCE: *IN VIVO* FUNCTION OF AVIAN ANKLE EXTENSORS

Monica A. Daley and Andrew A. Biewener
Concord Field Station, Harvard University, Bedford MA USA
E-mail: mdaley@oeb.harvard.edu

INTRODUCTION

How do muscles differ in their ability to contribute to force and mechanical work during locomotion? Lateral Gastrocnemius (LG) function among different birds appears to differ substantially. The LG of running turkeys contracts nearly isometrically during level running, but can shorten more to contribute substantial positive work during incline running (Roberts et al. 1997). In contrast, the LG of mallards shortens and does work during level running, possibly increasing its cost for force production (Biewener and Corning 2001). Like turkeys, guinea fowl (*Numida meleagris*) are cursorial birds, suggesting that their ankle extensors may also contract isometrically to lower the cost of force production. To test this, we compared *in vivo* work production by two ankle extensors of the guinea fowl during level and incline locomotion.

METHODS

We recorded muscle-tendon force, fascicle length and electrical activity from the LG and the Digital Flexor to the lateral toe (DF4) of the guinea fowl during level and 16° incline running. 'E'-type tendon buckles attached to the free tendon measured muscle-tendon force. Sonometrics™ 1.0mm and 0.7mm crystals were implanted along the axis of the muscle fibers to measure muscle fascicle length. Bipolar EMG electrodes were implanted immediately adjacent to the sonomicrometry crystals. Lateral-view digital video (Redlake Motionscope PCI 500) recordings at 250 f/s were used to correlate muscle measurements with kinematics.

RESULTS AND DISCUSSION

Both the LG and DF4 substantially lengthen and shorten during active force production (Fig. 1). The timing of active strain is different for the two muscles; the LG undergoes shortening followed by lengthening, while the DF4 lengthens and then shortens. This may be due to the different joints that the muscles cross. Both muscles act at the ankle and knee, but DF4 also acts about the tarsometatarso-phalangeal (TMP) joint. The TMP flexes substantially during the first half of support, thus DF4 is stretched during this time.

Both muscles produce similar net work during running. LG produces $3.6 \pm .1$ and 5.6 ± 0.9 (mJ/Kg) net work per stride during level and incline running, respectively. DF4 produces

1.6 ± 2 (mJ/Kg) and 6.4 ± 2 (mJ/Kg) during level and incline running. In doing so, DF4 absorbs energy and does positive work, which sums to a small net value. LG absorbs less energy than DF4, and produces a small net positive work. Together they contribute 14% of whole-body work necessary to move up the incline. If distributed equally among extensors (based on mass), these muscles would be expected to produce about 30% of the total work.

Figure 1 Representative force versus length work loops for LG (left) and DF4 (right) during level (solid line) and 16° incline (dashed line) running at 1.25 (m/s). The support phase of the stride is shaded. The work loops are positive for both muscles during level and incline running.

SUMMARY

In contrast to the near isometric function of LG in running turkeys (Roberts et al. 1997) and hopping wallabies (Biewener et al. 1998), the LG and DF4 of the guinea fowl operate at strains greater than 13%. Although they undergo substantial length change during active force development, their contribution to whole-limb work is low. This suggests that in this smaller cursorial bird, these distal muscles play a minor role in work modulation during steady level running, as well as when moving uphill, but operate primarily in force production. However, they do not operate in a manner consistent with economic force production.

EFFECT OF ETHANOL ON NEURONAL STRAIN TRANSDUCTION

Theresa A. Lusardi, David F. Meaney

Department of Bioengineering, University of Pennsylvania, Philadelphia, Pennsylvania, USA

INTRODUCTION

Under normal physiological motions, central nervous system (CNS) neurons exist in a 'mechanically protected' environment and experience little deformation. During traumatic injury, though, CNS neurons experience a rapid deformation that can produce lasting pathophysiological changes to neurons and cause the cell death that contributes to the long-term impairment in CNS injury.

We have shown previously that cultured hippocampal neurons experience an acute calcium transient following stretch that is both strain and rate dependent. The most prominent mechanism for this calcium increase is from influx from the extracellular space through the NMDA receptor associated channel. In this study, we consider how altering the plasma membrane properties affect the initial response of the cultured neuron to rapid mechanical stretch.

METHODS

Hippocampal cells were isolated from E17-E18 rat embryos using procedures discussed previously (Lusardi et al., in press). Cells were plated onto flexible silastic membranes (Specialty Manufacturing), allowed to mature for 10 days in vitro, and attached to a custom-designed cell stretching system (Smith et al, 1999). A rapid (20.5 ms) pressure pulse caused the underlying membrane to deform rapidly, in turn stretching the neuronal culture once at a defined rate and magnitude. All results were compared to sham experiments (0% strain) in which cultures were exposed to maximum pressure (12 psig) but no stretch.

To measure the response of the cells to mechanical stretch, we used a cytosolic calcium indicator (5 μ M Fura-2am in 0.4% DMSO and 0.1% Pluronic; Molecular Probes, Inc.). Immediately prior to testing, Fura-2AM loaded cells were rinsed with control saline solution (CSS) and allowed to incubate for 10 minutes in CSS, with or without the addition of 200 mM ethanol. For these experiments, normalized peak calcium change is reported as the ratio for each cell of the peak fura ratio during the first 40 seconds following stretch normalized by the baseline (pre-stretch) ratio for that cell.

RESULTS AND DISCUSSION

As the stretch level increased, the peak calcium response in untreated cells increased. At the high stretch, the average calcium response over a five-minute monitoring period showed the cell population returning only transiently toward calcium homeostasis, with a secondary rise in calcium. At the low stretch level, the average calcium response continued to return toward baseline over 5 minutes following the stretch.

The addition of ethanol into the media did not change the peak calcium response at the highest stretch level, but did attenuate the response at the lowest stretch level. In comparison, the peak calcium response increased under ethanol treatment for a chemical agonist (100 μ M NMDA). Interestingly, calcium regulation returned in the cell population at the high stretch level after treatment with ethanol.

Figure 1: Ethanol pretreatment blocks the stretch response but potentiates the agonist response.

Together, these data show that ethanol has a complex effect on mechanically injured neurons. At the high stretch level, the alterations in the membrane properties appear to allow the membrane to recover more rapidly from stretch. In contrast, the attenuated response at the low stretch level suggests a direct suppressive effect of ethanol on mechanically induced receptor sensitivity.

SUMMARY

The plasma membrane is often considered merely as a holder for the more important players in signal transduction such as ion channels, metabotropic receptors, and focal adhesion complexes. However, this and other research suggest that the plasma membrane may have an active role in signal transduction, both as a modulator of ion channel properties and as a force transducer in its own right.

CHANGES IN H-REFLEX AMPLITUDE AFTER SPINAL MANIPULATION IN HEALTHY AND PATHOLOGICAL SUBJECTS

Esther Suter¹, Gordon McMorland², Walter Herzog¹

¹ Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada, suter@kin.ucalgary.ca

² Hillhurst Chiropractic Clinic, Calgary, Alberta, Canada

INTRODUCTION

A recent study has shown that spinal manipulation of the sacroiliac (SI) joint improves quadriceps function in anterior knee pain patients (1). The exact underlying mechanisms are not known, but it has been suggested that spinal manipulation activates receptors in and around the treated joint which may help to restore afferent input. The present study was aimed at determining the reflex responses associated with spinal manipulation. Specifically, changes in soleus H-reflex amplitude was assessed after manipulation of the SI joint in healthy and pathological subjects.

METHODS

Thirteen healthy subjects (age 25 ± 3 yr) and 15 patients with low back pain of various etiologies (age 32 ± 11 yr) gave informed consent to participate in the present study. H-reflex of the soleus was measured using standard methodology (2). Briefly, the tibial nerve was stimulated at the popliteal fossa using an electrical pulse of 1ms duration. Soleus H-reflex was recorded using Ag-AgCl electrodes of 1cm active diameter. The gain was set at 200, and sampling frequency was 2000Hz. Recruitment curves were performed to find the optimal stimulation intensity, which was identified as maximal H-reflex amplitude with no or minimal M-wave. After establishing baseline recordings of the H-reflex, a spinal manipulation of the SI joint was conducted on the left side in healthy subjects, and on the dysfunctional side in low back pain patients as identified by the treating clinician. H-reflex was recorded immediately after manipulation for 15 minutes. In 3 healthy subjects (HB) and all 15 patients, H-reflex recordings were performed with subjects lying supine, and the SI joint manipulation performed in side-lying position. In 10 healthy subjects (HS), all measurements were done with subjects lying on the side throughout the whole procedure to test for possible repositioning artifacts in H-reflex amplitude. In these 10 healthy subjects a sham manipulation was also performed.

H-reflex amplitudes were calculated using custom-made software, and post-treatment values were normalized to baseline values for comparison between subjects.

RESULTS AND DISCUSSION

Healthy subjects: The HB group showed significant depression of the H-reflex amplitude following treatment. H-reflex amplitude in the HB group returned to pre-treatment values after approximately three minutes. H-reflex depression after manipulation was not evident in the HS group (Figure 1).

Sham manipulation was also not associated with any changes in H-reflex amplitude.

Low back pain patients: H-amplitudes were largely decreased immediately following SI joint manipulation. In 6 subjects, H-reflex amplitude did not recover to baseline values over the 15-minute period measured, but remained about 20% lower. In another 6 subjects, after initial depression, the H-reflex amplitude stabilized at a higher level than baseline.

Fig 1: H-reflex amplitude following spinal manipulation with measurements performed in supine or side lying position

The present study confirmed a significant transient depression of the H-reflex amplitude after SI joint manipulation for all subjects that were measured in a supine position, as documented in a previous study (3). However, no depression in H-reflex amplitude was observed when the position of the subjects during the measurement procedure and the spinal manipulation was not changed. This suggests that the transient depression of the H-reflex amplitude may be a repositioning artifact rather than a direct effect of the spinal manipulation. In 12 out of 15 patients with low back pain, H-reflex amplitude remained altered throughout the post-treatment measurement period. The relationship between etiology of low back pain and changes in H-reflex amplitude after SI joint manipulation is not clear and needs further investigation.

ANALYSIS OF IN VIVO CARPAL BONE AND LIGAMENT KINEMATICS USING CT AND MR DATA

Anwar Upal¹, David Pichora, and Carolyn Small

Human Mobility Research Center, Queen's University, Kingston, Ontario, Canada

¹ Submit communications to upal@me.queensu.ca

INTRODUCTION

In spite of the prevalence of wrist disorders, the *in-vivo* three-dimensional kinematics of the wrist in pathological conditions is poorly understood. Many researchers have used CT data to analyze carpal bone kinematics; however CT data does not provide the required information about the attaching ligaments. MR data provides information about the surrounding soft-tissue and ligament structure, which is crucial for proper functioning of the joint. The purpose of this project was to develop easy-to-use software that calculates the distances between the carpal bones, the volume of the carpal bones, and the carpal bone displacement and rotation from both CT and MR data. This technique will allow carpal bone kinematics to be analyzed with emphasis on the surrounding soft-tissues, which are crucial for the proper functioning of the wrist.

METHODS

CT data was acquired using a GE Light Speed Plus CT scanner and MR data was acquired using a GE 1.5T MRI scanner. The voxel size was varied between 0.15mm X 0.15mm X 0.75mm and 0.75mm X 0.75mm X 1.25mm. Data was collected at 30, 45 and 60 degrees of flexion and extension; 10 degrees of radial deviation; and 30 degrees of ulnar deviation. The data includes the distal ends of the radius and ulna bones. Figure 1 shows the software validation experiment carried out using nine phantoms and one cadaver wrist. One volunteer subject's wrist kinematics were analyzed.

Figure 1: Validation experiment jig

The images were imported into a segmentation program to construct three-dimensional models of the Scaphoid, Lunate, Triquetrum, Trapezoid, Trapezium, Hamate, Capitate, Pisiform, and Radius and Ulna. Software with an easy to use interface was developed to quantify the movement and rotation of all the carpal bones and Radius and Ulna. The software uses principal axes analysis and describes bone motion using Screw Axis and Euler Angle kinematic parameters. One window of the carpal bone motion wizard is shown here in Figure 2.

Figure 2: Carpal bone motion software interface

RESULTS AND DISCUSSION

This study has verified that both MR and CT data may be used to analyze carpal bone kinematics, and that any carpal bone kinematics may be analyzed using high-resolution CT and MR data. In our future research soft-tissues from MR data will be morphed with information about the location of the carpal bones from CT images to calculate ligamentous strains. This approach will allow analysis of carpal bone kinematics with reference to the surrounding soft-tissues providing a deeper understanding of carpal bone and ligament mechanics.

SUMMARY

A simple software tool was developed to render carpal bone meshes with the respective principal axis and to calculate the kinematic parameters for each bone relative to the radius. CT scans of one cadaver wrist and nine phantoms were used to validate the software, and CT and MR scans of one volunteer's wrist were obtained to analyze carpal kinematics. Combining CT and MR technology to look at both bone and soft-tissue mechanics may help develop better treatments for many joint disorders.

LINEAR MODEL OF RESISTANCE TO PASSIVE STRETCHING IN INDIVIDUALS WITH BRAIN INJURY: RELIABILITY & VALIDITY

Patrick H McCrea^{1,3}, Janice J Eng^{2,3}, and Antony J. Hodgson¹

Dept. of Mechanical Engineering¹ and School of Rehabilitation Sciences², University of BC
Rehabilitation Research Lab³, GF Strong Rehab Centre, Vancouver, Canada
www.rehab.ubc.ca/jeng

INTRODUCTION

Spasticity, the velocity dependent resistance to passive stretch (Lance, 1976), commonly affects the elbow flexors in individuals who have sustained a brain injury. Over 94% of health care professionals consider spasticity to be of clinical importance (Hass, 1994). Elbow flexor spasticity is quantitatively related to the magnitude of the torque response to constant velocity angular extensions (Knutsson, 1985). The mechanical response to a physical disturbance can be described in terms of stiffness and damping (eqn. 1).

$$\tau(\theta, \dot{\theta}) = k\theta + b\dot{\theta} + \tau_0 = k(\theta - \theta_0) + b\dot{\theta} \quad (\text{eqn. 1})$$

Here k is the stiffness, b is the damping, and τ_0 is a constant; alternatively, the constant τ_0 can be expressed in terms of an equilibrium position, θ_0 . The goals in this study were to determine (1) the ability of a linear spring-damper model to describe passive resistance, (2) the test-retest reliability of these parameters between days, and (3) the relationship of these parameters to a clinical assessment of spasticity.

METHODS

Nineteen individuals with stroke (mean age=61±6 years, duration of injury=4.4±2.6 years, Fugl-Meyer upper extremity score=38±18 Ashworth=1.2±.9) were tested during two sessions. We measured the velocity dependent resistance of elbow flexors of the more affected arm using a Kin-Com isokinetic dynamometer in passive mode. The arm was stabilized in a gravitationally neutral position with the shoulder abducted and flexed to 90° and 45°. The elbow was then extended through its available passive range at speeds of 30, 60, 90, 120, 150, and 180 %/sec. For each trial, the resistance-angle profile was windowed for the region of constant speed; this rotational resistance of the elbow was ensemble averaged over three trials for each speed.

The ensemble-averaged profiles for each speed were combined to create a 3-dimensional profile of the elbow flexor response to passive extensions. This profile was linearized for independent variables of angular displacement and velocity using a least-squares fit in the form of equation 1. Stiffness, damping, and equilibrium position parameters were identified for each participant as well as the value of R^2 . Intraclass correlations (ICCs) were used to identify the test-retest reliability of these parameters. Stiffness, damping, and equilibrium position parameters were entered as independent variables in a multiple regression with the Ashworth spasticity scale (Ashworth, 1964) as a dependent variable.

RESULTS AND DISCUSSION

The mean R^2 value of the spring-damper models was .92. Stiffness, damping, and equilibrium position ICCs were .98, .86, and .95 respectively. Given the excellent test-retest reliability, further analyses used data from only one session.

Figure 1. Passive resistance data fit to linear spring-damper model. The upper curve is the least squares fit to extensions at different speeds. Residuals are plotted on the lower curve.

Correlations of stiffness, damping, and equilibrium position with the clinical assessment of spasticity were all significant ($p < .01$). A stepwise entry of predictor variables into the regression rejected damping and position parameters. The resulting equation relating spasticity to stiffness was (eqn. 2):

$$\text{Ashworth Score} = 32.2 \times \text{stiffness} + .272 ; R^2 = .864 \quad (\text{eqn. 2})$$

SUMMARY

The linear spring-damper model showed excellent reliability and validity with clinical measures. Scales based on continuous measures of these parameters have potential to provide higher resolution than conventional ordinal scales.

THE INFLUENCE OF NORMAL HORMONAL FLUCTUATIONS IN WOMEN ON THE BIOMECHANICS OF STEPPING AND CUTTING

HJ Yack, R Chandran, S Rao, J Wilken
Orthopaedic Gait Analysis Laboratory
Physical Therapy & Rehabilitation Science
The University of Iowa
Iowa City, IA 52242

INTRODUCTION

Normal hormonal fluctuations, that are associated with the menstrual cycle, is one factor that has been used to help explain the two to eight time higher rate of knee injuries in female athletes. Results from prospective studies that have tried to establish the link between injury and the menstrual cycle are inconsistent (Huston, 2001). Few well controlled studies have attempted to examine how performance might be affected by hormonal changes in the uninjured population. The purpose of this study was to identify biomechanical changes in performance that could be associated with hormonal variations during the normal menstrual cycle.

METHODS

Ten female recreational athletes participated in the study. The month prior to data collection subjects monitored their menstrual cycle and the timing of the luteal surge was identified. During the following month testing was started in a randomized manner to capture the three phases: follicular (days 2-4), ovulatory (LH surge, within 1 day), and luteal (6-8 days before the end of the cycle). On the day of testing serum samples were collected. Subjects warmed up by running on a treadmill for 20 minutes. Markers were placed on each subject to capture the 3-D motion of the right lower limb, pelvis and trunk. Subjects stepped off a raised (20 cm) walkway while walking at 1.8 m/s, with their right foot landing on a force platform. A directional light, triggered by the subject, randomly determined if they should continue straight ahead or cut at a 45° angle to the left or right. Five trials of each direction were collected.

Marker positions were captured in 3-D (Optotrak) at 60 Hz. and force plate data were captured at 300 Hz. Data were filtered at 6 Hz. and processed to obtain kinematic and kinetic measures using KinGait3 software.

RESULTS & DISCUSSION

Preliminary analysis of the results for three subjects demonstrate overall greater variability and a greater magnitude in the knee frontal plane (abductor) moment during the initial part of weight acceptance when subjects were in the follicular phase. This initial period of weight acceptance has been identified as being important in helping to control the knee and may be associated with give-way episodes in ACL deficient patients (Houck, 2001).

Figure1: Comparison of frontal plane moments, over the first 50% of stance, for the three phases of the menstrual cycle for five repeated trials on three subjects while performing straight ahead stepping activities. Increase variability and increased amplitude of frontal plane moment during weight acceptance (un-shaded area) is apparent during Phase I (follicular phase).

SUMMARY

An apparent association between the phase of the menstrual cycle and performance on a stepping activity was observed in the initial analysis of the data. Such an association could have implication for control of the knee that might be associated with a predisposition to injury.

SYMMETRY IN KINETIC VARIABLES IS ACCOMPANIED BY SYMMETRY IN TEMPORAL BUT NOT DISTANCE VARIABLES OF GAIT IN PERSONS WITH STROKE

Janice J Eng^{1,2} and C Maria Kim^{1,2}

School of Rehabilitation Sciences¹, University of British Columbia
Rehabilitation Research Lab², GF Strong Rehab Centre, Vancouver, Canada, www.rehab.ubc.ca/jeng

INTRODUCTION

Gait patterns with respect to time, distance, and vertical force have been reported to be asymmetrical in pathological gait. The purpose of this study was to 1) determine whether symmetry in temporal-distance (T-D) measures is accompanied by symmetry in kinetic measures during gait, and 2) evaluate the effect of symmetry on gait speed in individuals with chronic stroke.

METHODS

Twenty-eight individuals with stroke (age of 62.5 ± 8.2 years, height of 1.68 ± 0.12 m, duration of injury of 4.4 ± 2.8 years, affected side: 14 left/14 right, sex: 20 males/8 females) participated in this study. An optoelectronic sensor was used to track infrared emitting diodes attached to the lateral malleolus and mid toe while subjects walked along an 8-m walkway over three force plates at their self-selected speed five times. Gait speed (normalized to leg length) and other T-D variables (stance time, swing time, step length) were calculated using the forward distance covered by the markers and the corresponding elapsed time. The average magnitude of the vertical ground reaction force (GRF) was measured over the stance phase of gait. A symmetry index (SI) (Robinson et al., 1987) was used to quantify asymmetries in gait:

$$SI = \frac{V_{\text{paretic}} - V_{\text{nonparetic}}}{\frac{1}{2}(V_{\text{paretic}} + V_{\text{nonparetic}})} \times 100$$

where V_{paretic} is any variable recorded for the paretic limb and $V_{\text{nonparetic}}$ is the corresponding variable for the non-paretic limb. Spearman correlation was used to quantify the relationship between a) gait speed and SI for each variable and b) T-D symmetry and GRF symmetry.

RESULTS AND DISCUSSION

Concurrent with previous findings (Titianova & Tarkka, 1995), the mean symmetry indices deviated considerably from zero (i.e. perfect symmetry) (Table 1).

Table 1: T-D and GRF measures and absolute SI's (mean \pm SD), N=28.

Variable	Paretic side	Non-paretic side
Stance time (s)	0.79 ± 0.20	0.89 ± 0.25
Swing time (s)	0.49 ± 0.11	0.37 ± 0.07
Step length (mm)	475.5 ± 130.3	484.8 ± 113.5
Vertical GRF (N)	537.1 ± 122.5	605.1 ± 131.0
Gait speed (s^{-1})	1.07 ± 0.34	
SI _{stance}	13.6 ± 9.1	
SI _{swing}	27.3 ± 19.8	
SI _{step}	17.3 ± 18.0	
SI _{GRF}	12.8 ± 9.5	

Correlations revealed that a) gait speed was significantly correlated with the symmetry of temporal measures and GRF and b) symmetry in GRF was correlated with symmetry in temporal but not distance measures of gait (Table 2). The significant correlation between GRF symmetry and gait speed provides some support for interventions aimed at improving weight bearing through the paretic limb to establish symmetry and ultimately increase function. Likewise, the significant relationship between GRF symmetry and temporal symmetry further supports intervention aimed to enhance symmetrical weight bearing. As a cautionary note, previous investigations have suggested that weight shifting activities must be practiced within the context of walking in order to enhance gait performance. In a controlled experimental study, Winstein et al. (1989) found that a balance retraining program that lead to a reduction in standing balance weight-bearing asymmetry did not lead to a concomitant reduction in temporal asymmetry during gait in persons with stroke.

Table 2: Spearman correlation between gait speed and symmetry indices

	Gait speed	SI _{GRF}
SI _{GRF}	-0.686** (N=25)	
SI _{stance}	-0.426* (N=26)	0.586** (N=25)
SI _{swing}	-0.567** (N=25)	0.678** (N=25)
SI _{step}	-0.321 (N=25)	0.199 (N=25)

* Significant at $p < 0.05$ ** Significant at $p < 0.01$

SUMMARY

This is the first study to report a relationship between symmetry in kinetic variables and symmetry in T-D variables of gait. A more symmetrical weight bearing between the two limbs was related to more symmetrical temporal but not distance measures during gait. GRF symmetry and temporal symmetry may be influenced by similar factors (e.g. balance) while other factors (e.g. compensatory strategies) may be more important in determining step length symmetry especially in chronic stroke survivors.

INDUCED POSITIONS: INTUITIVE QUANTITIES FOR CHARACTERIZING MUSCLE FUNCTION

Frank C. Anderson^{1,2}, Saryn R. Goldberg¹, Marcus G. Pandy³, and Scott L. Delp¹

¹Department of Mechanical Engineering, Stanford University, Stanford, California, USA, ²fca@stanford.edu

³Department of Biomedical Engineering, The University of Texas at Austin, Austin, Texas, USA

INTRODUCTION

Even if the force exerted by a muscle during an activity is known, it can be difficult to determine the motions it generates. One reason is that a muscle accelerates all of the joints of the body, not just each joint it spans. Zajac and Gordon (1989) formulated a method for quantifying the accelerations induced by muscles. Although induced accelerations can be informative, they can also be difficult to interpret. In this paper, we extend the idea of induced accelerations by integrating them to produce induced positions. To illustrate the insight afforded by induced positions, we computed the knee flexion angle induced by muscles and other forces during the swing phase of gait.

METHODS

The dynamic equations of motion for a musculoskeletal model allow one to quantify the accelerations of the generalized coordinates (\ddot{q}) in response to the forces acting on the body:

$$\ddot{q} = \bar{I}^{-1} \{ \bar{F}_G + \bar{F}_C + \bar{F}_M + \bar{F}_S \}, \quad (1)$$

where \bar{I}^{-1} is the inverse of the system mass matrix, and \bar{F}_G , \bar{F}_C , \bar{F}_M , and \bar{F}_S are vectors of generalized forces due to gravity, Coriolis and centripetal forces, muscle forces, and contact forces, respectively (Zajac and Gordon, 1989). The contact forces might be, for example, spring forces that represent ground contact. When the contact forces are viewed as reaction forces resulting from other forces within the system, they can be decomposed:

$$\bar{F}_S = \bar{F}_S^G + \bar{F}_S^C + \bar{F}_S^M, \quad (2)$$

where \bar{F}_S^G , \bar{F}_S^C , and \bar{F}_S^M represent the contributions of gravity, Coriolis and centripetal effects, and muscles to \bar{F}_S (Anderson and Pandy, *in review*). The accelerations induced by a force component i are computed from the sum of its force and the reaction forces it generates:

$$\ddot{q}_i = \bar{I}^{-1} \{ \bar{F}_i + \bar{F}_S^i \}, \quad i = G, C, M, \dots \quad (3)$$

Induced positions are then computed by twice integrating the induced accelerations:

$$\bar{q}_i = \iint_{t_i} \ddot{q}_i dt, \quad i = G, C, M, \dots \quad (4)$$

If the induced accelerations of Eq. (3) satisfy superposition, then the induced positions will as well. Thus, they can be used to reconstruct the simulated generalized coordinates:

$$\bar{q} = \sum_i \bar{q}_i. \quad (5)$$

We performed an induced-position analysis based on a dynamic optimization solution for normal gait obtained by Anderson and Pandy (2001). The musculoskeletal model had 23 degrees of freedom and was actuated by 54 muscles. We quantified how muscle forces and other forces acting on the body contribute to knee flexion angle during the swing phase of normal gait. The contribution made by the initial knee flexion velocity at toe-off was computed by integrating this constant over time.

RESULTS AND DISCUSSION

If the body were acted on by no forces at all during swing, the knee would have flexed by about 150° by the time of heel strike due to the initial knee flexion velocity, which was 375°/s (Fig. 1(a)). The muscle and ligament forces that acted after toe-off extended the knee by about 125°. All other forces, but mainly centrifugal forces, were responsible for extending the knee by another 75° so that at heel strike the knee was nearly fully extended.

Stance-leg and back muscles induced 268° of knee extension. The swing-leg muscles, in contrast, induced 112° of knee flexion. In the swing leg, active forces in iliopsoas and the dorsiflexors generated large induced knee flexion angles, but these were offset by knee extensions induced by passive forces in the vasti and the plantarflexors (Fig 1(b)).

Figure 1: Knee angles induced by (a) initial velocity, muscles, ligaments, and all other forces, and (b) swing-leg muscles.

Induced positions provide an absolute measure in degrees of how muscles contribute over a time to an observed joint displacement. In contrast to induced accelerations, they are easy to interpret and allow the effects of forces and velocities on motion to be compared directly.

VISCOELASTIC CHARACTERIZATION OF ULTRA HIGH MOLECULAR WEIGHT POLYETHYLENE

INTRODUCTION

Mechanical characterization of ultra high molecular weight polyethylene (UHMWPE) is important to predict stress and strain distributions occurring within total joint replacements. The purpose of this study is to examine the stress-strain behavior of UHMWPE under impact compressive load. The dynamic response was modeled with the three-element viscoelastic solid as a first step toward development of the dynamic constitutive law. In addition, viscoelastic properties of UHMWPE were compared with those of compact and trabecular bone tissues, which consist of implanted joints.

MATERIALS AND METHODS

Six cylindrical specimens, 5.3mm in both diameter and length, were cored from an unused tibial insert of total knee replacement system (Axiom Standard Knee, Write Medical Technology Inc., Arlington, TN) that had been sterilized with ethylene oxide. Specimen's axis was perpendicular to the articular surface of the insert and care was taken to produce parallel ends. Impact compression tests were performed using the split-Hopkinson pressure-bar (SHPB) technique (Lindholm, 1964) to determine the dynamic stress-strain relation and to characterize viscoelastic behaviors by the method previously developed (Tanabe et al., 1994).

RESULTS

Figure 1 shows the representative dynamic stress-strain curve at a strain rate of 230/s. The stress-strain relation was almost linear and its slope determined dynamic Young's modulus, E_D . The transient response obtained from the SHPB test was modeled with the three-element viscoelastic solid consisting of a serial spring E_1 and dashpot η connected in parallel with a second spring E_2 (Fig.2). Table 1 lists the mechanical properties for UHMWPE, human tibial compact bone (Kobayashi et al., 1993) and bovine femoral trabecular bone (Kobayashi et al., 1997).

DISCUSSION AND CONCLUSIONS

The agreement shown in Fig. 2 suggests that the three-element viscoelastic solid is applicable to UHMWPE below its yield stress. The present result will allow a reliable prediction of dynamic stress and strain distributions on and within UHMWPE inserts. Further, the dynamic load transfer mechanism in implanted joints for many clinical situations can be studied with the viscoelastic parameters for bone tissues.

THE CHANGE IN THE ROTATION RATE OF A BACTERIUM MOTOR CAUSES THE DIFFERENCE BETWEEN FORWARD AND BACKWARD SWIMMING SPEEDS OF *Vibrio Alginolyticus*

²University of Shiga Prefecture, ³National Food Research Institute

INTRODUCTION

A difference in the swimming speeds between forward and backward motions has been observed for the bacterium, *Vibrio alginolyticus*, (Magariyama et al (2001)) though the cause of the difference is not illustrated yet. There are some possible reasons to count on; the deformation of a flagellum which is caused by the fluid force exerted on the flagellum, the hydrodynamic interaction between a cell and a slide, the changes in speed of revolution of a flagellar motor.

In order to investigate the cause of the difference, we measured cell body rotation rates simultaneously with swimming speeds while the cell swims forwards and backwards. The results suggested that the difference was mainly caused by the variation in the rotation rates of the flagellar motor.

METHODS

Cells of *V. alginolyticus*, each of which possesses only one flagellum, were incubated in HI broth with shaking at 30°C. The cells were harvested by centrifugation and were suspended in HG300 medium. The suspension was left at room temperature for over 30 minutes before the experiment. Then, 3μl of the suspension were sealed between a glass slide and a cover slip; the distance between them was about 10μm.

Motion of the bacteria was observed though a dark-field microscope and was recorded by a VCR. The recorded images of some wobbling cells whose flagella were at an angle to their cell bodies were chosen. Instantaneous cell body rotation rates (*f*) were calculated from the wobbling frequencies and corresponding swimming speeds (*v*) were also measured from the images.

RESULTS AND DISCUSSION

Figure 1 shows the relationship between *v* and *f* of a certain cell. The backward swimming speed is considerably bigger than the forward speed as described by Magariyama et al (2001). In addition to that, we noticed two things; one is that the swimming speed is proportional to the cell body rotation rate and the other is that the proportional constants are same in the two cases of forward and backward motions.

The former fact exhibits that the fluid motion associated with the swimming motion of the bacterium is a viscous dominated flow. In fact, the swimming speed of *V. alginolyticus* has been predicted well by using the boundary element method for creeping flows (Goto et al (2001)). This also means that the cell body rotation rate is proportional to the flagellar rotation rate.

The other fact suggests that the difference between forward and

backward swimming speeds is rather due to the variation in flagellar motor rotation rates than the deformation of the flagellum.

We defined two indices I_v and I_f from a set of adjoining forward and backward swimming speeds (v_f, v_b) and a corresponding set of cell body rotation rates (f_f, f_b) as $I_v = (v_f - v_b) / (v_f + v_b)$ and $I_f = (f_f - f_b) / (f_f + f_b)$, respectively. Figure 2 shows histograms of the indices of 159 sets obtained for 35 cells. This figure entirely supports the things mentioned above for one cell, namely, that v_b is greater than v_f and the shape of the histogram of I_v is almost same as that of I_f .

SUMMARY

The speed and the cell body rotation rate of *V. alginolyticus* were simultaneously measured during both forward and backward swimming motions. The difference between forward and backward swimming speeds is mostly attributable to the variance in the rotation rate of the flagellar motor.

INTRODUCTION

Bioresorbable implants manufactured from polymers like polylactides, polyglycolides and co-polymers slowly degrade and are reabsorbed from the human body and removal operations after fracture surgery are not necessary. Due to their limited mechanical properties, the polymer screws and pins are mostly used in the treatment of non weightbearing simple fractures. Basing on the technique of Microfibrillar Composites, a new procedure for rapid manufacturing of bone nails with higher mechanical properties by injection molding is investigated.

METHODS

Bone nails are prepared according to the technique of Microfibrillar Composites from polymer blends of immiscible partners having different melting points, T_M , like compositions of polylactides and polyglycolides (see table 1). The essential stages of the preparation with this new technique are: (i) blending, (ii) drawing and (iii) injection molding above T_M of the lower-melting component and below T_M of the higher-melting one. During drawing fibrils are created and in the subsequent injection molding step melting of the lower-melting component occurs with preservation of the fibrillar structure of the higher-melting component. It should be mentioned, that the fibrils are not added as a separate material, in fact the structure is created during manufacturing.

RESULTS

Due to the high oriented polyglycolid fibrils, the composite shows higher mechanical values than each component. A special focus is set to the drawing step to achieve a good orientation of the harder polyglycolid component and to obtain synergy effects of both materials. The polyglycolid content of the composite varies from 10 to 30 volume percent.

Figure 1: Photograph and cross-section of the bone nail made of a polylactide/polyglycolide microfibrillar composite.

SUMMARY

The new composite bone nail shows promising mechanical values under ambient conditions and a high manufacturing speed is possible. Regarding the processing, this technique allows a wide range of different implant forms like the conventional injection molding technique. Finally this investigations shows the possibility of producing complete degradable reinforced implants by injection molding.

ANISOTROPY OF MODULUS CHANGES IN TRABECULAR BONE FOLLOWING SHEAR OVERLOADING

Glen L. Niebur and Xiangyi Liu

Department of Aerospace and Mechanical Engineering, University of Notre Dame
Notre Dame, IN 46556, USA; gniebur@nd.edu

INTRODUCTION

When trabecular bone is damaged by overloading¹ or fatigue,² its elastic modulus decreases. At the macroscopic level, the decreased modulus will redistribute the applied loads and may increase fracture risk.³ At the microscopic level, damage to the trabecular matrix will stimulate bone remodeling.^{4,5} As such, damage development in trabecular bone has implications for both whole bone strength and age related bone degeneration.

It has been suggested that both microdamage and modulus reductions in trabecular bone depend on the damage loading mode.^{6,7} It is complicated to evaluate the anisotropy of damage experimentally, as it requires modulus measurements in multiple loading modes on a single specimen. In this study, computational models were used to simulate damage in trabecular bone specimens in order to investigate the anisotropic damage behavior due to shear loading.

METHODS

High-resolution finite element models were created from seven bovine tibial trabecular bone specimens. The effective tissue elastic moduli for the models were calibrated from the apparent moduli in an earlier study.⁸ The full apparent elasticity tensor for each model was calculated using a representative volume method.⁹ Nonlinear models⁸ were used to simulate apparent level damage induction by pure shear stress to 1.75% strain in an on-axis-transverse plane and in the transverse plane. An isotropic, perfectly damaging constitutive model was assumed for the tissue (Fig. 1). The damaged tissue modulus was calculated for each element Gauss point based on the maximum strain level attained.

The damaged tissue moduli were used to calculate an apparent level damaged elasticity tensor. The percentage reduction in each of the six orthotropic elastic moduli was calculated from the undamaged and damaged elasticity tensors.

RESULTS

Shear in the transverse plane caused the transverse shear modulus to decrease by more than twice as much as the two on-axis shear moduli, on average ($p < 0.01$, Fig. 2). Similarly, the two axial moduli in the transverse plane decreased by more than twice the amount that the on-axis modulus decreased after transverse shear damage.

Shear in the on-axis plane decreased the on-axis shear modulus more than the remaining five moduli ($p < 0.01$). The transverse axial modulus in the plane of shear decreased

almost twice as much as the other axial moduli ($p < 0.01$), which were not significantly different from one another.

Figure 1: The tissue level damage behavior in principal strain space.

Figure 2: Reduction of orthotropic moduli due to apparent level shear damage. The XY coordinate plane is the transverse plane, and the Z axis is aligned with the principal trabecular orientation.

DISCUSSION

The on-axis modulus is the least sensitive of the six orthotropic moduli to shear loading. As such, if the bone does not fracture following a shear overload, it maintains most of its mechanical stiffness for habitual loading. For a specific strain level, the decrease following shear loading in a plane aligned with the principal trabecular orientation is more detrimental than shear loading confined to the transverse plane. The anisotropy of damage at the apparent level indicates that microdamage for a specific loading mode is localized. As such, damaged regions following off-axis loading are protected during normal loading, facilitating repair. Because of the localization, this damage repair process could result in structural adaptation of the microarchitecture.

SWING PHASE REDUCTION IN ABOVE-KNEE AMPUTEE RUNNING

Christiane Bohn¹, Gongbing Shan², Thomas Korff³, Hagen Schaper¹, Klaus Nicol¹

¹Institute of sports sciences, University of Muenster, Germany

²Department of Kinesiology and Health Education, University of Texas at Austin, USA

³Department of Kinesiology, University of Lethbridge, Canada

INTRODUCTION

Since the repeal of prohibition for amputee running in 1991 the development of technical equipment is standing in the centre of interest (e.g. Knicker/Bloch 1996). But winning at a high competition level depends also on improvement of individual running technique. Therefore, the aim of this study was to improve the individual sprinting technique of above-knee amputees by computer simulation.

Previous research (Bohn 2001) shows that above-knee amputee runners often extend the knee of the prosthesis side already in the middle of the swing phase. This increases moment of inertia and thus increases flight phase and reduces running velocity. Aim of the study is to find out if it is possible to delay knee extension (to which the athlete has no direct control) by modifying hip torque (to which he has control).

METHODS

Computer simulations were conducted to analyse the influence of the hip muscles on swing phase performance on the prosthesis side. Three high performance amputee sprinters took part in the study which among others was conducted for attaining parameters for the model. In a first step, kinematic and dynamic parameters of the subject were obtained. The experimental set up included two high speed video cameras (250 Hz) and a 240 x 80 cm² segmented 3-component force platform (170 Hz). Three successive running steps were recorded at 5.7 m/s - 7.2m/s running velocity, data were filtered with a 2nd order low pass butterworth filter at 70 Hz.

In a second step, a two dimensional model with three segments (trunk, thigh and lower leg) using DADS 9.0 forward dynamic modelling software was constructed and based on the anthropometrical data of each subject. Using a procedure by Patil/Chakraborty (1991), the hip torque curve was modified in order to fit the model movement to the empirical data. In a third step the hip torque curve was modified for reducing flight phase.

RESULTS AND DISCUSSION

Simulation showed that less flexion and more extension net torques at the hip were necessary to increase knee flexion as shown in Figure 1. In this way, moment of inertia is decreased which leads to reduced swing phase duration.

It was possible for all subjects to find hip torque curves which lead to reduced swing phase and thus to higher velocity in case they manage to keep stride length constant.

Figure 1: *Knee angle curve of the subject during flight phase (continuous line) and simulated knee angle curve caused by modified hip torque (dashed line). This modification gives less moment of inertia and swing phase duration and thus possibly higher running velocity.*

CONCLUSION

Simulation shows that flight phase reduction and thus possibly increase of running velocity can be achieved by reasonable modification of hip torque. Ongoing research should show whether the subjects did not produce the calculated torques due to muscle weakness, or due to deficit co-ordination. Furthermore simulation might lead to feasible modifications of the prosthetic material.

APPLICATION OF FIBRE LASER SCANNING CONFOCAL MICROSCOPY TO STUDY OF THE BIOMECHANICS AND MICROSTRUCTURE OF ARTICULAR CARTILAGE

Jianping Wu¹, Brett Thomas Kirk¹, Peter Delaney², Nick Milne³, Daniel Smolinski¹ and Karol Millar¹

¹ The Department of Mechanical & Materials Engineering, The University of Western Australia, Australia; ² Optiscan Pty Ltd, Australia; ³ The Department of Anatomy & Human Biology, The University of Western Australia, Australia.

INTRODUCTION

The aim of this study is to develop a fibre laser scanning confocal microscopic methodology to examine the biomechanical functions of articular cartilage in relation to the collagen matrix.

Articular cartilage has a unique structure while provides it with exceptional biomechanical properties. Articular cartilage is composed of a small portion of chondrocytes and an extracellular matrix which mainly consists of water with dissolved electrolytes, collagen fibres (mainly type II) and proteoglycans. The collagen fibres form a three-dimensional meshwork which entraps a swollen proteoglycan gel. Articular cartilage is thus provided with resilience and load capacity.

METHODS

Fibre optic laser scanning microscopy (FLSCM) uses a single mode optical fibre for transmission of the illumination and imaging signal. The FLSCM offers compact resolution and imaging capability when comparing with a conventional confocal microscope (Delaney et al, 1994). The mechanism of the FLSCM has allowed the development of potential clinical applications (Smolinski et. al, 2001). In this study, the FLSCM was modified with compression apparatus as shown in Figure 1, which incorporates a proportional pressure regulator, a pressure transducer and LVDT. Therefore, the pressure applied to the cartilage can be controlled and displayed digitally by the Pressure transducer. The displacement occurring in the articular cartilage can simultaneously be recorded using data acquisition software via the LVDT.

Figure 1. A modified FLSCM for study of the biomechanics of articular cartilage in relation to its internal structure.

Articular cartilage specimens attached to subchondral bone, $1.5 \times 1.5 \times 3$ mm, were obtained from the central weight bearing region of femoral condyles of approximately two-year-old cows within twenty-four hours of slaughter. After

using immunofluorescence for tracing type II collagen, the specimens were placed on the platform of the FLSCM. Using F900e software (Optiscan Pty Ltd, Australia), the three-dimensional image stacks of the collagen fibres were recorded. Using Voxblast, the image stacks were reconstructed into three-dimensional image as shown in Figure 2.

RESULTS

This study explored the three-dimensional structure of type II collagen fibres in articular cartilage. It has been confirmed that the collagen fibres in the superficial zone are parallel to the surface of the articular cartilage and predominately orientated in one direction, shown in Figure 2 (left). The collagen fibres in the transitional zone change their direction compared to the radial zone and start to become parallel to the surface of the cartilage as they approach the superficial zone, as shown in Figure 2 (middle). The collagen fibres in the radial zone are arranged predominately perpendicular to the surface of the articular cartilage as shown in Figure 2 (right).

Figure 2. Three-dimensional images of the collagen fibres of bovine articular cartilage. Collagen fibres in the superficial zone (left). Collagen fibres between the transitional and radial zones (middle). Collagen fibres in the deep zone (right).

SUMMARY

In current study, based on using FLSCM, a methodology has been developed to study the biomechanical function of collagen fibres.

THE IMPORTANCE OF CERTAIN DESIGN FEATURES IN A BACKPACK

Joan M. Stevenson, Susan A. Reid, J.Tim Bryant, Ronald P. Pelot, Evelyn L. Morin

Ergonomics Research Group, erg@post.queensu.ca

Queen's University, Kingston, Ontario, Canada

INTRODUCTION

There is a paucity of biomechanical studies in scientific literature for load carriage. Most designers merely use feedback from expert trekkers to develop new features on a backpack. The purpose of this study is to show how biomechanical tools can be used to assist with the design process. To complete this research, two biomechanical tools used to develop the Canadian Forces load carriage system will be used: 1) Load Carriage (LC) Simulator (measured forces, moments, displacement and pressures); and 2) the Load Distribution Mannequin (separated and measured out the forces experienced by the upper and lower body).

DESIGN OF THE SHOULDER STRAPS

In this study, the purpose was to determine the optimal shoulder strap design to minimize forces and pressures on the torso. For this study, the Load Distribution Mannequin (LDM) was used to provide information on shoulder and lumbar forces as well as shoulder pressures. In the first study, the lower shoulder strap attachment point was moved along the vertical pack edge and horizontal belt line by reinforced D rings so that fourteen different shoulder strap angles could be created. To assess the upper shoulder straps three different shapes (A,B,C) were designed with common characteristics (width of 9.5cm and a distance of 3.5cm between the upper attachment points on the pack) and variable shapes in their radii of curvature toward the armpit;

Figure 1. Effect of strap angle on peak contact pressures

A-no curvature, B-5.5cm, C-9cm. Results for the lower shoulder strap attachment point found that the shear forces were below recommended levels for all configurations, but significantly better when the strap was less than 40° from the vertical. The changing angles affected the skin contact pressure with dramatic effects in the axilla above 35° angle from the vertical. It was concluded that an attachment point 24° to 30° from the vertical would be optimal for the lower

shoulder strap attachment point. For the upper shoulder strap attachment point, peak pressure, average pressure and contact area over the anterior shoulder were examined. Prototype C with the longer radius of curvature had the best force distribution, least peak pressure in the axilla and least tendency to twist.

LATERAL STIFFNESS RODS

The purpose of this study was to examine the change in load distribution characteristics associated with adding lateral stiffness elements (rods) to a rucksack. Two 3D load cells were used to determine the load applied to the shoulders and upper torso independent of the load applied to the hips and lower trunk. Position and mass of the payload (25 kg) was fixed at the centre of the volume of the rucksack and held constant during all testing. It was hypothesized that lateral rods would provide a force bridge that transfers part of the vertical load of the pack from the upper back and shoulders to the hip belt (supported by the iliac crest) thereby reducing the vertical load on the torso, and possibly reduce the horizontal reaction force that produces a shear load on the spine. Results showed that this active stiffness

Figure 2. Vertical load force for the rod / no-rod conditions.

element shifted 10% of the vertical load from the upper torso to the pelvic region. Lumbar shear load remained unchanged between the rod and no-rod conditions for all combinations of shoulder strap and waist belt tension. The lateral rods also provided a greater extensor moment about the medio-lateral axis at the L3-L4 level. It was concluded that biomechanical tools can add knowledge and reduce design time and costs.

DEVELOPMENT OF A TRIFILAR PENDULUM FOR MEASURING MOMENT OF INERTIA

J.Tim Bryant, Joan M. Stevenson, Rad Zdero, Lindsay Hadcock
Ergonomics Research Group, erg@post.queensu.ca
Queen's University, Kingston, Ontario, Canada

INTRODUCTION

One requirement often needed for dynamic biomechanical modeling is the location of the centre of gravity and moment of inertia of large complex objects, such as a person, prosthetic limb or a backpack. These irregular shaped objects have a heterogeneous mass distributions or awkward shapes. Numerous methods have been reported in the scientific literature, such as: photogrammetry¹, computed tomography², magnetic resonance imaging³, mathematical modeling⁴ and body segment pendulum methods⁵. This paper describes a tool called a trifilar pendulum that can provide this information for non-homogenous objects quickly and simply.

THEORETICAL BASIS

The trifilar pendulum consists of a round plate of a homogenous material, suspended in the horizontal plane by three cables of equal length equidistantly placed from the center of the plate (Figure 1). When the pendulum is twisted around a vertical axis running through the center of the plate, it oscillates with a period that is a function of cable length, plate radius, plate mass, local gravitational acceleration, and plate moment of inertia. This can be derived as follows:

$$I = 0.2485 r^2 / L (mT^2 - m_p T_p^2) \quad (1)$$

Where: I = mass moment of inertia of test object [$\text{kg}\cdot\text{m}^2$]

m = mass of plate/object assembly [kg]

T = period of plate/object assembly [s]

m_p = mass of plate [kg]

T_p = period of plate [s]

r = effective radius of plate [m]

L = length of filaments [m]

Figure 1. Trifilar Pendulum with backpack

When an object is placed on the plate such that its center of gravity (CG) is coincident with the plate CG, the resultant

object/plate assembly can be treated as a new pendulum. Since all factors other than mass remain constant, the change in the period of the new pendulum is related to differences in the mass moments of inertia of the old and new pendulums. The mass can be easily measured and the moment of inertia of the object can be determined using equation (1).

CENTER OF GRAVITY VALIDATION TESTS

The purpose of this experiment was to determine the ability of the trifilar pendulum to predict the centre of gravity of a test object, a necessary requirement the correct calculation of moment of inertia as the plate centroid and object centroid must be in line. The system was calibrated at 15 distinct locations on the plate, repeated twice, using 13.6 and 45.5 kg masses. Results showed high correlations between measured (x,y) coordinates and trifilar pendulum locations ($r = 0.98:1$ and $0.99:1$, respectively). The average absolute total error E_T is 15.5 mm (3.5 % of the radius). The accuracy of the device would improve as the weight of the object being measured increases due to the precision of the scales. The precision error is ± 0.45 kg. Thus, 13.6 and 45.5 kg objects have errors of ± 3.3 and $\pm 1\%$, respectively.

MOMENT OF INERTIA VALIDATION TESTS

The purpose of this experiment was to validate the ability of the pendulum to provide accurate physical measures, which in turn yield an accurate moment of inertia. The three test objects (3.69, 6.81 and 10.2 kg) were composed of three sets of equal mass. Each weight series was placed on the pendulum plate at three locations (0.2 m, 0.25m and 0.3m) from the centre along lines drawn from the center to the turnbuckles. The angle measurement pegs were inserted and the pendulum was rotated freely through 10 degrees 10 full rotations. Tests were repeated 10 times and results averaged. From equation (1), the moment of inertia was determined for values ranging from 0.16 to 0.95 $\text{kg}\cdot\text{m}^2$. The average percent error between theoretical and measured values was 6.0 %. However, accuracy improved significantly with increased mass, as the percent error reached a minimum value of 0.32 % for a 10.2 kg load located 0.25 m from the center of the plate.

RESIDUAL STRESS AND STRAIN IN THE LAMELLAR UNIT OF THE AORTA: EXPERIMENT AND ANALYSIS

Takeo Matsumoto, Taisuke Goto, and Masaaki Sato
Biomechanics Laboratory, Tohoku University, Sendai, Miyagi, Japan
For correspondence: takeo@biomech.mech.tohoku.ac.jp (T.M.)

INTRODUCTION

If one cut a ring-like segment of an aorta radially, it usually springs open to become an arc. It has been pointed out that this happens because circumferential stress in the aortic wall distributes uniformly in the radial direction *in vivo*, and as a result, the segment at no load has compressive residual stress near the inner wall and tensile near the outer. The opened-up configuration is stress-free if the aortic wall is homogeneous. However, the wall is not homogeneous in a microscopic level: its media has a layered structure called lamellar unit which is a pair of elastic lamina (EL) and a smooth muscle rich layer (SML). Recently, we found that the EL is much stiffer than the SML (Goto, 2002). Thus, if the circumferential stress in the *in vivo* condition is the same between the two layers, residual stress of each layer in this direction should be different because the stress-strain relationships differ. Such residual stress is not released fully by radial cutting, but is released in the area close to the cut surface, causing hills and valleys on the surface due to compressive and tensile stresses, respectively. In this study, we have developed a scanning micro indentation tester (SMIT) to measure the topography and the stiffness distribution of the cut surface, and estimated residual stress and strain in the lamellar unit.

SCANNING MICRO INDENTATION TESTER (SMIT)

It is a tester to measure the surface topography and stiffness distribution of a specimen surface by pressing a cantilever tip against the surface while scanning it like the atomic force microscope in the contact mode. The cantilever was made by pulling a micro glass plate of 65mm x 1mm x 0.15mm to make its tip diameter 3–5 μm and bending it at right angle at the point 4mm from the tip. The cantilever was driven by a PZT actuator and the displacement of its tip was measured with a laser displacement meter. The specimen bath was set on a motor-driven XY stage to scan the point of measurement. The contact point was determined at the point where the cantilever began deflecting, and a stiffness index α was obtained as the initial slope of the indentation-deflection curve. The index α was converted to elastic modulus E with the formula E (kPa) = $1.88\exp(2.54\alpha)$ obtained by calibrating the tester with silicone elastomers with known elastic moduli.

MEASUREMENT OF SURFACE TOPOGRAPHY

Rectangular specimens of 5x10 mm (2–3 mm thick) were excised from porcine descending thoracic aortas. Macroscopic residual stresses are removed during excision. Each of the specimens was sliced with a vibrotome in the saline to obtain the surface perpendicular to the circumferential direction. The specimen with its bath was then mounted on the XY stage of the SMIT for the surface measurement. The surface of the section shows hill and valley pattern aligned with the circumferential direction (Fig. 1). The distance between the peaks and the peak height were ~ 25 and ~ 8 μm , respectively.

The elastic modulus estimated from α was ~ 180 kPa at the peak and ~ 52 kPa at the bottom. On a separate study, we observed the change in thickness of EL and SML in response to radial compression and found that the elastic modulus of EL is 2.5 times higher than that of SML (Goto, 2002). Thus, we suppose the hill must be EL and the valley SML, i.e., EL may be compressed and SML stretched in the lamellar unit.

ESTIMATION OF RESIDUAL STRESS AND STRAIN

The stress distribution required to restore the hill and valley pattern to the plane where the specimen was cut corresponds to the residual stress distribution. Such distribution was estimated on a 2D simplified model based on the data shown in Fig. 1. Following assumptions were made: 1) lamellar unit is made of two layers EL and SML with uniform thickness; 2) the thickness of EL and SML are 6 and 22 μm , respectively; 3) the height of each layer is uniform and the difference between the two is 8 μm ; 4) EL and SML are linearly elastic with the elastic modulus of 180 and 52 kPa, respectively; 5) residual stress is released upon cutting to the depth l_0 ; 6) shear stress and lateral deformations are negligible. To estimate the depth l_0 , thin slices with various thickness were removed from the surface with the vibrotome while measuring surface topography with the SMIT. The height difference between hills and valleys did not decrease unless the thickness was smaller than 70 μm . Thus, we roughly estimated l_0 to be 70 μm . The model analysis showed that the residual stress and strain increased with the decrease in l_0 , and that the residual stress is at least -10 kPa for the EL and 3kPa for the SML and the residual strain is at least -6% for the EL and 5% for the SML. These values are almost comparable to those estimated to be in ring-like segments of the aortas in no load condition. Fairly large stress may still reside in the opened-up aortic wall, which had been believed to be stress-free. Microscopic viewpoint is necessary when studying mechanical environment of the smooth muscle cells in the aortic media.

INTRODUCTION

The internal structure of articular cartilage is critical to its biomechanical function. Cartilage is known as one of the most intricate and difficult tissues to study. The primary reason for this is that its functional characteristics depend heavily of the three dimensional microstructure of the tissue, while most microscopy methods can display only two dimensional representations of the cartilage. The sectioning requirements for most forms of examination also destroy the integrity of the tissue, making it impossible to concurrently examine the structure and function of the tissue. The development of confocal microscopy internal examination of loaded tissue for the first time, facilitating direct examination of the association between structure and function of the tissue (Guilak, 1994).

The structure/function relationship is critical to the study and the advancement of clinical treatment techniques for cartilage disorders. Osteoarthritis is characterized by severe disruption to the cartilage matrix. The emergence of autologous chondrocyte implant (ACI) therapy as a method for repairing cartilage defects has further increased interest in clinical techniques for the examination of cartilage structure and function. A confocal arthroscope has therefore been developed (7mm diameter) to facilitate clinical examination of cartilage structure (Figure 1). This, in turn, allows the functional characteristics of the tissue to be deduced.

Cartilage exhibits little intrinsic repair (Ghadially, 1983), making biopsies undesirable. Thus, with respect to cartilage in particular, the developed technologies promise to enable study to a level of detail which was previously impossible.

Figure 1: The prototype confocal arthroscope. Probe diameter is 7mm [Optiscan Pty Ltd]

METHODS

Bulk cartilage and bone specimens were frozen post mortem. After thawing the specimens were immersed in 0.05g/l Acridine Orange for 6 minutes. The specimens were then examined using the developed confocal arthroscope. Confocal images were recorded from various locations in the weight bearing regions of the joints. Figure 2 (left) shows an image obtained from asymptomatic tibial cartilage. Figure 2 (right) shows an image obtained from osteoarthritic cartilage.

Figure 2: Confocal arthroscopic images of asymptomatic tibial (left) and osteoarthritic femoral (right) articular cartilage.

SUMMARY

A confocal arthroscope has been developed and used on articular cartilage. Clear differences between asymptomatic and osteoarthritic cartilage can be seen. These differences are consistent with the histology of cartilage and the etiology of osteoarthritis. Clinical potential for the methods clearly exists for monitoring both arthritic conditions and ACI repair tissue. Further development of both equipment and methods is required before clinical trials can progress.

DEVELOPMENT OF A 3D FINITE ELEMENT MODEL OF HUMAN FOOT AND ANKLE

Ming Zhang¹, Jason Tak-Man Cheung¹, Yubo Fan² and Aaron K.L. Leung¹

¹Rehabilitation Engineering Centre, The Hong Kong Polytechnic University, Hong Kong, China, rcmzhang@polyu.edu.hk

²Laboratory of Biomechanical Engineering, Sichuan University, Chengdu, China

INTRODUCTION

Information on the internal stress and strain of the foot and ankle during walking is useful in enhancing knowledge on the biomechanical behaviour of the ankle/foot complex. Direct measurement of those parameters is difficult, while a comprehensive computational model can be useful. This will help to design a proper foot support. Foot model have been developed based on a certain assumptions (Chen 2001, Funk 2000, Gefen 2000, Jacob 1999). In this study, a three-dimensional finite element model of the human foot and ankle was developed using 3D actual geometry of both foot skeletons and soft tissues. The objective is to investigate the biomechanical interaction among bones, ligaments and tendons, and interaction between foot plantar and different supports under various loading conditions.

METHODS

The geometry of the FE model was obtained from 3D reconstruction of MR images from a right foot of a normal male subject. The bony structures and the soft tissue boundaries in MR images were identified and segmented using MIMICS v7.10 (Materialise). The boundary surfaces of different components obtained were processed using SolidWorks in order to form a surface model for all bones and foot surface, as shown in Fig. 1. The surface models were d meshed using ABAQUS v6.2 FE package.

Figure 1: Bones and foot surface obtained from 3D reconstruction of MRI.

The metatarsals and the phalanges are jointed together by 1mm thick cartilage. The interaction among the metatarsals, cuneiforms, cuboid, navicular, talus, calcaneus, tibia and fibula were defined by contact surfaces, which allow more relative movement. The mesh structure for bones is shown in Fig. 2. The major ligaments were attached on the corresponding points on the bones. They were defined as

tension only truss elements. The analyses can offer stresses/strains among bones and ligaments, and stress distribution between the foot and the support surface. The plantar pressure distribution can be measured to validate the finite element model.

Figure 2: Mesh structure of foot bones.

RESULTS AND DISCUSSION

The present study developed a FE model and provides preliminary results on stress/strain. It can provide quantitative analysis of normal and pathological foot and ankle motion. With further improvement, correlation of various foot pathology or deformity between the corresponding biomechanical outcomes can be documented efficiently with appropriate simulation. Other potential clinical applications include studies of the biomechanical effects of varying geometrical and material factors of different structures of the foot, prediction on different surgical outcomes and orthotic performances.

SUMMARY

A 3D FE model of foot/ankle complex was developed using the actual geometry. It can offer useful information in the stress and strain among the bones and ligaments. The model can be used in clinical applications to simulate foot behaviour and to design a good foot support.

BIOMECHANICAL ANALYSIS OF TAKEOFF TO BACK HANDSPRING AND BACKWARDS SOMERSAULT

Pia Melcher¹ and Erik B. Simonsen²

¹Institute of Exercise and Sports Sciences, University of Copenhagen, Denmark (p.melcher@mai.ku.dk). ²Anatomy Department C, Panum Institute, University of Copenhagen, Denmark.

INTRODUCTION

The body position at takeoff in gymnastics jumping (tumbling) is very important for attaining adequate height and rotation in the following jump.

Rotation can only be created during ground contact, because it requires an external force. This is a consequence of Newton's second and third laws (conservation of angular momentum).

Rotation is created if the reaction force passes outside the body's center of mass (CM). This is obtained by leaning the body either forward or backward, or by *pushing* on the ground in either forward or backward direction; which can be done by a fast hip flexion or extension.

The purpose of this study was to investigate the strategy behind the takeoff from a *round-off* to a back handspring (also called *flic flac*; FF) and from a *round-off* to a *backwards somersault* (BS). We tested the hypothesis that the body position at takeoff to the BS shows a larger inclination than the body position at takeoff to the FF and therefore a larger sagittal force. In this context, inclination is defined as when the line of action from the gravitational force falls behind the contact point of the feet.

We expected the CM to reach higher in vertical direction in the BS than in the FF. Because the mechanical energy is conserved, the peak height that the CM will reach can be calculated as $h = v^2/2g$ (v is the vertical takeoff velocity).

METHODS

Nine male elite gymnasts took part in this study (25.2yrs, 1.77m, 76.78kg). They all performed the two jumps described above.

The jumps were recorded on highspeed film (120 Hz) in the sagittal plane (2D) combined with registration of the ground reaction forces. At takeoff the subjects had one foot on the platform and the other on the floor.

The video sequences were digitised by APAS (Ariel Performance Analysis System, Ariel Dynamics Inc.). A two dimensional model with 7 segments (foot, leg, thigh, truncus, upper arm, forearm and head) was defined from the antropometric data and the video data.

Net joint moments (M) about the ankle, knee and hip joints were calculated from the ground reaction forces and the video data by inverse dynamics and normalized to body mass.

The power production (P) about a joint was calculated as the product of the joint angular velocity (ω) and the net joint moment (M).

Differences in the size of the sagittal force, F_y , jumping height and net joint moments between the two jumps were evaluated statistically by a two-tailed paired t-test. The level of

significance was in all cases set to 5%. Results are given as mean \pm SD.

RESULTS AND DISCUSSION

Kinetics. The force data showed that the reaction force in the sagittal direction was two times larger for takeoff to the BS than to the FF ($P=0.004$).

Kinematics. At takeoff to the BS the net hip moment was flexor dominated throughout the contact phase (mean peak moment 25.96 Nm/kg \pm 11.27) while in the landing phase the net hip moment for takeoff to the FF initially was flexor dominated (mean peak moment 8.63 Nm/kg \pm 4.50) ($P=0.003$), and then in the takeoff phase the moment shifted to extensor dominance. The simultaneously negative power output for the hip in BS indicated that the hip flexors worked eccentrically to keep the upper body in a more upright position at the takeoff. At the takeoff to FF the upper body extended more in the last phase of the takeoff and the power output is positive, which indicated concentrically muscle contraction in the hip extensors.

The hip joint angle changed approx. 50° in BS (from 130°-180°) and approx. 80° in FF (from 110°-190°), which corroborates the moment and power data.

For BS the path of CM showed a steeper rise while the path was more flat for the flic flac. In correspondance with this we saw that the jumping height was six times higher in the BS (0.50 m \pm 0.07) than in the FF (0.08 m \pm 0.03) ($P<0.001$).

Clearly, our results show that the gymnasts use different strategies in the takeoff to these two jumps although the initial movement (the *round-off*) was the same.

SUMMARY

The peak height of CM was higher in BS than in FF. The sagittal force was larger during the takeoff to the somersault than to the flic flac. The hip joint extended more in the flic flac while in the somersault the position was more upright and the angular displacement in the hip joint angle was smaller.

A METHOD FOR DETECTING THE MOMENT OF PUNCTURE USING THE FORCE PROFILE

INTRODUCTION

A needle insertion that is common procedure in blood sampling, biopsy and injection is one of the most popular surgical procedures. Needle insertion, on the other hand, requires high skill and much experience to stop a tip of a needle in the diseased part because a tip is not seen during needle insertion. To prevent the medical accident, especially biopsy, a needle insertion is operated with X-ray images. To avert X-ray exposure, therefore, it is necessary that a method does not depend on X-ray images to detect a moment of puncture of tissue. Generally speaking, mechanical properties of the diseased part are different from those of around the affected part. Hence, it is considered that the force profile that acts on the needle is available to detect a moment of puncture of an affected part. An objective of this study was to clarify whether the force profile was available for detection of a moment of puncture during needle insertion or not.

METHODS

The force that acted on the needle was divided into 2 parts and measured, respectively. One was the reaction force of cutting tissue by a tip of a needle. Another was friction force that acted on side of a needle during inside tissue. To measure both reaction and friction force, a load transducer consisted of 2 types of load transducer. One was the 6 axes load transducer. Another was 1 axis one (z-axis force was detected). These load transducers had same z-axis and were connected in series. Needle was divided into an inner part and an outer one. An outer part surrounded an inner one except a tip of it. An inner part was connected to 1-axis load transducer and an outer part was connected to 6-axes one. The lever of living porcine under general anesthesia was used. This experiment was approved by the Committee on Animal Experiments of Institute for Human Science and Biomedical Engineering in compliance with the Regulation for the Animal Experiment Ethics of Institute for Human Science and Biomedical Engineering. To detect a moment of puncture of tissue, video image was taken during experiment. Table 1 gives all experimental conditions.

Table 1: Experimental conditions

Insertion speed (mm/sec)	Tip types (diameters of outer needles: mm)
3 (const.)	Bevel (2), triangular pyramid (0.8, 1.2), cone (0.8, 1.2)

RESULTS AND DISCUSSION

Figure 1: The force-time curve of triangular pyramid tip of needle (diameter = 0.8 mm). Vertical axis shows force (N), and horizontal axis shows time (sec). The line across the time axis shows the moment of puncture of tissue from video image.

Figure 1 shows that a force-time curve of triangular pyramid tip of needle (diameter = 0.8 mm). A reaction force decreased and a friction force increased instantaneously when tissue was punctured. These force profile patterns were shown in all experimental conditions. A whole of force that acts on needle, however, was hardly changed.

SUMMARY

In this study, force that acted on a needle during needle insertion was divided into a reaction force and a friction force and measured, respectively. As a result, it was clarified that the force profile of reaction force and friction force were available to detect the moment of puncture of tissue.

COMPARISON OF SIMULATED PROJECTILE AND BATON BLOW IMPACTS ON SHIN GUARDS USED IN CROWD MANAGEMENT INTERVENTION

Jean-Philippe Dionne, Ismail El Maach, Kevin Semeniuk, Aris Makris

Med-Eng Systems, Ottawa, Ontario, Canada
Corresponding author, jpdionne@med-eng.com

INTRODUCTION

There exists no standard procedure for testing the protection offered by shin guards used during Crowd Management Intervention (CMI). Bir *et al* (1995) investigated the impact performance of soccer shin guards, using a pendulum impactor. However, a pendulum impactor is not appropriate for generating the high level of impact energies typical of CMI. Most threats that security officers have to face in the event of a CMI can be classified into two categories: launched projectiles, and hand held blunt weapons. The Blunt Impactor (BI) and the Pitching Machine (PM) were used in the present study, to simulate these threats and assess the injury probability when subjected to blunt impacts on the leg.

Figure 1: Blunt Impactor (left), and Pitching Machine (right)

METHODS

Nine pairs of shin guards (Med-Eng Systems Inc., Canada) were tested against baseball bat blows generated by the BI and ball impacts generated by the PM (Fig. 1). The shin guards were secured to a maple wood surrogate (diameter 9cm) attached to a force platform (3 force transducers and an accelerometer). The BI uses a pneumatic system to power a baton or baseball bat. The balls used with the PM weighed 140 grams, and their velocities were measured with a radar system. Control tests were first carried out, in which the surrogate was directly subjected to the two types of threats, without any protective equipment. Tests were then performed with the protective equipment fitted on the surrogates.

RESULTS AND DISCUSSION

The forces measured are plotted against the impact energy (Fig. 2). Although injuries can occur prior to bone fracture, the force required to break bones is often used for injury thresholds. In a recent study, Porta (1996) found a higher limit

of tibia fracture thresholds of 8.93 kN. Based on this threshold, it is found that much higher impact energies can be tolerated with the PM, as compared to the BI for the same impact energy, and that the shin guards provide a significant reduction in injury potential, as compared to the unprotected case.

The injury analysis presented here is conservative. The actual protection offered by the V-Top shin guard may be underestimated due to the fact that the fracture thresholds were obtained based on experiments with aged donors, soft tissues equivalent were not incorporated in the surrogate, the test surrogate was constrained, and protective equipment is designed to distribute the transmitted force over a large surface area (only a global force transmission was measured in the present study).

Figure 2: Peak forces for the unprotected surrogate (left) and shin guard (right) as a function of the impact energy for both threat simulators. Tibia fracture threshold shown.

SUMMARY

The above results stress the importance of wearing protection during crowd management interventions. Moreover, the large differences observed between the results obtained with the two threat simulators illustrate the large dependence on test conditions in impact tests, and the need to appropriately replicate the threats, when evaluating the protective capability of personal protective equipment.

CARTILAGE DEFORMATION OF THE FELINE PATELLOFEMORAL JOINT OBTAINED FROM LASER SCANNING

Sylvain Couillard¹ and Walter Herzog²

Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada

¹ MSc student, Dept of Mech. Eng., sylvain@kin.ucalgary.ca, ² Faculty of Kinesiology, walter@kin.ucalgary.ca

INTRODUCTION

It is commonly accepted that abnormal mechanical loading and subsequent articular cartilage deformation play an important role in the initiation and development of osteoarthritis (OA). We know that normal articular cartilage deforms under load, but the magnitude of this deformation in-vivo is currently uncertain. The purpose of this study was to quantify in-situ articular cartilage deformation in the feline patellofemoral joint with an improved laser scanning technique.

METHODS

To quantify articular surface deformation, two left limbs were used. A custom-built joint fixture (Couillard et al., 2000) was attached to the hindlimb before dissection. The patella and femur were then taken apart and the intact articular surfaces were scanned in 2.5 minutes with a commercially available laser scanner with a precision (2SD) below 25 μm (Couillard and Herzog, 2001). After repositioning the bones within 30 μm of their original position, the joint was statically loaded in-situ at 135 N for 4 hours and 25 minutes and chemically fixed (Hunziker et al, 1982). The bones were then separated and the deformed articular surfaces were scanned. Finally, the cartilage was removed from the articular surfaces with a bleach solution and the bone surfaces were scanned. Each surface scan comprised 57,600 data points over an area of 144 mm^2 and was repeated three times.

The median of three repeat measurements was taken, low-pass filtered, and resampled to reduce data size. The resampled surface points for the three states (unloaded cartilage, loaded cartilage, bone) were aligned using spherical ceramic bone markers. The filtered data was then modeled with interpolating thin-plate splines (Boyd et al., 1999) and subtracted along the surface normals of the unloaded surface to quantify articular cartilage surface deformation and cartilage thickness.

RESULTS AND DISCUSSION

Three-dimensional cartilage surface deformation plots were obtained and showed that cartilage from the femoral groove was compressed up to 150 μm and elevated up to 250 μm in the areas surrounding the contact (Figure 1). The contact area was 23.4 mm^2 , which gives a pressure of approximately 5.8 MPa. These values compare well with other results obtained in-situ (Clark et al., 2002). Cartilage thickness measurements were not entirely reliable since negative values were obtained. We suspect that cartilage translucency allowed for refraction and internal reflection of the laser beam through the cartilage layer. We suggest that a thin uniform layer of

reflective coating be used on the articular surface to avoid this problem. Results for the patella were difficult to obtain since the number of bone markers on the patella was insufficient to allow for three-dimensional surface alignments.

This improved laser technique, based on Haut et al. (1998), had an accuracy of 2.9 μm on an inert surface. It allowed to quantify articular cartilage surface deformation with an estimated accuracy of approximately 100 μm , and a precision less than of 30 μm . The approach developed here may prove useful when attempting to correlate cartilage mechanics to structural deformation (chondrocytes, collagen fibres), and the corresponding biosynthetic response.

IN VIVO RABBIT PATELLAFEMORAL JOINT LOADING VIA MUSCLE STIMULATION

*Sean Craig and *Walter Herzog

*Human Performance Laboratory, The University of Calgary, 2500 University Dr NW, Calgary, Alberta Canada. T2N 1N4
Email: sttcraig@kin.ucalgary.ca

INTRODUCTION

It is generally accepted that mechanical loading of musculoskeletal tissues may cause injuries and diseases such as the tennis elbow, carpal tunnel syndrome, and osteoarthritis. However, the mechanisms underlying the relationship between loading and disease/injury are ill understood. It is not even understood why an apparently similar loading condition (for example at the work place) may cripple one person while leaving another completely unaffected. Here, we attempt to gain insight into the relationship between mechanical loading of articular cartilage and the corresponding biological (adaptive or degenerative) response. Typically, the relationship between articular cartilage loading and biological response is determined for in vitro explants. The importance of these in vitro studies for in vivo functioning is not known. Therefore, we wanted to establish a protocol to investigate the relationship between controlled, physiological joint loading and the corresponding articular cartilage response.

METHODS

Eight skeletally mature (1 year old) female New Zealand white rabbits were used. The Rabbits were anesthetized using Isoflurane and prepared for the loading procedure (both hind limbs shaved). They were then placed supine on a custom made experimental platform with the right leg secured to a force transducer bar, in order to measure the knee extensor moments produced by the quadriceps muscles (Forces were recorded using Windaq® data recording software). Mechanical loading was produced in vivo in the rabbit patellofemoral joint through knee extensor activation. Loading was created via surface electrodes controlled by a Grass S88 stimulator. The loading protocol consisted of one hour of cyclic loading. Loading was brought about by stimulating the extensors once every 30 seconds for a duration of 1 second. This was done so that 80% of maximal force was attained throughout the 1 hour. Upon completion of the 1 hour loading protocol, cartilage from the retropatellar surface and patella femoral groove (of both the experimental/right and contralateral control/left leg) was harvested, and incubated in 24-well plates in 1mL of medium (DMEM with 1% penstrep). Samples of medium were collected at 1, 8, 24, and 48 hours post loading and immediately frozen (-20 °C). Fluid samples were then tested for the presence of Sulfated Proteoglycans (sPG's), by a known dimethylmethylene blue (DMMB) assay.

RESULTS AND DISCUSSION

In this initial study, relating the mechanical loading of a fully intact joint to the corresponding biological response, we wanted to establish a method for the non-invasive, high level,

and consistent loading of the intact rabbit knee while continuously monitoring and controlling the amount of loading. We were successful with the current protocol to produce approximately 80% of the initial maximal isometric response throughout this one hour loading period (Fig. 1.)

Figure 1. Sample force curve for 1 hour loading protocol

Since the forces applied to the patellofemoral joint were within the physiological range, and since the forces were applied by knee extensor contraction to the fully intact knee, we expected to see a positive loading response that would be associated with an increase in sPG production in the loaded compared to the contralateral, unloaded control cartilage. Our preliminary data, based on two independent observations per time point, do not support this hypothesis, as sPG values were similar at each time point of sample collection (Table 1.) The increase of sPG from 1 hour to the values obtained at 8, 24, and 48 hours in both, the experimental and contralateral knee articular cartilage cannot be explained at present.

In order to understand articular cartilage adaptation or degeneration, it is essential to know that biological response to physiological loading conditions. This type of research has typically been done by loading articular cartilage explants (Kurz, 2001), or by impacting joints via external devices. (Ewers, 2001) We feel that such attempts are ultimately of little relevance to what happens in an intact joint subjected to in vivo muscular loading. This study, hopefully, will be a first step towards gathering this physiologically relevant information.

Table 1. Mean data for DMMB assay.

Hours Post Loading	Experimental (ug/g of cartilage)	Control (ug/g of cartilage)
1	47 ± 25	39 ± 13
8	114 ± 24	113 ± 15
24	128 ± 24	128 ± 25
48	141 ± 25	135 ± 22

IN VIVO CHANGES IN MUSCULAR ACTIVATION BEFORE AND AFTER ANTERIOR CRUCIATE LIGAMENT TRANSECTION IN THE FELINE HINDLIMB

Meredith MacNaughton¹, Tim Leonard and Walter Herzog
Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada
¹meredith@kin.ucalgary.ca

INTRODUCTION

Transection of the anterior cruciate ligament (ACL) in the cat knee has been established as a reliable model of osteoarthritis (OA). In the past, ACL transection models have attributed the onset of OA to the instability of the joint following ACL transection. We believe that part of the joint degeneration may be associated with the loss of motor function in the relevant hindlimb muscles. Since there is no evidence showing long-term muscle activation patterns in any osteoarthritis model we wanted to, as a first step, establish whether muscle coordination following ACL transection might be changed. Based on preliminary data, we hypothesize that some of the muscle coordination patterns, such as that of semitendinosus, might change dramatically post ACL transection in order to compensate for the loss of the mechanical function of the transected ACL. Furthermore, some of the limb extensor muscles, such as triceps surae and rectus femoris, might be greatly inhibited and thus produce erratic EMG signals.

METHODS

One adult male cat was trained to walk on a motor driven treadmill at speeds ranging from 0.4m/s to 0.7 m/s. Under sterile conditions, indwelling, bipolar EMG electrodes with an interelectrode distance of about 5 mm were imbedded into the midbelly of eight muscles in the left hindlimb: the vastus lateralis (VL), semimembranosus (SM), semitendinosus (ST), rectus femoris (RF), soleus (SOL), medial gastrocnemius (MG), tibialis anterior (TA) and extensor digitorum longus (EDL). The EMG wires were then fed subcutaneously to the back of the cat. Here the leads were soldered to their corresponding terminals on a 50g, eight channel connector (backpack) secured by four sutures. EMG data were collected before surgical intervention, after a sham ACL transection, and post ACL transection for slow (0.4m/s) and, when possible, for fast (0.7m/s) treadmill walking. The ACL transection of the left hindlimb was confirmed *in vivo* (by anterior drawer tests). The experimental protocol was reviewed and approved by The University of Calgary Animal Research and Ethics Committee.

RESULTS AND DISCUSSION

Preliminary data show distinct changes in the activation patterns of most muscle recordings. The limb extensors, specifically, which initially manifested continuous activation patterns during the stance phase, began to exhibit sporadic bursts during the activation phase post ACL transection (Figure 1). Furthermore, we found that over time, the burst-like activation of the extensors became more normal (i.e. continuous; data not shown). Finally, we found that following the sham surgery, the activation patterns remained unchanged

(i.e. continuous; data not shown) suggesting that the observed change in activation patterns post ACL transection were caused by the physical transection of the ACL and the corresponding instability of the knee, and not the surgical intervention.

CONCLUSION

Sham transection of the ACL did not cause a change in the activation patterns of major hindlimb muscles in the cat, whereas the actual ACL transection did. Specifically, the hindlimb extensors displayed an abnormal burst-like pattern post ACL transection that would likely have caused the corresponding jerk-like patterns in muscular forces, as found by Hasler et al.,(1998). These preliminary results leave open the hypothesis that loss of neuromotor control might play an important role in joint degeneration in general, and in the development of osteoarthritis, specifically.

WOLFF'S LAW OF CANCELLOUS BONE AS A SOLID-LIQUID TWO-PHASE BODY

Gang Qinguo^{1,2} Hua Zhuxin² and Yang Guitong³

¹Department of Kinesiology, University of Waterloo, Ontario, Canada

²City College, Hebei University, Baoding, Hebei Province, PRChina, 071002

³Institute of Applied Mechanics, Taiyuan University of Technology, Shanxi Province, PRChina

INTRODUCTION

The physiological structure of cancellous bone is composed of the trabecular architecture and the tissue fluid, which is full of the porous skeleton. Therefore, from the microscopic view, the cancellous bone is a typical solid-liquid two-phase body. The Wolff's law, which was put forward by Wolff, describes the relationship between the trabecular architecture and the principal stress in the cancellous bone. Some researchers had given the mathematical formations of this law[1-2]. But, in there papers, the cancellous bone was as the elasticity. In our paper, we will discuss the formation of the Wolff's law when the cancellous is as the solid-liquid two-phase body.

In the paper [1], the Wolff's Law is :

$$H : \sigma = \sigma : H \quad (1)$$

H is the fabric tensor and σ is the stress tensor. This formation only showed that the direction of the principal stress in the trabecular architecture was the same as the one of the fabric tensor. In the paper [2], Turner further provided a quantitative form of the Wolff's law, which was :

$$|\sigma_i| = \alpha H_i^3 \quad (2)$$

i=1,2,3. α is a constant. σ_i and H_i are the principal stress and the principle component of H. In this paper, we consider the above formations of the Wolff's law as the relation between the trabecular architecture and the stress in the trabecular, not the stress in the cancellous bone. So, we provided an new formation according the two-phase theory.

CONSTITUTIVE RELATIONS OF MEDIA WITH POROUS

The media with porous often shows the anisotropic mechanical properties. It's constitutive equations are :

$$\sigma = E : \varepsilon \quad (3)$$

ε is the stain tensor, and E is the elastical tensor.

The anisotropic mechanical properties of the media with porous was mainly decided by it's microscopic structure. Then, according to the knowledge in the structure mechanics, E is further expressed as :

$$E = E_1 : E_0 \quad (4)$$

E_0 is the elastical tensor of the component of media. E_1 is the function of the geometric structure form in the media, and called the geometric tensor in this paper. Substituted (4) into (3), we obtained:

$$\sigma = E_1 : E_0 : \varepsilon = E_1 : \sigma_0 \quad (5)$$

σ_0 is the stress in the component of media. The relation between σ_0 and ε show the mechanical properties of the component. In the (4), the component was as the linear elasticity. If the component has the mechanical properties of liquid, the second equation in (5) is also used.

WOLFF'S LAW OF CANCELLOUS BONE

In this section, the cancellous bone was as a two-phase body. So, according to the mixture theory[3], the total stress σ is :

$$\sigma = \sigma_1 + \sigma_2 \quad (6)$$

σ_1 is the stress in the trabecular architecture, and σ_2 is the stress in the tissue fluid. Based on the results in the last section, σ_2 can be:

$$\sigma_2 = E_2 : \sigma_{20} \quad (7)$$

E_2 and σ_{20} are the geometric tensor and the stress tensor of the tissue fluid. Further, the decomposition of σ_{20} is :

$$\sigma_{20} = S_{20} + pI \quad (8)$$

I is the identity tensor, p is the mean normal stress and S_{20} is the deviatoric stress tensor. With the forms (6) and (7), we obtained:

$$\sigma_1 = \sigma - \sigma_2 = \sigma - E_2 : S_{20} - \alpha_2 p \quad (9)$$

$\alpha_2 = E_2 : I$ is a tensor. Substituted (9) into (1) and (2), it showed :

$$H : (\sigma - E_2 : S_{20} - \alpha_2 p) = (\sigma - E_2 : S_{20} - \alpha_2 p) : H$$
$$|(\sigma - E_2 : S_{20} - \alpha_2 p)_i| = \alpha H_i^3 \quad (10)$$

which were the Wolff's law of cancellous bone as the two-phase body.

SUMMARY

The formations (10) showed that H was the functions of σ , S_{20} and p. If one of them is changed, H will change with it.

INTRODUCTION

Microindentation offers significant advantages for mechanical characterization of soft tissues like articular cartilage (AC). It requires minimal specimen preparation, can test mm-size specimens, can provide a detailed spatial distribution of properties, and for AC, it simulates in vivo loading. However, conventional methods (Oliver & Pharr, 1992) do not account for time-dependent and large deformation behavior of soft tissues. Here, alternate model-based simulations are explored.

METHODS

Experimental details are provided in the companion paper (Lewis & Simha, 2002). Here we focus on simulations. A FEM model of the indentation contact problem was constructed using ABAQUS. Length units are in μm and 1600 axisymmetric, quadrilateral, bilinear, hybrid elements were used for the hyperelastic incompressible tissue. Indenter is rigid and contact is frictionless. Elastic parameters will be evaluated by minimizing the error between predicted and measured force-displacement curves; similarly, viscous parameters can be evaluated from creep data. Fortran minimization routines are coupled with ABAQUS simulations using the PYTHON programming language. In indentation tests, force-displacement curves are the only measurement, hence the guiding principle is to choose the simplest possible constitutive model that predicts these curves. A quasilinear viscoelastic model with nonlinear elastic and linear viscous properties will be adopted for AC. Nonlinear elasticity is modeled by Mooney-Rivlin energy density with parameters C_1 and C_2 or exponential energy with parameters B_1 and B_2 . The viscous relaxation is a two-term exponential function. A procedure for evaluating model-parameters is outlined.

RESULTS

So far, FEM simulations have been performed for the large deformation Mooney-Rivlin model. Parametric studies show that varying the sum C_1+C_2 (at fixed C_1/C_2) has a stronger effect than varying C_1/C_2 (at fixed C_1+C_2). For instance, doubling (C_1+C_2) from 1 to 2 MPa causes a 100% increase in force (see Fig 1), whereas changing C_1/C_2 from 2 to 4 causes a 10% decrease in force. By examining small displacements superposed on biaxial stretch, Beatty & Usmani (1973) obtain $P=\mu(16\tan\alpha/\pi)(C_1+C_2)D^2$ for a conical tip with included angle 2α . However, Costa and Yin (1999) show the quadratic form is valid only for indentation depths less than 10% of the tissue thickness. Hence, quadratic fits with coefficient β to curves shown in Fig 1 for $D<150\mu\text{m}$ resulted in $\mu=0.274$ and the correlation $(C_1+C_2) = 0.297 \beta$.

Figure 1: Force-displacement curves at fixed $C_1/C_2=8$

The minimization procedure to extract material properties is demonstrated by using the loading part of an indentation test with $D_{\max}=230\mu\text{m}$ (see Fig 1). A quadratic fit to $D<150\mu\text{m}$ data and the above correlation gave $(C_1+C_2)=1.2\text{MPa}$. Using initial guesses of $C_1/C_2=2$ and 16, the minimization procedure obtained the values $C_1=0.96\text{MPa}$ and $C_2=0.24\text{MPa}$ in two iterations.

Other important results from the parametric studies are: 1) The resolution for the 67° tip is $R=0.375D_{\max}$ where $R/2$ is the radial distance at which the strain energy decreases to 1% of its maximum value. 2) The deformation beside the conical tip is primarily a shear. 3) The contact area predicted by FEM model at $D_{\max}=400\mu\text{m}$ is 63.4% smaller than linear elastic results (indicating need for large deformations). 4) Rounding the conical tip with a sphere of radius $53\mu\text{m}$ increases the predicted area by 28.8%

This is ongoing work; detailed results for the exponential energy and viscous parameters will be presented at the conference. These will provide a basis for finding the elastic and viscous properties of AC and other soft tissues from micro and AFM-type indentation tests. A related issue is the fracture toughness of AC. At high forces conical tips penetrate AC by tearing the surface, and new methods for fracture toughness are being developed (Lewis and Simha, 2002). A critical step involves the separation of the input work during penetration into fracture work and viscoelastic work. By providing estimates for the viscoelastic work, this study will help validate methods for fracture toughness.

SENSITIVITY OF A HILL BASED MUSCLE MODEL TO PERTURBATIONS IN MODEL PARAMETERS

Carol Y. Scovil and Janet L. Ronsky

Human Performance Laboratory and Department of Mechanical Engineering
University of Calgary, Calgary, Alberta, Canada. jlrnsky@ucalgary.ca, www.ucalgary.ca/~cyscovil

INTRODUCTION

Hill muscle models are commonly used in musculo-skeletal models to predict muscles forces (Zajac 1989). The model can take several forms. In this study three common elements will be discussed. 1. The contractile element (CE) generates force, taking into account force-length (FL) and force-velocity (FV) muscle properties. 2. The series elastic element (SE) models the tendon, aponeurosis, and soft tissue stretch. 3. The parallel elastic element (PE) models the passive properties of the muscle fibers. In some studies, PE is ignored, in other models, pennation angle or viscous elements are considered. For any muscle model properties must be taken from literature. No one study includes all values necessary to describe properties of the muscle; they must be compiled from several sources. In addition, different studies have found a range of values for these parameters. There has been no evaluation of the effect the values used to create muscle models have on the resulting muscle output. The purpose of this study was to evaluate the sensitivity of the muscle model to perturbations in each of the parameters during physiological movement.

METHODS

The Hill based muscle model described in Nagano and Gerrisen (2001) was used to model the muscle forces in the forward dynamics running model of Wright et al. (1998). This model was able to match the kinematics and ground reaction forces from experimentally determined running within two standard deviations. At each timestep, the inputs for the muscle model were the lengths of the muscle (L_{MUS}) and the contractile element (L_{CE}). The outputs from the model were the force in the muscle (F_{MUS}), and the velocity of the contractile element (V_{CE}), to allow the integration of L_{CE} for the next timestep. To evaluate the sensitivity of the model, L_{MUS} and L_{CE} for the rectus femoris (RF) were taken from the running simulation, and F_{MUS} and V_{CE} were calculated throughout stance phase. This ensured a physiological range of muscle lengths. The muscle model parameters were varied

from those used in the model by a factor of 0.5 to 1.5. F_{MUS} and V_{CE} were compared to the original model output, and ranked according to the amount of change observed. (Table 1)

RESULTS AND DISCUSSION

The muscle model was very sensitive to changes in L_{SEsl} and U_{SE} . V_{CE} was also sensitive to changes in L_{CEopt} , F_{ASYMP} and $WIDTH$. These are the parameters with which the modeler should take the most care in using values from literature. The muscle parameters summarized in Yamaguchi et al. (1990) list, for the RF, values of 0.346-0.410 m for L_{SEsl} , and a range in L_{CEopt} of 0.055-0.084 m. This sensitivity analysis further emphasizes how important the choice of these parameters is. The muscle model is somewhat sensitive to F_{MAX} and SF . Variations in the parameters A_{REL} , B_{REL} and SL have little effect on model outputs. Similar sensitivity was observed in the other muscles in the leg. The assumption that the PE does not affect forces during running is confirmed by this study. Likely, this is applicable to other movements that do not take the muscle to extreme ranges of motion. It seems reasonable that the PE could be ignored in models of locomotion.

SUMMARY

Parameters of the Hill muscle model have a varying sensitivity to small changes in their value. Care should be taken when using parameters from literature that the model is most sensitive to: L_{SEsl} , U_{SE} , L_{CEopt} , F_{ASYMP} and $WIDTH$. The PE may be ignored in muscle models used with locomotion.

Table 1: Parameters in the muscle model. Sensitivity of the model classified as: 1) None: no change due to perturbation. 2) Small: change of much less than the perturbation. 3) Linear: change of similar magnitude to the perturbation. 4) Large: change far larger than the perturbation. 5) Extreme: change in the resulting value by a factor of 50 or greater. Values marked * are specific to the RF.

Parameter	Definition	Initial Value	F_{MUS} Sensitivity	V_{CE} Sensitivity
A_{REL}	constant in hyperbolic FV equation	0.41	None	Small
B_{REL}	constant in hyperbolic FV equation	5.22 s^{-1}	None	Small
F_{ASYMP}	force where the FV curve becomes asymptotic	$1.5 F_{MAX}$	None	Large
F_{MAX}	maximum isometric force	*1560 N	Linear	None
L_{CEopt}	length of fiber (the CE) at F_{MAX}	*0.084 m	None	Large
L_{PEsl}	slack length of the PE	$1.4 L_{CEopt}$	None	None
L_{SEsl}	slack length of the SE	*0.346 m	Extreme	Extreme
SF	eccentric/concentric FV curve slopes as $V \rightarrow 0$	2	None	Linear
SL	slope of asymptote in FV curve	200 s^{-1}	None	Small
U_{PE}	force in PE at max. L_{CE} before $F = 0$	$0.5 F_{MAX}$	None	None
U_{SE}	stretch in SE at F_{MAX}	0.04	Large	Extreme
$WIDTH$	width of parabola in FL curve	*1.44	None	Large

EVALUATION OF 3D KNEE KINEMATICS WITH AND WITHOUT PLANTAR ORTHOPAEDIC PROCESSING

Mathieu Tremblay, Nicola Hagemeister, Michel Pelletier, Jacques De Guise

Laboratoire de recherche en imagerie et orthopédie (LIO), Centre de recherche du CHUM, Hôpital Notre-Dame,
Montréal, Québec, Canada
mathieu.tremblay@umontreal.ca

INTRODUCTION

Although plantar orthoses are regularly prescribed to correct lower limb kinematics, only few studies evaluated in a quantitative and non-invasive way the effect of plantar orthoses on knee kinematics. Our research group developed an non-invasive harness allowing three-dimensional (3D) assessment of knee kinematics while limiting errors caused by soft tissue movements with respect to underlying bones¹⁻³. The purpose of this feasibility study was to evaluate the capacity of the harness to detect small variations of knee kinematics following orthotic treatment of rear foot valgus.

METHODS

For a preliminary study, four female subjects aged between 16 and 54 years ($m = 27.3$; $S = 18.0$) were selected. All presented a rear-foot valgus greater than 5° . One subject was evaluated for both left and right knees. The orthoses types used were Bioptech and Biopform (Bi-Op, Joliette, Canada). The Bioptech is a semi-rigid orthosis with high control and Biopform is flexible and exerts a lighter control. The subjects were wearing standardized sandals and were asked to walk on a tread mill at comfortable speed without orthosis, with Biopform and with Bioptech. Order of testing was selected randomly before the experiment. Real time recording of the bone's space position was performed via infra-red emitting diodes which were attached non-invasively on the harness and a system of three cameras (Optotrak, Northern Digital, USA). The harness allows to measure the knee movements in the sagittal, frontal and transverse plane with an average precision of 0.4° for the abduction/adduction and 2.3° for tibial rotation movements².

RESULTS AND DISCUSSION

Results showed that, depending on the subject, immediate effect of foot orthotic treatment on 3D knee kinematics could vary. In 4 of 5 cases, decreased internal tibial rotation of the knee was observed when subjects walked with the orthoses compared to the walk without orthosis. In two cases, an increase of knee adduction was also observed. In one subject, however, decreased adduction was observed, which seems to be an adverse effect of the orthosis in this case. Figure 1 shows an example of a subject for whom an increase of adduction was observed with the wear of the Bioptech orthosis, whereas the Biopform orthosis had no effect.

Most observed effects are in accordance with the desired correction of orthoses as well as the work presented in the literature. For example, a study⁴ using cortical pins showed a decrease of internal tibial rotation after rear-foot valgus reduction. Nevertheless, more subject must be evaluated, to be able to perform quantitative and statistical analysis of results. Altogether, 30 patients will be assessed during the study.

▲ Figure1: 3D kinematic curves for subject #2. Black lines represent knee joint angles during gait without orthosis. Grey dotted lines give the acquisition error (mean standard deviation). Grey dotted lines represent gait with Bioptech orthosis. Grey plain lines represent gait with Biopform orthosis. Only stance phase of gait was analysed (grey part of the figure). A: Flexion/extension curve, flexion positive; B: Ab/adduction curve, Adduction positive; C: Internal/external tibial rotation, external rotation positive.

SUMMARY

This study aimed at assessing the effect of plantar orthopaedic processing on 3D knee kinematics. Preliminary results on five knees (four subjects) showed that the method allowed to detect small variations in 3D knee kinematics during gait on a tread mill when a foot orthosis was inserted in standardized sandals, compared to gait without orthosis. More patients are required to perform quantitative and statistical analysis.

THREE-DIMENSIONAL FINITE ELEMENT ANALYSIS OF THE ACL UNDER ANTERIOR TIBIAL LOADS

Georges Limbert^{1,2}, Mark Taylor² and John Middleton¹

¹Biomechanics Research Unit, University of Wales, College of Medicine, Cardiff, UK, LimbertG@cardiff.ac.uk

²Bioengineering Science Research Group, School of Engineering Sciences, University of Southampton, Southampton, UK

INTRODUCTION

The anterior cruciate ligament (ACL) plays an essential role in knee stability and is the most commonly injured ligament of the human body. Stress and strain distributions within the ACL are key elements for the general understanding of its mechanical behaviour and failure mechanisms in extreme conditions. Finite element (FE) analysis techniques are helpful in conducting this kind of investigation. The common assumption of mechanical isotropy of the ACL has been shown to lead to unrealistic results (Limbert and Taylor, 2001). In this study, a constitutive 3D transversely isotropic finite element (FE) model for the ACL is proposed in order to circumvent these limitations. The model is tested under simulated clinical testing procedures: a drawer test and a Lachman test.

METHODS

A 3D FE constitutive model of the ACL was implemented in the commercial FE code ABAQUS/Standard (HKS, Inc., Pawtucket, RI, USA). The ACL is assumed to be a fibre-reinforced composite material where collagen fibres are embedded in a compliant solid matrix. The constitutive law is based on the definition of an incompressible transversely isotropic hyperelastic strain energy function ψ :

$$\psi = \psi_m(I_1, I_2) + f(\lambda) = c_1(I_1 - 3) + c_2(I_2 - 3) + f(\lambda) \quad (1)$$

where ψ_m represents the mechanical contribution from the matrix and $f(\lambda)$ that of the fibres. I_1 , I_2 are the first two principal invariants of the right Cauchy-Green deformation tensor \mathbf{C} and λ , the stretch in the local fibre direction, is an invariant characterizing the anisotropic properties. Structural properties of the ligaments lead to the following choice for f :

$$f(\lambda) \text{ is such that } \frac{df(\lambda)}{d\lambda} = \begin{cases} 0 & \text{if } \lambda \leq 1 \\ c_3[e^{c_4(\lambda-1)} - 1]/\lambda & \text{if } \lambda \geq 1 \end{cases} \quad (2)$$

c_i , ($i=1..4$) are material parameters which were determined from experimental data (Pioletti, 1997). Stress and elasticity tensors were derived from ψ (Limbert and Taylor, 2002). The geometry of the insertion sites of the ACL were obtained from a previous experiment performed on a cadaveric knee. The 3D geometry of the ACL was built by connecting these two surfaces.

Passive knee flexions were performed and the kinematics of these tests were used as displacement driven boundary conditions for the following FE analyses:

1. Lachman test: knee flexed at 30° and then anterior tibial displacement of 4mm.
2. Drawer test: knee flexed at 90° and then anterior tibial displacement of 4mm

These FE analyses were also repeated by considering the existence of an initial force of 135 N present in the ACL when the knee is at full extension.

RESULTS AND DISCUSSION

During knee flexion, isotropic models of the ACL generate high non physiological compressive stresses at the tibial insertion site in the posterior part of the ACL. The model proposed here was able to address this issue and has shown that the anteriomedial band of the ACL carries the maximum load during the flexion. This feature has also been observed in experimental studies (Butler et al., 1992). At 30 and 90° of knee flexion the maximum von Mises (vM) stresses were respectively 2.68 and 6.36 MPa and were located on the anteromedial part of the ACL at the femoral insertion site. The location of maximum stress is related to clinical reports which show that injury of the ACL mostly occurs at the femoral insertion site. For the Lachman and drawer tests the maximal vM stresses were respectively 6.15 and 9.69 MPa whilst the total resultant forces within the ACL were respectively 30 and 35 N. It is now widely accepted that the ACL is composed of two main fibre bundles. These bands have different lengths and mechanical properties. This issue has not been addressed in the present model, but may have a significant influence on the pattern of deformation, and thus the stress within the ACL.

QUASI-LINEAR VISCOELASTIC MODELING OF TAIL TENDON FASCICLES FROM TRANSGENIC MICE

Dawn M. Elliott¹, Paul S. Robinson, Jon A. Gimbel, Joseph J. Sarver, Renato V. Iozzo, Louis J. Soslowsky
McKay Orthopaedic Research Laboratory, University of Pennsylvania. ¹delliott@mail.med.upenn.edu

INTRODUCTION Tendon is primarily composed of aligned type I collagen fibers in an amorphous extrafibrillar matrix of proteoglycan, glycosaminoglycan, and water. This structure and composition results in a nonlinear, viscoelastic, and anisotropic tissue. Tendon's elastic behavior is generally considered to arise from the collagen fibers, while the viscoelastic behavior is generally considered to arise from the extrafibrillar matrix. However, little quantitative data exists to formally supports these concepts. The objective of this study was to use quasi-linear viscoelastic modeling to quantitatively examine mechanical properties in mouse tail tendons with genetically engineered alterations of extracellular matrix proteins.

METHODS Tendon fascicles were prepared from the tails of three mice from each of the following genetically engineered or control groups: 8 week decorin knockout (DKO8, n=8 fascicles), 8 week reduced type I collagen (C1M8, n=9 fascicles), 3 week control (CTL3, n=7 fascicles), and 8 week control (CTL8, n=14 fascicles). Incremental stress-relaxation experiments in tension were performed as described previously (Gimbel et al, 2002). Briefly, a displacement corresponding to 0.5% strain was applied, held for a 10 min relaxation period, and repeated until failure.

The Quasi-Linear Viscoelastic (QLV) model proposed by Fung (1968) was used fit to the stress-relaxation data. This model combines elastic and time-dependent components of the stress-strain response using the convolution integral of $\sigma(\varepsilon, t) = G(t) * \sigma^e(\varepsilon)$. The reduced relaxation function (G) was defined as, $G(t) = \frac{1 - 0.577C - C \ln(t/\tau_2)}{1 + C \ln(\tau_2/\tau_1)}$, and the elastic stress response as, $\sigma^e(\varepsilon) = A(e^{B\varepsilon} - 1)$ (Woo et al, 1981). Each relaxation step was curve-fit using a custom-written Matlab program and the two elastic parameters (A and B) and three viscous parameters (C , τ_1 , τ_2) were determined. For each fascicle, the average value of each parameter was calculated over four strain increments. A total of 7-14 fascicles were tested for each group. Between group differences were evaluated with an ANOVA followed by a Fisher's LSD post-hoc test with significance set at $p < 0.05$.

RESULTS AND DISCUSSION The stress-relaxation response was well-described by the QLV model averaged over four strain increments. Significant differences between the elastic and viscoelastic parameters among the four groups existed (Table). Average parameters were used to graphically depict the elastic response (Fig 1A) and relaxation function (Fig 1B) for each group. The linear-region modulus of the four groups appears to be similar (Fig 1A), consistent with our

previous findings (Robinson et al, 2001). The toe-region of the stress-strain response is shorter and extends to a lower stress for the genetically engineered DKO8 and C1M8 compared to the control groups.

The DKO8 group had the fastest relaxation response and the CTL3 had the longest relaxation time (FIG 1B). We have previously shown that CTL3 has more glycosaminoglycan (CSDS/dry weight) than the other groups (Lin et al 2002). These findings support the notion that the primary mechanism for viscoelasticity in tendon fascicles is related to the glycosaminoglycan content and likely to its associated water content. Together, these findings begin to quantify important tendon relationships of tissue composition and structure with both the elastic and viscoelastic mechanical properties.

A STUDY OF BACK MUSCLE FATIGUE IN HELICOPTER PILOTS DURING REGULAR FLIGHTS

Carlos Gomes de Oliveira^{1,2} and Jurandir Nadal²

¹ Physical Activity Science Institute of Aeronautics – Rio de Janeiro – RJ – Brazil – CEP: 21740-000. Email: oliveiracg@yahoo.com

² Biomedical Engineering Program – COPPE-UFRJ

INTRODUCTION

High prevalence of backache in helicopter pilots has been reported being its etiology focused by many investigators. The constrained and asymmetric posture that the pilot adopts in-flight and the vibration are the most important causes postulated and discussed (Bonger et al., 1990). Both are accepted to induce stress in the back muscle leading to pain. Pope et al. (1986) found significant muscle fatigue as a result of the sustained static posture but not due to vibration in a simulated UH-1H cockpit (Pope et al., 1986). Nevertheless, a study conducted in UH50 helicopters during short flights (De Oliveira et al., 2001) reported very low activity in the low back muscle indicating that the pain could not be due to muscle stress but no muscle fatigue was investigated in such study. This study investigates the presence of fatigue in the low back muscle of Helicopter Pilots (HP) through the behavior of the power spectra of the electromyography (EMG) signal during regular flights.

METHODS

Regular flights lasting 2h in average of 5 HPs were monitored. It was measured the surface EMG from the left and right Erector Spinae (ES) muscle through electrodes placed 3 cm on both sides of the L3 vertebrae – 2.5 cm inter-electrode distance. The EMG was amplified by the ME3000P (Mega Electronics, Finland) and passed to a second stage raising a total gain of 3000 (20-500 Hz). For further filter the noise artifact in the EMG due to vibration, the latter was collected through a triaxial accelerometer 4322 and passed to a charge amplifier 5974 (both from Brüel&Kjaer, Denmark). All signals were recorded on a Digital Audio Tape PC208A (Sony, Japan). The tests were conducted in two different helicopters, BELL 412 and SK76. The data were analyzed in a PC after digitized with a sample rate of 1000 Hz. A procedure of previous study (De Oliveira et al., 2001) was performed to reduce the EKG in the EMG. Thus, windows of EMG and vibration were observed together with their corresponding spectra. Artifact in the EMG at the same frequency presented in the vibration was reduced by filtering the EMG at the corresponding frequency. Finally, consecutive FFTs were calculated over 1000 samples, averaged for each 10s and their Mean Frequencies (MF) computed. Each time series of MF was checked visually and the bias was tested by Runs Test. Failing the Runs Test the coefficient of regression was computed to verify the trend of the MF during the flight.

RESULTS AND DISCUSSION

From the 5 pilots investigated no bias in the time series of FM was evidenced by Runs Test in 2. For the remaining the

coefficients of regression were either positive and very low or not significant (Table 1). Figure 1 illustrates the behavior of the time series of MF for one pilot (no bias detected).

It has been proposed that during muscle fatigue the spectrum of the EMG goes toward low frequencies causing a decrease in the MF. In this study, the trend, when present, was to slightly increase the MF indicating absence of fatigue in ES muscle during the investigated time. The EMG signals found were generally very low as observed by Hosea et al. (1986) for automobile driver and De Oliveira et al. (2001) for helicopter pilots. This could explain the lack of evidence of fatigue in the investigated muscles in this study.

Table 1: Coefficients of Regression (CR) and Pearson (r) calculated over the time series of MF for the HP whose Runs Test failed (bias detected).

HP	Right ES		Left ES	
	CR	r	CR	r
1	0.03	0.16	0.04	0.26
2	0.15	0.37	0.30	0.64
3	*	*	0.18	0.51

* Values not significant ($p < 0.01$).

BONE-MUSCLE-LIMB MORPHOLOGY AND MOVEMENT DYNAMICS / ENERGETICS

Leah Dellanini and David Hawkins¹

Human Performance Laboratory, University of California, Davis, CA, USA
¹ email: dahawkins@ucdavis.edu

INTRODUCTION

Animal movement performance, and in many cases survival, depends in part on the morphology of the animals' limbs. Limb morphology depends primarily on the size and shape of the muscle-tendon units, the bones, and the fat comprising the limb segments. Though fundamental physical and biological principles indicate that limb morphology affects joint strength, limb inertial characteristics, bone fracture strength, and the energy required to move the limbs, the interactions between these quantities has not been thoroughly investigated. Understanding these interactions is fundamental for understanding evolutionary changes and movement performance capacity.

The objectives of this study are to characterize the fundamental interactions between bone and muscle distribution, limb inertial properties, and limb movement dynamics and metabolic energy expenditure. These objectives will be achieved using musculoskeletal modeling and movement simulation.

METHODS

Five steps are required to achieve the stated objectives. First, an existing digital model of the human leg (Barr and Hawkins, 2000) was modified to include the inner bone surfaces that were not digitized in the original construction of the leg model. This step was necessary to provide data for manipulating not only muscles but the cortical bone thickness as well. Second, the Visual Basic software written by Hawkins and Barr (2001) for morphing muscle size was modified to morph bone and to accommodate the new data set. Third, a set of bone and muscle conditions were identified that provide reasonable representation of evolutionary and species variations in musculoskeletal design. Fourth, the bone and muscle conditions were simulated using the VB program and the limb inertial parameters determined and compared. Finally, the interactions between the various musculoskeletal designs and movement dynamics are being investigated using movement simulation techniques (SIMM-Musculographics, Inc.). Movement speed and the metabolic cost of movement are being compared between the different musculoskeletal designs.

RESULTS AND DISCUSSION

The first three steps of the project have been completed. The bone geometry was validated through repeat digitizing and the expansion/contraction algorithms were validated with a data set of known geometries and volumes. A variety of muscle to bone mass and thigh to shank mass ratios exist among

animals. Bone size was selected to represent normal sized bones and bones with 22% larger cortical thickness, representing the size needed to prevent fracture in the absence of remodeling processes (Martin, in review). Major muscles were atrophied by 0, 20 and 40% to represent various limb ratios that are present in nature. Corresponding limb inertial parameters were quantified and described in terms of muscle and bone contributions (Fig. 1).

Figure 1. Shank moment of inertia for bone and muscle conditions.

It was found that increases in cortical bone thickness increase limb moment of inertia. It is hypothesized that this will result in a decrease in limb velocities achieved during a movement task. The effects of muscle atrophy are less clear. Muscle atrophy decreases muscle strength and the moment of inertia of the limb spanned by the muscle. This may lead to decreased movement velocity of the distal limb acted on by the muscle (due to strength deficits), but increases in movement velocity of the limb spanned by the muscle (due to reduced moments of inertia).

SUMMARY

The results of this study will characterize the complex interactions between bone, muscle, and limb mass distribution and the effects this mass distribution has on movement performance. Understanding these relationships will improve our understanding of movement performance as affected by evolutionary changes and tissue mass distribution.

SURGICAL HAMSTRING LENGTHENING INCREASES CONCENTRIC MUSCLE VELOCITY DURING GAIT

Michael Orendurff

Gait Analysis Lab, Center of Excellence for Limb Loss Prevention and Prosthetic Engineering,
Veterans Hospital, Seattle, Washington, USA. morendurff@hotmail.com.

INTRODUCTION

In determining the indications for surgical hamstring lengthenings for individuals with cerebral palsy, physicians may assess crouch by computerized gait analysis, but also rely on physical examination to determine hamstring length and spasticity. Hamstring muscle modeling has shown normal lengths for individuals with crouch gait (Delp, et al., 1996), however improvements in knee extension are seen following surgical hamstring lengthenings (Rethlefsen, et al., 1999). The goal of this study was to evaluate physical exam measures before and after hamstring surgery and to determine if these changes are reflected in hamstring muscle velocity.

METHODS

Twenty-three individuals (40 sides) with cerebral palsy who underwent computerized gait analysis and hamstring lengthening surgery were reviewed retrospectively. All individuals underwent medial and lateral hamstring lengthenings; 22 sides also underwent adductor lengthenings, 9 sides had distal femoral derotational osteotomies, 5 sides had iliopsoas lengthenings, 4 sides underwent rectus femoris transfers, 4 sides had triceps surae lengthenings and 2 sides had subtalar fusions at the time of their hamstring surgery. Nine sides had hamstring surgery only. Physical examination of the hamstring muscle (popliteal angle) was assessed preop and about one year postop by placing the patient supine, flexing the hip to 90° and extending the knee (slow). A rapid extension of the knee was then performed to assess the velocity-dependent tone, or spasticity of the hamstrings (quick). The angles were measured with a goniometer. Gait data was collected with a 6-camera Vicon 370 system prior to and about one year following surgery. Three dimensional kinematics were calculated in Vicon Clinical Manager. Biceps femoris lengths were calculated from the kinematic data using the methods of Visser, et al., (1990). Muscle velocity data was calculated using a 3-point finite difference algorithm. Concentric (maximum) and eccentric (minimum) hamstring muscle velocities were extracted preop and postop. Maximum knee flexion in stance was calculated preop and postop. Variables were compared preop to postop using repeated measures ANOVAs. Multiple linear regression was performed to assess the relationship between quick and slow popliteal angles and hamstring muscle velocity during gait both preop and postop. An alpha level of $p < 0.05$ was chosen a priori.

RESULTS

Following surgical lengthening of the hamstring muscles, knee flexion during stance improved significantly from preop ($30.1 \pm 13.1^\circ$) to postop ($7.6 \pm 13.0^\circ$; $p = 0.0001$). The relationship between quick and slow popliteal angles and hamstring muscle eccentric velocity during gait was not significant either preop ($p = 0.551$; $R^2 = 0.033$), or postop ($p = 0.947$, $R^2 = 0.003$).

Table 1. Muscle velocities (%anatomic neutral length / %gait cycle) and popliteal angles before and after surgical hamstring lengthening. n = 40 sides (23 individuals). * indicates significance at $p < 0.05$.

	Preop	Postop	p-value
Biceps Femoris			
Eccentric Velocity	0.58 ± 0.20	0.60 ± 0.17	0.4540
Concentric Velocity	-0.35 ± 0.13	-0.43 ± 0.10	0.0207*
Popliteal Angle			
Slow	-56.6 ± 12.4	-36.3 ± 16.0	<0.0001*
Quick	-86.7 ± 12.0	-55.3 ± 16.6	<0.0001*

DISCUSSION

Improved knee flexion in gait following surgical intervention in this study was consistent with other authors (Rethlefsen, et al., 1999). Accompanying this decrease in crouch gait, concentric velocity of the hamstrings (stance phase) improved significantly following surgical intervention. Contrary to expectations, eccentric velocity (swing phase) did not improve. However, the physical exam measures of slow popliteal angle and quick popliteal angle were unable to predict muscle velocity in gait with any certainty, either preop or postop. This suggests that physical exam hamstring measures have limited value to physicians deciding which individuals are candidates for hamstring lengthening. If this is the case, then were the correct candidates for surgical hamstring lengthenings chosen in the first place? If the group included those who would not benefit, then it is quite unlikely that postop these measures would have any greater success in predicting muscle velocity. Although every subject showed improvement in knee flexion in stance phase postop, 12 sides showed a worsening of concentric velocities of the hamstrings postop. Excluding these twelve did not improve the statistical significance or the variance accounted for in the regression equations. It may be that there is substantial error associated with the physical exam measures, contributing to their lack of predictive power. It is quite likely that complex interrelationships between the many muscles crossing the hip, knee and ankle joints influence knee flexion in stance. Physicians are likely to incorporate a vast array of information into their decision making process, not relying on just a select few. Since all the subjects showed improvement in knee flexion, but not in hamstring muscle eccentric velocity, spasticity may not be a principle cause of crouch gait. The results do support the concept that surgical lengthening alters the concentric velocity characteristics of the hamstring muscle, but does not alter the eccentric velocity.

ELECTROMYOGRAPHIC ANALYSIS OF SELECTED MUSCLES DURING A SIMULATED SOCCER GAME

Nader Rahnama, Adrian Lees, Thomas Reilly

Research Institute for Sport & Exercise Sciences, Liverpool John Moores University, Webster Street, Liverpool, L3 2ET England
HUMNRAH@LIVJM.AC.UK

INTRODUCTION

Surface electromyography (sEMG) analysis has been useful in comparing muscular activity among different sports movements and it is a valuable technique for evaluating activation, co-ordination and fatigue. Since these important variables have not been investigated during the full game in soccer, the present study aimed to make a descriptive analyses of muscle activities of major lower extremity muscles during a soccer simulation protocol with reference to running as a selected fundamental movement appropriate to soccer.

METHODS

Ten professional soccer players (age 21.40 ± 3.13 yr; height 1.77 ± 0.63 m; mass 74.55 ± 8.5 kg) volunteered to participate in this study after signing written informed consent. All participants were tested during the 2000-2001 English competitive soccer season. All tests were performed on a programmable motorised treadmill (Pulsar, HP Cosmos, Nussforf-Traunstein, Germany). The sampling frequency was set at 1000Hz. EMG activity was recorded and stored using a biopac system (MP 100 system, INC, Biopac systems INC, Santa Barbara). EMG data were analysed using custom written software. Recordings were made from the rectus femoris (RF) biceps femoris (BF) tibialis anterior (TA) and gastrocnemius (GC) muscles. Each subject performed a warm-up including some specific soccer stretching exercises and running at a slow speed on treadmill. Then the subject performed the testing protocol including walking (6 km), jogging (12 km), running (15 km) and sprinting (21 km) for duration of 10 seconds to 30 seconds in a variable order, during which the sEMG was recorded. The first recorded was taken before commencing the simulation game. The subject then performed a 45-min soccer-specific intermittent exercise protocol which consisted of the four different exercise intensities. The EMG activity was recorded after finishing the first half of simulation game. Finally, the EMG activity was recorded for the third time after finishing the second half of the

simulation game. Each muscle was analysed with a 2 factor (condition \times speed) repeated measure ANOVA. The level of significance on all tests was set at $P < 0.05$.

RESULTS

With regard to RF, a significant main effect ($F_{(3, 27)} = 106.35$, $P < 0.001$) was found for condition (pre-game, half-way and post-game), speed (6, 12, 15 and 21km) ($F_{(1.286, 11.577)} = 106.35$, $P < 0.001$) and interaction between condition and speed ($F_{(6, 54)} = 6.85$, $P < 0.001$). The root mean square (RMS) value was greater in pre-game than post-game and the RMS increased with increasing speed continually from 6km to 21km. For BF a significant main effect ($F_{(2, 18)} = 7.57$, $P < 0.01$) was found for condition, speed ($F_{(1.33, 11.79)} = 122.33$, $P < 0.001$) and interaction between condition and speed ($F_{(6, 54)} = 10.81$, $P < 0.001$). The RMS value was greater in pre-game than post-game and the RMS value increased with increasing speed continually from 6km to 21km. With regard to TA, a significant main effect ($F_{(2, 18)} = 4.27$, $P < 0.05$) was found for condition, speed ($F_{(1.53, 13.79)} = 101.09$, $P < 0.001$) and interaction between condition and speed ($F_{(2.60, 23.41)} = 3.53$, $P < 0.05$). The RMS value was greater in pre-game than post-game and the RMS value increased with increasing speed continually from 6km to 21km. For GC, a significant effect was not found using for condition and interaction between condition and speed, but a significant main effect ($F_{(3, 27)} = 51.93$, $P < 0.001$) was found for speed, with the RMS value increasing with increasing speed continually from 6km to 21km.

CONCLUSION

In conclusion, the results indicated that the EMG activity in major lower limb muscles was greater before than after a simulated game. This showed that fatigue has an effect on muscle activity and is likely to be cause of reduced activity during exercise which mimicked work-rate in soccer. RMS values increased with increasing speed of running on treadmill, which revealed that muscle activity increased with increasing speed.

³Centre de recherche interdisciplinaire en réadaptation du Montréal Métropolitain (CRIR)

Email: plamondon.andre@irsst.qc.ca

INTRODUCTION

Exercise therapy is an essential component in the treatment of chronic low back pain (LBP) but there is little agreement as to which exercise programs are the most effective. There are several exercises aimed at improving the muscular function of the back. One such traditional exercise, known as the Sorensen test (Biering-Sorensen, 1984), is the prone back extension (PBE) exercise in which the subject's upper body is unsupported in a horizontal position against the force of gravity with arms on each side. Usually the subject maintains the horizontal position until the isometric contraction can no longer be sustained. Another way to do the exercise is to perform a large number of repetitions where there is a short period of static muscular contraction and a short period of rest (intermittent contractions). This latter form of exercise is more specific to an everyday life activity. The purpose of this study was to assess the muscular fatigue of the low back and hip extensors muscles during the performance of a dynamic-intermittent PBE exercise in males and females participants.

METHODS

Forty-one healthy students (24 males and 17 females) performed, while lying prone on a bench with the legs fixed, two maximal voluntary contractions (MVC) in extension, a maximum of 100 repetitions of an intermittent PBE exercise and a final MVC in extension. The PBE exercise consisted of while lying prone on a bench (10° below horizontal), repeating a task of 100 repetitions broken into four 1-s segments: (1) raising the trunk to a horizontal position; (2) holding the trunk in the static phase (10° above horizontal); (3) returning to the original position; and (4) resting on the bench. To assess the level of effort involved during the PBE exercise, electromyography (EMG) was collected to measure the level of muscle activity (erector spinae ES, gluteus maximus GT, hamstrings HA) relative to the maximum voluntary EMG (MVE). Muscular fatigue during the static phase of the exercise was estimated through the gradient change of the median frequency in time (MF_{grad}) using power spectrum analysis.

RESULTS AND DISCUSSION

Most of the subjects (34 out of 41) completed the 100 repetitions without excessive muscular fatigue according to the post exercise MVC values (decrease of 20% in male and 14 % in female). There was no gender difference in all EMG measurements. It was found that the level of muscular activation (% MVE) of each muscle group increased with the number of repetitions (figure 1: Peak activity of ES; figure 2:

Average activity of ES) and the level of muscular fatigue (MF_{grad}) was greater for the ES muscles than for the GT and the HA muscles. Moreover, it was demonstrated that the subjects who did not complete the test had a higher rate of fatigue of hamstrings (MF_{grad}) than the other subjects.

Figure 1. Peak activity of ES for male participants

Figure 2. Average activity of ES during static phase

CONCLUSION

The PBE exercise as performed in the present study (including rest intervals) was not very strenuous for our healthy subjects but seems to be an adequate exercise to measure and to train the aerobic capacity of the back muscles. The best predictors for the subjects that did not complete the 100 repetitions were a high level of muscle activity in the HA and a low level of back muscles force.

BIOMECHANICS OF PLAQUE RUPTURE IN ATHEROSCLEROTIC CORONARY ARTERIES

Jean Brunette¹, Rosaire Mongrain^{1,2} and Jean-Claude Tardif¹

¹Montreal Heart Institute, ²McGill University, Montreal

INTRODUCTION

Cardiovascular diseases are the leading cause of death in North America. A mechanical event is generally at the origin of a myocardial infarct, where the plaque cannot bear the different stresses anymore. This may result in a rupture of the plaque's fibrous protective cap. Exposure of the blood to the pro-aggregative content of the atheromatous gruel may result in the formation of a clot which can eventually lead to a myocardial infarct. Plaque vulnerability to rupture can be evaluated by means of a finite element analysis (FEA) over a 3D model obtained from an intravascular ultrasound imaging (IVUS) series. The mechanical properties of coronaries can be evaluated from elastography. The different stresses in conjunction with the mechanical properties of the tissues can permit the evaluation of plaque vulnerability to fissure, help to choose a proper therapeutic approach, and assess balloon size and inflating pressure during percutaneous transluminal angioplasty.

METHODS

A 3D model can be obtained from the segmentation of *in vivo* sequences of intravascular ultrasound images. The segmentation coordinates of the layers, inclusions and plaque are imported from a segmentation software to a computer aided design (CAD) package. Once the model is created, it is then exported, by means of a regular IGES format to a mesher that prepares the model for a computational fluid dynamics (CFD) solver. At this point, the mechanical properties of the artery, obtained from elastography of the intravascular images, can be incorporated into the model. Once the boundary conditions are set, velocities and shear stresses can be determined over the model. With a fluid to wall interface analysis, different stresses in the artery wall can be obtained, and their integration yields the different forces applied on the plaque and its propensity to fissure.

DISCUSSION

Three types of stresses resulting from blood dynamics can be identified along the artery wall: circumferential stress, pressure gradient stress and shear stress (see **Figure 1**). The circumferential stress has been previously described in the literature and is sometimes approximated, with some limitations, by the Laplace law. The pressure gradient stress results from the blood pressure and may create longitudinal forces on the plaque. This type of stress has been largely neglected in the literature. The third type of stress, the shear drag force results from the shear of blood circulation on the inside boundary due to blood viscosity. This shear stress can be integrated over the surface to give a longitudinal drag force applied on the plaque. This type of stress has been largely covered in the literature (Ilegbusy et al 1999), but only from a local physiological approach on the endothelium cells; however, it never has been considered under a global mechanical point of view. Fissuring results from a conjunction of the different forces applied and the mechanical properties of the plaque.

Figure 1 : Schematic of the different forces over an artery model under physiological perfusion. Three types of forces can be identified: circumferential forces (T), pressure gradient forces (P) and shear forces (τ). These forces along with the mechanical properties of the plaque (which can be determined by elastography) may result in plaque rupture, which may cause an infarct.

Plaque properties can be determined from elastography on IVUS images obtained at different blood pressures over the cardiac cycle (de Korte *et al* 1998). These mechanical properties are applied on the 3D model. Different forces calculated by CFD and FEA can be validated with a phantom in which different stress gauges can be inserted. The phantom can be made of an agar-based compound reproducing the different layers and inclusions (Brunette *et al* 2000).

SUMMARY

Plaque fissuring is at the origin of myocardial infarct. This event is a direct consequence of different blood circulation forces in conjunction with plaque mechanical properties. A 3D model can be obtained from segmentation of IVUS series, and tissue mechanical properties can be determined by elastography. The model can then be imported into a finite element solver in order to study the mechanical behavior of the coronary artery and its plaque, and to evaluate its vulnerability. This can be of great utility in a clinical environment for the evaluation of patient risk. This technique can also be useful to better determine the best therapeutic approach, and to determine balloon size and inflating pressure of percutaneous transluminal angioplasty (PTCA).

TESTING THE RELIABILITY AND VALIDITY OF SACROILIAC JOINT ROTATIONS MEASURED WITH A MAGNETIC TRACKING DEVICE

Melanie Bussey and Toshimasa Yanai

School of Physical Education, University of Otago, Dunedin, New Zealand

mbussey@pooka.otago.ac.nz

INTRODUCTION

Measuring the motion of the sacroiliac joint (SIJ) is problematic due to the relatively small range of motion available at the joint ($<10^\circ$). Most techniques for measuring the SIJ range of motion are invasive, involving the implantation of titanium markers or k-wires and requiring multiple radiographs subjecting the participant to large doses of radiation (Sturesson et al., 2000; Jacob and Kissling, 1995; Egund, 1978). The error ratio of non-invasive techniques has been considered too large to reliably evaluate such small rotations. Therefore, the aim of this study was to test the reliability and validity of SIJ rotations measured from a non-invasive palpation and digitising technique using an electro magnetic tracking device.

METHODS

Fifteen healthy subjects (11 females and 4 males) between the ages of 20 and 40 gave their informed consent to participate in this study. Each subject attended two testing sessions held on two separate days and each testing session consisted of two separate trials. SIJ rotation was generated via full hip abduction with external rotation from a secured prone position. To standardize the initial subject position a wooden frame was built to which the subject was secured. The pelvic landmarks, right and left anterior superior iliac spines (ASIS) and posterior superior iliac spines (PSIS), were palpated and digitized using the magnetic tracking device with stylus (Fastrack, Polhemus Incorporated, Colchester, VT, USA).

The mean rotational motion after four trials was calculated for both right and left SIJ and the standard deviation was calculated as the variability of the individual results from the group means. To test the reliability of the palpation and digitizing technique, a trial-to-trial comparison using Pearson correlation was performed on the average of the first trial each day and the average of the second trial each day. To test the individual subject variability in SIJ range of motion, a day-to-day comparison using Pearson correlation was performed on the average of the day one trials and the average of the day two trials. To test for significant differences in both the subject variability and the measurement variability paired t-tests ($p=0.5$ level of significance) were conducted. Measurement validity was tested through the use of CT scans on six randomly selected subjects.

RESULTS

The correlation coefficients of the SIJ range of motion measurements range from 0.78 to 0.84 for the day-to-day

testing (Table 1) and from 0.83 to 0.90 for the trial-to-trial testing (Table 2), representing a strong correlation between the measures. Additionally, the range of error in the measurements was less than one degree and all but one paired t-test, right day-to-day, were non-significant.

The difference between the range of motion detected with the palpation and digitising method and that detected with the CT method is small, less than one degree. The correlation coefficient was high (0.9), validating the SIJ rotation measurement.

Table 1: Results of day-to-day reliability testing

SIDE	CORRELATION	MEAN DIFF. (DEG)	SD OF DIFF (DEG)	T-TEST
Left	0.80	0.27	0.82	P=0.21
Right	0.78	0.77	1.20	P=0.03
Total	0.84	0.50	1.61	P=0.24

Table 2: Results of Trial to trial reliability testing

SIDE	CORRELATION	MEAN DIFF. (DEG)	SD OF DIFF. (DEG)	T-TEST
Left	0.83	0.10	0.82	P=0.40
Right	0.80	0.14	0.80	P=0.80
Total	0.90	0.26	0.90	P=0.24

DISCUSSION AND SUMMARY

This study established the reliability and validity of SIJ rotations measured with the magnetic tracking device. The positional error for the tracking device was calculated as the mean difference between the two sets of known distances and was found to be less than 1 mm. The maximum relative error, analysed by observing the length change of the segment vectors, was 2mm, which would translate into a maximum rotational error of 1° . This measurement technique may be suitable for more quantitative clinical evaluations of the SIJ.

EFFECTS OF STRETCHING AND SHORTENING ON ISOMETRIC FORCES ON THE DESCENDING LIMB OF THE FORCE-LENGTH RELATIONSHIP IN CAT SOLEUS MUSCLE.

Rachel Schachar, Walter Herzog, and Tim Leonard

Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada, raschach@ucalgary.ca

INTRODUCTION

Steady-state, isometric force enhancement (FE) following stretch and force depression (FD) following shortening, is a well-accepted property of skeletal muscle (Abbott and Aubert, 1952). The force-length (F-L) curve describes the relationship between the maximal isometric force and the corresponding muscle length. This F-L relationship is considered an important mechanical property of skeletal muscle. The textbook F-L relationship for muscle is obtained through a series of independent static contractions. The purpose of this study was to examine, through systematic tests, the effects of stretching and shortening on the isometric forces at different lengths on the descending limb of the F-L relationship.

METHODS

Ten cat soleus (SOL) were studied. Cuff electrodes were surgically implanted on the tibial nerve (Schachar, et al., 2002). Animals were secured in a stereotaxic frame. The distal insertion of the SOL on the Calcaneus was attached to a muscle puller (Schachar, et al., 2002). The F-L relationship was determined for each muscle, and the descending limb identified. Two sets of tests were performed. In the first set, the muscle was stretched at various speeds and by various amounts on the descending limb. In the second set of tests, the muscle was shortened at various speeds and by various amounts on the descending limb. Isometric reference contractions were performed at the initial and final lengths for each stretching and shortening contraction. Both force and displacement were continuously recorded. Active forces were calculated by subtracting the passive forces from the total forces.

RESULTS AND DISCUSSION

Data were collected from 120 stretching and 120 shortening contractions. Forces following muscle stretches were greater than the purely isometric forces at the initial (and therefore also the final) muscle lengths for all stretch contractions, and the maximal isometric forces following shortening were depressed compared to the corresponding isometric force (Figure 1). The total forces following muscle stretch were greater than the corresponding isometric forces at optimal muscle length. However, this could have been an artifact caused by an increase in the passive forces. In order to resolve this problem, the active (total-passive) forces were calculated, and it was found that for some stretch tests, the steady-state isometric force following SOL stretch clearly exceeded the purely isometric force at optimal length (Figure 2).

Figure 1. Example of F-L relationship and corresponding steady-state isometric F-L curves preceding dynamic stretching or shortening on the descending limb.

Figure 2. Example of active FE and active FD following muscle stretch.

The primary mechanism associated with FE is the “sarcomere length non-uniformity theory”. According to this theory, stretch on the descending limb causes non-uniformities in sarcomere lengths, and thereby non-uniformities in the forces that can be exerted by sarcomeres. One of the conditions associated with the sarcomere length non-uniformity theory is that the steady-state forces following stretch cannot exceed the isometric forces at optimum sarcomere length. However, here, we demonstrate that such forces in excess of those observed isometrically at optimum length can be found for some stretch conditions, thereby suggesting that the sarcomere length non-uniformity theory alone cannot explain the observed results. We found that following active stretching of SOL, there was a considerable increase in passive force compared to the passive force obtained following isometric contractions or passive stretch (results not shown). This passive FE following active stretch must be analyzed carefully in the future, as it might explain the novel and unexpected results found here.

INTRODUCTION

In an attempt to achieve excellent surgical outcome after total knee arthroplasty (TKA), several computer-assisted systems have been developed. As one of such systems, we developed an intraoperative knee-motion monitoring system based on a photostereometry using linear CCD cameras and LED markers mounted on the TKA component (Nishino, et al., 1999). Employing this system, the femorotibial joint motions after TKA have been measured. The motion data obtained was evaluated as movement of contact area between the femorotibial components (Nishino, et al., 1998). This study aims to apply this method to motion analysis between the unresurfaced patella and the femoral component after TKA.

MATERIALS AND METHODS

The patellar surface data was obtained by digitization of the cartilage surface from magnetic resonance images. The femoral surface data was measured by means of a precise three-dimensional digitizer (BH504, Mitsutoyo, Japan). The computer model of each surface was mathematically expressed by a set of six bicubic B-spline patches fitted to the surface data. The relative motion between the femoral component and the patella was measured by using LED markers mounted on them. The position of the patellar surface relative to the LEDs mounted on the patella was directly measured by means of an original digitizer with LEDs. By this registration of its measurement data and the patellar surface model, the model data could be combined with the motion data (Besl and McKay, 1992). The motion data was visualized as the movement of the patellar model relative to the femoral component model (patella tracking). Additionally, the contact or near-contact area between the articular surfaces was calculated, and then the patello-femoral joint motion was also evaluated as the movement of the contact area. Five cadaveric knees after TKA were measured during knee flexion and extension ranging from 0 to 90 degrees. As total knee system, Genesis II cruciate retaining type (Smith & Nephew, Richards, USA) was used.

RESULTS AND DISCUSSION

It took about 50 seconds to complete the registration of the model data. Consequently, the registration error lay within 1.6 degrees and 2.1 mm in terms of the rotation and translation, respectively. In patella tracking, the patella deviated slightly

from lateral side to medial side relative to the femoral component during knee flexion (Figure 1). The contact area on the patella moved proximally during knee flexion (Figure 2). This method can be assessed the movement of the patello-femoral joint high speed and dynamically, thus it was suggested to have a potential of employing as motion analysis of the patello-femoral joint during TKA.

THE HEMODYNAMIC EFFECTS OF PARENT VESSEL INFLOW ANGLE ON A CEREBRAL SIDEWALL ANEURYSM

INTRODUCTION

The nature of flow in aneurysms depends on many factors including the complex three-dimensional geometry of the aneurysm and parent vessel. Computational fluid dynamics (CFD) allows for the analysis of hemodynamics in complex three-dimensional systems. The effect of the parent vessel inflow angle is intuitively relevant but has not been well studied. Using CFD, we examined the influence of the inflow angle in order to understand the hemodynamics factors that may lead to aneurysm rupture. Three-dimensional cerebral saccular sidewall aneurysms with various inflow angles are used in this analysis.

METHODS

In the present study, the flow is assumed to be incompressible, steady and laminar. The parent vessel is 3mm in diameter; the aneurysm size is 12mm in diameter and the sac-to-neck ratio is 3:1. Fully developed velocity profile and pressure gradients are specified at the inlet and outlet of the vessel. The pressure drop between the inlet and outlet is 50 Pa. Inflow angles of 0, 10, 20 and 40 degrees are examined.

The 3D Navier-Stokes equations are solved by commercially available package STAR-CD (Adapco, NY). The code is based on finite volume approach. We used Proam to generate approximately 120,000 of cells. The density of fluid, 1056kg/m³ and viscosity of 0.0035kgm/s were chosen in the computation. Velocity, and pressure distribution are computed numerically.

RESULTS AND DISCUSSION

The computational results show that the flow enters the aneurysm at the distal neck (inflow zone) and joins the parent vessel at the proximal (outflow zone). Vortex structure is observed inside the aneurysm. This vortex moves towards the dome as the inflow angle increases. High-pressure region is found at the inflow zone. As the inflow angle increases, the pressure at the in flow zone increases and tends to grow. As the angle of inflow increases, more rapid flow activity is observed inside the dome. Flow velocity entering the

aneurysm is much faster when the inflow angle increases. However, the velocity near the dome is almost stagnant.

Figure 1: Relative pressure contour at the center plane for (A) 10° (B) 20° (C) 40° of the inflow angle. Flow is from right to left. As the inflow angle increases, higher pressure develops and grows in the inflow zone.

SUMMARY

Three dimensional velocity profiles and pressure distributions of a cerebral aneurysm with variable parent vessel inflow angle have been obtained. The high-pressure zone is developed at the inflow zone. As the inflow angle increases pressure in the inflow zone increases and distributes over a wider area. This phenomenon may affect aneurysm growth and rupture. Future studies will include the effect of pulsatile flow.

INTRODUCTION

We present our preliminary work with the use of computational fluid dynamic (CFD) study of hemodynamics of cerebral sidewall aneurysms. Aneurysm size is known to influence rupture risk. The hemodynamic effects of aneurysm size are not clearly understood. The effect of aneurysm size on maximal velocity in the parent vessel, maximal pressure and shear force at the neck were investigated.

METHODS

The basic models consist of a tube with diameter of 3 mm representing a constant parent vessel diameter. The aneurysm size varies for each model from small (8 mm), large (12 mm) and giant (28 mm); the neck size being constant. The computational mesh is generated using Pro*am®, a commercial code by CD-adapco. Figure 1 shows a sectional view of mesh for a large size aneurysm model.

Fig. 1 - Sectional view of computational domain

The numerical simulation is carried out using StarCD®, a commercial CFD code by CD-adapco. The flow is modeled to be steady state, isothermal, incompressible and laminar. A constant pressure, 120 mm of Hg, is specified at the inlet. The mean peak value of blood velocity in large arteries is around 0.2 – 0.5 m/s (Cooney, 1976). A constant outlet pressure is specified so as to get the maximum value of flow velocity in the above range. A wall boundary condition (no slip, no penetration) is specified along the tube and aneurysm walls. The convergence of the flow solution is verified by the comparison of outlet velocity profile with parabolic velocity profile for laminar flow.

RESULTS AND DISCUSSION

The CFD results show that the flow activity inside the aneurysm is of an order of magnitude smaller than inside the parent vessel. It reveals the reversed flow (vortex flow) occurring inside the aneurysm. Table 1 gives the comparison of flow properties for three models.

Table 1: Flow dynamics for three models

Aneurysm size	Max. velocity in parent vessel (m/s)	Max. pressure at neck (N/m ²)	Max. shear force at neck (N)
Small	0.387	15990	0.3193-e-6
Large	0.3823	15983	0.2585-e-6
Giant	0.3207	15958	0.5074-e-6

SUMMARY

The effect of aneurysm size on parent vessel and aneurysm hemodynamics is complex. In this study we have attempted to analyze this effect using CFD. Many physical factors can potentially influence aneurysm hemodynamics. CFD allows for the isolation of specific factors while maintaining other factors constant. It is hence an excellent tool for deciphering cause and effect relationships in hemodynamic analyses. In summary we found that velocity in the parent vessel and maximal pressure at the neck decrease with increasing aneurysm size. Our results for maximal shear force at the neck are not straightforward. This may reflect an interesting phenomenon or may reflect limitations in our methods and calculations. Nevertheless, the ability to analyze aneurysm hemodynamics in such a manner may eventually become relevant in assessing the rupture risk of real human aneurysms.

EFFECTS OF OSCILLATION ON ELEVATING SHEAR STRESSES

Sakhaeimanesh Ali A.

Biomedical Engineering Group, Faculty of Engineering, University of Isfahan, Isfahan, Iran, sakhaei@eng.ui.ac.ir

INTRODUCTION

In artificial heart valves, the problems of haemolysis, platelet destruction, thrombus formation, perivalvular leakage, tissue over growth and endothelial damages are directly related to the fluid dynamic characteristics of flow past artificial heart valves (Reul et al., 1993 and Yoganathan et al., 1995). Therefore, haematologically, It is highly desirable that a valve design shouldn't produce excessive turbulence, which may cause haemolysis (Yoganathan et al., 1995). In this study the effect of oscillation on elevating turbulent shear stresses through the jellyfish and St. Vincent valves has been investigated.

METHODS

Flow was driven by a servo-controlled piston pump (VSI pump) that compressed the ventricle to simulate the physiological flow. A model of the left ventricle and load was incorporated with the drive unit for testing artificial valves in the aortic position under practical flow and loading conditions. DANTEC, two-colour 5 Watt Argon-Ion laser was used to determine the velocity and turbulent components of the valve.

The axial and radial mean velocities, \bar{U} and \bar{V} , the r.m.s. of axial and radial fluctuation components, turbulent intensity, T , and the cross, \overline{uv} , were calculated. More details of mock circulatory system and LDA technique are given somewhere else (Sakhaeimanesh et al., 1999).

RESULTS AND DISCUSSION

Comparison between two valves revealed that at 0.5D downstream of the valves the magnitude of shear stresses in the Jellyfish valve were much higher than those of the St. Vincent valve at cardiac outputs of 4.5 and 6.5 l/min. Furthermore, at 3D and 5D downstream off the Jellyfish valve the magnitudes of shear stresses reduced dramatically to 4 and 1 N/m² respectively at cardiac output of 6.5 l/min. At 3 and 5D downstream of the St. Vincent valve, on the other hand, showed maximum shear stresses of the values of 49 and 16 N/m² respectively at the same cardiac output.

It is hypothesized that the cause of high shear stresses in close proximity to the Jellyfish valve was due to the oscillation of the membrane which in turn generated a wake downstream of the valve (in the core of valve chamber) and produced a wide region of disturbance further downstream. This resulted in further pressure drag and consequently, higher pressure drops across the valve and higher shear stresses downstream of the valve.

This idea was supported by the results of shear stress (table 1) and pressure drop measurements. Maximum and mean shear stresses at 0.5D downstream of the Jellyfish valve were about twice those of the St. Vincent valve and pressure drops across the Jellyfish valve were up to 93 % higher than those of the St. Vincent valve under steady flow rates between 10 to 26 l/min

The effect of oscillation can also be seen from the results of turbulence intensities. Maximum and mean turbulent intensities 0.5D downstream of the Jellyfish valve were as high as 723 and 255 % respectively at cardiac output of 6.5 l/min. At 3D downstream of the valve, maximum and mean turbulent intensities reduced dramatically to 17 and 8 % respectively at cardiac output of 6.5 l/min. Reduction in turbulence, and consequently in shear stress estimation in the 3D and 5D downstream measuring planes of the Jellyfish valve, indicated that the effect of the membrane oscillation decayed beyond 1D at all cardiac outputs.

BIOMECHANICAL TESTING OF AN INTRAMEDULLARY LOCKED NAILING FOR METACARPAL SHAFT FRACTURES

Gabriela Contreras^{1,2}, Nils Götzen², Michael Morlock², Miguel Cerrolaza¹

¹ Centro de Bioingeniería, Universidad Central de Venezuela, Caracas, Venezuela, gabriela_contreras@web.de

² Biomechanics Section, Technical University Hamburg-Harburg, Hamburg, Germany, goetzen@tuhh.de

INTRODUCTION

An intramedullary locked nailing system has been developed at the Central University of Venezuela in order to allow early postoperative movement for the patient. It will be used for the treatment of diaphyseal fractures at the metacarpal bones, thus hopefully shortening the recovery time. The main goal of this study is to evaluate the mechanical behavior of the nailing system. Biomechanical testing and finite element analyses were performed to determine the ultimate strength and analyze the fatigue behavior under physiological loads.

MATERIALS AND METHODS

Experimental Study

The nail was connected by bone-screws to cylindrical clamps, made from acrylic. Four standard mechanical tests, based on standard specification for intramedullary fixation¹, were conducted to determine the ultimate strength of the nail-clamp assembly: compression test; tension test; four-point-bending test, and torque test. Three specimens were tested within each test. Additional cyclic tests were conducted to evaluate the mechanical behavior under repeating *in-vivo* loads². Compression force (100N) and torque moment (100Nmm) were simultaneously applied at a rate of 1Hz for 10000 cycles. Afterwards, the nail, screws, and clamps were analyzed.

Numerical Analyses

The finite element analyses were performed to evaluate the loading condition and stress distribution within the nail, the screws, and the clamps. They were also necessary to quantify the difference in the load transfer for the nail-assembly with acrylic clamps or cortical bone clamps. All static experimental tests were numerically investigated. A FE-Model, using the symmetry of the assembly and loading conditions was developed. Steel and acrylic were modeled as isotropic linear-elastic materials. Cortical bone was modeled as orthotropic linear-elastic material. Interface conditions between screws, nail, and clamps were modeled with contact elements. Physiological loads representing tip pinch were applied and transferred loads were evaluated. These loads were compared to load in the experimental setup.

RESULTS AND DISCUSSION

The obtained ultimate strength values (Table 1) are all significantly larger (factor 16 –30) than physiologically occurring loads. But all specimens showed plastic deformation after the strength test. The yield strength has to be therefore smaller. Cyclic loading showed no signs of plastic

deformation in the nail or screws. All of the specimens proved to be strong enough. The numerical analyses showed that the acrylic clamps create slightly larger bending moments in the screws (Fig.1) then a cortical bone clamp would do. This is due to the larger compliance of this material. The resulting stress concentration in the screws is therefore also slightly larger.

Fig.1: Bending moment in the upper screw at a compression load of 50 N.

The mechanical conditions, created in the experimental tests are very similar to the *in-vivo* loading conditions.

Table 1: Experimental strength values

Test	Strength Value
Compression	1674 ± 66 N
Tension	672 ± 42 N
Bending	6889 ± 1044 Nmm
Torsional	3270 ± 626 Nmm

The experimental and numerical studies in this investigation show clearly the sufficient mechanical strength of the nail-system.

ACKNOWLEDGEMENTS

METHODOLOGICAL CONCERNS USING INTRA-CORTICAL PINS TO MEASURE TIBIOFEMORAL KINEMATICS

daniel.benoit@ks.se

INTRODUCTION

Currently, the most sensitive and accurate means to directly measure tibiofemoral joint motion is with the use of invasive markers implanted in the tibia and femur (Ramsey et al, 1999). To date, we have measured the skeletal kinematics of both the anterior cruciate ligament deficient and the normal knee using this technique (Ramsey et al., 2001). The purpose of this paper is to address the methodological concerns related to the femoral pin and to discuss reliable and safer insertion sites.

METHODS

The skin, subcutaneous tissue and periosteum were anaesthetised with standard anaesthetic and a 15 mm skin incision was cut. The retinaculum patellae laterale was split longitudinally approximately 25 mm. A Hoffman pin (Stryker Howmedica AB Sweden, 3.2 mm diameter, #5038-5-80) was inserted through the cortice of the femur using a manual drill. The pin penetrated the bone obliquely in a postero-medial direction from the frontal plane (Figure 1) to a depth of 10-15mm. Insertion ceased when the subject experienced discomfort. The surrounding area was then wrapped in sterile bandages. Following the surgical procedure, the subjects performed active flexion and extension movements while standing to identify whether movement restrictions were evident. If necessary, range of motion was limited. Subjects were then transported to the laboratory for data collection of the following movements: normal walking, One Legged Jumps, and lateral cut manoeuvre. Having completed the experimental protocol, subjects returned to the operating theatre to have the dressing and pins removed.

Pin Testing

A testing apparatus was designed to determine the amount of force required to permanently deform the bone pins. Pins were secured in a mechanical vice at a depth of 18 mm, approximating the average insertion depth among our subject population. Under two testing conditions, loads were applied perpendicular to the longitudinal axis of the pin at a distance of 15 mm and 20 mm respectively from the insertion sight. A regression line of the applied load was derived and the first inflexion point of the load curve was considered the point of permanent deformation of the bone pin.

RESULTS

Three of the ten subjects bent the femoral pin during activity, the result of an interaction with the surrounding soft tissue and musculature (Figure 2).

During mechanical testing of the pin, experimental load force magnitudes between 36.6–58.7N permanently deformed the pin, dependent upon where the load force was applied.

DISCUSSION

At this insertion depth (18mm) the highest load will be applied over the threaded section of the pin. In this region, the pin has a smaller cross-sectional area and thus is less resistant to bending. Customised pins with a shorter threaded section of 10-15 mm may negate bending. This would result in the threads being completely inserted into the cortice of the bone while exposing the more bending resistant area of the pin. Alternatively, a solution may be to align the pin through the incision and have the subjects perform dynamic open chain flexion and extension movements while on the operating table. This may stretch the IT band and quadriceps tendon and may guide the femoral pin into a more optimal position prior to it being inserted into the cortex of the bone. With longer longitudinal incisions about the insertion site and by correctly aligning and inserting the femoral pin between the IT band and quadriceps tendon, impingement problems would be diminished.

FLUID STRUCTURE INTERACTION OF HEART VALVES

Gaetano Burriesci¹, Chris J. Carmody², Ian C. Howard² and Eann A. Patterson²

¹Dipartimento di Meccanica e Aeronautica, University of Palermo, Palermo, Italy, g.burriesci@sheffield.ac.uk

²Department of Mechanical Engineering, University of Sheffield, Sheffield, United Kingdom

INTRODUCTION

The understanding of physiological function and operational mechanisms of heart valves has a fundamental role in the design process for prosthetic and, in particular, bioprosthetic substitutes. In fact bioprosthetic heart valves, realized using biological membranes, aim to offer advantages in terms of hemodynamic performances and biocompatibility over their mechanical counterparts by reproducing the behavior of natural valves.

In recent years, the use of the finite element method has led to significant contributions in the simulation of the mechanical behavior of valves. Although, the accurate modeling of these biological components is associated with a great numerical complexity, involving the coupling of non-linear deformable structures with pulsatile fluid flows. Because of these computational difficulties, the fluid and structural phenomena have been studied separately until recently. This implies that assumptions about the load distributions or the valve's instantaneous shape were necessary, introducing approximations in the analyses.

The new available computational technologies permit fluid structure interaction (FSI) to be performed with an increasing degree of confidence.

In this work, the FSI model of a natural human aortic valve is analyzed, and its fluid and mechanical behavior is studied. The model includes the full description of the flow field together with large deformation, material non-linearity and contact. Valve motion is entirely due to the inertia of a fluid moving in a physiological manner.

METHODS

An explicit finite element code with the ability to undertake fully coupled fluid-structure interaction (LS-DYNA 3D) was used to perform the analyses. Moreover, the selected package has already been successfully used to carry out analyses of large deformations of soft biological materials.

The valve geometry was based on data from Thubrikar work (1990), and the root and sinuses on data from Tindale (1984). The model considered the strong material non-linearity typical of leaflets, and included contact routines to deal with the coaption of the leaflets. The change in thickness and the anisotropy of the leaflets is not considered in the model (their effect was studied by the authors previously).

RESULTS AND DISCUSSION

This work illustrates some of the potential of FSI modeling. The predicted flow field showed the important role of the sinuses, where vortexes are produced which determine the closure initiation. Moreover, the FSI model enabled the determination of the spatial pressure distribution acting on the leaflets, which can be of possible application on simpler dry models.

Figure 1: section of the FSI model of the aortic valve. It is possible to observe the presence of vortex in the sinuses, which determine the closure initiation.

INTRODUCTION

Measurement of the physical strength of the bonds linking circulating cells to each other or to adjacent tissue surfaces is an important prerequisite for the characterization of adhesion processes occurring in the blood microcirculation. The measurement of the energy involved in cell-cell interactions has significant implications in biological and medical sciences. Quantitative determination of the energy exchanged during immunologic agglutination of red blood cells (RBC) induced by monoclonal antibodies (MAbs) is of great importance, since it gives very useful information to estimate the quality of the antibody (Ab). The quality of an antibody is related to its affinity expressed by the equilibrium constant. The biological activity of an Ab can be estimated by the strength of antigen-antibody bridges. An optical method is proposed to estimate the specific binding energy using the dissociation behaviour of suspended RBC agglutinates in a shear flow and measuring laser backscattering. A constant increase of intensity was observed when the shear stress raises, pointing to a progressive dissociation of RBC agglutinates into smaller ones. The final break-up of two-cell rouleaux is produced at critical shear stress (τ_c), which reflects the mechanical action required to dissociate the molecular bridges between cells. The critical shear stress permitted to define the specific surface adhesive energy (Γ) by using the Derjaguin relation. τ_c provides a good way to assess the functional characterization of specific immunoglobulins, which could be very useful for Ab quality control.

MATERIALS

Blood samples. Fresh A₁, B, A₁B and O blood samples were collected from healthy donors and anticoagulated with EDTA

RBC suspensions. Blood samples were centrifuged 10 min at 2500g. RBCs were washed three times with PBS, containing 0.5% human serum albumin, and finally resuspended at 40% hematocrit in the suspending medium containing MAbs

Suspending media. A solution of Dx 70 (Dextran 70 - MW-70.000 -Sigma Chem. Co. D.1537) at 4.1% in PBS was used

Monoclonal antibodies. Anti-A (lot P47-2) and anti-B (lot P47-4B6) murine MAbs supplied by the Blood Transfusion Centre (CHU of Liege-Belgium) diluted in the suspending medium at 11.25 μ g/ml. as determined by the sandwich ELISA method.

METHODS

The Erythroaggregometer (EA) is an automatic optical device built by Stoltz et al. to analyse erythrocyte aggregation, using the light backscattering theory developed by Mills and Aufreire. It measures the intensity backscattered by a thick concentrated suspension of free and aggregated RBCs confined in the gap between two relatively rotating coaxial cylinders. The internal cylinder is fixed while the external one is transparent and rotates at controlled speeds. The EA is coupled to a PC, which commands the whole instrument operation. Agglutinate suspension (1.6 ml) is poured into the gap between both concentric cylinders of the Erythroaggregometer. Samples are exposed to a rotational shear stress (τ) increasing by steps. The application of a constant shear flow in one-direction causes a slow disaggregation of agglutinates. Backscattered intensity (r) is recorded at each step of the applied stress (τ) showing a linear correlation with the logarithm of τ , which is calculated at each step using the shear rate (S_R) and the suspension viscosity:

RESULTS AND DISCUSSION

The complete dissociation of agglutinates is only approached asymptotically, so the final break-up of doublets is produced at critical shear stress (τ_c) which is defined by extrapolating the linear portion of the curve r (log τ) to r_0 (complete dissociation). The critical shear stress τ_c acts over the upper area A_0 of the cell. R_c is the mean curvature radius of the bridging membranes. The Derjaguin relation states that the fracture energy Γ is: $\Gamma = (\tau_c A_0 W) / (2\pi R_0)$, where $W \cong 0.1$. The so obtained Γ value is the specific surface adhesive energy characterizing the intercellular adhesiveness (Table I). The more important conclusion is that this innovating method can help in the quality control of monoclonal antibodies and in the diagnostic of immune diseases such as Auto-Immune Hemolytic Anemias.

THE EFFECT OF VARYING FREQUENCIES ON THE STIMULATION OF THE AGGREGAN PROMOTER OF CHONDROCYTES EMBEDDED IN AGAROSE GELS

Chi S¹, Chung M¹, Hulme P¹, Doege K², Duncan NA¹, and Matyas JR¹

²Tampa Shriners Hospital, University of South Florida, Tampa, FL, USA,

INTRODUCTION Cartilage is composed of extracellular matrix and chondrocytes, which are responsible for synthesizing and maintaining the matrix. When isolated and cultured in a surrogate matrix of agarose, chondrocytes continue to synthesize extracellular matrix rich in type II collagen and proteoglycans (Buschmann et al., 1992). Aggrecan is the most abundant proteoglycan of cartilage and its rate of synthesis in chondrocytes embedded in agarose increases in response to dynamic compression, but decreases in response to static compression (Buschmann et al., 1995). Less is known about aggrecan gene expression in this gel system, though studies of cartilage explants suggest that aggrecan mRNA parallels aggrecan proteoglycan biosynthesis in response to load (Valmhu et al., 1998). Green fluorescent protein (GFP) is a tool that can be used to monitor the expression of genes and gene promoters in living cells. Splicing the aggrecan gene promoter to the GFP gene allows aggrecan promoter activity to be monitored by following GFP fluorescence in cells. We sought to assess how the frequency of mechanical compression influences aggrecan gene promoter stimulation in chondrocytes embedded in agarose.

METHODS Articular cartilage was harvested from the knee joints of skeletally mature dogs. Chondrocytes were isolated by digestion either: (a) sequentially with hyaluronidase, pronase, and collagenase to produce isolated chondrocytes (IC), or (b) dispase-collagenase to yield enzymatic chondrons (EC). Cells were seeded in hemi-cylindrical 4% agarose gels (4 mm x 4 mm x 2 mm) at a density of $\sim 1 \times 10^6$ cells·mL⁻¹. The 0.9 kb promoter fragment (B18) of the aggrecan gene was cloned into a promoterless GFP vector (pTimer-1, Clontech). Cell-gel constructs were transfected using FuGENE™6 reagent and cultured in DMEM/F12 (10% FCS and 1% pen/strep/fungizone). Untransfected cell-gel constructs served as controls. On culture days 5-14, GFP fluorescence was assessed before and after compression using confocal fluorescence microscopy (Zeiss LSM 510). The constructs were compressed dynamically in a specially designed loading jig for 3 hours to a peak strain of 15% at frequencies of 0 Hz (static), 0.001 Hz, 0.01 Hz, 0.3 Hz and 1.0 Hz.

RESULTS AND DISCUSSION Little or no fluorescence was observed in the cell-gel constructs prior to loading. Increased fluorescence was observed for ECs loaded at 0.01, 0.3, and 1.0 Hz (Figure 1). Fluorescence did not increase appreciably for ICs loaded at any frequency. GFP expression did not change appreciably in the unloaded condition for both

ECs and ICs. These results are summarized in Table 1. The threshold frequency for stimulating the aggrecan promoter in this experimental system is between 0.001 and 0.01 Hz. Between 0.01 and 1.0 Hz, the change in the intensity of GFP fluorescence increases in parallel with loading rate.

INTRODUCTION

There is a long history of investigation into the mechanisms by which soft connective tissues from otherwise healthy normal individuals heal in the absence of any clinical intervention. Skin healing has been studied more extensively than the healing of any other soft tissue, thus providing the major database against which all other soft tissue repair can be compared. Current evidence suggests that soft connective tissues other than skin appear to heal via a similar sequence of events. However, in most studies, healing has been investigated in wounds of only one tissue from individual animals, such as skin, abdominal wall, intestine, nerve, bone, tendon or ligament. The comparison of healing in different tissues, therefore, has been based on results gained in different groups of animals or even in different species. Studies on the relationship of the rate of healing of different tissues would be more relevant if carried out on the same animal, because it would eliminate not only the heterogeneity among groups of animals but also variations in the other factors that can cause interanimal variability. The purpose of this study was to assess the healing of skin, patellar tendon (PT), and medial collateral ligament (MCL) wounds in the same rabbit.

METHODS

Eight skeletally mature 12-month-old female New Zealand White rabbits (mean body weight: 5.8 kg) were used in this study. Z-plasty wounds were created in dorsal skin, left PT, and right MCL in each rabbit. Because the PT may function under high loads compared to skin and the MCL, stress shielding (Ohno, 1993) was applied to the PT by shortening the PT length using a flexible wire and a rod. Postoperatively, all animals were allowed unrestricted cage activity. Six weeks after surgery, all rabbits were sacrificed. To standardize the width of skin to the MCL, dumbbell-shaped 4 mm wide specimens were punched with scar tissues in the centre. Likewise, the patella-PT-tibia complexes were prepared by removing the medial and lateral part of the PT leaving a 4 mm wide central PT bundle. Femur-MCL-tibia complexes were prepared by mounting the knee in a MTS test system and dissecting out all structures except the MCL. All scar samples were held at 1N of tension while cross sectional area was measured, using an area caliper (Shrive, 1988). Failure tests were performed on each scar tissue at a rate of 20 mm per minute. To estimate the surface strain on scar tissues, two parallel dye lines were marked on the margin of scar tissues and tissue images were recorded with a CCD camera during

failure tests. Three samples of each scar tissue were prepared for histology.

RESULTS AND DISCUSSION

Four wires used in PT stress shielding failed, so these samples were excluded from the PT data. Failure data of the skin, the PT, and the MCL scars are presented in Table 1. The skin scars showed statistically significantly lower failure load, stiffness, and failure stress compared with the PT and the MCL scars. The skin scars had significantly higher failure strain than the PT and the MCL scars. There were no significant differences between the PT and the MCL scars in the parameters shown in Table 1. All scar samples failed in the scar region. Histologically, the skin scars showed that the extracellular matrix was disorganized and cells were not aligned in any particular orientation. On the other hand, the extracellular matrix of the PT and the MCL scars were organized and cells were aligned with the longitudinal axis of the PT and the MCL. Thus, according to these results, the skin scars were not similar to the PT and MCL scars biomechanically and histologically. These results suggest that soft tissue repair is driven more by environmental factors than genetic factors. However, dealing with structures such as skin, in which the fibres are arranged in a multidirectional way, the orientation of the fibres with respect to the load axis must be taken into consideration (Reihnsner, 1998). There might be a limitation in the uniaxial test to compare skin scars with PT and MCL scars.

SUMMARY

The failure properties of skin, PT, and MCL scars in the same rabbits were investigated. Skin scars had significantly lower failure load, stiffness, and failure stress compared with PT and MCL scars. Skin scars had significantly higher failure strain than PT and MCL scars. There were no significant differences in these properties between PT and MCL scars.

CLINICAL AND PLANTAR LOADING RISK FACTORS OF SUBJECTS WITH HALLUX VALGUS

Thomas W. Kernozek^{1,2}, Abdulaziz Elfessi³, Steven Sterriker⁴

INTRODUCTION

Previous studies (Yamamoto, et. al., 1996, Blomgren et al., 1991) have addressed some of the differences between the normal foot and the foot with hallux valgus, none have attempted to assess the strength of clinical and plantar loading risk factors in the prediction of the mild to moderate hallux valgus deformity. The present study attempts to do just that.

METHODS

Forty participants with moderate hallux valgus deformity and 51 healthy control subjects of similar age and body weight were studied. The following measurements were obtained: perceived pain while walking, seated first metatarsophalangeal (MPJ) joint range of motion of the involved limb, and resting calcaneal stance position. Plantar loading was assessed barefoot using a capacitive pressure measurement platform (EMED SF, Novel GMBH, Munich). Five trials were gathered for each participant. The intraclass correlation coefficient for stance time for all subjects across all participants was 0.84 indicating a high amount of reliability between trials.

For each pressure measurement trial, 7 plantar regions on the foot were identified: one heel region, one midfoot region, three forefoot regions, and two toe regions. The following variables calculated for each plantar region: peak pressure (PP), peak force (PF), pressure time integral (PTI), and force time integral (FTI). Based on the literature, only the medial forefoot, central forefoot and hallux region were analyzed. Force data was normalized to % body weight.

RESULTS AND DISCUSSION

A logistic regression analysis was used to predict the probability of presence or absence of hallux valgus given a set of scores on the risk factors (independent variables).

Table 1: Logistic regression results using the three clinical variables

Variable	B	Wald	p-value	odds ratio
First MPJ plantar flexion	-.15	9.32	.002	.858
Pain while walking	2.16	6.53	.011	8.69
Resting calcaneal stance position	2.27	7.96	.005	9.71

B=regression coefficient, MPJ = metatarsophalangeal joint.

Table 2: Classification table using the clinical variables (overall classification=91.5%)

		Predicted	
		Normal	Hallux valgus
Observed	Normal	49(98%)	1
	Hallux valgus	5	16(76.2%)

Table 3: Logistic regression results using the three plantar variables

Variable	B	Wald	p-value	odds ratio
Hallux Region PF	-.963	8.10	.004	.382
Hallux Region PP	.059	3.03	.082*	1.06
Hallux Region FTI	3.91	5.90	.015	50.1
Central Forefoot FTI	1.01	4.78	.029	2.75

B=regression coefficient, MPJ = metatarsophalangeal joint, *=alpha < .10

Table 4: Classification table using the plantar loading variables (overall classification=93.3%)

		Predicted	
		Normal	Hallux valgus
Observed	Normal	47(94%)	3
	Hallux valgus	3	36(92.3%)

SUMMARY

High values for two (pain while walking and resting calcaneal stance position) of the three clinical variables increased the probability of being a subject with hallux valgus. High values for the three (hallux region peak pressure, hallux region force time impulse and central forefoot force time integral) of the plantar loading variables increased the probability of having hallux valgus. High values on both hallux region peak force and first MPJ joint plantar flexion increased the probability of being a normal subject. Results from this study demonstrated that the clinical and plantar loading variables are able to differentiate significantly between the two subject groups. The evidence from this research suggests the plantar loading variables had more predictive power in classifying the subject with foot deformity than the clinical variables that we chose to examine. The same variables incorrectly predicted 6% of the normal subjects as having hallux valgus (false-positive prediction). The clinical variables had a 2% false-positive prediction rate for hallux valgus.

MODEL BASED AUDITORY FEEDBACK ON THE LIFTING TECHNIQUE MAY REDUCE SPINAL MOMENTS OF WAREHOUSE WORKERS

Thomas W. Kernozek^{1,2}, Brian Langenhorst³, Jessica Woodworth¹, William Haviland¹

INTRODUCTION

Exposure to physical stress has been related to low back pain and injury (Norman et al., 1998). Brophy et al. (2001) reported that the reduction of low back injuries reduces financial costs associated with low back injury and lost workdays. Auditory feedback during performance has been used effectively to reduce the peak ground reaction forces during landing from a jump and with lifting (McNair et al. 2000, Lavender & Andersson, 2000). Perhaps, coaching and performance based auditory feedback of warehouse workers can reduce the peak spinal moments during lifting/lowering. The purpose of this paper was to address this question.

METHODS

A 6-week study was completed at a local distribution center. Twenty male workers that performed a variety of warehouse tasks participated. Ten of these workers were placed into an experimental group (receiving technical and performance based auditory feedback) and 10 served as a control group. Each group was divided equally based on anthropometric data. Baseline data on the side-bending, flexor, and rotary moments at L5/S1 of each participant were collected with the Motion Monitor Electromagnetic Tracking Device (IST, Inc., Chicago, IL) during lifting scenarios for 6 lift-lowering tasks. This system uses analog scale data and X, Y, Z coordinate data of the participant to calculate the spinal moments at L5/S1 (Lavender & Andersson, 2000). On week 2, the experimental group received technique coaching and auditory feedback through the computer speakers based on the magnitude of the moments during lifting-lowering (Lift Trainer software, IST, Inc., Chicago, IL). On week 4, the experimental group received the same coaching and auditory feedback. On week 6, all participants were tested under the same conditions as during the baseline testing.

RESULTS AND DISCUSSION

A series of repeated measures analysis of variance [1 between (Group), 1 within (Time)] were performed on the average maximum moments from 6 lift/lowering cycles in all three directions: side-bending, flexor and rotary. For the side-bending and rotary moment the absolute values were used in the calculations. There was a significant group X time interactions for the side-bending moment ($p < 0.05$), the flexor moment ($p < 0.05$) but not the rotary moment ($p > 0.05$)

Figure 1: Average Maximum Side-bending and Flexor Moments (Average Maximum from 6 lift/lowering cycles) for Groups (Experimental, Control) over Time (Pre/Post).

SUMMARY

Coaching combined with auditory feedback during lifting/lowering may be effective in reducing the average maximum side-bending and flexor moments of warehouse workers over the short term (6 weeks).

DYNAMIC Ca^{2+} RESPONSE IN VASCULAR ENDOTHELIAL CELLS SUBJECTED TO VARIOUS FLOWS

INTRODUCTION

Intracellular calcium, a primary regulator of physiological functions, is involved in a variety of mechanotransduction signaling pathways in the vascular endothelium when subjected to different fluid flows. The activity of the constitutive endothelial nitric-oxide (NO) synthase is regulated by the level of Ca^{2+} binding to calmodulin, which plays important vascular physiological functions, such as regulation of blood flow, prevention of adhesion of platelets and leukocytes, etc.

METHODS

The study of Ca^{2+} dynamics in living cells has been revolutionized over the past decade by the development of dyes that exhibit fluorescent property changes upon binding Ca^{2+} . Fura-2 has been extensively used to measure endothelial $[\text{Ca}^{2+}]_i$ in individual cells and isolated vessels and organs using ratiometric fluorescence imaging. Binding to Ca^{2+} under the excitation of UV light, Fura-2 emits green light at the wavelength of 510 nm (Grynkiewicz, 1985; Haugland, 1996). The emission intensity is proportional to the calcium concentration when excited by radiation shorter than approximately 360 nm (isobestic point), and inversely proportional to the calcium concentration under the longer excitation wavelength. This allows one to take the ratio of the emission intensities excited by the source light at two different wavelengths (i.e. 340 nm and 380 nm) commonly used for Fura-2, which is directly related to $[\text{Ca}^{2+}]_i$, and independent of dye concentration, source intensity, and optical path length.

RESULTS AND DISCUSSION

Using an oil immersion lens (100x) and our Zeiss Axioskop 2 motorized focus research microscope for ratiometric imaging, fluorescence signals emitted from Fura-2- Ca^{2+} compounds can be measured under excitations of 340 nm and 380 nm. Figure 1 shows the images of vascular endothelial cells under 380 nm

excitation. At the conference, we will present our measurements of the real-time Ca^{2+} in vascular endothelial cells subjected to various simulated fluid flows. We will also elucidate the interrelationship between the intracellular Ca^{2+} level with the corresponding synthesis and release of various signaling factors important to atherosclerosis development.

IN VIVO TIME-DEPENDENT TENSILE DEFORMABILITY OF HUMAN LUMBAR SPINE SEGMENTS, MEASURED IN TRACTION BATH THERAPY IN TERMS OF AGING, SEXES, WEIGHT AND HEIGHT

Marta Kurutz¹, Eva Bene², Antal Lovas¹, Erika Monori³, Peter Molnár³

¹Budapest University of Technology and Economics, Budapest, Hungary, kurutzm@eik.bme.hu

²Hungarian Institute of Rheumatology and Physiotherapy, Budapest, Hungary,

³Szent Imre Hospital, Budapest, Hungary

INTRODUCTION

In vivo experimental results for tensile deformability of human lumbar motion segments are presented. Elongations of lumbar segments were measured during the usual traction bath hydrotherapy of patients, where the lumbar segments are subjected to pure centric tension, and the effect of muscles can almost be excluded. The aim was to document the time and load related spinal deformations in terms of aging, sexes, body weight, body height and their combinations. Viscoelastic characteristics of segments have also been obtained. Based on the experimental results, in vivo numerical tensile model of human lumbar segments has been created.

METHODS

Weightbath therapy is applied to stretch the different parts of spinal column. The therapy has been introduced by Moll (1953,1956,1963), later described by Bene (1988), biomechanics, indications and contraindications are detailed by Bene and Kurutz (1993). The patients are suspended cervically in water for 20 minutes, loaded by extra lead weights on the ankles. The free elastic suspension in lukewarm water and buoyancy help to relax muscles and let the traction effect optimally develop. Tensile deformations are considered as the decrease of compressive deformations existing before the treatment. Deformations have been measured by using a special subaqual ultrasound measuring method developed by the authors. A mobile ultrasound instrument connected to a computer has completed the weightbath equipment. A special software has been used for analyzing the ultrasound pictures. Deformation of segments was considered as a change of the distance between the spinous processes of neighboring vertebrae. In vivo deformations of segments L3-L4, L4-L5 and L5-S1 were measured. More than 3000 ultrasound pictures of about 400 segments of 155 adult patients have been evaluated in terms of aging, sexes, body weight, body height and their combinations. 88 patients with extra lead loads, 67 patients without extra loads have been measured.

RESULTS AND DISCUSSION

Percentage of deformability of segments is illustrated in Fig. 1 during the traction bath treatment in group with extra loads, for a general lumbar segment LIII-SI, for sexes. By distinguishing the segments, for LIII-IV, the ratio of deformed segments was 52% at t=0 min, 74% at t=3 min, and 85% at t=20 min. For LIV-V it increased from 47% through 60% to 70%, for LV-SI it changed from 29% through 49% to 68%.

Figure 1 - Ratio of segment deformability during the treatment

Figure 2 shows the mean elongations of each segment in the different phases of the treatment. Both the ratio and the value of tensile deformability increased during the traction treatment, with a decrease in distal direction. Just being suspended (t=0 min), due to the decompression and the buoyancy, unloading of discs and segments occur, even without any extra weights, significant elastic deformation develops (0,4-0,6 mm). At the end of the treatment (t=20 min), the mean viscoelastic elongations were 0,8-1,0 mm without, and 0,8-1,4 mm with extra weights. During the treatment, both the ratio and the value of deformability

increased with a decreasing tendency in distal direction.

Figure 2 - Mean elongations of segments during the treatment

Correlation was found between deformability and aging. The scales of elongations with the associated mean ages demonstrate in Fig. 3 that higher deformation values occur

generally at younger age.

Figure 3 - Elongation decrease vs aging

SUMMARY

By means of a large-scale in vivo experimental analysis the tensile deformability of lower lumbar segments LIII-IV, LIV-V and LV-SI has been numerically documented in terms of certain biomechanical parameters. Time-, age-, sex-, weight- or height-dependence have been numerically verified for each segment. Viscoelastic numerical model was created with elastic and damping coefficients for each segments and sexes, based on in vivo measured results.

AGE- AND SEX-DEPENDENT IN VIVO VISCOELASTIC NUMERICAL TENSILE MODELS OF HUMAN LUMBAR SPINE SEGMENTS

Marta Kurutz

Budapest University of Technology and Economics, Budapest, Hungary, kurutzm@eik.bme.hu

INTRODUCTION In vivo experimental results for tensile deformability of human lumbar motion segments are reported by Kurutz *et al* (2002a, 2002b). Based on the measured time related spinal deformations in terms of aging, sexes, body weight and height, large-scaled parameter-dependent numerical viscoelastic models of human lumbar spine segments have been created for tension.

METHODS Segment deformations were measured during the usual traction bath therapy of patients, where the lumbar segments are subjected to pure centric tension, and the effect of muscles can be excluded. Weightbath therapy of spine has been introduced by Moll (1956), biomechanics of the treatment by Bene and Kurutz (1993). In weightbath, patients are suspended cervically in water for 20 minutes, with extra lead weights on the ankles. Deformations of segments were measured by using a special subaqueal ultrasound method reported by Kurutz *et al* (2002). Time-related in vivo deformations of segments L3-L4, L4-L5 and L5-S1 were documented. More than 3000 ultrasound pictures of 409 segments of 155 adult patients have been evaluated.

For the viscoelastic numerical model, the versions of Poynting-Thomson spring-dashpot models have been used (Figs 1 and 2). Spring constants c_1 and c_2 represent the elastic properties, damping coefficient k concerns the creep effects. From three time-related measured elongation values u_1 , u_2 , u_3 , the elastic and damping moduli c_1 , c_2 and k have been determined for all the 409 measured lumbar segments with the creep functions for both model A and B.

Figure 1 – Viscoelastic model A

We supposed that the last state at the 20th minute of the treatment concerns the steady state of the viscoelastic process. Creep functions of the lumbar segments have been obtained in terms of sexes, aging and other parameters.

Figure 2 – Viscoelastic model B

RESULTS AND DISCUSSION At the beginning of treatment, just being suspended in water ($t=0$ min), due to the decompression and buoyancy, unloading of discs and segments occur, so significant elastic deformations develop. The initial elastic moduli are seen in Fig. 3, demonstrating that the rigidity of segments increases significantly with aging, and increases also in distal direction. Based on the measured time-related elongations in vivo, the creep functions of segments are obtained.

Figure 3 – Initial Young moduli vs sexes and aging

Figure 4 – Creep functions of lumbar segments

Figure 5 – Creep functions vs aging and sexes

Decreasing deformability and increasing damping can be observed in distal direction in Fig. 4. Influence of aging and sexes is illustrated in Fig. 5 for general lumbar segments LIII-SI. Due to the increasing damping with aging, the decreasing creep and deformability is numerically verified. In Kurutz *et al.* (2002a, 2002b) a difference was reported in reaction time of males and females. This observation has been verified by means the creep analysis: while males have higher instant elastic deformations, due to the smaller damping of females, the deformation propagation of women almost overtakes that of the men.

SUMMARY Based on large-scale in vivo experiments, viscoelastic tensile behaviour of human lumbar segments has been numerically verified. Numerical creep models of lumbar segments have been created in terms of several parameters. Elastic and damping moduli with creep functions have been calculated for each case. Mechanical models A and B are offered for numerical aims, to model each of the component organs of lumbar spine segments (vertebrae, discs, ligaments, etc.) in pure centric tension.

APPLICATION OF BIO-ELECTRICAL IMPEDANCE METHOD FOR ESTIMATING THE RATIO OF EXTENSORS TO FLEXORS IN THE MUSCLE VOLUME OF THE UPPER ARM

Masae Miyatani¹, Noriko Ishiguro¹, Yoshihisa Masuo², Hiroaki Kanehisa¹ and Tetsuo Fukunaga¹

¹Dept of Life Sciences (Sports Sciences), University of Tokyo, Japan, cc07725@mail.ecc.u-tokyo.ac.jp, ²Art Haven 9 Co., LTD

INTRODUCTION The force generation capacity of a muscle is closely related to its size. Therefore, to establish the method for quantifying muscle volume (MV) conveniently is important in sports sciences and/or clinical research fields. Recent studies indicated that bio-electrical impedance (BI) method was useful to estimate the muscle volume of the upper arm (Miyatani et al. 2001a). By the use of BI method, however, no study has tried to quantify the MV of muscle group located in either anterior or posterior sites of limbs. On the other hand, we recently found that BI method could be applied to determine the length changes in the muscle and tendon tissues of the elbow flexors (EF) while this muscle group contracted isometrically (Miyatani et al.2001b). This implies that the changes in the length of EF during elbow flexion can be also detected using BI method. Hence, we tried to estimate the ratio of elbow extensors (EE) to EF in the muscle volume (V_{EE}/V_{EF}) by applying an electrical parallel-circuit model constructing the two muscle groups (Figure 1). In this model, we hypothesized five conditions. First, each the muscle volume of EE (V_{EE}) and the muscle volume of EF (V_{EF}) is constant whatever the elbow joint angle (θ) changes. Secondly, the length change of EF ($L_{EF}(\theta)$) is expressed as a function of the changes of θ . Thirdly, the changes in the BI of EE (Z_{EE}) during elbow flexion are very small in comparison with those of EF (Z_{EF}) regardless of θ , because the specific resistivity of EE ($\rho_{EE}(\theta)$) (Gielen et al. 1981) and the length of EE ($L_{EE}(\theta)$) (Murray et al. 2000) act reciprocally to cancel their influences on Z_{EE} during elbow flexion. Therefore, Z_{EE} can be considered relatively constant regardless of θ , and so the whole upper arm BI ($Z_T(\theta)$) reflects $Z_{EF}(\theta)$. Fourthly, $Z_{EF}(\theta)$ is replaced to $Z_T(\theta)$ and expressed as a function of θ and V_{EE}/V_{EF} (Figure 1, eq.1). Fifthly, based on the assumptions mentioned above, V_{EE}/V_{EF} can be calculated using $Z_T(\theta)$ for two known θ conditions (Figure 1, eq.2). The present study aimed to examine this hypothesis by comparing the data obtained from MRI method.

Figure 1: The principle of the estimation for the ratio of EE to EF in the muscle volume using BI method.

METHODS Subjects were thirteen healthy adult men (n=6) and women (n=7). Z_T of the right upper arm (shoulder-to-elbow) was measured at each of elbow joint angles of 180° and 70° by the use of a BI analyzer (Muscle α , ART HAVEN 9, Japan) with an operating frequency of 50KHz at 500 μ A. MRI method was used to determine the MV values of the EE and EF in the right arm. Transverse scans were carried out with 1cm thickness with no gaps, from the elbow joint to the head of humerus. By summing up the anatomical cross-sectional area of each of EE and EF along its length and then multiplying by the interval of 1cm, the MV was determined. V_{EE}/V_{EF} in the MV determined by MRI method was calculated and referred to as $V_{EE}/V_{EF} \text{ (MRI)}$. In the case of BI method, $V_{EE}/V_{EF} \text{ (BI)}$ was estimated from the relation between the ratio of Z_T at 180° ($Z_{T(180)}$) to that at 70° ($Z_{T(70)}$) ($Z_{T(180)}/Z_{T(70)}$) and $V_{EE}/V_{EF} \text{ (MRI)}$.

RESULTS AND DISCUSSION $V_{EE}/V_{EF} \text{ (BI)}$ was significantly correlated to $V_{EE}/V_{EF} \text{ (MRI)}$ with a correlation coefficient of 0.832 ($p < 0.01$, $\text{SEE} = 0.123:11.0\%$, Figure 2). This validates the electrical parallel-circuit model used in this study and implies that $V_{EE}/V_{EF} \text{ (MRI)}$ can be estimated using Z_T value determined at two elbow joint angles. Since the total MV of EE and EF can be determined by dividing the right upper arm length² by Z_T at 180° (Miyatani et al.2001a), the MV of each of EE and EF can be estimated by using $V_{EE}/V_{EF} \text{ (BI)}$.

Figure 2: The ratio of EE to EF in the muscle volume measured using BI method ($V_{EE}/V_{EF} \text{ (BI)}$) and MRI method ($V_{EE}/V_{EF} \text{ (MRI)}$)

OPTIMAL ANALYSIS OF MUSCULOTENDINOUS FORCE DURING INDEX FINGER MOTION

Shigeru Tadano¹ and Kazuki Fukada²

Division of Mechanical Science, Hokkaido University, Sapporo, Japan

¹Professor, tadano@eng.hokudai.ac.jp, ²Graduate Student

INTRODUCTION

Hand-finger motion realizes fundamental activities on human daily life as pinching, gripping and holding. In the human finger, because so many muscles and tendons run to be intermixed, it is impossible to measure these forces using a bioinstrumentation as myoelectric potential. Therefore, some numerical analyses have been tried for the estimation of musculotendinous force. The aim of this work is to propose a three dimensional model of the index finger and to analyze musculotendinous forces and joint reaction forces using optimizing method of numerical analysis for an indeterminate structure.

METHOD

When a three dimensional model of index finger was constructed with eight muscles and tendons, the following assumptions were considered; no friction in joints and tendon sliding, bone as a rigid body without mass, DIP and PIP joint in one axial rotation and MP joint in two axial rotations. Each musculotendon is defined as a straight element from the origin to the insertion. Positions of the origin and the insertion were measured from X-ray CT image. The static analysis, which uses static equilibrium equations of force and moment, was applied to this model. Because twelve unknown parameters of eight musculotendinous forces and four joint reaction forces must be solved from six equilibrium equations on force and on moment in three-dimensional directions, this analysis is statically indeterminate problem of structural analysis. The SQP method (Successive Quadratic Programming Method) of optimization analysis was applied to this model. For constraint conditions, musculotendinous forces are always compression and joint reaction force at only vertical direction is always compression. The optimization process is to minimize the objective function defined as the summation of force square, taking these constraint conditions into account.

RESULTS AND DISCUSSION

The touch-typing motion was analyzed as a typical finger motion. In this case, the index finger moves in flexion-extension by three finger joints in wrist joint fixation at middle position. Vertical force to axial direction against radius was applied at the tip of index finger. Every joint angle was decided in advance. Figure 1 shows the result of touch-typing.

Here muscle and tendon force at each position are expressed with nondimensional value divided by applied force. From the figure, every force varied with moving. For example, radial interosseus (R) decreased gradually with moving, and terminal extensor tendon (T) showed zero value to No. 3 position, and increased after that. It is clear that the total force shows the minimum value at No. 4. This position will be the optimal position at touch-typing.

SUMMARY

From X-ray CT image, a 3D musculotendinous model of index finger could be constructed in faithful to the anatomical structure. Using the SQP method of the optimizing analysis, musculotendinous forces or joint reaction forces at index finger in touch-typing motion could be calculated and an optimal posture could be confirmed.

PREDICTION OF THE METABOLIC ENERGY CURVE DURING RUNNING AGAINST INCLINES: IMPLICATIONS FOR DELTA EFFICIENCY

Kirsten E. Bijker, Gert de Groot and A. Peter Hollander

Institute for Fundamental and Clinical Human Movement Sciences, Faculty of Human Movement Sciences, Vrije Universiteit Amsterdam, the Netherlands, K.Bijker@fbw.vu.nl

INTRODUCTION

The delta efficiency during running is much greater than the muscle efficiency. Recently, Bijker et al. (submitted) suggested that the combination of eccentric and concentric leg muscle actions, together with the large difference in their efficiency explains the great delta efficiency during running against small inclines. With running against steeper inclines, the amount of concentric contractions increases whereas the amount of eccentric contractions decreases and eventually becomes negligible (Taylor, 1994). This consequently should lead to an exponential increase in the oxygen consumption and a smaller delta efficiency. Our first hypothesis was that the delta efficiency during running against steep inclines is much smaller than the delta efficiency based on small inclines.

During level running, the horizontal component of the ground reaction force (CRF) can be divided into a braking and propulsive phase. The braking phase includes eccentric muscle actions, whereas in the propulsive phase concentric contractions dominate (Dickinson et al., 2000). Our second hypothesis was that the shape of the metabolic energy curve during running against inclines is determined by changes in braking and propulsive impulses.

METHODS

To run against steep inclines at a submaximal level, we used a reduced gravity simulator (Donelan and Kram, 2000). Seven subjects ran against inclines ranging from 0-13% at 50% simulated reduced gravity. Delta efficiencies were calculated from the regression coefficients of the regression lines, describing the external mechanical and metabolic power data. Braking and propulsive impulses were obtained by integrating respectively all negative and positive values of the GRF component parallel to the treadmill surface over the time of ground contact. Braking and propulsive impulses were divided by efficiencies of eccentric and concentric exercise (80% and 18%, Minetti et al., 1994) to obtain a metabolic measure of both muscle action types. For each incline, these concentric and eccentric metabolic measures were summed to obtain predicted metabolic energy curves in arbitrary units.

RESULTS AND DISCUSSION

With running against steeper inclines, all subjects showed an exponential increase in oxygen consumption (Fig. 1). Consequently, the delta efficiency during running was dependent on the range of inclines used. For inclines ranging from 0-5%, the mean (\pm SEM) delta efficiency was 59% (\pm 9.3), whereas for the inclines, ranging from 8-13%, the mean delta efficiency was 24% (\pm 1.5) ($p < 0.05$).

Furthermore, with running against steeper inclines, the propulsive impulse increased, whereas the braking impulse decreased. Figure 1 shows the mean measured as well as the mean predicted metabolic energy curve, which was based on braking and propulsive impulses. The correlation coefficient between both metabolic energy curves was 0.99.

Figure 1: mean measured (squares) and predicted (triangles) metabolic energy consumption for running in a 50% simulated reduced gravity situation.

The results of the present study clearly show that the delta efficiency during running is dependent on the amount of applied load (incline). Furthermore, the results confirm our hypothesis that changes in horizontal braking and propulsive impulses determine the shape of the metabolic energy curve and consequently also the delta efficiency during running against inclines. We therefore suggest that the delta efficiency during running is mainly determined by the relative contribution of concentric and eccentric muscle actions.

QUANTIFICATION OF SOFT TISSUE VIBRATION FREQUENCY IN HEEL-TOE RUNNING

Benno M. Nigg, Katherine A. Boyer, James M. Wakeling

Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

Impact forces in heel toe running can be characterized as an input signal with an amplitude and frequency, typically 10-20Hz. It is expected that vibrations of the soft tissue packages of the lower extremities would be initiated and that they would be substantial when the frequency of the impact force and natural frequency of the specific soft tissue package are close. Oscillations do occur but are small and of short duration indicating that the soft tissue packages oscillate in a damped manner. To avoid resonance phenomena the muscle(s) in a soft tissue package must change their mechanical properties by changing the natural frequency and/or the damping characteristics (Nigg and Wakeling, 2001). It has been shown for isometric and isotonic contractions of the leg that such changes in mechanical properties do occur through changes in muscle activity (Wakeling and Nigg, 2001). However such changes under the dynamic conditions of human locomotion have yet to be documented. Thus, the purpose of this study was to test the hypothesis that soft tissue vibration frequencies change within one step of heel-toe running. It is expected that the maximum vibration frequency of the soft tissue packages will occur shortly after the impact force peak as a protective measure to avoid coinciding with the input frequency.

METHODS

Accelerations of three soft tissue packages of the lower extremity (gastrocnemius, quadriceps and hamstrings) and ground reaction forces were measured for ten recreational runners during heel-toe running on an indoor track surface. The running speed remained constant. Data was collected for 10 steps using a remote data acquisition system. The vibration frequencies in three orthogonal planes were determined by tri-axial accelerometers mounted on the skin overlaying the selected soft tissue packages. A uni-axial accelerometer (<1g) was attached to the heel cup of the right running shoe to determine the time of first ground contact for each step. Voltage signals from both the accelerometers were transmitted to a base computer via a wireless transceiver.

The accelerometer signals were resolved into time- frequency components using wavelet techniques (von Tscharner, 2000). The mean frequency at each sampled time was then calculated.

RESULTS AND DISCUSSION

The results showed that the natural vibration frequencies of soft tissue packages change through the stance and swing phases of heel-toe running. The results from one subject are shown (Fig. 1), the vibration frequency ranges from 9Hz in the swing phase to a peak of 24Hz shortly after impact. Changes in mean frequency during each stride occurred for all three measured soft tissues. These results indicate that soft tissue packages do change their mechanical properties, specifically their mean vibration frequency, during heel-toe running. The peak natural frequency illustrated for one subject, one shoe condition, one specific speed and one soft tissue package is greater than the frequencies measured for impact forces and hence the likelihood of resonance phenomena in this example is minimal. However, it is speculated that selected soft tissue packages show more changes in vibrations for different running speeds or different shoe conditions.

Figure 1: Gastrocnemius mean vibration frequency for axial (dashed), mediolateral (solid), and anterior-posterior (dotted) directions for heel-toe running.

SUMMARY

The results of this study show that under the dynamic conditions of running soft tissue packages do change their mechanical properties.

TRUNK STABILITY AND MUSCLE ACTIVITY: CHANGES IN PERTURBATION ENERGY AND PRELOADS

Gregory Slota and Kevin Granata, Ph.D.

Gslota@Virginia.edu

Motion Analysis & Motor Performance Laboratory, University of Virginia, Charlottesville, Virginia, USA
Departments of Biomedical Engineer and Orthopedic Surgery

INTRODUCTION

Low-Back Disorders (LBD) are a significant musculoskeletal problems in the United States (Bureau of Labor Statistics 1994). Spinal stability may be a primary factor in controlling LBD risk. Stability of the spine is influenced by muscle stiffness and controlled by muscle response strategies.

The control diagram (Fig.1) illustrates the interaction between the trunk stiffness (k) and perturbation invoked muscle response ($G e^{-\tau}$). The combinations of these two factors are the key to the stability of the low-back. The trunk stiffness and reflex gain are related to the recorded EMG preparatory levels and reflex response relative peak values. The goal of this study was to quantify stiffness and muscle responses vs. trunk moment and impact energy.

METHODS

To test stability and muscle activity, an experiment was performed wherein applying static flexion loads and dynamic sudden loads were applied to the trunk. Eleven males and ten females with no history of low back pain participated after providing informed consent. Trunk and spinal motion, kinetics and trunk muscle activities were recorded during each trial. Static extension exertions (preload) required the subjects to maintain an upright posture against a horizontal flexion force of 110 N applied to the trunk. Sudden-loads were applied by applying brief (less than 10 msec) flexion perturbations of approximately 75N (1.0m drop) and 37.5N (0.5m drop) independent of the static extension exertions.

The pelvis and lower extremities were restrained while the added loads were connected to the subject via a pulley system and chest harness. EMG signals were collected from the left and right erector spinae (ES) as per Mirka (Mirka, 1991) and normalized with respect to maximum voluntary contractions.

RESULTS AND DISCUSSION

Trials, without the added preload, show significant trends wherein increased perturbational forces resulting in increased trunk deflections and increased muscle reflex responses. (Table 1)

With the addition of the preload, significant increases in the preparatory level of the erector spinae muscle groups were observed. With this increase in the muscle activity, there was a reduction in the trunk flexion displacement angles, indicating increased muscle stiffness, and a significant decrease in the muscle responses.

$$T/M = 1 / [s^2 + bs + (k + G^{-\tau} - V)]$$

Figure 1: System control diagram

SUMMARY

To maintain the stability of the trunk when perturbed by an external moment, the combination of the trunk stiffness (k) and the muscle reflex ($G e^{-\tau}$) must be greater than gravitational energy (V). Greater perturbations elicit increased muscle reflexes response. If the trunk stiffness is increased, then a reduced muscle response is required to maintain stability. Stability is achieved and improved upon with the addition of the preload.

MARKER-BASED RECONSTRUCTION OF THE KINEMATICS OF A CHAIN OF SEGMENTS; A NEW METHOD THAT INCORPORATES JOINT KINEMATIC CONSTRAINTS

Miriam Klous¹ and A.J. "Knoek" van Soest²

¹Institute of Sport Science, University of Salzburg, Salzburg, Austria, miriam.klous@sbg.ac.at

²Faculty of Human Movement Sciences and IFKB, Free University, Amsterdam, The Netherlands

INTRODUCTION

Several methods have been proposed (Veldpaus et al. 1988, Cappello et al. 1997) to minimize noise error in the reconstruction of kinematics based on skin marker measurements. In these studies, segments are described as independent rigid bodies. Hence, "dislocation" of the joints is generally found (Kepple et al. 1994), resulting in unreliable values of joint kinematics (Lafortune et al. 1992) and in problems in inverse dynamics modeling. The purpose of this study was to devise a new method for (1) optimal estimation of the joint positions in segmental frames of reference and (2) reconstruction of the kinematics of a chain of rigid body segments from noisy marker position data, that takes the joint kinematic constraints into account.

METHODS

The method consists of two parts: (1) a method to automatically determine the joint positions in order to minimize systematic errors in a multi-link model, (2) a method to determine the position and orientation of a chain of rigid segments, taking joint kinematic constraints into account.

Method to determine joint center positions

When analyzing a multi-link chain of segments in 2D inverse dynamics, joints are usually modeled as hinge joints. Thus, the movement of markers on a segment, in a frame of reference, fixed to an adjacent segment should be part of a circle, the center of which is the joint axis (Fig. 1). Based on Crawford (1983), an analytical method was formulated that yields the parameters of the circle that best fits the marker paths. This method was extended to 3D, where hinge joints can be generalized to ball and socket joints and a sphere is fitted.

Optimization method for reconstruction of the kinematics of a chain of rigid segments, including joint kinematic constraints

This method combines a numerical with an analytical approach. The numerical part determines the translation vector of the overall model with a least square method. The analytical part determines the orientation of all the segments. So, for any number of segments in 3D, the numerical part is concerned with finding three variables, the rest is calculated analytically.

The analytical part is based on a study of Veldpaus et al. (1988) in which a least square algorithm is described to estimate the translation vector and rotation matrix of a moving rigid body. The important characteristics of this algorithm are that the translation vector is calculated for the center P_0 , which is a virtual marker calculated from the marker distribution and that the rotation matrix is calculated based on the distribution of the markers around this center. This characteristic is used to create an optimization method for a multi-link chain.

In our method the measured marker positions for any segment

are first reflected in the point of rotation, so the point of rotation is the center of the marker distribution. This is also done for the modeled marker positions by reflecting the markers in the model joint position. This guarantees that the optimization routine will put the joint positions exactly on top of each other. The unaffected DOF for the optimization routine are in the rotation matrix. So, the optimal rotation matrices can be determined and the joint position will match.

To validate this method, virtual data in 3D were created for a chain of three segments with five markers each. The difference in accuracy between the optimization method for a chain of segments (OMC) and an analytical optimization method in which each segment is treated separately (OM) (Veldpaus, 1988) is analyzed by adding noise to the data. The minimized value is defined as the absolute Euclidian distance between the 'measured' coordinates and the reconstructed coordinates. This value is used to express the accuracy of the methods.

RESULTS AND DISCUSSION

The minimized value for OM and OMC as a function of the standard deviation of noise are shown in fig. 2. The results obtained with the OM follow the standard deviation of the noise as expected. In OMC, joint dislocation does not occur by definition, at the cost of a slightly higher average marker error (see Fig. 2).

Figure 2: Minimized value for OM and OMC for different noise gain

It is concluded that OMC yields a description of kinematics that lends itself, at least theoretically, better to a subsequent inverse dynamics analysis than the classical OM method. In future work, we will establish the consequences of the assumptions made in kinematic modeling on the results of inverse dynamics calculations.

IN VIVO MUSCLE FIBER BEHAVIOR OF THE TRICEPS SURAE MUSCLES DURING CONCENTRIC AND ECCENTRIC PLANTAR FLEXIONS

Chino K., Oda T., Kurihara T., Kawakami Y., Kanehisa H., Fukunaga T.

Department of Life Science (Sports Science), University of Tokyo, Komaba, Japan, cc16731@mail.ecc.u-tokyo.ac.jp

INTRODUCTION

Isokinetic dynamometers have usually been used to study force-velocity relationship of in vivo human muscles. In many of these studies, velocity was measured as angular speed at the joint and not as linear velocity of muscle fiber shortening and lengthening. Some studies have tried to estimate muscle shortening velocity from isokinetic data (Bobbert M. F., van Ingen Schenau G. J. 1990, Martin A. et al. 1994), but their models required a number of assumptions and approximations. In the present study, muscle fiber behavior of the gastrocnemius and soleus muscles during isokinetic concentric and eccentric actions was directly measured in vivo.

METHODS

The subject (n= 7 men) was seated on an electrical myometer with the right knee extended and performed maximal voluntary concentric and eccentric plantar flexions at four different angular velocities: 60, 120, 180 and 240deg/s. The range of motion was -15 to +35deg (0; neutral position, positive values are planter flexion angles). With the use of ultrasonography, longitudinal sections of medial gastrocnemius (MG) and soleus (SOL) muscles were visualized continuously (65 frames/s) during contraction. From the ultrasonographic images, muscle fiber lengths and pennation angles of MG and SOL were measured.

RESULTS AND DISCUSSION

From the time course of muscle fiber length (Fig.1), muscle fiber shortening and lengthening velocities of MG and SOL were calculated (Fig.2). There was almost a two-fold difference in the mean velocities between MG and SOL (Fig.3). Considering the effect of pennation angle, muscle shortening and lengthening velocity was also calculated. The difference between MG and SOL became smaller, but the change of the velocity with increasing angular velocity was larger in MG than in SOL. These results show different force-velocity characteristics between MG and SOL even during isokinetic contraction.

SIMULATING DETAILED KINEMATICS OF THE SPINE – EXTRAPOLATION OF FUNCTION FROM THE 3D FORM OF STRUCTURES DERIVED FROM THE VISIBLE HUMAN CT DATA BASE

William L. Buford, Jr., Clark E. Andersen

Orthopaedic Biomechanics Laboratory, Department of Orthopaedics and Rehabilitation,
University of Texas Medical Branch, Galveston, TX 77555-0892, wbuford@utmb.edu

INTRODUCTION

Form and function have long been synergistic in the understanding of skeletal kinematics. For example, the understanding of thumb carpometacarpal motion has been interpreted based upon the toroidal shape of the first metacarpal and trapezial joint surfaces. Resultant axes extrapolated from these shapes are two non-orthogonal, non-intersecting lines – one for flexion-extension motion running through the trapezium and the other for abduction-adduction running through the base of the first metacarpal (the AbAd axis is linked to the FE axis) [1]. Iterative adjustment of these axes with a detailed, interactive, real-time kinematic data structure assists in definition of the joint kinematics including limits in the ranges-of-motion. This becomes true for many other joints and coupled with a variety of experiments lends well to the iterative improvement of kinematic simulation [2]. Can this method be applied to kinematics of the spine? What level(s) of detail will be required? This report investigates these questions with the use of a kinematic hierarchical structure developed from the highest density CT scans available from the male Visible Human Data Set.

METHODS

The simulation development environment is a dual 700Mhz Pentium IV with Windows 2000 using Visual C++ v5.0, and OpenGL with the GLUT Library. The graphics driver is the Tornado with Evans & Sutherland's Realimage technology. In addition to mouse and keyboard interactive methods, this system utilizes pop-up menus with control widgets and 6 DOF control using a Spaceball (Spaceball model 2003, Spacetec IMC Corp., Lowell, MA). Programs developed in C++ and OpenGL are transferrable between NT and Unix systems with minor program modification. Use of the system for simulation of the extremities is described in [2].

Structures for the spine kinematic model are derived from axial computerized tomography (CT) slices of the NLM Visible Human (male). The frozen CT structure is used because the slices are spaced at one mm apart (maximum vertical resolution). Also, because the data set was built to maximize planar resolution, the in-plane pixel size varies from .53 to .94 mm/pixel. The images are run through the MIMICS interactive software package that creates triangular polygons representing each bone. MAGICS software (MIMICS and MAGICS are from Materialise, Inc) is used where required to edit and combine the polygonal files. Files (in .stl format) for each bone then serve as the base level structures in the OpenGL kinematic hierarchy.

RESULTS

The Figure to the right is the spine simulation data structure including preliminary defined axes of motion (3DOF for all but atlanto-occipital with 2 and atlanto-axial with 1). The entire structure is nearly 500,000 triangular polygons (ranging from 6000 [C6] to 130,000 [pelvis]). 28 bones and 73 axes are linked in the hierarchical kinematic structure. Initial placement of axes and range-of-motion is based upon generalized knowledge from the literature.

SUMMARY

When viewing form at the level-of-detail represented in this Figure the structural detail derived from the NLM database is sufficient. However, since separation at the facet joints is approximately 1 pixel for most segments, optimization of the finer motions will require improved resolution (initial estimate of .25 mm, which worked quite well in the small joints of the fingers [2]). In the meantime, the simulation reported here is proving to be a provocative heuristic modeling environment. For instance, the intertransverse ligament (at T08-T09 in the Figure) experiences nearly 9% strain when the structure above T08 is rotated $\pm 2^\circ$ about neutral (lateral flexion).

A METHOD FOR ANATOMICAL - FUNCTIONAL STUDIES OF ARTICULAR JOINTS

Sandra Martelli

Istituti Ortopedici Rizzoli, Lab. Biomechanics, Bologna, Italy
s.martelli@biomec.ior.it

INTRODUCTION

At present the relative motion of two rigid bodies or joints can be tracked in two ways. Either recording motion through reference markers attached to the two bodies (e.g. RSA or spatial linkages), or recording the shapes of the surfaces as they move on each other to deduce information on the nature of the relative movements (e.g. dynamic x-rays or MRI). None of the two approaches, separately, can handle the analyses of the correlation between anatomical structures and kinematic parameters during non-static motion. In this paper we describe a new methodology for the acquisition and computer elaboration of joint anatomy and motion and the study of their correlation (E.P. 00128769.7, Dec 30, 2000)

METHODS

The acquisition protocol consists in standard digitization of surfaces for anatomical acquisition and standard use of the electrogoniometer FARO Arm (FARO Technologies, Lake Mary, FL, USA) to record motion. In addition a fast "matching phase" has been designed and tested to allow the accurate correlation between anatomy and motion. The computer elaboration allow the 3D display of the joint state during the recorded motion, the computation of 2D sections of the digitized structures and least square fitting with lines or conics, the computation of standard kinematic models such as Euler angles and helical axis. Moreover original dynamic computations can be performed to check and quantify contact areas, tracking of points and axis during motion, relative translation and rotations of bones, user's defined anatomical landmarks or calculated objects.

An accuracy study was performed on mechanical models and through numerical analysis of the software and simulation. The method was also used for an experimental geometrical and functional analysis of the knee in order to test its practical performances (Figure 1).

RESULTS

In tests of geometric acquisition on a perspex cylinder, a perspex parallelepiped and a metal flat and in tests of sliding and rotations of the geometric models and of a 2-degrees-of-freedom hinge the method yielded the following accuracies: the anatomical structures are reconstructed with 0.3 mm precision, the kinematic features are computed with 0.3mm and 0.8° precision, and all computations concerning the use of

both geometrical and kinematic data with less than 1 mm and we expect 1.5° accuracy (including tracking of numerical errors). Moreover, the error on the computed geometrical or purely kinematic results equals the acquisition error (due to equipment and experimental conditions), while the error on reconstructed motion of geometrical data could be double.

Figure 1: Use of the method to image the knee joint during the passive range of motion. On the left the acquisition phase; on the right the computer reconstruction of the joint at 90° flexion.

DISCUSSION

The main advantage of this methodology is the possibility of making fast, accurate and comprehensive analyses of individual knee behavior. It could be used easily in new computer technologies for assisted medical treatment, be particularly useful for knee model validation or to study the anatomical position of helical axes, to track instantaneous translation in diarthroid joints, such as hip or shoulder, to perform instrumented examinations instead of manual ones.

The disadvantage to the present method is that one of the two rigid bodies must be fixed and the need to expose involved structures. Therefore the method is well suitable for in-vitro studies, eventually open surgery, but difficult to use in clinical diagnosis, minimally invasive interventions or in vivo measurements.

A TRANSVERSELY ISOTROPIC AND TRANSVERSELY HOMOGENEOUS MODEL OF CARTILAGE INCLUDING CHONDROCYTES AND A STATISTICAL DISTRIBUTION OF COLLAGEN FIBRES

Salvatore Federico¹, Walter Herzog², John Z. Wu², Guido La Rosa¹

INTRODUCTION

The mechanical properties of articular cartilage are determined by its microstructure. The arrangement of the collagen fibre network, and the distribution of the chondrocytes are such that cartilage can be modelled by a transversely isotropic and transversely homogeneous composite, the transverse plane being parallel to the articular surface and the cartilage-bone interface. In this work, the homogenisation procedure of Qiu and Weng for aligned inclusions (1990) was extended to take into account an inclusion phase in which the orientation of the inclusions follows a statistical law. This approach is used to represent collagen fibres in cartilage: collagen fibres are perpendicular to the cartilage-bone interface in the deep zone, parallel to the surface in the superficial zone, and the orientation is almost random in the middle zone. A directional averaging method for any statistical distribution of the orientation of the inclusions is proposed, in order to substitute the fibres with a phase of “equivalent aligned inclusions”.

METHODS

In the Qiu-Weng method (1990), the elasticity tensor L for a mixture of $N + 1$ phases (phase 0 is the matrix) is given by:

$$L = [\sum_{r=0}^N c_r L_r A_r] [\sum_{r=0}^N c_r A_r]^{-1} \quad (1)$$

For each phase r , c_r is the volumetric concentration, L_r is the elasticity tensor, and A_r is the average strain-concentration tensor of a single r -th phase inclusion embedded in an infinite matrix.

Neglecting the fluid phase, cartilage is modelled as a tri-phasic composite: proteoglycan matrix (index 0), cells (index c) and collagen fibres (index f). To show the proposed method, a parallelepiped cartilage sample, cut such that the top base is the cartilage surface and the bottom base is the interface with the subchondral bone, is considered. The 1-axis of the global reference frame $\{e_1, e_2, e_3\}$ is perpendicular to the bottom base. Since the morphologic properties of cartilage (cell concentration and shape, fibre concentration and orientation) change as a function of the distance from the bone-cartilage interface, all physical quantities depend on the non-dimensional distance $\xi \in [0,1]$. Substitution of the fibre phase with the “equivalent aligned inclusions” phase (indicated by the index a), is made through three steps: 1) calculation of the tensor A_f for a generic fibre whose tangent is parallel to the e'_1 direction (defined by the latitude $\vartheta \in [-\pi/2, \pi/2]$ and the longitude $\varphi \in [-\pi, \pi]$, with respect to $\{e_1, e_2, e_3\}$), in the local reference frame $\{e'_1, e'_2, e'_3\}$; 2) calculation of A_f in $\{e_1, e_2, e_3\}$; 3) calculation of A_a for phase a via the directional average:

$$A_a(\xi) = (1/2\pi) \int_{-\pi}^{\pi} \left[\int_{-\pi/2}^{\pi/2} \gamma(\vartheta; \xi) A_f(\vartheta, \varphi) d\vartheta \right] d\varphi \quad (2)$$

$\gamma(\cdot; \xi) : [-\pi/2, \pi/2] \rightarrow \mathbf{R}_0^+ : \vartheta \mapsto \gamma(\vartheta, \xi)$ is a (normalized) probability distribution in the variable ϑ , having ξ as a parameter, and not depending on the longitude φ (in order to respect the restraint of having transverse isotropy). $\gamma(\cdot; \xi)$ is built such that: for $\xi \rightarrow 0$ (bone-cartilage interface) it is highly peaked around $\vartheta = 0$ (vertical fibres), for $\xi \rightarrow 1$ (articular surface), it is highly peaked around $\vartheta = \pm \pi/2$ (horizontal fibres), for ξ in the neighbourhood of the value $1/2$ (middle zone), it is almost flat (randomly oriented fibres).

RESULTS

The predicted non-dimensional axial and transversal moduli (E_{11}/E_0 and E_{22}/E_0 , where E_0 is the elastic modulus of the proteoglycan matrix) were plotted as a function of ξ , for one of the configurations studied (defined by the form of function γ , fibre concentration, cell shape and concentration).

Figure 1: Non-dimensional moduli as a function of the non-dimensional depth ξ

From the deep to the superficial zone, E_{11}/E_0 decreases by a factor of about 23 (a result that agrees well with the experimental observations of Shinagl et al., 1997), while E_{22}/E_0 increases by a factor of about 4.

CONCLUSIONS

The developed method is able to simulate a variety of different configurations, whose stability can be checked by use of the thermo-dynamical restrictions on the elastic constants of the homogenised mixture. Once the configuration that best models real cartilage is found, accurate FEM models of articular cartilage, involving the fluid phase, can be created for simulation of compression tests and contact problems.

AN INVESTIGATION ON THE VENTILATION OF OPERATING THEATRES

Vasco Campos; Jose CF Teixeira and Senhorinha FCF Teixeira ⁽¹⁾

School of Engineering, University of Minho, Azurem, Guimaraes, Portugal

⁽¹⁾ Corresponding author, st@dps.uminho.pt

INTRODUCTION

In the ventilation of operation theatres, it is required a constant supply of fresh air in the vicinity of the operating table. This is necessary in order to guarantee an acceptable level air quality and to mitigate the propagation of infections and bacteria. The traditional approach is to supply the fresh air from the ceiling as a laminar jet over the operating table. As the air is supplied at a lower temperature than the surrounding air, room cooling is also achieved. The difference in temperature allows the fresh air to be supplied at very low velocities, which is of great importance in terms of human comfort. However, this flow pattern is very much influenced by the presence of various obstacles in the room, particularly those which generate temperature gradients relatively to the surrounding air. Of particular interest is the room illumination and technical equipment. The complexity of the system and the required accuracy for the solution requires the use of a detailed model for the room simulation.

The present paper reports both a numerical and experimental investigation aiming at validating a simulating tool for the ventilation of an entire operating room.

NUMERICAL MODEL

In order to model the non-isothermal flow pattern inside the operating room the conservation equations for both the flow field and the temperature field have been implemented. The two dimensional time dependent equations for the mass, momentum and energy conservation are discretized using a finite volume technique upon a collocated grid. The set of equations is solved using the SIMPLE algorithm. Appropriate boundary conditions are established for the wall temperature, heat sources inside the room and mass inlet and outlet areas. In this, the best configuration for both the temperature and flow velocity can always be achieved.

EXPERIMENTAL DETAILS

In order to validate the numerical calculations, a 1:5 scale model was built. In this rig configuration, the air flow is fed through the room ceiling through a low turbulence inlet section. Upstream, the flow is cooled through a cross flow air-water heat exchanger. The model is built in plexiglass for optical access. The velocity field is measured by a two-velocity component LDA operating in backscatter. The Doppler signals are processed by two Burst Spectrum Analyzers and the resulting information is loaded to a PC for subsequent processing. Room temperature is measured across

the room by a bank of thermocouples linked to a data acquisition board.

PRELIMINARY RESULTS

Figures 1 and 2 show the velocity field and the temperature contours for a symmetrical inlet at the room ceiling and four outlets.

Figure 1: Velocity field.

Figure 2: Temperature contours.

GENDER DIFFERENCES IN LOWER EXTREMITY SHOCK ABSORPTION DURING VERTICAL DROP LANDINGS

Michael J. Decker¹, Michael R. Torry¹, Douglas J. Wyland², William I. Sterett², and J. Richard Steadman²
Steadman♦Hawkins Sports Medicine Foundation¹ and Clinic², Vail, CO, USA, mike.decker@shsmf.org

INTRODUCTION

Landing from a jump is one of the primary non-contact mechanisms for ACL injury (Feretti et al., 1992; Noyes et al., 1983). Several researchers have shown that female athletes have a greater incidence of ACL injury than their male counterparts (Arendt and Dick, 1995; Feretti et al., 1992). Biomechanical performance studies reveal that females execute high-demand activities in a manner that may make them more prone to ACL injury (Colby et al., 2000; McLean et al., 1999). Specifically, reports indicate that the female knee is in a more extended position at ground contact, forcing the ACL to bear greater loads during a period of large eccentric quadriceps force. Further, hamstring activation may be less, or delayed, in females compared to males (Colby et al., 1999; Rozzi et al., 1999). This would indicate that the energy absorption strategy of the lower extremity may have a strong influence on the pre-disposition to ACL injury. However, no study, to our knowledge, has quantified or compared the energy absorption differences between genders in the entire lower extremity. The purpose of this study was to determine whether gender influences the energy absorption strategy during landing.

METHODS

Coordinates of a 13 marker body system (120 Hz, 3D) and ground reaction forces (1200 Hz) were collected from 12 healthy males and 9 females during 60 cm drop landings. All subjects were recreational athletes that were involved in jumping and landing sports at least 3 times a week. Hip, knee and ankle kinematics were calculated for the landing phase. Negative joint work values (energy absorption) were calculated during the first 100 ms after initial ground contact. An independent t-test was used to determine differences in total landing time and maximum knee flexion. A 2x3 (gender x joint) repeated measures ANOVA and Tukey post-hoc tests were used to contrast initial contact position, range of motion and energy absorption between the two groups ($\alpha=0.05$).

RESULTS AND DISCUSSION

Both groups performed soft landings (maximum knee flexion: males, $-93.0 \pm 10.8^\circ$; females, $-98.4 \pm 10.6^\circ$) in the same amount of time (landing phase time: males, 0.191 ± 0.046 s; females, 0.209 ± 0.034 s) (both $p>0.05$). However, the females demonstrated more knee extension and ankle plantarflexion at initial ground contact, and subsequently utilized greater knee and ankle ROM (all $p<0.05$). The males demonstrated no energy absorption differences between the hip, knee and ankle, whereas the females had greater energy absorption values at the knee and ankle compared to the hip. Although both groups demonstrated the greatest amount of energy absorption at the knee, between group differences

indicated that the males performed greater energy absorption at the hip, and the females greater at the knee and ankle (all $p<0.05$).

Table 1. Means and standard deviations (parentheses) for initial contact angle (deg), range of motion (deg) and energy absorption (%BW*ht).

Variable	Hip	Knee	Ankle
Cont-M	-30.8 (7.8)	*-30.0 (7.7)	*-11.3 (5.1)
Cont-F	-24.0 (10.6)	-22.8 (8.0)	-21.3 (9.6)
ROM-M	50.4 (13.0)	*63.4 (9.3)	*41.6 (6.9)
ROM-F	57.9 (13.8)	75.8 (9.1)	58.0 (7.9)
Work-M	*-4.9 (1.4)	*-6.6 (2.1)	*-4.7 (1.4)
Work-F	-3.2 (1.9)	-8.6 (2.2)	-6.4 (1.7)

* $p<0.05$

Although the knee was the primary functional shock absorber, the results indicate that gender does influence the energy absorption strategy of the lower extremity during landing. The males supplemented the large shock absorption role of the knee extensors with the hip extensors, whereas the females supplemented the knee extensors with the ankle plantarflexors. This muscular shock absorption strategy may indicate that the females used a smaller hip extensor, or hamstring, force for a given quadriceps force, that when combined with shallow knee flexion angles at ground contact may contribute to an increased ACL injury rate during the landing maneuver.

Soft landings are generally instructed to prevent ACL injury. Greater knee extension at initial ground contact may be required to perform progressively softer landings. It is well documented that a more extended knee provides a mechanical disadvantage to the hamstring muscles and may allow the quadriceps muscles to pull the tibia anteriorly resulting in larger values of ACL strain. Thus, instructing athletes to have greater knee flexion at contact may be an important addition to current, injury prevention training techniques for soft landings.

SUMMARY

This study provides support to the notion that the higher ACL injury rate in females during landing may be attributed to both kinematic and muscular strategies.

MUSCLE ACTIVATION DIFFERENCES BETWEEN THE UPPER AND LOWER SUBSCAPULARIS MUSCLES DURING ABDUCTION AND ROTATION

Michael J. Decker¹, Michael R. Torry¹, Henry B. Ellis¹, John J. Tokish², and Richard J. Hawkins²
Steadman♦Hawkins Sports Medicine Foundation¹ and Clinic², Vail, CO, USA, mike.decker@shsmf.org

INTRODUCTION

The broad origin of the subscapularis muscle may indicate that the upper and lower portions have different actions. Indeed several investigators have shown that the upper and lower portions of the subscapularis muscle are independently innervated (McCann et al., 1994) and activated (Kadaba et al., 1992). Recent studies (Otis et al., 1994) suggest that the upper and lower portions have different moment arms with varying positions of shoulder rotation and abduction, however, some EMG studies seem to not reflect these anatomical differences (Kadaba et al., 1992). The purpose of this study was to examine the muscle activation patterns of the upper and lower subscapularis muscles during different shoulder rotation and abduction positions.

METHODS

Applied force and EMG data were collected (1200 Hz) from 15 healthy subjects while they performed internal shoulder rotation exercises from 70° of internal rotation to 90° of external rotation at 0°, 45° and 90° of shoulder abduction. Resistance was provided by an elastic resistance device (ERD) and applied force was monitored with a force transducer in line with the ERD. Muscle activities of the upper and lower portions of the subscapularis muscle were monitored with indwelling electrodes (Kadaba et al., 1992). All exercises were performed at a load that could only be performed for five repetitions while maintaining a pace of 54 beats per minute. A 2x3 mixed factor ANOVA was used to contrast mean, peak and average EMG activity (%MVC), and a one-way ANOVA was used to contrast peak applied force (Tukey post-hoc tests, alpha=0.05).

RESULTS AND DISCUSSION

Given the same peak applied force ($p>0.05$), the upper and lower portions of the subscapularis muscle responded differently to internal shoulder rotation across the three positions of shoulder abduction (interaction $p<0.05$). Upper subscapularis muscle activity did not change across the three shoulder abduction positions ($p>0.05$), but lower subscapularis muscle activity decreased from 0° to 90° abduction ($p<0.05$). These changes yielded greater muscle activity values for the upper subscapularis at 45 and 90° of shoulder abduction ($p<0.05$).

The changing muscle moment arms in abduction and rotation may assist in the functional interpretation of the muscle activation differences noted between the upper and lower subscapularis muscles. At 0° of shoulder abduction, both the upper and lower subscapularis muscles have similar internal

rotation muscle moment arms (Otis et al., 1994), thus accounting for their similar muscle activation levels.

The upper subscapularis muscle has a greater abduction moment arm than the lower subscapularis muscle, and this moment arm is progressively greater with external shoulder rotation (Liu et al., 1997; Otis et al., 1994). Thus, upper subscapularis muscle activity may have been consistently large across shoulder abduction positions, and greater than lower subscapularis muscle activity at the 45 and 90° shoulder abduction positions, due to the active performance of both internal shoulder rotation and shoulder abduction.

The smaller shoulder abduction and internal rotation moment arms for the lower subscapularis muscle may indicate that its primary function is to depress the head of the humerus and only supplement internal shoulder rotation or abduction. Further, protraction and upward rotation of the scapula during arm abduction may require less inferiorly directed force from the lower subscapularis muscle. Taken together, progressively decreasing lower subscapularis muscle activity would be logically predicted with greater arm abduction positions.

Table 1. Means and standard deviations (parentheses) for peak applied force (N) and muscle activity (%MVC)

Shoulder Position	0°	45°	90°
Peak Applied Force	268 (29)	268 (32)	271 (31)
Avg Upper Subscap	50 (24)	53 (41)	60 (40)
Peak Upper Subscap	85 (36)	87 (58)	91 (53)
Avg Lower Subscap	40 (28)	26 (19)	15 (11)
Peak Lower Subscap	70 (41)	51 (31)	34 (23)

SUMMARY

Previous descriptions of the muscle moment arms of the upper and lower subscapularis muscles provide support to the muscle activation differences noted during internal rotation at various abduction positions. It was concluded that larger activation levels from the upper subscapularis during greater abduction positions were due to the muscular demands of internal rotation and abduction, whereas the lower subscapularis muscle may act primarily as a humeral head depressor and only supplement internal rotation and abduction.

THE EFFECT OF TIBIAL TRAY SURFACE ROUGHNESS AND INSERT MICROMOTION ON BACKSIDE WEAR

Dwight T. Todd, Bob Jones, and Abraham Salehi
Smith & Nephew, Inc., Orthopaedic Division, 1450 Brooks Road, Memphis, TN 38116,
dwight.todd@smith-nephew.com

INTRODUCTION

Examination of the backside of retrieved tibial inserts has revealed varying degrees of polyethylene wear. Many contributing factors have been suggested including micromotion between the tibial tray and insert, tibial tray surface finish, and patient and surgical factors. The purpose of this study was to assess the effect of tibial tray surface roughness and micromotion on the backside of the insert under identical fatigue loading conditions.

METHODS

The surface roughness of five different commercially available tibial trays was measured with an optical interferometer (RST Plus, Wyko Corp.) before and after fatigue testing. Four measurements were taken from one component of each design. The components tested are designated as designs A, B, C, D, and E. Each cruciate-retaining tibial and femoral component was mounted at 20° flexion in an MTS mechanical test frame with four LVDTs (LBB-375TA-100, Lucas Schaevitz) attached to the test fixture anteriorly, posteriorly, medially, and laterally. Opposing LVDTs were placed in contact with the tray and insert to record the relative motion between the two components. A 2 Hz. compressive sinusoidal load of 222/2224 N was applied for 5 million cycles. Micromotion between the insert and tray was sampled for 20 cycles at intervals of 20,000 cycles. The backside of each insert was examined and photographed under a scanning electron microscope (SEM) before and after fatigue testing.

RESULTS AND DISCUSSION

The polished tibial trays had the smoothest surface and were significantly smoother ($p < .05$) than the roughest tray E, (Table 1). Post-fatigue measurements were taken in the wear area beneath the tibiofemoral contact area. A slight roughening effect was observed for the three smoothest trays after fatigue testing. This effect was statistically significant for tray B ($p < .05$). Conversely, a slight polishing effect was observed for the two roughest trays. The polishing effect was statistically significant for tray D ($p < .05$).

Implant	Surface Finish	Pre-Fatigue R_a (μm)	Post-Fatigue R_a (μm)
A	Polished	$.052 \pm .006$	$.086 \pm .017$
B	Polished	$.088 \pm .004$	$.149 \pm .024$
C	Satin	$.417 \pm .029$	$.440 \pm .018$
D	Glass-bead	$1.203 \pm .026$	$.887 \pm .013$
E	Grit-blast	$3.782 \pm .427$	$3.679 \pm .456$

Table 1: Tibial tray surface roughness

Anterior-posterior (A/P) micromotion between the insert and tray was less than 14 μm for 4 of the 5 knee systems tested

(Table 2). Each of these designs has a locking mechanism that extends medially, laterally, posteriorly, and anteriorly. Insert and tray E yielded significantly more micromotion in the A/P direction than the other tibial components ($p < .01$). The locking mechanism of this tray has opposing points of contact anteriorly and posteriorly.

Implant	A/P (μm)	M/L (μm)
A	$11.18 \pm .100$	8.13 ± 0.70
B	12.70 ± 1.13	10.92 ± 1.20
C	7.62 ± 0.74	10.92 ± 0.89
D	13.97 ± 3.19	1.78 ± 0.75
E	53.34 ± 1.13	4.06 ± 1.29

Table2: A/P and M/L micromotion at 5 million cycles

The prosthesis with the roughest tray surface and greatest amount of micromotion exhibited the most wear on the backside of the insert. The original machining lines of this insert were completely removed after fatigue testing (Figure 1). In contrast, the original machining lines on the backside of the inserts with polished trays were still clearly visible after fatigue testing (Figure 2).

Figure 1: Backside of E insert before (left) and after (right) fatigue testing (50X)

Figure 2: Backside of A insert before (left) and after (right) fatigue testing (50X).

SUMMARY

These results demonstrate that the potential for backside wear increases as the tibial tray surface roughness increases while the locking mechanism permits greater micromotion. Strong peripheral locking mechanisms can reduce but not eliminate micromotion. A polished tray surface should be considered to help reduce the potential severity of backside wear.

EFFECT OF ORTHOPAEDIC SHOES WITH ORTHOSES FOR IMPROVEING THE AMBULATION ABILITY OF DOWN'S SYNDROME CHILDREN

Saiwei Yang, Cheng-Wei Shih,
Institute of Biomedical Engineering, National Yang Ming University, Taipei, TAIWAN.
Email: swyang@bme.ym.edu.tw

INTRODUCTION

In associate with the delay development and musculoskeletal dysfunctions the Down's syndrome children (DSC) also show poor gait functions. The stance phase was longer and step length was shorter than normal subjects. And the gait pattern delays about 18 months and more in comparing to that of normal children who have their mature gait at the age of 2.

The purpose of this study was to evaluate the efficacy of new design orthopaedic shoes without or with orthoses to improve the ambulation ability by using the evaluation parameters of foot pressure and electromyography.

METHODS

Seven aged 5 years of Down's syndrome children, who could walk independently, were recruited. In addition, 24 children aged 4 to 5 years were used as the control group. Basic information and physical evaluation of entire lower extremity was done prior to the gait analysis.

Each subject was asked to walk over 8-meter distance with his own shoes. The DSC group had additional trials for a new designed orthopaedic shoes without orthosis, and followed with orthoses Plantar pressure parameters (measured by Pedar insole sensor system, Novel, Germany) and EMG pattern of anterior Tibialis, Peroneus longus (MA300, Motion Lab, USA) were analyzed to compare the difference between two groups and effect of shoes.

RESULTS AND DISCUSSION

The average cadence of normal subject was 0.85 second with stance phase of 62%. For DSC group, they were 0.95 second and 64%, respectively. The highest peak pressure of normal children of age 4 was located at the lateral calcaneus ($15.34 \pm 5.57 \text{ N/cm}^2$). For children of age 5, it was located at the hallux ($13.77 \pm 4.31 \text{ N/cm}^2$), followed by the lateral calcaneus of ($13.74 \pm 3.30 \text{ N/cm}^2$). Statistically, the two age groups showed no difference in plantar pressure measurement ($p > 0.05$). The DSC with his own shoes had the maximum pressure presented at the metatarsal areas, and the minimum value at lateral toes area. Wearing the orthopaedic shoes, the maximum value shifted to the calcaneus and the minimum value was at the lateral toes and midfoot areas. The plantar pressure distribution was similar to that of normal children. Adding the orthoses the highest plantar pressure was located at 2nd metatarsal head (Fig 1). Down's children have their arch index similar to that of the normal children (0.24~0.32 for DSC, 0.20~0.32 for normal children, respectively) which may imply that the Down's children are not all pes planus.

The general pattern of Down's children was maintained at a firing level during a gait cycle. This might resulted in Down's children to be easily tired when walking. After wearing the orthopaedic shoes w/o orthoses, both could effectively control muscle activities. This effect can increase the muscle endurance and decrease the muscle fatigue.

Figure 1: Peak plantar pressures with different orthoses

SUMMARY

- The Down's syndrome children's presented higher plantar pressure at the metatarsal heads while the normal one had their peak pressures located at heel. This result reveals the step gait pattern of DSC.
- This new design orthopaedic shoes seem to be good for Down's children to rebuilt their arch structure, to correct the foot alignment, to have foot pressure redistributed to normal, and to decrease the energy expenditure during walking. But the arch support may not be suitable for each individual.

INTRODUCTION

The crystalloid perfused isolated heart model has been extensively used for characterizing myocardial function and metabolism. However, because of lower O₂-carrying capacity and higher O₂-tension than blood and without corpuscles, crystalloid perfusates will be perfused differently from blood, especially at a microvascular level. Thus, with a research hypothesis that spatial patterns of crystalloid and blood perfusion within isolated hearts differ, we measured myocardial flow distributions of isolated rat left ventricles under Tyrode and blood perfusion by quantitative digital radiography using a molecular flow tracer, tritiated-desmethylinipramine (HDMI).

MATERIALS AND METHODS

Crystalloid perfused model Isolated rat hearts (12-14 wks) were perfused with Tyrode buffer containing 0.1%BSA at 37°C with the 100-mmHg head pressure according to the Langendorff technique. The perfusate was gassed at 95%O₂ and 5%CO₂, resulting in a pH of 7.4. Perfusion rate was measured with an ultrasonic probe in the aortic inflow line.

Blood perfused model A support rat weighing 6-700 g was anesthetized and ventilated to keep physiological arterial pH and blood gases. Both carotid arteries were connected to a 37°C water-jacketed reservoir, which supplies blood to an isolated rat (12-14 wks) heart with the 100-mmHg head pressure. The coronary effluent was conveyed to another 37°C water-jacketed reservoir and returned to the support rat via a femoral vein.

Reactive hyperemia Isolated hearts were paced at 300 bpm in both perfused models. After the heart was subjected to 30-sec global ischemia, peak reactive flow was measured.

Tracer injection and perfusion imaging HDMI (2 µCi) was injected into the perfusion line. The sample was excised from left ventricular free wall and sliced (10 µm) from subendocardium to subepicardium using cryostat microtome. Twenty-eight slices per heart were exposed to the tritium-sensitive sensor. The HDMI density, i.e., within-layer relative flow, was converted into 10-bit digital data of 100-µm pixels.

Image data analysis Two normalized indices, CV and CA, were used; CV (SD of regional flows/mean flow) is related to global flow heterogeneity and CA is given by

$$CA = [\sqrt{2} C(d) + C(\sqrt{2} d)] / (1 + \sqrt{2})$$

$$C(r) = [\langle m_i \cdot m_j \rangle - \langle m_i \rangle \cdot \langle m_j \rangle] / [\langle m_i^2 \rangle - \langle m_i \rangle^2]$$

where C(r) is the spatial correlation function of flows in regions r µm apart; d is the pixel size; m_i is the HDMI density of the i-th pixel; < > denotes an average over all the pairs of i- and j-th pixels r µm apart. Thus, CA quantitates the degree of

adjacent flow similarity. For the description of resolution-dependence of spatial flow pattern, CV and CA were computed with increasing pixel size up to 800 µm.

RESULTS

In Tyrode- and blood-perfused model, perfusion rate were 18.6±4.4 and 1.4±0.5 ml/min/g, respectively. The reactive hyperemic flow was smaller in Tyrode-perfused than in blood-perfused myocardium (11 vs. 116%). Regional myocardial flows showed lower heterogeneity (CV) and lower local similarity (CA) under Tyrode perfusion (figure 1). The increasing rates of CV and CA with reducing pixel size from 400 to 100 µm were both smaller in blood-perfused model (42 vs. 13% and 22 vs. 9%, respectively).

Figure 1: Myocardial perfusion heterogeneity (CV) and local flow similarity (CA) in Tyrode- and blood-perfused heart.

SUMMARY

These data suggest that the myocardial flow patterns of crystalloid-perfused isolated hearts differ from those of blood-perfused hearts. The less preserved vascular tone and lower flow resistance under crystalloid perfusion will be responsible for lower flow heterogeneity. The corpuscles may function to homogenize the flow within capillary beds.

INTRODUCTION

Electrocardiogram (ECG) reflects the conduction of action potential in the heart. ECG consists of several elements of electronic events in the heart. ECG was widely used for diagnostics of the heart disease as a noninvasive marker. To get enough information directly from the ECG tracings, enough training is necessary for an interpreter. Several computer-aided methods (Arthur, R.M. (1995), Kinoshita, O. (1992)) including R-R interval detection have been designed in the previous studies. To extend its use to the health-care device at home, a simple methodology with spectrum analysis to distinguish irregular conduction from normal one was investigated in this study.

METHODS

The electrocardiogram (ECG) was induced between the left ankle and the right wrist. The electrodes of disk type (diameter of 8 mm) were stuck via conductive gel on the surface near the joint-pivot to minimize intermixture of the electromyogram. After the signal was modified so that the frequencies lower than 0.08 Hz or higher than 1 kHz were cut off through the electric filter, it was converted into digital signal with the sampling rate of 256 Hz, and recorded with a personal computer. The segmented ECG data of one second between P wave and T wave were analyzed with fast Fourier transform (FFT). Data at the base line of ECG were added before P wave, when the cyclic period was shorter than one second.

Normal 30 segments of regular signal were collected from five volunteer human subjects between 21 and 25 years old at rest. Some segments of irregular signal were picked up from these measurements, and the data with compensatory ventricular premature contraction or with interpolated ventricular premature contraction were analyzed.

RESULTS AND DISCUSSION

The ECG spectrum decreases from 20 Hz to 40 Hz. The ECG spectrum can be represented with the range from 1 Hz to 60 Hz.

The data were displayed in the three-dimensional figure, when the interval of analysis was extended gradually from P wave to T wave with a step of 0.04 s. The spectrum at the time of one second shows datum at the whole cardiac cycle.

In the data from a normal ECG, the spectrum was distributed

between 1 and 10 Hz during P-Q interval, while it was distributed 1 Hz and 40 Hz in the whole cardiac cycle. This is because the steepest wave occurs in QRS complex.

In the data both with compensatory ventricular premature contraction and with interpolated ventricular premature contraction, the spectrum significantly decreased between 20 Hz and 40 Hz. This is because of the extension of QRS wave width. Timing of irregular wave in the cardiac cycle did not affect the spectrum distribution.

The R-R interval analysis is useful to detect arrhythmia but is not useful to detect wave modification in a pre-excitation syndrome. The proposed method has enough availability to detect ECG wave change in heart disease, and can be applied to screening test in diagnosis for ventricular premature contraction.

SUMMARY

This paper proposes a simplified methodology to detect irregular conduction of potentials in heart during cardiac cycle using spectrum analysis of electrocardiogram.

INTRODUCTION

We have previously shown that reflex activity mediated by periarticular tissue afferents can be elicited consistently in knee muscles under the application of valgus perturbations at the human knee joint (Dhaher et al., 2002 and Dhaher et al., 2001). Considerable evidence derived from both animal and human studies suggest that signal transmission concerning hip position to the spinal cord play a significant role in modulating reflex transmission during walking and stance. It has been shown also that static hip changes are capable of modulating H-reflex excitability of distant limb muscles such as the soleus muscle (Chapman et al., 1991). There is also evidence that activation of cutaneous afferents registering changes in hip position can influence spinal reflex excitability. Furthermore, studies on decerebrate cats report that hip position is important in initiating the stance to swing transition (Hiebert et al., 1996). In the present study we investigated the effect of the change of hip angle in the modulation of the reflex response originating from periarticular tissue afferents, elicited via application of valgus positional perturbations in the human knee joint.

METHODS

The experiments performed have been described in detail previously (Dhaher et al 2001 and Dhaher et al, 2002) and will be briefly presented below. In summary, after securing the subject's leg in a single-degree of freedom servomotor system, the knee joint was pre-loaded (4° of valgus) to ensure initial stretch of passive joint tissues. The subject was asked to maintain three different knee muscle co-contraction levels as a percent of the valgus passive torque (VPT) measured at the joint's pre-loaded position: 5-10, 10-20 and 20-30% of VPT measured with a six-degree of freedom load-cell. Multiple 7° valgus perturbations were applied at the knee at two different hip flexion angles (90° and 50°) and repeated at all three co-activation levels. Surface electrodes recorded the muscle activity of a flexor, semitendinosus (ST), and an extensor, rectus femoris (RF). The normalized reflex response was then quantified as follows:

$$NR = \frac{EMG_{rms}^{reflex} - EMG_{rms}^{baseline}}{EMG_{rms}^{MVC} - EMG_{rms}^{baseline}} \quad (1)$$

where EMG_{rms}^{reflex} is the time average of the rectified and smoothed EMG during the reflex activity period (computed from the time where the ramp input reaches its peak value and the end of the plateau period of the positional perturbation) $EMG_{rms}^{baseline}$ is the time average of the baseline activity calculated over 100 msec before the onset of the mechanical perturbation, and EMG_{rms}^{MVC} was the time average of the EMG activity recorded over 100 msec at maximum

MVC in flexion or extension. For each muscle, the maximum NR across both hip angles and contraction levels was used to normalize all reflex intensities for the specific muscle.

Figure 1: Normalized reflex activity as a function of hip angle and pre-activation co-contraction level.

RESULTS AND DISCUSSION

The amplitude of the reflex response of both the RF and ST muscle exhibited a statistically significant decrease ($p < 0.001$) with increasing hip flexion (Fig.1). A significant trend of the reflex intensity was seen in the RF as a function of background activation at both hip angles. Specifically, a consistent decline with background activation at 90° and a modal response at 50° was observed for the RF reflex intensity ($p < 0.001$). On the other hand, ST showed statistically insignificant change in the reflex intensity across all contraction levels for both hip angles.

SUMMARY

Our results show that hip extension results in decrease of the reflex response, originating from periarticular tissue afferents at the knee. The observed reduction was consistent in both flexor and extensor muscles. This effect can be attributed to one of three potential factors: 1) vestibular input, 2) hip joint proprioceptors input, and 3) input from muscle spindles of the pre-activated muscles. All these factors taken together indicate that other sensory layers derived from global sensory modalities could potentially influence the local varus/valgus-stabilizing role of reflexes deriving from the joint's periarticular tissue afferents.

PERIODONTAL LIGAMENT BIOMECHANICS OF INTRUSIVE AND EXTRUSIVE ORTHODONTIC LOADING

Stephanie R. Toms, Jack E. Lemons and Alan W. Eberhardt

University of Alabama at Birmingham Department of Biomedical Engineering
stoms@mail.dental.uab.edu

INTRODUCTION

Previous studies of periodontal ligament (PDL) have applied relatively high stresses (>2.5 MPa) to isolated dental units to examine stress-strain behavior (Mandel et al, 1986). The mechanical properties of PDL at low stress (i.e. <0.05 MPa) suitable for orthodontics have not been reported. In the present study, cadaveric specimens of mandibular premolars from adult donors were tested to characterize (PDL) over an orthodontic force range. We hypothesized that stress-strain behavior would be nonlinear and dependent on load direction and anatomic location.

METHODS

Cadaveric specimens of four adult mandibles were sectioned to isolate a premolar and adjacent PDL and bone. Transverse sections ($n=58$), approximately 0.85 mm thick, were made using a water irrigated circular saw. The sections were categorized according to anatomical location as cervical, midroot, and apex.

Figure 1. View of the specimen in the clamping apparatus a) before and b) after load application.

Fixtures were fabricated to clamp the bony part of each specimen firmly and allow for extrusive (out of the socket) and intrusive (into the socket) loading of the sections

immersed in saline solution (Figure 1). Stress was calculated as applied force/A, where $A = \text{tooth perimeter} \times \text{thickness}$. The tissues were preconditioned extrusively to 0.05 MPa stress for two cycles and load-displacement data was taken from the third cycle of loading. After recovery, the specimen was turned over, preconditioned, and load-displacement data was taken for intrusion loaded to 0.05 MPa stress. The student's t test was used to determine differences in calculated shear moduli (Figure 2), based on load direction and anatomic location.

RESULTS AND DISCUSSION

Distinct linear and toe regions were observed for all specimens in both loading directions (Figure 2). The average linear modulus in intrusion (1.043 ± 0.349 MPa/rad) was significantly higher ($p=.001$) than that for extrusion (0.688 ± 0.136 MPa/rad). No significant differences in intrusion moduli (linear and toe) comparing midroot specimens to the non-midroot (cervical margin and apex) specimens were observed. No significant difference was found for the toe modulus in extrusion. However, the linear modulus in extrusion was significantly different for the midroot and non-midroot locations ($p=.0015$). The extent of the toe region was smaller for intrusion (0.1060 ± 0.0778 rad) than extrusion (0.1628 ± 0.0778 rad).

SUMMARY

The current study offers unique information about the nonlinear elasticity of the PDL in the range of orthodontic forces for intrusive and extrusive loading. Less strain is needed to bring the ligament to orthodontic stress in intrusion than extrusion, and linear modulus of midroot regions is less than cervical and apex regions.

Figure 2: Example of stress-strain data of PDL for two loading directions.

FINITE ELEMENT ANALYSIS OF A MANDIBULAR PREMOLAR SUBJECTED TO ORTHODONTIC LOADING: EFFECTS OF PERIODONTAL LIGAMENT THICKNESS AND NONLINEAR MATERIAL PROPERTIES

Stephanie R. Toms, Jack E. Lemons, and Alan W. Eberhardt
University of Alabama at Birmingham Department of Biomedical Engineering
stoms@mail.dental.uab.edu

INTRODUCTION

Finite element analyses offer a means of determining stresses in the periodontal ligament (PDL) for a broad range of orthodontic loading scenarios. Regions of excessive orthodontic stress and potentially pathologic tooth movement can be identified. A comprehensive mathematical description for the PDL has not been reported and is a recognized weakness in computer simulations (Qian et al., 2001). The purpose of this study was to incorporate our own experimental data of PDL geometry and stress-strain relationships as input to a finite element model (FEM) to determine the influence of nonlinear and location-dependent properties on the stresses produced in the ligament due to orthodontic force.

METHODS

A two-dimensional plane-strain FEM of a mandibular premolar was constructed (Cosmos/M, SRAC, Los Angeles, CA) using anatomical data from a cadaver tooth (Figure 1). The model was an assembly of transverse sections of tooth/PDL/bone of the specimen from which nonlinear stress-strain behavior was determined experimentally (Toms et al, 2002). The model had 1674 elements and 5205 nodes, and was composed of dentin, PDL and bone. A line load equivalent of 1 N (extrusive or tipping) was applied to the midpoint of the crown occluso-lingually. The bone was fixed at the base of the mandible.

Figure 1. Finite element model of a mandibular premolar subjected to orthodontic forces on the buccal midpoint of the crown of the tooth.

Material properties for tooth, bone, and linear PDL were taken from previous FE studies (Wilson et al., 1993). Nonlinear material properties for PDL were based on experimental stress-strain data of five transverse sections of tooth/PDL/bone.

Parametric analyses of the model were performed to determine the significance of PDL thickness (uniform 0.25 mm thick, and nonuniform anatomical), linear versus nonlinear elastic behavior of PDL,

and consequence of load direction. Comparisons were made of the maximum principal stresses and shear stress in the PDL of the mandibular premolar.

RESULTS AND DISCUSSION

The maximum principal stress (Figure 2) and shear stress for a linearly elastic PDL did not differ significantly comparing the PDL of uniform width and the nonuniform anatomic model. In addition, predicted stresses were within the orthodontic range, i.e. <0.04 MPa (Boester and Johnson, 1974) for nearly all locations on the root for the linear models. The nonlinear extrusive model, however, revealed maximum principal stresses at the apex and cervical margins in excess of recommended orthodontic levels. Likewise, the nonlinear tipping model had excessive stresses at the cervical margin. The model suggests that the apex and cervical margin areas of PDL are vulnerable to pathologic stress levels

Figure 2. Maximum principal stress in PDL subject to low force on the buccal crown.

SUMMARY

This analysis suggests nonlinear material properties for PDL are required to quantify stress in PDL for orthodontic loading, and that linear material properties may underestimate the stress.

RELAXATION FUNCTION AND A GENERALIZED SOLUTION FOR A NONLINEAR RHEOLOGICAL MODEL OF BIOLOGICAL SOFT TISSUES

David T. Corr¹, Ray Vanderby Jr.² and Thomas M. Best^{2,3}

¹Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada, dcorr@kin.ucalgary.ca

²Department of Orthopedics and Rehabilitation, University of Wisconsin, Madison, Wisconsin, USA

³Department of Family Medicine, University of Wisconsin, Madison, Wisconsin, USA

INTRODUCTION

A nonlinear rheological model (Fig. 1) was recently developed to describe the strain-stiffening behavior displayed by many biological soft tissues (Corr *et al.*, 2001). A closed-form solution had been provided for the specific case of constant-rate (iso-velocity) stretch or shortening (Corr *et al.*, 2001). To extend the model's range of application, this study sought to determine a closed-form solution to constant length (hold) or stepped displacement. Additionally, the relaxation function, $K(t)$, was to be determined, leading to a generalized convolution solution according to the Boltzmann hypothesis. These solutions will broaden the model's range of applicability with respect to loading conditions, and in doing so, allow for its application to a variety of soft tissues.

SOLUTION DEVELOPMENT

By applying equilibrium, the model's (Fig. 1) force becomes

$$F(t) = c\dot{x} = k_1\delta + k_2\delta^2, \quad (1)$$

where x and δ are the displacement from rest of the springs and dashpot, respectively, such that the tissue length, $L(t)$, is

$$L(t) = x(t) + \delta(t). \quad (2)$$

For the case of constant tissue length ($\dot{L}(t) = 0$) the time derivative of (2) gives the relation

$$\dot{x}(t) = -\dot{\delta}(t), \quad (3)$$

which when substituted into (1) and simplified yields

$$\dot{\delta} = \frac{-k_1}{c}\delta + \frac{-k_2}{c}\delta^2, \quad (4)$$

a nonlinear first order differential equation with constant coefficients. Thus, with $a = -k_1/c$ and $b = -k_2/c$, (4) separates to

$$\frac{d\delta}{\delta(a + b\delta)} = dt. \quad (5)$$

When expanded with partial fractions, simplified and integrated, (5) gives the spring displacement equation for constant whole tissue lengths,

$$\delta = \frac{Zae^{at}}{1 - Zbe^{at}}, \quad (6)$$

where Z denotes the arbitrary integration constant.

For a Heaviside step-displacement at time τ , the change in tissue length, ΔL , gives the boundary conditions

$$\Delta L = \begin{cases} \delta & \text{when } t = \tau^+ \\ x & \text{when } t \rightarrow \infty \end{cases}. \quad (7)$$

Figure 1: The nonlinear rheological model, consisting of a parallel arrangement of a linear spring (k_1) and second-order spring (k_2), in series with a dashpot (c). (Corr *et al.* 2001)

GENERALIZED SOLUTION

The tissue's force response to unit-step displacement ($\Delta L = 1$) yields the relaxation function, $K(t)$,

$$K(t) = k_1\delta(t) + k_2\delta(t)^2 \quad (8)$$

where $\delta(t)$ is given by (6) and boundary conditions are

$$Z = (a + b)^{-1}, \quad (9)$$

with $\delta=0$ as time goes to infinity. Thus, for a generalized solution, the relaxation function is convolved to yield

$$F(t) = \int_0^t K(t - \tau) \frac{dL}{d\tau} d\tau, \quad (10)$$

a separable, nonlinear function in time. This general solution gives the effect of numerous incremental steps, and sums their responses; a process termed nonlinear superposition, thereby allowing any arbitrary displacement function to be analyzed.

SUMMARY

These closed-form solutions grant the nonlinear rheological model the ability to interpret data from force-relaxation experiments, as well as piecewise continuous solutions for various ramp-and-hold experiments, when teamed with the previously published iso-velocity solution. Furthermore, the development of a relaxation function lead to a general solution that extends the model's range of applicability to include any arbitrary displacement function, thereby allowing a greater variety of biological soft tissue to be analyzed.

IN VIVO & NONINVASIVE LOAD SHARING AMONG QUADRICEPS COMPONENTS IN PATELLAR MALALIGNMENT

Mohsen Makhsoos^{1,2}, Amanda F. Lin^{1,2}, Jason T. Brizzell⁴, Jason L. Koh³, Li-Qun Zhang¹⁻⁴

¹Rehabilitation Institute of Chicago, ²Department of Physical Medicine and Rehabilitation, ³Department of Orthopaedic Surgery,

⁴Department of Biomedical Engineering, Northwestern University, Chicago, IL, 60611, l-zhang@northwestern.edu

INTRODUCTION

Although unbalanced load sharing among the quadriceps components may be closely related to pathological conditions like the patellofemoral pain (PFP) with patellar malalignment¹, it is not clear how load is shared among the quadriceps components in either healthy subjects or PFP patients. In studies using cadaveric knees or computer modeling, loading of the quadriceps components has been simulated rather differently. For *in vivo* study, it is difficult and impractical to directly measure the force generated by each of the quadriceps components. The purpose of this study was to determine *in vivo* and noninvasively load sharing among quadriceps components (VL, VML and VMO) during isometric voluntary knee extension in PFP patients.

METHODS

Ten healthy subjects and ten PFP patients participated in the study. The subject was seated upright with the knee at 60° flexion and a fiberglass-tape cast was made at the ankle to attach it to a measuring device². The VL, VML or VMO was activated selectively (one component at a time) using electrical stimulation using a pair of surface electrodes. The evoked M-wave from each of the quadriceps components were recorded using a second pair of surface electrodes, together with the isometric knee extension moment. The relationship between the knee extension torque generated by an individual component and the corresponding M-wave over different contraction levels was established for each of the three components. The subject was then asked to generate several steady levels of voluntary knee extension torque (from ~5 N·m to 50 N·m) to match a target knee extension torque displayed on a computer monitor. The same pair of electrodes used to record the M-wave was used to record the corresponding voluntary EMG signal.

Since exactly the same electrodes were used to record the M-wave and EMG signals for each quadriceps component during the stimulation-induced and voluntary knee extensions, respectively, it was assumed that the EMG amplitude of a quadriceps component and the torque generated by the component during voluntary contraction was similarly related as the relationship between the M-wave and knee extension torque established for each component during the stimulation test. The corresponding EMG signals during voluntary contractions were then calibrated with these M-wave-torque relationships to determine load sharing among the different components³. Specifically, the torque ratios of VMO/VML,

VMO/VL, and VML/VL were determined and compared between the PFP and normal groups.

RESULTS AND DISCUSSION

For both normal and PFP groups, the VMO contributed less than VML to knee extension torque, and the VML generated less extension torque than the VL. The VMO and VML of the PFP patients contributed significantly less to knee extension torque than their counterparts in normal controls ($p < 0.001$) (Fig. 1). In normal subjects, the combination of VML and VMO generated roughly the same amount of knee extension torque as the VL. However, in the PFP patients, VML+VMO contributed to the knee extension significantly less than the VL ($P < 0.0001$). In normal group, the VML and VL contracted synergistically to extend the knee and the VML increased its relative contribution when higher knee extension torque was generated. In the PFP group, however, the VML and VMO always played minor role in generating the knee extension torque. Of note is that the remaining quadriceps components, the VI and RF, were not evaluated due to the difficulty involved, which is a limitation of the study.

Figure 1: The torque ratios between individual quadriceps components over multiple subjects.

SUMMARY

The study provided us an *in vivo* and noninvasive way to evaluate load sharing in PFP. It was found that the VMO and VML contributed less to knee extension in PFP patients than that in normal controls.

INTELLIGENT STRETCHING AND EVALUATION OF SPASTIC ANKLES USING A PORTABLE DEVICE

Li-Qun Zhang^{1,4}, Sun G. Chung^{1,2}, Zach Bai^{1,2}, Elton M. van Rey^{1,2}, Thomas H. Grant⁵, and Elliot J. Roth^{1,2}

INTRODUCTION

Spasticity, contracture, and muscle weakness are major sources of disability following brain damages, and their development and recovery are closely interrelated. There is a strong need to treat spastic joints of the patients effectively to reduce spasticity/contracture and evaluate the outcome. The purposes of the studies were to use an innovative stretching device with intelligent control to treat spastic ankles of stroke patients and evaluate the outcome in terms of joint elastic stiffness, viscous damping, tendon reflex gain, reflex threshold, muscle force-generating capacities, and mechanical properties of the Achilles tendon (using ultrasonography).

METHODS

Twenty-four stroke patients with spastic plantar flexors (Ashworth and tendon reflex scales were 2.3 ± 1.0 and 3.0 ± 1.0 , respectively) participated in various aspects of the study. The subject was seated (or supine when ultrasound images were taken) with the foot and leg strapped to a foot attachment and leg support, respectively (Fig. 1). The stretching device was controlled by a digital signal processor which adjusted the velocity every 0.5 ms and make it inversely proportional to the resistance torque. Near extreme ROMs, the increasing resistance slowed down the device and muscles-tendons were stretched slowly and safely. Once a peak resistance torque was reached, the joint was held statically for a period of time. In the middle ROM, the ankle was moved at higher speeds.

Fig. 1. Experimental setup for stretching spastic ankles and evaluating outcome.

To evaluate joint dynamic properties, the stretching device applied small-amplitude random perturbations to the ankle while the subject relaxed or maintained a steady flexion torque during a perturbation trial. Joint elastic stiffness and viscous damping were estimated from the measured position and torque using a system identification technique. Passive ROMs in dorsi- and plantar flexion were evaluated at controlled peak resistance torque in the stretching process. Additionally, under an isometric condition that minimized non-reflex contributions associated with joint movement, Achilles tendon reflex was evaluated with the tapping force and reflex torque taken as system input and output, respectively. Muscle strength was evaluated in plantar and dorsi- flexions. In 4 stroke patients

and 4 healthy subjects, Achilles tendon mechanical properties (length, strain, force, stress) during stretching and triceps surae contractions were evaluated using ultrasonography (ATL HDI 5000 with a 12 MHz linear array probe).

RESULTS AND DISCUSSION

The stretching loosened the spastic triceps surae muscle-tendon unit and increased the passive dorsi-flexion ROM from $10.4 \pm 8.8^\circ$ to $13.3 \pm 10.2^\circ$ at 10 N·m torque ($P=0.004$ with paired t-test). Plantar flexion ROM was increase from $25.2 \pm 11.6^\circ$ to $37.0 \pm 13.1^\circ$ at 5 N·m torque ($P=0.036$). Joint elastic stiffness with triceps surae muscle contraction was reduced after stretching (significant at 2, 3, 7 and >9 N·m, Fig. 2(a)). Similar reduction was observed for viscous damping (Fig. 2(a)). Although some patients showed considerable reduction in tendon reflex gain, stretching-induced changes in tendon reflexes across patients were not significant.

After stretching, the patients were able to generate higher plantar flexion MVC torque (paired t-test with $P=0.005$). The increased force-generating capacity was corroborated by increased torques induced by matched electrical stimulation of the spastic muscles before and after stretching (Fig. 2(b)). It was reported that spastic muscles had elongated sarcomere length¹. Using ultrasonography, we observed that stretching elongated the Achilles tendon in the spastic ankles, which might have put muscle fibers in a better operating range in the sarcomere force-length curves. The stretching might have also changed the abnormal rearrangement of the excessive connective tissues and atrophied muscle fibers in the spastic muscles, which would contribute to the increased force output.

Fig. 2. (a) Elastic stiffness (left) and viscous damping (right) before (black Δ) and after (blue $*$) stretching. (b) Plantar flexion torques induced by stimulating the gastrocnemius at constant intensity at several positions (30, 20, 14, 0, and -2° PF) before (thin lines) and after (thick lines) stretching.

In summary, the study presented a useful approach to treat spastic/contractured joints and evaluate treatment outcome in multiple aspects. Further work needs to be done to better understand the mechanisms underlying spasticity/contracture and the treatment-induced changes.

DOES SIMULATED DORSAL KYPHOSIS ALTER LOWER LIMB KINEMATICS, KINETICS, AND EMG PATTERNS DURING GAIT?

Joshua (Sung) You¹, Joseph Gieck², and Evangeline Yoder³

^{1,3}Department of Physical Therapy, Hampton University, Hampton, VA, U.S.A., sung.you@hamptonu.edu

²Department of Kinesiology, Clinical Orthopedics & Sports Medicine, Head Athletic Trainer, University of Virginia, Charlottesville, VA, U.S.A.

PURPOSE. The purpose of this study was to investigate the effects of simulated dorsal kyphosis on locomotor patterns in normal subjects.

SUBJECTS. Three (3) healthy males and six (6) females aged 20-43 years participated in the study.

METHODS. Using a Vicon motion analysis system, kinematic, kinetic, and electromyographic (EMG) data were collected from the L5-S1 segment, pelvis (S2), and the hip, knee, and ankle joints. Apatio-temporal data was recorded while each subject walked at a constant velocity, with and without, an orthosis, which simulated dorsal kyphosis.

DATA ANALYSIS. Descriptive analysis using means, percentages of means, and standard deviations (SD) was used to analyze the data.

RESULTS. Results are summarized in **Table 1**. Mean values for all kinematic, kinetic moment and power, and EMG values were decreased by 83%, 53%, 17%, and 76%, respectively during 'kyphotic' walking as compared to walking without the orthosis.

CONCLUSION. Results of the study suggest that kyphotic posturing causes increases in kinematic, kinetic and and EMG values, while dorsal kyphosis decreases stride length and velocity.

Figure 1: Hip extension moments between normal (red) vs. simulated kyphotic posture (blue).

RELEVANCE. Analysis of postural kyphosis in the elderly should be the subject of future studies to determine the possible relationships between alterations in gait determinants and falling.

Table 1: Comparison of Spatiotemporal, Kinematic, Kinetic, and EMG Patterns Between Upright vs. Simulated Kyphotic (Right Side Only)

	Stride Length (cm)	Velocity (m/s)	Peak Angular Displacement in hip extension (°)	Peak moment in hip extension (Nm/kg)	Peak Power (W/kg) in hip joint	Peak EMG Amplitude (unitless) in hip extensor
Upright Gait	0.67 ± 0.11	1.03 ± 0.38	5° ± 1.5°	0.7 ± 0.1	1 ± 0.1	0.26 mv
Kyphotic Gait	0.59 ± 0.63	0.94 ± 0.21	-30° ± 4.5°	1.5 ± 0.15	1.2 ± 0.25	1.07 mv

*Please note that spatiotemporal data were acquired from all nine subjects and kinematic, kinetic, and EMG data were collected from three subjects.

MOVEMENT CHARACTERISTICS IN CHILDREN WITH LESCH-NYHAN SYNDROME (LNS)

Joshua (Sung) You¹, Linda Bunker², and Evangeline Yoder³

^{1,3}Department of Physical Therapy, Hampton University, Hampton, VA, U.S.A., sung.you@hamptonu.edu

²Department of Kinesiology, Motor Learning, University of Virginia, Charlottesville, VA, U.S.A.

PURPOSE

The purposes of this study were to determine in children with Lesch-Nyhan Syndrome (LNS): 1) angular accelerations required for forward reaching at the shoulder, elbow, wrist, first digit, and 2) timing characteristics during the reaching.

SUBJECTS

Two (2) ten-year right-handed male fraternal twins with LNS were subjects for the study.

METHODS

While subjects performed in sitting a right-handed forward reaching task, angular accelerations were measured at the shoulder, elbow, wrist and first digit, respectively, using the Ariel Performance Analysis System (APAS)TM. (**Figure 1**).

DATA ANALYSIS

Recorded angular accelerations were analyzed in terms of: 1) movement time (MT), 2) movement units (MU), and 3) initiation, meter, and sequencing of segmental components.

RESULTS (Table 1)

As compared with healthy children, subject's MTs were increased by 50%, and MU's were 80% greater. Segmental movement irregularities included inconsistencies in sequencing and dysmetria.

CONCLUSION

Movement impairments in the study subjects demonstrated patterns consistent with extrapyramidal disorder.

CLINICAL RELEVANCE

Objective measurement of impairments in children with movement disorders is essential in order to document outcomes following intervention.

Figure 1: Comparison of movement unit derived angular acceleration profiles between normal (black) vs. LNS (blue).

INTRODUCTION

Important fossils believed to sample the evolutionary record near the point of divergence of apes and humans have been recovered from four locations within the Late Miocene Lukeino Formation in the Tugen Hills of Kenya. Radioisotopic determinations from geological deposits underlying and overlying the fossil remains indicate an age of about 6 million years before the present, consistent with the divergence time predicted three decades ago (Eckhardt 1972). Materials recovered so far number 13 specimens, all but one collected in October and November of 2000, representing at least five individuals. Included in the sample are two mandibular fragments, six teeth, one manual phalanx, a distal humeral fragment, and three femoral fragments. Functional inferences about posture and locomotion, significant in their own right, also are critical in helping to resolve questions about the early phases of hominid phylogeny.

METHODS

Descriptive morphology is based on the most complete femoral specimen (BAR 1002'00), which comprises the left femoral head, neck, and shaft; approximately 2/3 of the intact bone is represented by the total preserved length of approximately 215 mm. The proximal portion of the bone, including the neck and head, makes direct contact with a substantial portion of the shaft across a slightly worn post-mortem break at about the level of the *trochanter minor*.

Finite element analysis in this report focuses on the shaft of BAR 1002'00. Computerized tomography was used to image 170 fossil cross-sections, on which it is possible to delineate the inner and outer boundaries of the compact bone, as well as the medullary cavity in some regions. Outlined cross-sections are transferred into an FEM program. Solid model is then created, meshed with hexagonal elements. Functional inferences about posture and mode of locomotion are supported by analyzing stresses in BAR 1002'00. Optimization of cross sections for prevailing loading conditions are used to analyze mode of locomotion. Subsequently these will be compared with CT images on samples of extant chimpanzees, for the later species a model has already been created (see reference for standardized femur).

RESULTS AND DISCUSSION

The well-defined femoral head is spherical (33 mm in both antero-posterior and perpendicular diameters), with slight anterior rotation, and exhibits a moderately wide *fovea capitis*. Compared to extant humans, the head is smaller in proportion to the shaft, but is proportionally larger than in some other specimens accepted as early hominids (e.g. AL-288.1). The presence in BAR 1002'00 of an intertrochanteric groove which runs from a small, moderately deep *fossa trochanterica* to a region just above the *trochanter minor* is a feature that has been related to bipedalism (see Senut et al 2001 for further details). The femoral neck makes direct contact with a substantial portion of the shaft across a slightly worn post-mortem break. In BAR 1002'00, cortical thickness at midshaft is 5.2 mm (anterior and posterior), 7.4 mm (medial) and 5.5 (lateral). In the finite element analysis, stresses in the femur of the fossil specimen are estimated.

SUMMARY

Descriptive morphology and finite element analysis enable exploration of both details of form and inferences about features related to locomotor function in the femur of BAR 1002'00. This specimen appears to exhibit characteristics, some of which are consistent with bipedal locomotion, but on balance present an overall pattern with aspects as yet not duplicated in all details among other early hominids.

A COMPARISON OF ACL FORCE DURING SOFT AND STIFF DROP-LANDINGS

Mary A. Pflum¹, Kevin B. Shelburne³, Michael R. Torry³, Michael J. Decker³, Marcus G. Pandy²
¹Department of Kinesiology and ²Department of Biomedical Engineering, University of Texas, Austin, TX
³Steadman ♦ Hawkins Sports Medicine Foundation, Vail, CO mpflum@mail.utexas.edu

INTRODUCTION

Many ACL injuries occur by non-contact mechanisms, which are often marked by sudden deceleration of the center of mass, as in the case of landing from a jump. Previous landing studies have traditionally defined landing techniques in terms of *soft* or *stiff* according to the degree of maximal knee flexion angle attained during the landing phase (Devita and Skelly, 1992). The purpose of this study was to predict and explain ACL force for soft and stiff drop-landings. ACL force during the drop-landing task was calculated using a forward dynamics computer simulation. We hypothesized that peak ACL force for a stiff landing would be higher than that for a soft landing.

METHODS

A 3D model of the body (Anderson and Pandy, 2001) was used to simulate drop-landings from a height of 60 cm. The input muscle excitation patterns for the model were based on EMG measured *in vivo*. Since EMG activity was not available for all the muscles in the model, the excitation patterns for these muscles were modified until the calculated joint motions and ground-reaction forces (GRFs) were found to be consistent with *in vivo* measurements of the same quantities obtained from five healthy subjects. Knee flexion angle at ground contact in the soft condition was 24° with a terminal knee angle of 92°. A second stiff landing simulation was run with a knee flexion angle at ground contact of 10° and a terminal knee angle of 33°. Time to maximum knee flexion for the stiff landing was approximately one third of that for the soft landing. The muscle forces calculated by the model were then used as input to a sagittal-plane model of the knee (Shelburne and Pandy, 1997) to determine the pattern of ACL loading during the landing phase. All surfaces in the knee model were assumed to be rigid and frictionless; thus, tibiofemoral and patellofemoral articulation were each modeled as single-point contact. Eleven elastic elements described the geometric and mechanical properties of the cruciate and collateral ligaments plus the posterior capsule.

RESULTS AND DISCUSSION

Peak ACL force was substantially higher in the stiff landing simulation (847 N) than the soft landing simulation (329 N). For the duration of the soft landing, the tibial shear force due to the resultant GRF is directed posterior relative to the tibia (Fig. 1). This posterior shear force dominates the total resultant tibial shear force during the soft landing. Thus, ACL force was highest when posterior tibial shear force due to resultant GRF was lowest (Fig. 1). Peak vertical GRF during the stiff landing was roughly 3.4 times higher than that for the soft landing. Due to the higher vertical GRF and lower knee angle, peak tibiofemoral compressive force for the stiff

landing was 1.9 times higher than that for the soft landing. In the knee model, tibiofemoral compressive force results in an anterior tibial shear force due to the posterior slope of the tibial plateau. This anterior shear force dominated the total resultant shear force at the knee during the stiff landing (Fig. 2). Thus, the peak ACL force for the stiff landing depends mainly on the peak tibiofemoral compressive force and to a lesser extent on the peak vertical GRF.

Figure 1: ACL force (black line) and the posterior tibial shear force due to resultant GRF (gray line) during a soft landing.

Figure 2: ACL force (black line) and anterior tibial shear force due to tibiofemoral compressive force (gray line) during a stiff landing

SUMMARY

ACL force predicted for the stiff landing was roughly 250% higher than that calculated for the soft landing. While the stiff landing increased load in the ACL, the maximum force in the ACL did not exceed the ultimate failure load required for rupture (Woo et al., 1991). This suggests that other factors, in addition to landing style, contribute to injury of the ACL.

MODELING OF ACL IMPINGEMENT USING SIMM

Mohsen Makhsous^{1,2}, Amanda F. Lin^{1,2}, David Fung^{1,4}, and Li-Qun Zhang¹⁻⁴

¹Rehabilitation Institute of Chicago, Departments of ²Physical Medicine & Rehabilitation, ³Orthopaedic Surgery, and ⁴Biomedical Engineering, Northwestern University, Chicago, Illinois, 60611. m-makhsous2@northwestern.edu

INTRODUCTION

The anterior cruciate ligament (ACL) impingement on femoral intercondylar notch wall is suggested as a high risk factor of noncontact ACL injury¹. It is very difficult to examine the impinging condition *in vivo*, although MRI may provide some indirect answers. The purpose of this study was to model/simulate ACL impingement using Software for Interactive Musculoskeletal Modeling (SIMM)/Dynamic Pipeline based on cadaver data in which ACL impingement was measured.

METHOD

Musculoskeletal model of the knee: A cadaver knee with narrow notch (notch width index=0.22)² was used to establish the model. The tibiofemoral kinematics was recorded by an OPTOTRAK[®] system and the impinging force was detected using FlexiForce[®] force sensors at the ligament-notch wall-interface. ACL length-tension properties were determined along the ACL-axis (30° knee flexion) using a linear load-displacement device³ and used in the impingement modeling. The knee was then dissected and the bone surfaces of femur and the tibia were digitized with a 3-D digitizing probe and used to build a musculoskeletal knee model in SIMM.

Simulation of the ACL impingement: Initially, each of ACL bundles (anteromedial (AM), posterolateral (PL) and intermediate (I)) was modeled as a spike cylindrical bone described by polygonal mesh representing the ACL orientation along the line connecting the origin and insertion. The contacts between the “ACL-bone” and intercondylar notch, if any, were detected using the SIMM/Dynamic Pipeline ‘contact detection’ function. An ellipsoid was fitted to the small surface around the contact points on the notch wall with the ellipsoid imbedded into the lateral femoral condyle. The ellipsoid was used as a wrap object to prevent the penetration of ACL into the bone. The contact points served as the wrapping tangential points. The “ACL-bone” was then replaced with the ligament object wrapping around the ellipsoid and the ACL force generated in the wrapping/lengthening was determined from the length-tension relationship obtained above. Contact force applied to the ACL by the impinging points on the notch wall was then calculated by adding the two force vectors pointing away from the impinging point to the ACL origin and insertion (Fig. 2(a), $F_c = F_1 + F_2$). Frictionless contact was assumed at the ligament-notch wall interface.

RESULTS AND DISCUSSION

ACL impingement detection: For all the kinematic trials with the combination of flexion/extension, adduction/abduction, and internal/external axial rotation, the method using “ACL-bone” successfully detected the impingement on the notch wall of the ACL AM band (Fig. 1(a) & (b)). No impingement was found for PL or I band in the simulation. The contact points found by the simulation were in the same small area as observed in the experiment (Fig. 1(c)).

ACL impinging force: The ACL-notch interface contact force predicted by the model simulation is shown in Fig. 2(b) as red dots for one of the kinematic trials during which impingement was observed with the FlexiForce[®] readings (solid blue line). Results show that the model prediction matches the force measured.

The impingement force of the AM bundle was found to be higher in a flexed knee with tibial abduction and external rotation. The impingement of the AM bundles is consistent with previous studies⁴ that the AM bundle is tighter in flexion than the PL bundle, the latter do not show any impingement in the simulation.

Figure 1: ACL impingement detection. A flexed left knee with tibial abduction and external rotation.

Figure 2: ACL impingement force.

SUMMARY

The method is a useful tool in analyzing/visualizing ACL impingement and it can potentially be applied to clinical problems to evaluate noncontact ACL injuries or to predict likelihood of potential injuries. Further studies are needed to identify risk factors and prevention strategies should be employed.

MATHEMATICAL MODELING OF ACL IMPINGEMENT AGAINST THE INTERCONDYLAR NOTCH WALL

David Fung^{1,2} and Li-Qun Zhang¹⁻⁴

¹Sensory-Motor Performance Program, Rehabilitation Institute of Chicago, Departments of ²Biomedical Engineering, ³Physical Medicine & Rehabilitation, and ⁴Orthopaedic Surgery, Northwestern University, Chicago, Illinois, Email: d-fung@northwestern.edu

INTRODUCTION

While many ACL injuries may have resulted from direct loading of the ligament, the ACL may also be injured due to its impingement against the intercondylar notch wall. A number of studies have been conducted to evaluate the relationship between the intercondylar notch width and risk of noncontact ACL injury, based on planar notch-view X-ray¹. Considering the complex shape of the notch and oblique arrangement of the ACL, it is needed to investigate the impingement accurately in 3-D space. The purpose of this study was to evaluate ACL impingement against the notch through computer modeling based on data from individual cadaver knees in which ACL impingement was measured.

METHODS

In five cadaver knee specimens with intact ligaments, ACL impingement against the intercondylar notch was evaluated visually by moving the tibia passively relative to the femur. In one representative specimen with low notch width index (0.22), impingement was measured with paper-thin FlexiForce force sensors at the ligament-notch wall-interface. The corresponding tibiofemoral kinematics, measured in six degrees of freedom, provided details on the kinematic conditions at which impingement occurred. ACL origin (O), insertion (I), and a small patch surface representing an area around the impinging points on the medial edge of the lateral intercondylar notch wall were digitized and used in the modeling (Fig. 1).

Fig. 1: A left cadaver knee in abduction and external rotation used for modeling.

ACL impingement against the notch was determined as follows. First, the small patch surface was fitted by bicubic splines with continuity up to the second derivative². Positions of the anteromedial, intermediate, and posterolateral bands of the ACL during the impingement were represented by lines connecting their respective origins and insertions. If impingement of any band occurs, its corresponding line would generally intersect with the patch surface at two points, an entry point E_1 and an exit point E_2 (Fig. 2). E_1 and E_2 were determined by detecting intersection between the line OI and the small triangular polygons that were generated to represent the meshed surface. Second, using E_1 and E_2 , and a third point H , the highest point along the path E_1E_2 on the fitted surface, an initial plane P_1 was generated, followed by a family of incremental planes (P_i , $i=2,3,4,\dots$) rotating about an axis defined by line E_1E_2 (Fig. 2). The impinging band of the ACL should wrap around the curved notch surface in the plane that gives the shortest ACL length. Third, the wrapping path on each plane was determined by “crawling” on the surface from E_1 to E_2 in small steps. Starting from E_1 , point C advances a small step along the Y-axis to obtain a new location on the surface. If C is off the plane, an adjustment along the X-axis

will be made until C is in the plane (Fig. 3), reaching the next point on the ACL path. C then continues to “crawl” in small steps along the possible ACL path in the plane until its tangent at point C matches the slope of line OT_1 . This location marks the tangential point T_1 where the impinging band makes its first contact with the curved surface (Fig. 2). From T_1 , point C continues to crawl in the plane until reaching tangential point T_2 where the path’s tangent matches the slope of line T_2I . The impinging band conforms to the curvature of the surface between T_1 and T_2 , and connects directly between O and T_1 and between T_2 and I (Fig. 2). The deformed length of the ACL in each plane was determined by adding the linear lengths of OT_1 and T_2I , and the curved length T_1T_2 .

Fig. 2: Fitted surface and incremental planes.

Fig. 3: “Crawling” on the surface.

RESULTS AND DISCUSSION

Since the impingement site was located on the medial side of the lateral notch wall in the specimen, impingement was induced by abduction and external rotation. At the impinging position, the AM band with an initial length was 25.5mm showed impingement bending and a deformed length of 25.7mm ($OT_1=8.0\text{mm}$, $T_1T_2=0.4\text{mm}$, $T_2I=17.3\text{mm}$), and 0.78% strain. The I and PL bands showed less strain than the AM band.

Fig. 4: Impingement of AM band shown in model

SUMMARY

The mathematical model provided a useful method to determine ACL impingement in 3-D space, including its bending, length, and strain as it wraps around the notch surface. It was shown that ACL impingement on the intercondylar notch stretched the ACL considerably. Further work needs to be done to identify the different impingement areas of the notch and to corroborate the results quantitatively with the force measurement.

IN VIVO PATELLAR TRACKING IN PATELLAR MALALIGNED KNEES

Amanda Lin^{1,2}, Mohsen. Makhsous^{1,2}, and Li-Qun Zhang¹⁻⁴

¹Rehabilitation Institute of Chicago, Departments of ²Physical Medicine & Rehabilitation, ³Orthopaedic Surgery, and ⁴Biomedical Engineering, Northwestern University, Chicago, Illinois, 60611 1-zhang@northwestern.edu

INTRODUCTION

Patellofemoral pain (PFP) syndrome is one of the most commonly observed physical abnormality involving the knee in sports medicine clinics, and is often associated with patellar malalignment and abnormal tracking.^[1] The purpose of the study was to study 3-D patellar tracking pattern in the PFP patients through *in vivo* and *noninvasive* method and compare it to that of the normal group. Patellar tracking was generally evaluated using cadaveric specimens, and in some cases, *in vivo* and invasive measurement was used^[2,3]. The purpose of this study was to investigate *in vivo* patellar tracking non-invasively in PFP patients during selective contraction of individual heads of the quadriceps muscle and during voluntary knee extension.

METHODS

Eight PFP patients and 17 normal subjects participated in the study. Patellar tracking was evaluated with the experimental setup reported previously^[4,5]. Patellar movements were described in the coordinate system shown in Fig. 1(c). For the right patella, the x, y and z axes pointed medially, proximally, and anteriorly, respectively. The patellar rotations about the x, y and z axes were defined as flexion/extension, mediolateral tilt, and mediolateral rotation, respectively. The positive directions of the rotations were flexion, medial tilt, and medial rotation, respectively. Function of each individual head of quadriceps during individual quadriceps head activation was determined by DOR and DOT described previously^[4,5]. Patellar translations were normalized to the knee width of the subjects.

RESULTS AND DISCUSSION

Patellar tracking associated with knee voluntary extension shows the patella was extended $7.4 \pm 3.4^\circ$ (mean \pm SE), medially tilted $3.2 \pm 5.6^\circ$, and little rotated during a 15° knee extension. At the same time, the patella shifted laterally, proximally, and anteriorly. Compared with previously data on normal subject^[5], patellar tracking in knee voluntary extension for PFP patients in this study had almost the same pattern but with significantly more lateral tilt (Fig.1 (a)) ($p < 0.001$), and the lateral tilt continued to full knee extension.

At 20° knee flexion, the VMO mainly medially rotated the patella and shifted it medially and anteriorly. The VML extended and medially tilted the patella and shifted it anteriorly and proximally. VL laterally tilted the patella and shifted it laterally and proximally. Compared with patellar tracking at more flexed knee positions, stimulation of the VMO generated major patellar motion as extension, medial and proximal shift, and the former major motion as anterior

shift at 20° knee flexion decreased to be negligible. At fully extended knees, VL changed its major motion of medial rotation to extension.

Significant differences for function of VMO were found between normal and patient groups both in the patellar translations and rotations. For normal subjects, medial shift was the only major translation generated by VMO, while in PFP group proximal shift was found as an additional major motion. Also found was that VMO did less medial tilt at full knee extension than that of normal ($p < 0.001$). Similarly, substantial changes were shown in the major function of VL. For PFP group, VL laterally tilted and shifted patella more than those of normal, both at full knee extension and 20° flexion (both with $p < 0.001$) (Fig. 1 (b)). The major function of VML did not change much from those of normal group.

Figure 1: Comparison of the patellar tracking in normal and PFP patient.

SUMMARY

Data from PFP patients showed larger variations than that from normal subjects, possibly due to different pathological conditions among patients in this study. Abnormal patellar tracking was found in PFP patients as the more lateral tilt of patella during voluntary knee extension. Besides, significant abnormal tracking patterns were found in the function of VMO and VL between PFP and normal groups. The method presented in this study can be a quantitative 3-D tool to evaluate patellar tracking *in vivo* and non-invasively in patients with patellofemoral disorder and malalignment

BIOMECHANICAL CHANGES IN SPASTIC ANKLES OF STROKE PATIENTS

Sun G. Chung^{1,2,5}, Elton van Rey^{1,2}, and Li-Qun Zhang^{1,4}

¹Rehab Inst. of Chicago, Depts. of ²Physical Med & Rehab, ³Orthop. Surg., and ⁴Biomed. Eng., Northwestern Univ., Chicago, IL
⁵Dept. of Rehab Medicine, Seoul National University, Seoul, South Korea, suncg@northwestern.edu

INTRODUCTION

Spasticity and contracture at the ankle are among the major sources of disabilities following stroke. Spastic hypertonia has biomechanical as well as reflex components, and contracture is directly related to biomechanical changes of the muscle tendon units. The purpose of this study is to investigate the biomechanical changes in the passive ankle of stroke patients in both the plantar and dorsiflexor muscles-tendons, including shortened muscle-tendon unit, decreased range of motion (ROM), and increased stiffness (loss of compliance).

METHODS

Twenty-four stroke survivors (15 male and 9 female, 55.3 ± 10.1 years old) and 32 normal subjects (17 male and 15 female, 42.1 ± 20.5 years old) participated in the study. Subjects sat with the knee at 60° flexion and the leg supported. The foot was held firmly on a footplate, which was mounted onto the shaft of a servomotor. The ankle flexion axis was aligned with the shaft of the motor by adjusting the footplate and the seat. A 6-axis force sensor was mounted between the motor shaft and the footplate. The device was controlled digitally with position/velocity and torque feedback to move the ankle into both dorsi-flexion (DF) and plantar flexion (PF) extreme ROMs. The motor moved the ankle at slower speeds as the joint was moved into extreme ROMs and the maximum speed allowed in the middle ROM was set at $300^\circ/\text{sec}$. Gravitational forces of the foot and the footplate were compensated. The DF and PF ROM were measured at the resistance torques of $10 \text{ N}\cdot\text{m}$ and $5 \text{ N}\cdot\text{m}$, respectively. The torque-angle curves were plotted to get the hysteresis curves (Fig. 2). The slopes at 0 and 10° DF and 0 and 30° PF angles of the ascending limb of the hysteresis curves were taken as the quasistatic stiffness. The DF areas of the hysteresis curves were considered as the amount of energy lost during the passive DF stretch.

RESULTS AND DISCUSSION

Passive ROM in the normal subjects was $18.9 \pm 10.5^\circ$ (mean \pm standard deviation) and $45.7 \pm 7.8^\circ$ in DF and PF, respectively (Fig. 1). The dorsiflexion ROM was similar to what was reported previously (Moseley et al. 2001). In contrast, the DF and PF passive ROMs in the stroke patients with spastic ankles were $9.3 \pm 9.5^\circ$ and $25.2 \pm 11.6^\circ$, respectively, which was significantly smaller than their counterparts in normal controls ($P \leq 0.007$ with Student t-test) (Fig. 1(a)).

The quasistatic stiffness was significantly higher in the spastic ankles than that in normal controls at 0 and 10° DF and at 0 and 30° PF positions (Fig 1(b)). The increased quasi-static stiffness was consistent with previous studies, which evaluated

the dorsiflexion stiffness bilaterally in 8 hemiplegic patients (Harlaar et al. 2000).

Figure 1: (a) DF and PF passive ROMs in normal and stroke subjects (*: $p < 0.05$). (b) Quasi-static stiffness at several points of the hysteresis curves in normal and stroke subjects (†: $p < 0.01$).

Figure 2: Typical hysteresis curves from a representative healthy subject and a stroke patient.

SUMMARY

It was shown that in both plantar flexion and dorsiflexion, the spastic ankles in 24 stroke patients showed decreased passive ROMs and increased stiffness compared to normal controls.

INTRODUCTION

As people age, the neurological reflex properties may undergo considerable changes. Functionally, such changes may be associated with limitations in joint mobility and slower movements. Evaluation of reflexes is generally done by measuring the muscle responses (EMG recordings) and/or joint torque, each of which are net system outputs due to neuromuscular stimulation (e.g., stretching the muscles). Without adequate controls, the sensory input stimulus may vary considerably from one trial to another and lead to large variability in the response output. The purposes of this study was to evaluate reflexes while minimizing these confounding sources of variability with the reflex excitability evaluated with tendon reflex gain, contraction rate, and reflex threshold.

METHODS

Eight elderly (4 male and 4 female) and eight young (4 male and 4 female) subjects with no prior history of neurological disorders participated in the study. The age of the elderly subjects was 69.4 ± 9.7 years. The young participants' age was 26.0 ± 6.9 years. The participants were seated comfortably on a custom designed chair. The foot was placed on a footrest, knee joint positioned in 60 degree of flexion with the trunk, thigh and ankle strapped to the seat. The footplate was mounted onto a motor shaft through a torque sensor measuring the ankle flexion torque. The ankle joint was restricted at an isometric condition in order to minimize the contributions of the passive/intrinsic components associated with joint movement. Four EMG-electrodes were placed on the tibialis anterior, soleus and the medial and lateral head of the gastrocnemius muscles.

The Achilles tendon was tapped by using an instrumented tendon reflex hammer, with a force sensor mounted on the head. Before tapping the Achilles tendon, the participants were asked to relax entirely and not to expect / anticipate to the tapping. The tendon tapping force, lower-leg EMG signals and the reflex torque were sampled by a computer at 500 Hz after low pass filtering at 230 Hz. To evaluate and characterize tendon reflexes, a system identification approach was used to characterize the reflex output responses and stimulus input simultaneously, which is more reliable than measuring the output responses (EMG or reflex-mediated torque) alone. Furthermore, reflex excitability was characterized as a function of the stimulus threshold measured in tapping force, which provided a usually ignored but important component of reflexes (Zhang et al. 1999).

RESULTS AND DISCUSSION

Tendon reflex gain of the younger subjects was higher than that of the elderly group ($P = 0.049$, 0.002 and 0.074 for 15° dorsiflexion, neutral and 15° plantar flexion, respectively), reflecting weaker reflex actions in the elderly (Angulo-Kinzler et al. 1998). Furthermore, the contraction rate in the elderly subjects was lower than that of young subjects ($P = 0.053$, 0.003 and 0.082 for 15° dorsiflexion, neutral and 15° plantar flexion, respectively), indicating slower contractile mechanics in the elderly. On the other hand, the reflex threshold in tapping force was higher for the elderly than that for the young subjects ($P = 0.038$, 0.20 and 0.027 for 15° dorsiflexion, neutral and 15° plantar flexion, respectively), indicating the need for a stronger stimulation to elicit reflex responses in the elderly subjects. In addition, the reflex-mediated output responses showed lower peak reflex torque and lower peak reflex EMG signal in the elderly group than their counterparts in the young subjects.

Figure 1 (a). The tendon reflex gain of elderly versus young. (b) Reflex threshold in elderly and young subjects.

SUMMARY

In summary, elderly subjects showed diminished reflex excitability, as indicated by the decreased reflex gain, reduced contraction rate, and increased reflex threshold. The Achilles tendon reflex becomes hypoactive in elderly subjects, which could be due to reduced power generating capability of the muscles and decrease of sensitivity of the muscle spindles in the aged participants. The above approach provided us a simple and convenient way to evaluate aging-related reflex changes quantitatively in several aspects.

INTERSEGMENTAL DYNAMICS DURING MULTIJOINT ARM REACHING: IMPLICATIONS FOR CONTROL OF LIMB MOVEMENT

Gail F Forrest¹, Sue Ann Sisto¹, Quin Bond¹, Stephen Page¹, Peter Levine¹

¹Kessler Medical Rehabilitation Research and Education Corporation, West Orange, NJ, USA
gforrest@kmrrec.org

INTRODUCTION

Hemiparesis is a significant clinical impairment of stroke that can precipitate functional disabilities (Gowland, et al 1992). The restrictions in voluntary movement for patients with upper limb hemiparesis may be functionally apparent but the quantitative data to explain the mechanisms related to the deficits of control of multi-joint movements is limited - particularly when the multi-joint motion is performed in 3D space. The objective of this study is to utilize inverse dynamic modeling for quantifying arm-reaching multijoint movement and compare changes in the arm intersegmental dynamics after a mental imagery intervention.

METHODS

A 56-year-old male with left hemiparesis due to stroke was tested pre and post an imagery intervention (Page et al., 2001). Testing involved 3 repeated trials of an arm-reaching task. Kinematic data were collected at 120Hz using Vicon Work Station and a 6-camera setup. A 4th order Butterworth filter with forward and reverse phase to eliminate phase delays was applied to the Cartesian 3D positional data. Residual analysis (Winter, 1990) determined the choice of cut frequencies. To analyze the motion of the arm segment, 'each limb was modeled as three interconnected planar rigid segments' (Schneider and Zernicke, 1991). Limb dynamics were calculated in the local moving plane with calculation of orientation angles for each segment relative to the right horizontal. Inverse dynamic modeling (Schneider and Zernicke, 1991) was used to quantify the net torque, gravitational and intersegmental torque and the residual term (muscle torque) for the shoulder, elbow and wrist. Net joint torque describes the joint motion. Additionally impulse values were calculated using an integration trapezoidal algorithm.

RESULTS AND DISCUSSION

After the intervention there was an increase in total net shoulder torque and impulse (pre: -0.436 ± 0.07 N.m.s; post: 0.77 ± 0.06 N.m.s) and elbow net shoulder torque and impulse (pre: 0.12 ± 0.05 N.m.s; post: 0.81 ± 0.21 N.m.s) which was reflected in the increased orientation angle (with respect to the right horizontal) of the affected shoulder and elbow. The overall shoulder intersegmental impulse (pre: 1.13 ± 0.22 N.m.s; post: 2.67 ± 0.48 N.m.s) and torque were greater after the intervention. This was due to an increase in both the angular acceleration of the upper arm (i.e. acceleration torque) and the angular acceleration of the forearm - both accelerations are components that contribute to the shoulder intersegmental torque. Overall, the increase in shoulder net torque precipitated an increase in residual muscle torque that indicated an improved control following the intervention.

SUMMARY

Improved movement of the forearm, upper arm and increased shoulder muscle torque suggested an improvement in function of the arm and improved coordination. Therefore, a sensitive way to measure change of complex multi joint movement is implement to inverse dynamic techniques.

FOOT SENSATION AS A PREDICTOR FOR RESPONSE TO FOOTWEAR INTERVENTIONS

Matthew Nurse[†] and Benno Nigg

Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada

[†]Corresponding Author: manurse@ucalgary.ca

INTRODUCTION

Lower extremity muscle activity can be altered by afferent cutaneous feedback (ie Zehr et al., 1997). Sensory feedback from the plantar surface of the foot may be altered by changing the geometry, texture (Watanabe & Okubo, 1981), or density (Wu & Chiang, 1996) of materials underfoot. Footwear interventions may provide long term changes in sensory feedback from cutaneous mechanoreceptors.

Subject specific responses to footwear interventions may be due in part to the subjects' ability to discriminate changes in sensory input. It is speculated that individual differences in plantar sensitivity may play a role in the response to different footwear conditions underfoot. The purpose of this study was therefore to examine gait responses to footwear interventions as a function of subject plantar foot sensitivity.

METHODS

Sensitivity thresholds to high (250Hz) and low (10Hz) frequency vibrations were collected from 30 subjects. Each subject was tested at the heel, first metatarsal head, and hallux using a validated psychophysical algorithm (Nurse and Nigg, 2001). Subjects from the top and bottom 10th percentiles in plantar sensitivity were selected to participate in this study.

Four subjects, two from each percentile, walked on a treadmill in two different footwear conditions. The control condition involved a normal, commercially available running shoe. The shoe insert was then removed and replaced with a heavily textured foam insert. The texture was noticeable enough to elicit a subjective response from all subjects. EMG measurements were obtained from the medial gastrocnemius (MG), soleus (SL), tibialis anterior (TA), vastus medialis (VM), rectus femoris (RF), and biceps femoris (BF). EMG recordings were pre-amplified (10^6), and lowpass filtered at 3Hz to obtain a linear envelope of the muscle signal. All EMG signals were time normalized, and RMS was calculated for the stance and swing phase for each of the muscles.

RESULTS AND DISCUSSION

While wearing the textured shoe insert, TA activity was lower for all subjects (Figure 1). For the highly sensitive subjects, the depression in TA activity was significant ($p < 0.025$ for both subjects). Electrical stimulation of the tibial nerve, which innervates the plantar surface of the foot, has been shown to result in suppression of TA during the later portion of the swing phase (Van Wezel et al., 1997). However, electrical stimulation is usually delivered at a multiple of perception threshold, and does not account for potential differences in the subjects' ability to detect stimuli underfoot. It is speculated

that the textured shoe insert increased afferent input from the foot (Watanabe et al., 1981), resulting in decreased TA activity during the swing phase.

Small and less consistent differences were observed in the other muscles of the lower extremity. It would be expected footwear effects would be most dominant during the stance phase as this is when the foot is most loaded against the shoe insert. However, contra-lateral effects of cutaneous stimulation have been demonstrated. This direction of research is ongoing, and will examine kinematic and kinetic responses, as well as EMG, to footwear interventions.

Figure 1: RMS muscle activity for TA while walking in two footwear conditions.

SUMMARY

Differences were observed in the activity of the selected muscles. Tibialis activity was suppressed in the swing phase while wearing a shoe with a textured insert, especially for subjects who were are highly sensitive to high frequency vibrations. Differences in plantar sensitivity may explain certain subject specific responses to footwear interventions.

TRABECULAR TISSUE STRESSES AND STRAINS IN MECHANICALLY INDUCED ANABOLIC BONE ADAPTATION: A FINITE ELEMENT STUDY

Steven Boyd¹, Stefan Judex², Yi-Xian Qin², Simon Turner³, Ralph Müller¹, and Clinton Rubin²

INTRODUCTION

Mechanical stimuli play an important role in bones' adaptive processes. Recently, it has been shown that low magnitude, high frequency (<10 microstrain, >20 Hz) mechanical signals can increase bone formation in sheep (Rubin et al., 2002). This mechanical stimuli results in stiffened trabecular bone, reflected by an increase in bone density, and has a high clinical potential for the treatment or prevention of osteoporosis in patients.

To date, mechanical testing has confirmed increased stiffness of the trabecular bone (Rubin et al., 2002), however, it is remains unknown how the trabecular structure is affected. In particular, with respect to osteoporosis, it is important to understand the affect on stresses and strains, and particularly if it results in reduced peak strains. Using finite element (FE) analysis based on micro-computed tomography (μ CT) data, tissue-level stresses and strains can be evaluated (van Rietbergen et al., 1999). Therefore, the purpose of this study was to quantify changes in stress and strain peaks, as well as their distributions within the adapted trabecular bone tissue.

METHODS

Twenty adult female sheep (Warhill intact ewes, 60-80kg) were randomly assigned to two groups: experimental and controls. The experimental group stood with their hind limbs on a vibrating plate (30 Hz, 0.3 g) for 20 min/d, 5 d/wk. At the end of one year, 1 cm cubes of trabecular bone were excised from the medial femoral condyles.

Cubes were scanned by μ CT (nominal, isotropic resolution of 34 μ m), and to reduce computational requirements for the FE analysis, the voxel data was resampled (isotropic size of 68 μ m) and converted directly into a hexahedron-based FE mesh. The boundary conditions were chosen to simulate axial compression (1% strain), and FE simulations were performed for each specimen along all three axial directions (Boyd et al., 2002). Bone material properties were assumed homogeneous and isotropic: Tissue modulus = 5 GPa, Poisson's ratio = 0.3.

The FE models were solved using an iterative-based method. The stress and strain state of each element (>1,000,000/model) were sorted into histograms after normalization by the applied

global stress and strain, respectively. Thus, the arbitrary tissue modulus and applied strain had no effect on the results.

RESULTS AND DISCUSSION

The apparent-level trabecular elastic modulus calculated by FE was greater in the experimental sheep in the longitudinal (17%), anterior-posterior (25%), and medial-lateral directions (44%). The resultant stresses and strains were more evenly distributed in the experimental sheep, and peak strains were reduced. Thus, more of the trabecular tissue was subjected to intermediate strains in experimental sheep than in the controls.

Figure 1: Histograms sorting elements by calculated stress (σ_{33}), normalized by the resultant apparent stress ($\sigma_{33 \text{ app}}$). Results for the three testing directions are shown. A ratio of 1.0 occurs when tissue stress equals resultant apparent stress.

SUMMARY

The adaptive process of trabecular bone to low level mechanical loads involves a spatial homogenization of the tissue stresses and strains, and consequently results in reduced strain gradients. The change in stiffness was greatest off-axis (i.e., other than physiological longitudinal loading direction) which may be important for prevention of fracture, particularly in a fall with lateral impact. The stiffer structure has reduced tissue strains for a given load, and is less prone to fracture.

INFLUENCE OF FLOW RATE AND AXIAL POSITION ON SHEAR STRESSES

Sakhaeimanesh Ali A.

Biomedical Engineering Group, Faculty of Engineering, University of Isfahan, Isfahan, Iran, sakhaei@eng.ui.ac.ir

INTRODUCTION

Prosthetic heart valves are commonly used for replacement of natural valves, in ventricular assist devices (VADs) and total artificial hearts (TAHs). To locate the maximum and mean turbulent shear stresses, in both time and space, and to determine how shear stresses depend on the flow rate and downstream measuring planes, this study was carried out.

METHODS

Flow was driven by a servo-controlled piston pump (VSI pump) that compressed the ventricle to simulate the physiological flow. DANTEC, two-colour 5 Watt Argon-Ion laser was used to determine the velocity and turbulent components of the valve. The axial and radial mean velocities, \bar{U} and \bar{V} , the r.m.s. of axial and radial fluctuation components, turbulent intensity, T , and the cross, \bar{uv} , were calculated. More details of mock circulatory system and LDA technique are given somewhere else (Sakhaeimanesh et al., 1999).

RESULTS AND DISCUSSION

graphs of shear stress-flow rate and shear stress-axial location are presented in figure 1 to 3. All instantaneous flow rates were measured by an electromagnetic flow meter. Furthermore, as maximum shear stress and its mean absolute value of each valve occur at the same measuring plane, comparison of the mean absolute shear stresses is considered valuable, because this may reduce measurement error.

As can be seen in figure 1, maximum and mean turbulent shear stresses estimated at 0.5D downstream of the valve showed a direct relationship with flow rate both in the Jellyfish and St. Vincent valves. Our results are consistent with the finding of Schwartz *et al.* (1988). The magnitude of both mean and maximum shear stresses in the Jellyfish valve was found to be higher than that of the St. Vincent valve at 0.5 and 1D downstream of the Jellyfish valve. In figures 2 maximum and mean turbulent shear stresses are presented as a function of downstream axial distance for the Jellyfish valve. Maximum shear stresses were found in close vicinity to the valve where, highly disturbed flow with steep velocity gradients were observed. At 1D downstream of the valve, high shear stresses were also found in the valve. Further from the 1D measuring plane, flow disturbance was reduced resulting in a dramatic reduction in shear stresses in the Jellyfish valve. This was attributed to diminishing the effects of oscillation of the Jellyfish valve beyond the 1D measuring plane.

Figure 1: Mean and maximum shear stresses measured at 0.5D downstream of the Jellyfish and St. Vincent valves as a function of flow rate. Measurements were made at peak systole at cardiac outputs of 3.5, 4.5 and 6.5 l/min.

Figure 2: mean and maximum shear stresses as a function of downstream axial position of the Jellyfish valve. Shear stresses were found at peak systole at cardiac outputs of 3.5, 4.5 and 6.5 l/min.

- Schwarz A.C., et al (1988). Influence of cardiac flow rate on turbulent shear stress from a prosthetic heart valve, *J . Biomechanical Engineering*, **110**, 123-129.

INTRODUCTION

In pulsatile flow, both flow rate and pressure drop, which are a function of the time are important in judging artificial heart valve performance. Pressure drops across the valves in forward flow and the amount of backflow in the regurgitation stage is of great concern in pulsatile flow investigations (Jansen J, Ruel H, 1992 and Knott E. et al 1986).

The instantaneous relationship between pressure drop, $\Delta P(t)$, and flow rate, $Q(t)$, can be obtained as a phase graph on an X-Y plane during a whole cardiac cycle. These can be regarded as dynamic flow characteristics of an artificial heart valve. This method may facilitate a more proper model of the valve in circulation simulation and provide a new way to evaluate the performance of a tested valve.

METHODS

The pulse duplicator designed by Vivitro System Inc. was used in the present investigation. The artificial heart and connecting tubes were arranged vertically and valves were mounted in their correct position in an especially moulded flexible ventricle. Flow was driven by a servo-controlled piston pump (VSI pump) that compressed the ventricle to simulate the physiological flow. More details of mock circulation are given somewhere else (Morsi Yos S. and Sakhaeimanesh Ali A. 2000).

RESULT AND DISCUSSION

The continuous monitoring of the time histories of flow and pressure revealed useful details of the complex flow as well as helping to establish location and timing of the peak parameter values. The $\Delta P - Q$ relation is presented for the Jellyfish and St. Vincent valves in figure 1 at cardiac output of 4.5.

The trace of $\Delta P(t)$ starts on the $\Delta P - Q$ graphs from a point near the negative pressure drop axis and rises to positive Q axis and develop to maximum flow rate (peak systole). This period is the acceleration (ejection) phase of heart cycle. From peak systole it turns back along flow axis and become negative after crossing pressure drop axis. This period is the deceleration phase. At this stage, pressure drop across the St. Vincent valve was higher than that of the Jellyfish valve. This shows that the occluder of the St. Vincent valve produced high resistant to forward flow, which was due to its high mass moment of inertia. When flow rate became negative, the closure phase of the valves started.

Figure 1: Instantaneous pressure drop versus flow rate during whole cycle of the Jellyfish and St. Vincent valves at cardiac output of 4.5 l/min.

High closure flow rate of the St. Vincent valve is evident in the graph. At the start of closure phase, when adverse pressure gradient across the St. Vincent valve was not enough to overcome the resistance of the valve occluder, a large amount of flow retarded to the ventricle. On the other hand, flexible membrane of the Jellyfish valve, with its low mass moment of inertia, responded to low adverse pressure gradient and closed rapidly, resulting in lower closure flow rate. At the end of closure phase (traces close to the pressure drop axis), the leakage phase of cardiac cycle started. As can be seen in the graphs, the magnitude of flow rate did not increase so much while the magnitude of pressure gradient was apparently larger than that in forward flow. This meant that leakage flow across the valve faced a larger pressure gradient than in forward flow causing high jet flow within the leakage gap. Higher leakage flow rate in the St. Vincent valve is also evident in the figure 1. The non linear phenomena of the $\Delta P - Q$ relationship which exists in pulsatile flow cannot be obtained in steady flow testing especially in backflow stage where flow rate changes a little while pressure gradient has some variation.

³Professor, Faculty of Kinesiology

INTRODUCTION

The control of individual muscles during skilled or repetitive movements has been of interest to researchers for a long time [Herzog, 1996]. For a given movement, a unique combination of muscle forces, typically, does not exist. One method of extracting a unique set of muscle forces is the formulation of an optimization problem [Crowninshield et al 1981, Herzog, 1996]. In most cases, the mathematical optimization problem is solved numerically for large models [e.g. Glitsch, 1997, Li et al 1999] or analytically for simple models consisting of a small number of degrees-of-freedom in a two-dimensional model [e.g. Herzog et al 1993]. These numerical approaches or analytical solutions for specific, small scale musculoskeletal models do not provide general solutions of the optimization approach that are valid independent of the geometry of the model at hand. In these cases, it was typically thought that non-linear optimization could not predict the co-contraction of a pair of single joint antagonists, but this conclusion was based on planar models of the musculoskeletal system. Recently, Li et al [1999] numerically demonstrated that non-linear optimization could predict such activity in a three-dimensional model. Therefore, the purpose of this work was to examine predictions of co-contraction between pairs of antagonistic muscles in a three-dimensional model, analytically.

METHODS

It is typically assumed that the muscles crossing a joint are primarily responsible for generating the required moment at that joint, i.e. $\mathbf{b} = \Sigma(\mathbf{r}_i \times \mathbf{f}_i)$, or in matrix form $\mathbf{A}\mathbf{f} = \mathbf{b}$, where \mathbf{b} is the joint moment vector; \mathbf{r}_i and \mathbf{f}_i are the moment-arm and force vectors of the i^{th} -muscle; \mathbf{A} is the matrix of moment-arms; and \mathbf{f} is the vector of unknown muscle force magnitudes. To extract a unique set of muscle forces, a convex cost-function, $\phi(\mathbf{f})$, is minimized subject to mechanical and muscular constraints [e.g. Crowninshield et al, 1981]. Given two arbitrary antagonistic muscles in a musculoskeletal system, and using Karush-Kuhn-Tucker multipliers, the set of intersegmental moments, \mathbf{b} , for which these two muscles co-contract can be determined; unless the moment-arm vectors of the two muscles are co-linear.

RESULTS

First, we determined that the mathematical representation of a three-dimensional musculoskeletal model and a planar model having equal degrees-of-freedom are equivalent. Thus, it is

possible to generalize results from two-dimensional to three-dimensional systems. Also, using Karush-Kuhn-Tucker multipliers, a set of intersegmental moment directions for which optimization predicts the co-contraction of a pair of antagonistic muscles can be found. This set of intersegmental moments is independent of the magnitude of the resultant moment, therefore, it can be represented by a set of intersegmental moment directions. Also, the region of co-contraction becomes smaller for increasing amounts of antagonism between antagonistic muscles.

DISCUSSION AND CONCLUSION

By showing that a three-dimensional model has a mathematical equivalent planar system, we were able to study the prediction of co-contraction independent of the dimensionality and geometry of the musculoskeletal system. One of the main limitations of inverse dynamics optimization models [e.g. Crowninshield et al 1981] has been the apparent impossibility of predicting co-contraction between single joint antagonists, but this limitation was found for planar systems. However, real anatomical joints are typically not planar. Therefore, it is possible to predict co-contraction of single joint antagonists, if three-dimensional joints are considered. We also show that there is a specific set of intersegmental moment directions for which optimization will predict the co-contraction of any pair of muscles, and this region becomes smaller as a pair of antagonistic muscles becomes increasingly antagonistic. Therefore, one possible method for evaluating optimization models is to determine the actual directions of movement that include the co-contraction of a pair of antagonistic muscles. Finally, we would like to emphasize that the purpose of this study was to evaluate the possibility of non-linear optimization models to predict co-contraction of antagonistic muscles, and that further experimental testing is required to validate optimization approaches.

²Faculties of Kinesiology and Engineering, University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

The superimposed twitch technique is one of the preferred methods to determine muscle inhibition in normal and patient populations (Merton 1954, Belanger and McComas 1981). One of the limitations of this method is its variability for given contractile conditions. For example, a contraction of 50% of the Maximal Voluntary Contraction (MVC) may be associated with a variation in muscle inhibition values from 10-70% in a given subject.

Recently, we conducted an investigation aimed at determining muscle inhibition obtained using the superimposed twitch technique for contractions performed at 50% of MVC. Specifically, we tested whether potentiation, force magnitudes, or the rate of change in forces might explain the observed variations. We found that a great part of the variations could be explained with minute deviations of the force from the 50% of MVC target value. In other words, it was found that muscle inhibition values were very sensitive to whether the actual force was 47% or 53% of MVC at the instant of superimposed twitch application. The purpose of this study was to test whether variations at 100% of MVC could also be explained with small changes in the actual force.

METHODS

Eleven normal subjects (age 30 years \pm 7; height 177cm \pm 11; mass 74kg \pm 12) volunteered to participate in this study. Subjects were seated on a Biodex strength dynamometer for isometric knee extensor contractions at 90 deg of knee flexion. Knee extensor stimulation was performed via percutaneous stimulation of the femoral nerve (Lee et al., 2000). Doublet stimuli (120 V, 0.8 ms, 8 ms inter-twitch interval) were given for knee extensor stimulation.

Protocol: Subjects were asked to perform ten MVC knee extensor contractions with a two minute interval between contractions. Prior to and after each contraction, three resting twitch stimuli were given for normalization of the superimposed twitch. Each MVC was sustained for 5s. After about 4s, a doublet twitch stimulus was superimposed onto the fully contracted muscle. Muscle inhibition was calculated as the percent ratio of the superimposed twitch torque divided by the resting twitch torque. The contraction that produced the greatest torque was taken as the true 100% MVC. All other contractions were expressed as a percentage of the true 100% MVC. Linear regression was used to test for statistical trends between muscle inhibition and knee extensor force.

RESULTS AND DISCUSSION

Muscle inhibition was negatively related to the amount of force produced by the knee extensor muscles (Fig.

1). Although the linear regression gave a significant result, the coefficient of variation was small (0.1043), indicating that the variations in knee extensor force accounted only for about 10% of the variations observed in muscle inhibition. Although the variations in knee extensor force were small, muscle inhibition values ranged from 0-60%. This result confirms that muscle inhibition for similar efforts varied greatly.

In our previous work we found that variations in muscle inhibition at 50% of MVC were greatly reduced when accounting for the actual knee extensor force values. We expected that the same result would hold true for contractions at, or near, 100% MVC. However, variations in muscle inhibition were great for force values ranging from 95-100% of MVC, and although there was a significant relationship between knee extensor force and muscle inhibition, the coefficient of variation was small, and variations in muscle inhibition were not greatly reduced when accounting for the knee extensor force variations. These results, imply that the variations in muscle inhibition around 50% of MVC are explained to a great degree by the corresponding variations in knee extensor force. However, this result does not seem to be correct for the variations in muscle inhibition around 100% of MVC. We conclude from these results that at 50% of MVC, muscle inhibition values give a very good account of the actual muscle force, whereas at 100% of MVC, muscle inhibition values vary greatly without an apparent cause.

⁵ Department of Orthopaedic Surgery, Niigata Kobari Hospital, Niigata, Japan

INTRODUCTION

Leg alignment assessment is an important key to the success of total knee arthroplasty (TKA) in orthopaedics (Robert et al., 1990). We have developed the leg alignment assessment system for the precise determination of three-dimensional coordinate system necessary for TKA by the use of bi-planar X-rays (AP and 60 degrees oblique) in combination with computed radiography (CR) system. This system enabled us to determine the coordinate system with the accuracy of angle less than 0.37 degrees with respect to all coordinate axes. However, a part of its operation was very time consuming due to the use of individual CT data. Therefore, the objective of this study is to develop an alternative technique to reduce the time of operation using a deformable bone model instead of the CT data.

MATERIALS AND METHODS

CR images were transferred to a computer. The several X-ray markers were digitized to measure the points of X-ray resources and three-dimensional space which consisted of two planes of film cassette holder was established. The origin of femoral coordinate system was the midpoint on the line A, drawn between the centers of the medial and lateral posterior femoral condyles determined as circles (Figure 1). The x-axis was laid on the line A. The line B was the connecting line from the origin to the center of the femoral head, and on the x-z plane. The z-axis crossed at right angle to the x-axis.

Figure 1: Femoral coordinate system

We estimated clinical parameters such as anterior bowing rate, lateral bowing rate, angle of the neck to the shaft, femoral

anteversion angle and parallel to posterior peaks of condyles line using CT data of dry bones, deformable bone model and only CR data. One of the five dry bones was selected to construct a three-dimensional bone model by CT as standard, and the other four bones were used as targets for deformable bone model.

RESULTS AND DISCUSSION

No significant difference in anterior bowing rate was found between the data by CT and by deformable bone model, but the CR data yielded significantly larger anterior bowing rate than the CT data. The lateral bowing rate of deformable bone model and CR data agreed well with that of CT data. The deformable bone model showed us better results than the CR data with respect to both the angle of the neck to the shaft and the femoral anteversion angle. Thus, the deformable bone model enabled us to perform more precise assessment of the leg alignment than the CR technique (Table 1).

Table 1: Relative errors of deformable bone model and CR in clinical parameter values to the standard CT data.

	Deformable bone model (mean \pm SD)	CR (mean \pm SD)
Anterior bowing rate	0.03 \pm 1.0 %	0.9 \pm 1.3 %
Lateral bowing rate	0.3 \pm 0.7 %	5.1 \pm 0.9 %
Angle of the neck to shaft	0.8 \pm 1.6 deg.	10.1 \pm 16.2 deg.
Femoral anteversion angle	0.5 \pm 2.3 deg.	2.1 \pm 1.6 deg.
Parallel to posterior peaks of condyles line	1.1 \pm 1.6 deg.	

SUMMARY

We have developed a new method, deformable bone model, to estimate clinical parameters for three-dimensional leg alignment assessment. The deformable bone model required AP and 60-degrees CR images and deformation of the original three-dimensional CT data. We estimated the clinical parameters by CT data, deformable bone model and only CR data. The results obtained by the deformable bone model showed the accuracy within 3 degrees in the associated angle and 3 % in anterior and lateral bowing rates. It can be concluded that the proposed method should be clinically useful for assessing the leg alignment.

INVESTIGATION OF THE PERMEABILITY OF OSTEOPOROTIC BONE FOR CEMENT AUGMENTATION PROCEDURES

Gamal Baroud^{1*}, John Z. Wu², Thomas Steffen¹

¹Orthopaedic Research Laboratory, McGill University, Montreal, QC, Canada; *email: gbaroud@orl.mcgill.ca

²National Institute for Occupational Safety & Health, Morgantown, WV, USA.

INTRODUCTION

Cement augmentation (vertebroplasty) is an emerging surgical treatment for patients suffering osteoporotic vertebral compression fractures. The procedure produces significant and rapid pain relief in 80-90% of patients, although the long-term safety and efficacy remain to be proven. Vertebroplasty is still experimental, and much needs to be done to make it a reliable and safe procedure. The purpose of this study is to investigate, theoretically and experimentally, the permeability of the bone with respect to time, viscosity, shear rate, and the volumetric porosity of the cancellous bone.

METHOD

The cement flow through the permeable bone is slow, so it can be approximated using Darcy's law:

$$v = \kappa(\alpha, \eta) \cdot \nabla p \quad (1)$$

where v is the infiltration rate, κ is the bone permeability, and ∇p is the directional pressure gradient. The cement is a very thick viscous fluid, its permeability, κ , is a function of time, volumetric porosity in injection direction, and viscosity:

$$\kappa = \kappa(\alpha) \cdot \kappa(\eta) \quad (2)$$

where $\kappa(\alpha) = A \frac{\alpha}{\alpha-1}$, ($A=0.9$), the porosity dependence (Baroud, 2002), was fit to the test data (Nauman, 1999).

Cement viscosity is time, t , and shear-rate, γ dependent. Cement viscosity was measured with respect to t and five different shear rates with a capillary rheometer. The test data were taken from Krause et al., (1982) and used to fit the dependence of the viscosity on the time and shear rate:

$$\eta = \left[a \left(\frac{t}{t_s} \right) + b \right] \cdot \left(\frac{\gamma}{\gamma_s} \right)^{[-c \left(\frac{t}{t_s} \right) + d]} \quad (3)$$

Where $t_s = 1.0$ min and $\gamma_s = 1.0$ 1/s are a characteristic time and shear rate, respectively; a , b , c , d are viscosity material parameters.

Infiltration experiments on isolated cores of osteoporotic bone, Fig 1, were performed to measure the pressure drop in response to the cement propagation through the core samples. Using an MTS testing machine, the plunger was pressed down at a constant speed of 2 mm/s, forcing the cement to flow through the interstitial space of the cancellous bone. Pressure-displacement curves were recorded. Tests were performed approximately 2.5 min after the cement mixing.

From the force-balance analysis, we obtained the relationship for the time and injection-speed dependent permeability:

$$\kappa(t) = \frac{v \cdot d}{p \cdot (t) - \frac{2}{r} (h_0 - vt) \cdot v \cdot \eta(t)} \quad (4)$$

where v is injection speed, r is the tube radius, p' is the pressure measured at the plunger tip and is related to injection

force, F , by $p' = F/\pi r^2$; h_0 denotes the initial height of cement column, and d is the thickness of the bone core.

Figure 1: Experimental set-up for the determination of the permeability

RESULTS

Using the experimental data (Krause, 1982), the viscosity material parameters Eq (3)

were found to be $a = 590.0$ (Pa*s), $b = -1048.8$ (Pa*s), $c = 0.026$, and $d = 0.290$. Based on these parameters and the average pressure gradient of our 10 infiltration tests, the time-dependent permeability of cement penetrating through the bone specimen has been determined, as in Fig 2. The permeability is strongly time-dependent, while the effect of viscosity through the tube wall is not significant.

Figure 2: Time-dependent permeability for different shear rate.

DISCUSSION

We carried out our infiltration tests using 1 cement (Simplex). However, our approach is generic and, therefore, applicable to any cement. We

determined vertebral permeability only in superior-posterior direction, assuming uniformity. In reality, the bone voids are non-uniform and the porosity depends on the void location and orientation. These effects have not been accounted for.

SUMMARY

This study is first to analyze cement flow through osteoporotic bone. The findings presented would help optimizing this procedure (e.g., pressure, viscosity) for clinical practice.

INTRODUCTION

The interactions of biological and mechanical factors in the pathogenesis of secondary osteoarthritis are not well understood. We have previously reported alterations in joint kinematics due to ligament deficiency in an in vivo ovine stifle joint model of osteoarthritis¹. These kinematic changes were associated with severe cartilage degeneration 20 weeks after ligament transection. The same model has been used to investigate the hypothesis that the in vivo kinematics at the joint surface are altered following ligament transection.

METHODS

Six skeletally mature trained Suffolk sheep were studied while walking at 2mph on a standard treadmill. The in vivo kinematics were measured for thirty strides with the joint intact and at 2, 4, 8, 12, 16, and 20 weeks following combined transection of the anterior cruciate and medial collateral ligaments.

A rigid surgically implanted bone marker system was used to define the 3D positions of the tibia and femur during the in vivo motion¹. The 3D spatial positions of the markers during gait were recorded using a 4 camera high speed (120Hz) video based motion analysis system (accuracy 0.15mm). Following euthenization, the bone markers positions were precisely digitized ($\pm 0.05\text{mm}$) relative to anatomically based coordinate systems originating at the insertions of the ACL (anteromedial band) into the tibia and femur. The 3D marker coordinates were tracked and smoothed (quintic spline; f_{cutoff} 6Hz), and then normalized to percentages of the gait cycle between successive hoofstrikes. Tibial joint angles and translational positions were described using a joint coordinate system and then differentiated twice to obtain tibial velocities and accelerations. For each specimen, the in vivo kinematics of the transected joint were compared with those of the intact condition, with significance of changes in joint motion assessed using a 2-tailed students t-test ($p < 0.05$). The pooled data were assessed using a t-test for paired samples ($p < 0.05$).

RESULTS AND DISCUSSION

Results from four sheep show the joint flexion angle increased at 2wks after transection during the first 46% of the gait cycle ($0.007 < p < 0.045$). At 20 weeks normal flexion was restored throughout the gait cycle in all animals studied (Figure 1A). A plot of angular velocity vs flexion angle demonstrates that the

range of flexion angular velocities was similar pre and post transection (Figure 1C).

A significant anterior tibial shift was observed in all sheep studied (Figure 1B). Anterior velocity increased prior to hoof strike and during the loading phase of initial stance ($0.002 < p < 0.04$), and decreased or increased in the posterior direction during the joint flexion of swing ($0.001 < p < 0.043$). A plot of anteroposterior velocity vs position (Figure 1D) shows the anterior tibial shift and the increased anterior tibial velocities at both 2 and 20 wks following transection. Anteroposterior acceleration remained within the range of normal variability following ligament transection.

Figure 1: A) joint flexion angle
B) anteroposterior joint position
C) flexion angular velocity vs angle
D) anteroposterior velocity vs position

SUMMARY

Ligament transection alters in vivo kinematics at the joint surface. Normal flexion kinematics are restored with time. In contrast, large changes in anteroposterior position and velocity persist at 20 wks following transection. We postulate that the kinematic changes at the joint surface are important in the development of the cartilage degeneration observed in this in vivo model of osteoarthritis.

HAEMODYNAMICS OF THE FONTAN CONNECTION

Keri Moyle¹, Gordon Mallinson¹, Brett Cowan², Chris Occleshaw³, Tom Gentles³
¹Dept of Mechanical Engineering, ²School of Medicine,
University of Auckland, Auckland, New Zealand
³Green Lane Hospital, Auckland, New Zealand

INTRODUCTION

The Fontan connection is used to bypass the right side of the heart in cases of pulmonary atresia, tricuspid atresia, and univentricular hearts. Long term success is heavily dependent on the haemodynamics and the surgical nature of the connection. This study produced three dimensional, patient specific simulations of the haemodynamics within connections using a method that combines magnetic resonance imaging (MRI) data with computational fluid dynamics techniques.

METHODS

Patients who had a Fontan connection were recruited and scanned using a 1.5T Seimens Vision MRI scanner. A three dimensional Voronoi-cell based computational mesh was created specific to the anatomy of each patient using an in-house program, ModelMaker, to identify boundaries of each vessel, and reconstruct the 3D representation shown in Figure 1, and CFX-5 to create a Delaunay triangulation of the surface (Figure 2). The volume mesh was created using Dr Were's program, GENMESH.3D phase contrast MRI scans were used to measure the velocity fields at the inlets and outlets of the connections. These were used as boundary conditions and validation data for the CFD models. The CFD flow solution was obtained using an Arbitrary Lagrangian Eulerian (ALE) finite volume method that has second order spatial accuracy.

The CFD solutions are being validated by a rigorous mesh refinement study for both test configurations and for real patient data. Comparison between outflows predicted by the CFD analysis and the MRI measurements are the basis for our assessment of the validity of the numerical predictions.

Structural details of the flow fields in the connections are also used as a basis for comparison.

RESULTS

Shown in Figure 1 is the progression from reconstructed surface, to computational model, to results. This patient has a total cavopulmonary connection that baffles the inferior vena cava through the right atrium to the superior vena cava. Figure 2 shows an MRI vector field through the pulmonary arteries, and the corresponding slice through the computational model. These preliminary results show qualitative agreement, and are being assessed more rigorously for detailed flow structures and quantitative comparison.

SUMMARY

A method for the creation of three dimensional, patient specific simulations of the haemodynamics of the Fontan connection has been devised and implemented successfully. Simulation results are in general agreement with MRI data and are being further analysed.

REGULATION OF MOTOR UNIT RECRUITMENT IN THE CARDIAC MUSCLE

Carmit Levy and Amir Landesberg

Department of Biomedical Engineering, Technion-Israel Institute of Technology, Haifa, Israel.

amir@biomed.technion.ac.il

INTRODUCTION

The regulation of cardiac muscle contraction is determined by coupling calcium kinetics with cross-bridge (Xb) cycling. Calcium binding to the troponin regulatory complexes regulates Xb recruitment. Our theoretical studies suggest the existence of a dominant positive feedback mechanism, denoted as the cooperativity mechanism, whereby the affinity of troponin for calcium depends on the number of force-generating Xbs.

OBJECTIVES

The suggested cooperativity mechanism leads to the prediction that there is no unique force-length relation. The generated force is determined by the bound calcium and calcium affinity. Hence, for a given sarcomere length (SL), the force should be higher when the SL is approached from longer SL and smaller when it is approached from shorter SL. To test this hypothesis we examined the force responses to SL oscillations, at constant free calcium concentration and tetanus contraction.

METHODS

Eight trabeculae obtained from rat right ventricles were studied. SL was measured by laser diffraction techniques (Resolution of 3nm). The force was measured by a silicon strain gauge (Resonance frequency of 1.3 kHz). Muscle length was controlled by a fast servomotor (rise time of 0.25msec). The fibers were tetanized using 8Hz stimulation (pulse width of 40ms) in the presence of cyclopiazonic acid ($[Ca]_0=6mM$, $25^{\circ}C$). To quantify the force responses to the sarcomere length perturbations - small sinus oscillations of $40\pm 11.02nm$, at various frequencies (1, 2 and 4Hz) were imposed. The number of strong Xbs was quantified by measuring the stiffness, utilizing additional smaller ($2.47\pm 0.39nm$) and high frequency (50Hz) oscillations.

RESULTS

The force response lagged the SL oscillations, for oscillation frequency smaller than 4Hz (111.87 ± 40.98 msec at 1Hz). The oscillations of the force and the stiffness were closely aligned, suggesting that the force response was determined primarily by the regulation of XB recruitment, and not by changes in the average force per XB. A counter clockwise hysteresis was obtained between the force and the SL and for a given SL the force was higher when the SL was approached from longer SL, in accordance with the prediction. The hysteresis between the force and the SL resembles the hysteresis between the stiffness and the SL: similar direction and phase shift. The

counter clockwise hysteresis implies that the muscle generated external work during the oscillations. Hence the phase delay between the SL and the force relates to delay in the regulation of Xb recruitment.

CONCLUSION

There is no constitutive unique force-length relation, and the instantaneous force depends on the instantaneous length and on the history of contraction. The counter clockwise hysteresis between the stiffness and the SL implies that the lag in the force response is due to the delay in Xb recruitment. The counter clockwise hysteresis implies also that work is done by the muscle and the hysteresis cannot be attributed to visco-elastic properties of the muscle (which will lead to clockwise hysteresis). Therefore, the counter clockwise hysteresis validates the existence of the cooperativity mechanism that regulates Xb recruitment.

SIGNIFICANCE

The cooperativity mechanism provides the switching mechanism for cross-bridge recruitment in the cardiac muscle. It explains the steep force-length relation in the cardiac muscle, describes the adaptive control of energy consumption by the prevailing loading conditions and provides the molecular basis of the Frank Starling law at the whole heart level.

INCREASED INTRA-ABDOMINAL PRESSURE IS COUPLED WITH TRUNK MUSCLE CO-CONTRACTION DURING STEADY STATE EXERTIONS

Jacek Cholewicki, Paul C. Ivancic, and Andrea Radebold

Biomechanics Research Laboratory, Yale University School of Medicine, Department of Orthopaedics and Rehabilitation
New Haven, CT, 06520 USA jacek.cholewicki@yale.edu

INTRODUCTION

Theoretically, spinal unloading due to increased intra-abdominal pressure (IAP) is possible if the transversus abdominus and/or oblique muscles are recruited preferentially for generating IAP (Daggfeldt and Thorstensson 1997). However, Cholewicki et al. (1999) documented a significant increase in the electromyographic (EMG) activities of all major trunk muscles, in association with voluntarily elevated IAP during isometric trunk exertions. Therefore, the purpose of the present study was to investigate whether increased IAP could be achieved without elevating overall trunk muscle co-contraction and hence, without increasing spinal compression force.

METHODS

Ten subjects performed isometric trunk flexion, extension, and lateral bending exertions in a semi-seated position while generating 0, 40 and 80% of their maximum IAP or while co-contracting trunk muscles (CC) without consciously raising IAP (by keeping their glottis open). The isometric target force was set at 35% of the subject's maximum effort.

An EMG assisted biomechanical model (Cholewicki and McGill, 1996) was used to quantify trunk muscle co-contraction with calculations of spine compression force. The EMG signals were recorded from 12 major trunk muscles: left surface and right rectus abdominus, external and internal oblique, latissimus dorsi, thoracic and lumbar erector spinae.

Correlation coefficients between IAP and L4-L5 joint compression force were computed to determine the association between IAP and measures of muscle co-contraction.

RESULTS AND DISCUSSION

In parallel with increased IAP, spine compression force increased significantly ($p < 0.05$) in all isometric exertion directions (Figure 1). Increased spine compression force reflected an increase in the overall co-contraction of trunk muscles, which was accomplished with significantly greater activation of all 12 trunk muscles monitored.

None of the subjects were able to co-contrast their trunk muscles without increasing IAP. They generated an average of 30 (SD=14) percent of their maximum IAP in the CC trials. The amount of trunk muscle co-contraction, quantified with spine compression force, relative to the increase in IAP was the same regardless of whether the subjects intentionally generated IAP or consciously avoided it (Figure 1). It appears that the motor control strategy of increasing IAP during steady state, physical exertions is not to reduce spine compression force, but rather to increase the stability of the spine.

SUMMARY

During steady-state exertions, it was not possible to co-contrast trunk muscles without generating IAP, or conversely to generate IAP without trunk muscle co-contraction.

STRESS ANALYSIS ON MECHANICAL VALVE LEAFLET USING BLOOD FLOW PROFILE THROUGH THE VALVE

S. M. Rajaai

School of Mechanical Engineering, Iran University of Science and Technology, Tehran, Iran

Lecturer and Head of Biomechanics Group, s_rajaai@sun.iust.ac.ir

INTRODUCTION

In a previous research linked with this, Rajaai S. M. and Rahmani A., 1998, fifteen various valve models, with different geometrical dimensions, were studied using finite element method. From the models one of them is selected as the optimum design. The obtained model is acceptable as a result of biomechanical and spatial constraints in aorta root. In this paper, pressure distribution has been conducted on the valve leaflets applying finite element analysis in sectioning method.

METHODOLOGY

Designing of geometrical shape of leaflet of mechanical heart valve has accomplished in regard to the situation of aorta. To do this the results of H. Raul et. al., 1990 have been used. To design and select the best model, 15 models were compared on a trial & error process and the best one was selected. This comparison was held in main cross-section of aorta (Fig. 1)

Fig.1 The dimensions of aorta (dimensions are based on centimeter)

Navier Stokes equations for viscous fluid and continuity equations considering the following assumptions have been used to analyse the blood flow around the valve.

- Blood considered as a newtonian fluid
- The blood viscosity considered equal to 3.5cp
- The flow considered as steady – state, the rhythmic nature of blood pulse has been avoided, and the aortic wall is considered rigid.

RESULTS AND DISCUSSION

Velocity equation in x direction is as follows:

$$u_x = (\beta / 4\mu) \cdot (R^2 - r^2); \beta = [(128 \cdot q \cdot \mu) / (\pi \cdot D^2)] \cdot (R^2 - r^2) \quad (1)$$

After selecting the suitable model, leaflet profile should be found by calculations. Total curve of leaflet is obtained from shear contact of surface (which has 25 degree angle) to z axis

and to a cylinder with y axis, equation of this surface is as follows (The x'z' plane is the surface of the leaflet):

$$x'^2 = R^2 - 0.821z'^2 \quad (2)$$

To design the location of produced joint and to present the velocity profile in different cross-sections of the aorta, sectioning method has been used. The entering velocity profile of blood to aorta is gained by contact of parabolic velocity profile of fluid with crossing surface: $q=20(\text{lit/min})$

$$u_x = 74.29[R^2 - (y^2 + (n \cdot a)^2)] \quad (3)$$

Equation 3 gives profile of entrance velocity in each cross-section, in this equation 'n' is the number of sections and 'a' is the distance between each cross-section. After finding velocity profile by finite element method and NISA software fluid pressure profile has been obtained and the values have been shown as contours.

Mechanical properties of the graphite layer of polycrystalline, which is covered by alloy, made of pyrolytic carbon & silicon (%10-%20 by weight) has been considered for solid analysis. Solid analysis has been performed in critical conditions, one with closed valve and the other with open valve in closed situation, the worst condition was considered with discrepancy pressure of 11 (Kpa). For analysis of critical conditions, the contact velocity has been considered up to 72 (m/s). The maximum velocity occurs between two leaflets and maximum positive pressure occurs on the edge of the leaflet against the blood flow. The maximum negative pressure occurs up site of the leaflet and around the joint.

SUMMARY

The solid analysis on mechanical valve leaflet has been carried out for two modes of open, and closed. In each case tensile stress, shear stress, main stress, VON MISES stress, and octahedral stress contours are offered on the valve leaflet. It was found out that the open state of the valve is more critical than the closed state. The most critical amount of stress is 254.3E6 (pa) related to VON-MISES stress.

INTRODUCTION

The possibility of focusing ultrasonic waves at a focal zone has accelerated its use for non-invasive therapies, like extracorporeal shock wave lithotripsy and hyperthermia. This trait of ultrasonic waves makes non-invasive surgical applications feasible, using focused ultrasound to deliver intense vibrational energy to a focal zone, with no significant effect on surrounding tissues. Consequently temperature rises at the focal zone to relatively high values. This process provides a non-invasive technique with the property of destroying cancerous tissues in a well-defined target zone.

METHODS

In order to destroy cervix cancerous tissues, it is needed to gain a high level of acoustic pressure in the focal zone that can be done by an annular transducer [Table 1]. In such cases the amount of acoustic pressure can be calculated using the following equation [1,2]:

$$p(R) = \frac{\rho c}{\lambda} \int_s \frac{e^{-(\alpha + jk)R}}{R} dS$$

Applying acoustic pressure in the following equation, radiation power at the target surface can be obtained:

$$W = \frac{1}{\rho c} \iint_s p^2 dS$$

Using the bio-heat transfer equation the rate of temperature rise in the cancerous tissue can be studied [3]:

$$\rho_t c_t \frac{\partial T}{\partial t} = \nabla \cdot K \nabla T - W_b c_b (T - T_a) + W$$

RESULTS AND DISCUSSION

In this study, obtained results out of simulations and analytic calculations on the energy and frequency dependence during the ultrasonic waves' propagation in the cancerous tissue has been discussed.

Considering non-perfection of blood vessels in cancerous tissue and limitations of temperature rise in healthy tissues (41 °C) and cancerous tissue (43 °C), one of the main targets in transducer design should be increasing energy transfer rate [3]. For this purpose the relation between ultrasonic waves'

frequency and the maximum energy of the focal zone has been studied [Fig.1].

According to the simulation results, it can be said that for cancerous tissues small in size, the frequency should be risen and vice versa [Fig.2].

INTRODUCTION

The importance of wall shear stress in the initiation and progression of atherosclerosis has been recognised for some time. A novel way to quantify wall shear stress under physiologically realistic conditions is to combine MRI and CFD. This combination of techniques has been regarded as a powerful tool for the investigation of flow in real arteries, since it is capable of providing data that are difficult to measure *in vivo*. The present study aims to investigate the reproducibility of the simulated flow by using such a combined approach.

METHODS

The right carotid bifurcations of 8 healthy subjects were scanned twice with MRI with a time-interval of at least one week. Three-dimensional geometries of the carotid arteries were reconstructed for each of the two scans and for each subject, resulting in a total of 16 carotid bifurcation models. Differences in reconstructed geometries resulting from the two scans of the same subject were evaluated using three quantitative measures, namely the centre-line distance, cross-sectional areas and shape factor. Pulsatile flows through these models were calculated with the same inlet and outlet boundary conditions to assess errors associated with the predicted flow parameters. This was done by comparing various wall shear stress indices, including time-averaged wall shear stress (TAWSS), oscillatory shear index (OSI), wall shear stress gradient (WSSG) and the wall shear stress angle deviation (WSSAD) (Hyun, 2000). Comparisons were made between the two sets of results obtained for the same subject by averaging the above-mentioned parameters on “patches” on the vessel wall. Differences in patched data between the two

Figure 1: Time-averaged wall shear stress for the **a.** first scan; **b.** second scan. The scale is logarithmic.

Figure 2: “Patched” oscillatory shear indices for the external carotid artery in **a.** the first scan; **b.** the second scan. Note the brown colors are patches over maximum value shown in the legend. The blood flows through the vessel from down to up in this representation of the vessel wall.

scans were compared using a paired Student’s t-test, $p < 0.05$ was considered significant.

RESULTS AND DISCUSSION

Predicted TAWSS maps for two different scans of the same subject are shown in Figure 1. Differences in geometry between the models were found to be: centreline-error of 0.536 mm, shape factor errors of 6.53% (CCA), 9.44% (ICA) and 11.22% (ECA). Qualitatively, the TAWSS appears similar between scans. Figure 2 shows the colour-coded OSI distribution on the ECA vessel wall in a patched manner. All four parameters (TAWSS, OSI, WSSG, WSSAD) did not differ significantly ($p > 0.1$ for all) in CCA, but the reproducibility in the ICA and particularly the ECA was less satisfactory.

SUMMARY

Reproducibility of predicted wall shear stress in the carotid bifurcation using a combined MRI and CFD method has been quantified. The overall reproducibility was found to be satisfactory although better results were obtained for the CCA than its branches. Further study will aim to correlate predicted wall shear stress errors with geometrical errors, in order to identify the most sensitive geometrical parameter that affects the predicted wall shear stress.

MOTION CONTROL SHOES REDUCE MIDFOOT RANGE OF MOTION DURING RUNNING

Richard.M.Smith¹ and Renee.L.Attwells¹

¹School of Exercise and Sport Science, University of Sydney, Australia

INTRODUCTION:

Excessive pronation is associated with a variety of injuries, particularly when running and this has stimulated investigation of rearfoot motion relative to the leg during running with and without footwear (eg Stacoff et al., 1991). Nigg and co-workers (cited in Clarke et al 1983) have shown that, with additional medial support in the footwear, the average pronation in subjects with over-pronation problems was reduced to below that shown in symptom free subjects. Little has been done to investigate the effect of footwear on the midfoot region of the foot. Other authors have measured significant relative motion between the forefoot and the rearfoot during the stance phase of running barefoot (Attwells and Smith, 2001). However, when wearing motion control footwear for example, the addition of midsole support may restrict the motion of the foot around the midfoot joints. The purpose of this paper was to investigate the range of motion in the midfoot region during the stance phase of heel-toe running while wearing motion control running shoes and barefoot.

METHODS:

Ten Subjects (five control and five clinically diagnosed overpronators) underwent five running trials with and without footwear. Surface markers were placed on the lower right leg and foot, and a metal shim was attached to the calcaneus. A wand marker system (Attwells and Smith, 2001) was fixed to the shim by a slot and lock mechanism. Three markers placed on the navicular, first and fifth metatarsal heads in the barefoot condition and on the surface of the shoe in the same positions for the footwear condition defined the forefoot. The three-dimensional position of these markers during stance phase of movement was captured using a seven-camera motion analysis system and the relative angles, corrected for standing eversion angle, between the forefoot and rearfoot segments calculated using a joint co-ordinate system.

RESULTS AND DISCUSSION:

A main effect of footwear was seen for dfpf ($F = 437$, $p < 0.001$) (Table 1 and Figure 1) and adab ($F = 42$, $p < 0.001$) but not for inev ($F = 3.9$, $p = 0.082$). There was no main effect of pathology for any angle. The only significant interaction between footwear and pathology was for dfpf ($F = 7.3$, $p = 0.027$) with the footwear causing a greater decrement for pronators than normals.

The shoe exhibited less range of motion around its midsole region than the foot did in the barefoot condition. Although the experiment had not measured the forefoot directly while in the shoe, the tightness of the fit of the shoe at both heel and forefoot would suggest that the shoe used in this experiment did limit the range of motion around the midfoot during the

stance phase of running. One effect of limiting dfpf in the midfoot is an increase in range of dfpf at the ankle (Attwells and Smith, 2001). The effect of limiting the other angles and possible deleterious effect on the functioning of the foot deserve further investigation.

Table 1 Range of motion (mean SD) for the forefoot/foreshoe relative to the rearfoot.

	Range of Motion (deg)							
	normals				pronators			
	barefoot		shoe		barefoot		shoe	
df/df	27.1	3.2	9.6	3.1	31.3	3.6	8.5	1.7
in/ev	7.2	4.0	5.3	1.6	7.8	2.5	5.0	1.9
ad/ab	7.2	4.0	3.2	0.6	11.8	4.7	2.8	1.0

SUMMARY

The motion control shoes used in this study showed a decreased range of motion about the midsole region during the stance phase of heel-toe running compared with the range of

Figure 1 Time series for dfpf for the footwear and barefoot conditions.

motion observed for the bare foot. If the shoe is close fitting this implies that the foot has a decreased range of motion about its midfoot region also. One outcome is a greater range of dfpf at the ankle joint. Whether this or other restrictions of range of motion are deleterious to foot function needs further investigation.

ESTROGEN DEPLETION IS ASSOCIATED WITH CHANGES IN OSTEON MORPHOLOGY

Lanny V. Griffin, Lisa Christensen, Ryan Vandenbosch, Melanie Fish, Robbie Bigley
Bioengineering Laboratory, California Polytechnic State University, San Luis Obispo, CA
lgriffin@calpoly.edu

INTRODUCTION

It is well accepted that estrogen deficiency associated with menopause increases the risk of osteoporosis and bone fragility in women. Les and coworkers have found that estrogen depletion affects the microstructure and properties of cortical bone (2001). We hypothesized that osteon morphology would also be effected by estrogen depletion.

METHODS

We obtained twelve 1.5 cm long segments of cortical bone taken from the proximal radius/ulna of six-year-old Warhall breeder sheep. At the age of 3, six of the sheep were ovariectomized (Ovx) and six were subjected to a sham surgery (Non-Ovx). The bone was kept in gauze, soaked with calcium buffered saline and frozen, except when machining. We machined 4x4x15 mm blocks from the caudal and cranial regions of each bone of using a low-speed diamond sectioning saw (Buehler Isomet 1000, Lakebluff, IL) under constant irrigation of distilled water. We set aside five 100µm thick sections from each block for each region. The sections were lightly deburred and polished using 600 grit abrasive media moistened with calcium buffered saline, then mounted on a slide for histologic evaluation at 100x. At this magnification, approximately 20 fields were required to cover the entire section. The sections examined under polarized light to determine the collagen fiber-birefringence pattern using the osteon classification of Ascenzi (1976) and Martin (1996). We counted and recorded the diameter and type of osteon, in five of the twenty fields per section, 2 periosteal, 2 endosteal and one central field using an image analysis program (Bioquant 5.0, Nashville, TN). Volume fraction of osteon was calculated as the (area of osteon type)/(section area). Statistical analysis was conducted using a GLM procedure with volume fraction and diameter as the independent variables, with factors anatomic region, zone (periosteal/endosteal), osteon type, and Ovx/Non-Ovx. Multiple pairwise comparisons were made using the Bonferroni method and significance was reported for $p < 0.05$.

RESULTS AND DISCUSSION

We found that darkfield and hooped osteons are more prevalent in the caudal and cranial regions ($p < 0.0001$) and that osteons tended to be more prevalent in the endosteal portion, rather than periosteal portion of the cortex ($p < 0.0001$). In the sheep we examined, there was a great deal of primary lamellar bone on the periosteal portion of the cortex, with little evidence of remodeling activity.

We found that estrogen deficiency significantly increases the volume fraction of osteon type ($p < 0.0001$) with greater numbers of darkfield and hooped types of osteons being recorded.

We found that the diameters of the osteons are regionally dependent ($p < 0.0001$), caudal being larger than cranial (130 µm and 100 µm, respectively). The diameter appears to be a function more of anatomic region rather than estrogen deficiency ($p = 0.510$). We also found that osteons tended to be larger in the endosteal portion of the cortex (125 µm vs 100 µm). Since osteoporosis is more associated with trabecular bone, it seems reasonable that changes to cortical bone would tend to be near the inner portion of bone. Moyle and Gravens (1986) showed that the work to fracture of bovine tibia is related to osteon size and so we expect there is regional variation in the fracture properties of the sheep bone as well.

SUMMARY

We were able to demonstrate estrogen deficiency significantly effects the microstructural organization of cortical bone in a sheep model. Specifically, we found greater numbers of darkfield and hooped osteons in estrogen deficiency in bone and that most of the changes in morphology occur in the endosteal portion of the cortex.

INTRODUCTION

Tissue engineering procedures open the way to achieve living implants for a variety of medical applications. In principle, cells are yeasted from the living organism by biopsy, then expanded in culture in the laboratory. Preferably, pre-dispositioned autologous cells are used to avoid rejection of the implants after the operation.

The cells need a structure to grow on. These are e.g. biodegradable polymers, collagen scaffolds, fibrin gel or chitosan. Premature progress of differentiation has to be prevented. Cartilage repair by membrane-bound autologous implantation (MACI, VTSI Verigen Inc.) is described as state of the art in clinical approach. For enlarged defects, 3-dimensional (3D) matrices with autologous chondrocytes may be the next step. This study demonstrates how 3D-scaffolds are obtained, and that cells of different type grow into the scaffold.

METHODS

Collagen sponges are produced by freeze-drying of collagen suspensions. The porous structure can directly be controlled by the ice crystal morphology (Fig. 1) since after removal of the ice by vacuum-drying the pore structure of the collagen is a replica of the ice structure.

Homogeneous solidification of fingerlike ice formation can be obtained under almost stationary freezing conditions which is possible by applying unidirectional solidification techniques. This can be achieved by using the Power-Down-Technique to imprint a constant temperature gradient on the sample. During the freezing procedure the bottom and the top of the sample are cooled down with the same cooling rate. We investigated the variation of crystal sizes that can be adjusted by freezing parameters and composition of the collagen suspension.

Fig. 1: The porous sponge structure is determined by the ice

crystal-morphology in frozen collagen suspensions.

RESULTS AND DISCUSSION

The ice formation can be organized very regularly resulting in corresponding regular sponge structures as shown in Figure 2. By adding acetic acid to the collagen suspension in varying concentrations we adjust the crystal size and thus obtain pores in the range of 20 – 100 µm. The pores formed in parallel to the heat flow showed no irregularities throughout large dimensions, even up to 10 mm thickness (cf. Fig. 2).

Fig. 2: SEM picture of a collagen sponge produced by directional solidification and freeze-drying according to the Power-Down technique.

It is shown for selected cell types that the cells are not only growing on the sponge surface but really penetrating the sponge. For different cell types such as chondrocytes, adipocytes, nerve cells, epithelium cells or fibroblasts, we will investigate whether the dimensions of the collagen sponge have to be "designed" individually for optimal ingrowth.

SUMMARY

3-D collagen structures can be produced as well defined and regular sponge-like scaffolds. The dimensions can be varied by selection of the process parameters and additives. The growth of different cell types indicates that viable implants can be obtained by using adequate sponges.

MECHANICAL BEHAVIOUR OF BASEBALLS DURING COMPRESSIVE LOADING TO BAT-BALL IMPACT LEVEL

Rochelle Nicholls^{1,2}, Karol Miller² and Bruce Elliott¹

¹ Department of Human Movement & Exercise Science, University of Western Australia, Perth, Western Australia

² Department of Mechanical & Materials Engineering, University of Western Australia, kmiller@mech.uwa.edu.au

INTRODUCTION

Impact from the batted ball is responsible for 4-5 deaths per year amongst baseball pitchers (Adler & Monticone, 1996). The material properties of the ball affect the dynamics of the bat-ball interaction, and thereby the ball exit velocity and subsequent time available for the pitcher to take evasive action. During bat-ball impact, a baseball is compressed to 50% of its original diameter (Adair, 1994). Previous investigations of baseball material properties using quasi-static uniaxial compression have typically tested to 10% compression, as the force-displacement relationship is linear in this range and ball stiffness can be determined as the gradient of the curve (Hendee, Greenwald & Crisco, 1998). In order to predict baseball impact response and behaviour under maximal conditions, this research undertook compression to 50% to obtain more realistic measures of material behaviour.

METHODS

70 new baseballs from 7 models were tested, representing balls used in professional and college baseball. Uniaxial compression testing was conducted using the Instron 8501 (Instron Corp., Canton, Massachusetts). Each ball was positioned between two circular stainless steel platens: the upper platen was attached to a calibrated 100 kN load cell and lowered toward the stationary lower platen at 1 mm/s. The onset of the loading phase was indicated by the first non-zero force reading, and terminated at 50% of baseball diameter (35.86 mm). One loading cycle was completed for each ball. Force-displacement data was sampled at 5 Hz using LABTECH Notebook software. The data were normalised to 100 data points (as a percentage of maximum displacement).

RESULTS AND DISCUSSION

The nonlinear behaviour of baseballs under compression to 50% of original diameter is evident in Figure 1. The curves are concave-upward for all models, containing no linear portion from which elastic modulus can be determined.

Directional effects: The surface of the baseball is asymmetric due to its pattern of raised seams. Testing for effects of ball orientation on the force-displacement curve was undertaken using 5 orientations: 3 in which the contact points were on the ball cover (at the widest point in the xy, xz and yz planes), and 2 in which the ball was orientated on its seams. Repeated measures ANOVA for normalised force indicated no significant differences within the cover or within the seams orientations ($p=0.210$). However a distinct directional effect was evident between cover and seams orientations ($p=0.000$), with cover orientations being steeper with greater peak force (Figure 1).

Ball stiffness: Some quasi-static properties of baseballs have been previously correlated with ball impact characteristics, particularly peak force and stiffness (Hendee *et al.*, 1998).

Figure 1: Force-displacement curves for Model 2 in cover and seam orientations.

Modification of the procedure adopted by Hendee *et al.*, (1998) was used to estimate ball stiffness for compression to 50%. Data from four balls in each model were selected at random and averaged to represent that model. Linear least-squares fit was applied to the 10 (normalised) data points preceding maximum displacement for each ball model. Stiffness was determined as the gradient of this fit line (Table 1). These values are significantly higher than those reported by Hendee *et al.* (1998) for 10% compression (mean 2340 ± 441 N/cm, $n=7$) and verify the distinct directional effect.

	Cover	Seam
Model	Stiffness (N/cm)	Stiffness (N/cm)
A	18004	12977
B	20039	15813
C	17541	12751
D	19769	14438
E	16175	13853
F	17187	13575
G	18089	14128

Table 2: Linear fit stiffness data for all ball models

SUMMARY

Baseball stiffness during compression to 50% of initial diameter has been determined. The directional effect has implications for ball design: the reduced peak force and stiffness during compression on the seams indicates a potential control strategy for ball performance. A mathematical model to predict the behaviour during high-speed impact should be developed.

EFFECT OF DYNAMIC COMPRESSION ON $\beta 1$ INTEGRINS (CD49D, CD49E) AND CD44 ADHESION MOLECULES EXPRESSED BY ARTICULAR CHONDROCYTES.

C. Gigant-Huselstein¹, D. Dumas¹, D. Baptiste², WH Liu¹, X. Wang¹, S. Muller¹, P. Netter², E. Payan², J.F. Stoltz¹

INTRODUCTION

In diarthrodial joints, articular cartilage experiences a variety of stresses, strains and pressures that arise during normal activities of daily living. The cartilage matrix functions to distribute relatively large loads across the bony ends. Its homeostasis is maintained in part through the chondrocyte response to mechanical stimulation.

The integrin family and the CD44 adhesion receptors appears to play a major role in mediating chondrocyte-matrix interactions.

The aim of this work was to observe, with 3D microscopy techniques, cellular dimension, the expression of $\beta 1$ integrins (CD49d and CD49e) and CD44 adhesion molecules within compressed explants. A numerical simulation was also performed to determine local deformation of the cartilage under mechanical stress.

METHODS

Tissue culture and mechanical compression

Femoral heads were harvested on healthy rats. Compressive loads were applied to individual explants using a specially designed apparatus (Flexcell International). Five percent compressive strain amplitude was applied to the femoral head dynamically (Frequency=0.5 Hz) for 48 hours.

Cellular dimension and $\beta 1$ integrin and CD44 receptors expression

First, images acquired by Confocal Laser Scanning Microscopy (CLSM) were used to calculate dimensional data like length, width and volume. Then, the $\beta 1$ integrins and CD44 receptors were analyzed by indirect immunofluorescence assay with an Optical Scanning Microscopy (OSM) technique combined to a 3D iterative deconvolution process (CellScan EPRTM) and CLSM (SP2 Leica Microsystem).

Type I and II collagen production

Types I and II collagens were analyzed qualitatively by indirect immunofluorescence assay using the CellScan system.

Numerical simulation

In order to determine local deformation of the cartilage femoral head under compression, a numerical simulation was performed. The cartilage was considered as a semi-spherical homogeneous elastic shell with a given Young's modulus. A finite element package (MARC) was used to solve the

equilibrium equation of the shell under imposed displacement. This simulation allowed us to know quantitative deformation at every point of the cartilage and helped us to better understand the modification of the biological function of chondrocytes situated in different area.

RESULTS AND DISCUSSION

A series of confocal scans through the center of individual cells revealed a change from spherical to an elliptical morphology. This change was a direct consequence of a significant increase of the length (static : $11.60 \pm 1.34 \mu\text{m}$; compression : $14.91 \pm 1.85 \mu\text{m}$) and a significant reduction in width (static : $10.34 \pm 1.61 \mu\text{m}$; compression : $7.41 \pm 1.31 \mu\text{m}$). These observations included also trends for cell directional strains, confirming a role in chondrocyte metabolic response to compression [1].

The quantification with 3D fluorescence microscopy showed that dynamic compression induced an increase of CD49d and CD44 expression but any variation of CD49e adhesion molecules. Results suggest that $\beta 1$ integrins and CD44 receptors could potentially act as initiators of mechanotransduction pathways under mechanical compression.

SUMMARY

Mechanotransduction events in articular cartilage may be resolved into extracellular components followed by intracellular signalling events, which finally altered cell response [2]. The aim of this study was to examine, with 3D microscopy techniques (deconvolution and confocal), the cell deformation and adhesion molecules such as $\beta 1$ integrin or CD44 receptors expressed by chondrocytes within compressed explants. Results suggest that the application of compressive strain to chondrocytes in femoral head induces a number of strain events, such as cell deformation, variation of the $\beta 1$ integrins and CD44 receptors expression.

EFFECT OF RHEIN ON INTRACELLULAR IL-1 β PRODUCTION AND α 1 INTEGRINS EXPRESSION IN STIMULATED CHONDROCYTES –

C. Gigant-Huselstein (1), D. Dumas (1), S. Muller (1), D. Bensoussan (1), J.F. Stoltz (1)

e-mail : stoltz@medecine.uhp-nancy.fr

INTRODUCTION

Osteoarthritis (OA) is a degenerative disease of diarthrodial joints in which degradative and repair processes in articular cartilage, subchondral bone and synovium occur concurrently. Diacerhein is one of the proposed therapeutic agents to regulate the inflammatory process [1]. The drug and its active metabolite rhein, exerts inhibitory effects on interleukin-1 (IL-1)-induced expression of cartilage degrading enzymes [2]. However, its mechanism of action is not completely understood.

The present study was designed to quantify the receptors α 1 integrin CD49d and CD49e and the intracellular IL-1 β in stimulated chondrocytes by TNF- α and rhIL-1 β . Then, we evaluated the *in vitro* effects of rhein on intracellular IL-1 β and on α 1 integrin expression.

EXPERIMENTAL METHOD

Chondrocytes cell culture

Human chondrocytes monolayer were incubated for 12, 24 and 48 hours in the presence of TNF- α or rh-IL1 β . On the other hand, we have evaluated the *in vitro* effects of rhein (10⁻⁵ M, Negma, France) on stimulated or no-stimulated chondrocytes.

Intracellular IL-1 β production :

Chondrocytes were fixed, permeabilised and incubated with fluorescein isothiocyanate conjugated monoclonal antibody IL-1 β . Then, cells were analyzed by flow cytometer and observed under an epi-fluorescence inverted microscope equipped with the CellScan EPRTM optical scanning acquisition system [3].

α 1 integrin CD49d and CD49e expression :

Adhesion receptor expression was determined by a direct immunofluorescence assay. The quantification of CD49d and CD49e expression was performed using Quantum Simply Cellular calibrator (Sigma, France). Calibration beads were used to transform the conventional mean fluorescence intensity obtained in flow cytometry as arbitrary units into an absolute number of antibody molecules bound per cell

RESULTS AND DISCUSSION

Flow cytometry and 3D microscopy showed that cells stimulation by TNF- α and rhIL-1 β induced a significant increase of intracellular IL-1 β production. Whereas, the addition of rhein lead to a reduction of intracellular IL-1 β production.

The quantitative study of CD49d and CD49e receptors showed that normal chondrocytes expressed more strongly CD49e receptor than CD49d receptor. Moreover, stimulated cells by proinflammatory cytokines induced a significant increase of CD49e from 24 hours of incubation, suggesting a role of this receptor in transduction signal generated by rhIL-1 β or TNF- α . A weak increase of CD49d receptor expression was also observed from 12 hours to 24 hours. When chondrocytes are treated with cytokines and rhein, a decrease of α 1 integrins receptors expression was observed, suggesting an action of rhein on these integrins receptors expression.

SUMMARY

Diacerhein has shown to be effective and well tolerated in the long term treatment of OA however, its precise mechanism of action on chondroprotection is unclear. The aim of this study was to estimated the intracellular IL-1 β production and the expression of α 1 integrins receptors (CD49d and CD49e) on stimulated or no-stimulated chondrocytes. Then, we studied the effect of rhein, the active metabolite of diacerhein, on these parameters. From this study, it seems that rhein partially reduce cytokine-induced intracellular IL-1 β production, and it has a weak action on CD49d or CD49e receptors.

FORCE ENHANCEMENT IN SINGLE SKELETAL MUSCLE FIBRES ON THE ASCENDING LIMB OF THE FORCE-LENGTH RELATIONSHIP

Danny Peterson, Dilson Rassier, Walter Herzog

Human Performance Laboratory, University of Calgary, Calgary, AB, Canada

INTRODUCTION

Force enhancement following an active stretch in skeletal muscles has been associated with sarcomere non-uniformity on the descending limb of the force-length relationship (Edman et al., 1982; Morgan et al., 2000). According to this theory, during stretch, some sarcomeres elongate less than average, while others elongate more than average and produce most of their force passively as this is the region where non-uniformity develops. One of the predictions of this theory is that force-enhancement is only possible on the descending limb of the force-length relation. However, Herzog and Leonard (2002) have shown a small, but consistent force-enhancement on the ascending limb of the cat soleus muscle. This study was aimed at investigating whether force-enhancement on the ascending limb is a property of single skeletal muscle fibres.

METHODS

The experiments were performed with single muscle fibres ($n=7$) dissected from the flexor digitorum brevis (FDB) of the frog *Rana pipiens*. The tendons of the dissected fibres were gripped with T-shaped pieces of aluminum foil and mounted in an experimental chamber between a servomotor length controller (Aurora Scientific) and a force transducer (Sensoror). The chamber was filled with Ringer's solution and the temperature was regulated at $\sim 7^{\circ}\text{C}$. Stimulation (Grass S88, Grass Instruments) was given through two platinum wire electrodes placed on either side of the muscle fibre. Following an experimentally determined force-length relationship, several isometric and stretch contractions (6 s long) were recorded along the ascending limb of the force-length relationship. Stretches were performed with a velocity of 0.8 mm/sec and an amplitude of 0.2 mm (approx. 10% of fibre length).

RESULTS AND DISCUSSION

Of the 7 fibres tested, 4 showed force-enhancement on the ascending limb of the force-length relationship. The magnitude of force-enhancement appears to increase when moving up towards the plateau of the force-length relation. The following figures show stretches beginning at the same length on the ascending limb and ending at the plateau of the force-length relationship. Figure 1 shows force traces of an experiment in which force enhancement was observed. Figure 2 shows force traces of an experiment in which force enhancement was not observed.

Figure 1: Fibre showing force-enhancement ($\sim 4\%$) on the ascending limb of the force-length relationship.

Figure 2: Fibre showing no force-enhancement on the ascending limb of the force-length relationship. However, note that forces at the initial length were not exactly the same, thus possibly hiding a small force enhancement.

We conclude that single cells may produce force enhancement on the ascending limb of the force-length relationship. If, as typically assumed, sarcomeres are stable on the ascending limb of the force-length relationship (Morgan et al., 2000), the sarcomere length non-uniformity theory cannot explain our current observations. The dichotomous results observed here may be a consequence of different fibre types in the FDB muscle.

WALL SHEAR STRESS WITH INITIATION OF ANEURYSM AROUND ANTERIOR COMMUNICATING ARTERY IN STEADY FLOW

Ryuhei Yamaguchi¹, Susumu Kudo¹, Nobuhiko Nakazawa¹
and Hiroshi Ujiie²

¹Department of Mechanical Engineering, Shibaura Institute of Technology, Tokyo, Japan

²Department of Nerosurgery, Tokyo Women's Medical University, Tokyo, Japan

INTRODUCTION

The aneurysm in the cerebral artery is apt to initiate around the "Circle of Willis". The anterior communicating artery (ACoA), which composes one of major part of the circle of Willis, is the most predilection artery of the aneurysm.

In the present paper, the change of flow structure such as the wall shear stress at the apex of ACoA with the initiation of aneurysm is described in steady flow. Once the early aneurysm initiates at the apex in one confluent tube with much flow rate, the distribution of wall shear stress abruptly changes around the early aneurysm. The relation between the initiation and the development of aneurysm is physiologically discussed from the viewpoint of hemodynamics.

METHODS

The flow field around ACoA is simulated by two confluent tubes joining at the angle of 60 degrees, two parallel bifurcating tubes, and the junctional tube, bypass (ACoA), connecting four tubes at normal condition. The flow model with the early aneurysm is simulated as the concave with small radius around the apex in the right confluent tube with much flow rate Q_R as shown in Fig.1. In experiment, the velocity profile is measured by LDA and the wall shear stress is estimated from the velocity gradient near the tube wall. The saturated sodium iodide NaI solution with the same refractive index of 1.49 as the channel material, acrylic plate, is employed as the working fluid in velocity measurement.

RESULTS AND DISCUSSION

The measurement has been carried out at the Reynolds number of $Re=2R_0U/\nu=400$ and the confluent ratio of $Q_R/Q_L=2.2$. U is the mean velocity based on the average flow rate $(Q_R+Q_L)/2$ and ν is the kinematic viscosity.

The velocity profile around ACoA is shown in Fig.1. Except for the flow field around the early aneurysm, the velocity profile around ACoA as a whole is similar to that without the aneurysm at normal condition. The velocity through ACoA is several times as large as the maximum velocity in the right confluent tube. The core flow in the right confluent tube impinges at the right apex, right medial corner. There is a small recirculating flow in the concave, aneurysm.

Except for the flow field around the aneurysm, the distribution of wall shear stress around the ACoA as a whole is also similar to that without the aneurysm at normal condition as shown in

Fig.2. The wall shear stress changes around the right apex. Particularly, this change is extremely large around the concave. Therefore, this abrupt change of wall shear stress may induce the progressive development of aneurysm.

FOOT ROLL OVER SHAPES IN TRANSTIBIAL AMPUTEES: IMPLICATIONS FOR PROSTHETIC ALIGNMENT

¹National Centre for Prosthetics and Orthotics and ²Musculoskeletal Research Centre
La Trobe University, Melbourne, Australia

INTRODUCTION

During stance phase in human walking, the ankle acts to adjust limb length, to provide shock absorption and to enable forward rotation of the leg over the fixed foot. If the ankle is fixed, it is important to compensate for lost function. In ankle foot orthoses, rocker soles are sometimes used to simulate the rocker action of the ankle. In prosthetics, this is achieved through foot design and alignment.

Hansen *et al.* (2000) introduced the concept of the foot roll-over shape (FROS) to explain the relationship between prosthetic foot design and prosthesis alignment in amputee gait. FROS was defined as the geometry of the plantar surface of the foot with respect to the leg during the single support phase of walking. Mechanical testing and “simulated” amputee gait were utilized to quantify FROS for a number of prosthetic feet.

There are three shortcomings of the study of Hansen and co-workers. Because the definition of FROS did not include terminal stance phase, it excluded the very important shape change which occurs in the anatomical foot with plantarflexion at terminal stance. The study did not measure FROS under conditions of amputee gait. Finally, the “anatomical” FROS data presented was based on a single subject reported by other investigators.

For the purposes of the present investigation, FROS was defined as the shape described by the sagittal plane projection of the center of pressure (CoP) during stance phase expressed in the local coordinate system of the leg.

The aim of this investigation was to measure FROS in a group of amputees and to compare data to able-bodied controls.

METHOD

Subjects: 11 able-bodied adults (4 female, 7 male) and nine male transtibial amputees participated in this investigation.

Apparatus: A Vicon motion analysis system and Kistler force platform were used to obtain motion and force data. Amputees wore experimental prostheses fabricated using modular componentry and Otto Bock SACH feet.

Procedures: Height and weight were measured and recorded. Reflective markers were placed on the lateral malleolus and head of fibula in normal subjects. In amputees, markers were placed on the pylon just above the distal adaptor and on the midline of the socket. Data was collected during normal velocity walking along a 10 m walkway. Trials were deemed successful if the limb contacted the force platform cleanly

during stance phase. Three shod trials were collected for amputee subjects. Three shod trials and three barefoot trials were collected for able-bodied subjects.

Analysis: Marker data were reconstructed. CoP coordinates were expressed in the local coordinate of the leg with the coordinate origin at the ankle and the y axis passing through the proximal marker on the leg or socket. Data were normalised for stature, averaged across trials within subjects and across subjects within groups.

RESULTS

Figure 1. FROS for able bodied controls and amputee subjects. The ankle is at the coordinate origin. Heel Contact (HC) occurs at the left, Toe Off (TO) at the right.

DISCUSSION

The prosthetic FROS is different from the FROS of able-bodied controls (Figure 1). The control shape is concave throughout single support but a sharp reversal occurs as a result of plantarflexion during terminal stance. The prosthetic FROS is flat until the GRF passes the keel of the prosthetic foot. At terminal stance, the prosthetic shape appears to provide a compromise between the maximally dorsiflexed and plantarflexed points of the able-bodied FROS. It may be possible to utilise FROS information to improve bench alignment methods for prostheses. An optimisation approach could be developed to facilitate dynamic alignment. Further investigation of the FROS concept is warranted.

MECHANICAL ENERGY LOSS AT THE STUMP-SOCKET INTERFACE IN TRANSTIBIAL PROSTHESES

T. M. Bach^{1,2}, G. Halford¹ and D. Orr³

¹National Centre for Prosthetics and Orthotics, ²Musculoskeletal Research Centre
and ³Department of Human Physiology and Anatomy
La Trobe University, Melbourne, Australia

INTRODUCTION

Reduction of energy costs for people with amputations is considered desirable. A site of possible energy loss is the interface between the prosthesis and the residual limb (Lilja *et al.* 1993). Previous x-ray studies have demonstrated differences in displacement of residual limbs within different socket designs (Narita *et al.* 1997). These differences could result in differences in energy loss but concurrent force and displacement data is necessary for definitive measurements.

The aim of this study was measure mechanical energy losses at the stump-socket interface for two socket types. A further aim was to ascertain if mechanical energy loss was related to metabolic energy cost of walking. Based on the earlier work of Narita *et al.* 1977) it was hypothesized that a PTB prosthesis would result in larger displacements, larger mechanical energy losses and higher metabolic energy costs during walking compared to a Silicone suspension system.

METHOD

Subjects: Nine male transtibial amputees participated in the investigation.

Apparatus: A Vicon motion analysis system and a Kistler force platform were used to collect motion and force data. Douglas bags and Beckman O2 and CO2 analysers were used to measure oxygen consumption during ambulation. Amputees were fitted with two prostheses: a standard PTB with cuff and a hydrostatic socket with Comfort Plus silicone liner and pin suspension. Prostheses consisted of modular components and Otto Bock SACH feet.

Procedures: Two reflective markers were placed on the thigh along a line connecting the lateral epicondyle of the knee and the Greater Trochanter. Two markers were placed on the stump with the prosthesis doffed. Data was collected while the subject flexed and extended his knee. Circles fitted to the stump marker data enabled calculation of the knee center in the local coordinate system of the thigh. Stump markers were removed, one prosthesis was donned and two markers were placed on the lateral midline of the prosthesis. Subjects marched on the spot with the prosthetic foot contacting the force platform while data was collected for 10 s. Subjects were fitted with a headpiece with a one-way valve connected to a Douglas bag. They ambulated for 300 m back and forth along a 15 m course while energy expenditure was measured. The process was then repeated for the prosthetic socket. Order of presentation was rotated between subjects.

Analysis: From the force and motion data, longitudinal displacements of the socket with respect to the knee center were calculated. Force-displacement graphs were generated and from these, energy losses for each loading cycle were computed by integration. Differences between socket conditions were analysed using t-tests for matched pairs.

RESULTS

The prosthetic coupling displayed viscoelastic properties as evident from the load displacement curves. The PTB prosthesis was associated with larger displacements (mean = 2.7cm) and mechanical energy losses (mean = 4.2 J) than the TSB silicone system (1.8 cm and 2.1J respectively). Differences were statistically significant ($p < 0.05$). No differences in metabolic energy cost were found.

DISCUSSION

In this investigation, substantial energy losses were observed at the stump-socket interface. We have estimated that, for PTB sockets, these losses represent approximately 5% of the mechanical energy cost of amputee gait. Silicon liners significantly reduced pistoning of the stump within the socket and halved the energy losses. Although differences were statistically significant, they may be too small to be considered clinically significant. Measurement of metabolic energy expenditure may not be sufficiently sensitive to reliably detect the small differences in metabolic energy expenditure which may be associated with the different socket types.

MODELING AND VISUALIZATION OF THE MECHANICAL BEHAVIOUR OF SKELETAL MUSCLE USING A CONTINUUM APPROACH

Robson Lemos¹, Marcelo Epstein², Walter Herzog³, and Brian Wyvill¹

¹Department of Computer Science, www.cpsc.ucalgary.ca/~lemos

²Department of Mechanical Engineering, ³Faculty of Kinesiology
The University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

The purpose of this study is to investigate muscle function and deformation in whole muscle. Muscle models and geometric models have been developed to analyze the characteristics of force production [1], and to determine muscle deformation based on architecture [2][3][4]. To the best of our knowledge none of the previous models include, simultaneously, a detailed description of the three-dimensional skeletal muscle architecture, and a physically consistent model to simulate the deformation behaviour during muscle contraction. We would like to incorporate several levels of representation in a single computational model of skeletal muscle in such a way that there are basic building blocks that can be well understood and are interconnected. In this study, we present a non-linear, stand-alone computational model which contains different levels of representation of skeletal muscle using the theory of continuum mechanics and the principle of virtual work.

METHODS

For the geometric, three-dimensional representation of skeletal muscle architecture, we adopted an assembly of eight-node brick-like elements. The structural representation of the muscle architecture was obtained through the association of each brick-like element with the soft tissue information that it represents. The geometric representation of muscle architecture consists of an assembly of four main elements: muscle tissue, aponeurosis tissue, tendon tissue, and muscle fibre tissue. All these separate tissues may be considered as a particular case, represented by a unified brick-like element, which contains an underlying passive tissue matrix. In order to obtain realistic muscle deformations, we formulate a non-linear finite element analysis using the theory of continuum mechanics and the principle of virtual work. In the constitutive law for all passive tissues, we assume hyperelastic behaviour, namely the existence of a stored energy function from which the stress is obtained. In the constitutive law of the active muscle fibres we adopt a basic quadratic force-length relationship with a positive slope in the descending limb.

RESULTS AND DISCUSSION

The development of a muscle model using computational mechanics allows for the inclusion of the following features: interactive visualization techniques, full implementation of the muscle architecture, and of the behaviour arising from its complexity using a fibre bundle as the basic structural unit, application of a variety of tissue constitutive and activation/recruitment relations, and geometric constraints, such as incompressibility, that can be enforced through Lagrange multipliers.

SUMMARY

In conclusion, the model is general enough to incorporate several levels of representation of skeletal muscles. The lowest level is the muscle fibre, allowing for the full implementation and representation of the muscle architecture, and the highest level is the whole muscle allowing for the calculation of work, analysis of control phenomena, and description of generalized muscle deformation. The principle of virtual work, in the presence of geometric constraints, represents a physically consistent model to simulate the deformation behaviour of skeletal muscles.

THE EFFECT OF GAIT TRANSITION ON DUTY FACTOR IN THE HORSE (*EQUUS CABALLUS*)

Witte T.H. Lichtwark G.A. Wilson A.M.

Structure and Motion Lab, The Royal Veterinary College, North Mymms, Hatfield, Herts, AL9 7TA England

INTRODUCTION

Ground reaction force (GRF) equals body weight in a standing animal. In locomotion, however, limbs must be lifted and repositioned for forward motion and can therefore only apply a vertical force for part of the stride. Averaged over the complete stride the mean GRF must still equal the body weight ie the sum of the vertical impulse applied by all the limbs must equal the product of body weight and stride time. The proportion of time a limb spends in stance is given by the duty factor; this is $T_{\text{stance}} / (T_{\text{stance}} + T_{\text{protraction}})$. The ground reaction force curve shape is cosine shaped and relatively invariant, so as duty factor drops peak limb force rises (Alexander *et al*, 1979).

In faster locomotion the leg sweeps back more quickly and despite some increase in sweep angle (Farley *et al*, 1993) a reduction in duty factor has been observed in all species studied. This results in an increase in limb force with speed. The cost of locomotion is closely related to peak limb force in a range of animals (Kram & Taylor, 1990). This relationship has been exploited to predict the energetic cost of locomotion in humans (www.fitsense.com; Weyand *et al*, 2001).

In man gait transition is complicated by changes from inverted pendulum to springing gait, but animals are able to employ several spring-like gaits; trot, canter and gallop. The deployment of limb pairs however changes from symmetrical to asymmetrical at the trot-canter transition.

Two explanations for why an animal changes gait have been proposed. Studies on horses indicate that the minimum energetic cost (expressed as J per meter traveled) coincides with the preferred speed within each gait (Hoyt and Taylor, 1981). The shape and intersections of the curves are much less distinct when expressed as actual cost of locomotion against speed. The transition from trot to canter in horses occurs not at an energetic minimum but rather at a speed appropriate to minimise limb force - weighted horses make the trot/canter transition at a lower speed than when unloaded (Farley and Taylor, 1991). This is a more convincing explanation because limb force will be mirrored by the volume of muscle activated to resist that force and because biological transducers exist (muscle spindles, Golgi tendon organs) which are appropriate to monitor the force experienced by muscle-tendon units. In this study we hypothesise that each gait transition results in an increase in duty factor as a function of speed (and hence a reduction in peak limb force).

METHODS AND RESULTS

Six thoroughbred-type horses were exercised on a high speed treadmill at speeds ranging from 1.8 to 13ms⁻¹. Speed was

incremented with steps of 0.5ms⁻¹. Stance time, protraction time and duty factor were determined using radio telemetry of data from foot mounted accelerometers.

RESULTS

These data are all for the forelimbs. Limb protraction time was about 400ms at walk and slow trot, dropped to 350ms at the highest speed of trot and remained around that value for all speeds of canter and gallop. Stance time dropped in a curvilinear manner with speed from 400ms to 200ms through trot and 200ms to 110ms through canter and gallop. Sweep angle increased linearly with speed from 36 to 64 degrees. Duty factor dropped from 0.65 at walk to 0.22 at gallop. There was no effect of gait transition on the gradient of the relationship between speed and any of the parameters measured. Duty factor was 2% shorter in the lead leg than the non lead leg during canter and gallop locomotion. At canter the peak force on the lead leg of a pair (the second leg to hit the ground) is 20% lower than on the non-lead leg. (Merkens *et al* 1993). The Alexander equation does not reproduce this difference. This is because the centre of mass displacement, and hence effective vertical limb stiffness (Farley *et al*, 1993) is different during the stance of each limb.

CONCLUSIONS

There is no evidence for a change in duty factor at gait transition. Transition to canter and gallop gaits will unload one limb but at the expense of a concomitant increase in load on the contralateral limb. This may explain why lame trotting horses prefer to canter as they can unload the painful limb. Gait transition may also enable horses to achieve the higher sweep angles needed for high speed locomotion, contribute to elastic energy storage in the tissues of the spine (Alexander, 1985) and / or reduce external work on the center of mass.

HISTORY-DEPENDENCE OF FORCE PRODUCTION IN SKELETAL MUSCLE

Dilson E. Rassier and Walter Herzog

Human Performance Laboratory, University of Calgary, Calgary, AB, Canada

INTRODUCTION

When activated skeletal muscles are stretched on the descending limb of the force-length relationship, the resulting force is higher than the isometric force produced at the corresponding final length (Edman et al, 1982; Herzog and Leonard, 2000; Morgan et al, 2000). Experiments with the cat soleus have shown that muscle shortening preceding muscle stretch decreases the level of force (Herzog and Leonard, 2000), suggesting the engagement of a passive element associated with force enhancement. However, experiments with single cells from the frog show that force enhancement is not affected by previous shortening, when an interval is introduced between the length changes (Edman et al. 1982). The present study was aimed at re-evaluating the effects of shortening on the stretch-induced force enhancement in single cells, with and without intervals between length changes.

METHODS

Single cells dissected from the flexor digitorum brevis muscle of the frog were used in this study. Isometric contractions (2 s) were performed to derive a force-length relationship for each cell. Starting on the descending limb of the force-length relationship, stretch and shortening contractions were performed with amplitude of 10% of fiber length, at a velocity of 40% fiber length/s. Shortening-stretch cycles were also performed on the descending limb of the force-length relationship. These shortening-stretching cycles were done without intervals between length changes, and with intervals of 500 ms and 1000 ms between the shortening and the stretch contractions. Contractions were sustained for at least 4.5 s after the final stretch.

RESULTS AND DISCUSSION

When cells were activated, and then stretched, the steady-state isometric force following the stretch was higher than the isometric force at the corresponding final length (Fig. 1). When cells were activated, and then shortened, the steady-state force was lower than the isometric force at the corresponding final length. When muscle shortening was followed immediately by muscle stretching, the level of force enhancement was decreased (Fig. 1). However, when intervals were introduced between the shortening and stretching phases, the effects of shortening on the stretch-induced force enhancement decreased. Different amplitudes of shortening had similar effects on force enhancement (Fig 2).

In conclusion, shortening preceding stretching affects the stretch-induced force enhancement, but this effect is diminished by the introduction of intervals between the length changes. These results suggest that force enhancement is

partially caused by the engagement of a passive element during an active stretch. Engagement of this passive element decreases with shortening; thus, shortening decreases force enhancement. The effects of shortening on the passive element engagement appear to decrease when the fiber is held isometrically between the shortening and stretching phases.

Figure 1: Force enhancement in a single muscle fiber. The traces were recorded after a single stretch (Str), and after stretches preceded by shortening with (Sho-In-Str) and without (Sho-Str) interval (500 ms). The isometric force at the final length is also shown (Iso).

Figure 2: Force enhancement in a single muscle fiber. The traces were recorded after a single stretch (Str), and after stretches preceded by shortening of different amplitudes (Sho-Str). The isometric force at the final length is also shown (Iso).

SMELLING WITH HAIRY LITTLE NOSES: THE PHYSICAL DESIGN OF OLFACTORY ANTENNAE

Mimi A. R. Koehl

Department of Integrative Biology, University of California, Berkeley, CA, 94720-3140, USA,
<http://ib.berkeley.edu/labs/koehl>

INTRODUCTION

Appendages bearing arrays of hair-like structures serve important biological functions in many animals from a variety of phyla: feathery gills take up oxygen, chemosensory hairs on olfactory antennae capture odorant molecules, filamentous suspension-feeding structures catch single-celled algae, setulose appendages create ventilatory or feeding currents, and bristly legs or wings propel little animals through the surrounding water or air. To perform any of these functions, an array of hairs must interact with the surrounding fluid. We have been studying the fluid dynamics of arrays of cylinders to elucidate basic rules governing how hairy appendages work (Cheer & Koehl 1987; Koehl, 1995). The present study uses these rules to determine how the physical designs of olfactory antennae affect how they filter chemical information from the environment (Koehl 1996; 2001).

Many animals use chemical cues in the water or air around them to detect mates, competitors, food, predators, and suitable habitats. The first step in processing olfactory information, before neural filtering, is physical capture of odorant molecules from the surrounding fluid. Many crustaceans capture scents by flicking antennules that bear arrays of chemosensory hairs. We studied how the hydrodynamics of crustacean olfactory antennules flicking in turbulent odor plumes physically alters the spatio-temporal patterns of concentration arriving in the receptor area.

METHODS

We conducted high-speed video analyses of antennule flicking kinematics and SEM determination of antennule morphometrics (Goldman & Koehl 2001). Dynamically-scaled physical models and mathematical models were used to quantify the small-scale flow fields around antennule chemosensory hairs and the diffusion of odorant molecules to hair surfaces (Koehl 2001). Planar-laser-induced fluorescence was used to measure the fine-scale structure of odor plumes in turbulent water currents in a flume, and the instantaneous patterns of odorants arriving among the sensory hairs on antennules flicking in such plumes were recorded using high-speed, high-magnification video (Koehl *et al.* 2001).

RESULTS AND DISCUSSION

Lobsters and mantis shrimp flick their olfactory antennules in a critical Reynolds number range for their particular arrangements of chemosensory hairs (Reynolds number, Re , represents the relative importance of inertia to viscosity). They flick in the Re range in which the ability of water to

penetrate into the hair array changes with velocity. We found that water flows through the hair array during the rapid flick, but not during the slower return stroke. In turbulent water currents, odor plumes are made up of fine-scale filaments of scent whose pattern varies with distance from the source. Water carrying these patterns of concentration penetrates into the array of chemosensory hairs only during the rapid flick, and is retained until the next flick.

SUMMARY

We used the antennules of spiny lobsters and mantis shrimp to analyze the critical first step in determining the spatial and temporal patterns of odor pulses arriving at receptors: physical interaction of the olfactory organ with an odor plume. The chemosensory hairs these olfactory antennules operate in a range of Re and hair spacings in which changes in velocity can have profound effects on the flow near the hairs, and thus on their performance in capturing molecules from the surrounding fluid. Our work has revealed how lobster olfactory antennules hydrodynamically alter the spatio-temporal patterns of concentration in turbulent odor plumes. Antennules flick: water penetrates into their chemosensory hair array only during the fast downstroke, carrying fine-scale patterns of concentration into the receptor area. Hence, because of the hydrodynamics of their antennules, these animals take discrete odor samples in space and time (i.e. they sniff).

INTRODUCTION

Over the last thirty years, improvements in legislation and technology have successfully reduced the number of deaths (due to head and thoracic) injuries occurring to the occupants of cars involved RTAs. However, the number of disabling lower limb injuries continues to rise.

This study was designed to enable thresholds for fractures to the calcaneus, talus and tibial plafond to be established. These fractures have been shown to result in significant long term morbidity in a large UK accident study (Taylor 1997).

Within the Institute of Biomechanics a dedicated sled test facility has been constructed. The sled is capable of creating a validated and repeatable crash pulse. The pulse was modelled on the toe-pan recordings from a full-scale crash test using a standard mid range car in frontal impact. This sled was used to subject post mortem human surrogate (PMHS) lower limbs to dynamic frontal car impact loading. Previous work (Manning 1997) has recognized the importance of inertial loading of the lower limb and pre-impact tensioning.

METHODS

The PMHS specimens were screened to exclude prolonged pre-morbid bed rest, previous trauma or surgery. All specimens were prepared preserving the knee joint and were fresh frozen.

The sled impactation rig provided impact velocity of up to 50 Km/h with delayed application of axial loading. This delay was 50 ms after the initial deceleration of the sled, realistically simulating brake pedal intrusion. The axis of load was applied directly via a simulated brake pedal to the mid-foot in axial line with the anterior tibial border.

Realistic braking pressures were simulated by applying a plantar flexing moment at the ankle via a tension of 1KN in the achilles tendon.

Instrumentation of both the PMHS specimens and the sled rig has allowed for extensive biomechanical data collection up to and including the point of failure (fracture). Forces monitored include, direct loads applied, sled decelerations, PMHS accelerations and brake pedal intrusion.

High-speed film recording enabled additional kinematic analysis. Acoustic monitoring of the specimens provided

additional data used in injury timing and to help in injury identification.

Only one impact was applied to any specimen. Specimens were randomised into one of four impact severity groups. In 50 % of the tests, the applied loading was reduced to a sub injury impact.

At the conclusion of each test the specimens were examined for injury using X-rays and necropsy.

RESULTS

This paper presents the methodology and techniques employed in the test program.

The results from twelve PMHS specimen impacts are presented. In addition, a preliminary analysis of the biomechanical data together with detailed description of the fractures created is described. The authors put forward injury threshold levels to be considered in the drafting of future requirements for cars in legislative car crash testing.

DISCUSSION

Delaying the application of axial loading after the initial impact and sled deceleration effectively imparts momentum into the specimen preloading the foot and ankle. This increases the bracing effect, provided by the Achilles tendon tensioning.

This series accommodated the movement of hip, knee and ankle that intrusion of the foot-well and pedal mechanism may impart. There was no attempt to recreate the effect that the knee/dashboard interaction may have on ankle injuries.

A Weibull curve of injury risk against axial load was produced. The paper discusses its significance in the prediction of injury in impact testing using dummy limbs.

TAKE-OFF OPTIMIZATION PATTERNS IN SKI JUMPING: GENERAL VERSUS INDIVIDUAL MODELS

Frantisek Vaverka and Miroslav Janura

Dept. of Biomechanics and Engineering Cybernetics, Faculty of Physical Culture, Palacky University, Olomouc, the Czech Republic
tr. Miru 115, 771 11 Olomouc, the Czech Republic, vaverka@ftknw.upol.cz

INTRODUCTION

The designation of a model of ski-jumping take-off as optimal is a key problem in the training process. The basic question to be posed can be characterized as follows: Is there only one acceptable take-off model which should be the goal of all training efforts of both coaches and competitors, or is it possible to define several variants of a ski jumping take-off models and then work with individual models suited to individual competitors? The data so-far gathered in numerous research studies (for example Vaverka et al, 1997; Virnavirta, 2000) indicate that the degree of inter-individual variability of biomechanical characteristics is substantial for both the in-run and take-off phases of ski-jumping and that there is a very low level of statistical dependence between the in-run, the take-off and the performance in ski-jumping. In practice this means that competitors with similar individual take-off models achieve very different performance results and, conversely, competitors who perform the take-off variously have similar performance results. The solution of this problem, interesting from both the theoretical and the practical points of view, is the object of this analysis.

METHODOLOGY

This solution is based on kinematic analyses of the take-off and in-run phases of ski-jumps as performed in the Intersport tournament competitions held in Innsbruck 1991-2000. Over the course of a decade, a kinematic analysis (2D) of the take-off phase (480 analyses) and the in-run phase (940 analyses) was carried out annually on the same jumping hill, during the same events, observing the best international competitors. An analysis of the take-off in the last four meters provided us with 27 variables (course, angle, time, velocity, angular velocity), and the analysis of the in-run phase produced eight variables. The resulting jump performance was characterized by the length of the jump expressed in percentages of the critical point of the jumping hill (CLJ). The statistical analysis of biomechanical data was aimed at solving the relationship between measured variables and the resulting jumps at the level of inter-individual variability as seen in the sets of all starting jumpers ($n=40-55$, correlation and factor analysis), comparison of selected sets of competitors on various performance levels (best and low level of performance, $n=6-10$) and comparison of individuals – intra-individual variability (take-off phase, 18 jumpers, the average number of take-offs for each individual was 7.6; in-run position, 10 jumpers, analysis of variance). Further information as to the methodology used can be found in the following literature: Vaverka et al. (1997) and Janura et al. (1998).

RESULTS AND DISCUSSION

Analyses of correlational relationships between sets of biomechanical characteristics of the in-run and take-off phases and jump length proved a very low dependence between the execution of movement and jump length (in-run: 8%, take-off: 17% explained variability of the CLJ). The result of the analysis of the inter-individual variability of biomechanical variables signals a great degree of individuality in the performance of movements by jumpers. The analysis of individuals (intra-individual analysis) has proven very limited individual models of the performance of the studied ski-jumping phases. Based on the example of a comparison of five competitors of various performance levels (Fig. 1) it is evident that every athlete carries out movement in a personal, specific way.

Figure 1: An example of the intra-individual variability of some selected athletes. Take-off, 0.0 m, variables: AT, AG, CLJ (criterion of the length of jump).

SUMMARY

The results of a great quantity of inter- and intra-individual analyses have indicated predominant individual variations in the in-run and take-off patterns for individuals. The resulting findings influence, in a substantial way, our opinion of the formulation of an optimal model for observed ski-jumping phases and make a significant impact on forming and correcting ski-jumping technique in training practice.

INTRODUCTION

The FIS rule concerning ski jumping equipment has been changed during the last years. First, the ski length was defined one's body height plus 85 cm with the unregulated toe binding location. The thickness of the suit was 8 mm, and permeability 30 l/m²/s. Next, the rule changed to height plus 80 cm with the binding location of 57% of the ski length and the suit did not change. Last, the 146% rule and change in suits (thickness 5 mm and permeability 40 l/m²/s) were adopted provisionally for a trial year 1998-1999. It allows jumpers taller than 173 cm to use longer skies while jumpers less than 173 cm are forced to use shorter skis than previously. The current 146% rule seems unfair to shorter jumpers.

The purpose of this study is to clarify effects of equipment and performance characteristics based on wind tunnel measurements using a 2/3 scale model and Aquila simulator.

METHODS

The equipment of the 2/3 model for the wind tunnel measurements was as follows: skis, helmet, shoes and official competition clothing. The measurements were performed in a subsonic Göttingen type closed circle wind tunnel where the cross section in the measurement area was 3.68 m² (Luhtanen et al., 1995). The model was attached to an overhead six-component platform-balance. The force measurement accuracy was better than 1% with the blockage ratio at most 5% and sampling rate for the force measurements 1 Hz. The force values were averaged for six seconds. The typical angle of attack range of the ski plane was 22 - 42 degrees. It was measured between each 2 degree. The relevant measurement parameters kinetic pressure, flow velocity and Reynolds number were taken into account. The drag, lift and pitching moment were transformed into dimensionless coefficients. The lift to drag ratio was calculated.

Two suit materials with the permeability of 40 l / m² / s were measured without and with the reference ski (length 169 cm, width at front 71 mm, at binding 65 mm and at rear 71 mm). The frontal binding of the ski location was 57%. The additional skis with the frontal binding location of 57% were in length 170, 175 and 180 cm (width at front 86 mm, at binding 78 mm and at rear 86 mm).

For simulation of jumps, the Aquila simulator was applied to Lillehammer K 120 jumping hill.

RESULTS AND DISCUSSION

The length of ski did not differentiate the polar curve clearly. It was observed that the longer the ski the higher is starting point on the polar. If the aerodynamic force production of the skis was about 40% and the difference in surface area between the shortest and longest ski was about 5% the increase in the magnitude of aerodynamic force was about 2%. It was observable that the longer skis tended to have larger range of negative pitching moment coefficient slope against incidence. The results, in the lift, drag and resultant force indicated that 60% of aerodynamic forces were acting on the jumper body and 40% on skis. With shallow incidence angles (ski plane incidence 22 degree) the drag proportion of body was about 73%. It decreased gradually when increasing incidence ending down to 57% at steep angles (ski plane incidence 42 degree). The change of lift was opposite. At shallow angles the proportion of lift on the body was about 55% and steep angles up to 60%.

SUMMARY

Concerning several jumping hills it was found that the increment of 22-29% in ski area increased about 40% in total aerodynamic forces adding jump length 9-12%. The effects of large variation in air permeability were on the drag even 7-12% and lift 12-25%. The selected averaged effects on the jump lengths in a K 120 hill due to the equipment and performance characteristics are shown in Table 1.

Table 1. The effects of relative changes (Δp , %) in lift (Cl), drag (Cd), reference area (S), mass, friction and takeoff force on the absolute (ΔJL , m) and relative jump length (ΔJL , %) in a K 120 m hill

Variable	Δp , %	ΔJL , m	ΔJL , %
Cl	+1	1.5	1.25
Cd	-1	0.8	0.67
S_reference	+1	0.9	0.75
Mass	-1	1.2	1.03

HEAD RESTRAINT POSITION AFFECTS OCCUPANT RESPONSE IN REAR-END COLLISIONS

INTRODUCTION

Head restraints were installed in vehicles to prevent whiplash injuries at a time when the mechanism for whiplash injury was thought to be head/neck hyperextension. Although head restraints reduced the frequency of whiplash injuries, the reduction was small (<25%, Kahane, 1982). One reason proposed for this relatively small reduction was the poor vertical adjustment of most head restraints, many of which remained in the full-down position despite being adjustable (Viano and Gargan, 1995). The goal of this study was to examine the effect of vertical head restraint position on the kinematic and kinetic responses of vehicle occupants during a low-speed rear-end collision and to examine how these differences might affect injury potential.

METHODS

A BioRID II rear-impact dummy was placed in the right front seat of a 1990 Honda Accord and exposed to a series of rear-end collisions (speed change = 8 km/h; duration = 125 ms). Three head restraint conditions were studied: full up (UP), full down (DOWN) and no head restraint (NONE). Five collisions were performed for each head restraint condition and test order was randomized. Prior to each test, the position and angle of the dummy pelvis were set and the dummy's head was then positioned 4.5 cm forward of the head restraint while in the UP position. After the dummy's pre-test position was established, the head restraint condition was changed for the test. Head extension relative to T1, and retraction, defined as the rearward horizontal displacement of the head centre of mass relative to the T1 spine block in the lab reference frame, were measured using sagittal-plane high-speed video. Shear (Fx) and axial (Fz) forces applied to the head by the neck at the head/neck junction, i.e., the atlanto-occipital joint, were measured using a 3-axis upper neck load cell and reported in the head reference frame. A one-way analysis of variance was used to assess differences in the response of each dependent variable between the three head restraint conditions. Scheffé tests were used for post-hoc testing and a significance level of $p=0.05$ was used for all tests.

RESULTS AND DISCUSSION

Peak head extension was $5.3 \pm 0.5^\circ$ in the UP condition, smaller than in both the DOWN ($8.6 \pm 0.9^\circ$) and NONE conditions ($45 \pm 1^\circ$) ($p<0.0001$). Peak retraction was also smaller in the UP condition (6.23 ± 0.05 cm) than in either the DOWN or NONE conditions ($p<0.0001$) (Figure 1a). Peak shear force (Fx) at the atlanto-occipital joint was 119 ± 3 N in the UP condition, and was significantly lower than in either the DOWN or NONE conditions ($p<0.0001$) (Figure 1b). Peak amplitudes of the shear forces in the DOWN and NONE conditions were not significantly different ($p=0.42$), however,

peak shear force occurred earlier in the DOWN condition than in the NONE condition. The tensile axial force (Fz) at the atlanto-occipital joint was 274 ± 6 N in the UP condition; 109 N lower than when in the DOWN condition ($p<0.0001$) and 139 N higher than when in the NONE condition ($p<0.0001$) (Figure 1c).

Figure 1: Mean (SD) of retraction, neck shear force (Fx) and axial force (Fz) for the UP, DOWN and NONE head restraint conditions. Fx, positive forward; Fz, positive downward.

SUMMARY

Based on the current data, head restraint position affected both the kinematic and kinetic responses of the BioRID II dummy in an 8 km/h speed change. As was the design intent, the head restraint decreased peak head/neck extension in both the UP and DOWN positions compared to no head restraint. The effect of head restraint position on peak retraction was similar. Upper neck forces, however, varied differently with head restraint position. Peak shear force at the atlanto-occipital joint was only reduced when the head restraint was properly positioned, i.e., in the UP position. Peak tensile forces at the atlanto-occipital joint were largest when the head restraint was present, but in the DOWN position, i.e., poorly adjusted. These data suggest that head/neck kinematics are sensitive to the presence of a head restraint, whereas upper neck loads are sensitive to the position of the head restraint. The larger neck loads observed with poor head restraint position may explain the marginal reduction in whiplash injury frequency observed with the introduction of head restraints.

INTRODUCTION

We have devised a method using neonatal rat cardiomyocytes to create a putative 3-dimensional construct of cardiac muscle. This construct, which we designate as a BAT or bioartificial trabeculum, rhythmically contracts in culture at about a 100 beats per min. Our purpose is to develop a model system for studying the effect of mechanical loading on cardiac physiology, and we feel a 3-dimensional tissue system is an effective vehicle for studying this question.

METHODS

Rat cardiomyocytes are isolated from 1-day-old rat pups using the Worthington Cardiomyocyte Isolation Kit and a slightly modified protocol. The rat neonatal cardiomyocytes are mixed into a solution of vitrogen collagen and plated into Flexcell Tissue Train plates and placed in a 37 C incubator with 5% CO₂ for 2 Hrs before adding M199 medium with 10% FBS. The Tissue Train plates have two nylon tethers at opposite ends of each well and a flexible silicon rubber bottom. When making the BAT the Tissue Train plate is mounted over a plastic mold shaped like a trough, which runs between the two nylon tethers. Vacuum is applied and pulls the silicon bottom of the plate into the trough forming a mold that the vitrogen can be pored into. After adding medium the strand “floats” in the medium attached to flexible nylon anchor stems at each end. (See Figure 1). Pulsatile stretch can be applied to the BATs in the Tissue Train plates by using a computer controlled vacuum source and a special mount to hold the plate in place.

Results- After 4 days in culture, the heart cells migrate toward the center of the gel and form a dense cord of “tissue” that extends between the two loading posts. This strand of tissue beats in a coordinated manner that is easily observed with a

low power microscope. Immunostaining with an antibody against Troponin I revealed striations characteristic of cardiac tissue and staining with an anti-Connexin 43 antibody shows cell to cell coupling through gap junctions characteristic of cardiac tissue. We have tested several stretching regimens on BATs and found that the BATs can tolerate pulseatile stretching and we plan to determine what effects stretch stimulation has on aspects such as beat rate and contractile strength.

CONCLUSIONS

Our long-term goals are to apply this system to study the effects of mechanical loading on normal cardiac physiology and to develop a model system for the study of cardiac pathologies such as congestive heart failure.

COMPUTATIONAL MODELING AND EXPERIMENTAL VALIDATION OF HUMAN EYE INTERACTION WITH HIGH-SPEED FOAM PARTICLES

Joel D. Stitzel, Erik D. Power, Joseph M. Cormier, William J. Hurst, Ian P. Herring, Stefan M. Duma
Virginia Tech, Impact Biomechanics Laboratory, Blacksburg, VA Email: duma@vt.edu

INTRODUCTION

A recent trend in automotive interior design has the air bag placed behind a seamless module cover. During the air bag deployment process, it is possible for foam particles from the dashboard to be released at high velocities, potentially resulting in eye injuries (Duma, 2000). The purpose of this study was to validate a computational model of the human eye suitable for investigating high-speed impacts from foam particles.

METHODS

A total of five simulations were performed at a range of impact velocities to correspond with five impact experiments performed with human cadaver eyes. The model of the human eye consists of a cornea, sclera, lens, ciliary body, zonules, aqueous humor and vitreous body (Power, 2000). A total of 464 membrane elements were used for the cornea and sclera and 152 brick elements comprised the aqueous and vitreous. Nonlinear, isotropic material properties of the sclera and cornea were gathered from uniaxial tensile strip tests performed up to rupture (Uchio, 1999). Components surrounding the eye such as the bony orbit, fatty tissue and extraocular eye muscles were included in the model. Foam hardness for the simulations matched that used in the experiments. The model was generated in I-DEAS (SDRC, Milford, OH) and then material properties and geometry were imported into Madymo (TNO, Troy, MI) for dynamic impact simulations. The velocities modeled in Madymo were those attained during experimental testing.

For experimental validation, eyes were enucleated within 6 hours postmortem and refrigerated less than 48 hours postmortem prior to usage. Eyes were pressurized to normal physiological pressure prior to testing using a needle inserted tangentially at the limbus prior to testing. Foam particles with a 6.3 mm diameter, 77.5 mg mass, 192 kg/m³ density, and 0.552 MPa hardness (at 25% compression) were projected onto the eyes. A pneumatic cannon was used to propel the foam at velocities ranging from 14 m/s to 32 m/s. The distance between the end of the pneumatic cannon and the eye was set to approximately 8 cm, as greater distances made it difficult to impact the eye consistently. All tests were recorded with high-speed digital color video at 7100 frames per second (Vision Research, Wayne, NJ). High-speed video was used to determine velocity of the foam particle, as well as globe deformation.

Additional instrumentation included ultrasound crystals that were used to measure deformation (Sonometrics, London, Ontario, Canada). Each eye was mounted in a synthetic orbit and held in place by a 10% gelatin solution designed to simulate the orbital fatty tissue. Injury analysis included fluorescein dye and ophthalmic ultrasound, as well as necropsy to further examine tissue damage.

RESULTS AND DISCUSSION

A range of five impact velocities were used with no injuries induced in any of the specimens (Table 1). Sample video frames are shown for comparison with the computational results (Table 2). The particle modeled had a velocity of 18.9 m/s as used in test number three. This value was chosen for the simulation because it represented the median value of the test velocities. Experimentally, this impacting particle caused the corneal apex to deflect 2.1 mm posteriorly, determined from the digital frames. From this simulation, the FE eye model predicted a corneal apex deflection of 2.26 mm, 7.6% greater than experimental results. From Table 2, the foam particle can be seen being deflected off the cornea after 2 ms. Both experimentally and computationally, the particle was in contact with the cornea for approximately 1 ms. Globe rupture has been shown to occur at approximately 9.5 MPa peak stress. The FE eye model in the simulation with the foam particle did not predict globe rupture, nor was globe rupture observed experimentally. The model developed will be useful as an aid to airbag design, and for other blunt impact studies such as baseballs and BB's. As the mechanisms of eye trauma are better understood, the model can be used to predict ocular trauma computationally and reduce the burden of eye injury.

THE HIGH FREQUENCY MATERIAL PROPERTIES OF BRAIN TISSUE AS DETERMINED BY ULTRASOUND

Samuel A. Lippert¹, Elizabeth M. Rang¹ and Michele J. Grimm²

Bioengineering Center, Wayne State University, Detroit, Michigan, USA

¹Graduate Research Assistant, Biomedical Engineering

²Associate Chair, Biomedical Engineering, grimm@rrb.eng.wayne.edu

INTRODUCTION

With the development of detailed computer models for simulating the response of the brain-skull system to impact loading, it has become vitally important to fully characterize the material properties of the brain, and thus ensure the accuracy of the models. Although brain tissue is well characterized at frequencies up to 200 Hz (Koeneman, 1966; Fallenstein *et al*, 1969; Galford and McElhaney, 1970; Wang and Wineman, 1972; Shuck and Advani, 1972; Hirakawa *et al*, 1981; Bilston *et al*, 1997; Donnelly and Medige, 1997; Arbogast and Margulies, 1998; Thibault and Margulies, 1998; and Brands *et al*, 1999), these frequencies fall short of those present in an impact event. As brain tissue exhibits viscoelastic behavior, the properties vary with respect to frequency, and thus utilizing properties obtained at lower frequencies can introduce unacceptable inaccuracies into the computer models. As mechanical rheometry is currently only possible at frequencies up to 1000 Hz, we utilized the ultrasonic wave-in-a-tube method (Lippert *et al*, 2001) to characterize the tissue at frequencies ranging from 100 kHz to 10 MHz.

METHODS

The heads of 12 lambs were obtained, 4 at a time, within 15 minutes of slaughter, from a local source. Upon removal of the brains, blunt dissection was utilized to separate the tissue white and gray matter. For each sample, the separated tissue was used to fill a tube 15.7 mm in diameter and 135 mm in length. This tube was then sealed on each end with ultrasonic transducers, and a measurement taken at each of 4 frequencies: 1 MHz, 2.25 MHz, 5 MHz and 10 MHz. Measurements at 500 kHz required use of a transducer 25.4 mm in diameter, and a correspondingly larger tube; to obtain these measurements, the tissue from 4 brains was combined, while still keeping the white and gray matter separate. The 100 kHz transducers were 50.8 mm in diameter, requiring the combination of the white and gray matter. As a general rule, the first measurement was taken within 90 minutes of the death of the animal, with the final measurement taken within 3.5 hours.

RESULTS AND DISCUSSION

Although elastic modulus, bulk modulus, Poisson's ratio as well as shear modulus can be obtained from the wave-in-a-tube technique, shear modulus is the most useful when it comes to

the construction of computer models, as well as for comparison with previously reported values. Thus the shear moduli we obtained are summarized in Table 1.

Frequency	White (Avg. G*)	Gray (Avg. G*)
100 kHz	80 MPa**	80 MPa**
500 kHz	195 MPa	214 MPa
1 MHz	252 MPa	195 MPa
2.25 MHz	320 MPa	347 MPa
5 MHz	358 MPa	435 MPa
10 MHz	353 MPa	471 MPa

Table 1: Average shear modulus for various frequencies obtained by the wave-in-a-tube method. ** indicates a combined modulus for white and gray matter.

Our values for shear modulus are several orders of magnitude higher than those established previously. This is not surprising, given that our frequency of excitation was several orders of magnitude higher. This type of behavior is not uncommon with viscoelastic materials.

INTRODUCTION

Osteosynthesis of adjacent lumbar vertebral bodies with the use of PLIF cages is a necessary procedure for degenerative spine disease. Since carbon-carbon composites exhibit good biocompatibility, stimulate ossification, are transparent for screening and can be made with mechanical properties approximating those of bone tissue, C-C components have been designed for application in the cage structure

METHODS

C-C composite samples (Torayca T800H fibres with Umaform LE phenolic resin as a matrix precursor) were prepared in various modifications: carbonised, impregnated, infiltrated and coated with PyC (pyrolytic carbon), and with PyC + pHEMA (poly[2-hydroxyethyl methacrylate]) + collagen. The biological characteristics of the samples were tested *in vitro* – cell adherence, proliferation, etc., and *in vivo* – C-C+PyC+pHEMA implanted into the intercondylar region of a hind leg femur of pigs, Fig.1, and Fig.2, together with comparative samples of steel, titanium, and C-C composite without coating. The basic material characteristics of the C-C composite were tested on the MTS 858.02 Mini Bionix Testing Machine.

Figure 1: C-C+PyC+pHEMA sample implanted in a pig hind leg femur

Figure 2: The trabecular bone gathers around the implant position (*) after 3 months

Based on a preliminary investigation, two modes of cages,

using a C-C composite core, reinforced with: **A)** a titanium shell, Fig. 3; **B)** a plastic shell (e.g., PEEK), Fig. 3, were designed by the research team. With mode **A**, the C-C-core protrudes over the Ti-shell ends, thus enabling a softer contact with the bone.

Fig. 3 Ti-shell + C-C-core **Fig. 4** Plastic-shell + C-C-core

RESULTS AND DISCUSSION

The bio tests of the C-C+PyC+pHEMA samples proved: *in vitro* – the metabolic activity of the fibroblasts shows a multiple increase and the content of inflammatory cytokines decreases; *in vivo* – better integration with the tissue than the other samples; preventing loosening of the carbon parcels, Fig.2. Mechanical compression tests of C-C composite samples, made by various technologies, served for choosing the optimal composite and together with an analysis of the L3 and L4 spine segment (based on experiments by G.Bergman - FU, Berlin), provided loading data for use in the FEM cage models, which simulated the stress distribution in the cages when implanted in the human spine.

SUMMARY

Several types of C-C composites have been developed for integration into PLIF cages, aiming at achieving a softer contact with the vertebral bodies and stimulating a better ossification process. Biological and mechanical tests proved the suitability of the materials. Based on FEM simulation, two cage modes (Figs. 3 and 4) with C-C composite cores have been designed for use in human surgery.

INTRODUCTION

A primary function of the airway liquid lining is to protect the lung from potentially harmful inhaled particles. While many previous models have sought to describe the distribution of particles that impact on airway walls throughout the lung, less attention has been paid to the details of the adhesive interaction between a particle, the airway liquid lining and the underlying epithelium. A full understanding of the dynamics of particle/liquid-lining interactions, which are controlled in part by competing surface tension and viscous forces, is important in implementing appropriate boundary conditions in aerosol inhalation simulations, and may be valuable in the development of improved inhalation therapies.

Figure 1. Model I: a particle partially immersed in a liquid pool in an alveolar corner drifts sideways under surface tension forces. Model II: a particle immersed in an initially uniform liquid layer generates an unsteady capillary wave, while trapping fluid at its base.

Schürch *et al.* (1990) have shown how surface tension, mediated by pulmonary surfactant, can pull a particle downwards into the liquid lining, indenting underlying epithelial cells. Motivated by these observations, we have investigated two model problems theoretically (Figure 1), relevant to micron-scale particles that can access unciliated peripheral airways and alveoli. Model I describes the quasi-steady normal and lateral displacement of a particle partially immersed in a laterally bounded liquid pool, as may arise in the corner of a polyhedral alveolus. We assume that, in the presence of pulmonary surfactant, the liquid wets the particle and the airway wall with zero contact angle. Model II describes the large-time unsteady response of an initially uniform airway liquid lining to the impact of a large particle.

METHODS

In both models we consider a two-dimensional geometry, recognising the potential limitations of this approximation, and represent the particle as a cylinder. In Model I, equilibrium free-surface locations are computed and are used to determine the net capillary force on a partially immersed particle. The speed of motion is controlled by viscous resistance, which is dominated by the flow in the narrow gap between the particle and the epithelium. This is computed using lubrication theory. In Model II, the unsteady evolution of the liquid lining is determined by finding asymptotic and numerical solutions of a thin-film equation of the form $h_t + (h^3 h_{xxx})_x = 0$, where $h(x, t)$ represents the liquid-lining thickness.

RESULTS AND CONCLUSIONS

In Model I, the particle can move either towards the centre of the pool or towards its edge, depending on the fluid volume, particle size, wedge angle and initial particle location. The particle's speed and distance of travel are influenced by non-specific surface forces and by deformability of the underlying epithelium. In Model II, an impacting particle creates a damped capillary wave that spreads outwards along the liquid layer, while a small volume of fluid remains trapped between the particle and the substrate. By computing this volume we can evaluate the dynamic adhesive force imposed by the liquid lining on the particle.

Our results demonstrate that (i) surface forces can cause slow lateral particle motion in directions that are hard to predict intuitively, and (ii) the adhesive force between a particle and a film can be controlled by long-range adjustment of the liquid layer in response to particle impact. The idealised models presented here provide a framework for the inclusion of important additional effects, such as epithelial stretching, dynamic surfactant readjustment and more realistic airway geometries.

INSPIRATORY FLOW IN BRONCHIAL AIRWAY MODELS: BIFURCATION PLANE ROTATION

Colin Caro¹, Robert Schroter¹, Nicholas Watkins¹, Spencer Sherwin² and Veronique Sauret³

¹Bioengineering and ²Aeronautics, Imperial College, London, ³Medical Physics and Bioengineering, Southampton General Hospital, UK
c.caro@ic.ac.uk

INTRODUCTION

The flow associated with non-planar branching and curvature of arteries directs attention to bronchial airway flow. In vivo and model studies indicate that characteristics of arterial flow include swirling, a relatively uniform distribution of wall shear and residence times, and inhibition of flow separation and flow disturbances (Caro *et al*, 1996; 1998; Sherwin *et al*, 2000). Model studies of flow in larger human bronchial airways have generally assumed planar geometry. Several consecutive generations of larger airway bifurcations are planar, but consecutive bifurcation planes are approximately orthogonal (Kaye and Schroter, 1993; Caro *et al*, 2002).

METHODS

The model is comprised of a straight, $l/d \sim 15$, inlet tube and two generations of planar symmetrical 'bronchial' bifurcations (Figure 1). Branching angle (θ) was 32.5° at 1st generation and 32.5° or 55° at 2nd. The angle of rotation of the bifurcation plane between the 1st and 2nd generations (ϕ) was 0° or 90° . Terminal resistances ensured the same volume flow in the 2nd generation daughter tubes, irrespective of θ or ϕ . The model was coated internally with litmus-containing water/starch paste. Inlet tube airflow, which carried hydrochloric acid vapour, was steady (8 l/min or 24 l/min, giving inlet tube Reynolds numbers, Re_{it} , of 600 and 1800, respectively). Acid arriving at the wall caused the litmus to redden. The local rate of change of colour indicated to approximation local relative wall shear rate, because of the effect of wall shear rate on the concentration gradient for the species between the fluid and the wall.

Figure 1: (a) Residual linear blue streaks at outer walls of 1st and 2nd generations where $\phi = 0^\circ$. Reddening symmetrical at 2nd generation where $\phi = 90^\circ$ (one daughter hidden but see also (b)). Reddening asymmetric where $\phi = 0^\circ$. (b) Residual linear blue streaks at outer walls of 1st generation. Residual helical blue streaks at 2nd generation where $\theta = 32.5^\circ$. Faster reddening and disappearance of streaks at 2nd generation where $\theta = 55^\circ$. $\phi = 90^\circ$ at both 2nd generation bifurcations.

Experiments were done with $Re_{it} = 600$, $\theta = 32.5^\circ$ at 1st and 2nd generations, $\phi = 0^\circ$ or 90° ; $Re_{it} = 600$, $\theta = 32.5^\circ$ at 1st generation and one 2nd generation bifurcation, 55° at other 2nd generation bifurcation, $\phi = 90^\circ$ at both 2nd generation bifurcations; $Re_{it} = 600$ or 1800 , $\theta = 32.5^\circ$ at 1st generation and one 2nd generation bifurcation, 55° at other 2nd generation bifurcation, $\phi = 90^\circ$ at both 2nd generation bifurcations.

RESULTS AND DISCUSSION

The findings of this branching model included:

- Symmetrical distribution of reddening between 2nd generation daughter 'bronchi' where $\phi = 90^\circ$ and asymmetrical distribution where $\phi = 0^\circ$, implying asymmetrical distribution of wall shear rate.
- Residual linear blue streaks (implying low wall shear rate) along outer walls of 1st generation bifurcation and daughter 'bronchi', and along outer walls of 2nd generation bifurcation and daughter 'bronchi' where $\phi = 0^\circ$. Residual helical blue streaks along outer walls of 2nd generation bifurcation and daughter 'bronchi' where $\phi = 90^\circ$, implying swirling flow.
- For given Re_{it} , reduction of swirl pitch and increased rate of reddening associated with increase of θ .
- For given θ , apparent reduction of swirl pitch associated with increase of Re_{it} .

Flow associated with orthogonal consecutive bifurcation planes resembles flow associated with non-planar branching. Findings are expected to have implications for all airway transport processes, including those for particles (Comer *et al*, 2000).

ANALYSIS OF ACROMIAL FIXATION OF GLENIOD COMPONENTS USING A 3D FINITE ELEMENT MODEL OF THE SCAPULA WITH COMPARISON TO RESULTS USING PHOTOELASTICITY

Linda A. Murphy and Patrick J. Prendergast

Department of Mechanical Engineering, Trinity College, Dublin 2, Ireland, www.biomechanics.ie

INTRODUCTION

The requirement for increased reliability and improved performance of implants necessitates rigorous pre-clinical testing. However, for the case of total shoulder arthroplasty (TSA), there is a plethora of glenoid prosthesis designs lacking this rigorous testing. Without improved pre-clinical analysis, glenoid component loosening rates will continue to be high.

This analysis will test the durability of an existing glenoid component fixation system. The hypothesis behind the design is that attachment of the glenoid prosthesis to the acromion, reduces the rate of loosening (Gagey *et al.*, 1990). Investigation of this design is carried out using a three-dimensional finite element (FE) model of the scapula (Lacroix *et al.*, 2000). Furthermore, this study will attempt to confirm the FE results where similarity of stress data will be investigated using the technique of photoelasticity.

METHODS

The 3D finite element model of the scapula was generated using CT data for geometric and material property definition [2]. The inhomogeneous nature of the material was described using 35 different Young's moduli. A model of a metal-backed acromion fixated prosthesis was inserted with bone cement and vitallium screws, see Fig. 1. The Young's modulus and Poisson's ratio for the polyethylene, metal-backing (cast vitallium), cement mantle and cancellous bone screws were taken to be 0.5 GPa, 220 GPa, 2.2 GPa, 220 GPa and 0.4, 0.32, 0.3 and 0.32 respectively. Motion between the acromion and glenoid under the action of the muscle forces analysed to determine if load sharing to the acromion occurs. Muscle and joint loads were applied for 30, 60, 90, 120, 150 and 180 degrees of abduction (van der Helm).

Figure 1 Acromion prosthesis and fixation with mesh of scapula.

For confirmation of the FE model, six scapulae were coated with a birefringent polymer using the contouring technique. The scapula was loaded using the modular head of a humeral prosthesis, see Fig. 2. The FE model of the scapula was also coated with the photoelastic material ($E=2.9\text{GPa}$, $\nu=0.36$), restrained along the medial border and the glenoid was loaded parabolically to the same order of magnitudes. Plots of shear

stress distributions on the experimental coating and on the finite element coating are compared.

Figure 2 Experimental set-up.

RESULTS AND DISCUSSION

Regarding our confirmation of results, calculation of the shear stress values corresponding to regions of high stress in the FE model, we find that shear stresses in the same order of magnitude were observed. For example, for $N=4$, a maximum shear stress of 30 MPa was reached experimentally at the superior border. Similarly, maximum shear stresses of 25 MPa and greater were seen at the superior border of the finite element model.

In general, the stress distributions produced in the cement mantle are quite low ($<3\text{MPa}$). However, very high peak stresses are also reached, in the order of 20 MPa. The relative displacement between the glenoid and the acromion, under the action of the muscle loads, shows that a small but significant amount of motion occurs ($\sim 1\text{mm}$). This resulted in high stresses being produced in the acromion prosthesis arm ($\sim 50\text{MPa}$). Furthermore, stresses produced in the acromion bone for this design are higher than the natural case, i.e. with no prosthesis fixation ($\sim 16\text{MPa}$ higher). Since this design is recommended for cases of deficient rotator cuff function, mainly seen in rheumatoid arthritis, problems with fracture of the acromion may occur due to these higher stresses.

SUMMARY

Results for the FE model and the photoelastic analysis are sufficiently similar, thus allowing us to use the FE model for analysis of glenoid components in TSA. Acromion fixation may prove problematic due to peak stresses seen in the cement mantle, acromion fixation bar and in the acromion bone itself.

ALPINE SKI RACING AND OPTIMAL CONTROL

Yoichi Hirano

Faculty of Science and Engineering, Chuo University, Bunkyo-ku, Tokyo, Japan

hirano@indsys.chuo-u.ac.jp

INTRODUCTION

In alpine ski racing it is very important for the racers to find and follow the quickest descent line between the many gates which make up the race course. Here, optimal control theory is applied to calculate the quickest line between two points on a ski slope.

SNOW RESISTANCE FORCES

During the motion of turning while skiing down a ski slope, gravitational force and snow resistance forces from the snow surface act on the skier. The equations of motion of the ski-skier system can be solved providing the resistance forces are known. Tada and Hirano determined compact snow cutting force equations by applying multiple regression analysis to experimental results, finding these forces to be functions of edging angle α and attack angle γ . These angles are respectively the angle between the ski sole and snow surface and the angle between the system velocity vector and the longitudinal ski axis.

APPLICATION OF OPTIMAL CONTROL THEORY

The objective function is the descent time t_f of a skier between two points on a ski slope. The control variable is the edging angle α , which can be adjusted by the skier, while the state variables are position (x,y) and velocity of the skier; all of which are a continuous function of time. Control and state variables, however, are discretized at time t_i ($i = 0, 1, \dots, N$), with time t_i being given by $(t_f/N)i$. The original optimal control problem can now be converted into an optimization problem in which the discretized system state variables are made to be continuous at the middle point between two consecutive time points t_i and t_{i+1} . These conditions are the equality constraints. The problem is to minimize t_f with respect to the edging angle under the equality constraints. This nonlinear programming problem is solved by Sequential Quadratic Programming (SQP) using MATLAB Optimization Toolbox software.

NUMERICAL RESULTS AND DISCUSSION

A ski slope of 15° angle is considered in which the x and y coordinate axes are taken in the steepest and horizontal direction of the slope, respectively. Calculating the quickest line between two points on the slope is now possible. The upper point is located at $x = 0$ m, $y = 0$ m and the lower point is located at $x = 20$ m, $y = 30$ m. The mass, ski length, and moment of the inertia of the system are 80 kg, 1.8 m, and $2.5 \text{ kg} \cdot \text{m}^2$, respectively. The ski boot is located at 50.5% of the length of the ski starting from the top of the ski. At the upper point a skier

has an initial velocity of $dx/dt = 6 \text{ m/s}$ and $dy/dt = 6 \text{ m/s}$. The initial angle between the longitudinal ski axis and the horizontal coordinate axis on the ski slope is 30° .

In Fig. 1, curve A is the resultant quickest line with a descent time of 5.179 s, while curve B is a line obtained for comparison by considering the problem as a Brachistochrone problem. Note that in this case the decent time is only 3.283 s, being faster because only gravitational force is considered. The quickest line is a rather straight line connecting two points, which is not surprising. Figure 2 shows the control variable (the edging angle) which changes from 0.2 to 1.2 radians during descent. If many gates are taken into account, it is expected that new unexpected lines will be found; thereby suggesting that skiers follow the lines by controlling the edging angle.

Figure 1: Quickest line between two gates on ski slope.

Figure 2: Control variable (edging angle) versus time.

COLLAGEN NETWORK AND MECHANICAL PROPERTIES OF ARTICULAR CARTILAGE: EXPERIMENTAL AND NUMERICAL STUDY

RK Korhonen¹, J Töyräs¹, MS Laasanen², R Lappalainen¹, HJ Helminen² and JS Jurvelin¹

¹Department of Applied Physics, University of Kuopio, Kuopio, Finland, rami.korhonen@uku.fi

²Department of Anatomy, University of Kuopio, Kuopio, Finland

INTRODUCTION

Collagen network contributes significantly to dynamic compressive and tensile stiffness of cartilage (Bader, 1992). Proteoglycans (PGs) induce swelling, controlled by collagens, and strongly determine equilibrium compressive stiffness. Nevertheless, cartilage structure-function relationships, especially the role of anisotropic collagen network, should be studied more thoroughly. Objectives of the present study were to investigate **1)** the role of collagen network in cartilage stress-relaxation under compression, **2)** the compression-tension non-linearity characteristics, **3)** the effect of superficial collagen network on the cartilage equilibrium response in different measurement geometries. For these objectives both experimental tests and numerical simulations were used.

MATERIALS AND METHODS

Sample preparation. **Group 1:** Cylindrical cartilage samples ($\varnothing=4\text{mm}$) were harvested from bovine patellae. Chondroitinase ABC was used for PG digestion (44h, $n=6$) and collagenase for collagen degradation (44h, $n=6$). **Group 2:** Humeral osteochondral samples ($n=6$, $\varnothing=4\text{mm}$) were prepared. **Group 3:** Osteochondral samples ($n=6$, $\varnothing=13\text{mm}$) were drilled from bovine patellae. **Mechanical tests.** **Group 1:** Stress relaxation tests (12.5kPa pre-stress, 10% step) were conducted in unconfined compression. **Group 2:** Samples were glued between metallic platens and tested in unconfined compression (stepwise stress relaxation in tension and compression, strain up to $\pm 6\%$). **Group 3:** Stress-relaxation tests (12.5kPa pre-stress, $4\times 5\%$ step) were conducted in indentation geometry. Subsequently, cartilage ($\varnothing=4\text{mm}$) was detached from the subchondral bone and measured in unconfined compression using the same protocol. **Finite element analyses.** Mechanical tests were simulated with finite element (FE) method (Abaqus 5.8). In axisymmetric models, cartilage consisted of 8-node quadratic poroelastic elements and nonlinear spring elements. Young's modulus of solid matrix (E , simulates mechanical role of PGs), Young's modulus of fibril network ($E_f=E_f^e\varepsilon_f+E_f^0$, simulates mechanical role of collagen), and permeability (κ) were incorporated in the fibril reinforced poroelastic models (FRPE) (Li, 1999).

RESULTS AND DISCUSSION

Group 1: Experimental collagen degradation by collagenase decreased short- and long-term responses of cartilage typically by 75% and 50%, respectively (Fig. 1a). FRPE predicted the same behavior by a major decrease of E_f^e (2500 \rightarrow 750MPa), supplemented by a decrease of E (0.2 \rightarrow 0.1MPa). The decrease in E was attributed to secondary, experimentally verified PG loss. PG digestion by chondroitinase ABC decreased short- and long-term responses of cartilage typically by 15% and

80%, respectively (Fig. 1a). FRPE predicted this behavior by a major decrease of E (0.35 \rightarrow 0.04MPa). **Group 2:** Experimental equilibrium stress-strain behavior of cartilage was significantly different in tension than in compression, as assessed in the direction perpendicular to articular surface (Fig 1b). Contrary to isotropic model without fibril network (poroelastic (PE)), FRPE with high E_f^e in axial direction (1090MPa) predicted this compression-tension non-linearity. **Group 3:** FRPE with high E_f^e (5300MPa) in superficial layer (25% of cartilage thickness) simulated differences in cartilage equilibrium response in unconfined compression and indentation (Fig. 2). PE or FRPE with homogenous fibril network throughout the tissue (E_f^e :430MPa) could not predict the differences.

Figure 1: Typical experimental and numerical analyses: a) time-dependent behavior of cartilage after collagen or PG degradation, b) equilibrium stress-strain behavior of cartilage in compression and tension perpendicular to articular surface.

Figure 2: Experimental and numerical equilibrium stress-strain behavior of cartilage in unconfined compression and indentation.

SUMMARY

FRPE analyses with realistic values of model parameters suggest that collagen network modulates short-term response as well as contributes to compression-tension non-linearity of cartilage. Also, superficial tangential collagen network may be a predominant factor inducing differences in cartilage behavior under different loading geometries. We conclude that models comprising compression-tension non-linearity are needed to predict complex structure-function relationships in cartilage (Li, 1999; Soltz, 2000).

DYNAMIC COMPRESSION INFLUENCES THE SYNTHESIS OF NITRIC OXIDE AND PGE₂ BY IL-1 β STIMULATED CHONDROCYTE SUB-POPULATIONS CULTURED IN AGAROSE CONSTRUCTS

Tina T Chowdhury, David A Lee, Dan L Bader.

IRC in Biomedical Materials and Medical Engineering Division, Department of Engineering, Queen Mary, University of London, Mile End Road, London. UK. d.l.bader@qmw.ac.uk

INTRODUCTION

The structural heterogeneity of the load-bearing tissue, articular cartilage, is produced by a relatively low cell density of chondrocytes. It is well established that in vitro mechanical strain applied to 3D constructs seeded with isolated chondrocytes from full depth, superficial and deep zones, induces a range of distinct metabolic responses [1, 2]. Recently, dynamic compression at physiological frequencies was shown to downregulate the production of nitric oxide (NO) and PGE₂ in the presence of the pro-inflammatory cytokine, IL-1 β , in full depth chondrocytes [3]. The present study tests the hypothesis that dynamic compressive strain alters the synthesis of NO and PGE₂ by IL-1 β stimulated chondrocyte sub-populations.

METHODS

Superficial and deep chondrocytes were seeded in 3 % agarose (type VII), at a density of 4×10^6 cells.ml⁻¹, and cultured in 1 ml of DMEM + 20 % FCS for 24 hours. Constructs were incubated for a further 48 hours in radiolabelled medium containing 10 ng.ml⁻¹ IL-1 β , either in the presence or absence of 1 mM L-NIO, an inhibitor of NO. In a separate experiment, constructs were subjected to 15 % dynamic compressive strain at 1 Hz for 48 hours in 1 ml of radiolabelled medium containing 0 or 10 ng.ml⁻¹ of IL-1 β , and / or 1 mM L-NIO. Nitrite was measured using the Griess assay, PGE₂ synthesis was determined using an ELISA kit and [³H]-thymidine and ³⁵SO₄ incorporation were assessed by TCA and alcian blue precipitation, respectively.

RESULTS AND DISCUSSION

The effects of mechanical stimulation on both chondrocyte sources in terms of the synthesis of nitrite and PGE₂, are shown in Figures 1A and B, respectively. It is clear that IL-1 β stimulated both molecules at least twofold for superficial chondrocyte constructs, compared to a minimal induction in the deep cells.

In the absence of IL-1 β , dynamic strain reduced levels of nitrite and PGE₂ production compared to unstrained controls in cells from both sub-populations. Moreover in the presence of IL-1 β , the upregulation of nitrite and PGE₂ values in unstrained constructs seeded with superficial cells was reversed with dynamic compression. Similar findings were observed for deep cell constructs, although the values were significantly lower. Compression-induced inhibition of nitrite was reversed with L-NIO for superficial cell constructs. By contrast, the IL-1 β induced inhibition of PGE₂ synthesis was enhanced with L-NIO for superficial cell constructs. Furthermore, nitrite and PGE₂ synthesis for IL-1 β stimulated deep cell constructs subjected to dynamic compression, was not affected by L-NIO.

In untreated cells, the level of stimulation of [³H]-thymidine and ³⁵SO₄ incorporation was significantly greater in the deep

cells compared to the superficial cells (data not shown). The IL-1 β induced inhibition of [³H]-thymidine incorporation was partially reversed with L-NIO in both cell sub-populations. By contrast, ³⁵SO₄ incorporation was not affected by IL-1 β or L-NIO under dynamic loading for both cell types.

Figure 1 Nitrite synthesis (A) and PGE₂ production (B) by superficial and deep chondrocytes, seeded in 3 % agarose Type VII and subjected to 15 % dynamic compressive strain at 1 Hz for 48 hours.

SUMMARY

This study has demonstrated that dynamic compression, a physiologically relevant loading regime, counteracts the effects of IL-1 β on superficial cells by suppressing both NO and PGE₂ production. A similar trend was apparent in deep cell constructs although the values were significantly lower, suggesting that the superficial chondrocytes are a major source of NO and PGE₂. The inhibition of both molecules by dynamic compression could contribute to novel strategies for the treatment of degenerative diseases of cartilage.

INTRODUCTION

Control of many cell functions including growth, motility, migration, mechanotransduction, critically depends on mechanical stress-induced alterations in global and local cell shape and structure. These functional alterations are mediated through changes in the cytoskeleton (CSK), a hierarchical and multi-modular structure of polymeric interconnected elements which constitutes multiple transmission pathways organized at different scales (Ingber, 1997). Cellular tensegrity explains how prestress, generated either at global scale (contractile apparatus), or locally (force exerted by molecular filaments), is balanced by interconnected elements compressed at various scales; e.g., microtubules (MTs) stabilize the entire cell or cytoskeletal filaments stabilize specialized microdomains of the cell surface. In the present study, we attempted to theoretically quantify the structural properties of the cortical component of the CSK (basically the actin-ankyrin spectrin network which contains a high number of slightly-dense and short actin filaments), by comparison to the internal CSK component (basically the internal CSK network of highly-dense and long actin filaments interconnected with MTs and intermediate filaments), the two CSK components being attached to the extracellular matrix through the adhesion complex. In a recent *in vitro* study, the mechanical properties of the cortical vs cytosolic CSK component were estimated by twisting magnetic cytometry and cortical stiffness and prestress were found smaller for the cortical than for the cytosolic CSK compartments (Laurent *et al.*, 2001). In an attempt to relate these results to the specific structure of each CSK component, we studied the effect of changing the number of constitutive elements in simplified "spherical" tensegrity models including the well known 30-element tensegrity structure (Cañadas *et al.*, 2001, Stamenovic *et al.*, 1996, Wendling *et al.*, 2000).

METHODS

We have tested four spherical models of tensegrity structures composed of a discontinuous network of quasi-rigid bars compressed by a continuous network of pre-stretched and elastic cables: (i) the *simplex*, composed of 3 bars and 9 cables, (ii) the *quadruplex*, composed of 4 bars and 12 cables, (iii) the *octahedron*, composed of 6 bars and 24 cables and (iv) the *cubeoctahedron*, composed of 12 bars and 48 cables. Constitutive cables and bars are defined by their length and cross-sectional area, and their mechanical properties. Each elastic cable behaves as a prestressed linear spring. Extension forces were applied in quasi-static conditions at the 3 nodes of the superior plane (resp. 4 nodes for the *quadruplex*). The structures were all anchored to a rigid base by spherical joints

at the 3 (resp. 4) inferior nodes. The overall deformation of the structure was deduced from the nodal displacement using a finite element method of resolution. The structural elasticity modulus was deduced from the stress-strain relationship of an equivalent cylinder embedding the structure at small deformation (e.g., <5%). The apparent elasticity modulus E , the internal tension T and the length L of constitutive bars were normalized by the local properties of the elastic cables.

RESULTS AND DISCUSSION

The normalized elasticity modulus E^* was expressed, for the four tensegrity models tested, as a function of three local normalized parameters, i.e., L^* , T^* and the number of elements N ($= 12, 16, 30, 60$). E^* exhibits a marked negative dependence of L^* (i.e., slope -2 on the $\log E^* - \log L^*$ curve) which extends previous *octahedron's* results (Wendling *et al.*, 1999). Noteworthy, E^* exhibits, independently on L^* , a stronger negative dependence of N , (i.e., slope $\approx -2,7$ on the $\log E^* - \log N$ curve). This result, once extrapolated, means that increasing the number of interconnected elements in a "spherical" tensegrity structure tends to soften the structure. Estimating the cellular L^* and N values lead to consider that L^* is 1 order of magnitude smaller and N about 2 orders of magnitude greater in cortical CSK (compared to the cytosolic), meaning that structural stiffness of cortical CSK would be smaller than the cytosolic CSK as experimentally observed. Moreover E^* slightly increased with T^* in the 4 models, confirming *octahedron's* results but the rate of T^* -increase depended on L^* and N . A rough estimate of prestress values in elastic fibers and filaments in each CSK compartment lead to consider T^* values about 2 orders of magnitude smaller in the cortical compared to the cytosolic CSK which also contribute to the smaller values of structural cortical stiffness. Note that smaller rigidity and prestress measured and predicted for the cortical structure are consistent with its functional role, i.e., maintaining an intimate contact of the cell with its mechanical surrounding and sensing very local deformation forces.

INTRODUCTION

Cellular deformability and transmission of mechanical forces, (e.g., from the membrane to the nucleus) are known to implicate the cytoskeleton (CSK) structure whose mechanical properties are now recognized to play a critical role for many biological functions (Ingber *et al.*, 1989). Understanding the mechanical properties of cytoskeleton is difficult because CSK is a complex tridimensional network of interconnected biopolymers (actin filaments, microtubules, intermediate filaments) which is physically linked to the extracellular matrix (ECM) through focal adhesion sites. Spatial re-arrangement of CSK-filaments, tension in viscoelastic actin filaments, compression in microtubules and in the non-flexible ECM (Wang *et al.*, 2001) would all contribute to cellular prestress, stability, and CSK mechanical properties (Stamenovic *et al.*, 1996, Ingber *et al.*, 1989). Recent oscillatory cellular measurements have shown that frictional mechanical energy arises within the CSK, by coupling with elastic energy storage (Maksym *et al.*, 2000). We presently attempted to evaluate the theoretical contribution of structural re-arrangement of CSK elements to the CSK viscoelastic response. We purposely developed a CSK model based on a previously studied tensegrity structure and analyzed the main parameters governing its viscoelastic response. Structural viscoelasticity of the cellular tensegrity model appears to satisfactorily agree with measurements of viscoelastic response in human alveolar epithelial adherent cells.

METHODS

We numerically simulated creep tests of a CSK tensegrity model composed of a continuous network of 24 pre-stretched cables which compress a discontinuous network of 6 rigid bars. By contrast to previous studied models, each cable was supposed to behave as a viscoelastic “solid” (i.e., Voigt body composed of a spring in parallel to a dashpot). The viscoelastic tensegrity model was supposed to be anchored to a rigid, non planar substratum through the four lower nodes. Elementary transient forces were externally applied to the nodes at the ends of the upper bar. Four types of loading were tested, i.e., extension, compression, shear and torsion. The creep “nodal displacement vs time” curve of the structure was numerically obtained from the resolution of the linearized system of differential equations using Euler's incremental formulation:

$$\{dF_i\} = [K(U_{i-1})] \cdot \{dU_i(t)\} + [C(U_{i-1})] \cdot \{d\dot{U}_i(t)\}$$

The actual force vector $\{dF_i\}$ is related to the actual nodal displacement $\{dU_i\}$ and speed $\{d\dot{U}_i\}$ vectors, via the global

rigidity $[K(U_{i-1})]$ and global damping $[C(U_{i-1})]$ matrices which both reflect the spatial organization of the structure before loading. Overall time constant (τ) and elasticity modulus (E) of the tensegrity model were obtained by curve-fitting analysis via an equivalent cylindrical Voigt body embedding the entire tensegrity structure, i.e., diameter and height equal l_0 , viscosity modulus η was then calculated by $\eta = E \times \tau$. Normalized structural properties were obtained by dividing the overall viscoelastic properties of the tensegrity structure by local properties of its constitutive cables (τ_c , η_c , E_c), i.e., $\tau^* = \tau/\tau_c$, $E^* = E/E_c$ and $\eta^* = \eta/\eta_c$.

RESULTS AND DISCUSSION

Present numerical results show that values of τ^* , E^* , η^* vary with (i) local physical properties of constitutive elements, i.e., the normalized length L^* and cable initial extension T^* which represents the structural prestress, and, (ii) the type of loading. While previous studies have shown that E^* exhibits a positive dependence on T^* (i.e., $E^* \propto T^{*+0.5}$, Wendling *et al.*, 2000), τ^* exhibits in present study a negative dependence on T^* (i.e., $\tau^* \propto T^{*-0.5}$). However, both η^* and E^* appear to follow the same negative L^* -dependency (i.e., $\eta^* \propto L^{*-2}$ and $E^* \propto L^{*-2}$). Tensegrity concept predicts that a tensed structure has a faster time response than a less tensed structure, which seems to be consistent with our experimental observations showing the ‘solid-like’ behavior of adherent living cells by contrast to the ‘fluid-like’ behavior of suspended cells (Laurent *et al.*, 2002). Moreover, the apparent viscous CSK modulus measured by different techniques in adherent cells seems to exhibit a strongly negative probe-size dependence similar to the L^{*-2} -dependency observed for η^* and E^* in the tensegrity structure. On the whole, present study provides new arguments supporting the idea that structural rearrangement of CSK-elements critically contributes to cellular viscoelasticity.

THE EVOLUTION OF PASSIVELY-ASSISTED HUMAN-POWERED LOCOMOTION

Alberto E. Minetti

Centre for Biophysical and Clinical Research into Human Movement, Department of Exercise and Sport Science
Manchester Metropolitan University, UK, a.e.minetti@mmu.ac.uk

INTRODUCTION

In this paper the history of passive tools devoted to improve the locomotor performance is reviewed, with particular reference to the biomechanical advantage introduced by each of them: the cross-country skis (CCS), the ice/in-line skates (S, ILS), the halteres (H), the different bicycles (Hobby Horse – HH, modern – MB). All of them were meant to increase the progression speed and/or to surpass the body limitations with respect to the motion in difficult environments.

LOCOMOTOR TOOLS

ICE/IN-LINE SKATING (3000 BC- / ca 1980)

Also used for transportation on the iced Amsterdam canals (about 14th century), the modern version of S is the fastest non-wheeled human-powered locomotion, both because of the very low friction (0.003-0.007) and because no body part has to stop with respect to the ground, even when contributing to propulsion. The lateral push while sliding allows knee and ankle extensor muscles to operate within the optimal contraction speed range. The reduced added mass and speed of limbs with respect to the body centre of mass (BCOM) implies a low mechanical internal work (W_{INT}) too.

The modern roller in-line skating, while being slower because of the higher rolling resistance, benefits from the same physio-mechanical strategy of S.

CROSS-COUNTRY SKI (2000 BC-)

Originally a mean of travel and communication in Scandinavia and Russia, CCS is today the second fastest non-wheeled locomotion because of the very low friction (0.05-0.20) and the small added mass involved. The diagonal stride (DS) and the double pole (DP) are the slower techniques mainly because the propulsion is achieved by the push of skis and poles, which stop with respect to the ground. The involved body segments has thus to be accelerated, with respect to BCOM, at the same speed of the progression one, with detrimental effects on W_{INT} and the muscle efficiency. The fastest technique in CCS is skating (SK, 1980), which adopted the ice-skating strategy for lower limbs (lowering W_{INT} and increasing muscle efficiency) and made a better use of 'energy recovery', i.e. the exchange between the potential and kinetic energy of BCOM (Minetti et al 2001).

HALTERES (500 - 300 BC)

The first passive tool devoted to increase the human performance in the ancient Olympics standing long-jump event, the halteres represented added hand-held loads (1.2-4.5 kg). Their role was: a) to produce a higher ground reaction force by a more efficient use of shoulder extensor muscles, and b) to alter the BCOM position at take-off (more anterior) and landing (more posterior). There are clues (Minetti 2002) that these effects increased the jump range.

BICYCLE (1820-)

The idea behind it is again an alteration of body geometry in order to escape from the rimless wheel metaphor of walking and running. By suspending the body at a fixed height from the ground, the wheels-frame structure almost completely prevents vertical displacements of BCOM, so that lower limb muscles can be used mainly to overcome rolling resistance and air drag. By progressing from the Hobby Horse (1820), where the rider pushed directly on the ground, to the High Wheeler (1870) and the modern bicycle (1890), the metabolically equivalent cruising speed, with respect to walking (1.5 m/s), increased 3.3 times (≈ 5.0 m/s, Minetti et al 2001). The major determinants of such a progress in locomotor economy were: 1) the decrease of the overall bicycle mass (from 24 to 16 kg), which helped to further decrease 2) the decreased rolling resistance (0.027 to 0.008), due to the transition from metal to solid and inflatable tyres, 3) the concurrent lengthening of the distance travelled per pedal revolution (2.8 to 5.5 m), which caused 4) the decrease of pedalling rate ($\dot{\theta}$) at a given speed and, consequently, 5) the decrease of W_{INT} (which in cycling depends on $\dot{\theta}^3$). In addition, the last 2 effects maximized the efficiency of knee extensor muscles at high progression speed, allowing them to keep on contracting within the optimal speed range.

MICRO-SCOOTER (1920, 1985)

This recent and fashionable device has been reintroduced mainly due to its compact size and the better rolling resistance of modern roller skate wheels. While at 1.5 m/s it is metabolically equivalent to walking, at 2.7 m/s the energy consumption corresponds to walking at 1.9 m/s (Minetti and Zamparo, personal observations). The small advantage in comparison with the other types of wheeled locomotion is due to the residual vertical excursion of BCOM and the push limb which stops with respect to the ground.

CONCLUSIONS

The increase of economy/cruising speed (or of jumping range) has been obtained by each of the illustrated passive appendices throughout a combination of the following strategies: a) the decrease of the mechanical external work, b) the decrease of the internal work, c) the modification of body configuration, and c) the maintenance of muscle performance optimization despite of the increase in speed.

MECHANICAL ENERGY TRANSFER BETWEEN ADJACENT JOINTS BY TWO-JOINT MUSCLES

Boris I. Prilutsky¹ and Vladimir M. Zatsiorsky²

¹Center for Human Movement Studies, Georgia Institute of Technology, Atlanta, GA, USA

²Biomechanics Laboratory, Pennsylvania State University, State College, PA, USA

The goal of this presentation is to review and discuss the issues related to the energy transfer between adjacent joints by two-joint muscles. This energy transfer and its functional significance have been debated for over a century (for review, see van Ingen Schenau 1990; Prilutsky 2000; Kuo 2001).

A simple physical model of the leg (Fig. 1) can be used to illustrate the mechanism of the energy transfer between adjacent joints by two-joint muscles. This model is made of four rigid links interconnected by revolute low friction joints. The model in the squat position (left panel) has only one source of mechanical energy: the stretched rubber band, GLM, which spans only the hip joint. Nevertheless, when the model is released from the squat position, all three joints extend (right panel), and positive mechanical work is done at each joint. The mechanical energy generated by the knee and ankle joint moments during extension has its origin in the energy generated by the GLM. It has been transferred to the knee and the ankle joints by the two-joint non-stretchable ropes RF and GA, respectively, which, by themselves, do not generate any mechanical energy.

With the advent of modern methods of inverse and forward dynamics analyses, and musculoskeletal modeling, it has become possible to clearly define energy transfer by two-joint muscles in ways that allow for quantitative estimations of the transported energy (van Ingen Schenau, 1990; Prilutsky, Zatsiorsky, 1994; Jacobs et al., 1996). For example, the rate of energy transfer by two-joint muscles to or from an adjacent joint, $P_j(t)$, can be estimated from the equality

$$P_j(t) = P_j^T(t) - \sum_j P_j^M(t) \quad (1)$$

where $P_j^T(t)$ is the power of torque at the j th joint and $\sum_j P_j^M(t)$ is the sum of powers developed by all muscles serving the j th joint. If all muscles crossing the joint are one-joint muscles, then $P_j^T(t) = \sum_j P_j^M(t)$ and $P_j(t) = 0$. However, if among muscles serving the j th joint there are two-joint muscles, the rate $P_j(t)$ is not necessarily equal to zero. For example, in the push-off phase of the model on Fig. 1, $P_j(t) > 0$ at the knee and ankle joints because $P_j^T(t) > 0$ and $\sum_j P_j^M(t) = 0$, i.e. energy comes to these joints through the action of the RF and GA. At the same time, $P_j(t) < 0$ at the hip joint because $P_j^T(t) < \sum_j P_j^M(t)$, i.e. energy transported from the hip to the knee through the RF.

These new theoretical methods have also permitted assessments of the potential performance of musculoskeletal models with altered designs that prevent the transfer of energy by two-joint muscles (Pandy, Zajac, 1991; Bobbert, van Zandwijk, 1994). It has been demonstrated, for example, that maximum jump height may be increased by about 2 cm, due to the inclusion of the two-joint gastrocnemius muscle, having specific moment arm values about the ankle and knee joints (Bobbert, van Zandwijk, 1994). More accurate estimates of, and new insight into, the transfer of energy by two-joint muscles have become available following the development of methods for making in-vivo recordings of the forces exerted

Figure 1: A physical model of the leg. A rubber band imitates a one-joint hip extensor, gluteus maximus (GLM). The two non-stretchable ropes represent the two-joint rectus femoris (RF) and gastrocnemius (GA). When model is released from a squat position (in which the GLM is stretched), all three joints extend and the joint moments in each joint do positive work, i.e. generate mechanical energy.

by two-joint muscles. By knowing the force exerted by a two-joint muscle, and its estimated rate of length change, one can calculate muscle power and, subsequently, the amount of energy transferred by the two-joint muscle (Prilutsky et al., 1996).

Estimated values of the mechanical energy transferred between adjacent joints range from 6 to 39 percent of the work done at a given joint in a variety of human and cat movements including walking, running, landing, and jumping (Bobbert and van Zandwijk, 1994; Prilutsky, Zatsiorsky, 1994; Jacobs et al., 1996; Prilutsky et al., 1996). These numbers indicate that a substantial part of energy released in a given joint can be generated by muscles that do not span it. This energy transfer appears to have important functional significance. Apart from the increase in the performance of explosive movements, it seems to allow proximal muscles (that generally have larger volumes than distal muscles, and thus have greater potential to generate and dissipate mechanical energy) to realize their work potential more fully. Because of the action of two-joint muscles, the large proximal muscles can do work on distal joints, and work done on distal joints by external forces can be partly dissipated by the proximal muscles.

TENSILE PROPERTIES OF THE *IN VIVO* HUMAN GASTROCNEMIUS TENDON: RELEVANCE TO FUNCTION AND LOCOMOTION

Constantinos N. Maganaris¹ and John. P. Paul²

¹Centre for Biophysical and Clinical Research into Human Movement, Manchester Metropolitan University, Alsager ST7 2HL, UK, c.n.maganaris@mmu.ac.uk

²Bioengineering Unit, University of Strathclyde, Glasgow G4 0NW, UK

INTRODUCTION

Over the previous years, we have developed a method for *in vivo* measurement of human tendon mechanical properties (e.g., Maganaris & Paul, 1999 and 2000). The technique is based on displacement measurements of ultrasound echoes generated from the tendon, and avoids several problems associated with *in vitro*-material testing. In the present experiment we applied this *in vivo* method to obtain the tensile properties of the human gastrocnemius tendon, a high-stressed tendon suitable for spring-like action during locomotion. We sought to answer the following two questions: 1) Are the material properties of *in vivo* tendon related to its physiological function and loading. To answer this question, the results of the present study were compared with previous *in vivo* results from measurements in the human tibialis anterior tendon, which acts as force transmitter and is less highly stressed physiologically. 2) Does the spring-like action of gastrocnemius tendon contribute to the external work produced by the locomotor system during walking? To answer this question, we combined the present results with previous results of tendon behaviour and external work during walking.

METHODS

Measurements were taken in six men. The gastrocnemius tendon elongation during tendon loading–unloading induced by muscle contraction–relaxation was measured using real-time ultrasonography. Tendon forces were calculated from the moment generated during isometric plantarflexion contraction using tendon moment arm length data measured *in vivo* from Magnetic Resonance Images (MRIs). Tendon stiffness data were calculated from the slope of the tendon force–elongation curve, and were then normalized to the tendon's original dimensions, obtained from morphometric analysis of sonographs and MRIs, to estimate the tendon Young's modulus. Mechanical hysteresis values were obtained from area calculations by numerical integration.

RESULTS AND DISCUSSION

The elongation of the tendon increased curvilinearly with the force acting upon it, from 1.7 ± 1 mm at 87.5 ± 8.5 N to 11.1 ± 3.1 mm at 875 ± 85 N (Fig. 1). The tendon Young's modulus and mechanical hysteresis were 1.16 ± 0.15 MPa and $18 \pm 3\%$, respectively. These values are very similar to the respective values previously obtained from *in vivo* measurements in the human tibialis anterior tendon (1.2 MPa and 19%; Maganaris & Paul, 1999 and 2000), thus indicating that the material

properties of tendon are independent of physiological loading and function. Similar conclusions have previously been reached from *in vitro*-based measurements (Pike *et al.* 2000; Pollock & Shadwick, 1994). Combining the present tendon force–elongation data with previously reported data of gastrocnemius tendon elongation during walking (Fukunaga *et al.* 2001) indicates that the gastrocnemius tendon would provide ~6% of the total external work produced by the locomotor system. This estimate illustrates the contribution of passive elastic mechanisms on the economy and efficiency of walking. The contributions would be greater in more active exercise such as running.

TENDON MECHANICAL PROPERTIES FOR LOCOMOTION

Robert F. Ker

School of Biology, The University of Leeds, Leeds, LS2 9JT, UK

r.f.ker@leeds.ac.uk

INTRODUCTION AND TENDON FUNCTION

Locomotion requires the co-ordinated use of numerous skeletal muscles and their tendons. Each tendon is under tension while it transmits force. It must, necessarily, have adequate stiffness, strength and resistance to fatigue for this function. Furthermore, mammalian tendons show low hysteresis loss under cyclic loading in tension. With a few exceptions, tendons bend readily and therefore buckle easily.

All tendons can store strain energy. This spring-function is made full use of in some of the ankle extensors and toe flexors of the larger mammals to save energy when running. It may also be used in other situations, such as jumping, tail-waving or wing-beating. A spring functions by stretching, but for other tendons extension can be inconvenient. For this reason, tendons differ widely in the strains and stresses to which they are subjected in life (Ker et al, 1988, Pollock and Shadwick, 1994b). The high stress of tendons used as springs is achieved by having muscles of relatively large physiological cross-sectional area. Stress and/or strain have been measured *in vivo* for a number of tendons (e.g. Komi et al., 1992; Biewener and Baudinette, 1995; Maganaris et al., 1999). For the others, we rely on assessments calculated from measurements of the areas and lengths of tendons and their muscles.

STIFFNESS AND HYSTERESIS

The elastic modulus of adult mammalian tendon in the linear region of the stress-strain curve (stress > 20 MPa) is between 0.9 and 1.8 GPa. Variations do not correlate with whether the spring-like properties of the tendon are used or with the mass of the mammal (Pollock and Shadwick, 1994a). Elastic modulus increases during growth. For low stress tendons, the effective modulus is less because these operate in the toe region. At very low stress, the modulus is effectively zero as tendons are pulled taut from a buckled condition.

The hysteresis loss is around 10%. Variations are considerable but, as with stiffness, do not seem to correlate with tendon function or animal mass.

STRENGTH

Most tendons are far too thick to be at risk of rupture from over-stretching. To put this the other way round, the muscle has much too small an area to break its tendon, typically by a factor of 5-fold. The situation with the tendons used as springs is entirely different. They probably have low safety factors, though the measurement of strength is difficult and therefore safety factors cannot be assessed with much certainty. Ultimate tensile strength is ≥ 100 MPa.

FATIGUE QUALITY

The resistance of tendons to fatigue varies by perhaps two orders of magnitude in step with the variations in stress-in-life (Ker et al., 2000). Each tendon seems to be designed to be only just good enough for its function. Being 'good enough' includes allowing for the availability, in life, of repair. It seems that all tendons must be subject to ongoing repair of fatigue damage (Wang et al., 1995; Schechtman and Bader, 1997; Ker et al. 2000). With tendons functioning as springs, because of the low safety factor, the first symptom of a lapse in the balance between damage and repair may be rupture. Rupture is a clinical problem with the human Achilles tendon and the horse superficial digital flexor tendons.

THE DESIGN OF TENDONS FOR LOCOMOTION

For most tendons, the primary need is for the correct stiffness and this is adjusted by altering thickness. The strength of the resulting tendon is more than adequate. In contrast, for spring-tendons, the first need is for sufficient strength. In each case, fatigue quality appears to be adapted to make the tendon just capable of living with its stress-pattern. In limbs, only those tendons which are maximally loaded at the mid-point of ground contact are major springs. Even with this restriction, only some of the potential is used to full advantage. In most limbs, the deep toe flexor is of relatively low stress. In many mammals, only one of the gastrocnemius and plantaris tendons of the hind limb has a strikingly high stress. Presumably, the other tendons and their muscles have functions additional to energy saving. Small mammals, do not have even one tendon of really high stress and thus seem not to take much advantage of the possibility of energy-saving. This fits in with their observed high cost of locomotion, but leaves unanswered the question as to why small mammals are designed in this way.

LOSS BEFORE RECOVERY: SOME PARTIAL ANSWERS TO OLD LOCOMOTION QUESTIONS

John E.A. Bertram¹, Andy Ruina² and James R. Usherwood¹¹Nutrition, Food and Exercise Sciences, Florida State University²Theoretical and Applied Mechanics, Cornell University

INTRODUCTION

Recent advances in our understanding of locomotion using legs, stemming largely from work modeling artificial passive dynamic systems (Garcia et al., 1998; Kuo, 2001; McGeer, 1990), provide an opportunity to re-evaluate a wide range of terrestrial locomotion strategies. The key feature in this approach is to evaluate the cause of mechanical energy loss, attributed to collisional loss at foot contact, rather than the more traditional tracking of energy exchange and recovery. It is found that collisional loss so dominates the energetics of mammalian legged locomotion that remarkably simple models are able to explain the basic mechanics behind a number of misunderstood mammalian locomotion behaviors. We demonstrate this by using a common approach to two quite different examples: gibbon brachiation and the quadrupedal gallop.

METHODS

Limbs contacting the ground with non-negligible velocity will result in loss due to inelastic collision. The component of the velocity lost will depend on the orientation of the CoM velocity vector and its relationship to the contacting leg (Fig. 1). That component oriented parallel with the leg will be lost. The remainder, perpendicular to the leg, is available to continue the motion of the animal. Within the constraints of a given locomotory system, analysis of the collision geometry indicates the consequences of moving on a finite number of limbs.

Fig. 1: Simple collision-based model of limb interaction with substrate. Vectors indicate velocity of center of mass before and after foot contact.

RESULTS AND DISCUSSION

Gibbon: Brachiation has intrigued locomotion researchers for a long time, largely due to the resemblance of brachiation to the swing of a pendulum, with the potential for mechanically efficient motion. However, pendular dynamics do not explain much of the fast moving brachiator's behavior. The gibbon inhabits an extremely complex environment and must face the challenge of adjusting sequential step lengths to match support opportunities. We demonstrate that adjusting the ballistic path of the flight phase between handholds to reduce collisional loss is a key feature of brachiation, and conclude that the energetics of brachiation relates to the skipping of a stone on a pond surface, and the pendulum model is actually quite uninformative.

Gallop: The quadrupedal gallop displays features in common with both pendular and spring-based exchange. However, the functional reason behind the details of these gaits has been elusive. We show that consideration of collision loss can account for many aspects of this gait, even without consideration of spring-based storage and recovery.

SUMMARY

Analysis of collision interaction of the support limb with the supporting substrate provides an alternate approach to understanding the function, behavior and morphological features of much of mammalian legged locomotion.

MECHANICAL DETERMINANTS OF THE METABOLIC COST OF WALKING: WORK, FORCE AND SWING

Rodger Kram

Department of Kinesiology and Applied Physiology, University of Colorado USA

rodger.kram@colorado.edu

<http://stripe.colorado.edu/~kram/>

INTRODUCTION

The basic energy saving mechanism in walking is the inverted pendulum-like exchange of kinetic and gravitational potential energy. This mechanism allows nearly perfect mechanical energy exchange during the single stance phase. However, during the transition between support legs, mechanical energy is dissipated and must be replaced by the muscles. Further, metabolic energy is required to generate the forces needed to maintain the stance leg as a strut that can resist gravity. Some metabolic energy is also needed to swing the legs relative to the center of mass. My goal in this presentation is to weave together recent experiments that have quantified these major components of the metabolic cost of walking.

METHODS

To quantify the external mechanical work performed by each limb, my colleagues Max Donelan and Art Kuo developed the individual limbs method (ILM) (Donelan *et al.*, 2002). This work is needed to redirect the center of mass from a downward arc at the end of the stance phase to an upward arc over the subsequent stance leg. Two force platforms recorded the individual foot forces. The summed force signals of both platforms were used to calculate the center of mass velocity. The power performed on the center of mass was calculated as the dot product of each individual leg ground reaction force and the velocity of the center of mass. Integrating power yielded work. Donelan *et al.* (2001) measured both the ILM work and net metabolic cost for humans walking over a range of speed and stride length combinations. In all experiments described here, net rates of metabolic energy consumption (walking – standing) were measured from expired gas analysis. In a related study, Jinger Gottschall and I estimated the metabolic cost of generating horizontal propulsive forces in walking by applying an external horizontal forward pulling forces to the waists of subjects walking on a treadmill. We inferred that the reduction in metabolic cost when aiding forces were applied reflected the metabolic cost of generating the propulsive forces with muscles during normal walking. To infer the relative contributions of performing external ILM work, supporting body weight and swinging the legs Tim Griffin and I used loading experiments. Subjects walked with strips of lead (= to 0, 10, 20 and 30% of body mass) wrapped symmetrically around the waist. We calculated the cost of generating force from the active muscle volume needed to support body weight and used the inverse of contact time as a proxy for the rate of force generation.

RESULTS & DISCUSSION

The individual limbs method revealed about 33% more external work than would have been calculated using the combined limbs method. For walking at 1.25 m/sec the efficiency of performing positive mechanical work was about 21%. Knowing that and the ILM power allowed us to calculate that the work of re-directing the center of mass during double support accounted for about 60% of the net metabolic cost of walking. A similar conclusion was drawn from the horizontal aiding force experiments. When a steady external force of 10% of body weight was applied at the waist that acted to re-accelerate the center of mass, the net metabolic cost was reduced by 53%. The loading experiments showed that the net metabolic cost of walking increased in a greater than proportional manner with the load. In contrast, the ILM work increased in direct proportion to the load. Compared to the ILM work, the cost of generating force appeared to more closely parallel the increase in metabolic cost when loads were carried. The loading experiments did not alter leg swing mechanics, yet the net metabolic cost increased in greater than proportionate manner with the waist carried load. We infer that the metabolic cost of swinging the legs is likely small at 1.25 m/sec.

2002 marks the 25th anniversary of Cavagna, Heglund and Taylor's classic paper that established that legged animals use two basic mechanisms to conserve mechanical energy (Cavagna *et al.*, 1977). They described a dichotomy between the inverted-pendulum model for walking and the spring mechanism of running. Recent discoveries described above complement the classic inverted pendulum model so as to better explain the energy costs and savings involved in walking. Ultrasound recordings of calf muscle fascicle length changes during walking (Fukunaga *et al.*, 2001) and other innovative non-invasive experiments (Hof *et al.*, 2002) indicate that springs are also important in walking. A hybrid model for walking appears to be emerging.

STICKS-CONNECTED-BY-HINGES MODELS OF HUMAN WALKING: RESULTS TO DATE

Andy Ruina

Theoretical and Applied Mechanics, and Mechanical and Aerospace Engineering, Cornell University

INTRODUCTION

Robots have motors and people have muscles. What for? To guide motions and to make up for lost mechanical energy. How much guidance is fundamentally needed for repetitive tasks? How much energy needs to be supplied for what losses? One approach to understanding the need for motors and controllers is what can be done without them. Tad McGeer demonstrated (e.g., 1990) with simple computational models and with physical devices that uncontrolled human-like walking motions can be achieved with, to put it simply, sticks and hinges that walk downhill. The motions of these toy-like devices are energetically efficient (low specific transport cost) and stable (limit-cycles with linearized stability). How much can we learn from these simple devices?

METHODS

Over the past several years we (faculty, students, post-docs and visitors at Cornell) have continued the approach of McGeer using heuristic reasoning, experiments, analysis and computational models based on basic ideas in dynamical systems theory.

RESULTS

We have found that, in principle, some of these devices can walk on arbitrarily small slopes and thus approach perfect efficiency and that robot configurations that have this efficiency are reminiscent of the human design. These models can also limp (period 2), waltz (period 3), and stumble (chaos). The devices obey an energy scaling law where (gravitational) power consumption is proportional to v^4 , a feature the human control system may seek to avoid. One unintuitive feature we have discovered both in experiment and simulation, is that it is possible to have a walking machine that has no stable standing posture, yet can walk stably. Another device we have built has a more natural looking gait, we believe, than any robot ever built. The talk will be illustrated by pictures, simulations, and videos of our devices.

Fig. 1: A walking toy that cannot stand still.

SUMMARY

A few morals seem to be exposed: much of the coordination observed in locomotion can be understood from a purely mechanical point of view, locomotion efficiency seems to be based on impacts and avoidance of impacts, and stability comes in part from utilizing the non-holonomic constraint of Intermittent contact.

VARIABLE GEARS IN ANIMAL LOCOMOTION: EFFECTS OF SPEED, GAIT AND SIZE

Andrew A. Biewener

Concord Field Station, Department of Organismic and Evolutionary Biology, Harvard University, Cambridge MA, USA
abiewener@oeb.harvard.edu

INTRODUCTION

Animals walk, run and hop with characteristic postures. Limb posture, in turn, affects the magnitude of joint moments and muscle forces that must be exerted to support an animal's weight on the ground. Size-related differences in limb posture have been found to influence the scaling of muscle limb mechanical advantage (LMA) in terrestrial animals, enabling them to maintain uniform muscle and bone stress (constant safety factor; Biewener, 1989). By running on more upright and slender limbs, large animals reduce the magnitude of joint moments and hence, musculoskeletal force that their limbs must transmit to support ground reaction forces imposed during running. However, adjustments in limb mechanical advantage to accommodate large differences body size necessarily have an inverse gearing effect on the velocity and range of limb movements. This paper explores how limb mechanical advantage changes with speed, gait and body size. It also examines how changes in LMA affect the speed and range of limb movements in animals of different size.

MUSCLE MECHANICAL ADVANTAGE

Muscle mechanical advantage is often defined simply as the moment arm of a muscle acting at a particular joint. However, the force (F) that agonist muscles must generate to counteract external joint moments produced by the ground reaction force (G) acting on the limb is determined by the ratio of muscle mechanical advantage (r) to the mechanical advantage (R) of G acting about limb joints ($R/r = JG/JF$). **Fig. 1**

Muscle mechanical advantage at individual joints (JG/JR) can be averaged to determine overall LMA. Although this analysis ignores segmental and gravitational moments of limb segments, external moments exerted by G dominate during limb support and thus are considered here in relation to muscle force requirements for weight support and limb movement during stance.

METHODS

Different-sized mammalian species ran, trotted or hopped over a force platform with high-speed video or film recordings made from a lateral view. Muscle moment arms were determined from limb dissection or palpation. From these recordings and measurements, overall LMA was determined as a function of speed, gait and body size.

RESULTS & DISCUSSION

Except for humans, LMA of all species examined did not change significantly with running speed or change of gait (L-S regression slopes not significantly different from 0). When humans change gait from a walk to a run, however, LMA is significantly reduced (27%, $p < 0.01$), largely due to decreased JG/JF at the knee (Biewener & Chang, 1992); associated with a more flexed posture and spring-like use of the limb (McMahon & Cheng, 1992). Changes of LMA associated with speed changes within human walking and running gaits however were not significant. The scaling of LMA (r/R) in more closely related rodents (from deer mice to capybara, 0.02 to 35 kg) $\alpha M^{0.25}$ ($R^2 = 0.84$) closely matched the more general relation for quadrupedal mammals as a whole (Biewener, 1989), indicating that adjustments of LMA also occur within more closely related taxonomic groups.

The increase in LMA with size indicates a trade-off in the speed of locomotor movements for enhanced weight support. Given that the distance ($dL \propto Rd\Phi$) and speed of movement (dL/dt) of more distal limb segments, or the limb as a whole, depends on the rate and distance of muscle shortening (dS) in relation to the muscle's moment arm ($dS \propto rd\Phi$), the scaling of LMA suggests $dS/dL \propto M^{0.25}$. Assuming equivalent fractional shortening of muscle fibers (dS/L_f constant) in different-sized animals, such that $dS \propto L_f \propto M^{0.25}$ (Alexander et al. 1981), this suggests that the absolute distances of limb segment motion and rates of movement remain constant across size (dL and $dL/dt \propto M^0$).

A similar result was obtained by Hill (1950) in his classic lecture presented to the Royal Society relating the mechanical properties of muscles to the dimensions and locomotor movements of animals. Hill's analysis assumed isometric scaling, or geometric similarity. Although terrestrial mammals scale close to isometry (Alexander et al. 1979 & 1981), they exhibit allometric patterns of muscle architecture, with larger animals having shorter-fibered, more pinnate muscles than small animals. This is matched by the scaling of LMA to predict generally similar locomotor speeds across size.

WORK OR FORCE MINIMIZATION AS A CRITERION FOR THE EVOLUTION OF LOCOMOTION

R. McNeill Alexander

School of Biology, University of Leeds, Leeds LS2 9JT, UK

r.m.alexander@leeds.ac.uk

INTRODUCTION

Humans and horses tend to adjust their speeds and gaits, and humans adjust their stride frequencies, so as to minimize metabolic energy costs (Hoyt and Taylor, 1981; Minetti *et al.*, 1995). It seems likely that other animals (fliers and swimmers as well as walkers and runners) also prefer patterns of movement that minimize metabolic costs. Our understanding of locomotion could be greatly improved, if we could confidently predict how a change in a pattern of movement would affect these costs.

THE METABOLIC COST OF WORK

It is generally much easier to calculate the work done in a movement, than to predict metabolic costs from first principles. The hypothesis, that work is minimized in locomotion, has often been adopted (for example Cavagna *et al.*, 1977 on walking and running; Rayner, 1999 on flight). Such discussions tend to imply that metabolic energy costs are proportional to work. However, the efficiency of a muscle depends on the rate at which it is shortening, and muscles differ in efficiency even at their optimum shortening speeds. Also, the efficiencies with which work is performed in locomotion are much lower for small running and flying animals than for large ones (Full and Tu, 1991; Rayner, 1995).

THE METABOLIC COST OF FORCE

Muscles require metabolic energy to generate force, even when the contraction is isometric and so does no work. Roberts *et al.* (1998) have shown for mammals and birds that metabolic rate while running can be predicted by a calculation that takes account of the forces exerted, but not of the work done. It is assumed that the metabolic rate of a muscle is proportional to (force \times intrinsic speed), and that the intrinsic speed (v_{\max}) is inversely proportional to foot contact time.

CALCULATING METABOLIC ENERGY COSTS

Alexander (1997) and Minetti and Alexander (1997) used empirical equations that took account of both force and work to calculate metabolic energy costs for simple models of locomotion. We had some success in explaining the changes of duty factor, force pattern and stride length that humans make, as they walk or run at different speeds.

It can be shown from the equations of Alexander (1997) that the rate of use of ATP energy P of a muscle exerting force F while shortening isotonically at speeds v between 0 and $0.5v_{\max}$ is given approximately by

$$P \approx 0.07Fv_{\max} + 2.3Fv \quad 1.$$

Notice that the first term on the right hand side of this equation is proportional to the force F , and the second to the rate Fv at which the muscle is doing work. Thus the metabolic rate of an active muscle may be regarded as the sum of the energy cost of exerting force, and the cost of doing work. Disappointingly, equation (1) fails to explain the low efficiency of running for small mammals.

If muscles always operated at the same value of v/v_{\max} , the two terms on the right of Equation (1) would be proportional to one another, and metabolic rates could be calculated equally well from forces or from work performance. However, constant v/v_{\max} cannot be assumed, in analyses such as that of Alexander (1997) that seek to predict optimum muscle properties for particular patterns of movement.

Equation (1) is based on experiments in which muscles made single isotonic contractions. However, locomotion generally involves repeated cycles of lengthening and non-isotonic shortening. The behaviour of muscle in such cycles cannot be predicted accurately from the results of isotonic experiments (Askew and Marsh, 1998). We need better understanding of the physiology of cyclic contraction, to enable us to predict metabolic costs of different styles of locomotion. There are many variables that may affect the cost of cyclic contraction, but it may be worthwhile to test the hypothesis, that the metabolic cost is simply a function of (mean force $\times v_{\max}$) and mean power output. This could be done by experiments in which the heat produced in cyclic contraction was measured (Barclay, 1994), while varying the ratio of mean force to power output by varying the timing of stimulation (Josephson, 1985).

TIME-DOMAIN REPRESENTATION OF VENTRICULAR-ARTERIAL COUPLING AS A WINDKESSEL AND WAVE SYSTEM

John V. Tyberg,¹ Jiun-Jr Wang,¹ Nigel G. Shrive,² and Kim H. Parker³

²Department of Civil Engineering

University of Calgary, Calgary, Alberta, Canada

³Physiological Flow Studies Unit, Imperial College of Science, Technology and Medicine, London, United Kingdom

INTRODUCTION

Shape differences between central aortic pressure (P_{Ao}) and flow waveforms have never been explained satisfactorily in that the assumed explanation — the presence of substantial reflected waves during diastole — has never been demonstrated. We propose a functional, time-domain, arterial model that combines a blood-conducting system and a reservoir (i.e., Frank's hydraulic integrator, the Windkessel).

METHODS

Aortic pressures, flows, and diameters were measured in 16 anesthetized dogs (paced at ~ 70 bpm), so we could calculate their Windkessel pressure (P_{Wk}) and volume (V_{Wk}) which were compared with thoracic aortic volume. Windkessel pressure was determined by the difference between aortic inflow and its outflow, $\frac{dP_{Wk}(t)}{dt} = \frac{dP_{Wk}}{dV_{Wk}} \frac{dV_{Wk}(t)}{dt} = \frac{Q_{in}(t) - Q_{out}(t)}{C}$, where $C = \frac{dV_{Wk}}{dP_{Wk}}$ is the compliance. The outflow was assumed to be driven by the difference between the Windkessel pressure and the asymptotic pressure (P_{∞}) toward which diastolic aortic pressure decayed exponentially: $Q_{out}(t) = (P_{Wk}(t) - P_{\infty})/R$. R is the effective resistance of the peripheral systemic circulation. We calculated the total work performed by the LV during systole from the area of the P-V loop and then determined the fraction of this work that was done in charging the Windkessel. The remainder, "pulsatile work," was considered to be the sum of the work done overcoming the proximal resistance and that done overcoming inertance.

Fig. 1: A 3-D plot of aortic pressure versus time and distance (by 2-cm increments from the aortic root to the femoral artery) in a single dog. After waves have dissipated during diastole, pressures are almost equal at every location.

RESULTS AND DISCUSSION

To demonstrate that aortic pressure is the combination of the effects of waves and the Windkessel mechanism, a 3-D pressure-distance-time plot was constructed by measuring aortic pressure at 2-cm increments from the aortic root to the femoral artery (Fig. 1). During diastole, when there are no waves, pressure is distance-independent as Frank postulated.

We find that P_{Wk} is proportional to thoracic aortic volume and that the volume of the thoracic aorta comprises $45.0 \pm 1.8\%$ (SE) of total V_{Wk} . We calculated the fraction of the total LV work that is expended in charging the Windkessel (recoverable) and found it to be $86.8 \pm 1.1\%$, the remainder being due to pulsatile work. When we subtracted P_{Wk} from P_{Ao} , we found that the difference (excess pressure, P_{ex}) was proportional to aortic flow, thus demonstrating that the shape differences between aortic driving pressure (P_{ex}) and flow are negligible and implying that reflected waves are minimal (Fig. 2). The ratio of P_{ex} to aortic flow is equal to characteristic impedance (from Fourier analysis), consistent with there being a resistive loss in ejecting blood into the Windkessel.

SUMMARY

We suggest that P_{Ao} is the summation of a time-varying reservoir pressure (i.e., P_{Wk}) and pressure due (primarily) to forward-going waves. Most ($\sim 87\%$) of the total energy is used to charge the Windkessel, which can be considered useful work because ultimately it propels blood through the peripheral resistance into the venous system during diastole. Waves account for $\sim 13\%$ of the total LV work, which is used to overcome (proximal) arterial resistance and inertance.

Fig. 2: Left. Typical aortic root pressure (P_{Ao}) and calculated Windkessel pressure (P_{Wk}). Right: Excess pressure (thick dashed line; P_{ex} , calculated by subtracting the Windkessel pressure from the aortic pressure) and aortic flow (Q_{in} ; thin solid line) plotted against time and scaled to equalize their peak values. Their shapes are almost identical.

A NOVEL AGE-RELATED INDEX OF CARDIOVASCULAR FUNCTION

Kiyomi Niki¹, Motoaki Sugawara¹, Chang Dehua¹, Takashi Okada², Akimitsu Harada²

¹Department of Cardiovascular Sciences, Tokyo Women's Medical University School of Medicine, Tokyo, Japan, E-mail:mniki@nora.hij.twmu.ac.jp

²Research Laboratory Aloka Co. Ltd, Tokyo, Japan

INTRODUCTION

The maximum values of blood flow acceleration (dU/dt) and the rate of change in diameter $[(dD/dt)/D]$ in the carotid artery during initial ejection are higher in younger than older subjects. $WID=(dU/dt)(dD/dt)/D$ is a modified wave intensity, which is a novel index of cardiovascular function. We hypothesized that the reciprocal of the maximum value of WID, which is defined as $\alpha = 1/\text{Max}(WID)$, is in proportion to age in the normal group. We evaluated α in normal subjects and patients with dilated cardiomyopathy (DCM), old myocardial infarction (OMI), and hypertension (HT).

METHODS

We studied the common carotid artery in the normal ($n=126$, mean age 45, range 10 - 74 years), DCM ($n=40$, mean age 47, range 20 - 75 years), OMI ($n=14$, mean age 67, range 56 - 77 years), and HT ($n=11$, mean age 65, range 52-76 years) groups using a specially designed wave intensity system (Aloka SSD-5500), which simultaneously measures flow velocity and diameter by Doppler and echo tracking, and provides WID, and hence α .

RESULTS AND DISCUSSION

In the normal group, α was linearly related to age with a very narrow 95% confidence interval (goodness-of-fit $r^2=0.52$). In the DCM group, α also increased with age ($r^2=0.32$). However, the slope of the regression line was significantly steeper, and the 95% confidence interval was much broader compared with the normal group. In the OMI and HT groups, α was not related to age, but α in the OMI group was significantly higher compared with a subgroup of the normal group older than 62 years ($P<0.001$, Dunnett's test following ANOVA with the normal, HT and OMI groups).

SUMMARY

α was closely related to age in the normal group, and may be a good index of youthfulness of the cardiovascular system.

Figure 1: Relationship between α and age.

INTRODUCTION

Wave intensity (WI) is a new hemodynamic index, which is defined as $(dP/dt) \bullet (dU/dt)$ at any site of the circulation, where dP/dt and dU/dt are the time derivatives of blood pressure and velocity, respectively. However, pathophysiological meanings of this index have not been fully elucidated. Accordingly, we investigated the characteristics and clinical significance of WI.

METHODS

The study subjects consisted of 64 patients with coronary artery disease who underwent cardiac catheterization using a catheter-tipped micromanometer. WI was obtained at the right carotid artery using a newly developed system in which combined color Doppler for velocity measurement and echo-tracking method for acquiring vessel diameter changes (SSD-5500, Aloka, Tokyo, Japan) were applied. Using this system, vessel diameter changes were converted to pressure waves. Then, the temporal alteration of calculated $(dP/dt) \bullet (dU/dt)$ was automatically displayed.

RESULTS

The WI of the subjects showed two positive sharp peaks (**Figure 1**). The amplitude of the first peak during very early left ventricular (LV) ejection correlated significantly with $\max.dP/dt$ of LV pressure rise ($r=0.74$, $p<0.001$). The magnitude of the second peak at the end of ejection correlated significantly with $\min.dP/dt$ of LV pressure decay ($r=-0.61$, $p<0.001$) and with time constants of LV relaxation (tau from a phase loop: $r=-0.77$, $p<0.001$; tau from Weiss's method: $r=-0.63$, $p<0.001$).

Figure 1: Representative simultaneous recordings of blood pressure, velocity, and WI waveforms at the carotid artery. FP: first peak, SP: second peak

CONCLUSION

Using the WI at the carotid artery, hemodynamic information of LV contraction and relaxation can be obtained noninvasively. Furthermore, one can evaluate both LV systolic and early diastolic performance at the same time using this method.

NON-INVASIVE MEASUREMENT OF WAVE INTENSITY - REPRODUCIBILITY AND EFFECT OF GTN

Christopher J. H. Jones, Eleftherios Nicolaides, Lucy Boden, Alan Fraser and Michael Frenneaux

Wales Heart Research Institute,
University of Wales College of Medicine,
Cardiff, UK.

INTRODUCTION

The haemodynamic forces integrating arterial blood flow may be considered as elemental wave fronts, travelling forwards from the heart toward the periphery, or backwards after reflection. Wave intensity (WI), calculated simply as the product of the derivatives of measured pressure and velocity, measures the relative contribution of forward and backward wave fronts and thus separates upstream from downstream events that influence blood flow. Diameter may be substituted for pressure, allowing non-invasive assessment in man. We describe initial clinical data obtained using an ultrasound system adapted specifically for WI analysis (Aloka, Japan).

METHODS

In all studies, WI was measured in the right carotid artery in normal subjects, after 30 minutes supine rest in a temperature-controlled room. β and E_p were calculated as measures of arterial stiffness. Heart rate and BP were measured by finger cuff.

Study 1. Reproducibility: For acceptable statistical power for intraobserver, interobserver and visit-to-visit variability, WI was measured twice by 2 observers on 2 occasions 2 weeks apart in 26 subjects.

Study 2. Effect of GTN: WI was measured before and after administration of sublingual GTN or placebo in 12 subjects.

RESULTS

WI exhibited 2 positive peaks, signifying periods of dominant forward compression and expansion waves (CW and EW). Forward CW increase pressure and velocity in early systole; forward EW decrease pressure and velocity in later systole. The CW were followed by negative WI values, signifying reflections (WR) from the cerebral circulation.

Study 1. Reproducibility: Coefficients of variation for different WI measurements are shown below:

	Intra-observer (%)	Inter-observer (%)	Temporal (%)
<u>Compression Wave</u>	2.24	10.45	16.10
<u>Expansion Wave</u>	11.23	20.32	26.68
<u>Mid-systolic reflection</u>	14.04	19.23	28.42
<u>Beta</u>	11.63	10.05	14.81
<u>E(p)</u>	10.74	9.93	16.30

Study 2. Effect of GTN: Compared with placebo, GTN decreased diastolic BP and increased heart rate, consistent with reflex sympathetic activation. CW amplitude increased, presumably due to increased myocardial contractility. WR normalised for the CW decreased, consistent with peripheral vasodilatation. β and E_p both increased, indicating increased carotid stiffness.

DISCUSSION

WI may be measured non-invasively in real-time in man. Most WI measurements are highly reproducible during a single sitting; some measures also show acceptable variability from visit to visit. CW amplitude is an extremely stable physiological measure. WI analysis shows that GTN exerts a complex effect, causing direct microvascular dilatation and reduced backward wave travel and indirect reflex sympathetic activation with reduced diastolic BP but increased heart rate, forward wave travel and local arterial stiffness.

SUMMARY

WI analysis of non-invasively acquired data can provide a reproducible assessment of travelling wave fronts, elemental forces that govern arterial blood flow. The use of GTN, a physiologically complex intervention, demonstrates how WI analysis can resolve upstream, downstream and local influences on blood flow. WI analysis provides a clinically feasible approach to the study of intact system haemodynamics and has considerable potential as a physiological research tool.

SHEAR STRESS-INDUCED ATP RELEASE AND CALCIUM SIGNALING IN ENDOTHELIAL CELLS

Joji Ando¹, Kimiko Yamamoto¹, and Akira Kamiya²

¹Department of Biomedical Engineering, Graduate School of Medicine, University of Tokyo, ²Interdisciplinary Science Center, Nihon University, Tokyo, Japan

INTRODUCTION

Vascular endothelial cells (ECs) recognize shear stress, a mechanical force generated by flowing blood, and transmit a signal to the cell interior that leads to cellular responses involving changes in morphology, function and gene expression. Ca^{2+} signaling plays an important role in the shear stress signal transduction. Our previous studies demonstrated that shear stress activates Ca^{2+} influx into ECs via a subtype of ATP-operated cation channels, P2X₄. Recently, shear stress has been shown to induce ATP release from ECs. In this study, we examined the role of endogenous ATP released in response to shear stress and flow-related Ca^{2+} signaling.

METHODS

Human pulmonary artery ECs (HPAECs) that had been cultured on a coverslip were loaded with the Ca^{2+} indicator Indo-1/AM. The coverslip was then placed in a parallel plate flow chamber, and the chamber was mounted on the stage of a confocal laser scanning microscope. The entire circuit was filled with Hanks' balanced salt solution. By changing the height of the reservoir and monitoring the flow rate using a flow sensor, the cells were subjected to stepwise increments in shear stress. Changes in intracellular Ca^{2+} concentrations ($[\text{Ca}^{2+}]_i$) were monitored. The amount of ATP released in response to shear stress was determined using a bioluminescence assay and the uciferin-luciferase reaction.

RESULTS AND DISCUSSION

$[\text{Ca}^{2+}]_i$ in HPAECs increased in a stepwise manner in response to stepwise increments in shear stress. When extracellular Ca^{2+} was eliminated with EGTA, the Ca^{2+} responses disappeared, indicating that the response was due to the influx of extracellular Ca^{2+} across the

plasma membrane. The shear stress-dependent Ca^{2+} influx was almost completely blocked in HPAECs treated with antisense oligonucleotides targeting P2X₄ receptors. Thus, P2X₄ receptors probably play a crucial role in shear stress-dependent Ca^{2+} influx in HPAECs. Apyrase, which degrades ATP, significantly suppressed the P2X₄-mediated Ca^{2+} influx, indicating that endogenous ATP released from HPAECs may somehow be involved in this process. We next examined whether ATP was released from HPAECs by shear stress. A stepwise increase in shear stress induced a stepwise increase in ATP release. When the HPAECs were treated with known inhibitors of F₁-F₀ ATP synthase (oligomycin and angiostatin), the shear stress-dependent ATP release was markedly reduced and the shear stress-dependent Ca^{2+} influx was inhibited. These results suggest that endogenous ATP released from ECs in response to shear stress plays an important role in shear stress calcium signaling via P2X purinoceptors.

SUMMARY

We have shown that shear stress stimulates ATP release from ECs in a dose-dependent manner, contributing to Ca^{2+} signaling via P2X₄. These data suggest the existence of an autocrine and paracrine ATP signaling cascade that is linked to shear stress signal transduction. Further studies are needed to clarify the shear stress-dependent mechanism of ATP release in ECs.

IDENTIFICATION OF GENES REGULATED BY MECHANICAL FORCES USING MICROARRAY TECHNOLOGY IN HUMAN ENDOTHELIAL CELLS

Larry V. McIntire, E.D. Butcher Professor and Chair (mcintire@rice.edu)
Institute of Biosciences and Bioengineering, Rice University, Houston, Texas

INTRODUCTION

Two of the mechanical forces that act on vascular cells, shear stress and cyclic strain, are thought to contribute to the atherogenic properties of blood vessels. Northern blot analyses utilizing endothelial cells show that both protease activated receptor-1 and endothelin-1 gene expression are increased with cyclic strain and decreased with shear stress. This trend indicates that these mechanical stimuli may have opposing genetic influences on disease progression in the arterial system. Therefore, a comparison between the effects of these two mechanical forces on human umbilical vein endothelial cells (HUVECs) was conducted. HUVECs were subjected to shear stress at 25 dyn/cm² in a parallel plate flow chamber. Employing mRNA from sheared and static cells, differential expressions of over 4000 genes were evaluated simultaneously. Next, HUVECs were subjected to cyclic deformation at 10% strain, microarrays were again used for the strained, motion control and static cells. Northern blot analysis was performed on selected genes to verify the accuracy of the microarrays. Comparison between shear stress and cyclic strain data revealed differential gene expression.

METHODS

Gene microarray analysis is a powerful method for analyzing the effect of biological stimuli on gene expression profiles. We used Research Genetics microarray GF211, which contains over 4000 known human genes, to identify those regulated by fluid shear stress exposure. Message levels of genes in primary human umbilical vein endothelial cells exposed to a shear stress of 25 dyn/cm² or 10% cyclic strain⁽¹⁾ for 6 or 24 hours were compared with message levels in control cells. For several of the genes, Northern analysis was used to confirm the results.

RESULTS AND DISCUSSION

The microarray analysis identified many shear stress regulated genes, including genes that have been previously shown to be regulated by shear stress such as endothelin-1, monocyte chemotactic protein-1 and prostaglandin transporter. Overall the expression of 32 genes increased two fold or greater and the expression of 20 genes decreased 50% or more in response to shear stress⁽²⁾.

The most dramatically upregulated gene expression was observed in cytochromes P450 1A1 and 1B1. Classically, the CYP gene families have been associated with cellular detoxification mechanisms. However, primary HUVECs have been shown to produce CYP1A1, and recent evidence has shown that the production of an endothelial derived relaxing factor from arachidonic acid in endothelial cells is catalyzed by CYP1A1. In addition, loss of this gene in cultured ECs correlates with dedifferentiation. No association of CYP 1B1 with ECs has been reported. It may be a factor in mammary carcinogenesis, thus associated with angiogenesis. The strong induction of these CYP genes by shear stress is consistent with the suggestion that physiological levels of shear stress are atheroprotective. The other genes, whose biological functions are known, are connected with biological systems that are regulated at least in part by shear stress. By identifying additional genes in these systems it is possible to further define the mechanisms by which shear stress controls them.

SUMMARY

Shear stress is considered by many to be the most important stimulus for NO production in EC. Several genes identified as being shear stress responsive from our DNA microarray analysis may play a role in the regulation of NO production by shear stress, and suggests exciting new pathways for shear stress regulation of NO production in endothelial cells. The use of microarray technology to study the biological effects of shear stress has the potential to expedite our understanding of the role of shear stress in vascular biology and to allow the development of new hypotheses concerning genetic networks regulated by mechanical forces.

THE ROLE OF INTEGRIN IN MECHANOTRANSDUCTION IN ENDOTHELIAL CELLS

John Y.-J. Shyy

Division of Biomedical Sciences, University of California, Riverside, CA, USA, 92521-0121.

Email address: john.shyy@ucr.edu

RESULTS AND DISCUSSION

Evidence emerging from both *in vivo* experiments using animal models and *in vitro* experiments using flow channels indicates that fluid shear stress modulates many physiological and pathological processes. In the vessel wall, vascular endothelial cells (ECs) are constantly exposed to shear stress and thus play a crucial role in maintaining vascular homeostasis. The shear stress-mediated homeostasis is maintained through the expression of proteins and factors involved in vessel constriction and dilation (e.g., nitric oxide and endothelin-1), inflammation (e.g., intercellular adhesion molecule-1 and monocyte chemoattractant protein-1, MCP-1), and growth regulation (e.g., tumor suppressor p53 and platelet-derived growth factors). Mechanotransduction mechanisms by which ECs convert shear stress to biochemical signaling are responsible for these shear stress-mediated transcription events.

Integrins are a family of transmembrane heterodimers composed of α and β subunits. The extracellular domain of integrins binds to various ligands, including extracellular matrix (ECM) proteins such as fibronectin, vitronectin, and collagen. The cytoplasmic domain of integrins interacts with cytoskeletal proteins (e.g., actin filaments) and kinases (e.g., focal adhesion kinase, FAK, and c-Src) in the focal adhesion sites. The unique structural features of integrins enable them to mediate inside-out and outside-in signaling during many biological processes, including cell adhesion to ECM and migration. Inside-out signaling, which is also known as "integrin activation", modulates the affinity of integrins for extracellular ligands in response to intracellular signals. Outside-in signaling induces the intracellular signaling cascade as a result of integrin activation. Thus, integrins can function as both adhesion receptors and signal transducers to regulate cytoskeletal reorganization, intracellular ion transport, lipid metabolism, kinase activation, and gene expression. Conceptually, integrins in ECs can serve as mechanosensors by transducing the mechanical stimuli acting on the plasma membrane to ECM through inside-out signaling. Alternatively, signaling molecules associated with focal adhesions and cytoskeleton can be activated by integrins through outside-in signaling.

We and others have used flow channel system to investigate the role of integrin in mechanotransduction in ECs in response to shear stress. Results from our early studies demonstrate that shear stress modulates the expression of the MCP-1 gene in ECs, which is regulated by the mitogen-activated protein kinase (MAPK) pathways, including ERK, JNK, and p38.

Using these shear stress-modulated events as readouts, we found that kinases in the focal adhesions and the Rho small GTPases, which are signaling molecules engaged in integrin activation, are all activated by shear stress in ECs. The blockade of integrins with blocking-type monoclonal antibodies (mAbs) such as LM609 anti- $\alpha_v\beta_3$ inhibits the activation of MAPKs and the MCP-1 gene by shear stress. Furthermore, the Src-homology domain-2 (SH2) containing molecules, including Shc and growth factor receptor binding protein 2 (Grb2), constitute a crucial part of the integrin-mediated signaling. Shear stress activation of Shc was subsequently used as a readout to further elucidate the dynamic nature of integrins interaction with ECM in mechanotransduction. We found that the integrin-Shc association was abolished when new integrin-ECM ligand interactions were prevented by either blocking the integrin-binding sites of ECM or conjugating the integrins to immobilized anti-bodies. These results indicate that the dynamic formation of new connections between integrins and their specific ECM ligands is critical in mechanotransduction pathways.

Sterol regulatory element-binding proteins (SREBPs) are key transcription factors regulating sterol and lipid biosynthesis. Our recent results showed that shear stress causes the maturation of SREBPs in ECs. As a result, the expression of SREBP-mediated genes such as the low density lipoprotein receptor (LDLR) are modulated. Interestingly, blocking the β_1 -integrin with the AIIB2 blocking-type monoclonal antibody inhibited SREBP1 activation induced by shear stress. EC attachment to fibronectin or the activation of β_1 -integrin in the suspended ECs by the TS2/16 monoclonal antibody was sufficient for SREBP1 activation.

In summary, research performed in our laboratory during the last few years suggest that integrins interacting with ECM is important in mechanotransduction that regulates genes important in vascular biology, including those involved in cholesterol and lipid homeostasis.

STRESSING INTEGRINS ALTERS GENE EXPRESSION

Ning Wang

Physiology Program, Department of Environmental Health
Harvard School of Public Health, Boston, MA , USA

INTRODUCTION

How are mechanical signals transduced into biochemical signals and biological responses? Although it is known that fluid shear stress and stretching result in alterations in endothelin-1 (ET-1) gene expression, it is not clear what are the initial molecular pathways that are responsible for mechanotransduction. In this study we have set out to determine if the integrin-cytoskeleton pathway is involved in stress-induced alterations in ET-1 gene expression.

METHODS

Human umbilical vein endothelial cells were plated in 60-mm dishes and grown to confluence in culture medium. The dishes were washed twice with serum-free defined medium containing 1% BSA and 2 mg of ligand-coated beads were added into each dish for 30 minutes in serum-free defined medium (average 10 beads per cell). RGD (Arg-Gly-Asp) and acetylated-low-density-lipoprotein (AcLDL) were coated onto the beads at 50 µg protein per mg beads using the manufacturer's protocols. Anti-HLA antibody was coated at 20 µg protein per mg beads as previously described. In this study, we applied constant twisting fields at 40 Gauss (equivalent to 20 dyn/cm²) for 2 hrs with the beads remagnetized every 10 min. After mechanical stimulation of the cells, the supernatant was collected and the cells were lysed in RTL buffer. Total cellular RNA was obtained and northern analysis was performed according to the published methods. In situ hybridization was performed according to the published methods.

RESULTS AND DISCUSSION

Twisting RGD-containing-peptide-coated ferromagnetic beads (4.5 µm in diameter) increased ET-1 gene expression by more than 100%. In contrast, twisting scavenger receptors with AcLDL-coated beads or twisting HLA antigen with anti-HLA antibody coated beads did not lead to alterations in ET-1 gene expression. In situ hybridization showed that the increase in ET-1 mRNA was localized in the cells that were stressed with the RGD coated beads. Blocking stretch-activated ion channels with gadolinium or chelating calcium

with EGTA inhibited stress-induced ET-1 mRNA elevation. Similarly, inhibition of tyrosine phosphorylation with genistein abolished stress-induced ET-1 mRNA elevation. Inhibiting pre-existing cytoskeletal tension (prestress) with an inhibitor of the myosin ATPase, with an inhibitor of myosin light chain kinase, or with an actin microfilament disrupter, blocked twisted-induced increases in ET-1 expression. These results are consistent with other findings that integrins are important for mechanotransduction such as stress-induced intracellular calcium elevation, protein phosphorylation, and mRNA recruitment. Our results are consistent with the hypothesis that the molecular structural linkage of integrin-cytoskeleton is an important pathway for stress-induced endothelin-1 gene expression and that stretch-activated ion channels, protein tyrosine phosphorylation, and the prestress are important in transducing mechanical signals into gene expression.

SUMMARY

We have shown that ET-1 gene expression is upregulated when integrin receptors are stressed but not when other non-adhesion molecules are stressed. This work demonstrates the importance of the specific transmembrane molecular pathway (integrins), the integrity of the cytoskeletal structure, and the prestress in mediating stress-induced gene expression.

THE FREE VOLUME THEORY OF MECHANOCHEMICAL TRANSDUCTION

John A. Frangos

La Jolla Bioengineering Institute
La Jolla, California, USA
<http://www.ljbi.org>

The ability of cells to respond to hydrodynamic stimuli is ubiquitous amongst all cells and organisms, and has been implicated in a number of physiological and pathological processes. While many of the biochemical transduction pathways have been characterized, the primary mechanoreceptor(s) remain(s) unknown. It is our hypothesis that hydrodynamic shear destabilizes the plasma membrane, leading to a decrease in membrane microviscosity, or more precisely, an increase in membrane free volume. Mechanochemical transduction is proposed to occur when membrane-associated signaling proteins are activated by the increase intramolecular mobility.

A number of studies have implicated a role of heterotrimeric G proteins in the mediation of cellular responses to fluid shear stress and stretch. Studies from our lab demonstrate that

heterotrimeric G proteins are rapidly activated by hydrodynamic shear, representing the earliest known biochemical response to mechanical stimulation presented. Furthermore, both fluid shear stress and membrane fluidizing agents activate these G proteins in the absence of classical G protein coupled receptors. Using fluorescent molecular rotors it was recently shown that hydrodynamic shear increases membrane free volume. Taken together, these results demonstrate that hydrodynamic shear stress stimulates cellular responses by increasing membrane fluidity and activating heterotrimeric G proteins.

The presentation will discuss these results in the context of the membrane free volume theory of mechanochemical transduction.

CHANGES OF CAVEOLIN-1 IN HUMAN ENDOTHELIAL CELLS EXPOSED TO SHEAR STRESS

INTRODUCTION

Caveolae are special invaginated microdomains (50-100nm) at cell membrane of many cell types, such as epithelial cells and vascular endothelial cells.

Caveolins are the main structural proteins of caveolae and form a scaffold by the interaction with each other and binding to cholesterol for the attachment and assembly of many classes of signaling molecules. Caveolins can directly interact with these signaling molecules and regulate their activation (Schlegel and Lisanti 2001).

Considering that vascular endothelial caveolae could be flow-sensors converting mechanical stimuli into chemical signals transmitted into the cell, this work studied the changes of caveolin-1 expression and distribution in cultured endothelial cells exposed to laminar flow. In addition, the influence of cytokine TNF- α on caveolin-1 was also investigated.

METHODS

HUVECs were harvested from human umbilical cord veins. For shear experiments, the cells were seeded on glass slides coated with 1% gelatin. The cells of passage 2 were used in our experiments.

The slide with an endothelial monolayer was assembled to a widely used parallel rectangular flow chamber and a steady flow rate was generated by a peristaltic pump with a damping system. ECs were exposed to shear stress of 1.0 Pa for different times (4-24h). Cells cultured in static condition were considered as normal control and cells stimulated by TNF- α (100U/ml) as control of biochemical effect.

In order to observe the effect of F-actin organization on caveolin-1 distribution, certain cells were pretreated with cytochalasin-D (2 μ M/ml) before TNF- α stimulation.

After exposure to shear stress or stimulation by TNF- α , the cells were fixed and permeabilized. Caveolin-1 was labeled with indirect immunofluorescence method. Labeled cells were observed with a 3D optical sectioning acquisition system CELLscan. Western Blot analysis was used to evaluate caveolin-1 expression in the cells under different condition.

RESULTS AND DISCUSSION

The results showed that in control cells, caveolin-1 was primarily localized on the cell surface (Fig.1A), which corresponded to the peripheral distribution of F-actin, and presented a discrete concentrated distribution. In cells exposed to laminar flows, caveolin-1 distribution showed a time-

dependent variation. After 24h of shear, we found not only more caveolin-1 in the cells, but also a local caveolin-1 concentration, in most cells, at the upstream side of cell body (Fig.1B). In contrast, TNF- α induced a decrease of caveolin-1 in the cells. F-actin organization seemed to be correlated to caveolin-1 distribution.

Figure 1: Distribution of caveolin-1.

A: static condition

B: 24h, 1.0Pa

If we consider the subcellular distribution of mechanical forces, an interested theoretical analysis result of the flow in the vicinity of an endothelial monolayer was found (Waché et al 2000). The distribution of mechanical forces is not uniform on the cell surface. In fact, the shear stress is maximum at the top of the cells, but the hydrostatic pressure is maximum at the upstream side of the cells; also this area has a high spatial gradient of shear stress.

CONCLUSIONS AND PERSPECTIVES

The results suggest that: 1) shear stress can sufficiently induce caveolin-1 translocation, but TNF- α down-regulates caveolin-1 expression; 2) there is a relation between the local distribution of caveolin-1 and that of hemodynamic forces (shear stress gradient and/or pressure) at cell surface; 3) there could be a correlation between caveolin-1 distribution and F-actin organization.

However, further studies are necessary to elucidate the mechanism of these changes of caveolin-1. It would be particularly interesting to study the role of F-actin, caveolin-1 tyrosine phosphorylation and effect of cholesterol content.

INTRODUCTION

Shear stress is a tangential component of hemodynamic forces that acts mainly on vascular endothelial cells (ECs) and is now generally considered to play a role in development of some cardiovascular diseases, such as atherosclerosis. The conversion of mechanical stimulation into cells seems to be associated with cytoskeleton. But the molecular mechanisms have not yet been clearly established. Recent elucidation of the primary vasodilator-stimulated phosphoprotein (VASP) structure suggests that VASP is a potential component of focal contacts which may link to signal transduction pathways (Salazar et al. 1999). Hence, the aim of the study is to evaluate shear stress-induced changes of VASP expression in ECs.

METHODS

Cell culture: Human umbilical endothelial cells (HUVECs) were cultured according to a modified method of Marin et al. (2001).

Shear experiments: The cells were divided into three groups which would be exposed to different shear stresses (2, 10, and 15 dyn/cm²) for duration variable from 1 to 24 hours. A conventional parallel-plate flow chamber was used to create laminar shear stresses.

Protein isolation and western blot analysis: Cells were scraped into a lysis buffer. After centrifugation, the supernatant was subjected to SDS/PAGE analysis followed by immunoblottings followed by pixel detection (HPIAS-1000 software, QianPing company, China). Primary antibody was anti-VASP serum M4.

Indirect immunofluorescence: Confluent HUVECs were fixed and permeabilized, then incubated with primary anti-VASP antibodies IE273 and secondary antibodies AlexaTM 488. Phalloidine-rhodamine was used for cytoskeleton labelling.

RESULTS AND DISCUSSION

Time course of VASP expression : Figure 1 shows OD values of VASP expression at 46kD in HUVECs stimulated by 3 different levels of shear stresses. The shear stress of 15dyn/cm² led to a rapid increase followed by a transient decrease of the VASP expression, accompanied by a rapid phosphorylation of VASP at 50kD (Data not shown). While a lower shear stress (2 or 10 dyn/cm²) had slower effects on the same tendency.

Immunofluorescence staining: Figure 2 shows a double fluorescence staining of VASP and F-actin. In static HUVECs,

VASP was only a weak decoration of stress fibres along their entire length (Fig.2 A). After exposure to shear (15dyn/cm², 24h), HUVECs presented an assembly of subplasmalemmal F-actin with thicker VASP than in control, targeted to the ends of stress fibres (Fig.2 B).

Figure 1: OD values of VASP expression in sheared HUVECs.

Figure 2 : Double immunofluorescence staining of F-actin and VASP in HUVECs. A : static control ; B : HUVECs exposed to a shear stress of 15dyn/cm² for 24 hours.

SUMMARY

Our experimental results show for the first time that shear stress induces VASP expression changes in a time-dependent manner accompanied by a rapid phosphorylation. These results suggest that VASP is a potential important component which participates in the regulation of cell actin remodelling induced by shear flow.

PREDICTION OF THREE-DIMENSIONAL ORIENTATION OF STRESS FIBERS IN CULTURED ENDOTHELIAL CELLS UNDER CYCLIC DEFORMATION

Hiroshi Yamada, Tohru Takemasa¹ and Takami Yamaguchi²

Department of Biological Functions and Engineering, Graduate School of Life Sciences and Systems Engineering,
Kyushu Institute of Technology, Kitakyushu, Japan, yamada@life.kyutech.ac.jp

¹Institute of Health and Sports Sciences, University of Tsukuba, Tsukuba, Japan

²Department of Mechatronics and Precision Engineering, Graduate School of Engineering, Tohoku University, Sendai, Japan

INTRODUCTION

To elucidate the mechanism of the orientation of intracellular stress fibers (SFs) in vascular endothelial cells, the effect of cyclic deformations on the orientation has been studied (Takemasa et al. 1998). Cyclic deformations with a constant strain range cause a reorientation of SFs in a certain direction depending on the magnitude of the strain range. Some hypotheses have been proposed to explain the two-dimensional (2D) orientations of SFs or cells along the surface of the substrate (Wang et al. 1995, Takemasa et al. 1998, Yamada et al. 2000). Three-dimensional (3D) orientations of SFs in cultured endothelial cells have also been reported under mechanical stimuli of fluid shear stress (Kano et al. 2000) or cyclic deformation (Wang et al. 2000). In this study we predicted 3D orientations of SFs under various types of cyclic deformation of a substrate on the basis of a hypothesis (Wang et al. 1995, Takemasa et al. 1998).

METHODS

The hypothesis which we used in this study was that SFs are realigned in the direction in which the strain is less than $\pm 5\%$ in a maximally deformed state of a substrate. Based on this hypothesis and under an incompressibility condition of a cell, we carried out numerical simulations. Boundary conditions were (1) uniaxial cyclic loading in x direction (Cauchy stress $\sigma_y = \sigma_z = 0$; stretch ratio $\lambda_y = \lambda_z = \lambda_x^{-1/2}$), (2) uniaxial cyclic stretch in x direction ($\lambda_y = 1, \sigma_z = 0; \lambda_z = \lambda_x^{-1}$), (3) equi-biaxial cyclic stretch ($\lambda_x = \lambda_y > 1, \sigma_z = 0; \lambda_z = \lambda_x^{-2}$) where the x-y plane and z-axis corresponded to the substrate surface and its normal direction, respectively. It was also assumed that a line element with a unit length represented an initial SF and that an end of a SF was always located at the origin of the x,y,z coordinate system and the other end changed its position following a deformation of the substrate.

RESULTS AND DISCUSSION

Figure 1 shows numerical simulation results of 3D orientation in SFs under the uniaxial cyclic loading (Fig. 1 (a)), the uniaxial cyclic stretch (Fig. 1 (b)), and the equi-biaxial cyclic stretch (Fig. 1 (c)) with a strain range $\lambda_x = 1.12$. In these figures, an end of a SF is located at the origin O and the other end at an arc of each surface which intersects with a surface of a unit sphere. Each sector-like surface from the front to the back in Fig. 1 (a) and Fig. 1 (b) and each from the back to the front in Fig. 1 (c) correspond to the cases of SFs with a length of 0.95, 1 and 1.05 in a maximally deformed state of a

substrate, respectively. These results predict 3D formation of SFs; both ends of which attach to the basal membrane (x-y plane), or one end attaches to the apical membrane and the other to the basal one, depending on the deformation type of the substrate. The result in Fig. 1 (c) qualitatively agrees with an observation of “tent-like” structure in an equi-biaxial cyclic stretch for cultured endothelial cells by Wang et al. (2000).

Figure 1: Orientations of SFs in the unloading state with a strain range $\lambda_x = 1.12$ under the boundary conditions: (a) $\sigma_y = \sigma_z = 0$, (b) $\lambda_y = 1, \sigma_z = 0$, and (c) $\lambda_x = \lambda_y, \sigma_z = 0$. The length of the SF is 0.95, 1 or 1.05 in a maximally deformed substrate.

SUMMARY

3D orientations of SFs were predicted theoretically under various boundary conditions of cyclic deformations. The simulation result under equi-biaxial cyclic deformation agreed with an observation of “tent-like” structure of SFs in the literature. These predictions give an insight of the formation in SFs under mechanical stimuli from a mechanical viewpoint.

INTRODUCTION

This study is to explore the properties of the binding force between a pair of ligand and receptor. LFA-1, an integrin molecule, and ICAM-1, an immunoglobulin superfamily molecule, which is a pair of adhesive molecules, and is central to many leukocyte adhesive events in inflammation, immigration and endothelium injury.

MATERIALS AND METHODS

For studies on the interaction of LFA-1 with ICAM-1, SKW-3, [kindly provided by Dr. Periasamy Selvaraj of Emory Univ. School of Medicine, (Atlanta, GA, USA)], a human T-cell leukemia cell line, which expresses LFA-1 on the membrane, and health human RBC were the carriers respectively for LFA-1 and ICAM-1. For carrying ICAM-1, first the health human RBCs were coated with CA7 (an monoanti-ICAM-1) by an improved chromium chloride, then the RBCs coated with CA7 were incubated with human plasma for CA7 to conjugate soluble ICAM-1.

SKW-3 and RBC coupled with ICAM-1 were respectively held by micropipettes with negative pressure, brought into contacting with constant contacting area, and the certain contacting duration, upon retracting the deformation of the RBC were observed for judging the happening of adhesion and measuring the adhesion force. Each pair of cells was subjected with 100 cycles for contacting and retracting.

Cells were divided into 5 groups: (1) non-stimulated SKW-3; (2) SKW-3 incubated with sLe^a (the ligand for L-selectin on the membrane of SKW-3); (3) SKW-3 incubated with Dreg-56 (the mAb for L-selectin); (4) SKW-3 incubated with PHA; (5) SKW-3 cells incubated with PHA and Tetramethylpyrazine simultaneously

RESULTS AND DISCUSSION

The binding force is not obviously and directly related with different groups, while the binding force were found to have an approximate linear relation with the adhesion probability (Fig.1) According to the two-dimensional receptor-ligand binding kinetics, under this range of adhesive probability, most of adhesion were between one ligand and one receptor, and were considered as a single bond of receptor and its ligand. The following hypotheses may be

Fig.1 The relation of adhesive force with the adhesive probability

the possible reason for this relation: (1) this binding is via weak bonds, hydrogen bond and van der Waals attraction, which bond energy are respectively about 7.0 pN.nm and 0.7 pN.nm, which is not so much larger than the thermal motion energy kT (here k is Boltzmann constant, T is temperature ($^{\circ}K$)), then the binding force is not constant and has statistical properties. (2) This binding depends on the matching of conformation of receptors and its ligands, so-called lock-key relation, this matching creates good morphological condition for many hydrogen bonds and van der Waals bonds, then one single bond of a receptor and its ligand consists of many hydrogen bonds and van der Waals bonds, during the binding the matching sites of both receptor and its ligand can have a further modification to reach a stronger binding, which is a process during the interaction of receptor and its ligand and may cause the increases of the binding force with the adhesive probability. These hypotheses and the mechanism of the linear relation of adhesion force with adhesion probability is waiting for further exploring.

INTRODUCTION

The mathematical modeling and the numerical simulation of blood flow in the human cardiovascular system presents many challenges. A detailed study of the local flow pattern, as well as the wall shear stress in some critical regions, such as bifurcations or stenotic arteries, may provide very useful indications to the medical researcher; yet such an analysis can't leave aside the interaction with the remaining part of the circulatory system. Indeed, local flow features may have a global effect on circulation; for instance, a stenosis caused by an atherosclerotic plaque may change the overall characteristic of the vessels involved, and consequently have significant influence on the flow in the whole system. Hence, it lays the interest to set up a numerical device that could represent accurately both local and systemic features at the same time.

In this work we propose a modeling of the cardiovascular system based on a multiscale description. On the bottom level of complexity, we consider a "lumped" parameter model (hereafter called 0D model) that provides the time evolution of averaged quantities such as mean pressures and mass fluxes in some districts of the circulatory system. Such a model is represented by a system of ordinary differential equations and is traditionally described by means of an electrical network analogue.

As an intermediate level of complexity we propose monodimensional models (hereafter 1D models) that describe arteries as monodimensional entities and provide mean pressure and mass flux at each point along the arterial axis. These models are well suited to describe pressure waves propagation and may be used to capture spurious wave reflections due to the presence of a prosthesis or a stent in a trait of artery. Simple 1D models derived for a cylindrical rectilinear artery with uniform mechanical properties have been proposed and widely used in the literature. Improvements on these models may be achieved by accounting for non-uniform (or even discontinuous) mechanical characteristics of the vessel wall, curved geometries or branching. We will present recent results on that direction.

Finally, models that provide a very fine description of the local fluid dynamics are based on a set of partial differential equations. They account at the same time for fluid flow and structure deformation and provide a fine description of fluid quantities (pressure and velocity field) as well as vessel wall deformations. At a numerical level they are the most costly in computational time and memory requirement; moreover, their discretization is not an easy task. Indeed, on one hand, fluid

equations should be solved on a moving domain; this implies the development of special techniques such as the so-called Arbitrary Lagrangian Eulerian (ALE) formulation, which we have adopted in our numerical simulations. On the other hand, staggered algorithms aiming at solving sequentially fluid and structure equations are very critical regarding the stability properties of the numerical solution. A deep investigation is, thus, demanded to devise stable, accurate and efficient algorithms. We will present some theoretical and numerical results concerning finite element approximations of this fluid/structure problem.

By suitably coupling the three models we may realize a numerical device that is capable to simulate at the same time local and global phenomena. In figure 1 we show a possible application of this technique. The local fluid/structure model is used to simulate blood flow in a coronary anastomosis and is coupled with a 0D model of the circulatory system, here represented as an electric circuit. The 1D model is used to realize the transition between the local and the systemic model.

Figure 1: Example of a coupled 0D/1D/2D model for blood flow in a coronary anastomosis.

WAVE PROPAGATION IN BLOOD VESSELS USING VELOCITY PROFILES BASED ON BOUNDARY LAYER THEORY

Frans N. van de Vosse

Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, The Netherlands,
F.N.v.d.Vosse@tue.nl

INTRODUCTION

Lumped parameter models (0D), pressure and flow wave propagation models (1D) and models based on numerical solution of the full Navier-Stokes equations (3D) can give valuable contribution to answers on (patho-)physiological questions in diagnostics and treatment of cardiovascular disease. As fully 3D models are consuming too much computer time to be useful in a clinical setting, lumped parameter and 1D wave propagation models are still most suited to obtain patient specific clinically relevant information and proper boundary conditions for local 3D analyses. The non-linear nature of the equations due to the convection terms in the Navier-Stokes equations and the non-linear constitutive equations that describe the mechanical properties of the arterial wall significantly complicate models that are based on a description in the frequency domain. Moreover, wave propagation phenomena are difficult to describe with lumped parameter models. In view of the above mentioned, in this study 1D wave propagation models in the time domain are considered. One of the shortcomings of the existing 1D models is that the non-linear convection terms and the friction forces both are based on an assumed velocity profile. In this study a velocity profile is derived from boundary layer theory based on an assumed boundary layer thickness.

METHOD

In order to derive a first order approximation of the velocity profile, the vessel is decomposed in an inviscid core where a flat velocity profile is assumed and a viscous boundary layer where the velocity profile is derived from boundary layer theory. The boundary layer thickness is assumed to be proportional to the reciprocal of the Womersley parameter α . The velocity profiles obtained in this way can be integrated and provide valuable expressions for the non-linear and friction terms in the 1D wave equations.

RESULTS AND CONCLUSIONS

For limiting values of the Womersley parameter ($\alpha=\infty$, $\alpha=0$) the wave equations based on the boundary layer profiles correspond with theory based on flat and parabolic profiles respectively as derived in Hughes and Lubliner (1973). In order to validate the velocity profiles as obtained from the boundary layer approximation, a comparison has been made with Womersley profiles for a given periodic flow pulse. As can be depicted from figure 1, a fair approximation of the velocity profiles and a perfect approximation of the wall shear stresses are obtained for single harmonic flow pulses for all values of the Womersley parameter.

Figure 1: The flow, pressure gradient and wall shear stress and the velocity profiles for aortic and coronary flow pulses as predicted with Womersley theory (- and Wo) compared to the predictions based on the boundary layer profiles (o and Bo).

The viscous forces are found to be proportional to the flow and pressure gradient with multiplication factors c_q and c_p respectively. Figure 2 shows that excellent agreement is found with the corresponding factors based on Womersley theory.

Figure 2: The parameters c_q and c_p (solid lines) as a function of Womersley parameter α compared to the corresponding values c_v and c_u of Young and Tsai (1973).

INFLUENCE OF CORONARY VASCULAR BED COMPLIANCE ON THE SHAPE OF PRESSURE-FLOW WAVES

Shmuel Einav¹ and Evgeny Shalman²
¹Tel-Aviv University and ²Florence Medical Ltd., Israel

INTRODUCTION

A new parameter, PTC, for assessing stenosis severity was recently introduced¹. PTC, or Pulse Transmission Coefficient, is the ratio of the high-frequency pressure components that are distal and proximal to a stenosis during early diastole. Clinical trials¹ have shown that PTC has high specificity and sensitivity. We developed an hemodynamic model for describing the decay of the high frequency pressure and flow component across a stenosis.

MATHEMATICAL MODEL

The hemodynamic properties of a stenosis are exhibited on a one-dimensional hydraulic model. The pressure gradient across the stenosis, ΔP , is assumed to be a quadratic function of the flow, Q . The usefulness of this model for studying coronary stenosis had been demonstrated earlier². The model of a vascular bed is similar to the well-known (RCR) or intramyocardial pump models³ which use two resistive compartments with a compliant compartment between them. We assume that a vascular bed consists of only one compartment that is both resistive and compliant. The vascular bed compliance, C , is inverse to its resistance, R : $C=k_c/R$. The systolic-diastolic change in resistance is described by step-wise functions of time. The arterial diameter and mean wall shear stress proximal to a stenosis define the flow at rest. The suggested model uses a minimal number of parameters and allows direct estimation of the influence of vascular bed compliance on the shape of the pressure wave. The obtained nonlinear stiff ordinary differential equation is solved by a CFD numerical procedure.

RESULTS

The model's calculations of coronary blood flow described the main features of the pressure signal distal to a coronary stenosis. The PTC was mainly dependent upon stenosis severity and early diastolic change in the vascular bed compliance (coefficient k_c). Calculations for a proximal pressure signal composed of the "smooth" low-frequency component and one high-frequency sinus wave were carried out, and an example of the calculation for vascular beds having various compliances is presented in the figure. A high-frequency component could be observed in the distal pressure signal when the vascular bed had low compliance ($k_c=0.025$). This component disappeared when the vascular bed had high compliance ($k_c=0.1$). The proposed model could also demonstrate an abrupt early diastolic drop in distal pressure.

DISCUSSION

The early diastolic filling of the coronary vascular bed has a strong impact on the shape of the pressure wave distal to a coronary stenosis. The PTC allows an estimation of stenosis severity at rest. Clinical application of the PTC will enable non-hyperemic assessment of stenosis severity.

INTRODUCTION

Hemodynamic studies have suggested that atherosclerosis is associated with areas of oscillating and low mean wall shear stress (WSS) values (Ku et al., 1985). This study investigates using velocity and geometry data from phase contrast magnetic resonance imaging (PC-MRI) to determine WSS values in symmetric stenosis geometries. The importance of using blood flow simulations is illustrated by comparing WSS values derived from computational fluid dynamic (CFD) simulations to the direct calculation of WSS from PC-MRI derived velocity profiles.

METHODS

Idealized models of common carotid arteries (6.35mm diameter) with 52.7% and 75.0% symmetric stenoses were manufactured from polyvinyl alcohol, which has MRI relaxation properties similar to arterial wall tissue. These models were placed in a clinical MRI scanner (Philips ACS-NT) and connected to a flow system containing a glycerin/water mixture with a viscosity similar to blood. This fluid was run through the models at rates equal to the average (270 mL/min) flow rates found in human common carotid arteries. Geometry and velocity data were acquired using spin-echo inversion recovery (IR) and phase contrast sequences with the following parameters: FOV = 128mm, scan matrix = 256x256, TR = 20msec, TE = 6msec, flip angle = 40 degrees, slice thickness = 2mm, 8 signal averages.

WSS values were calculated directly from the PC-MRI data by fitting quadratic curves to the near-wall velocity data. The near-wall fluid strain rates were determined from the slopes of these lines evaluated at the wall location as determined from the IR images. The IR images were also used to reconstruct the 3D geometry so that the hemodynamics through the model could be simulated using CFD (FIDAP 8.5) with the inlet boundary conditions taken from the PC-MRI velocity data. Gold standard WSS values were determined from CFD simulations using idealized geometries and idealized inlet boundary conditions.

RESULTS AND DISCUSSION

52.7% Stenosis: The maximum WSS was calculated directly from the PC-MRI derived velocity profiles as 21.6 dynes/cm², which was a 64.6% underestimation of the gold standard value (60.9 dynes/cm²). The CFD simulation yielded 35.5 dynes/cm², which was a 41.8% underestimation.

75.0% Stenosis: The maximum WSS was calculated directly from the PC-MRI derived velocity profiles as 51.6 dynes/cm², which was a 73.1% underestimation of the gold standard value (192.1 dynes/cm²). The CFD simulation yielded 148.0 dynes/cm², which was a 23.0% underestimation (see figures).

For both models, the calculation of WSS directly from the PC-MRI velocity profiles underestimated the peak WSS values more than the CFD simulations. Furthermore, the PC-MRI derived WSS values in both geometries took longer to return to baseline levels as compared to the CFD simulations. This is largely due to the low resolution of the PC-MRI data and the necessity to average velocity values over large voxels (2mm x 0.5mm x 0.5mm) to obtain acceptable signal-to-noise ratios. Large variations in WSS values at the same axial location and different angular locations were present in both methodologies. Inadequate in-plane resolution and ambiguity in wall location caused by low contrast between the PVA model and the fluid are thought to have caused the large standard deviations present in the data.

SUMMARY

CFD simulations based on PC-MRI data can better detect large WSS gradients due to higher near wall velocity resolution. Direct calculation of WSS from PC-MRI data is limited due to the large image slice thicknesses required to reduce signal noise and limited in-plane resolution. This leads to large voxels over which velocity data is averaged, effectively reducing the ability to detect large and small velocities and therefore large velocity gradients.

HEMODYNAMIC MODELING IN STENTED ARTERIES

James E. Moore Jr., Andreas O. Frank, Yong He, and Peter W. Walsh

Biomedical Engineering Institute, Florida International University, Miami, Florida, USA
james@eng.fiu.edu

INTRODUCTION

Stents are small, metallic tubes used to prop open arteries diseased with atherosclerotic plaque. While the deployment of a stent is considerably less traumatic than surgical alternatives, the procedure suffers from failure rates of 20% - 30% due to restenosis. The mechanical conditions inside the stented artery may be related to the development of restenosis. Stents are responsible for changes in flow patterns and artery wall stresses. These changes depend on the design of the stent. This research was initiated to quantify changes in arterial blood flow patterns as a function of stent design parameters. The data from flow simulations help explain the results of in vitro experiments on the role of flow patterns in restenosis development.

METHODS

Computational simulations of blood flow in stented arteries were performed using commercially available software. The artery wall was assumed to be rigid, and the stent struts protruded into the flow stream. The height of the stent struts was $H = 0.15$ mm. The stent strut spacing in this 2D model varied from $2.5 H$ to $7 H$. The flow rate was specified so that the wall shear stress in the absence of stent struts would be 10 ± 5 dynes/cm².

RESULTS AND DISCUSSION

The patterns of flow separation and wall shear stress depended strongly on the stent strut spacing. At stent strut spacings less than $3 H$, flow separation is continual from one strut to the next. For larger strut spacings, there is at least partial flow reattachment between the stent struts. The mean wall shear stress was less than 1 dyne/cm² between the struts for stent strut spacings less than $5 H$. At the largest stent strut spacing ($7 H$), the mean wall shear stress recovered to a maximum value of 45% of the nominal value.

SUMMARY

These results indicate that flow phenomena likely to play a role in stent restenosis. Additional in vitro experiments have demonstrated that platelet adhesion and endothelial cell regrowth are sensitive to flow conditions. Platelet adhesion is highest in regions of partial flow reattachment and low shear stress. Endothelial cell regrowth occurs fastest in regions of flow reattachment and high shear stress. These results aim to provide a more quantitative understanding of the role of flow patterns in restenosis, and to provide information that can be used to design better stents.

⁴Institute of Biomedical Engineering, University of Vienna, Vienna, Austria

INTRODUCTION

For the improvements of patency rates following peripheral blood vessel reconstructions in which synthetic prosthesis must be used because of insufficient autologous venous replacement material, several modifications at the distal bypass anastomosis have been suggested. The long term function of such vascular reconstructions is influenced by several factors. Apart from cell biological and biochemical influences on intimal hyperplasia in synthetic vascular prostheses reactive mechanisms resulting from non-physiological flow dynamical and wall mechanical conditions play a certain role in the disease process. The present study aims to investigate the relationship between flow characteristics and mechanical stresses and post-operative intimal hyperplasia in three established types of distal end-to-side anastomoses using expanded polytetrafluoroethylene (e-PTFE) prostheses. Related to the surgical techniques the models differ in shape and structure of the graft-artery connector region (Leuprecht et al.). A significant aspect of the modification is the reduction of the compliance mismatch between the prosthetic graft and the native artery using an interposed vein patch and cuff.

METHODS

Computer simulations based on casts of femoro-popliteal bypasses implanted in sheep were performed to analyse the flow dynamics and the wall and suture mechanics in anatomically correct bypass configurations related to the surgical techniques conventional type anastomosis, Taylor-patch and Miller-cuff anastomosis. Time-dependent Navier-Stokes equations describing the flow field and a non-linear shell structure for the vessel wall were coupled using finite element methods. Experimental-surgical investigations and computer simulations were carried out, and possible relations between flow characteristics and mechanical stresses and occurring post-operative intimal hyperplasia in the anastomoses have been studied. For morphometry of the intimal thickness the implanted grafts were explanted and prepared for histological examination after six months.

RESULTS AND DISCUSSION

The simulation analysis referring to medium diameter vessel replacements demonstrates the influence of geometrical asymmetries and irregularities on the anastomotic flow and wall shear stress patterns. The stress field calculation confirms that more compliant grafts result in lower principal stresses at

the suture lines. The in-vivo studies of our project demonstrate correlations to compliance mismatch to some extent, with the graft-artery junctions showing the largest amount of intimal hyperplasia in mean values. However, at detailed locations, the situation may look different, due to geometry and flow field influences. The design of a peripheral vascular bypass configuration may affect the long term patency of the reconstruction. The selection of suitable materials and the definition of suitable geometry are important features of increased performance. Intimal hyperplasia at graft-artery junctions are also affected by biochemical influences and material interactions as discussed by Kissin et al. Material characteristics and cell biological aspects are not included in the present mathematical analysis.

Figure 1: Miller-cuff anastomosis, anastomotic flow field.

SUMMARY

The results of this investigation confirm the advantage of modified anastomoses as compared to both other non-conventional combinations. They allow the conclusion that the long-term function of e-PTFE reconstructions with venous grafts according to Taylor and Miller (and Linton-patch, which was also included in the in-vivo study) is improved due to reduction of the compliance mismatch rather than to changes in local blood flow phenomena. The study confirms that graft-artery compliance mismatch promotes the suture line hyperplasia.

INTRODUCTION

Abnormal haemodynamic conditions are implicated in the development of anastomotic myointimal hyperplasia (MIH). These conditions are difficult to determine *in vivo*, prompting research using ex-vivo idealised models. To relate the understanding gained in idealised studies to anatomically correct conditions we have investigated an approach to characterise *in vivo* distal graft anastomoses and their inter-patient variability.

METHODS

Distal anastomotic geometries were acquired *in vivo* by MR angiography from 10 patients undergoing infrageniculate autologous venous bypass at a median 2 weeks postoperatively. Four patients underwent repeat examinations 13 to 49 days later.

For each geometry the two-dimensional MR slice data was segmented and then approximated by smooth splines and evaluated at discrete points as shown in figure 1(a). The lumen's surface was then interpolated through the discrete points using a zero level set of an implicit function (Turk & O'Brien) as indicated in figure 1(b). The implicit function was made up of a radial basis function that minimises curvature using a variational principle which ensures smoothness. At this stage further smoothing may be applied followed by another implicit surface representation. From the lumen representation we can construct a computational mesh (Peiró et al.) to simulate flow quantities such as the wall shear stress shown in figure 1 (c).

Figure 1: a) segmented MRI data, b) implicit surface reconstruction and centreline representation, c) wall shear stress distribution.

Alternatively we can use the lumen representation as a starting point to characterise the geometry. A skeletonization procedure (Palagyi & Kuba) was then applied to determine a centreline approximation which approaches the medial lines of

the geometry as indicated in figure 1(b). The proximal and distal host and the graft vessels were then approximated from the intersection point using a linear least squares fit using data over a range of segment lengths. The linear approximations were then used to define angles between graft and proximal host vessel (α), graft and distal host (β), proximal host and distal host (γ) and each angle was evaluated over a range of sample lengths as shown in figure 2.

Figure 2: Variability of graft angle with inspection length normalised by the diameter.

Diameter ratios between the graft and host vessels were also calculated from the cross-sectional areas of the three vessels at the reconstructed anastomosis boundaries. A preliminary distal anastomotic planarity index (API) based on the variation of the normal to the plane containing the end points of the linear fits has been also introduced (for a planar anastomosis API=0). The data is summarized in table 1.

RESULTS

Angles	Min	Max	Mean	S.D.
α	28	101	41.6	20.3
β	144	177	163.8	9.9
γ	113	175	148.4	16.3
Diameter ratio				
Prox. - Graft	0.35	0.79	0.56	0.16
Distal - Graft	0.41	0.96	0.59	0.16
API	0.04	1.4	0.37	0.34

Table 1

Good agreement was found between the distal anastomotic angles in the initial and follow-up examinations. The differences in the angles varied between 1 and 10 degrees with a mean of 4.3 degrees.

INTRODUCTION

Great advancements have been made in the simulation of blood fluid dynamics due to increased computer power, improved CFD algorithms, and better *in vivo* measurements through medical imaging. One can envision that a full and accurate simulation of a patient's hemodynamic environment could be available to the physician in the years to come. Thus, we are conducting research to determine how simulations can be used to predict disease, plan surgical procedures, or to assess the effectiveness of medical treatments. Conduit size and quality are major determinants of the long-term success of infrainguinal autologous vein grafting. However, accurate measurement of the internal diameter of vein graft is surprisingly difficult given their variable wall thickness and taper. The purpose of this study was to define the "effective" internal diameter of a vein graft according to its hemodynamic properties and to determine its significance for graft patency.

METHODS

Sixty infrainguinal bypass grafts performed on 57 patients were evaluated intraoperatively. Proximal and distal graft pressure and blood flow were measured with fluid-filled catheter transduction and ultrasonic transit-time flow meter (Transonics, Inc.). Waveforms were recorded under baseline conditions and after stimulation with 60 mg of papaverine. The Womersley solution for pulsatile flow in an infinitely straight circular pipe was used to calculate a theoretical flow waveform for a range of graft diameters with fluid viscosity (3.5 cP). These theoretical waveforms were then compared with the measured flow waveforms and the best-fit diameter was chosen as the "effective hemodynamic diameter" (EHD). After a mean follow-up of 12.5 months (range, 0.1-43.9 months), patency was determined by the life table method.

RESULTS

The mean EHD was 4.1 ± 0.1 mm with a range of 2.5 to 5.7 mm. Administration of papaverine caused significant changes in the pressure difference between the proximal and distal ends of the graft as well as the blood flow rate ($+71\% \pm 12\%$) as expected, but had almost no effect on EHD ($+0.05\% \pm 0.1\%$). Patency of small diameter grafts (EHD < 3.6 mm; n=11) was compared with patency of larger grafts (EHD > 3.6 mm; n=36) to test a frequently espoused clinical guideline. Grafts with an EHD less than 3.6 mm exhibited significantly lower secondary patency compared with larger grafts ($P=0.0001$) as shown in Figure 1.

DISCUSSION

The parameter EHD was defined to provide the physician with a way to characterize a vein graft with a single number. The EHD represents the diameter of a circular tube that would have a similar flow waveform if imposed by the same unsteady proximal and distal pressure waveforms. Note that while this circular tube has the same length as the vein graft, it is of constant diameter, fully developed pulsatile flow is assumed through the tube, and the fluid is assumed to be a Newtonian fluid. The EHD is not meant to correspond to a specific diameter measured at a point along the graft. It is the effective diameter along the length of the conduit that constrains the relationship between pulsatile pressure and flow. Since it is unaffected by papaverine stimulation, it is an inherent property of a given graft.

While the simulation technique is rather simple given the CFD resources available today, the resulting EHD does incorporate the true pressure drop associated with the *in vivo* complex 3D geometry since it is based on intraoperative measurements. Thus, any deformation, kink, or blockage due to a vein valve in the vein graft that would significantly increase the pressure drop would be reflected in a lower value of EHD. In conclusion, EHD is a unique parameter that quantifies a vein graft's resistive properties to blood flow and is predictive of graft patency.

WALL SHEAR STRESS AND ALBUMIN PERMEABILITY AT THE PORCINE AORTIC TRIFURCATION

INTRODUCTION AND SUMMARY

A knowledge of the normal relationship between fluid dynamic shear stress and vascular macromolecular permeability in vivo is essential to understanding the mechanisms by which these stresses affect the localization and progression of atherosclerotic disease. Such data are difficult to obtain because the complexity and variability of arterial geometry require that colocalized shear stress and permeability data be obtained in the same vessel. We report here on a first experiment in which the albumin uptake distribution at the porcine aortic trifurcation is correlated on a site-by-site basis with a CFD calculation of the wall shear stress distribution in a computational region derived from a luminal cast of the same segment. The results suggest that the normal permeability of the vessel decreases with increasing shear stress, reaching a plateau at shear stresses ca. 40 dynes/cm².

METHODS

Perivascular flow probes (Transonic Systems, Ithaca NY) were placed around the exposed femoral arteries of an anesthetized 72 kg female domestic swine. Evans Blue dye (EBD), 2:1 molar with blood albumin, was administered intravenously and allowed to circulate for 90 minutes. The animal was sacrificed and a silicone rubber/glass fiber casting mixture was injected at physiological pressure into the abdominal aorta. The cast replicated the animal's infrarenal aorta and iliac-femoral arteries. Once the casting material had cured, the cast and surrounding tissue were excised from the animal. The tissue was removed with a dorsal cut; the cut line marked the surface of the cast and was subsequently used for registration purposes.

The cast was laser scanned by Product Development Technologies, Inc. (PDT, Lincolnshire, IL) to generate a 3-dimensional cloud of 150,000 points representing the luminal surface. Using a custom mesh generator, a 3-dimensional 8-node brick element mesh representation of the terminal aorta and the common internal, external and circumflex iliac arteries was created. The mesh contained a total of 135,648 volume elements and 8,352 surface elements. The flows through each branch were adjusted using terminal porous plugs to obtain flow partitions that were estimated (Henderson et al, 1999) from the flow probe measurements.

Steady, laminar flow calculations were performed using the finite-element code FIDAP (Fluent, Inc.), a uniform inlet velocity profile and a no-slip boundary condition at the rigid walls. The aortic segment was sufficiently long that a well-developed velocity profile existed immediately proximal to the

trifurcation. The inlet Reynolds number was 985 and the fluid was Newtonian, with a kinematic viscosity of 3.3 cs.

The distribution of computed shear stress in the right and left external iliac arteries, from the trifurcation to the deep femoral ostia, was mapped to an en face image by a numerical transform that simulates the cutting and pinning out of the tissue, using the cut line on the cast. The transformed image was deformed to a standard template and the shear distribution was compared on a pixel-by-pixel basis (20,000 pixels total) against the optical density (OD) distribution of a similarly templated photographic image of the EBD-stained tissue removed from the cast. The technique for obtaining the OD distribution has been described elsewhere (Friedman et al, 2000). OD measures albumin uptake during the dye exposure and is proportional to local permeability.

RESULTS

The correlation of OD vs. shear stress is shown in Fig. 1. Permeability appears to decrease monotonically with shear stress until a plateau is reached at about 40 dynes/cm².

Figure 1: Normalized optical density vs. calculated wall shear stress for both external iliac arteries. For each 5 dynes/cm² shear stress interval, the OD's of all pixels whose shear value was in that interval were averaged and divided by the mean OD of all pixels in that segment.

INTRODUCTION

Vascular diseases including cardiovascular and cerebrovascular diseases are the leading causes of death in the industrialized world. They share a common background, atherosclerosis, and a common final event, the breakage or destruction of vascular structure. Atherosclerosis preferentially occurs at specific arterial sites, which are strongly suspected to be related with the wall shear stress (WSS) distribution. The final vascular events that induce a fatal outcome, such as acute coronary syndrome, are now strongly suspected of being triggered by the sudden mechanical disruption of atherosclerotic plaque on the coronary artery wall. Subarachnoidal hemorrhage, which is another very acute and fatal disease, is the direct result of the rupture of a cerebral aneurysm. Thus, both the onset and final outcome of fatal vascular diseases are related to mechanical events that occur on the vascular wall, probably due to alterations in blood flow. Consequently, the fluid-solid mechanical interactions between blood and the vascular wall must be analyzed in order to predict, diagnose, and prevent the fatal consequences of vascular disease. We need to use computational studies to elucidate the mechanism of such disease, to refine the diagnostic measures, and to develop therapeutic modalities, either invasive or non-invasive.

PARAMETRIC AND REALISTIC MODELING OF THE CARDIOVASCULAR SYSTEM

Fig.1 Simulated blood flow in the human aorta using an overset mesh technique.

In conventional modeling of arteries and the heart, parametric and realistic methods are regarded as different. In the former, some characteristic configuration of the vascular system is modeled using simple elemental geometrical modeling. In the latter, direct segmentation, registration, and vectorization of complex anatomical structures from medical images are carried out. We proposed the so-called differential geometrical method of modeling arterial trees as a method that combines these two methods. In our method, vascular trees are represented using their centerlines and their normal planes defined by a combination of normal and binormal vectors. Each branch is modeled separately and connected using an overset mesh technique when fluid mechanical computations are

made (Fig.1).

IMAGE-BASED MODELING AND CLINICAL INTERFACES

Due to the rapid advances in invasive and non-invasive imaging technology in clinical medicine, we can now obtain images of target organs to use in computational analysis modeling. However, the resolution and reproducibility of non-invasive methods, such as magnetic resonance imaging (MRI), are still insufficient for automatic modeling. Therefore, we believe that any clinical application should fully utilize human pattern recognition and image reconstruction abilities. This is also a practical and efficient way of processing images. Consequently, we have been developing a comprehensive computational analysis support system that includes the preprocessing of medical images, segmentation, structure registration, database and human interfaces, mesh generation, and the final evaluation of the computed results (Fig. 2).

CONCLUDING REMARKS

Fig.2 A clinical interface for computational analysis

We now expect that a prototype will be developed for clinical application within a few years, and that we will be able to accumulate the necessary data and experience from real patients once this system becomes available to medical practitioners.

NUMERICAL STUDY OF HUMAN AORTIC BLOOD FLOW: A COMPARISON BETWEEN HEALTHY AND DISTURBED FLOW DISTAL TO ARTIFICIAL HEART VALVES

Armin Leuprecht¹, Karl Perktold¹, Sebastian Kozerke² and Peter Boesiger²

¹Institute of Mathematics, Graz University of Technology, Graz, Austria, armin.leuprecht@tugraz.at

²Institute of Biomedical Engineering and Medical Informatics, University of Zurich and Swiss Federal Institute of Technology Zurich, Zurich, Switzerland

INTRODUCTION

Flow in the human ascending aorta is of very complex three-dimensional pulsatile behavior. During systolic acceleration blood is expelled from the heart through the aortic valve. Flow in a healthy configuration shows a significant jet in the centre of the vessel featuring essentially flat profiles. Velocity profiles downstream mechanical heart valves demonstrate substantially different patterns that depend mainly on the valve design. As such local flow disturbances have been associated with late complications it is of major interest to analyse the hemodynamic performance of artificial valves. In this study magnetic resonance imaging (MRI) and computational fluid dynamics (CFD) are used in combination to compare aortic flow patterns and related hemodynamic quantities between an individual healthy and an artificial valve configuration.

METHODS

Two volunteer individuals showing similar geometrical features and similar flow conditions have been selected for this study: a female patient with an implanted artificial heart valve (Saint Jude Medical[®] aortic valve) and a young, healthy, female subject. Using a Philips Gyroscan NT 1.5T whole body scanner time-resolved, three-directional phase contrast data of both geometries has been acquired (Kozerke, 2000). Within several reconstruction steps time-dependent, three-dimensional computer models of the arterial lumen have been generated for the entire pulse cycle. Cine magnetic phase contrast measurements were performed just downstream the aortic valve providing inflow velocity profiles for the computational study. The mathematical description of the pulsatile blood flow in the ascending aorta uses the incompressible Navier-Stokes equations for Newtonian fluids. With respect to the movement of the flow domain the Arbitrary Lagrangean-Eulerian technique is applied. The numerical solution procedure employs our recently developed finite element solver (Karner et al., 1999) that applies a streamline upwind stabilization scheme with respect to the highly convective flow.

RESULTS AND DISCUSSION

Especially during the systolic phase the inflow conditions differ significantly for the two configurations. During acceleration, however, the velocities develop very quickly to blunted profiles that are skewed to the inner wall of the aortic arch. In deceleration the specific shape of the inflow patterns is preserved much longer and extends to the entrance of the

aortic arch. Zones of reversed flow develop at the inner wall leading to C-shaped profiles in both cases.

Figure 1: Axial wall shear stress distribution during systolic deceleration in the artificial aortic valve configuration.

Wall shear stress distributions during deceleration (Figure 1) demonstrate these recirculation zones and show the regurgitation at the aortic root. Due to the shorter and steeper systolic phase of the artificial valve configuration wall shear stresses are considerably higher than in the healthy vessel.

SUMMARY

A newly developed MRI velocity mapping technique enables the in-vivo measurement of blood flow patterns following the aortic root. In combination with the CFD analysis accurate prediction of blood flow in the ascending aorta can be done. This study compares blood flow distal to an artificial heart valve with undisturbed healthy flow. Further studies shall – as long term objective – contribute to optimal valve design in humans.

EFFECTS OF VESSEL MOTION ON RIGHT CORONARY ARTERY HEMODYNAMICS

D. Zeng¹, Z. Ding², M. H. Friedman³ and C. R. Ethier¹

¹Department of Mechanical and Industrial Engineering, University of Toronto, Canada; ethier@mie.utoronto.ca

INTRODUCTION

Blood flow in coronary arteries depends on 3D vessel geometry, flow pulsatility, and vessel motion due to cardiac contraction. Here our objective was to evaluate the effects of vessel motion on right coronary artery (RCA) hemodynamics.

METHODS

Biplane cineangiography was used to determine the *in vivo* motion of an RCA segment beginning ~ 1.5 cm distal to the ostium and terminating near the interventricular bifurcation (Ding and Friedman, 2000). The extracted data contained the 3D positions of 126 markers on the vessel axis at selected times during a cardiac cycle. We assumed that: (i) the cross-sectional contours of the RCA were circles of uniform radius 1.24 mm; and (ii) the contours maintained an orientation normal to the local, time-varying axis tangent direction at all times. This allowed the contours to be displaced and rotated to follow the dynamic RCA axis, from which we reconstructed the dynamic RCA lumen geometry. Inlet and outlet extensions consisting of a straight, stationary section and a flexible connector section were added to the RCA segment (Figure 1). The 3D, unsteady, incompressible Navier-Stokes equations were numerically solved on this moving geometry using a carefully validated finite element code based on an arbitrary Lagrangian-Eulerian formulation and a torsional spring mesh updating scheme. Newtonian blood rheology was assumed. To isolate the effects of RCA motion, we imposed a steady (Poiseuille) inflow with inlet $Re_D = 233$. The Womersley parameter based on the heart rate (75 beats/min) was 1.82. For comparison, we also simulated steady flow in a static “average” RCA model, obtained by averaging the RCA axis marker positions over one cardiac cycle.

RESULTS AND DISCUSSION

The wall shear stress (WSS) varied significantly with both axial position and time (e.g. Figure 2). The distribution of time-averaged WSS in the moving RCA model was quite similar to the WSS distribution in the static “average” geometry, suggesting that temporal variation in WSS was due to changes in local geometry (curvature, torsion), rather than inertial effects due to vessel motion. The magnitude of the temporal variation of WSS at material points on the RCA was strongly dependent on axial location. The maximum (peak-to-peak) variations in WSS magnitude were $\sim 150\%$ and 200% of the Poiseuille inlet value along the inner and outer walls of curvature, respectively. In contrast, some axial locations showed almost no WSS variation over the cardiac cycle.

Figure 1: The RCA at time $t=0$. Left panel: Anterior-posterior view showing the primary curvature of the RCA and definitions of inner and outer walls. Right panel: A medio-lateral view approximately coincident with the plane of primary curvature, showing secondary curvature. Disks are the boundaries between the RCA and inlet/outlet extensions.

Figure 2. WSS vs. time at the location in the distal RCA shown by the arrow in Fig 1. The WSS at the same axial location on the static average mesh is shown by the dashed line. WSS values are normalized by the inlet Poiseuille WSS (41.9 dyne/cm^2), and time is normalized by the cardiac period.

SUMMARY

WSS patterns in a simplified right coronary artery model are strongly influenced by vessel motion. The large magnitude of the motion-induced temporal variations in WSS, and their strong dependence on axial location in the vessel, suggest that the role of vessel motion as a localizing factor in atherogenesis needs to be considered.

COMPUTED BLOOD FLOW DYNAMICS IN AN ANATOMICALLY REALISTIC CEREBRAL ANEURYSM

David A. Steinman^{1,2,*}, Jaques S. Milner¹, Chris J. Norley¹, Stephen P. Lownie^{1,2,3}, David W. Holdsworth^{1,2}

INTRODUCTION

Local hemodynamic factors such as wall shear stress, dynamic pressure, and residence time are thought to play key roles in the initiation and growth of aneurysms, and also the success or failure of interventional aneurysm therapies. To date most studies of aneurysm hemodynamics have been carried out in mathematically idealized geometries or models reconstructed from post-mortem casts. The former, while convenient, remain crude approximations to real aneurysm geometries, while creation of the latter is, as noted by Imbesi & Kerber (2001), “a tedious and technically difficult undertaking.” With recent advances in computational modeling and in vivo medical imaging technologies, it is now possible to reliably simulate blood flow dynamics in a prospective, patient-specific manner. In this paper we present a computational fluid dynamic (CFD) simulation of physiologically pulsatile flow in an anatomically realistic aneurysm reconstructed from in vivo 3-D imaging of a human subject.

METHODS

Computed rotational angiography (CRA; Fahrig et al. (1997)) was used to acquire high-resolution (0.4mm isotropic) 3-D images of a 58-year-old female patient with a giant internal carotid artery (ICA) aneurysm (Figure 1a). The lumen geometry was extracted from the CRA data using the semi-automated 3-D discrete dynamic contour (DDC) of Ladak et al. (2000) (Figure 1b). Outlet branches were truncated proximal to further branches, and the resulting triangulated surface was used to generate a sufficiently resolved volume mesh composed of 213,000 quadratic tetrahedral finite elements (Figure 1c). As the patient's blood flow rates were not available, we applied fully developed velocity boundary conditions at the inlet based on an ICA flow rate waveform measured via phase contrast MRI of a 73-year-old female volunteer. Traction-free boundary conditions were applied at

both outlets. CFD simulations were carried out on a Pentium workstation using an in-house solver.

RESULTS AND DISCUSSION

To visualize this complex flow field, we mimicked the slipstream visualizations of Imbesi & Kerber (2001) by tracking passive, non-diffusing tracers, seeded randomly within a small radius, at two locations near the model inlet, separated by 90°. As illustrated in Figure 2a, the resulting velocity field is largely free of secondary flow proximal to the aneurysm ostium, at which location the blue slipstream undergoes marked dispersion within the aneurysm sac while the red slipstream maintains its integrity as it divides between the two outlets, avoiding the aneurysm sac altogether. Cycle-averaged wall shear stresses (Figure 2b) were maximal at and distal to the narrowing of the ICA (caused by aneurysm-induced compression of the vessel against adjacent bone), and at the distal ostium, at which location flow from the parent vessel can be seen to be impacting the aneurysm wall.

Figure 2: Physiologically pulsatile flow in an anatomically realistic aneurysm (right-anterior-oblique view): (a) Virtual slipstreams; (b) Cycle-averaged wall shear stress magnitude (in dyne/cm²).

SUMMARY

Using computational fluid dynamics and high-resolution medical imaging, it is now possible to study, in a prospective, patient-specific manner, the complex fluid dynamics associated with cerebral aneurysms. Such techniques may be used to study the forces that predispose certain aneurysms to rupture, and also to predict the success or failure of interventional therapies that rely on altering the dynamics of flow within the aneurysm sac.

THE INFLUENCE OF RESTING PERIODS ON FRICTION IN THE ARTIFICIAL HIP JOINT

Michael M. Morlock¹, Roman Nassutt², Markus Wimmer³, and Erich Schneider⁴

¹Biomechanics Section, Technical University Hamburg-Harburg, Hamburg, Germany, morlock@tuhh.de

²eska implants, Lübeck, Germany

³Department of Orthopedics, Rush Medical Center, Chicago, Illinois

⁴AO Research Institute, Davos, Switzerland

INTRODUCTION

Insufficient tribological performance of total joint components has been identified as one major cause of prostheses failure. Wear has been studied intensively using testing machines that apply continuous motions. Human locomotion, however, is not well represented by continuous motions alone. Singular events as well as resting periods are a substantial part of daily activities. Resting does influence adhesion in the artificial joint with possible effects on friction, wear, and loosening. The purpose of this study was to evaluate the effects of resting on the frictional properties of hip prosthesis components.

METHODS

Friction measurements were performed using a pin-on-ball testing device placed into an acrylic container with stabilized bovine serum (diluted to 30%, 37°C) mounted onto a biaxial hydraulic material testing machine (sinusoidal motion of 1 Hz frequency, $\pm 20^\circ$ ball rotation, contact load 1000N, Fig. 1). The testing concept consists of a pair of concave pins pressed onto a conforming ball (Wimmer et al, 1998). The pins represent the same geometric and morphologic features as original hip cups, the ball a commercially available femoral head. Static friction was defined as the maximum friction peak during motion initiation after resting periods of certain durations (0, 1, 5, 10, 30 and 60s).

Figure 1: Pin-on-ball testing device.

Ceramic (BioloX®) and metal (Mathys Medical Ltd.) prosthesis heads were tested against pins made from UHMWPE (PolyHiSolidur). Metal pins were worked out of cups, ceramic pins sintered from BIOLOX Forte® and finished (polished). Five repetitions for 3 samples of each material combination were performed and analysed.

RESULTS

The level of friction was significantly higher for metallic heads compared with ceramic heads when paired with poly-

ethylene and also when paired with the respective hard partners at all tested load levels and for all tested resting durations (Fig. 2). For up to 10 seconds of rest, an increase in friction was observed, which then leveled out for all material combinations but not for metal-on-metal bearings, for which friction increased further with increasing resting durations (Fig. 2).

Figure 2: Friction coefficient for all resting durations and material combinations.

DISCUSSION

Static friction increased significantly with increasing resting duration. This basic relationship was pronounced for metal-on-metal bearings. The influence of resting periods on wear has not been shown yet. However, considering metal-on-metal prostheses with 48mm nominal head diameter in a patient with a body weight of 80kg and the static friction coefficient determined in this study, the calculated moment peaks reach 14.2Nm after 30 seconds of rest. This value is close to the interface strength of certain in-vitro determined press-fit cup fixations and highlights the fatigue problem which may arise during starting procedures if an unfavorable combination of parameters (high friction + large head diameter + overweight patient) coincides. The individual anatomic situation of the patient, the design of the implant, and the situation after surgery strongly affect the safety against frictional torque-induced loosening. Nevertheless, metal-on-metal articulations should be used with care in combination with big head sizes because of the friction characteristics.

DEVELOPMENT OF ORTHOPEDIC IMPLANTS - A FIELD OF TENSION BETWEEN RISK ASSESSMENT, PRE CLINICAL AND CLINICAL TESTING

Ulrich Fink

R&D, Aesculap AG & Co. KG, Tuttlingen, Germany, ulrich.fink@aesculap.de

PRESENT SITUATION

In recent years some serious systemic failures with orthopedic implants have been observed on the market. We saw for instance toxicological surface contamination on porous coated sockets (www.sulzermedica.com), we saw wear problems with highly crystalline phase modified polyethylene (Scott et al, 2000), we saw corrosion induced loosening of cemented titanium stems in hip arthroplasty (Willert et al, 1996) and we saw mechanical brake down of a PMMA bone cement due to problems with the glass transition temperature (Abdel-Kader et al, 2001).

All the above mentioned products failed despite intensive laboratory testing and the approval of regulatory or notified bodies either in the US or in Europe. That resulted on the one hand in harm to the patient, but also on the other hand affected the medical device company due to recourse claims from the patients, and in the midterm the loss of confidence from the surgeons.

In order to receive the selling permission from the certification or notified bodies, the medical device company has to document the safety and efficiency of the product as well as the reproducibility in production. For both cases it is a key feature to make a risk assessment to get an idea about the worst case scenario. Additionally several organizations for the standardization of test procedures and design features do exist. "Specialists" are consulted by these organizations in order to define the testing criteria. Nevertheless the aforementioned systemic failures still occurred. In contrast there are several restrictions for products from the government or notified bodies which the producers don't really understand, such as the restrictions on pedicle screws and on cementless joint replacements. The failures of medical devices in the past together with the key feature "risk assessment" required for the registration result in the situation, that in the best case a true evaluation can only be made for variations of existing products.

A Research and Development department has to keep in mind that the step from pre clinical lab testing into the clinical evaluation must be seriously combined with an intensive risk assessment, in which neutral experts to provide clinical outcome have to be involved. As mentioned above, the failures which showed up in the past were hardly predictable at the time the products were introduced into the clinic. During the step into the clinic evaluation the R&D departments are often too focused on the well known regulations of the registration procedure, not by the real clinical risks, which are much more difficult to identify.

This leaves the question "How to proceed ?", if the risks are not really predictable as with a completely new implant design. In this situation the only solution can be to go ahead with a well defined clinical evaluation investigating the safety and functionality of the product by statistical, relevant numbers. The obtained results must be supported by hard, objective facts as much as possible. For instance the x-ray picture in itself has nearly no value.

In the case of hip joint replacements very good survival rates of above 90% after 10 years can be called the "normal" standard today. However, in an early stage after implantation, unfortunately no signs of deterioration for the individual patient, whose prosthesis might fail earlier, are observed. This means for the statistical relevance of a clinical evaluation for a new product that either a high number of patients or more sensitive test methods are needed to predict the individual survival time. Unfortunately the clinical studies described in the literature are not reproducible in other hospitals or other situations. This is why for every new implant a new study, a new sample of patients has first to be treated to set the new standard. This requires a high input of man power, money and the feeling for the right business decisions. What can scientists do to improve this pending situation?

CONCLUSION

Every innovation with clinical relevance has to be compared with the actual outcome in the hospital. Pre-clinical laboratory testing is an absolute prerequisite for this comparison. However, the comparison can not only be made based on such laboratory tests since history showed, that many uncertainties in the risk assessment do exist. Computer models presently can also be only a hint towards the approval of a product and must in any case be validated by mechanical and/or in-vitro testing. In order to limit the effort and expenses for the regulatory work, and, more important, to provide the highest possible security for the patient, a well defined clinical procedure for the assessment of reproducible clinical outcome for standard indications has to be defined. To judge these comparative results it is necessary to develop improved measurements for the clinical outcome.

HIP CONTACT FORCES – SOME IMPORTANT OBSERVATIONS

G. Bergmann, F. Graichen, A. Rohlmann

Biomechanics Lab., Benjamin Franklin School of Medicine, Free University of Berlin, www.biomechanik.de

PEAK FORCES

With telemeterized hip implants contact forces were measured in 7 patients over periods up to 9 years (Bergmann et al. 1993, 2001B). Average forces during normal walking of 4 patients showed peak values of 233%BW (percent body weight) (Fig.1). In other patients they were higher. Slightly disturbed muscle functions and gait patterns increase the contact forces because muscles with less optimal lever arms have then to maintain the dynamic balance of moments. During slow jogging the highest peak contact force observed was 584%BW. Antagonistic muscle activities during incidental stumbling caused forces up to 870%BW.

Figure 1 Contact forces, 6 activities, average of 4 patient

FORCE DIRECTIONS

The range of forces directions in the frontal plane of the femur is very narrow for all activities if the force is larger than about 50%BW. Typical are angles between 20° and 30° relative to the long femur axis (Fig.2). In

the transverse plane the force directions approaches the anteversion angle with increasing magnitudes. The torsional moment in the transverse plane is an important factor for implant loosening. It is close to the torsion stability of the prosthesis. Implants should therefore have torque resistant cross sections.

Figure 2 Forces in frontal plane

TEMPERATURE INCREASE

Temperature measurements in the prostheses (ceramic head, polyethylene cup) indicate that the friction induced rise of implant temperatures may be one of the factors contributing to implant loosening (Bergmann et al. 2001A). After 1h of walking the temperatures in the middle of the head rose up to 43,2°C (Fig.3). No strong correlation could be found between peak temperature and body weight. Lower forces during

cycling at the same metabolic power clearly decreased the peak temperatures, however. Factors like the volume or lubricating properties of synovial fluid probably play an important role for friction induced implant heating.

Figure 3 Implant temperatures after 1 h of walking

INFLUENCE OF FLOOR MATERIALS AND SHOES

During walking and jogging the contact force in the hip joint reaches its maximum shortly before the straight leg passes through the vertical position. The short force peaks, observed at the foot at the moment of heel contact, are totally damped before reaching the hip joint (Bergmann et al. 1995). This is true for soft and hard shoe and floor materials. In general the heel contact occurs too early in the gait cycle as to have any effect on the force magnitudes in the joint. In contrast, due to the higher muscular effort required to balance the movement, soft shoe or floor materials even slightly increase the maximum contact forces.

JOINT SEPARATION DURING WALKING ?

It was reported that head and cup of the implants separate during walking and abduction detrimental effects on wear and implant stability were hypothesized. Based on analyses of contact force directions (Fig.4) and on fluoroscopic images we can exclude that such an effect occurred in the patients we investigated (Bergmann et al. 2001C).

INTRODUCTION

Robotics is a well-established method of process optimizing and quality increasing in industrial applications. The idea of using this approach in the field of orthopedic surgery originated in the USA in the early 1990s but has not yet been FDA approved. In Germany, with less strict legislation as in the USA, robots have already been used for more than 3,000 Total Hip Replacements (THR). However, no study is available demonstrating the clinical advantages of the robotic approach in comparison to the manual implantation. The purpose of this study was to compare prospectively robotic assisted to conventional manually implanted THR.

METHODS

154 patients scheduled for THR were randomly assigned to either the manual or the robot assisted implantation of a S-ROM® prosthesis. The surgeries were carried out using the same antero-lateral approach in a side position of the patient. The manual implantation was carried out according to the manufacturers specification whereas for the robot group the ROBODOC® was used (Figure 1).

Figure 1:
The control computer together with the ROBODOC® robot with 5 degrees of freedom. The pneumatic turbine with the reamers bearing sleeve is attached to the robot arm.

Pre-operatively as well as 3, 6, 12 and 24 months after surgery the scores according to Harris, Merle d'Aubigne and Mayo were determined. X-rays taken at these intervals were analyzed for prosthesis alignment, leg length discrepancy, loosening, and ossification. Maximum follow-up presently is 24 months.

RESULTS

Surgery had to be converted in 13/74=18% of the robotic procedure to manual due to failure of the system. Surgery

duration was higher in the robotic group (robotic / manual: 107.1±29.1 / 82.4±23.4min; $p<0.001$). Leg length equality (0.18 ± 0.30 / 0.96 ± 0.93 cm; $p<0.001$) and stem varus-valgus orientation (0.34 ± 0.67 / $0.84\pm1.23^\circ$; $p<0.001$) were better in the robotic group. After 6 months the robotic group showed a better Mayo-score (63.6 ± 15.0 / 56.0 ± 16.8 ; $p=0.01$) and after 12 month a better Mayo- (73.1 ± 7.3 / 62.8 ± 14.3 ; $p<0.001$) and Harris-score (85.9 ± 12.0 vs. 73.2 ± 16.9 ; $p<0.001$), whereas after 24 month no differences between the 2 groups of patients were found any longer. Slightly more ossifications were seen in the robotic group ($p=0.31$). In the robotic group dislocation was more frequent ($11/61=18\%$ / $3/80=4\%$; $p<0.001$). Recurrent dislocation and pronounced massive limping was the indication for revision surgeries in the robotic group (non-infectious etiology: $9/61=15\%$ / $0/78=0\%$; $p<0.001$). During reoperation, rupture of the abductor muscle tendon (pseudo-paralysis similar to the rupture of rotator-cuff) was observed (Figure 2).

Figure 2:
MRI of the abductor muscle- fatty degeneration of the medial gluteus muscle (left arrow).

DISCUSSION AND CONCLUSIONS

The robotic assisted technology showed advantages in pre-operative planning and accuracy of intra-operative procedure. Disadvantages are the un-acceptable high revision rate, which was probably caused by the amount of muscle damage and the longer surgery duration. The presented study shows that with the robotic a good or slightly better result than with the manual approach can be achieved – assuming that one is prepared to overlook the very high revision rate and the excluded patients. Such this study clearly shows that the described robotic approach, in its present form, is an endangerment to the THR patient: a dislocation rate of 18% and a revision rate within two years of 15% are well below today's (and those of 25 years ago) standards for THR.

ACTIVITY PATTERN AND JOINT MOTION PROFILE OF TOTAL KNEE PATIENTS

INTRODUCTION

Huge efforts have been undertaken to test novel cross-linked UHMWPE as a bearing surface for total joint replacement. The latter has proven outstanding wear characteristics for abrasive or adhesive wear mechanisms, which prevail at the artificial hip. At the total knee, fatigue related mechanisms are dominant, which is indicated by the analysis of failed tibial components. Since the fracture mechanical properties of cross-linked polyethylene are reduced, caution appears appropriate. For realistic knee testing protocols, basic knowledge about joint motion as well as frequency and duration of daily activities in patients after total knee arthroplasty (TKA) is required. The purpose of the study was to investigate the activity profile of TKA patients during the day and analyze motion of the artificial knee.

METHODS

37 TKA patients gave informed consent to participate in the study. The measurements were performed in the habitual environment of the patients and started as soon as after wake-up in the morning and continued until about 7 or 8 pm in the evening. The measurement time of each patient was normalized to 12 hours.

A portable measurement system was used to monitor daily activities. Two absolute inclination sensors (providing one-dimensional inclination in a global coordinate system), attached to the shank and the thigh, and an electro-goniometer were mounted along the anatomical axes of the lower extremities of the operated leg. Data were recorded at 30Hz. The system has been previously validated¹.

Using a classifying software program, frequency and duration of walking, standing, lying, sitting, stair climbing and stair descending were analyzed from each patient. Data analysis was based on a calibration protocol performed prior the measurements. In addition, the signal of the electro-goniometric sensor was processed to analyze the dynamic changes of the knee angle. Every 10 degrees, level crossings of the signal were counted (only when the knee flexion angle increased) and classified. The angular motion pattern of the ISO knee simulator served as a control, based on the generally accepted assumption that 1 million gait cycles represent 1 year of use.

RESULTS AND DISCUSSION

Three patients experienced technical difficulties, which left 34 patients for motion analysis. Their artificial joint crossed most often the 20°-level ($8.3 \pm 4.5 \times 10^3$ counts), while it is the 10°-level for the knee simulator (5.5×10^3 counts). Motion at knee angles beyond 50° occurred frequently in patients (e.g. for 70°: $1.8 \pm 1.9 \times 10^3$ counts), however, are not employed with the knee simulator. The activity pattern has been analyzed for 24 patients. Most of the time was spent in sitting (46%), followed by standing (17%) and walking (17%). Activities like stair climbing or lying played only a minor role (Table 1). On average, 13% of the recorded activities remained unknown.

Table 1: Load bearing activities during the day

	TKA Patients	Knee Simulator
# Steps (affected side)	6609 \pm 3353	2740
# Stairs (affected side)	232 \pm 346	-
# Standstills (upright)	666 \pm 452	-
# Sitting (up & down)	556 \pm 440	-
# Lying* (up & down)	6 \pm 18	-

*includes high foot resting

The most striking mismatch between patients and simulator is the difference in activity: 6609 vs. 2740 gait cycles per day. Further, there is a shift of the maximum of level crossings from 10° to 20° because most of the TKA patients did not reach full extension during the stance phase of gait. The occurrence of level crossings at higher knee flexion angles demonstrates the importance of activities like sitting down or rising from a chair. However, not all counted level crossings could be explained by known load bearing activities.

SUMMARY

Wear and failure of TKA is a function of relative motion and load. We tried to analyze patient activities and to assess relative motion with a level crossing classification. It was found that the TKA prosthesis undergoes higher demands in vivo than in vitro. Therefore, the testing protocols of knee simulators should be re-considered.

INTRODUCTION

Insufficient understanding of tribological behavior in total joint arthroplasty is considered as one of the major reasons for premature prosthesis failure. Contrary to movement profiles of hip simulators, human locomotion is of erratic shape containing motion interruptions among other irregularities. These occurring resting periods cause stick phenomena in metal-on-metal hip joints as is shown by another paper in this session. The aim of the study was to analyze the acting wear mechanisms of all-metal joints and identify in particular the interlocking bodies on in vitro and in vivo specimens.

METHODS

Twelve 28 mm commercially available CoCrMo-balls were tested against self mating concave pins with a radial clearance of $57 \pm 2 \mu\text{m}$ in a physiological fluid at 37°C under reciprocating, bi-directional sliding wear (1 Hz). The compressive load was const. 750 N (1 body weight). For two million cycles tests were carried out continuously and with periodically occurring resting periods.

In addition, 55 retrieved metal-on-metal prostheses from 18 male and 29 female patients with a complete record and regular follow-up were obtained. The implants were 11.5 years (range 1.3 ... 22) in situ and none of them was removed because of excessive wear, e.g. metallosis.

Figure: Tribochemical reaction product on the ball surface

Samples were rinsed in tap water, soaked in acetone and then ultrasonically cleaned in deionized water. The appearance of the worn simulator samples was macro- and microscopically compared to the retrieved specimens. All components were inspected without further preparation using light- and scanning

electron microscopy. The latter was equipped with energy dispersive x-ray for local and area distribution analyses of metallic and nonmetallic elements. On the basis of the observed wear appearances, the acting wear mechanisms were defined and evaluated as to their contribution to the wear behavior.

RESULTS AND DISCUSSION

Besides scratches and pitting, testing pins, balls and retrieved specimens showed distinct layers, which adhered rigidly to the surfaces (Figure). These precipitates were present within and - larger in number - at the edges of contact. They consisted mainly of carbon, containing little amounts of Na, Cl, K, Ca, P, O. Their shapes varied in a wide range between hilly and compact to flat and lengthy. Some of them exhibited cracks, or were scratched.

Wear mechanism: Due to the high local contact stresses surface fatigue prevails initially. Thus, Cr- and Mo-carbides are fractured and torn off the surfaces bringing about additional surface fatigue (by indentation) and abrasion. The weight loss can be predominately attributed to these mechanically dominated wear mechanisms. In parallel, the high contacts stresses on local asperities cause flash temperatures of $70^\circ\text{C}+$ as calculated using the Kuhlmann-Wilsdorf model. Hence, tribochemical reactions are initiated, which generate layers from denatured proteins. Once human or simulator motion comes to a complete stop, these layers start to adhere rigidly to the activated surfaces. This causes an interlocking phenomenon during motion re-initiation, and a frictional break-away torque is observed. While this may be interpreted negatively, the generated layers cover parts of the contacting surfaces avoiding adhesion. The wear outcome is therefore influenced by the alternating balance between surface fatigue and abrasion on the one side and by tribochemical reactions on the other side.

SUMMARY

Wear and friction are system properties rather than intrinsic material properties and are therefore affected by multiply variables. In order to understand and control the wear behavior of artificial bearings a close correlation between the microstructures of the material used and the acting wear mechanisms has to be found.

TIBIOFEMORAL CONTACT KINEMATICS DEPENDENT WEAR OF A UHMWPE TOTAL KNEE INSERT

T.S. Johnson, M.P. Laurent, and J. Q. Yao

Zimmer Research Department, P.O. Box 708, Warsaw, IN 46581-0708, USA, todd.johnson@zimmer.com

INTRODUCTION

The mechanisms of in-vivo UHMWPE wear at the tibiofemoral interface of a total knee replacement are dependent on the contact kinematics and the loading between the articulating surfaces. Previous studies have shown that a small threshold value of cross shear motion is sufficient to significantly increase the UHMWPE wear rate (Johnson et al., 2002) and that elimination of either internal/external rotation or anterior/posterior input motion significantly reduces in vitro knee simulator wear rates (Johnson et al., 2001a). The purpose of this study is two-fold: 1) to compare the contact kinematics path of motion profiles and in-vitro wear rates for two different wear protocols, standard and aggressive, implemented on a common posterior cruciate retaining (CR) knee design and 2) to analytically determine the relative tibiofemoral interfacial slip velocity v_s ($v_s = 0$ for pure rolling or no relative motion) in combination with the applied load for both protocols utilizing a wear intensity factor (WIF), where v_s was calculated using a previously described method (Johnson et al., 2001a).

MATERIALS AND METHODS

The standard walking gait protocol inputs consist of femoral extension motion from 0 to -58 degrees, -2 to 6 degrees of external tibial rotation, 5.2 mm of maximum posterior femoral displacement, and a peak load during the stance phase of 3188 N (ISO/WD, 1999). The aggressive protocol, which is based on in-vivo patient data (Johnson et al., 2001b), has femoral extension motion from 3 to -65 degrees and a heel strike sliding velocity transient with a maximum of 10.2 mm posterior femoral displacement. The external tibial rotation and load curves were identical. The tibiofemoral components were wear tested on an AMTI knee simulator as reported previously (Johnson et al., 2001b).

The horizontal low point in the medial/lateral and anterior/posterior direction for both compartments were chosen on the inserts to investigate the size and shape of the paths of motion. The wear simulator kinematics were recreated utilizing 3D CAD models of the components with the insert moving relative to a fixed femoral component, to obtain the points path of motion geometry. To gauge the combined effects of load and sliding velocity, a wear intensity factor (WIF) was calculated as $WIF = |v_s| \cdot P$, where $|v_s|$ is the slip velocity magnitude (m/s) and P is the applied compressive load (N).

RESULTS

The paths of motion in the lateral compartment for the standard and aggressive protocols are shown in Figure 1. The corresponding total path lengths are 59 and 95 mm and the corresponding in vitro knee wear rates are 14.4 ± 2.8 and 27.9 ± 2.9 mg/ 10^6 cycles (\pm std. dev). The WIF curves (lateral compartment) for both protocols are displayed in Figure 2. Immediately after heel strike and during the terminal swing phase, the WIF is approximately three times larger for the aggressive protocol.

Figure 1: Paths of motion for the standard and aggressive protocols.

Fi

figure 2: WIF for both testing protocols.

CONCLUSIONS

The wear rate and path length for the aggressive protocol are 94% and 61% higher, respectively, than for the standard protocol. The difference in wear rates may at least be partially due to the difference in sliding distances alone. The large differences in the WIF may provide additional insight into the actual wear mechanism. The swing phase of gait in conjunction with a heel strike transient may have important implications, not previously reported, in producing clinically relevant wear.

THE EFFECTS OF EARLY ROLLBACK IN TOTAL KNEE REPLACEMENT ON STAIR STEPPING

Louis Draganich¹, Gary Piotrowski, Lawrence Pottenger, and John Martell

Section of Orthopaedic Surgery and Rehabilitation Medicine, Department of Surgery, University of Chicago

¹ldragani@surgery.bsd.uchicago.edu

INTRODUCTION

Femoral rollback has been shown to increase the quadriceps lever arm in cadavera.¹⁻³ One of the purposes of the posterior stabilizer (PS) in total knee replacement (TKR) is to enforce rollback to increase the quadriceps extension moment (i.e., knee external flexion moment). However, the cam and post components of PS TKRs engage at different flexion angles and, therefore, enforce rollback at different flexion angles. We tested the hypotheses that a TKR that enforces sufficient rollback at a lower angle of flexion than those important to stair stepping would result in normal peak external flexion moments and that a TKR that does not enforce rollback until a higher angle of flexion than those important to stair stepping would result in reduced peak external flexion moments during stair stepping.

METHODS

There were 21 healthy control subjects. All TKRs in this study were posterior stabilized. There were 8 patients with the IBII (Zimmer) TKR, 9 patients with the Maxim (Biomet) TKR and 8 patients with the TRAC PS (Biomet) TKR. The Maxim and IBII are fixed bearing TKRs. TRAC PS is a mobile bearing TKR designed to have area contact throughout the range of motion and to maximize the quadriceps lever arm early in flexion. The posts and cams of the posterior stabilizers engage at approximately 73° for IBII, 20° to 30° for Maxim, and 8° for TRAC PS. The mean (SD) ages of the subjects were 61 years (7) for the controls, 67 years (9) for the IBII patients, 70 years (5) for the Maxim patients and 62 years (7) for the TRAC PS patients. Patients were required to have Hospital For Special Surgery Knee Scores of 85 points or more, no pain during ambulation, and be able to step on and over a step without aid. The postoperative time to testing averaged 15 months for the IBII patients (Range, 12-30 mos), 24 months for the Maxim patients (Range, 12-32 mos) and 31 months for the TRAC PS patients (Range, 25-38 mos). The protocol was approved by the Institutional Review Board and informed consent was obtained. Subjects were asked to stand, feet together, at a distance of twenty cm from the end of the subject's great toes to a 20 cm high step, step onto the step using the limb with the implant under investigation, step over the step and onto the ground with the opposite limb, step onto the ground with the implanted limb, and then walk along the walkway, all in a continuous fashion. The kinematic parameters were measured using the Watsmart (Northern Digital, Inc., Waterloo, Ontario, Canada) optical electronic three-dimensional digitizing system. Force parameters were measured with a multicomponent force platform (Advanced Mechanical Technologies, Inc., Newton, Mass.). The step was positioned on the force platform. The motion and force data were acquired at a rate of 100 samples per second. The motion and force data along with anthropometric measurements and

linear and angular velocities of the segments of the lower extremities were used to compute the external three-dimensional moments at the knee joint. Statistical differences were determined with two-way repeated measures analysis of variance and Tukey's test. P levels ≤ 0.05 were regarded as statistically significant. The Greenhouse-Geiser adjustment to the degrees of freedom was used in assessing significance levels based on the overall F-test.

RESULTS

The patterns and magnitudes of knee flexion were very similar for all of the subjects. The flexion angle of the knee at foot strike on the step was between 58° and 63°. At midstance, the knee extended to approximately 30° of flexion, which was the minimum amount of flexion attained. The knee flexed to a maximum of between 91° and 97° when the foot lifted off the step. The patterns of the external flexion-extension moments on the step were similar for all subjects. There were two moment peaks. For each peak, the knees of the control subjects generated the highest peak external flexion moments, followed by those of the TRAC PS and Maxim patients. The knees of the IBII patients generated the lowest peak external flexion moments. The peak external flexion moments of the knees of the controls, TRAC PS patients and Maxim patients were not significantly different ($p > 0.05$). However, the moments generated about the knees of the IBII patients were significantly less than those of the controls for both peaks ($p \leq 0.019$). Furthermore, the knee flexion angles of the IBII patients were 46° for the first peak moment and 65° for the second peak moment, which were less than 73°, the angle necessary for the post and cam to engage and enforce rollback.

DISCUSSION

These results support the hypotheses. The peak knee external flexion moments generated during stair-stepping for the TRAC PS and Maxim PS patients were not significantly different from normal. Those for the IBII patients were significantly less than normal in agreement with the literature.⁴ Thus, for normal stair-stepping function, the cam and post of a posterior stabilized TKR should engage to produce sufficient rollback at a knee flexion angle lower than those occurring when the peak knee external flexion moments are generated.

KINEMATIC OBSERVATIONS ACROSS THE SPECTRUM OF TOTAL KNEE REPLACEMENTS

Scott A. Banks and W. Andrew Hodge

The Biomotion Foundation, 1411 N. Flagler Drive, Suite 9800, West Palm Beach, FL 33401, banks@alum.mit.edu

INTRODUCTION

Surgeons use total knee replacements (TKR) to relieve pain and, hopefully, provide a very long lasting reconstruction with excellent mechanical function. Knee kinematics may or may not have a large effect on pain relief, but can certainly have an effect on knee function and device longevity. The goal of this summary is to present *in vivo* observations of motion with a wide variety of TKR designs, to identify trends in motion according to design class, and to demonstrate a relationship between articular motions and patient function.

METHODS

This study was conducted at 14 venues and included patients from 21 surgeons using 25 different articular designs. 213 well functioning TKR's were studied using fluoroscopy as subjects performed a dynamic stair ascent. There were 129 cruciate retaining fixed bearing knees (13 CR designs), 44 mobile bearing knees (8 MB designs), and 40 posterior stabilized knees (4 PS designs). CAD model based shape matching was used to determine 3D knee kinematics and the locations of medial and lateral tibiofemoral contact in 22,907 fluoroscopic images. The average center of axial rotation, or pivot location with respect to the tibial plateau, was computed over the entire motion. The medial/lateral location of the center of axial rotation was normalized to the width of each tibial component, and expressed as a percentage of tibial width, -50% (lateral) to +50% (medial). A subset of 121 knees of 15 articular designs was studied as patients performed a maximum weight-bearing flexion activity with their foot placed on a 25-42cm riser.

RESULTS

Posterior stabilized knees exhibited medial pivots (+14%) while cruciate retaining (-9%) and mobile bearing knees (-19%) exhibited lateral pivots on average (Table 1). Cruciate retaining fixed bearing knees exhibited slightly more axial rotation than did posterior stabilized knees. A relatively posterior position of the femur on the tibia was significantly correlated with greater maximum weight-bearing knee flexion (Figure 1, $p < 0.001$, linear regression). PS knees exhibited significantly greater posterior femoral position and maximum flexion than CR knees, which exhibited more posterior femoral position and greater maximum flexion than MB knees (Figure 1).

DISCUSSION

Since essentially all knees showed tibial internal rotation with flexion, the 'pivot' description for motion is simply a convenient parameterization describing anterior/posterior motion of the femur with respect to the tibia. Knees where the femur is forced posterior with flexion show medial pivots on average, whereas those that allow anterior translation of the femur in flexion show generally lateral pivots. The significance of this finding is in demonstrating a consistent relationship between the intrinsic anteroposterior control of the TKR and the

kinematics observed during a dynamic weight-bearing activity. TKR designs that intrinsically control femoral anteroposterior position in flexion achieve greater average weight-bearing range of motion.

Table 1. Computed medial/lateral locations of the pivot point, or average center of axial rotation.

Implant Type	# Knees	# Images	Average Range of Axial Rotation (deg)	Med/Lat Center of Rotation (%)
PS	40	4133	7.9 ± 1.5	$+14\% \pm 9\%$
CR	131	14646	9.3 ± 2.1	$-9\% \pm 16\%$
MB	44	4128	8.6 ± 1.0	$-19\% \pm 15\%$
KW-ANOVA on Ranks, Dunn's ($p < 0.05$)			CR > PS	PS > CR > MB

pKNEE ROTATION IN DEEP FLEXION AND TOTAL KNEE REPLACEMENT DESIGN

Thomas P. Andriacchi and Chris O. Dyrby

Biomechanical Engineering, Stanford University, Stanford, CA 94305-4038, USA, tandriac@stanford.edu

INTRODUCTION

Current designs of total knee replacement can accommodate approximately 130 degrees of flexion (Kim *et al*, 1995). However, deeper flexion is essential for activities of daily living for Indian, Middle Eastern and Japanese cultures. Even in western cultures there is a wide range of activities (recreational and occupational) that require deep flexion. The mechanics of the knee in deep flexion is not well understood. For example, it has been reported (Hefzy *et al*, 1998) that the knee must permit rotation in deep flexion. However, the relationship between flexion and rotation has not been quantified in flexion. The purpose of this study was to examine the relationship between rotation and knee flexion knee in deep flexion.

METHODS

Twenty (10 male, 10 female) native Japanese subjects (35 ± 13 years, $1.6\text{m} \pm 0.1$, $588 \pm 166\text{N}$) were tested while moving from standing into a deep squat resting position (both legs). All subjects were selected on the basis of a history of no previous musculoskeletal injury or disease that would influence performing a deep squat.

Knee kinematics were measured using a previously described technique (Andriacchi *et al*, 1998) based on a cluster of reflective markers distributed on the segments of the lower limbs. Markers were tracked with video based optoelectronic digitizer. Six degree-of-freedom motion of the knee was analyzed. Measurements were obtained bilaterally and a single left or right observation was randomly selected from each subject for observation. The rate of change of internal-external rotation was analyzed as a function of knee flexion. Rates of change were compared using paired T-tests testing for a significance level of $\alpha < 0.05$.

RESULTS

The squat activity began in a standing position and ended with the subject having both knees flexed to approximately 150 degrees in a resting squat. As the knee initially flexed in the range between 0 and 120 degrees, the femur externally rotated at a uniform rate. There was a significant relationship between knee flexion and internal/external rotation. As the knee flexed between 0 and 128 degrees, the femur externally rotated on the tibia (Figure 1). At an average of 129 ± 10 degrees of knee flexion, the rate of change of rotation significantly increased. The total external rotation prior to this break point was an average of 16 ± 6 degrees for the first 124

± 12 degrees of knee flexion or rate of $0.12 \pm .05$ degrees of rotation per degree of flexion angle. Past the break point, the knee flexed an additional 21 ± 10 degrees to 150 ± 11 degrees of flexion. The rate of external rotation of the femur on the tibia increased to 0.5 ± 0.2 degrees of external rotation for each degree of flexion.

Figure 1. An illustration of femoral rotation as a function of knee flexion while going from a standing position to a squat into deep flexion. Note the rate of external rotation with flexion increases substantially after 120 degrees of flexion (Point A).

DISCUSSION

Currently, most designs of total knee arthroplasty can achieve 120 degrees of flexion. However, patients requiring deeper flexion will need the capacity for substantial rotation beyond 120 degrees of flexion.

This information is important for understanding the mechanics of the normal knee, functional activities that required deep knee flexion and providing the basis for understanding the mechanics of knee replacement for individuals requiring increased ranges of motion.

CHANGES IN RANGE OF MOTION IN THE CERVICAL SPINE FOLLOWING SPINAL MANIPULATION - A REVIEW.

Niels Nilsson and Rene Fejer

Institute of Sports Science and Clinical Biomechanics, University of Southern Denmark, Odense, Denmark

n.nilsson@imbmed.sdu.dk

INTRODUCTION

With increasing evidence that spinal manipulation may have an effect on some disorders and not others, it becomes important to try to elucidate the biomechanical/physiological basis for such experimental observations. It is generally assumed among practitioners that spinal manipulation somehow affects the biomechanical behavior of the spine. Most common is the assumption that spinal manipulation results in an increase in either passive or active range of motion.

At present three trials exist comparing changes in range of motion in a spinal manipulation treatment group with changes in range of motion in a control group, not receiving any form of spinal manipulation.

All three trials use a strap-on head goniometer, blinded observers for measurements and randomization of subjects. A pattern seems to be emerging.

PASSIVE RANGE OF MOTION IN SUBJECTS WITH DECREASED ROM

This trial randomized 39 patients with objectively subnormal cervical range of motion into two groups, one of which received manipulation to the cervical spine twice a week for three weeks, while the other received low-level laser to the cervical area plus massage in the shoulder girdle region twice a week for three weeks. Cervical passive range of motion was measured at the start of the intervention period and again at the end of the three week period. There were no differences pre-post between the treatment group and the control group [Nilsson, 1996]

ACTIVE RANGE OF MOTION IN NORMAL SUBJECTS

20 symptom-free subjects with cervical range of motion in the low end of the normal range were randomized into two groups. One group received cervical manipulation twice a week for three weeks, and the control group a placebo treatment (detuned activator) twice a week for three weeks. Active cervical range of motion was measured pre and post the intervention phase and no differences were found between the two groups. [Petersen, 2002]

ACTIVE RANGE OF MOTION IN SUBJECTS WITH DECREASED ROM

105 patients with objectively decreased cervical range of motion were randomized into 2 groups. After a baseline observation period, Group 2 received manipulation to the cervical spine, while Group 1 received sham manipulation. In the next trial phase, Group 1 received manipulation, while Group 2 received no treatment. This was followed by the final trial phase, in which Group 2 received sham manipulation and Group 1 received no treatment. After each trial phase, active range of cervical motion was measured with a strap-on head goniometer by 2 blinded examiners.

Following the manipulation phases there were consistent and statistically significant increases in active cervical range of motion [Whittingham, 2001]

CONCLUSION

A pattern of results seems to be emerging; namely that spinal manipulation increases active range of spinal motion in those subjects who have decreased motion to start with, whereas, manipulation does not alter active motion in subjects with normal range of motion. In contrast passive range of motion is not affected.

However, more evidence is needed for any firm conclusions to be drawn.

NECK LOADS DURING SPINAL MANIPULATION

John J. Triano, DC, PhD

Texas Back Institute & UT Southwestern and Arlington Joint Biomedical Engineering Program

INTRODUCTION

Manipulation (SMT) of the cervical spine has been controversial but is increasingly used for patients with neck, arm and headache complaints. This project sought to understand their mechanisms and to quantify the relative biomechanical risks.

METHODS

Healthy volunteers signed informed consent approved by the committee for the protection of human subjects. Testing was block-randomized on two variables. The first distributed procedures to be applied from the left (n=35) or right (n=31). in the absence of quantitative data, the second divided the manipulations into groups based upon the intensity of effort defined as "hard" and "soft". A "hard" procedure was the greatest intensity considered safe for the subject's stature and age. Similarly, "soft" was the minimum to achieve treatment objectives. The four conditions; hard left & right (HL/HR), soft left & right (SL/SR); spanned the spectrum of intensity used in clinical practice. Prior to SMT, neck muscle myoelectric activity was calibrated for standardized isometric tasks. Intensities were systematically varied from 10% to 100% maximum voluntary contraction.

Subjects were positioned on a sensing table with imbedded AMTI force plate. Infrared diodes mounted on the head and thorax were monitored by a WATSMART system. Myoelectric activity was recorded as SMT was administered

randomly according to group. An inverse dynamics model first evaluated the passive loads through the neck at C2/C3. An RMS-myoelectric optimization model then predicted muscle tensions and were summed to predict total loads. Values were compared to volunteer studies of whiplash simulation.

RESULTS

Load-time histories showed no differences for right vs. left procedures. Differences were observed for procedure intensity ($0.000007 < p < 0.0294$) by ANOVA. Muscle contributions were negligible. No adverse reactions were reported. Table 1 compares the maximum loads in this study with loads tolerated in volunteer subjects without injury.

CONCLUSION

Maximum loads acting on the spine during SMT procedures were within the range of those tolerated during whiplash-type stresses to the neck. Relative load amplitudes can be controlled on demand. This data is the first quantitative data on transmitted neck loads and form a basis to begin understanding the mechanisms of action.

PARASPINAL MUSCLE SPINDLES RESPONSES TO BIOMECHANICAL CHANGES IN THE SPINE

OBJECTIVE

Muscle spindle activity from paravertebral muscles likely affect vertebral movement and posture because sensory feedback from muscle proprioceptors is important for motor control. Because mechanical stability of the lumbar spine requires muscle activity, studies were performed to understand how muscle spindles in lumbar paraspinal muscles respond to vertebral loading. The first study determined the effect of a static vertebral position on the sensitivity of lumbar paraspinal muscle spindles to subsequent vertebral displacement. The second study determined if lumbar paraspinal muscle spindles respond to a mechanical load whose force-time profile is similar to that of a spinal manipulation.

METHODS

Experiments were performed on 10 anesthetized adult cats anesthetized with pentobarbital sodium (35mg/kg). The L₆ dorsal root was isolated for electrophysiological recordings while leaving intact the L₆-L₇ vertebrae and associated paraspinal tissues. Single unit activity from lumbar paraspinal muscle spindles was recorded from teased afferent filaments isolated in the L₆ dorsal root. Receptive fields were in the lumbar multifidus or longissimus muscles. Controlled loads were applied at the spinous process of the L₆ vertebra using an electronic feedback control system (Aurora Scientific, Inc.).

To study the effects of static vertebral position on spindle sensitivity, the experimental protocol consisted of 4 parts: 1) muscle deconditioning, 2) muscle conditioning, 3) return to neutral position and, 4) test. Paraspinal muscles were deconditioned by rapidly extending and flexing the lumbar spine (1mm each direction, 10mm/sec). Conditioning consisted of statically holding paraspinal muscles shortened ("hold-short") or lengthened ("hold-long") for 5 seconds. After each type of conditioning the L₆ vertebra was returned to the same position (neutral position) and the sensitivity of the muscle spindles was tested by slowly displacing the L₆ vertebra (2 mm, 0.14 mm/sec) in a direction which stretched the muscle spindle.

For the second study a load simulating the force-time profile of a spinal manipulation was applied to the L₆ vertebra. The load consisted of 3 phases: 1) control (duration: 3.0s); 2) preload consisting of ramp-up (duration: 3.0s) and plateau (duration: 3.0s; force: 25% body weight); and 3) impulse (duration: 200ms, peak force: 100% body weight). Loads were applied in compressive and distractive directions with respect to the L₆-L₇ facet joint and at 2 different angles (0° and 45°) with respect to the long axis of the vertebral column.

RESULTS AND DISCUSSION

Hold-short conditioning sensitized paraspinal muscle spindles to subsequent muscle stretch during the test protocol. Mean afferent discharge rate increased 25%, 23%, 11%, 6% and 6% after "hold-short" compared with "hold-long" conditioning (Table). Four of the 5 muscle spindle afferents had receptive fields in the longissimus muscle very near the L₆₋₇ facet joint and one afferent's receptive field was in the multifidus muscle near the L_{7-S1} facet joint.

Table. Average muscle spindle discharge rates during the test.

Afferent Number	After hold-long	After hold-short†
	Mean ±SE (in Hz)	Mean ±SE (in Hz)
1	14.1 ±0.4	14.9 ±0.4
2	24.0±0.8	26.7 ±0.9
3	50.7 ±1.6	62.6 ±1.6
4	40.2 ±2.1	50.2 ±1.8
5	42.6 ±0.7	45.0 ±0.8

† p<0.07 compared with "After hold-long".

During the spinal manipulative-like load, muscle spindle discharge rate increased more to the impulse than to the preload during 10 of the 16 manipulations. Changing the angle of the manipulation could dramatically alter the response of a muscle spindle. Distractive manipulations loaded the spindles more effectively than compressive manipulations. After 7 of these 10 manipulations, muscle spindles became silent for 1.3 ±0.6s (range: 0.1–4.3s). Six of the 16 manipulations unloaded the muscle spindles.

SUMMARY

The results from the first study indicate that vertebral position, statically maintained for a relatively brief duration, alters a paraspinal muscle spindle's sensitivity to an identical rate and amount of vertebral movement. These findings support the conclusion that spinal postures which produce sustained vertebral positions elicit proprioceptive errors. These errors could adversely affect neuromuscular mechanisms stabilizing the vertebral column.

The results of the second study demonstrate that the high velocity, short duration load delivered during a spinal manipulation can stimulate muscle spindles more than the preload. The results may indicate that spinal manipulation's distinct effect on the response of paraspinal muscle spindles may contribute, in part, to the effects of spinal manipulation.

NEUROMUSCULAR IMPLICATIONS OF LUMBAR VISCOELASTIC TISSUES

M. Solomonow

Occupational Medicine Research Center

Bioengineering Laboratory --- Dept. of Orthopaedic Surgery

Louisiana State University Health Sciences Center

New Orleans, Louisiana 70112 USA — msolom@lsuhsc.edu

INTRODUCTION

The major viscoelastic tissues of the spine consist of its ligaments, discs and facet capsules. Such tissues have some classical mechanical behaviors which are well known such as hysteresis in a stretch – release cycle, dependence on strain rate, and creep when subjected to loads over time. While such viscoelastic behavior has direct implications on the mechanical properties of the spine, it may also have profound neurophysiological implications. Since these viscoelastic tissues are endowed with diverse types of sensory receptors (1, 2) which are known to reflexively activate various muscles (3, 4), it is clear that they may also have neurophysiological functions. Reflexive activation of the muscle is known, from the control point of view, to be part of the feedback associated with the movement control system (5, 6). A property inherent to most electro-mechanical systems is relatively small zone about the resting point which is not optimally functional, e.g., a dead zone. Panjabi (5) identified such a mechanical zone in the spine and termed it “Neutral Zone”; a range of intervertebral excursions which does not impact on spinal stability. He also went on to show that muscular activity is capable of modifying the range of such Mechanical Neutral Zones (MNZ). Recent work further demonstrated that the feedback loop of the spine also has neuromuscular neutral zones, e.g., small perturbations in viscoelastic tissue status that does not elicit feedback (reflexive) activation of muscles (7, 8). It is of interest and importance to assess the impact of spinal viscoelastic tissues behavior (such as hysteresis and strain rate dependence) on the function of the spine’s feedback network, e.g., the Neuromuscular Neutral Zones (NNZ).

METHODS

Anaesthetized feline specimens were used as the experimental model. Tests included linear stretch of the posterior lumbar spine into flexion at rates ranging from 17 – 100% /s (with 100% being $\frac{3}{4}$ of the physiological strain range of the ligaments) as well as single cycles of flexion – extension at frequencies ranging from 0.1 – 1.0 Hz in order to assess the response of the NNZ to velocity and hysteresis, respectively. EMG of the lumbar multifidus muscles was recorded by intramuscular wire electrodes. The range of elongation and its corresponding tension from the resting point at which the EMG was first recorded was defined as the NNZ. In the single cycle tests, the length and corresponding tension at which the muscles ceased activity in the release phase were also calculated.

RESULTS AND DISCUSSION

For linear deformation of the spine into anterior flexion, the NNZ was the smallest for the fastest rate of flexion. And gradually increased for decreasing rates. In general the elongation or tension in the viscoelastic tissues increased to above 5 – 15% of the physiological range before the muscles were reflexively recruited, and that range depends on the velocity of the movement. Faster velocities are associated with smaller NNZ.

For cycles of anterior flexion / extension, the NNZ were significantly lower in the flexion phase as compared to the extension phase. As the cycle frequency increased the NNZ became even smaller during flexion and larger during extension. The peak EMG was also dependent on the frequency of the cycle, being higher at higher frequencies.

CONCLUSION

Faster rates of movement develop higher tension in the viscoelastic tissues and trigger reflexive muscular activity earlier in the movement thus lending greater dynamic stability to the spine. This emerges due to the fact that viscoelastic tissues deformation is time dependent with respect to the tension they develop. Faster movements also elicit higher forces from the muscles which further stabilize the spinal joints. The hysteresis associated with a stretch – release cycle of the tissues, however, exposes the spine to a relatively increased NNZ at the end of extension. This period leaves the spine without muscular support especially in a fast extension, and is prone to instability and injury.

THE SACROILIAC JOINT, INTERVERTEBRAL DISC AND MUSCLE REFLEXES

Aage Indahl¹, Allison Kaigle², Olav Reikerås³, and Sten Holm²

¹Kysthospitalet, Stavern, Norway, Department of Orthopaedics, ²Sahlgrenska University Hospital, Göteborg, Sweden, and ³National Center for Orthopaedics, Oslo, Norway

OBJECTIVE

The lumbar motion segment is a complex joint with a network of different muscles crossing it. The sacroiliac joint (SIJ) is a true synovial joint which is richly innervated. It bears tremendous loads, but has a very limited amount of motion. Numerous spinal and gluteal muscles attach to the SIJ capsule and iliac crest. Loss of mechanical stability has been in focus as a key factor in dysfunction. The function or dysfunction of spinal reflexes responsible for muscle activation are less studied. The aim was to determine if stimulation of nerve elements in intervertebral disc, the SIJ and SIJ capsule could elicit contractions in porcine gluteal or lumbar spinal muscles.

METHODS

A porcine model was used to study the interaction between the intervertebral disc, zygapophyseal joints, sacroiliac joint and the paraspinal muscles. In the first experiment twenty-three pigs were used to measure the electromyographic response in the paraspinal musculature to electrical stimulation of the annulus fibrosus of the L3/L4 intervertebral disc before and after the introduction of normal saline to the zygapophyseal joint. Motor unit action potentials were recorded using three sets of needle electrodes placed in the deepest fascicles of the multifidus, bilateral to the L4 and L5 spinous processes, and into the central longissimus musculature, bilateral to the L4 spinous process. In the second experiment ten pigs were used to study the muscular response to electrical stimulation of nerve endings in the ventral and dorsal capsule of the sacroiliac joint. Six bipolar EMG needle electrodes were used for measuring compound motor unit action potentials (MUAPs) and inserted in the deep medial multifidus fibers lateral to L3-L5, the central belly of the gluteus medius and maximus and in the quadratus lumborum muscle lateral to L5.

RESULTS AND DISCUSSION

Stimulation of nerves within the posterolateral annulus of the disc elicited reactions in the paraspinal muscles, namely the lumbar multifidus and longissimus. Introduction of physiological saline into the zygapophysial joint resulted in a reduction in the motor unit action potential amplitude. This reduction was manifested as an immediate and constant reduction, a graded reduction, or a delayed reaction, during which the reduction occurred an average of 5 minutes after the

saline injection. This effect was most likely an inhibitory stretch reflex from the capsule that stimulated inhibitory interneurons, thus inhibiting motoneurons. Inhibitory discharges from the joint capsule can explain why manipulative treatment and mobilization of the zygapophysial joint provide relief in some cases. Thus, it appears that there is a delicate interaction between the different parts of the spinal motion segments, and proprioceptive nerve endings may play a vital part in load distribution during movements.

Stimulation of nerves and mechanoreceptors in the sacroiliac joint, as well as in the joint capsule, elicited motor unit action potentials in different muscles, which revealed an interesting activation pattern. Stimulation of nerve elements in the ventral area of the sacroiliac joint produced significant contractions in muscles located more distally from the lumbar spine, namely the gluteus maximus and quadratus lumborum. However, stimulation of the SIJ capsule elicited significant responses in the medially located multifidus fascicles. These findings suggest that the SIJ is involved in activating muscles responsible for overall posture control, as well as control on the segmental level in the lumbar spine. It is possible that the different areas of the sacroiliac joint play different roles in regulating the locomotive system, and the response may therefore vary depending on the stimulation site. Disturbances in the sensory part of the joint innervation may lead to altered muscular activation and represent the true dysfunction.

SUMMARY

The functioning of the motor system is intimately related to that of the sensory system. The proper moment-to-moment functioning of the motor system depends on a continuous inflow of sensory information. The afferent input from sacroiliac joint receptors, as well as mechanoreceptors in the intervertebral disc and zygapophysial joints, may contribute to different degrees of muscle activation and may constitute an integral regulatory system.

ROLE OF LOCAL BIOMECHANICS IN TEMPORAL BEHAVIORAL RESPONSES OF PAINFUL RADICULOPATHY

Beth A. Winkelstein PhD¹, James N. Weinstein DO MS², and Joyce A. DeLeo PhD^{1,3}
Dartmouth–Hitchcock Medical Center, Lebanon, NH 03756, Beth.Winkelstein@Dartmouth.edu

²Department of Orthopaedic Surgery

³Department of Pharmacology & Toxicology

INTRODUCTION

Nerve root injury resulting from herniated nucleus pulposus contributes to radicular pain mechanisms. Injury magnitude has been shown to directly modulate nociceptive responses, including mechanical allodynia (MA), which is an increased behavioral sensitivity to a non-noxious stimulus (Winkelstein et al., 2001). Studies report edema and increased endoneurial pressure in injured nerve roots (Lundborg et al., 1983; Olmarker et al., 1989). Yet, the simultaneous examination of local changes in structural geometry following compressive injury and central changes linked with the onset and maintenance of persistent pain remains limited. Therefore, this study temporally characterizes local nerve root geometric changes following compressive injury in a rat lumbar radiculopathy (LR) model and examines these structural changes in the context of pain behaviors (MA) and activation of two populations of glial cells, microglia and astrocytes, in the CNS.

METHODS

Male Holtzman rats were divided into a sham group with only nerve root exposure or a ligation group with tight ligation of the left L5 nerve roots. Using image analysis, nerve root compressive strains were calculated at injury and postoperative time points (Winkelstein et al., 2001). Mechanical allodynia was continuously measured to assess behavioral sensitivity. In a subset of animals, the nerve roots were reimaged on postoperative days 1,3,5,7 to quantify local swelling. In another subset of animals, lumbar spinal cord tissue was harvested on days 1,3,7,14 for immunohistochemical analysis of changes in glial activation using OX-42 and GFAP (Colburn et al., 1999).

RESULTS AND DISCUSSION

Mean applied compressive injury strain in the nerve roots was $30.8 \pm 14.5\%$. All postoperative tissue geometry changes were positive, indicating a relative swelling response in the nerve root (Fig. 1). Swelling was greatest at early time points following injury and then decreased over time. While the initial degree of swelling was dependent on the initial injury magnitude, swelling at later time points did not depend on injury magnitude and showed no direct relationship to MA. Likewise, microglial activation in the spinal cord showed a direct relationship with the magnitude of initial tissue injury (Fig. 2). However, the degree of astrocytic activation did not show a relationship with initial injury.

Fig. 1. Time course showing mean postoperative nerve root swelling and the corresponding mean MA for these animals at each time point.

Fig. 2. Microglial activation (using OX-42) in the L5 spinal cord dorsal horns at day 7 for a normal (A), a lower injury magnitude (B) and a higher injury magnitude (C) animal, showing graded activation.

SUMMARY

While pain-associated behaviors depend on the initial magnitude of nerve root deformation in LR, they cannot be explained by the temporal nerve root swelling. Spinal microglial responses also show a relationship with injury severity, but they are not related to MA. The OX-42 antibody to CR3/CD11b is a sensitive marker of injury, yet not necessarily behavioral sensitivity. Given earlier work showing spinal cytokine mRNA levels and behaviors depend on initial injury magnitude (Winkelstein et al., 2001), it is suggested that subpopulations of activated glia and their immunologic responses upon activation may play important roles in pain maintenance.

INTRODUCTION

The mechanisms underpinning manual therapy are poorly understood. This is particularly true of posteroanterior mobilisation (PA) a manual physiotherapy technique that is commonly used as an examination tool and a form of conservative treatment for spinal complaints. The evolution of open MRI scanners has provided a new non-invasive method of investigating the mechanics of mobilisation therapy. Studies to date (McGregor et al 2001) have recorded static spinal kinematics during the application of a PA mobilisation, but have failed to quantify the force applied during the technique. This study sought to develop and validate a tool that was capable of measuring the force applied to the cervical spine during the administration of a course of PA manual therapy within an open MRI scanner.

METHODS

Design Criteria: The force measurement device had to be MR compatible, give the correct feel to the examiner to simulate the normal PA manipulation technique, easy to read from within the iMR suite by the examiner, calibrated for specific levels of force application, and the force values had to be recorded simultaneously with the MR images.

Device Design and Use: A water filled pressure device was designed through which the force to the cervical spine could be applied. This consisted of a rubber tube of diameter 25 mm, and length 125 mm that was connected to a clear plastic hose of internal diameter 5 mm with one end open to atmospheric pressure. The pressure applied to the rubber tube by the examiner was then equal to the pressure change measured by the height change of the column of water in the clear hose. The device was calibrated by the application of constant loads, using weights, to the rubber tube, and then marking the clear hose at the level of the column of water. The clear hose was mounted on the iMR magnet within sight of the examiner, and within sight of the video recording device within the iMR suite. This device recorded the position of the examiner, the MR images produced by the manipulation, and the height of the column of water in the pressure measuring device.

Imaging Protocol: Subjects were scanned using a General Electric Signa SP10 Interventional MRI scanner (iMR). This is an open MRI scanner consisting of 2 connected but opposing ring "doughnut" magnets. The gap between these magnets is 56 cm generating a uniform field of 0.5Tesla. Subjects were scanned in the prone position with their necks in a neutral position. An experienced manipulative physiotherapist delivered an oscillatory PA forces to be spine

whilst getting feedback on the force produced. The maximum PA force applied was 140-150N (Lee & Evans 1992), and the frequency of the technique was in accordance with the iMR image acquisition rate (0.2 image per second). Each subject received 30 seconds of PA mobilisation at the spinous process of the fifth cervical vertebra level of the spine. Measurements of intervertebral rotation and translation were obtained from the sagittal images, alongside measures of soft tissue compression.

RESULTS TO DATE

Clear images of vertebral position could be obtained in each position during the application of a PA mobilisation within the open MRI scanner from which measurements of intervertebral angulation and translation could be obtained. These images suggest little or no movement of the vertebrae but marked soft tissue compression. Statistical analysis confirmed this finding on the 5 subjects scanned to date. Preliminary investigations confirm that the loads applied to the spine within the scanner are appropriate and that load can be recorded in the scanner during the technique. The load measurement system was adjusted so that the height change of fluid in the system was 1.5 metres for 145N.

DISCUSSION

These preliminary studies confirm that mobilisation of the lumbar spine does not produce any changes in vertebral kinematics and suggest that beneficial effects may be derived from changes in the soft tissues.

BIOMECHANICAL EVIDENCE FOR PROPRIOCEPTIVE FUNCTION OF LUMBAR FACET JOINT CAPSULE

Partap S. Khalsa, Jonathan B. Chiu, Nicholas J. Aliberti, and Michael Sileo

Dept. of Biomedical Engineering, Stony Brook University, Stony Brook, New York, (www.bme.sunysb.edu)

INTRODUCTION

The lumbar facet joint capsule can be a pain generator in low back pain patients (Cavanaugh 1995; Kuslich et. al 1991; Revel et. al 1998; Schwarzer et. al 1994). However, its proprioceptive role is largely theoretical (cf. Pickar & McLain 1995). Histological studies have conclusively established the presence of mechanoreceptors in human facet capsule (McLain & Pickar 1998), and animal models have demonstrated that capsule mechanoreceptors respond to loading (Pickar & McLain 1995; Yamashita et. al 1990). Here we present biomechanical data supporting a proprioceptive role for facet joint capsule.

METHODS

Post. Capsule Material Properties. Bone-capsule-bone (BCB) specimens were harvested from intact, cadaveric human spines, using a university approved protocol. The BCB specimens were trimmed to a rectangular shape to facilitate uniaxial tensile testing and loaded in a uniaxial tensile testing system (Tyttron 250, MTS, Inc.). Capsule geometry was measured optically, and the material testing was performed under strain control. Tensile stress was calculated from resultant force and cross-sectional area at mid-length. Following preconditioning, trials consisted of ramp displacements (1, 5, 10, or 15% strain/s) to a specified tensile strain (10, 20, 30, 40, or 50 %), which was held constant for 300 s, and then a ramp unload.

Post. Capsule Strains during Physiological Motions. Intact, human cadaveric, ligamentous, lumbar spine specimens were actuated at the L₁ vertebra (sacrum potted) with a linear, servomotor using a programmable controller and digital encoders. Motions consisted of flex., ext., and lat. bending (left & right). Vertebra angulation during motion was measured with two bi-axial inclinometers fixed to the ant. vertebral bodies of the studied joints. Joint moments were calculated from the moment arm and a force transducer in series with the actuator. 9 markers were glued to each studied post. capsule, forming a 3 x 3 array. The markers were optically tracked in three dimensions using a dual-camera kinematic system. Capsule plane strains were calculated using a Lagrangian, large strain formulation.

RESULTS AND DISCUSSION

Capsule stiffness was nonlinear and anisotropic up to its yield strength, and the stiffness was larger aligned parallel rather than perpendicular to the collagen fibers (Fig. 1). No significant differences in capsule stiffness were found for the different joint levels, nor for the left or right sides of the lumbar spine. Capsule stiffness was independent of the strain rates used for ramp loading.

Plane strains (referenced from the spine's neutral vertical position) in all joint capsules increased monotonically for all motions (Fig. 2), though intra-capsule strains were inhomogeneous. On average, shear strains (ϵ_{xy}) were larger than axial strains (ϵ_{xx} or ϵ_{yy}), with the largest strains in flexion at L₄-L₅ or L₅-S₁ joint levels and decreasing for more cephalic levels (Table 1). During ext., strains were mirror symmetric of flex.,

Fig. 1. Stiffness curves of human facet joint capsule parallel (n = 27) and perpendicular (n = 2) to the dominant orientation of the collagen fibers. A) Instantaneous or 'viscous' response. B) Relaxed or 'elastic' response. Error bars are std. devs.

negatively increasing for more caudal capsules, hence, indicating capsule relaxation. Mean strains during lateral bending motions were smaller than those in flex. ($\leq 1\%$ for L₁₋₂) and also demonstrated mirror symmetry between left & right bending (Table 1).

Fig. 2. E_{yy} strains at 5 capsule levels from full extension to full flexion.

Physiological motions of the in-vivo lumbar spine

would likely activate capsule mechanoreceptors.

	Flexion		Extension	
Strain	L ₁₋₂	L ₄₋₅	L ₁₋₂	L ₄₋₅
ϵ_{xx}	-0.003	-0.014	0.027	0.089
ϵ_{yy}	-0.006	0.082	-0.022	-0.070
ϵ_{xy}	0.004	0.131	-0.005	-0.167

Table 1. Comparison of capsule strains in flx. & ext. joint capsule mechanoreceptors have a mean tensile threshold of 5 kPa (Khalsa et. al 1996). At only 2% facet capsule tensile strain (from full ext.), estimated tensile stress (~21 kPa) would be over four times greater than threshold of Ruffini type mechanoreceptors (Khalsa et. al 1996), which also innervate human facet joint capsule (McLain & Pickar 1998). Hence, the biomechanics of lumbar facet joint capsule is favorably disposed to allow it to function neurophysiologically as a proprioceptive organ. A major question remains whether human facet capsule mechanoreceptors function similarly to those in other mammals & what is their threshold relative to capsule loading.

MODELS FOR WHIPLASH INJURY

Manohar M Panjabi

Biomechanics Laboratory, Department of Orthopaedics and Rehabilitation,
Yale University School of Medicine, New Haven, CT, USA

INTRODUCTION

Whiplash injury of the neck is usually caused by a rear impact at slow speed. Such injuries seem benign as they do not include vertebral fractures or dislocation, and are generally caused by low impact energy trauma. However, whiplash injury can result in severe pain that may last for many years. These injuries have been on the rise in recent times, due primarily to the increased traffic density. A 50% increase was noted in Sweden and a 100% in Germany in the last 20 years. The clinical symptoms associated with whiplash are well documented, but our understanding of the injury mechanism remains poor. Whiplash injuries are most commonly thought to be incomplete or subfailure soft tissue injuries of the spinal column, although, there are also hypotheses including injuries to the nervous system and muscle strains. The prevailing view of neck hyperextension causing the whiplash injury has not been supported by epidemiological studies. Understanding the mechanism of whiplash injury is important. It may help in automotive design to prevent the injury, in diagnosis to precisely locate the injury, and in treatment to make it more effective. Various models have been used to get to the mechanism of injury. These include: volunteers in cars or sleds; cadavers in sleds; cervical spine specimens with head; animal models; physical models or dummies; and mathematical models. The purpose of this communication is to present the latest findings using the cervical spine specimen model.

METHODS

Model I consisted of a human cervical spine specimen (occiput to T1, both mounted in epoxy mounts), devoid of musculature, thus allowing free access to vertebrae, discs and ligaments for monitoring during trauma (Panjabi 1998). The T1 was mounted on a mini-sled above a 6-component load cell, while the occiput was provided with a simulated head. The weight of the head was balanced by a suspension system carried on the sled. Various transducers were designed to monitor the deformations of capsular ligaments, vertebral artery, and alar ligaments during the trauma. Defining soft tissue injury was one of the primary goals. Multidirectional flexibility test was used before and after each trauma step, to quantify the resulting injury at each spinal level. The model was impacted sequentially at 2, 4, 6, 8, and 10 g. Model II, additionally, included caudally increasing compressive forces applied to

vertebrae via cables approximately passing through flexion/extension centers of rotation, based upon follower load concept (Patwardhan 2000). The compressive loads increased from 60 N at C0-C2 to 240 N at C6-T1. These forces, applied on the left and right sides of the specimen, stabilized the specimen in the frontal plane. To resist the horizontal loads in the sagittal plane, anterior and posterior forces were also included in the model. This muscle force replication system simulated the expected in vivo loads and stiffness in neutral posture, and thus helped bring the in vitro whiplash model closer to the in vivo situation.

RESULTS

The hyperextension hypothesis of injury mechanism was not supported. We found a bi-phasic kinematics response of the cervical spine during whiplash trauma. In the first phase, the spine formed an S-shaped curve with flexion at the upper levels and hyperextension at the lower levels. In the second phase, all levels of the cervical spine were extended, and the head-neck reached its maximum extension. The occurrence of anterior injuries at the C5-6 level in the first phase was documented by flexibility tests and functional radiography. The largest dynamic elongation of the capsular ligaments was observed at C6-C7 level during the initial S-shaped phase of whiplash. The same was true for the maximum elongation of the vertebral artery. Whiplash using the second model showed dramatic increases in the anterior force during whiplash trauma.

CONCLUSION

The isolated spine specimen models provide significant advantages because of their openness and easy accessibility to the vertebrae, discs, ligaments and vascular and neural structures. These spinal elements can be monitored during the simulated trauma. Another, equally important advantage is the quantification of the subfailure soft tissue injuries. Such detailed information may provide truer understanding of the whiplash trauma, and may help in improving the diagnosis, treatment, and prevention of these imprecisely defined injuries.

IN VIVO QUANTIFICATION OF DISC BULGING IN DIFFERENT ANNULAR REGIONS ALONG A RADIAL PATH

Greg Kawchuk¹, Allison Kaigle Holm², Sten Holm², Lars Ekström², Tommy Hansson²

¹Faculty of Kinesiology, University of Calgary, Calgary, Alberta, Canada, kawchuk@ucalgary.ca

²Department of Orthopaedics, Sahlgrenska University Hospital, Göteborg, Sweden

INTRODUCTION

The intervertebral disc is a load-bearing structure comprised of a gelatinous nucleus pulposus surrounded by concentric lamellae of the annulus fibrosus. During axial compression, the most external annular layer is known to bulge. While the magnitude and direction of external layer bulging has been quantified theoretically (Shirazi-Adl) and *in vitro* (Stokes), knowledge of the load-response of the remaining internal lamellae is limited to directional information only. Given that disc bulge is influenced by several factors including simulated injury (Brinckmann and Horst), understanding regional load responses within the annulus may be of clinical significance. Therefore, the purpose of this *in vivo* study was to compare annular bulging within different annular regions along a radial path.

METHODS

Seven mature Swedish Landrace pigs were utilized in this study. Each animal was anesthetized in a prone position and the posterior muscles of the spine partitioned to permit the installation of four bone pins into the pedicles of L3 and L4. A miniaturized hydraulic loading device was then attached to these pins and suspended above the back of the animal. Through a separate, retroperitoneal approach with psoasectomy, a 10 MHz ultrasonic transducer (Acuson) was placed in the coronal plane against the lateral aspect of the L3-L4 intervertebral disc. Cyclic compression loading of the L3-L4 disc was then performed (300N, 1Hz, 10 cycles) with concurrent imaging of the disc space. Ultrasonic images at minimal and peak compression loads were collected automatically from an image capture card using a synchronizing pulse from the hydraulic device. Image pairs from each compression cycle were then analyzed digitally using customized software. Specifically, a digital line was drawn in each image that bisected the L3-L4 disc mediolaterally (Figure 1) and the signal intensities of all pixels falling on the bisecting line determined. To account for movements of the transducer with respect to the vertebrae, the bisecting line in each image was referenced to a second, intersecting line connecting the inferiolateral aspect of L3 and the superiolateral aspect of L4 (Figure 1). Graphically, lamellae were characterized along each bisecting line as regions of high pixel intensity while interlamellar spaces corresponded to regions of low pixel intensity. Phase shifting of high intensity regions between images was interpreted as translation of the lamellae along the bisecting line. The direction and magnitude of lamellar translation in the middle 1/3 and outer boundary of the annulus was determined by the sign and magnitude of the pixel phase shift.

RESULTS AND DISCUSSION

Figure 1:

Coronal ultrasonic images of the unloaded L3-L4 segment showing the digital bisecting line (solid) and digital intersecting line (dashed).

The lamellae of the middle 1/3 of the annulus as well as the lamella defining the outermost boundary of the annulus were observed to bulge outward during compression loading. While all lamellae of each region were displaced in the same direction (outward), the magnitude of displacement was significantly greater in the middle 1/3 of the annulus (0.14 ± 0.10 mm) compared to the outermost boundary (0.06 ± 0.06 mm) (Wilcoxon Matched-Pairs Signed-Ranks Test $p \leq 0.03$).

While other studies have described alterations in external disc bulge at different circumferential sites (e.g. anterior vs. posterolateral), to our knowledge, this study is the first to quantify regional deformations of the annulus along a radial path. These *in vivo* findings are supported indirectly by previous *in vitro* studies that have demonstrated the capability of the internal lamellae to move independently of the external lamellae along a radial path during conditions of nuclear depletion (Meakin et al., Serousii et al.). Additional investigations to confirm these findings must be performed as the impact of a variety of known variables (e.g. load magnitude, disc height) and uncontrolled variables (e.g. out-of-plane imaging and off-axial loading) is unknown.

SUMMARY

The results of this *in vivo* study suggest that at a 300 N axial load, outward deformation in the middle 1/3 of the annulus is significantly greater when compared to the lamellae of the outermost disc boundary.

COORDINATION OF MUSCLE ACTIVATION TO ASSURE STABILITY OF THE LUMBAR SPINE

Stuart M. McGill¹, Sylvain Grenier¹, Jacek Cholewicki²

²Department of Orthopaedics, Yale University School of Medicine, New Haven, CT, USA
mcgill@healthy.uwaterloo.ca

INTRODUCTION

The spine is inherently unstable since, in vitro, the osteo-ligamentous lumbar spine buckles under compressive loading of only 90 Newtons. A critical role of the musculature is to stiffen the spine in all potential modes of instability (3 rotational and 3 translational). But given the wide range of individuals and physical demands, question remain as to what is the optimal balance between stability, motion facilitation and moment generation - if stability is achieved through muscular cocontraction, how much is necessary and how is it best achieved? The intention of this presentation is to define stability and to demonstrate that spine stability results from highly coordinated muscle activation patterns involving many muscles, and that the critical patterns must continually change, depending on the task.

ON STABILITY: THE FOUNDATION

During the 1980's, Professor Anders Bergmark of Sweden, very elegantly formalized stability in a spine model with joint stiffness and 40 muscles (Bergmark, 1987). In this classic work he was able to formalize mathematically, the concepts of "energy wells", stiffness, stability and instability using the elastic potential energy approach. The approach was limited to analysis of "local stability" since the energy wells are not infinitely deep and the many anatomical components contribute force and stiffness in synchrony to create "surfaces" of potential energy where there are many local wells. Local minima are located from examination of the derivative of the energy surface. Spine stability then, is quantified by forming a matrix where the total "stiffness energy" for each degree of freedom of joint motion is subtracted from the applied work (represented by a number, or eigenvalue). Eigenvalues less than zero indicate the potential for instability. Others have enhanced this work. The eigenvector (different from the eigenvalue) can then identify the mode in which the instability occurred while sensitivity analysis may reveal the possible contributors allowing unstable behaviour, or for clinical relevance - what muscular pattern would have prevented the instability?

SOME EXAMPLES OF MOTOR PATTERNS AND STABILITY

Several examples will be presented to demonstrate the dynamic nature of the "healthy" eigenvector that ensures stable conditions are preserved.

LOOKING FORWARD

There is no single muscle that is the best stabilizer of the spine – the most important muscle is a transient definition that depends on the task. Further, virtually all muscles work together to create the "balance" in stiffness needed to ensure sufficient stability in all degrees of freedom (or to maintain the appropriate level of potential energy of the spine). With the evidence supporting the importance of muscle endurance (not strength) and "healthy" motor patterns to assure stability, work must continue to: **1)** understand the role of various components of the anatomy to stability - and the ideal ways to enhance their contribution; **2)** understand what magnitudes of muscle activation are required to achieve sufficient stability; **3)** identify the best methods to re-educate faulty motor control systems to both achieve sufficient stability and to reduce the risk of inappropriate motor patterns occurring in the future. Much remains to be done.

INTRODUCTION

Numerous studies have identified changes in the trunk muscles in people with low back pain. These changes range from changes in the pattern of muscle activation (e.g. Hodges & Richardson, 1996) to deficits in strength and endurance (e.g. Roy, De Luca & Casavant, 1989). Several recent studies have highlighted changes in activity of the trunk muscles in postural tasks. For instance, during rapid arm movements the onset of activity of the deep abdominal muscle transversus abdominis (TrA) is delayed compared to control subjects (Hodges & Richardson, 1996). However, it is unknown whether these changes are the result of pain. Furthermore it is uncertain whether it is nociceptor stimulation or other elements of clinical pain, such as increased information processing demand, stress and fear that may cause changes in motor control. The postural response of the trunk muscles in association with arm movement provides a model to investigate these questions. The aim of this series of experiments was to investigate these questions.

METHODS

In the first study electromyographic (EMG) recordings of the abdominal (transversus abdominis (TrA), obliquus internus (OI) and externus (OE)) and paraspinal (deep and superficial fibres of multifidus) muscles were made in 7 healthy subjects. In standing, subjects rapidly moved the left arm in response to a light in a control trial, following the injection of isotonic (non-painful) and hypertonic (painful) saline into the longissimus muscle at L4, and during a 1-hr follow-up. Temporal and spatial parameters of EMG were measured.

In the second study the same EMG recordings were made in a separate group of 8 subjects. For this study rapid arm movements were performed in control trials, while performing an attention demanding task ('attention'; modified Stroop test); while performing the attention demanding task with negative feedback of performance ('stress'), during anticipation of randomly delivered electric shocks ('fear'); and following injection of hypertonic saline into the back muscles ('pain').

RESULTS AND DISCUSSION

In the first study, subjects reported pain of ~6/10 on a visual analog scale. The majority of muscles responded in a variable manner to hypertonic saline injection. However, the onset of TrA EMG was delayed by ~20 ms after hypertonic saline injection in 5/6 subjects for whom TrA data were collected. In

addition, the amplitude of TrA EMG in the 50 ms before and after the onset of deltoid EMG was reduced. The results suggest that nociceptor stimulation and/or pain alter feedforward postural responses, but this response is not consistent across apparently synergistic muscles.

The results of the experimental pain trials in the second study were consistent with those of study one. Delayed onset of TrA EMG was identified in all subjects. This change was not replicated in the attention trials. Instead, the onsets of TrA and deep MF EMG occurred earlier relative to that of deltoid as a result of delayed reaction-time for limb movement. When the attention task was made stressful by provision of negative feedback (e.g. 'you're not performing well enough') the latency between onsets of TrA and deltoid EMG were not different to the control trials. Unlike the attention and stress trials, when the arm was moved in the fear condition the onsets of TrA and deep MF EMG were both significantly delayed and the response of TrA was not different to that reported in the pain trials. Although consistent within-subject changes were observed in OI and OE EMG in all conditions, there was marked variability between subjects.

These data suggest that the change in postural activation of TrA associated with pain is not due to the competitive attention demand of pain, but may be due in part to anxiety associated with pain.

SUMMARY

These data confirm that changes in motor control of the trunk muscles in association with low back pain may occur as a result of the pain, rather than a predisposing factor. Furthermore, the changes may not be due to nociceptor stimulation, but instead could be mediated by processes such as fear. Finally, these data confirm the specificity of these changes to the deep intrinsic spinal muscles.

SPINAL STIFFNESS INCREASE WITH AXIAL LOAD: ANOTHER STABILIZING CONSEQUENCE OF MUSCLE ACTIVATION

Ian Stokes and Mack Gardner-Morse

University of Vermont, Department of Orthopaedics and Rehabilitation
Burlington, VT 05405-0084, USA, Ian.Stokes@uvm.edu

INTRODUCTION

The stiffness of motion segments, together with muscle actions, stabilizes the spinal column. The objective of this study was to compare the experimentally measured load-displacement behavior of porcine lumbar motion segments *in vitro* with and without physiological axial compressive preloads of 0, 200 and 400 N equilibrated with a physiological fluid environment to determine whether these preloads increased stiffness, hysteresis and linearity of the load displacement behavior.

METHODS

At each preload, displacements in each of six degrees of freedom (three translations and three rotations) were imposed and the applied forces and moments were recorded, using a "hexapod" apparatus (Stokes *et al.*, 2002). These tests were repeated after removal of posterior elements. Forces at the vertebral body center were related by linear regression analysis to the displacements by a symmetric 6x6 stiffness matrix. Also, the hysteresis and linearity of the load-displacement recordings were evaluated. Six diagonal and two off-diagonal load-displacement relationships were examined for differences in stiffness, linearity and hysteresis in each testing condition.

RESULTS

Motion segment and disc load-displacement behavior was stiffer, more linear and had greater hysteresis with axial compressive preload imposed. Mean values of the diagonal terms of the stiffness matrix for intact porcine motion segments increased significantly by an average factor of 2.2 and 2.9 with 200 and 400 N axial compression respectively ($p < 0.001$). Increases for disc-only specimens averaged 4.6 and 6.9 times with 200 and 400 N preload ($p < 0.001$). Changes in hysteresis correlated with the changes in stiffness. The load-displacement relationships were progressively more linear with increasing preload ($R^2 = 0.82, 0.97$ and 0.98 at 0, 200 and 400 N axial compression respectively). The increase in stiffness with preload was slightly nonlinear for the axial stiffness ($p = 0.012$).

DISCUSSION

These findings show that the elastic energy storage and energy absorption (damping) that occurs with displacements of motion segments *in vivo* increases with the magnitude of the prevailing muscle force and applied loading. This has implications for spinal stability.

Figure 1 Mean and standard error of diagonal terms of the stiffness matrix for intact motion segments at three levels of axial compressive preload.

Preload may cause an increase in stiffness and linearity of the load-displacement behavior of the disc. Broberg {1983} predicted a doubling in stiffness for rotational degrees of freedom with increased axial preload (700 N to 3000 N) in an analytical model. Janevic *et al* (1991) demonstrated this effect experimentally. We believe that a combination of fluid flow effects and viscoelastic tissue properties were responsible for the increase in hysteresis with preload.

SPINAL STABILIZING SYSTEM: CONSEQUENCES OF A SUBFAILURE INJURY

Manohar M. Panjabi

Department of Orthopaedics and Rehabilitation, Yale University School of Medicine, New Haven, CT
manohar.panjabi@yale.edu

INTRODUCTION

Chronic spinal pain (CSP), representing collectively the low back and neck pain, is an important societal problem causing patient suffering, consuming significant health resources, and costing large amounts of funds. Although there are many possible reasons, mechanical derangement has been considered as one of the most important causes. Several studies have documented the changes in the spinal column kinematics and the spinal muscle responses of CSP patients. For example, in comparison to the controls, the low back pain patients have more erratic and widely dispersed centers of rotation, greater out-of-sagittal plane torques during flexion/extension, muscle spasm, longer muscle reaction times to external events, greater muscle co-contractions while moving through the neutral posture, and antagonistic spinal muscle activity even when the external challenge to spinal stability has been removed. The whiplash patients have been described as trapped in the neutral zone. The basic understanding of these *in vivo* observations is not clear. Subfailure or incomplete injury of the soft tissues may be the initial event in the development of CSP. The purpose of this presentation is to examine a hypothesis which attempts to relate the diverse patient observations to the subfailure injuries, within the context of the spinal stabilizing system.

HYPOTHESIS

The spinal stabilizing system can be thought of as consisting of three subsystems: spinal column, spinal muscles, and the neural control unit. The spinal column is the multi-body mechanical structure to be stabilized (Panjabi 1992). The orchestration of the spinal muscle tensions and timings to achieve the needed multi-directional dynamic stability of the spinal column is the function of the control unit. The injury to the spinal column may affect both the mechanical properties of the spinal column and the proprioception received by the control unit. The former directly affects the stability of the spinal column, while the latter affects the muscle function, and, therefore, the spinal stability to even a greater extent. The proprioception obtained from the built-in transducers within the various soft tissues of the spinal column describes the spinal loads and motions, and thus, the dynamic stability. When a subfailure injury to one or more of the soft tissues occurs, the consequences depend upon the injury severity. If the injury is less severe (i.e. little change in mechanical properties), then it may corrupt the proprioception only, while a more severe injury, additionally, may cause changes in the mechanical properties. In the case of a more severe injury, with decreased stiffness and faulty proprioception, the control

unit may mobilize muscles maximally by increasing, in general, all muscle tensions all the time, leading to muscle spasm. However, with the faulty proprioception alone, the task for the control unit is more complex, and therefore, the results more varied. An example is the whiplash patients who moved within the neutral zone like the healthy, but did not move beyond it. With finite number of pre-programmed responses, which are designed for the healthy spine, the control unit may not be able to orchestrate efficiently the multitude of the spinal muscles. The control unit may take a little longer to activate the muscles, and it may do so erratically. It is possible, that over time a more severe injury may convert itself into a less severe injury due to ligament healing, osteophyte formation and other stabilizing changes of the spinal column. Thus, the less severe injury, and the faulty proprioception it generates, may be an important cause of CSP patients.

DISCUSSION

The hypothesis presented attempts to examine the consequences of the soft tissue injury to the spinal column, and subsequent muscle dysfunction within the context of the spinal stabilizing system. Many low back pain and neck pain problems involve trauma - multiple micro traumas or a single trauma. Seen biomechanically, trauma results in tissue injury. As the spinal soft tissues not only provide stiffness and strength to the spinal column, but also proprioception to the neuromuscular control system, it is reasonable to assume that the subfailure soft tissue injury may affect the proprioception as well as the mechanical properties of the functional spinal unit. As the built-in responses of the control unit are designed for the healthy spine, the control unit is not likely to function efficiently if the proprioception is faulty. This may result in various types of muscle dysfunctions which have been observed in patients. If this hypothesis can be validated by carefully performed experiments, then it may be possible to improve the diagnosis and treatment of CSP patients whose precipitating event was a soft tissue injury. This could be accomplished by re-programming the control unit by appropriate training or other means to come in synch with the altered spinal column structure and function.

MODELS OF NEUROMUSCULAR DISORDERS IN THE SPINE

M. Solomonow

Occupational Medicine Research Center

Louisiana State University Health Sciences Center

New Orleans, Louisiana 70112 USA — msolom@lsuhsc.edu

INTRODUCTION

The spine, a complex multi-joined structure, functions as a closed loop control system similar to the extremity joints (Solomonow, 1984, Panjabi, 1991). While many productive models describe the forward components of the spine functions and structures, (Marras, 1997, McGill, 1986), very little is known of the feedback functions, and this is the objective of this paper.

The literature points out that mechanoreceptors are located in the lumbar ligaments, discs and capsules (Yahia, 1991), and that a reflex activation of the multifidus and longissimus muscles is elicited upon stimulation of these structures (Indahl, 1995, 1997, Stubbs, 1998, Solomonow, 1998). It is of interest to describe the behavior of these feedback structures and to assess their role in low back disorders.

METHODS

An in-vivo anaesthetized feline preparation was used. Intramuscular EMG wire electrodes were inserted in the L-1/2 to L-6/7 multifidus (feline has 7 lumbar) in a bipolar configuration. The lumbar spine was loaded into moderate flexion via the L-4/5 supraspinous ligament using a MTS Bionix 858 in two conditions; displacement control and load control. Two paradigms were used to simulate repetitive and static flexion: a sinusoidal increase/decrease in force or displacement and a sustained step force or displacement of a given magnitude. The EMG, creep or tension - relaxation were measured simultaneously and stored in a computer for analysis. The loading of the spine was applied over a 20-minutes period followed by 7 - 8 hours of rest. During rest a brief 10-second tests were applied every hour to assess recovery of the muscles, ligaments, discs and capsule.

Models consisted of exponential functions, as it is the classical description of viscoelastic structures behavior. The models were applied to the mean \pm SD of the EMG, creep and displacement from a group of preparations tested in the same condition. A Marquardt-Levenberg non-linear regression was performed to determine the best fit model to the data.

RESULTS AND DISCUSSION

The analysis shows that under displacement control, the tension - relaxation and EMG are described with a bi-exponential models accounting for the large difference in the proportion of elasticity and viscosity between the ligaments and the discs. The general equations are given by:

For loading: $NIEMG_{(t)} = Ae^{-at} + Be^{-bt} + R$

For rest: $NIEMG_{(t)} = C(1-e^{-cT}) + D(1-e^{-d(t-T)}) + R$

The equations describe the biexponential decrease in EMG to 5% of its initial value due to the tension-relaxation during loading. Conversely, a biexponential rise in EMG is described with rest, as the ligaments recover to their resting length and the fluids slowly returns to the disc's interior.

Under load control, a completely different response was obtained. The best fit models predict a single exponential decrease in EMG during the loading and a single exponential increase during rest. The model, however, also includes description of an initial hyperexcitability in the first hour and a delayed hyperexcitability peaking 6-9 hours after rest initiation. Spasms were always observed under static load control but could not be described due to their unpredictable nature. Therefore, for load control the model is:

$NIEMG_{(t)} = Ae^{-at} + R$ during loading and

$NIEMG_{(t)} = C(1-e^{-cT}) + tFe^{-ft} + (t - T)De^{-d(t-T)}$
during rest.

CONCLUSION

Static flexion of the lumbar spine seems to elicit a complex transient neuromuscular disorder that may last up to several days. The disorder consists of four components: An exponential decrease in muscle activity during flexion, spasms superimposed on the decreasing EMG, initial hyperexcitability and a delayed hyperexcitability during rest. It seems that static flexion inflicts micro-damage on the collagen structure of the viscoelastic tissues which result in spasms and initial hyperexcitability and probably pain. The inflammatory response to the micro-damage require several hours to develop and the associated pain and stiffness are observed in the "morning after" and last more than 24-hours.

INTRODUCTION

The disc is the largest avascular tissue in the body with cells in the centre of an adult lumbar disc 6-8 mm from the nearest blood supply. In order to function and remain viable, the cells require an adequate nutrient supply, and an efficient means of removing products of metabolism such as lactate. Nutrients reach the nucleus cells by diffusing from blood vessels of the vertebral body through the cartilage endplate into the disc matrix. Even in a normal healthy disc, oxygen levels in the centre of the nucleus are low as the cells use oxygen even though metabolism is mainly anaerobic. Lactate is produced at high rates and accumulates away from the blood supply leading to a fall in tissue pH. Failure of nutrient transport and the consequent further fall in pO₂ and increase in lactate level could affect cellular activity and may thus be one route to disc degeneration. Here we describe measurements of nutrient supply to human discs in vivo, and the effect of fall in nutrient concentrations on cellular metabolism.

METHODS

In vivo transport and concentrations of small solutes was measured electrochemically as described previously (1, 2). Briefly, a silver needle microelectrode was inserted into the disc during routine anterior spinal surgery with the reference Ag/AgCl electrode attached to adjacent muscle. The electrodes were driven by a computer-controlled potentiostat. Currents were measured at 0.6v and -1.3v w.r.t to Ag/AgCl and converted to concentrations of N₂O and O₂ using calibration curves measured in bovine discs in vitro. Calculated versus expected N₂O concentrations provided a measure of transport inhibition.

For measurement of the effects of metabolites on cellular activity, discs were obtained from steer (18-24 months old) tails within 24hrs of slaughter, cells extracted, embedded in alginate and cultured under 5% CO₂ in air, at pH7.4 for 48 hours. The effect of varying pO₂ and pH on cellular energy metabolism (lactate measured using a Yellow-Springs analyser, ATP by a standard luciferin-luciferase assay) and matrix turnover (S³⁵-incorporation, MMP activity by zymography and fluorescence assays) was then examined.

RESULTS AND DISCUSSION

The measurement of N₂O concentrations in the disc of patients with scoliosis (22 discs) shows that transport into these discs is inhibited, possibly by calcification of the cartilaginous

endplate. Since pressure profiles in scoliosis are also abnormal (3), the blood supply to the scoliotic discs may also be affected adversely and contribute to the fall in nutrient supply to these discs. Both transport and oxygen concentration and as well as cell density were lowest and lactate concentrations greatest at the curve apex suggesting nutritional failure was involved in cell death (4).

In studies of cellular behaviour in vitro, we found that both low oxygen and acid pH affected cell behaviour markedly. Matrix synthesis rates and cellular ATP concentrations fell steeply as the extracellular pH fell below pH6.8; at pH 6.4 the rate of energy metabolism had fallen by 60% and that of sulphate incorporation by 90%. A fall in pO₂ similarly inhibited cellular activity, with both energy metabolism and rates of matrix synthesis falling steeply in a concentration-dependent manner, once pO₂ fell below 5% O₂. In contrast to the fall in matrix synthesis, MMP activity under these conditions, decreased only marginally.

The results show that in some pathological conditions, nutrient supply to the disc is diminished. In these discs, regions with the lowest nutrient supply have the lowest oxygen concentration and highest concentration of lactate, confirming that metabolite concentrations in vivo are affected by a fall in supply. In vitro evidence demonstrates that cells are very sensitive to the extracellular nutrient concentrations. Thus with loss of nutrient supply and consequent changes in extracellular concentrations of lactic acid and oxygen, cells are unable to maintain normal activity.

SUMMARY

The results of these test indicate that loss of nutrient supply will lead to a fall in matrix synthesis but not in MMP activity; matrix composition will no longer be maintained and the disc will eventually degenerate.

THE STRUCTURE AND FUNCTIONS OF ELASTIC FIBRES IN BOVINE INTERVERTEBRAL DISC

INTRODUCTION

Water movement in the intervertebral disc is important both as a determinant of the mechanical properties of the tissue and in the context of the convective movement of solutes. The role of proteoglycans in determining the hydraulic permeability of the extracellular matrix and in generating an osmotic (swelling) pressure and that of collagen in supporting tensile loads and determining stress and strain gradients in the matrix have been extensively discussed for the disc and other load-bearing tissues. Several authors report that the disc contains elastic tissue (1-3), but its potential functions have not been considered. We hypothesise that the elastic tissue is important for the recovery of the tissue after loading either because it itself forms an extensive network or because it links the essentially inextensible collagen fibres. Such roles would regulate tissue swelling pressure and thus influence fluid movement under osmotic and pressure gradients. As an initial step in determining its role in the disc, we have quantified the amount of elastic tissue, undertaken a microscopic examination of its organisation and partially characterised its biochemical composition.

METHODS

Discs were obtained from steer (18-24 months) or calf (12 days) tails. Elastic tissue was quantified as the insoluble residue remaining after autoclaving for 1 hr and then digested in 0.1 N NaOH at 98°C (4). Elastic fibre organisation, was determined in 30µm sections of snap-frozen tissue utilising orcein staining or immunostaining (rabbit anti-human α -elastin, Biogenesis). Amino-acid analyses were performed on the alkali digests and on the residues remaining after CNBr digestion (4). Selected residues and histological sections were examined by Raman microspectrometry.

RESULTS AND DISCUSSION

The alkali resistant residue and the residue after cyanogen bromide digestion of 18-24 month steer discs comprised 0.39±0.07% (n=10) and 2.45±0.38% (n=5) of the dry weight of the annulus respectively and appeared to increase with age.

Orcein and immunostaining revealed a similar pattern of fibres in the tissue sections. In the centre of the nucleus, long (>100µm), thin and straight fibrils appear to radiate from the centre. At the boundary between nucleus and annulus the orientation changes to form a lattice pattern. In the annulus

fibres are densely packed in the region between the lamellae and also form bridges between the lamella. Elastic fibres, parallel to the collagen fibres are also visible within the lamellae. At the bone-disc interface the fibres penetrate the cartilaginous end plate and terminate there.

The amino acid composition of the alkali residue contained less valine than elastin. The Raman spectra contained some unidentified peaks not found in arterial elastin. The fibres seen are thus predominantly formed of elastin but the residue remaining after alkali digestion is still contaminated with other polypeptides that require characterisation.

These results show that the disc has an extensive and organised elastic fibre network. Although we found that elastin comprises a relatively small percentage of the total dry weight, our extraction procedures possibly underestimate the amount present. With respect both to the geometry of the disc and to collagen fibres the organisation of the elastin network suggests that it has a mechanical role even in the nucleus. In the annulus, where the fibres are concentrated between lamellae, we suggest that they allow relative movement and elastic recovery of collagen fibres. However, further work on the nature of the association between the two proteins is necessary to provide insights into this interaction.

SUMMARY

The presence of an elastic component in the disc matrix would influence both tissue swelling pressure and the time-dependent deformations under load and could affect fluid and macromolecule movements through the tissues. The possible role of elastin in this regard should be considered in future modelling or experimental studies on transport in the disc.

OCCLUSION OF VERTEBRAL ENDPLATE OPENINGS: A MECHANISM FOR INTERVERTEBRAL DISC DEGENERATION?

Lorin M. Benneker, Suzanne E. Anderson¹, Paul F. Heini², Mauro Alini, and Keita Ito

AO Research Institute, Davos, Switzerland

¹Department of Radiology, University of Berne, Inselspital, Berne, Switzerland

INTRODUCTION

Much remains unknown about the etiology and pathogenesis of intervertebral disc degeneration. The nearest source of perfusion to the avascular disc, is the outer annulus and the capillary buds in the marrow contact channel (MCC) openings of the osseous endplate. With disease and age, calcification of the overlying cartilaginous endplates have been observed (Bernick & Cailliet), and it has been suggested that insufficient nutritional supply may contribute to disc degeneration (Nachemson et al). In this study, the relationship of endplate openings to disc degeneration is explored.

METHODS

39 human lumbar discs from 8 cadavers (19-86 years-old) were collected, and fresh MR images were graded. Discs were sectioned and graded according to morphological appearance (Thompson et al). Samples of nuclear and annular regions were evaluated for: water, proteoglycan (PG), total collagen, collagen-II contents, and % denatured collagen-II (Antoniou et al). After digestion with papain, endplates disc surfaces were sputter coated with Au/Pa, and imaged with backlighting. The caliber and distribution of endplate MCC openings for each disc were measured with image analysis software. Correlation between opening parameters and disc degeneration was analyzed using general linear regression models with backward elimination (10% sig. level) to identify opening size ranges of most significance.

RESULTS AND DISCUSSION

To date, only the nuclear endplate region has been analyzed. Density of all openings (# openings/endplate surface area) significantly correlated ($R=0.502$, $p=0.001$) to morphological degeneration grade (Fig. 1), and those with 20-50 μm equivalent diameter correlated most significantly ($R=-0.575$, $p<0.001$), accounting for 95% of the variability. Although the density of these openings also significantly correlated to age, it was not as strong. There was no significant correlation of % area of openings (cumulative opening area/ endplate area) to either degeneration grade or age. T2-intensity score also did not correlate to opening density. In contrast, 20-50 μm opening density significantly correlated to nuclear PG content ($R=0.628$, $p<0.001$). However all other biochemical parameters did not correlate to opening density.

Indirect correlation between 20-50 μm opening density and morphologic degeneration grade is particularly of interest as this size of opening has been shown to house capillary buds (Oki et al). Correlation to age was not as strong because of a degenerated younger spine specimen, but this illustrates that opening occlusion was not simply dependent on age. Also the % area of opening did not correlate to age or disc degeneration because of the increase in larger openings with degeneration.

Lack of correlation to T2-intensity loss may have been due to poor resolution of the scoring (3 levels), and quantitative MRI is recommended. Although correlation of biochemical degeneration descriptors to opening density was ambiguous, a strong indicator of degeneration, PG content, did correlate.

Figure 1: Endplate opening density and disc degen. grade.

SUMMARY

The results of this study support the hypothesis that occlusion of MCC opening in the vertebral endplates may deprive the cells of nutrients, leading to insufficient maintenance of the extracellular matrix and disc degeneration. However evidence of more causal relationships would be helpful to understand this mechanism.

INTRODUCTION

There is general agreement that mechanical load can contribute to the development of intervertebral disc degeneration. However, the fundamental mechanism of disc degeneration in relation to changes in mechanical load is not known. Many studies indicate that mechanical load has an important influence on matrix synthesis. Mechanical load alters the extracellular physical environment of the disc matrix in a complex fashion. When load is applied to the disc, the tissue deforms, leading to a rise in hydrostatic pressure. If the load is removed immediately, the disc returns to its original conformation and pressure. If the load is maintained for any length of time, fluid is expressed and leads to a change in ionic composition and hence to a rise in osmotic pressure. Because matrix synthesis is influenced by loading, the cells in the disc are responding to some or all of these matrix changes, but their relative contributions are unknown. This study clarifies the effect of extracellular physical factors on metabolism in the intervertebral disc.

METHODS

Bovine coccygeal and human lumbar discs were used. The specimens were divided into the nucleus pulposus, inner and outer annulus fibrosus and each region of the disc was incubated in a medium containing 35S-sulphate. Proteoglycan (PG) synthesis rate was determined by radioisotope incorporation. The production of matrix metalloproteinase-3 (MMP-3) and tissue inhibitor of metalloproteinases-1 (TIMP-1) were measured by a one-step enzyme immunoassay method using monoclonal antibodies. Hydrostatic pressure was applied by a water filled specially equipped pressure vessel. The fluid content was controlled by a small-pore dialysis tube and polyethylene glycol 20,000. Medium osmotic pressure and ionic composition were changed by adding sucrose or NaCl to the medium as required. Medium osmotic pressure was measured using a freezing-point osmometer.

RESULTS AND DISCUSSION

The effect of hydrostatic pressure on PG synthesis and MMP-3, TIMP-1 production: PG synthesis rate in the nucleus pulposus and inner annulus were highest at 3 atm pressure and decreased as pressure decreased (1 atm) or pressure increased (10, 30 atm). However, hydrostatic pressures had no apparent

effect on PG synthesis rate in the outer annulus. In the nucleus pulposus, MMP-3 production was stimulated at a pressure of 30 atm relative to 3 atm. The TIMP-1 production showed highest values at 3 atm pressure in the inner annulus.

The effect of water content, Na concentration and osmotic pressure on PG synthesis: In the medium, the nucleus pulposus swelled markedly and PG leached from the matrix. When 10% polyethylene glycol was added to the medium, tissue hydration was held close to that of the fresh tissues and PG synthesis rates were more than 2.5 times greater than in the medium alone. When NaCl was added to the medium, PG synthesis rate in the nucleus pulposus increased as NaCl concentrations increased; the peak in rates was found when the NaCl concentration was 200 mM. Also, PG synthesis rates increased with increase in sucrose concentration, and reached a maximum at 150 mM. Rates fell steeply as concentrations were further increased. It can be seen that the peak rate for both NaCl and sucrose occurred at an estimated extracellular osmolality of 430 mosmol.

Hydrostatic pressure and osmotic pressure levels in the disc have been found to vary with posture and activity, being lowest when lying down (3 atm, 440 mosmol) and highest when carrying weights (20-30 atm, osmotic pressure was not measured but higher than lying down). The disc slices incubated in the medium under atmospheric pressure swelled considerably and osmotic pressure was decreased (1 atm, 325 mosmol). This study clearly shows that a change in extracellular hydrostatic pressure and osmotic pressure, such as might occur physiologically during daily activity, had a marked effect on matrix synthesis and breakdown.

SUMMARY

Physiological hydrostatic and osmotic pressures appear to be essential signals for maintaining the disc matrix. Pressures that are too high or too low may have catabolic effects with reduction of PG synthesis and increase of MMP production, eventually leading to PG loss and disc degeneration.

CONVECTIVE MOLECULAR TRANSPORT IN THE INTERVERTEBRAL DISC

Stephen J. Ferguson¹, Keita Ito², Lutz-Peter Nolte¹

² AO Research Institute, Davos, Switzerland

INTRODUCTION

The intervertebral disc is the largest avascular structure in the body, with cells in the centre of the adult disc lying as far as 8 mm from the nearest blood supply [Katz et al]. It has been suggested that a deficiency in the nutrient supply to the disc may be a contributing factor in disc degeneration [Nachemson et al]. Previous studies have demonstrated that for small molecules diffusive transport alone likely fulfils the nutritional needs of disc cells [Holm et al, Roberts et al, Urban et al]. However, it has been often proposed that fluid flow into and within the disc may enhance the transport of larger molecules [Urban et al, MacMillan et al]. A substantial volume of fluid is expressed from the disc during daily loading [MacMillan et al], which is subsequently reimbibed overnight during rest, driven by osmotic potential. With aging, changes to disc and endplate permeability [Roberts et al] likely alter the magnitude of fluid exchange in the disc, which may have implications for disc metabolism if convection contributes substantially to molecular transport. The goal of this study was to predict the influence of this load-induced interstitial fluid flow on mass transport within the intervertebral disc.

METHODS

An iterative procedure was used to predict the convective transport of molecules of physiologically relevant size within the disc. An axisymmetric finite-element poroelastic model of the disc was developed, with unique material properties for the nucleus, annulus ground substance, annulus fibres, cartilaginous endplates and bone. The diurnal loading cycle (16 hours compression, 8 hours unloaded) was discretised into fixed time steps. At each time step, the fluid flow within the disc due to compression or swelling was calculated. The overall response of the poroelastic model was validated against in vitro creep / swelling data for isolated discs.

A separate diffusion / convection model was used to calculate the influence of the fluid velocities on solute transport, with a constant concentration of solute being provided at the vascularised regions of the endplates and outer annulus. Local fluid velocities calculated by the poroelastic model were transferred to the corresponding nodal points of the mass transport model. Loading was simulated for several diurnal cycles, and the relative convective and diffusive transport was compared for solutes with molecular weights ranging from 400 Da to 40 kDa, with diffusion coefficients based on in vitro measurements of solute transport through cartilaginous tissues [Quinn et al].

RESULTS AND DISCUSSION

Due to the strain-dependent permeability of intervertebral disc tissue, fluid re-imbibition during unloaded periods occurs much more rapidly than fluid expression under compressive loading. Fluid velocities are greatest immediately following load application or removal, with fluid exchange to and from the disc occurring predominantly across the permeable endplate, rather than across the annulus boundary.

Fluid velocities of the magnitude generated by daily loading did not enhance the transport of small solutes. Fluid flow within the intervertebral disc did enhance molecular transport for large molecules. During swelling, interstitial fluid flow increased the unidirectional penetration of 40 kDa solutes by approximately 100%. Due to the biphasic nature of disc loading, however, fluid expression during compressive loading reverses the direction of convective transport and opposes the diffusive transport resulting from concentration gradients. The net effect of convective transport for large solutes over a full diurnal cycle was therefore more limited, with a 30% increase in solute penetration compared to diffusion only.

The net fluid exchange over one entire diurnal loading cycle has only a modest influence on the transport of large molecular-weight solutes. However, convective transport during swelling is substantial. Furthermore, due to the non-linear response of the disc during compression and swelling, convective transport advances the solute quickly at the beginning of swelling, whereas convective transport of solutes occurs more gradually during loaded periods. Further study is required to determine the significance of large solutes and the timing of their delivery for intervertebral disc nutrition and the regulation of cellular processes.

DETERMINANTS OF LUMBAR DISC DEGENERATION AND LINKS WITH BACK SYMPTOMS

Michele C. Battié

Faculty of Rehabilitation Medicine, University of Alberta, Alberta, Canada

INTRODUCTION

Disc degeneration is commonly attributed to the accumulation of environmental effects, primarily mechanical insults and injuries, imposed on "normal" aging changes. Yet, the activities and agents that accelerate degeneration remain largely speculative. Among the factors most commonly suspected of accelerating degenerative changes in the discs are various physical loading conditions, such as heavy occupational materials handling, postural loading, and vehicular whole-body vibration. Numerous studies have examined the relationship between these factors and disc degeneration. However, most have been plagued by methodological constraints, including inadequate control of possible confounding factors, and have resulted in mixed findings related to the presence and degree of association with disc degeneration. Until recently, detailed studies focusing on hereditary aspects of disc degeneration and rupture have been lacking. My research group's goal has been to determine the roles of constitutional, behavioral and environmental factors in the development of lumbar disc degeneration, including the examination of gene-environment interactions, using study designs that allow for a high degree of control of extraneous factors. We have investigated the role of specific degenerative findings in back symptoms, as well.

SUBJECTS AND METHODS

We conducted a series of studies investigating the influences of commonly suspected risk factors on disc degeneration and back symptoms using monozygotic (MZ) twins highly discordant for the factor of interest, who were selected from the population-based Finnish Twin Cohort. Exposures were verified and data on potentially confounding factors were gathered in an extensive structured interview. Disc degeneration was assessed both quantitatively and qualitatively from MR imaging using a 1.5 Tesla scanner. The data from these studies were aggregated to allow multivariable analysis to examine the relative effects of lifetime exposures and familial aggregation on disc degeneration. Familial aggregation represents the effects of genetic and other shared family influences (e.g., shared childhood environment). DNA analysis using a candidate gene approach also was conducted in search of genotypes associated with disc degeneration. The association between specific degenerative findings and back pain history was investigated, controlling for age and physical loading.

RESULTS AND DISCUSSION

Our findings indicate that while physical loading involving materials handling, bending, and twisting appear to influence

disc degeneration, the effect size is very modest, which would help explain the inconsistent results of previous studies of occupational loading. Our investigation of MZ twins, highly discordant for lifetime occupational driving, did not demonstrate any significant differences between siblings in MRI findings of the lumbar discs, including quantitative measures of adjusted signal intensity, which should be highly sensitive for disc degeneration.

Conversely, we found disc degeneration could be explained to a great degree by familial aggregation, the combined effects of genetic and shared early environmental influences. In the multivariable analysis of the T12-L4 region, 61% of the variability was explained by familial aggregation, beyond that of age and occupational physical loading that together explained 16%. In the L4-S1 discs, physical loading and age explained 11%, which rose to 43% once familial aggregation was added to the model. Fifty-seven percent (57%) remained unexplained in the lower lumbar region. It will be important to disentangle the effects of genetic influences from those of shared childhood environments, which comprise familial aggregation, since genetic, childhood and work environmental exposures have very different implications for future research directions and prevention strategies.

Although our findings suggest that physical loading and other suspected environmental risk factors experienced in adulthood have modest effects on disc degeneration, it is possible that certain gene-environment interactions could have major importance. Our identification of two gene polymorphisms associated with disc degeneration, TaqI and FokI, each explained 6.5% of the variability in nuclear signal intensity, as well as subsequent discoveries of others, allows for the investigation of specific gene-environment interactions. The degenerative findings of outer annular tears and disc height narrowing are of particular interest because of their consistent pattern of associations with history of back-related symptoms in the study subjects.

SUMMARY

Intervertebral disc degeneration and failure and their sequelae lead the list of suspected culprits underlying back-related symptoms. The development of rational interventions is directed by knowledge of causal factors, the magnitude of their effects and possible interactions. Our study findings suggest that disc degeneration may be explained primarily by genetic influences, childhood environments and as yet unidentified factors, which may include complex interactions. Specific environmental exposures suspected of accelerating disc degeneration appear to have a more modest effect than previously believed.

EVIDENCE FOR DIFFERENCES IN MATRIX TURNOVER IN THE DEVELOPING AND DEGENERATING HUMAN LUMBAR INTERVERTEBRAL DISC

INTRODUCTION

Degenerative disc disease, viewed by most as an inevitable consequence of aging, is believed to begin as early as the second decade of life¹. Despite its prevalence, there is no clear distinction between what truly represents disc degeneration and normal maturation. The purpose of this study was to analyze how changes in matrix composition and matrix turnover (synthesis and degradation) varies with aging and degeneration in the human lumbar intervertebral disc. For this, we used available antibodies that recognize epitopes present either on newly synthesized proteoglycan and collagens, or epitopes exposed once type II collagen loses its triple helical configuration following cleavage by proteolytic enzymes.

MATERIALS AND METHODS

Twenty five whole lumbar spine specimens were harvested from fresh cadavers (within 18 hours of death). A total of 125 lumbar intervertebral discs were examined (five per spine). The age distribution ranged from 12 weeks up to 79 years of age (mean of 29 years). The lumbar spines (T12 to S1) were retrieved, and each segment was separated by sawing through the vertebral bodies. A 7mm thick midline sagittal slab was cut, and it was then separated into 2.5mm sections from the various defined regions of the disc (i.e., anterior annulus, anterior intermediate zone, nucleus pulposus, posterior intermediate zone, and posterior annulus). These were further cut into equally sized (2mmx4mmx7mm) sections through the use of a fine cutting block (approximately 50 mg each). Representative samples were extracted with 4 M guanidinium chloride for quantitation by immunoassay of 846 epitopes³ (a chondroitin sulfate epitope present on newly synthesized cartilage proteoglycan aggrecan molecules, and hence a putative marker of synthesis) and of C-propeptide of type II collagen (CPII, a marker of newly synthesized type II procollagen). In addition, the content of the C-propeptide of type I collagen (CPI, reflecting type I procollagen synthesis) was also measured on the same extracts (ELISA assay kit, Metra). Adjacent tissue blocks underwent alpha-chymotrypsin and proteinase K treatment to quantitate type II collagen percent denaturation². The third representative samples from each zone was dried at 110 C for 4 days to obtain the dry weight.

RESULTS

The results showed that the discs' synthetic ability, measured by the presence of the 846 epitope, the CPI and CPII contents, was at its highest in the neonatal (0-2 years) and in the juvenile groups (up to 15 years). Thereafter, the 846 epitopes and the CPII contents markedly diminished with increased

age. The CPI profile showed a more dramatic drop being at its lowest content already in the 15-40 years age group. Thereafter, it remained constant, except in the oldest age-group (60-80) or in high grade disc, where a significant increase was observed.

The percent of denatured type II collagen increased two fold when comparing the neonatal discs (0-2 age-group) to the young age-group (2-15 years old). Then, similar to the disc synthetic activity, it also rapidly decreased. However, in the oldest age-group (60-80), and in highly degenerated discs (Thompson gross morphology grade), the percent of denatured type II collagen was increased two fold.

DISCUSSION

This study examines the biosynthesis of type I and II procollagens, and the proteoglycans aggrecan (synthetic ability) in relationship to the denaturation of type II collagen (degradative processes) in the human lumbar intervertebral disc, with respect to growth, aging, and degeneration. The results suggest the presence of three distinct phases of matrix turn-over. Phase I is characterized by high synthetic activity of aggrecan and collagen I and II, associated with elevated levels of type II collagen denaturation, which are independent of disc degeneration (**growth phase**). Phase II features a drop in general synthetic activity along with a reduction in denatured type II collagen (**aging and maturation phase**). Phase III shows a grade dependent increase in collagen type II denaturation together with an increase in type I collagen synthesis, but not that of type II or aggrecan (**degeneration and fibrotic phase**). This identification of clearly recognizable changes in matrix turnover during growth, maturation and aging, and degeneration provide us with valuable new insight into disc pathology. This is an essential prerequisite for the identification of specific treatment modalities that may prevent or help contain excessive disc damage.

DEVELOPMENT OF THE INTERVERTEBRAL DISK

Jim Ralphs

School of Biosciences, Cardiff University, Cardiff, Wales, U.K.
ralphs@cf.ac.uk

INTRODUCTION

The intervertebral disk, consisting of the outer fibrous annulus fibrosus and inner cartilaginous nucleus pulposus, has a complex developmental origin. The initial pattern of disk-vertebral body-disk along the spine is set up in association with a cascade of expression of genes involved in embryonic axial pattern formation, notably PAX genes, which ensure that sclerotomally derived connective tissue precursors arrive in the right places and form the correct structures. This results in the fundamental pattern of the early spine: repeated longitudinal arrangements of loosely arranged mesenchymal cells, which will form the vertebral bodies, and dense condensation of cells, which will form the intervertebral disks, with the notochord running centrally through both. From this point onwards, discs become organised and differentiate, at least in part under mechanical regulation. I will concentrate mostly on the annulus fibrosus, although it should be noted that behaviour of the notochord and nucleus pulposus is crucial to annulus development and its later maintenance.

EARLY DIFFERENTIATION.

Within the disk condensations there is little extracellular matrix (ECM) and a large amount of cell-cell contact. The cells deep in the condensation, close to the notochord, tend to be larger and rounder than the more peripheral ones. The first sign of overt disk differentiation is the swelling of the notochord in the centre of each disk condensation to form the early nucleus pulposus. The swelling seems to be generated by pressure from the differentiation of the cartilage of the vertebral bodies, and probably triggers differentiation in the surrounding disk condensation: at the same time the inner part of the annulus fibrosus becomes cartilaginous, and the outer part fibrous.

DEVELOPMENT OF THE ANNULUS FIBROSUS

There are two important aspects of the subsequent development of the annulus fibrosus: the nature of the ECM made by the cells, and the way in which it becomes organised to form its functional collagenous lamellae.

Matrix composition. The inner part of the annulus forms an ECM containing markers typical of cartilage – type II collagen and the proteoglycan aggrecan, whereas the outer part contains type I collagen and versican, typical of fibrous tissues. This correlates with the later composition of the adult annulus. The cartilaginous nature of the inner annulus is associated with load experienced – it receives a large compressive load from the nucleus pulposus as the spine is compressed vertically by gravity and muscle action. The outer annulus is subject to more tensile and torsional loads due to bending and twisting of the spine, and thus contains predominantly tension-resisting extracellular matrix. The onset of this distribution in the

embryo may also be associated with loading. The expansion of the nucleus pulposus must compress the annulus at its inside and could thus promote cartilaginous differentiation, whereas at the outer annulus, cells must also be stretched because of the increased dimensions, promoting fibrous differentiation.

Matrix organisation. The outer part of the annulus fibrosus consists of a series of collagenous lamellae; each one contains parallel bundles of collagen fibres spiralling from one vertebral body to the next. Successive layers have their collagen fibres arranged at an angle of 50-60° to one another, forming a strong radial ply structure resisting pressure from the nucleus pulposus and tension and twisting from spinal movements. This structure arises at the earliest stages of disc differentiation. In the short period in which the notochord expands to form the nucleus pulposus cells become organised in the outer annulus: cells become arranged into parallel sheets, with the long axis of the cells in successive sheets alternating in angle by 50-60 degrees as do the collagen fibres in the adult annuli; the cell layers then deposit the oriented collagenous layers. Thus matrix orientation is preceded by cellular organisation. Cellular organisation occurs within 12 hours (in rat development) and is associated with the cytoskeletal component actin – cells develop large longitudinal actin stress fibres as they elongate and orient – and actin associated cell-cell junctions (adherens junctions). The pattern of cell-cell junctions seems to be important in determining the cell layers and cell orientation within successive layers. There is evidence of direct involvement of the cytoskeleton in orientation of deposited ECM. Actin stress fibres are associated intracellularly with the fibronectin receptor alpha5 beta1 integrin, which links to fibronectin fibrils on the cell surface which can subsequently bind collagen. Thus in addition to orienting cell sheets, the cytoskeleton has the potential to organise the early ECM deposited by the cells. Once orientation is established and collagenous lamellae become prominent, the actin stress fibres disappear. In the rat annulus, the whole process from cell orientation and stress fibre formation, to matrix deposition and loss of stress fibres takes only 4 days. At this stage, we assume that cells orient to the deposited matrix, rather than having to generate their own orientation. Whilst the above is based on rat embryos, the same histological sequence of events occurs in human annulus development and the same cellular mechanisms of development are likely to apply.

THE INFLUENCE OF MECHANICAL FACTORS ON INTERVERTEBRAL DISC DEGENERATION

J.C. Lotz

Orthopaedic Bioengineering Laboratory, Department of Orthopaedic Surgery
University of California
533 Parnassus Ave., San Francisco, Ca 94143-0514

INTRODUCTION

Intervertebral disc degeneration is defined by morphologic, cellular, and biochemical changes that commonly cause joint dysfunction and pain. Given the diversity of known risk factors, and the variability in which they present in back pain patients, the etiology and natural history remain poorly understood. From an epidemiologic perspective, repetitive spinal loading (e.g. manual materials handling) has been linked to increased rates of back pain and disc degeneration. To explore mechanisms of causality, our laboratory has developed an *in vivo* model system in which dose-response relationships between spinal stress and disc degeneration can be examined while minimizing the influence of confounding factors.

MATERIALS AND METHODS

Two types of external loading device (one static, one dynamic) were used to apply compression to the 10th coccygeal disc of Swiss Webster mice. To facilitate disc loading, two 0.4 mm diameter stainless steel pins were inserted percutaneously through adjacent vertebrae in each mouse tail. The static device consisted of calibrated elastics that applied one of three compressive stresses (0.4, 0.8 or 1.3 MPa) for variable durations (3 hrs through 7 days). The second device (Figure 1) consists of a ring-shaped latex bladder placed on the distal side of the subject disc, plastic washers and a cylindrical covering with a backing.

Inflation of the latex rubber bladder imparts disc compression. When the bladder deflates, the force is removed. An electronically controlled pressure valve mounted outside the animal's cage allows control of the pressure magnitude, duration and frequency. A flexible tube and swivel bridging the pressure generator and bladder permits the mouse free range of motion.

Dynamic exposures are applied 6 hours per day for 7 days. Discs were loaded according to a square wave function, which alternated between applied stresses of 0 MPa and one of two peak stresses (0.8 MPa or 1.3 MPa) at one of two frequencies (0.01 Hz or 0.1 Hz). For the remaining 18 hours each day, no load was applied.

Figure 1. Dynamic loading device

Outcome measures include histology to assess disc morphology, biomechanical testing to examine structural performance, *in situ* hybridization and TUNEL assay to investigate cell function, biochemical and

The results of these experiments clarify a number of dose-dependent cellular responses to spinal stress. These can be either anabolic or catabolic, depending on the specifics of the loading exposure. Importantly, the disc's viscoelastic nature leads to a complex pattern of tissue deformation. Correlation between temporal and spatial patterns of tissue deformation and cell function demonstrate that excessive tissue strain leads to cell death in both the nucleus and inner annulus. By contrast, intermediate dynamic deformations can lead to an anabolic response

Altered cell function, in turn, leads to changes in extracellular matrix and concomitant changes in biomechanical function. With excessive static compression or excessive dynamic stress, nuclear cell death leads to marked loss of disc height. At the same time, the inner annulus experiences loss of normal matrix architecture. Together, these architectural changes alter the disc's bending and compressive response leading to spinal instability.

Subsequent remodeling after load removal leads to an altered steady-state morphology that is characterized by loss of disc height, loss of distinction between the inner annulus and nucleus, and regions of fibrocartilage within the annulus fibrosus.

Dynamic loading experiments demonstrate effects of stress magnitude and frequency that are both anabolic (increased proteoglycan synthesis) and catabolic (increase cell death and enzyme activity). Interestingly, these were observed in the absence of any obvious structural damage.

DISCUSSION

This *in vivo* model system demonstrates that a number of morphologic features characteristic of aging and degeneration are induced by spinal stress. These occur in the absence of acute structural damage, which implies that disc remodeling is secondary to subtle load-induced changes in cell function that, over time, lead to altered tissue architecture and biomechanics. Which, if any, of these load-induced changes cause back pain remains unclear. Disc degeneration is common in asymptomatic humans, consequently, altered morphology by itself is an insensitive measure of disability. Future study is required to clarify mechanisms of discogenic pain and how these are linked to alterations in disc morphology and biomechanics.

Robert Jones and Agnes Hunt Orthopaedic Hospital NHS Trust, Shropshire, SY10 7AG, UK.
s.roberts.keele.ac.uk

INTRODUCTION

Intervertebral discs degenerate relatively early in the life of most mammals (Miller et al 1988) and in humans this process is associated with back pain. Disc extracellular matrix, like other tissues, is produced by cells within it. These cells are at a very low density compared to other tissues, but they are still responsible, not only for producing matrix, but also for breaking it down. The study of disc matrix and cells in health and disease provides insight into the normal equilibrium and how this might be disrupted in disc degeneration.

METHODS

Histological techniques have been used to study cell proliferation and cell death, synthesis and degradation of matrix components, in addition to the organisation of that matrix. Biochemical analysis of collagen crosslinks have been used to demonstrate collagen turnover (Duance et al 1998). *In vivo* and *in vitro* systems have been used in other laboratories to monitor the cells and their biosynthetic responses to changes in loading or other environmental factors such as osmolality.

RESULTS AND DISCUSSION

Disc degeneration is characterised morphologically by changes to the fibrous architecture and increased vascularisation and innervation. Clusters of cells occur due to cell proliferation (Johnson et al 2001) but there is also increased cell death. There is evidence for the production of newly synthesised extracellular matrix components (Roberts et al 1994) which, together with cell proliferation, could represent an initial repair phase. The production of degradative enzymes is present to some extent in virtually all discs but increasingly with degeneration. These include enzymes capable of degrading collagen, the collagenases (MMPs 1, 8 and 13) and proteoglycans (aggrecanases and

MMPs 1, 2, 3, 7, 8, 9 and 13; Roberts et al 2000). The elevated levels of enzymes is likely to be responsible for the increased degraded extracellular matrix components seen in degenerate discs (Antoniou et al 1996). Many of these changes can be induced in cells *in vitro* by varying mechanical and other factors (Ishihara and Urban 1999).

Hence changes seen in degenerate discs from patients with back pain are likely to have happened via the disc cells responding to stimuli such as altered incident loading or diminished nutrient supply.

SUMMARY

Disc degeneration results from disruption of the normal homeostasis of disc cell metabolism. There appears to be an initial repair phase, when cells increase their proliferation and synthesis of extracellular matrix. This is followed by a further shift of equilibrium towards the degradative processes when degeneration supercedes synthesis. It is important to understand the cell processes involved in disc degeneration and the sequence of and extent to which they occur and identify at what stage they might be reversible. This is necessary, not only for the successful development of pharmacological therapies, but also for the new generation of cell-based treatments and biological repair.

"FLEXIBLE" STABILIZATION OF THE SPINE - IS THIS THE FUTURE?

Thomas Nydegger

Biomechanical Analysis, Sulzer Orthopedics Ltd, Winterthur, Switzerland, Thomas.Nydegger@sulzermedica.com

OBJECTIVES OF "FLEXIBLE" IMPLANTS

For several decades the treatment of choice for degenerative spinal pathologies was the rigid fixation of the functional spinal units (FSU) to promote bony fusion. In recent years several alternative methods for dynamic stabilisation were suggested to restore and/or maintain the segmental motion to overcome certain disadvantages of fusion surgery. The main objectives for dynamic stabilisation of the spine are to eliminate donor-site morbidity, minimise stress on the adjacent segment, and to restore disc height and normal kinematics. Current concepts in the lumbar spine can be classified in three subgroups: partial disc replacement (i.e. nucleus replacement), total disc replacement and posterior dynamic stabilisation systems. The objectives of this presentation are to review current concepts, some pre-clinical data, and early clinical results with these techniques.

CURRENT CONCEPTS

Nucleus replacement: Two hydrogel concepts (AquarelleTM Stryker Spine; PDNTM Raymedica) and a polycarbonate urethane (PCU) spiral (NewcleusTM Sulzer Medica) are currently under clinical investigation. The hydrogel concepts aim to restore disc height by swelling due to hydration, whereas the spiral implant has a selection of fixed heights.

Total disc replacement: The three different concepts for total disc replacement are composed of two metal plates with a polyethylene inlay (SB Charité IIITM, W. Link GmbH; ProdiscTM, Spine Solutions Inc) or with a silicone elastomer core (AcroflexTM, Depuy Acromed). They completely replace the inner part of the disc; usually parts of the annulus are preserved. The biomechanical properties of the instrumented segment rely on the remaining part of the annulus and on the preservation of the facet joints and ligaments.

Posterior dynamic stabilisation systems: Graf ligaments consist of bilateral pedicle screws laced by an elastic PE tension band. They aim to stabilise the FSU by applying compression to the posterior complex of the spine. Another posterior device attempts to achieve normal kinematics and disc height by repositioning degenerative segments into a neutral position, (DYNESYSTM, Sulzer Medica). PCU spacers are inserted bilaterally between two pedicle screws to counteract compressive loads and PET cords are inserted through the core of the spacers and fixed in the screw heads to withstand tensile loads. This approach preserves the disc and facet joints and may unload these structures.

RESULTS AND DISCUSSION

Most of those devices have been under clinical investigation for several years and have shown promising short and midterm results [Blumenthal 2001, David 1999, Schwarzenbach 2000]. The ranges of indications of the different approaches are overlapping with each other and clearly also with current standard procedures. Nucleus replacement implants aim to address the problems occurring after herniation surgery, such as loss of disc height, increase of the annular bulge [Brinckmann 1991] as well as changes in the kinematics [Steffen 1991] and kinetics [Frei 1999] of the motion segment. Long-term results have yet to show improvement of clinical outcomes compared to the standard intervention. Total disc replacement implants have distinct benefits compared to fusion techniques. An in vitro study [Zollner 2001] has shown that after insertion of the implant, segmental mobility was restored to the intact situation. The maintained segmental motion may lead to lesser stresses on the adjacent segment, but it remains a rather invasive technique. From the posterior dynamic stabilisation devices, DYNESYSTM appears to be a promising system regarding the range of applications and clinical outcome [Schwarzenbach 2000]. Freudiger et al. reported the effectiveness of the system in the sagittal plane.

SUMMARY

Short and midterm clinical evaluations of these concepts have revealed promising results. However, scientific evidence for the long-term behaviour has yet to be shown. The often-heard analogy is that, "fifty years ago, hips were fused for degenerative problems, but the development of the low friction arthroplasty has superseded this treatment". Clearly, such a paradigm shift may be the future for the spine. In various parts of the world, "flexible" stabilisation for a number of indications is already a reality.

ANTERIOR AND POSTERIOR SPINAL FIXATION – AN *IN VITRO* SUMMARY

Peter A. Cripton

Exponent Failure Analysis Associates, Biomechanics Practice
2300 Chestnut St., Philadelphia, PA, USA, 19103
pcrition@exponent.com

INTRODUCTION

Surgical stabilization of the spine is performed for a variety of clinical indications including trauma, tumor, congenital deformity and pain, or neurological pathology secondary to degenerative changes. The ultimate goal of most of these procedures is to prevent motion at one or more intervertebral joints. This causes bony fusion to occur across the intervertebral discs and/or facet joints of the stabilized levels.

A wide variety of surgical techniques and implantable devices are currently used to provide the necessary stabilization in these areas. Techniques and implants have evolved which are specific for each region of the spine (cervical, thoracic and lumbar) and indication. For many indications, new techniques and implants are proposed with some frequency, and in these areas, the “state-of-the-art,” continues to evolve.

Biomechanical testing of these surgical techniques and implantable devices is an important step in the overall evaluation of their potential effectiveness in clinical practice. *In vitro* biomechanical testing using human cadaveric specimens is often used to model the immediate post-operative situation that these devices are exposed to. In this paradigm, the geometry of the human anatomy is used directly and then loads or displacements are applied to model particular loading cases representative of those believed to occur *in vivo*. Investigators have used this type of *in vitro* testing to compare existing devices, to evaluate devices prior to clinical introduction, and in attempts to establish the basic principles of operation of a device, device type or technique.

PRESENTATION SUMMARY

In this presentation, several common techniques and devices used for surgical fixation of the spine will be presented from an *in vitro* testing perspective. Emphasis will be placed on studies, which have elucidated the basic biomechanical mechanisms behind the function of particular types of anterior and posterior devices.

ANTERIOR TOPICS

In the anterior column of the spine, the most common surgical fixation techniques consist of anterior plates and devices which are inserted between the vertebral bodies such as interbody fusion cages or bone grafts.

Cervical Spine Strut Graft Mechanics

Analyses of the basic biomechanical function of anterior devices will be presented by considering anterior strut graft procedures in the cervical spine (Cripton *et al.*, 2002). A study in which load-sharing, stability and device loosening was quantified for three-level strut grafting of the subaxial cervical spine will be presented. The results of studies without defect-spanning anterior plates will be presented and compared to

similar studies, which included anterior plating. The likely consequences implied by these results with respect to the clinical performance of these techniques will be discussed and illustrated with references to the clinical literature.

Lumbar Interbody Fusion Cages

Studies focused on the biomechanical performance of posteriorly implanted lumbar interbody fusion cages (PLIF) from the perspective of compressive load bearing and multi-dimensional stability will be presented (Oxland *et al.*, 1996). Three diverse PLIF cages will be compared to evaluate the effect of cage design on biomechanical performance. The effect of cage design will be compared to other relevant parameters such as the presence of posterior instrumentation, bone mineral density and disc degeneration.

POSTERIOR TOPICS

In the posterior column of the spine, the most common surgical fixation techniques consist of rods or plates, which run longitudinally along the spine on either side of the spinous processes. These systems are usually connected to the underlying vertebra by transpedicular screws, hooks or wires.

Load-Sharing in the Stabilized Lumbar Spine

Longitudinal rods instrumented with strain gauges and intervertebral disc pressure sensors were used to study load-sharing in the stabilized lumbar spine segments (Cripton *et al.*, 2000). The results demonstrate the relative importance of specific anatomic structures to load-sharing in these systems as a function of the type of load applied.

Cross-Bracing of Posterior Fixation Systems

Cross-braces (also called transverse connectors) are available for the many contemporary posterior fixation systems. The biomechanical efficacy of these devices has not yet been definitively established. Two studies, which evaluated these devices using *in vitro* biomechanical techniques, will be presented (Lund *et al.*, 1998) and the application of these results within the clinical context will be discussed.

CONCLUSION

In vitro biomechanical studies have played a key role in evaluating the efficacy of contemporary spinal fixation techniques. This presentation will present several examples of the contributions made to this field using *in vitro* biomechanical techniques.

BIOMECHANICAL TESTING TO QUANTIFY ADJACENT-LEVEL EFFECTS

Manohar M. Panjabi

Department of Orthopaedics and Rehabilitation, Yale University School of Medicine, New Haven, CT

INTRODUCTION

To test spinal fixation devices using spine specimens, the flexibility protocol is often used. Here independent load components are applied individually in multiple directions and the resulting three-dimensional motions are recorded (Panjabi et al 1976, Panjabi 1988). Alternatively, in the stiffness protocol, independent displacement components are applied individually in multiple directions and the resulting six load components are measured. Which of the protocols is most suitable for studying adjacent-level effects in a specimen? There are some clinical observations to help in this decision. Patients, after a solid fusion, have been found to demonstrate approximately the same range of motion as before the fusion, between the body parts surrounding the fusion level, e.g. between the head and trunk for the cervical fusion. Thus, the motion between the body parts should be the independent parameter. The stiffness protocol seems to fit the bill. But there are several important, theoretical and practical, limitations to the use of the stiffness protocol as documented in some recent studies. The purpose of this presentation is to explore a hybrid protocol, from the viewpoint of its use in quantifying the adjacent-level effects due to an intervention at one or more levels. For example, the intervention may be an injury, a fusion or a disc replacement.

METHODS

The stiffness protocol requires the application of one independent motion component, out of a total of six, to the spine specimen, and measurement of the resulting six load components in the specimen. This brings up several issues and points to the disadvantages of this protocol type. First, how to apply a single component of motion, while blocking all other five motion components? If the motion component is one of the three rotations, then how is the axis of rotation chosen and defined uniquely within the spine anatomy? It has been shown that the axis of rotation makes a significant difference to the measured load displacement curves. Similar choices must also be made for each of the three translation components. Second, how to apply a displacement component, which does not cause tissue injury? Injuries have been documented using the stiffness protocol. Third, having applied a displacement component where and how to measure the resulting six load components in the spine specimen? Finally, the human spine *in vivo* does not move with one independent motion component alone, but moves naturally, for example during the flexing of the spine, the motion includes inferior and anterior translations and flexion rotation. It is easy to see that the requirements just mentioned, makes the stiffness protocol difficult to carry out.

RESULTS

An alternative is proposed, which uses a hybrid approach. This consists of two steps. As an example, let us assume that we are interested in the adjacent-level effects due to an intervention: fusion or a disc replacement at C4-C5 in the cervical spine. Assume further, for the sake of simplicity, that we want to study flexion and extension of the neck. Step 1. Using the flexibility protocol, apply unconstraining pure flexion and extension moments to the intact spine specimen, which result in motions similar to the physiological motions observed *in vivo*. Note the overall ranges of main motions. Step 2. Apply the same moments to the spinal construct (specimen plus the simulated fusion or artificial disc implantation), but this time the magnitudes are adjusted to obtain the same overall ranges of main motions as when the specimen was intact. During both the Steps, the responses of the spinal elements of interest, e.g. the motions and strains in discs and vertebrae, are monitored. The changes in the responses between the intact specimen and spinal construct constitute the adjacent level effects due to the intervention.

DISCUSSION

One of the advantages of this approach is that there is no need to determine before hand the axis of rotation around which the rotation is applied, as the stiffness protocol would require. Being unconstrained, the rotation axis is naturally floating as a response to the externally applied pure moment. As the specimen reaches the same end point in Steps 1 and Step 2, the protocol mimics the *in vivo* clinical observations mentioned earlier. There are some specifics associated with the hybrid protocol. Firstly, to mimic the *in vivo* situation, the ideal specimen length should be the same as the *in vivo*, e.g. whole cervical spine, for the fusion at C4-C5. Secondly, the motion between the body parts has six degrees of freedom. Therefore, in an ideal protocol, all the six degrees of freedom should be match between Step 1 and Step 2. Of course, each experimental design is a compromise, which balances the ideal against the practical.

IN VIVO LOADS ACTING IN THE SPINE AND IN SPINAL IMPLANTS

Hans-Joachim Wilke¹, Antonius Rohlmann², Georg Bergmann², Lutz Claes¹

²Biomechanics Laboratory, University Hospital Benjamin Franklin, Free University of Berlin, Germany, rohlmann@biomechanik.de

INTRODUCTION

In order to design spinal implants or to improve the methods to test them the load acting on the spine or in the implants during daily activities and in extreme situations have to be known. Unfortunately still few data are available.

In vivo data directly determined in the spine or indirectly with spinal implants are known from only few studies due to ethical reasons. The most known data came from intradiscal pressure measurements in the 60s and 70s (1), which were complemented with dynamical measurements only in 1999 (5). Implant loads were first measured exemplarily with an external fixator (4) and later extensively in internal fixators (2).

The objective of this paper is to summarize and compare results from these independent *in vivo* studies applying different methods to provide information about loads acting in the spine or its implants.

METHODS

The early intradiscal pressure measurements were performed with some twenty volunteers by inserting a stiff needle with an integrated pressure sensor into the center of the disc (1). The recent intradiscal pressure values were measured in only one volunteer with a similar technique but using a flexible transducer (5). They were recorded with a telemetry system over a period of 24 hours during daily activities, physiotherapy and manipulations, and during some sports activities.

Loads in the external fixator were measured indirectly through the deformation of the Schanz screws with strain gauges which allowed the estimation of loads in the spine (4). Internal fixator loads (three force components and three moments) were measured in the modified and telemeterized longitudinal rods of the bisegmental implant in ten patients in similar situations as above. This allowed a quantitative comparison of the pressures and the fixator loads for many different static and dynamic activities when normalized to standing (3).

RESULTS

For the pressure in the nucleus we found for lying in prone position 0.1 MPa, lying laterally 0.12 MPa, relaxed standing 0.5 MPa, standing flexed forward 1.1 MPa, sitting unsupported 0.46 MPa, sitting with maximum flexion 0.83 MPa, nonchalant sitting 0.3 MPa, lifting a 20 kg weight with round flexed back 2.3 MPa, with flexed knees 1.7 MPa, and close to the body 1.1 MPa. During the night, pressure increased from 0.1 to 0.24 MPa. 2.3MPa was the highest pressure for all situations measured. Although it is difficult to calculate spinal load directly from the pressure values they may be converted approximately by multiplying the pressure

with the cross-sectional area of the disc which was 18.2 cm² (e.g. lifting 20 kg with back flexed creates 2.3 MPa ca. 4200N).

Implant loads differed considerably from patient to patient depending, for example, on the indication for surgery and the surgical procedure. They were altered by anterior interbody fusion. Mostly, only small differences in implant loads were found for the various lying positions. Flexion bending moments were significantly higher in upright than in lying body positions. Loads on the fixators were not higher for sitting than for standing.

The results show that fixators may be highly loaded even after fusion has occurred. A flexion bending moment acts on the implant even with the body in a relaxed lying position. This means that already shortly after the anterior procedure, the shape of the spine is not neutral and unloaded, but slightly deformed, which loads the fixators. Pedicle screw breakage more than half a year after insertion does not prove that anterior interbody fusion has not occurred. The maximum bending moments were around 10 Nm.

DISCUSSION

During many exercises the new intradiscal pressure measurements showed a good correlation with Nachemson's data, but not in the comparison of standing and sitting or of the various lying positions. These differences may be explained by the use of different transducers in this study and those from before.

The normalized values of the new intradiscal pressure values and fixator loads corresponded in most cases. Both studies showed slightly lower loads for sitting than for standing and comparable low loads in all lying positions. Different relative values for intradiscal pressure and fixator loads were found when the load was predominately carried by the anterior column, as during flexion of the upper body or carrying a weight.

These few studies provide some absolute values for the load acting in the spine and the forces and moments seen by the implant. The combination of these two methods improves the understanding of the biomechanical behavior of the lumbar spine and the results may be used to design new implants or new testing procedures.

SPINAL FIXATION FROM A CLINICAL PERSPECTIVE

Marcel Dvorak, MD, FRCSC

Combined Neurosurgical & Orthopaedic Spine Program
Vancouver Hospital and Health Sciences Centre
Department of Orthopaedics
University of British Columbia
Vancouver, BC, Canada

INTRODUCTION

Internal spinal fixation is widely used to maintain spinal alignment and facilitate a solid osseous union. Common clinical problems include degenerative conditions such as lumbar scoliosis, spondylolisthesis, and internal disc derangement. Other conditions that frequently require internal stabilization include trauma, iatrogenic spine instability, and tumors. Major deformity correction also requires stabilization.

The surgeon is faced with a number of uncertainties while pre-operatively planning the approach and technique of fixation. In vitro biomechanical studies should assist in providing guidance to the surgeon. Some of the most frequently encountered clinical questions include:

1. When is anterior column support necessary in addition to posterior fixation?
2. What degree of posterior stability is necessary to enhance osseous union?
3. When is anterior instrumentation alone inadequate?
4. How to best optimize the implant-bone interface?

METHODS

A variety of clinical case examples focused on the cervical and thoraco-lumbar spine will be presented to highlight pertinent fixation issues. The clinically relevant unresolved issues relating to spine fixation will be outlined.

RESULTS AND DISCUSSION

Cervical Spine:

Traumatic injuries to the posterior and anterior elements of the cervical spine from C3-T1 have been successfully treated by anterior or posterior instrumentation alone, as well as by combined anterior-posterior fixation. Although posterior fixation has been reported to be superior to anterior in in-vitro testing, the clinical success seen with anterior stabilization alone questions the relevance of these studies. Newer dynamic anterior plate designs further confuse the indications for anterior alone or anterior-posterior fixation, particularly in long segment anterior fusions.

Thoraco-lumbar Spine:

Following vertebrectomy, the anterior column may be stabilized using autograft, allograft, or prosthetic replacements. Anterior and posterior fixation methods may sacrifice stability if the short segment fixation relies on few anchor points, but may be plagued by adjacent segment degeneration and instability if longer constructs are used. These questions gain further relevance in osteoporotic bone.

Many fixation challenges relate to failure at the implant-bone interface, particularly in osteoporotic bone. Revision and de-novo surgery is often complicated by less than ideal fixation to bone.

Degenerative conditions in the lumbar spine have been treated with anterior 'stand alone devices', posterior fixation alone, and circumferential arthrodesis. The optimal degree of added "surgical stability" necessary in many of these conditions is debatable. Lack of correlation between the clinical outcome and radiographic osseous union continues to fuel this debate.

SUMMARY

By presenting some clinical examples of unresolved spine fixation issues, it is expected that efforts may be directed at providing guidance to clinicians in choosing fixation constructs and approaches.

The development of new products should also keep these clinical issues uppermost.

BIOMECHANICAL TOOLS TO UNDERSTAND AND PREDICT THE EFFECTS OF INTERVENTIONS IN SCOLIOSIS

1- Dept. Mechanical Engineering, Ecole Polytechnique; 2- Sainte-Justine Hospital; Montreal; carl-eric.aubin@polymtl.ca

INTRODUCTION AND OBJECTIVES

Scoliosis is a complex musculoskeletal disease requiring treatment in moderate and severe cases. To investigate correction mechanisms, it is necessary to evaluate not only the geometry from imaging techniques, but also to assess the loads acting on the trunk and how they contribute to spine correction. This paper presents some biomechanical modeling applications to study the effects of intervention in scoliosis.

BRACE TREATMENT INVESTIGATIONS

The biomechanics of the Boston brace was studied using finite element models (FEM) and experimental measurements. Pressures generated by the brace on the torso and the strap tension were measured using 192 thin pressure sensors and force cells. They were used as input into a personalized FEM built using a multi-view radiographic reconstruction technique (Aubin et al., 1995). The brace treatment was simulated: 1) by applying equivalent forces calculated from the pressures; 2) by an explicit representation of the brace and its interface (contact elements) with the torso (Fig. 1), and a 3-step simulation: 1) brace opening to include the trunk; 2) brace closing; 3) strap fastening. The simulations were compared to the geometry of the patient wearing a brace by means of several geometrical indices. Simulation results showed the feasibility and the validity of such modeling approach, and pointed out the major influence of the boundary conditions.

Fig 1 – FEM of the trunk and brace

The FEM also was used to investigate the coupled mechanisms between the scoliotic spine and the rib cage subjected to brace loads (Aubin et al., 1997). Coupled mechanisms were found between the spine and rib cage. For instance, loads on the posterior rib hump tends to reduce sagittal curvatures (flat back phenomenon), and to increase the coronal deformation of the thoracic curve. FEM also was used to test novel orthotic approaches. An original concept consisting in applying differently the loads on the thorax was proposed and investigated. Optimization of brace treatment was realized by Gignac et al. (2000) to find the most favourable corrective load patterns in 3D. Optimal forces were mostly located on the convex side of the curve (postero- and antero-laterally), but they differed depending on patient shape. This study pointed out the usefulness of biomechanical modeling and optimization approach to develop better individualized brace design.

SPINE SURGERY SIMULATIONS

The biomechanics of scoliosis surgeries was studied using the FEM personalized using patient's 3D reconstruction. The C-D instrumentation procedure was simulated in 4 steps, similarly as in Gardner-Morse (1994): 1) installation of hooks/screws on instrumented vertebrae (calculated using geometric transformations from the post-op to the pre-op configuration). Links between the vertebrae and the hooks/screws were considered rigid. 2) translation and attachment of the hooks/screws on the

first rod on the concave side. Hooks and screws were free to rotate around the longitudinal axis of the rod. The 3D rod shape was obtained from a -90° rotation from the post-op reconstruction. 3) rod rotation (90°), hooks/screws lock up, and spring back (removal of the applied torque). 4) translation and attachment of the hooks/screws on the second rod on the convex side (idem step 1) followed with hooks/screws lock up. Good agreement was found between simulated and 3D reconstructed post-operative geometry of the spine (difference of 2° for the kyphosis, 6° for the Cobb angle). At the apical vertebra, traction loads were found in the ribs on the concave side of the curve, while on the convex side, lower compression loads were observed. Thus, the rib cage acts as a buttress on the spine leading to counteract the correction provided by the instrumentation stiffness and the surgical maneuvers. Biomechanical modeling also was used to simulate various designs of costoplasties. Gréalou et al. (2002) analyzed different procedures (side, location, length, and number of ribs to resect or to graft), to investigate their biomechanical effect and to also test corrective mechanisms involving the rib cage.

FEM has shown limitations to simulate surgical instrumentation, especially because of the difficulty to represent a discontinuous structure and the stiffness difference within components (mechanism). A novel approach using a kinematic model including flexible elements to represent each motion segment was developed to simulate the instrumentation maneuvers (Fig. 2) (Poulin et al., '98). This model is quite equivalent to the FEM, however it allows a much better and realistic way to model the instrumentation. Good agreement also was found between the simulated and 3D reconstructed post-op geometry (< 5° for the kyphosis and Cobb angle). We also found that boundary conditions were the most influential parameters, followed by individualized mechanical properties.

Fig 2 – Surgery model (flexible multi-body)

CONCLUSION

Biomechanical models, used under well understood conditions, are practical tools to understand and assist with orthotics and pre-operative planning, to test and build more efficient (rationalized) treatments.

INTERVERTEBRAL DISC STIFFNESS - PERSONALIZED VALUES AND USE IN SURGERY SIMULATION

W. Skalli¹, J. Dubousset², V. Lafage¹, and F. Lavaste¹

¹Laboratoire de Biomécanique, ENSAM, Paris, France (wafa.skalli@paris.ensam.fr)

¹Hôpital Saint Vincent de Paul, Paris, France

INTRODUCTION

Management of scoliosis and its treatment requires a good understanding of the behavior of the intervertebral spine soft tissues (mainly discs) for two reasons: 1/ the degree of correction depends on the specific stiffness of the segments included in the fusion, and 2/ the post correction behavior is related to stiffness of the remaining unfused segments. In vitro experiments and quantified clinical analysis can yield estimation of intervertebral stiffness. Finite Elements modeling helps to quantify stiffness and to study its effect on the behavior of the scoliotic spine during surgery.

METHODS

In vitro experiments: In the Ensam Biomechanics Laboratory, quantification of three dimensional load displacements curves has been performed since 1986, for more than two hundred functional units from the cervical, thoracic and lumbar spine. Results allow us to assess the range of variation in the behavior of non-scoliotic spines. These data form the basis of a global finite elements model of the spine used for surgery simulation (Leborgne & al. 1998, Lafage & al. 2001).

Clinical analysis: preoperative bending tests are routinely performed in St Vincent de Paul Hospital prior to surgery for scoliosis. The finite elements model is used to simulate these bending tests, and then the soft tissues mechanical characteristics of the model are adapted to achieve a simulation that renders the specific vertebral motion of a given patient. A first difficulty in this process concerns the reliable quantification of 3D vertebral rotations measurements from single plane bending Xrays. But the main difficulty is in assessing the proper mechanical characteristics for a patient. In the numerous simulations we performed for many patients, we observed that a very local change in disc stiffness often results in a modified response of the whole spine. These investigations yield progressive understanding of the very complex behavior of this mechanical system. We used a detailed model to complement the understanding of these phenomena (Lafage & al. 2001): geometric modification (wedging of vertebrae and discs does not explain this modified stiffness in scoliosis, which is probably related to physical changes in the tissues).

Pre and postoperative global analysis of posture and motion of the scoliotic subject are of high interest because they provide the pattern of motion of the unfused segments, before and after surgery. Indeed, the result of surgery depends on what has been done at the fused level, but also on the situation of the remaining unfused parts: disc height, stiffness, symmetry, and hip capability to compensate a part of the lost

spine motion. Considering spine 3D configuration with regard to the gravity line (Champain & al. 2001) is of particular interest, to consider spine balance and predictions of loads on the remaining discs.

Finite elements modeling is used in clinical research to understand surgery effects. Once the model is considered as representative of the patients spine, both for geometry and intervertebral stiffness, it can be used to investigate alternative possibilities of surgery correction. As an example, Figure 1 shows for a specific patient four virtual postoperative configurations resulting from alternative placement of hooks. Some of them yield undesirable global spine imbalance, or local excessive motion.

Figure 1: Four surgical strategies for the CD virtual correction

CONCLUSION

Intervertebral soft tissues are essential in biomechanics of the scoliotic spine. The use of personalized geometric and mechanical models allows us both to investigate the behavior of these tissues, and to analyze the effect of surgical treatment.

INTRODUCTION

Several hypotheses relate muscle activation with the control of body posture. Some propose that differing postures of the limb are produced by vector summation of several basic force fields, attractors, or primitives [1] or are combined of memorized postures with some weight coefficients [2]. For example, consider two force fields that in the absence of external loads stabilize the limb at two different configurations. Summation of these fields will produce an intermediate configuration with zero net torques at each joint. The resulting zero torque, created by the summation of opposing torques from the two fields, implies coactivation of two opposing muscle groups. This means that many postures of the body cannot be maintained without coactivation although empirical observations show that coactivation and postural control are in principle separate. One can easily co-activate and de-activate opposing muscle groups of the arm without changing arm configuration.

CONTROL LEVELS

Thus, control levels likely reset the initial postural attractor to a new point in space, rather than combining different attractors. Such a postural resetting mechanism for movement production was postulated based on the finding [3] that EMG activity of a single muscle occurs when its length exceeds a referent (threshold) length. It has been suggested that, by appropriate tuning of the intermuscular interaction mediated by proprioceptive afferents and appropriate spinal and supraspinal neurons, the nervous system specify a single threshold configuration of the body for all skeletal muscles. This threshold configuration may be considered a virtual, referent configuration (R) with which actual body configuration (Q) is compared. The muscles will be silent at the R configuration but will generate EMG activity and forces resisting from deviations of the body from it [4,5,6]. Physiologically, this resistance results from position- and velocity-dependent muscle forces strengthened by homonymous and heteronymous proprioceptive reflexes functioning according to the spatial thresholds determined by the R configuration. Control levels may change the R configuration and thus influence the difference between the Q and R, resulting in the generation of muscle forces. The system will then move until a final body posture is reached. The R hypothesis has been used to simulate trunk motion in healthy and scoliotic subjects.

APPLICATION TO SCOLIOSIS

The λ model for multi-muscle and multi-joint systems has been applied to the study of recruitment patterns in scoliosis patients. A biomechanical model representing the osseoligamentous structures of the trunk [7] has been complemented by the introduction of 160 muscle fascicles from the main agonist and antagonist muscles involved in lateral bending movement. The model geometry is personalized to the subjects using 3D reconstructions from multi-planar radiographs. Control commands in this finite element model of the trunk

were generated in accordance to the R hypothesis. Global movement involving the whole body from an initial to a final position (Q) is therefore a consequence of a change from an initial to a final R configuration, implying the modification of the 160 recruitment thresholds ($R_i = \{\lambda_{1,...,\lambda_{160}}\}_i \rightarrow R_f = \{\lambda_{1,...,\lambda_{160}}\}_f$) [8]. Right lateral bending test was investigated in scoliotic patients because it reflects the spine mobility in relation to thoracic scoliosis curve opening. Differences, in comparison to healthy subjects, were first observed as local disruptions in the recruitment patterns for right and left multifidus fascicles crossing the thoracic apex vertebra. Secondly, hyper recruitment was observed for left and right iliocostalis thoracis pars thoracis fascicles crossing the apex level (Figure 1). In particular, hyper-facilitation of agonists on the convex side and hyper-inhibition of antagonists on the concave side has clearly been noticed [9]. Correlation matrix analysis also revealed that the generation of central commands for healthy subjects was strongly correlated with the amplitude of the bending task ($r^2 = 0.92$) but the same relationship was much weaker for scoliotic subjects ($r^2 = 0.58$). This implies that the command-position relationship complexity could depend on geometry and may indicate that position is controlled differently in scoliosis patients.

Figure 1. Recruitment patterns of the left and right iliocostalis for scoliotic (dark curves) and healthy subjects (light curves).

CONCLUSION

This model provides also a framework for the study of the biomechanical effects of these fascicle recruitment patterns on the spine, and the investigation of the relation between the possible resulting adverse stresses on the vertebrae and the progression of the scoliosis deformities.

INTRODUCTION

Idiopathic scoliosis is known as a spinal irregularity with lateral curvatures. Considering function of the spine supporting body, investigation from mechanical aspect lays the foundations for investigation of etiology and development of treatments. However, the structure of spine is not so simple. So the finite element modeling and analysis play a key role as means of the investigation. This presentation describes how to construct a finite element model of the spine, how scoliotic deformations emerge and grow, and how to reinforce the spine structure to prevent the scoliotic deformations from the purely mechanical aspect.

HOW TO CONSTRUCT SPINAL FINITE ELEMENT MODEL

The spinal finite element model was constructed using a commercial spine surface data (Viewpoint Premier, catalog num. VP2886 and VP361). The material properties of bones were assumed using data by Yamada (1970). Material properties of disks and joints were identified by comparing with the experimental results by Lucas and Bresler (1961), Markolf (1972) and Schultz et al (1974) (Takeuchi et al 2001).

HOW SCOLIOTIC DEFORMATIONS EMERGE AND GROW

Using the spinal finite element model, buckling phenomena caused by the growth of vertebral bodies were analyzed by a commercial finite element analysis program (MSC.Nastran v.70). The growth was simulated by generating initial strain (thermal strain). Displacement was fixed only on the adjacent surface with sacrum. Figure 1 shows part of the results of the fourth and the sixth buckling modes. The shapes of the fourth and the sixth buckling modes accorded with the clinical shapes of single and double curves respectively.

A simulation of the progression of scoliosis was demonstrated by the authors (Goto 2000).

HOW TO REINFORCE TO PREVENT THE SCOLIOTIC DEFORMATIONS

If the buckling hypothesis is acceptable, sensitivity function with respect to the critical growth of thoracic vertebrae on the maximization problem of buckling load with the fourth and the sixth buckling modes gives us useful information to

improve and develop treatments for the idiopathic scoliosis. Figure 2 shows part of the computational results of the sensitivity function.

Fig. 1 Buckling modes: Fourth mode caused by growth of T4 to T10 (left) and Sixth mode by growth of T1 to L5 (right) (Takeuchi, et al. 2000).

Fig. 2 Distribution of sensitivity with respect to fourth buckling mode caused by growth of T4 to T10 (Takeuchi et al 2001).

BIOMECHANICS IN IDIOPATHIC SCOLIOSIS ETIOLOGY

V James Raso

Capital Health Authority, Glenrose Rehabilitation Hospital, Edmonton, Alberta, Canada
jraso@cha.ab.ca

INTRODUCTION

Biomechanical factors have been suggested to play a part in the etiology of idiopathic scoliosis and certainly play a significant role in its progression. Static mechanisms such as the constituent properties of the tissues, shape of the structure, loads on the spine or the spinal support conditions may cause a scoliosis to develop.

CONSTITUENT PROPERTIES OF THE SPINAL TISSUES

Significant differences in bone quality in patients with idiopathic scoliosis have been observed at sites that presumably are unaffected by the scoliosis, eg. the femoral neck, and so these differences may reflect an etiology rooted in the bony anatomy of the spine. Studies of soft the soft tissues suggest that joint laxity may contribute to the development of idiopathic scoliosis [2]. If general joint laxity is a primary cause of IS then a collage defect is a strong candidate as the source for the defect but Carr et al [3] found evidence against this.

ABNORMAL LOADING ON THE SPINE

Sevastik suggested that asymmetrical rib growth led to unusual lateral loading on the spine and the development of scoliosis [1]. The work culminated in a recent paper describing unilateral rib resections in the successful treatment of a scoliosis [6].

HYPOKYPHOSIS AND THE DEVELOPMENT OF SCOLIOSIS

Scoliosis may develop in an otherwise normal child if the spine is hypokyphotic and the child undergoes a sharp growth spurt. Scoliosis develops when the growth of the anterior aspects of the body is greater than posterior growth [5]. In this case, the spine loses the protection of a kyphotic shape and may buckle. The direction of the collapse depends on local conditions but is often determined by the lateral pressure exerted by the aorta. Dickson provides considerable circumstantial evidence in support of his thesis. Progress of the scoliosis is controlled by the extent of asymmetry caused by the rotation of the vertebrae [4].

Although considerable effort has been directed to understanding the importance of the sagittal profile to the development of scoliosis in the thoracic spine, very little work has been done on lumbar scoliosis.

SUMMARY

The lack of a good animal model to study the mechanics of the upright spine has made it difficult to prove many of the biomechanical theories of adolescent idiopathic scoliosis. Many of the animals used to model adolescent idiopathic scoliosis will develop scoliosis in response to numerous intervention and care must taken in generalizing results based on these studies to the people.

Spinal stability as a mechanical process involves continuous re-alignment of the spine based position sensing on both a local and on a global level. There is no strong evidence to support any particular biomechanical factor in the etiology of idiopathic scoliosis. Much of the evidence is contradictory and the reviewed papers were consistently weak in statistical analysis. Conclusions drawn from animal studies are difficult to transfer to humans because of the very different nature of the relevant mechanics in the two groups. There is little scientific evidence that biomechanics plays a direct role in the etiology of idiopathic scoliosis.

ANGIOGENESIS AND HEALING IN RABBIT KNEE LIGAMENTS

Robert Bray¹, Catherine Leonard and Paul Salo

Department of Surgery, University of Calgary, Calgary, Alberta, Canada

¹ Communicating author, rcbray@ucalgary.ca

INTRODUCTION

In clinical terms, functional recovery after anterior cruciate ligament (ACL) injury is generally poorer than after medial collateral ligament (MCL) injury. In experimental studies after induction of “damage” the early phases of ligament healing require an adequate vascular response in the form of augmented blood supply (Bray et al 1996; Frank et al 1999). In this study, we hypothesized that the differences in healing properties of the ACL and MCL would be reflected in their respective vascular responses to partial injury. This study therefore examines changes in ligament vascular volume following hemisection of the ACL and MCL.

METHODS

Standardized injuries were surgically induced in adult rabbit knees ligaments: partial ACL transection or partial MCL transection. Two, 6 or 16 weeks later, the vascular volume (a measure of microcirculation capacity) of the ACL and MCL were measured using carmine red dye infusion (McDougall and Bray 1998). Ligament blood flow was also measured using coloured microspheres. The results were examined in experimentally injured, control and sham operated animals.

RESULTS AND DISCUSSION

The mean vascular index for the MCL in control animals was $5.57 \pm 1.04 \mu\text{l/g}$ ($n=6$), while that of the ACL was $0.91 \pm 0.33 \mu\text{l/g}$ ($n=6$). In response to hemisection, the MCL showed a large significant increase in vascular index ($\mu\text{l/g}$) that was apparent at 2wk after injury, peaked at 6wk (5-fold increase, $p<0.001$) and was no longer different from sham operated animals by 16wk (Figure 1). In contrast, hemisected ACLs showed a significant sustained two-fold ($p<0.01$) increase in vascular index induced by injury (Figure 2).

The MCL showed significant increases in mass and water content 2 and 6 wk post-injury. In contrast, the water content of the ACL was unchanged from control values, and the mean mass was significantly decreased by 16 wk (Table). Results of blood flow are incomplete but will be presented.

SUMMARY

Ligament injury of the ACL and the MCL induces increased blood supply to healing tissue. The ACL and MCL show increases in vascularity in response to hemisection, but the MCL shows a much larger peak of angiogenesis during early scar formation at two to six weeks after injury. Water contents increased only in MCL tissue and paralleled the increased vascular volume observed in this structure.

Figure 1: Vascular index of the medial collateral ligament following direct ligament injury (hemisection).

Figure 2: Vascular index of the anterior cruciate ligament following direct ligament injury (hemisection).

	Control	2 week	6 week	16 week
MCL mass (mg)	85±3	199±11	147±9	119±8
MCL water (%)	63.2±1.3	74.7±9.4	72.2±1.1	66.7±1.6
ACL mass (mg)	44±3	56±3	36±2	34±4
ACL water (%)	66.2±1.8	66.2±1.0	66.8±1.8	67.4±1.7

THE EFFECT OF GROWTH FACTORS ON MECHANICAL PROPERTIES OF THE *IN SITU* FROZEN-THAWED LIGAMENT AND GENE EXPRESSION OF COLLAGEN IN EXTRINSIC FIBROBLASTS

Harukazu Tohyama and Kazunori Yasuda

Department of Medical Bioengineering & Sports Medicine, Hokkaido University School of Medicine, Sapporo, Japan,
tohyama@med.hokudai.ac.jp

INTRODUCTION

A number of studies have shown that, in the tendon autograft for ligament reconstruction, extrinsic cell infiltration occurs following intrinsic fibroblast necrosis, and that its mechanical properties are subsequently deteriorated. However, much remains unknown on the mechanism of the mechanical deterioration of the tendon autograft. Recently, many studies have reported that various growth factors regulate collagen-matrix metabolism in fibroblasts. Then, we have conducted two studies using the *in situ* frozen-thawed tendon and ligament, which have been established as idealized models of the autograft, in order to investigate the mechanism of the deterioration of the tendon autograft. The aim of the first study was to clarify the *in vivo* effect of administration of platelet-derived growth factor BB (PDGF-BB) and transforming growth factor beta 1 (TGF-beta1) on the mechanical properties of the the *in situ* frozen-thawed anterior cruciate ligament (ACL). The purpose of the second study was to elucidate the *in vitro* effect of these growth factors on gene expression of collagen in extrinsic fibroblasts derived from the *in situ* frozen-thawed patellar tendon (PT).

METHODS

Study I (*In vivo* biomechanical evaluation): In skeletally mature Japanese White rabbits, the *in situ* freeze-thaw treatment with a specially designed mini-cryoprobe was applied to the right ACL to kill intrinsic fibroblasts. Then, the rabbits were divided into three groups. In Group I, 400-ng rh-PDGF-BB was applied with 0.2-ml fibrin sealant around the frozen-thawed ACL. In Group II, 4-ng rh-TGF-beta1 was applied with 0.2-ml fibrin sealant in the same manner. In Group III, 0.2-ml fibrin sealant was applied as a control. All rabbits were sacrificed at 12 weeks after treatment. The cross-sectional area (CSA) of the ACL was determined with the optical method using a video dimension analyzer (VDA). Tensile tests for the femur-ACL-tibia complex were performed with non-contact measurement of ligament strain using a VDA.

Study II (*In vitro* evaluation of gene expression): In 16-week old Wistar rats, the *in situ* freeze-thaw treatment was applied to the right PT. At 6 weeks after the treatment, bilateral PTs were excised. Using the explant culture technique, we isolated extrinsic and normal fibroblasts from the frozen-thawed and non-treated PTs, respectively. Following the addition of rh-PDGF-BB or rh-TGF-beta1 under serum-free medium, the cell samples were collected at indicated times and total RNA was extracted. Then, Northern blot hybridization was performed to evaluate the effect of each growth factor on mRNA levels of types I and III collagens.

RESULTS

Study I: The CSA of Group II was significantly smaller than that of Group III, while there were no significant differences between Groups I and III (Figure 1-a). The elastic modulus of Group II was significantly higher than that of Groups I and III, while there were no significant differences between Groups I and III (Figure

1-b).

Study II: PDGF-BB or TGF-beta1 significantly increased mRNA levels of both collagens up to 36 hours. The effect of each growth factor was dose-dependent. TGF-beta1 stimulation significantly increased the ratio of type I collagen mRNA to type III collagen mRNA (I/III ratio) in both types of fibroblasts (Figure 2). However, PDGF-BB did not significantly affect the I/III ratio in extrinsic fibroblasts, although PDGF-BB significantly increased the ratio in normal fibroblasts.

DISCUSSION

The first study demonstrated that administration of TGF-beta1 has an significant inhibitory effect on the mechanical deterioration in the *in situ* frozen ACL *in vivo*, but that PDGF-BB does not have it. The second study showed that TGF-beta1 significantly increases the I/III ratio in extrinsic fibroblasts. In contrast, PDGF-BB does not increase the I/III ratio in extrinsic fibroblasts, although it significantly increases the ratio in normal fibroblasts. It is well known that the ratio of type I collagen to type III collagen is much lower in the scar tissue than that in the normal ligament tissue. Therefore, this study suggested that the inhibitory effect of application of TGF-beta1 on the mechanical deterioration in the *in situ* frozen ACL may be caused by an increase in the ratio of type I collagen to type III collagen, which is induced by extrinsic fibroblasts.

THE USE OF ROBOTIC TECHNOLOGY IN THE DETERMINATION OF *IN SITU* FORCES IN LIGAMENTS

Savio L-Y. Woo, Ph.D., D.Sc.

Musculoskeletal Research Center, Department of Orthopaedic Surgery
University of Pittsburgh, P.O. Box 71199, Pittsburgh PA, 15213, 412-648-2000
Email: decenzod@msx.upmc.edu Web: <http://www.pitt.edu/~msrc>

Ligaments in the knee and shoulder joints are frequently injured during sports activities. However, in order to understand injury mechanisms, knowledge of joint mechanics, specifically the forces in ligaments, is needed to improve surgical procedures and design better post-surgical rehabilitation protocols. We have developed a robotic/universal force-moment sensor (UFS) testing system designed to obtain the *in situ* forces in normal ligaments as well as the distribution of these forces in a non-contact manner [Fujie 1993, Rudy 1996]. Also, this methodology can be used to examine those for replacement grafts following ligament reconstruction using the same specimen, so as to eliminate the inter-specimen variation and to significantly increase the statistical power of the experimental data.

In this presentation, the results of several experimental studies will be presented. For example, there is a distribution of *in situ* forces in the ACL in response to an anterior tibial load, as its posterolateral bundle carries a different force than its anteromedial bundle throughout the range of knee flexion [Sakane 1997]. These results suggest that ACL reconstruction with a single graft may be inadequate to reproduce the function of the native ACL. The combination of axial compression and anterior tibial load can significantly reduce anterior-posterior translation as well as the *in situ* forces in the ACL. In addition, quadriceps and hamstring co-contraction protects the ACL from excessive forces. On the other hand, rotatory loads that simulate the pivot shift can cause significant increases in the anterior tibial translation and *in situ* forces in the ACL [Kanamori 2000]. A series of similar experiments on the PCL demonstrating its significant interaction with the posterolateral structures will also be shown.

We have also found both the bone-patellar tendon-bone and hamstrings grafts are effective in providing anterior knee stability during anterior tibial loads, but less so during rotatory loads [Woo 2002]. Comparison between ACL reconstructions using an anatomical double bundle with a traditional single bundle reconstruction shows the former reconstruction can more closely reproduce the knee kinematics and *in situ* forces of the native ACL.

The glenohumeral and acromioclavicular (AC) joints of the shoulder have also been assessed using the robotic/UFS testing system. For example, the *in situ* force in the superior AC ligament, in response to an anterior load, is 50% greater than all other ligaments. During posterior loading, both the superior AC and trapezoid ligaments have significant *in situ* forces [Debski 1999].

This innovative approach has provided important quantitative data on the ligaments around the shoulder and knee joints. It has many advantages suggesting that this experimental approach be adopted in future studies of the function of ligaments and tendons in other diarthrodial joints.

INTRODUCTION

The posterior cruciate ligament (PCL) is the largest and strongest ligament stabilising the human knee. Surprisingly, though, isolated rupture of the PCL is not usually greatly disabling, and many cases do not require surgery. There has been comparatively little work done on knee ligaments other than the cruciates, and so the objective of this talk is to describe work done recently on structures that may contribute to posterior knee stability, to help to understand why PCL deficiency is not necessarily disabling. These are: the PCL itself; the posterolateral structures such as the lateral collateral ligament (LCL) and popliteofibular ligament (PFL); the posteromedial structures such as the medial collateral ligament (MCL) and posteromedial corner complex (PMC); and the meniscomfemoral ligaments (MFL).

THE PCL

The fibres of the PCL diverge widely as they pass from the tibia to the femur, and have distinct patterns of slackening and tightening as the knee flexes. This means that different parts of the PCL are working at different points in the arc of flexion. This is seen if the PCL is separated into anterolateral (aPC) and posteromedial (pPC) fibre bundles. The aPC is slack when the knee is extended, and tight in mid flexion; the pPC is tight at both extremes of the arc of motion. Since the majority of the PCL strength is the aPC, and the pPC is oriented vertically in extension, the PCL does not resist posterior tibial translation well in the functional (extended knee) posture. Selective cutting has shown that it is only a secondary restraint to tibial posterior translation near knee extension. Therefore, the role of other structures in controlling tibial posterior laxity is important.

POSTEROLATERAL STRUCTURES

The posterolateral anatomy is complex and variable. The position of the fibula varies between specimens, around the lateral and posterior aspects of the proximal tibia. This leads to differing orientation of the LCL and PFL, that both pass from the femoral lateral condyle to the head of the fibula, and to inherent difficulty for surgical reconstruction to stabilise some knees. As the knee flexes, so the orientations of these structures alters, and the LCL slackens, so it cannot then resist posterior tibial translation. This leaves the PFL as the primary restraint to tibial external rotation. These structures are ruptured by combined varus plus hyperextension injury of the knee. Simulated injuries in vitro show progression of structural damage, that later propagates into the cruciates. Reconstructions using several common surgical methods

(Muller, Larson, modified Larson) all failed to restore normal knee laxity, with excessive laxity in knee extension (i.e. failure to restore knee stability) and significant overconstraint in flexion. More work on graft placement and tensioning is needed to optimise these reconstructions.

THE POSTEROMEDIAL CORNER

The medial ligaments have been described in different ways, and anatomical study suggests division into three main structures: superficial MCL (sMCL), deep MCL (dMCL) and a 'posteromedial corner complex' (PMC), that includes the knee capsule with various thicker bands of collagen fibres. The PMC is tight in knee extension, and slackens with flexion, while the MCL is approximately isometric. Tensile tests showed that these structures had strengths of 723N sMCL, 238N dMCL, 454N PMC, and failed at 10.7, 7.3, and 13.7 mm extension respectively. This explains the occurrence of deep ruptures of the MCL. Tests of anterior-posterior (AP) tibio femoral laxity with sequential cutting have shown how the PMC restrains posterior tibial translation, particularly in the extended knee with internal tibial rotation. At the same time, damage to these structures raises strain in the ACL (measured by DVRT), showing why they should be repaired or reconstructed at the same time as cruciate ligament surgery.

MENISCOFEMORAL LIGAMENTS

A literature review, plus our study of 85 knees, showed that at least one MFL is present in 93% of knees. The anterior MFL of Humphrey (aMFL) attaches distal to the PCL on the femur and is tight in knee flexion; the posterior MFL of Wrisberg (pMFL) attaches proximal to the PCL and tightens in knee extension. Tensile tests have found mean strengths of 301N and 303N for the a and pMFLs (n=10). This suggests that they have some load-bearing function. Selective cutting under cyclic anterior-posterior draw loading showed that the tibial posterior translation increased significantly after cutting the MFLs in PCL deficient knees. This is the first time that their role in knee stability has been shown, and suggests that they should be preserved. Their presence may help the PCL to heal close to its normal length after rupture, thus avoiding surgery.

CONCLUSIONS

The studies described all help to throw light on the behaviour of the knee under loads tending to cause posterior tibial translation/rotation, but it is clear that much more work is needed for more complete understanding of how best to deal with damaged posterior ligamentous structures of the knee.

COMPARISON OF SUBJECTIVE AND OBJECTIVE MEASUREMENTS OF BALANCE DISORDERS FOLLOWING TRAUMATIC BRAIN INJURY

Kenton R. Kaufman¹, Robert H. Brey¹, Li-Shan Chou², Ann Rabatin¹, and Jeffrey R. Basford¹

e-mail: kaufman.kenton@mayo.edu

INTRODUCTION

Clinicians use multiple approaches to assess balance impairment. However, these clinical measures are not sensitive to subtle changes in balance. The scientific analysis of balance is an emerging field. Objective measures of balance include posturography and gait analysis. The purpose of this study was to compare the relationship among the various measures of balance impairment.

METHODS

The study consisted of 10 patients (6 men and 4 women ranging in age from 18 to 65 years) who had a traumatic brain injury (TBI) and ten age, gender, and body mass index matched controls. The TBI designation was made on the basis of a documented TBI by physician assessment supported by additional information such as decreased Glasgow Coma Score within 24 hours of injury, documented loss of consciousness and findings on imaging. Subjects were required to be at least 3 months post injury, living in the community, and to have had normal gait and balance prior to their injury. In addition, the patients had to have current complaints of dizziness or unsteadiness when walking. Each subject's self-perception of disability due to symptoms of dizziness was measured using the Dizziness Handicap Inventory (DHI), a standardized, validated questionnaire (Jacobson and Newman 1990).

Balance impairment was objectively tested using two methods. A sensory organization test (SOT) that assessed the three components of balance (vision, proprioception, and vestibular function) was performed using computerized dynamic posturography (Equitest NeuroCom International Inc., Clackamas, Oregon). A gait study was used to quantify the displacement of the body center of mass (COM). Twenty seven reflective markers were placed on bony landmarks and an eight-camera ExpertVision® System (Motion Analysis Corp., Santa Rosa, California) was used to collect 3-D marker trajectory data. A biomechanical model consisting of 13 body segments (four upper extremity, six lower extremity, and one for the pelvis, trunk, and head) was used to compute the COM displacement.

RESULTS AND DISCUSSION

Based on the initial Glasgow Coma Score (GCS), four subjects had severe TBI (GCS < 9), two had moderate TBI (9 ≤ GCS ≤ 12), and four had mild TBI (GCS > 12). Tinetti Balance Assessments were obtained and the TBI group was not significantly different from the normal controls.

The DHI scores supported the subjects' complaints of "unsteadiness" and "imbalance". The DHI physical domain

score was 10.4 (± 5.3), emotional domain score of 10.2 (± 9.6), functional domain score of 11.6 (± 10.7), and total score of 32.2 (± 23.0). The subject's complaints of "dizziness" or "unsteadiness" were not detected by a clinical examination or the Tinetti balance scale score. However, the DHI indicated that this imbalance had effects on the physical, emotional, and functional aspects of individual's lives.

The SOT composite score was significantly lower in the TBI subjects (70 ± 12) compared to the normal controls (80 ± 8). Using posturography, four of the patients would be considered to have abnormal balance (SOT < 70). There were correlations between the SOT and DHI. However, none of these correlations were statistically significant and all correlations were only moderate to weak. There is controversy regarding the use of posturography as a measure of balance impairment. Some authors have stated that posturography does not predict stability (O'Neill, Gill-Body et al. 1998; Evans and Krebs 1999). In contrast, Furman (Furman 1994) believes that posturography provides an indication of the impact of balance impairment on daily activities.

The displacements of the COM in the anterior and vertical direction were negatively correlated with the components of the DHI, whereas the displacement in the medial/lateral direction was positively correlated. Most importantly, there was a significant correlation of the COM peak velocity in the coronal plane with the physical, functional, and total DHI scores.

SUMMARY

The present study found that posturography test scores do not correlate with the subject's clinical symptoms. Gait analysis techniques have not been used routinely to assess clinical complaints of imbalance from patients. However, this study has demonstrated that gait analysis can be used to objectively quantify the subjective complaints of unsteadiness reported by patients with balance disorders. Moreover, gait analysis techniques quantify the dynamic aspects of balance impairment which the patient senses.

¹Department of Biomedical Engineering davis@bme.ri.ccf.org,

²Orthotics and Prosthetics

INTRODUCTION

Traditional gait laboratories use floor-mounted forceplates to study joint kinetics and kinematics. These studies require that a patient correctly places his/her foot on a forceplate. In studies involving patients with limited walking abilities, this can often be problematic. In the current study, an instrumented treadmill was used to evaluate amputee gait patterns when prosthetic limbs of different compliance parameters were fitted to the residual limb.

METHODS

Eight subjects (mean age 45 years; mean time since amputation 65 months, 6 below-knee, 2 above-knee, 7 males) were fitted with prostheses with different cushioning. A Flex-Foot system (Fig 1) (spring cushion), a Stratus pylon (foam cushion), and a Lord Corporation pylon (polymer cushion) were tested in random order. Data were collected after initial fitting of the prosthesis and after 4 weeks of wear. Four 20s trials of force data were collected at 100Hz while walking at 3.2 km/hr on an instrumented treadmill.

Figure 1. The prosthetic devices: (a) Flex-Foot, (b) Lord Corporation and (c) Stratus.

For each trial, eight consecutive strides (32 total) were analyzed. For the natural (N) and prosthetic (P) sides two variables were calculated: peak impact (F1) as % of bodyweight (F1_%BW) and time (F1_T) in seconds to reach F1. ANOVA and post-hoc Student T-tests were used to compare prostheses and wear time (initial vs. 4 weeks later).

RESULTS

Wear time had no significant effect on the symmetry indices but prosthetic type did. For F1_%BW, the Stratus and Flex-Foot had greater %BW borne by the prosthetic limb resulting in less symmetry than the Lord pylon. The time to reach F1 was greater for the natural leg when the contralateral limb was fitted with a Flex-Foot (Symmetry index (SI)=7.66), whereas for the Stratus and Lord it was greater for the prosthetic leg (SI=-4.78 and -3.13, respectively). The difference between

natural and prosthetic legs resulted in less symmetry for the Flex-Foot compared to the Lord and Stratus.

DISCUSSION

Amputee patients typically expend less energy when walking symmetrically. In addition, recent prosthetic design trends have emphasized the need to avoid transient impact forces on the residual limb. Thus, this study evaluated gait symmetry in unilateral amputee subjects fitted with shock-attenuating prosthetic limbs.

For this subject cohort there was a rapid adaptation to wearing a new prosthesis as there was no significant change in gait symmetry due to wear time. For patients wearing the Flex-Foot system, the greater time to reach F1 for the natural leg indirectly suggests a slower rate of unloading for the prosthetic leg, which may be indicative of the Flex-Foot spring mechanism. For F1_%BW, the near perfect symmetry for the Lord device indicates equal loading on both legs.

Figure 2. Vertical ground reaction forces for seven consecutive left and right strides for normal gait on the instrumented treadmill.

Finally, to alleviate concerns that (i) treadmill gait is affected by fluctuations in belt speed and (ii) friction beneath the treadmill belt affects force readings, we have performed tests to examine these effects. Results for the treadmill currently used show belt speed fluctuations less than 1% of the nominal setting and correlations between treadmill force data (e.g., Figure 2) and instrumented pylon data that exceed 0.9.

ACKNOWLEDGEMENTS

Funding for the instrumented treadmill design was provided by the NIH, support from the NSF (through the NSF REU program) covered the design of the pylon force transducer, and funding for the pylon designs was provided by the Lord Corporation. The authors have no direct or indirect interests in the Lord Corporation.

STEPPING OVER OBSTACLES DURING LOCOMOTION IN ANTERIOR CRUCIATE LIGAMENT PATIENTS

INTRODUCTION

Stepping over obstacles is an inevitable part of daily locomotion. Fails to negotiate successfully the obstacle will result in falls, a serious problem in the elderly [1]. A safe and successful obstacle-crossing requires stability of the body provided mainly by the stance limb and sufficient foot clearance of the swing limb. These demands may not be met in patients with anterior cruciate ligament deficiency (ACLD) that impairs both the structural stability and sensory feedback of the joint [2]. The influence of these impairments on the performance in stepping over obstacles during locomotion has not been reported in the literature. The present study addresses this issue by comparing foot clearances and knee joint kinetics between ACLD, ACL-reconstructed (ACLR) patients and normal subjects. The potential advantage of reconstruction of the ACL in stepping over obstacles was investigated.

MATERIALS AND METHODS

Three groups of subjects participated in this study: six unilateral ACLD subjects (age: 23.2 ± 4.9 yr, height: 171.7 ± 5.8 cm, weight: 70.8 ± 7.1 kg), seven unilateral ACLR subjects (age: 27 ± 8.1 yr, height: 164.2 ± 10.5 cm, weight: 59.4 ± 13.65 kg) and eight normal controls (age: 20 ± 1.1 yr, height: 164.8 ± 6.1 cm, weight: 63.3 ± 14.3 kg). Each subject walked at self-selected pace and stepped over obstacles of three different heights (10, 20 and 30% of leg length). Twenty-eight markers were used to track the motion of both limbs. Kinematic and kinetic data were measured with a 7-camera motion analysis system (Vicon, Oxford Metrics, U.K.) and two force plates (AMTI, U.S.A.) placed on each side of the obstacle. The clearance distances of big toe, heel and lateral malleolus markers were calculated. A model of the lower limb was used to obtain the knee joint moments. Clearance distances and knee moments between limbs were compared using repeated t-test while independent t-test was used for between-group comparison. The significance level was set at 0.05.

RESULTS AND DISCUSSION

Compared to normal subjects, leading leg clearances of both affected and sound limbs in ACLD subjects were significantly smaller while in ACLR subjects those of the sound limbs were not significantly different from normal but those of the affected limbs were smaller, Fig.1. Leading leg clearances in affected limbs were significantly smaller than those in sound limbs for 20% and 30% conditions in ACLR group, and for 30% condition in ACLD group. These suggest that ACLD subjects are at higher risk in tripping over obstacles while ACL reconstruction could help to restore the subject's ability in successfully stepping over obstacles of lower heights. In ACLR subjects, the restored stability of the knee resulted in the close-to-normal clearances of the sound leading leg. The

smaller obstacle clearance of the affected limb may be due to the partial restoration of the proprioception of the joint.

Trailing leg clearances were indifferent among the groups and were found to be much bigger than leading leg clearances. The bigger clearance for the trailing limb is needed to ensure safe obstacle-crossing when visual cue is not available. The results suggest that this mechanism is less sensitive to the structural and proprioceptive impairment of the ACL.

Fig. 1: Comparison of clearances in different conditions.

* Significant difference between affected and sound limbs

† Significant difference between affected and normal limbs

‡ Significant difference between sound and normal limbs

Knee extensor moments in the sound stance limbs were significantly bigger than those of the affected stance limbs when crossing obstacles of all heights in both ACLR (14.8, 5.2 Nm, $p < 0.004$) and ACLD (14.1, 5.7 Nm, $p < 0.029$) groups. This may be a result of muscular adaptation that tries to reduce anterior tibial translation in ACLD patients and protect the reconstructed ACL from excessive stress in ACLR patients.

Injury of the ACL affected joint proprioception and stability, resulting in insufficient information for the appropriate positioning of the leading leg and altered muscular control and force-bearing in passive structures for necessary stability of the body. The results of the present study suggest that ACLD patients are at higher risk of stumbling or falling in stepping over obstacles during locomotion and reconstruction of the ACL could reduce the risk.

RELATIONSHIP OF ANIMAL TO HUMAN METHODS FOR *IN VIVO* TENDON STRAIN DETERMINATION IN BIPEDAL LOCOMOTION

Rebecca B. Campbell^{1,2}, Michael B. Bennett² and Christopher L. Vaughan¹

¹Biomechanics Laboratory, MRC/UCT Medical Imaging Research Unit, Cape Town, South Africa

²Department of Anatomy and Developmental Biology, University of Queensland, Brisbane, Australia

rebecca@sports.uct.ac.za

INTRODUCTION

Most *in vivo* research to date has utilised animal models to investigate muscle-tendon mechanics due to the ethical and methodological limitations involved in human research. However, with modern techniques, the study of *in vivo* muscle-tendon mechanics in humans has been realised. The question remains: how applicable and accurate are animal models for human studies?

Chronic soft tissue injuries that occur with running are thought to result from the accumulation of damage from sub-maximal forces within the musculo-tendinous structures. Measurements of these forces *in vivo* are required, but are essentially impractical for most human studies. Such measures may be obtained for locomotion through the use of animal models.

METHODS AND RESULTS

Turkeys present an ideal model to investigate the muscle-tendon mechanics of bipedal locomotion *in vivo*, due to the presence of mineralised tendons in their lower limbs. This mineralisation permits the surgical attachment of strain gauges for *in vivo* strain measurements, providing a direct measure of the forces involved during treadmill locomotion. Such an application for humans does not exist due to higher tendon compliance and lack of mineralisation.

Turkey tendon force levels were found to increase from walking to running (Figure 1).

Figure 1: Example of *in vivo* tendon force (lateral gastrocnemius) for increasing speed in turkey locomotion, presented as a percent of the estimated maximal isometric muscle force, as recommended by Ker et al. (1988). Stance and swing phases are normalised so that each represents half of the stride cycle.

DISCUSSION

The data presented here show that the peak force levels experienced during level walking and running (≤ 1.8 m/s), by the lateral gastrocnemius tendon, were less than one third of the maximal isometric force capability of the associated muscle. Treadmill locomotion on a 10° incline resulted in a dramatic increase in the forces recorded at any given speed, although peak forces were still less than 33% of the calculated isometric muscle force. These findings indicate that this muscle-tendon complex operates with a large safety factor during normal locomotion.

Early measures of tendon force in humans used force buckle transducers (Komi et al., 1987). Recent advances have used a relatively pain-free optical fibre technique to estimate Achilles tendon forces during walking (Finni et al., 1998). Finni et al. (1998) reported that the peak tensile stress for the Achilles tendon in humans during walking was 55% of the maximal isometric plantarflexion stress. The apparent large differences between gastrocnemius mechanics in humans and turkeys is probably due to a greater utilization of elastic strain energy for economical locomotion in the larger, more cursorial humans.

Accurate *in vivo* measures for muscle-tendon variables (namely moment arm lengths, fascicle lengths and pennation angles) by ultrasonography and nuclear magnetic resonance imaging (nMRI) are currently limited to isometric voluntary contractions on a plinth or during static postures (Rugg et al., 1990; Muramatsu et al., 2002). These methods are inadequate to fully describe and replicate the movement and forces involved during locomotion. Consequently, we are unable to accurately determine the function of human muscle-tendon mechanics during locomotion. Such measures do assist in the development of accurate theoretical models. The study of animal models remains an important area of research, for the determination of muscle-tendon mechanics during locomotion.

DIFFERENT MUSCLE ACTIVATION PATTERNS DURING WALKING AND RESPONSE TO COMMON PERONEAL STIMULATION

Jane Burridge¹, Lindsay McLellan¹, Paul Taylor² Duncan Wood²

¹University of Southampton, School of Health professions and Rehabilitation Sciences, Southampton UK (jhb1@soton.ac.uk)

²Department of medical Physics and Biomedical Engineering, Salisbury District Hospital Salisbury UK

INTRODUCTION

There is a growing body of research evidence to support the use of common peroneal nerve stimulation for the treatment of spastic drop foot (Burridge1997 & Wieler 1999), yet it is not commonly used in clinical practice. There may be many reasons for this, including cost, reliability of equipment, and problems experienced by users in effective application. One reason for poor acceptance, that may also explain the varied response identified in clinical trials, may be that effectiveness is dependent on underlying neurophysiology. An understanding of which may allow more precise selection of patients. Using the experience of Knutson (1994), this study investigated muscle activation patterns recorded during treadmill walking and related these to individual response to stimulation. The objective was to see whether response to stimulation could be predicted by certain abnormalities commonly observed in the upper motor neuron syndrome.

METHODS

Individuals with established hemiplegia (>6 months) following stroke, who had a drop foot that hindered walking, and age matched neurologically unimpaired volunteers were recruited. Individuals with hemiplegia were assessed on three occasions to establish a baseline, prior to using common peroneal stimulation, and volunteers were assessed once. Stimulation was applied using the ODFS III Pulse width 0 - 300µs (biphasic) frequency 40Hz, current 20-100mA. EMG was recorded using Medelec surface electrodes from the calf and anterior tibial muscles - Signals were pre-amplified at source (gain x15, bandwidth 10 – 1000 Hz, common-mode rejection 100 dB at 50 Hz). Further amplification was provided, before each signal was rectified, then integrated using a low pass filter, using a 2µF capacitor (time constant 13.8 seconds). Phases of the gait cycle were identified by Force Sensitive Resistor (FSR) foot-switches under the heel and 1st metatarsal heads of both feet. Digitised data were recorded on video-tape and five-second samples were retrieved for analysis at a later date. Ratios of calf and anterior tibial muscle activity during defined phases of the gait cycle were used to derive indices to describe three muscle activation patterns. a) ability to activate the anterior tibial muscles during the swing phase of walking (TAAI), b) ability to activate the calf muscles during push-off (POI) and c) inappropriate calf activity during early stance phase, described as premature calf activation, (PCAI). Spasticity of the calf was measured as response to passive stretch prior to the walking tests (Burridge 2000).

Response to common peroneal stimulation was measured as change in walking speed, and physiological Cost Index, both with and without stimulation, measured over 10m.

RESULTS AND DISCUSSION

18 hemiplegic subjects, 10 right and 8 left sided, mean age 61 years, 11 male, 7 female, mean time since stroke 3 years and 12 volunteers mean age 57 years, 5 male, 7 female were recruited and completed the study. Results were not normally distributed therefore non-parametric tests were applied and are summarised:

- A statistically significant difference between normals and hemiplegic subjects in PCAI $p=0.001$ and POI $p=0.001$, but not TAAI $p=0.325$
- A statistically significant correlation between PCAI and spasticity measured as a stretch index (Spearman) 0.582 $p<0.05$ ($n=16$) prior to the walking test described in a previous publication (Burridge 2000).
- A significant correlation between PCAI and increase in walking speed with stimulation (Spearman) 0.459 $p<0.05$
- Subjects who had premature calf activation tended to strike the ground with the toe before the heel

SUMMARY

In this small study statistical results should be interpreted with caution and validated with a larger sample of both impaired and unimpaired individuals. Nevertheless the following points could be considered:

- Patients with inappropriate calf activity may respond well to stimulation through the reciprocal inhibition mechanism
- If so, maintaining stimulation beyond heel strike may be beneficial
- There is no indication that inability to activate the anterior tibial muscles can be used to predict a good response to stimulation
- In some cases calf stimulation during the push-off phase may be useful - possibly in early rehabilitation
- A simplified version of the walking test may be useful clinically and to identify suitable subjects for future studies

SELF-ASSEMBLING PEPTIDE SCAFFOLD PROMOTES DIFFERENTIATION AND NETWORK FORMATION IN THREE-DIMENSIONAL CULTURE OF HUMAN MICROVASCULAR ENDOTHELIAL CELLS

Daria Narmoneva, Richard T. Lee¹, Jonathan G. Gertler², and Roger Kamm

Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, rdkamm@mit.edu

¹ Cardiovascular Research, Brigham & Women's Hospital, Boston, MA; ² Vascular Surgery, Mass. General Hospital, Boston, MA

INTRODUCTION

Engineering of vascularized grafts and organs is a rapidly evolving area of current biomedical research (Vacanti & Langer, 1999). Increasing understanding of the mechanisms that govern angiogenesis opens new opportunities for manipulating this process in both clinical and tissue engineering applications (Carmeliet & Jain, 2000). Recently, a new class of biomaterials - self-assembling peptide scaffolds - has been developed, which are extremely promising for use as biological scaffolds for tissue engineering (Zhang et al., 1995, Holmes 2002). This study presents evidence that one type of the self-assembling peptide scaffolds promotes a rapid angiogenic response and long-term survival of human microvascular endothelial cells, indicating the potential of this material for tissue engineering of vascularized organs.

METHODS

Human microvascular endothelial cells were isolated from fat tissue and cultured on gelatin-coated dishes. Cells (passage 4-6) were trypsinized, seeded on the surface of the self-assembling peptide gel (peptide RADII-16, 1%, Zhang et al., 1995) and cultured for up to 3 weeks using Medium 199 (Gibco) with 10% FCS, 5% heparin, and 1% ECGS (Sigma). Cells cultured on gelatin-coated dishes were used as controls. Cell phenotype was evaluated by immunostaining for human von Willebrand Factor (DAKO). Cell proliferation and apoptosis were assessed using BrdU kit (Zymed) and TUNEL assay (Roche), respectively. To characterize capillary network formation, cell cultures were fixed in 2% paraformaldehyde for 2 hr and stained using DAPI nucleic acid fluorescent stain (Molecular Probes) or anti-actin monoclonal antibody (Chemicon). Gray-scale images of the cell networks were taken using a fluorescence microscope (Nikon) and then used to calculate a correlation function $F(R)$, where r is a position vector measured in pixels on the original image, $R=(R,\theta)$ represents the correlation vector, $I(r)$ is image intensity at r , " $\langle \rangle$ " denotes averaging over r , I_{ave} is average image intensity,

$$F(R) = \frac{\langle (I(r) - I_{ave})(I(r+R) - I_{ave}) \rangle}{\sigma^2} \quad (1)$$

and σ is standard deviation for $I(r)$. The function $F(R)$ was then averaged over θ to obtain $F(R)$ as a function of distance.

RESULTS AND DISCUSSION

Within 2 hours of seeding on the peptide gel, cells attached and started to migrate toward each other. Initial structures were formed at 8 hours, and final structures were formed by 24 hours, with most cells assembled into capillary-like networks (Figure 1A). Correlation analysis demonstrated a gradual increase in characteristic size of the structures on the gel with time, while no structures were detected in control cultures (Figures 1B,C). During long-term culture, cells migrated into the gel and were actively proliferating with no significant signs of apoptosis and minimal gel degradation.

In summary, these data suggest that RADII-16 peptide gel supports endothelial cell migration, proliferation and capillary-like structure formation and survival for a period of at least 3 weeks. In contrast to other three-dimensional substrates used for studies of angiogenesis *in vitro* (Vailhé et al., 2001), this angiogenic response was observed in the absence of externally supplied angiogenic factors. These results indicate that the self-assembling peptide scaffold provides a substrate that triggers a self-sustaining angiogenic process in endothelial cell culture and therefore, is promising for *in vitro* studies of angiogenesis and engineering of vascularized organs.

INTRODUCTION Vascular disease represents a considerable health concern, and an inadequate supply of native vessels for bypass procedures has created a significant need for clinically successful alternatives. While small-diameter synthetic vascular grafts made from expanded polytetrafluoroethylene (ePTFE), polyethylene terephthalate (PET; Dacron) or polyurethane (PU) have been used to satisfy this need, they have not matched long-term patency rates of autologous vessels. Incorporation of proteins (e.g. albumin, collagen, gelatin or elastin) or treatment with anti-thrombotic agents (e.g. heparin or hirudin) have been evaluated to improve patency. To date, long-term improvement in patency has not been achieved with these treatments. Some improvements have been achieved with endothelialization; however, there is a continued interest in new approaches for designing vascular grafts to improve biocompatibility and long-term function. Using a cell-scaffold-based approach, we have developed small-diameter (<5-mm ID) tissue-engineered vascular grafts (TEVGs) by culturing allogeneic canine smooth muscle cells (SMCs) on porous PU, ePTFE or braided PTFE tubular scaffolds, followed by endothelialization with autologous microvascular endothelial cells (MVECs). The objectives of these studies were to optimize scaffold design and endothelialization and to evaluate TEVG performance in a canine carotid artery implantation model.

MATERIALS AND METHODS Porous (63-500- μ m pore sizes) aromatic polyether PU (Thermedics) tubular scaffolds (4-5- mm OD, 0.75-mm wall thickness, 7-cm length) were fabricated using solvent-casting particulate-leaching methods at 85-93% w/w ratio of salt to polymer. ePTFE scaffolds (4-mm ID, 20- or 120- μ m internodal distance [IND], 6-cm length) and braided PTFE scaffolds (5-6-mm ID, 6-cm length) were obtained from Atrium Medical Corp. and Prodesco, respectively. All scaffolds were irradiation-sterilized, coated with fibronectin, seeded with allogeneic adult canine SMCs (passage 5-8) and cultured for 2-5 wk in bioreactors under low-flow (10 ml/min) or high-flow (50 ml/min) conditions in 20% FBS DMEM growth medium containing CuSO₄ and ascorbic acid. Autologous falciform fat-derived canine MVECs were seeded at subconfluent densities onto the TEVG lumens and cultured under low fluid shear stress (0.5-0.75 dynes/cm²) for 3-4 d, followed by a stepped increase in fluid shear stress (3-6 dynes/cm²) for an additional 3-4 d. All cultures were maintained in 5% CO₂, 37°C humidified incubators. TEVGs were examined for cell viability (MTT mitochondrial assay), for collagen (hydroxyproline assay) and elastin (desmosine RIA) content, and for cell identification by immunohistochemistry and SEM. Endothelialized TEVGs (4-cm lengths) (n=4 PU-based, n=6 ePTFE-based, and n=6 braided PTFE-based) were implanted interpositionally (end-to-end anastomoses) in canine carotid arteries, and implant-phase patency was monitored by ultrasonography. All dogs received daily aspirin for the course

of the studies. All procedures and study protocols were reviewed and approved by the Univ. of AZ IACUC and carried out according to the *NIH Guidelines for the Care and Use of Laboratory Animals*. At explant, each TEVG and adjacent native vessel (>2 cm beyond each anastomosis) was harvested, photographed, fixed and prepared for histological, immunohistochemical and SEM assessment.

RESULTS PU scaffolds of 150-300- μ m pore size and 90% w/w and cultured at 10 ml/min were found to support optimal SMC tissue. This SMC tissue contained collagen types I and III and elastin and was capable of secreting a number of endothelial-responsive growth factors including vascular endothelial growth factor (VEGF). TEVG SMCs were oriented perpendicular to flow and stained positive for the intracellular contractile proteins SM α -actin, calponin and myosin heavy chain (the latter two being characteristic of differentiated SMCs in native tissues). MVECs adhered to the SMC tissue and SEM showed an intact monolayer with the MVECs aligned in the direction of fluid flow. Patency in both implanted PU MVEC-TEVGs and contralaterally implanted control grafts (untreated ePTFE) was 25% at 6-7 weeks. Several PU MVEC-TEVGs exhibited scaffold biodegradation and aneurysm formation that may have contributed to the decreased patency observed in this experimental group.

TEVGs made using ePTFE (120- μ m IND only) or braided PTFE scaffolds also showed SMC tissue formation and the ability to support endothelialization. One out of six implanted MVEC-TEVGs (for each group) occluded within 72 hr after implantation, whereas all other TEVGs remained patent. At 4 and 8 wk, one patent TEVG from each group was selected for explantation. Twelve-wk implant-phase ultrasound evaluation showed that each remaining TEVG (n=3 each) was patent with no evidence of anastomotic or mid-graft intimal thickening. Gross and histologic evaluation demonstrated the absence of aneurysm or thrombus formation, an intact endothelium on the luminal surface, and no occlusive intimal thickening of the underlying SMC tissue.

CONCLUSION Scaffold design (90% w/w and 150-300- μ m pore size for PU, 120- μ m IND for ePTFE and braiding for PTFE) was important for enhancing SMC neo-media development that provided a suitable substrate for endothelial cell adherence and maturation. The selected PU was not biostable in vivo and hence impacted TEVG performance. More importantly, the results with ePTFE-based and braided PTFE-based TEVGs demonstrated moderate- to long-term patency and that a cell-scaffold-based approach to tissue engineering can be used to modify synthetic materials. This approach holds significant promise towards development of an alternative small-diameter vascular graft.

TISSUE ENGINEERED BLOOD VESSELS (TEBV) : THE FUTURE IS NOW

François A. Auger M.D. FRCP (C)

Québec (Québec) G1S 4L8 Canada
Francois.auger@chg.ulaval.ca

INTRODUCTION

Successful tissue engineering of blood vessels is one of the most difficult goals in this field of biotechnology. It holds great promises but has also some very demanding hurdles before true clinical success can be achieved. The replacement of small-diameter blood vessels (≤ 6 mm) is a clinical situation frequently encountered by vascular and cardiothoracic surgeons.

TEBV CHALLENGES

During the last decades, progress in the field of tissue engineering has allowed investigation in this area. Our laboratory was implicated in such a project and, on the basis of previously published blood vessel models composed of living cells embedded in an exogenous collagen matrix, we developed, using the self-assembly approach, the first completely biological tissue-engineered blood vessel (TEBV) constituted of living human cells in the absence of any synthetic or exogenous material.

The TEBV produced has a morphological and histological structure closely comparable to a natural blood vessel. It is composed of an endothelium lying on a sub-endothelial layer of collagen fibers, a media, and an adventitia, respectively composed of smooth muscle cells and fibroblasts surrounded by their own extracellular matrix, as in a native vessel. In the absence of culture support, this TEBV does not collapse, shows an impressive burst strength resistance (2500 mm Hg) and can be easily handled as was proven when tested in femoral interposition prostheses in dogs [24]. In light of its composition, this TEBV has the distinct advantage of being completely biological and thus, presents the possibility of being produced autologously with a wide range of inner diameters (3 mm or more), is fully biocompatible and able to renew itself over time if damaged.

Consequently, the production of these autologous TEBV conduits, even though their preparation is quite long (4 months), could be the ideal solution for most clinical situations and could possibly eliminate reinterventions and anticoagulothérapies associated with biomaterial prosthesis implantations.

Thus, the characteristics of all vascular substitutes must reach a level of mechanical properties and biological functionalities unknown in any other tissue engineered construct. This presentation will address the clinical demands on both these aspects since they set the stage for some fascinating bio engineering challenges.

According to the method of tissue engineering reconstruction chosen in order obtain these TEBV some goals will be either easier to reach or not so.

Furthermore the aspects of TEBV in vitro applications will be assessed in the present context pertaining to angiogenesis.

CONCLUSION

Thus, the field of TEBV, which was deemed to be an impossible feat a decade ago, is now the Holy Grail of tissues regeneration. It has a bright future if all the obstacles are vanquished in this pursuit.

INTRODUCTION

Recent publications on cardiovascular tissue engineering have shown that this is a vibrant field of research. Nerem and Selikar (2001) reviewed the vascular tissue engineering. The issues addressed ranges from stem cells technology to know-how in scaffolds manufacturing. Work by Auger's team showed that by growing the cells in sheets and then rolling them into a tube eliminates immunological mismatch and the smooth muscles cells (SMCs) re-expressed desmin, a differentiation marker known to be lost under culture conditions. Large amount of extra cellular matrices (ECM) were produced and the structural integrity maintained. However, the handling of the sheets is delicate and it is not clear if the material would survive the viscoelastic compliance mismatch in long-term in vivo physiologic environment. One of the earliest report of a human trial is a 10 mm diameter artery (Shin'oka et al 2001). Here a biodegradable polycaprolactone (PCL)-polylactic acid (PLA) copolymer was seeded successfully with cells from the patient's peripheral vein. However for smaller diameter vessels less than 5 mm, there has not been significant breakthroughs. One major obstacle is the over SMCs proliferation. Recent work (Kaushal et al 2001) showed the role played by endothelial progenitor cells (EPCs) in inhibiting SMCs in a 4 mm vessel. It seems that the EPCs expressed nitric oxide. Similarly immobilizing dipyrildmole on surfaces of porous polyurethane 5 mm vascular prosthesis (Aldenhoff et al 2001) showed improved results as dipyrildmole is a strong inhibitor of SMCs and platelet activation.

In our present work we propose a composite layer-by-layer technique using ultra thin bioresorbable membrane. Figure 1 shows schematically the concept as applied to blood vessel and heart valve construct.

METHODS

Earlier publication described the method for producing ultra thin membrane and cells seeding (Ng et al 2001). The membrane is made by a special bi-axial stretching technique pioneered by our group using PCL of 80,000 molecular weight to a thickness less than 4 μm , a breakthrough in developing barrier membrane for tissue engineering. Human dermal fibroblasts were used as preliminary trials to see how the cells respond.

RESULTS AND DISCUSSION

We engineer the barrier membrane so thin that we hope to define the boundaries for cell proliferation and provide strength for long-term physiologic stress stimulation in vivo.

Figure 1: Schematic illustration of growing cells layer by layer on an ultra thin bioresorbable barrier membrane scaffold.

It is envisaged that the slow degradation of PCL would maintain the 3D geometry and invoke less severe host response to biodegradable products. The AFM result (Figure 2) shows that the membrane has nano-porosity. Figure 3 shows that the membrane is highly flexible but yet strong. The tensile strength is close to 50 MPa. The cells proliferate and conform to the surface morphology nicely (Figure 4).

Figure 2: AFM picture.

Figure 3: Ultra thin film.

This shows good biocompatibility and potential for composite tissue engineering layer-by-layer, a strategy for more viable tissue regeneration. The surface properties of the material have a strong biophysical influence on the cell kinetics. The PCL film can be surface modified to immobilize proteins, growth factors and SMCs inhibitors. Recently we saw vascular structures penetrating the film (Schantz et al 2002).

MECHANICAL PROPERTIES OF ELASTIN-HYBRID TISSUE ENGINEERED VASCULAR CONSTRUCTS

Joseph D Berglund, Athanassios Sambanis, Robert M Nerem
P H Petit Institute for Bioengineering and Bioscience, jdberglund@earthlink.net
Georgia Institute of Technology, Atlanta, Georgia, USA

INTRODUCTION

Collagen-based tissue engineered vascular constructs have many interesting properties and have been utilized to study various aspects of vascular biology for many years. Unfortunately, these constructs possess poor mechanical properties and are too weak to be implanted for *in vivo* studies. In addition to collagen, elastin fibers comprise a large fraction of the extracellular matrix (ECM) of native arteries and are responsible for elastic recoil during pulsatile blood flow. We have developed a method to incorporate elastin with organized structural architecture into collagen-based vascular constructs in an effort to better mimic the native arterial physiology and to improve the mechanical properties of the constructs. This study investigates some of the chemical, biological, and mechanical issues associated with these elastin-hybrid constructs.

MATERIALS AND METHODS

Intact elastin scaffolds were procured from porcine carotid arteries using a series of phosphate buffer rinses; autoclave cycles; trypsin, cyanogens bromide, and β -mercaptoethanol incubations; and ethanol washes. Purity of the elastin scaffolds were verified via immunohistochemical staining and amino acid sequencing. Hybrid constructs were formed using acid-solubilized Type I rat tail collagen and either human dermal fibroblasts (HDFs) or rat aortic smooth muscle cells (RASMs). Collagen solutions (2 mg/ml) containing suspended cells (1×10^6 cells/ml) were poured into tubular molds about the elastin scaffolds and gelled at 37°C. The resulting constructs were statically cultured for up to twenty-three days prior to analysis. Standard collagen constructs without elastin scaffolds were also cultured as controls.

Construct function and viability was assessed using live/dead analysis, gel compaction quantification, and Hoescht DNA assays. H&E and immunostaining was used to examine ECM organization. Mechanical strength and viscoelastic characterization was assessed using uniaxial tensile testing, creep analysis, and stress relaxation. The resulting stress-strain profiles were evaluated to obtain a number of mechanical parameters and fit to Burger's four parameter mathematical model using non-linear Newtonian regression.

RESULTS AND DISCUSSION

Concentric lamellar rings surrounded by loosely woven fiber lattices presented brightly in the isolated scaffolds when stained with the anti-elastin BA-4 antibody. Amino acid analysis of the digested scaffolds compared favorably with elastin values reported in the literature indicating a high

degree of purity. While the cells were able to rapidly remodel their surrounding matrix both with and without the matrix, the collagen-based controls compacted to a greater extent than the elastin-hybrid constructs. Additionally, HDFs compacted the gels to a larger extent than the RASMs.

Figure 1: Ultimate tensile stress mechanical parameters

Incorporation of elastin scaffolds improved the mechanical properties of the constructs. Shown in Figure 1, the ultimate tensile stresses (UTS) were significantly higher in the elastin-hybrid constructs. The viscoelastic properties of the elastin-hybrid constructs also improved (see Table 1). The η_1 parameters are of particular interest as they describe the long-term creep behaviors. No statistically significant differences were observed between days eight and twenty-three for either the elastin-hybrid or collagen control constructs.

SUMMARY

Hybrid constructs that combine intact elastin scaffolds with a cell-seeded collagen gel provide a promising approach for the development of a TE blood vessel model. These constructs remain viable for up to 23 days and exhibit improved mechanical properties compared to collagen controls. Current work efforts are focusing on optimizing the hybrid constructs in an attempt to expand our studies to *in vivo* investigations.

Table 1: Burger's model parameters of HDF constructs as determined through creep analysis (8 Days/23 Days)

	Collagen Control	Elastin Hybrid	Native Carotid
R_1 (Pa)	$4.2 \times 10^3 / 1.3 \times 10^4$	$6.3 \times 10^4 / 4.0 \times 10^4$	1.9×10^5
η_1 (Pa/s)	$3.7 \times 10^6 / 1.7 \times 10^7$	$1.9 \times 10^9 / 1.4 \times 10^9$	5.8×10^8
R_2 (Pa)	$7.2 \times 10^3 / 1.5 \times 10^4$	$4.2 \times 10^5 / 2.5 \times 10^5$	1.9×10^5
η_2 (Pa/s)	$2.8 \times 10^5 / 1.1 \times 10^6$	$3.7 \times 10^6 / 7.1 \times 10^6$	2.6×10^7

MECHANICAL FORCES AND ENGINEERED VESSELS

Laura E. Niklason and Amy Solan

Department of Biomedical Engineering, Duke University, Durham North Carolina

nikla001@mc.duke.edu

INTRODUCTION:

Blood vessels in the body are exposed to constant pulsatile physical forces due to the cardiac cycle. Native arteries are known to respond to changes in applied pressure and wall stress with changes in cellular proliferation and extracellular matrix deposition. Recently, several groups have shown that application of pulsatile physical forces in vitro can impact the development of tissue engineered arteries (Niklason 1999; Seliktar 2000). However, these effects have not been quantified in detail, and the impact of applied physical forces on engineered vessel mechanics have not been fully explored.

METHODS:

Porcine carotid vascular smooth muscle and endothelial cells were harvested from Yucatan miniature swine. Cells were cultured in Dulbecco's Modified Eagles Medium (DMEM) supplemented with fetal bovine serum, porcine serum, amino acids, copper and ascorbate. Vascular smooth muscle cells (SMC) were utilized at passage 3 to culture engineered arteries. Cells were seeded at 5×10^6 cell/ml onto polyglycolic acid mesh scaffolds that were secured in bioreactors and attached to a pulsatile perfusion system. Scaffolds were 8 cm in length, 3 mm internal diameter, and 1 mm thickness (Freed 1994). Vessels were cultured under one of three conditions: non-pulsatile, 1% distension at 90 beats per minute (bpm), 1% distension at 165 bpm. Vessel culture proceeded for 6-7 weeks, after which vessels were analyzed for cellularity, extracellular matrix composition, and mechanical properties.

Cellularity was determined from papain-digested samples that were reacted with H33258 Hoechst dye and analyzed in a spectrofluorometer at an excitation wavelength of 365 nm and an emission wavelength of 458 nm. Collagen (calculated as 10x hydroxyproline) was assayed by acid hydrolysis in 6 N HCl at 115° C for 18 hours, and reaction with p-dimethylaminobenzaldehyde and chloramine-T. Collagen covalent cross-links (pyridinolines) were assayed from acid hydrolysis samples by reverse-phase HPLC and detected by fluorometry. Matrix metalloproteinase-1 (MMP-1) and tissue inhibitor of MMP-1 (TIMP-1) were assayed using commercially available ELISA's according to manufacturer's instructions (BioRad). Vessel mechanical characteristics were measured using techniques similar to those previously described (Niklason 2001). We utilized a Canon XL1 digital video camera that is equipped with a 180 mm/3.5 F-stop lens with an effective pixel size of 20 microns to acquire images of vessels under a range of distending pressures. Data were

analyzed using NIH Image software and a MacIntosh G3 computer.

RESULTS AND DISCUSSION:

Pulsatile physical forces exerted during the culture period resulted in significantly increased accumulation of insoluble collagen in engineered blood vessels. This result was noted for both the 90 bpm and the 165 bpm conditions, as compared to non-pulsed controls. While both TIMP-1 and MMP-1 tended to increase under pulsatile conditions, these increases did not achieve statistical significance. Hence, it is likely that increased rates of collagen synthesis, as opposed to changes in collagen breakdown and remodeling, were responsible for the observed changes in collagen accumulation effected by pulsatile forces.

In keeping with the key role of insoluble collagen in blood vessel mechanics, vessels that were cultured under pulsatile conditions had increased burst strengths and improved tensile moduli as compared to non-pulsed controls. However, because of a substantive lack of insoluble elastin in these engineered constructs, vessels displayed substantial creep during in vitro testing. These results show that the application of pulsatile physical forces is key to the engineering of vascular grafts having improved compositional and mechanical characteristics.

ENGINEERED ARTERIAL RECONSTRUCTION: INTEGRATION OF BIOMECHANICAL, GENETIC, AND STEM CELL ENGINEERING

Takehisa Matsuda

Department of Biomedical Engineering, Graduate School of Medicine, Kyushu University, Fukuoka, Japan
matsuda@med.kyushu-u.ac.jp

INTRODUCTION

The patency of an implanted vascular graft is reduced by thrombus formation in an early period of implantation and an excessive intimal hyperplasia in a later stage, both of which become more critical as an inner diameter of the graft becomes smaller. To realize small-diameter graft in clinical application, a multifaceted approach is needed for vital functioning small-diameter graft. One such an approach which has been taken over two decades is to utilize vascular cell types as active components. However, clinical application has been limited due to difficulty endothelial of cell (EC) harvesting from patients. The other major problem is compliance mismatching of artificial graft or scaffold with native arteries, which has been discussed over the years, resulting in thrombus formation and excessive intimal tissue ingrowth, both of which are quite critical especially for a small-diameter graft. In this talk, our recent approaches to engineered arterial reconstruction will be described, which include

- 1) biomechanical design of scaffold to exhibit compliance matching with native arteries,
- 2) gene-transfected fibroblasts as transient antithrombogenic cells replacing with ECs, and
- 3) circulating endothelial progenitor cell as a novel cell source.

1) Biomechanical design of scaffold

Our small-diameter artificial graft is a co-axial double-tubular graft with a high compliant tube inserted into a less compliant tube, both of which are made of multiply micropored thin segmented polyurethane (SPU) films. This double-tubular graft exhibited “J-curve” in the intraluminal pressure-diameter relationship, resembling that of native canine carotid arteries. After surface photoprocessing leading to formation of heparin/gelatin gel layering on the inner tube and very hydrophilic polymer gel layer on the outer tube, these grafts were implanted into canine carotid arteries. The results up to one year showed excellent patency and well-controlled

neoarterial tissue formation. However due to an excess encapsulation at the outer surface of outer tube, a gradual deterioration of “J-curve” was noticed with time.

2) Genetical manipulation of fibroblasts as a transient cell source

Since fibroblasts are highly thrombogenic due to secretion of tissue factor (TF) which triggers the extrinsic pathway of coagulation cascade, in addition to no antithrombogenic bioactive machinery unlikely to ECs, fibroblasts, which can be easily harvested from patients’ skin, were gene-transfected with adenovirus encoding TFPI (tissue factor pathway inhibitor), CNP (C-type natriuretic peptide acts as multipotent tissue modulator) and/or VEGF (vascular endothelial growth factor). A tubular hybrid tissue fibroblasts inoculated collagen gel, transfected with these adenoviruses and wrapped with micropored SPU film, remarkably increased patency at one-month implantation into canine carotid arteries, and tissue remodeling proceeded well without endothelialization. The SEM observation showed minimal fibrin clot on the luminal surface, indicating that gene-transfected fibroblasts may be used as a luminal cell living.

3) Endothelial progenitor cells (EPCs)

EPCs were harvested and purified from monocyte fraction of circulating blood. The antithrombogenic potentials as compared with ECs were as follows: tPA (tissue plasminogen activator) fibrinolytic level of EPCs was almost same as that of ECs, whereas antiplatelet functional eNOs (NO synthase) and prostacyclin production were almost one-half to one-third of ECs. After complete monolayering of EPCs on collagen-fiber meshes, wrapped with the micropored SPU film, exhibited very high patency as same as that of EP-lined grafts. Thus, EPC is a high choice of cell source, and an EPC-engineered graft incorporated with matrix and scaffold engineering is a promising tissue-engineered vascular graft.

PRE-CLINICAL TESTING OF MECHANICAL HEART VALVES FOR POTENTIAL TO CAUSE THROMBOSIS: A MILK-BASED PROCEDURE AS AN ADJUNCT OR ALTERNATIVE TO ANIMAL TRIALS

Christy J.R.E., Martin A

University of Edinburgh, Edinburgh, EH9 3JL, Scotland, UK. E-mail: john@chemeng.ed.ac.uk

INTRODUCTION

Animal testing of artificial mechanical valves has for many years been the only accepted means of assessing the potential of the valve to thrombose or to cause thromboembolism. However, it is known that there are variations between species in both the chemical composition of the blood and the haemodynamics of the cardiovascular system. In addition, intra-species variations (as indeed are found in clinical practice) can lead to the necessity of extensive testing before reliable statistical data can be generated. This is especially true as valve designs improve and the differences in thrombogenic potential decrease. This is exemplified by experience in the mid 1990s of the Medtronic Parallel valve, where the valve showed no sign of thrombosis in animal trials, but thrombus formation in the region of the hinge came to light during clinical trials (Bodnar 1996).

An in-vitro procedure for assessing flow-related thrombosis, using milk as an analogue for blood (Lewis 1983, Christy 1989), has been developed to simulate the latter stages of thrombosis (i.e. the action of thrombin on fibrinogen). This procedure is reproducible, in that the enzyme, Chymosin, is added in controlled amounts to milk of known protein concentration. The test is not intended to model the activation of the clotting cascade but, in previous application to mechanical valves, comparison of milk-clotting with clinical thrombosis suggests that this is not important. In order to prove the usefulness of the technique in differentiating between valves whose potential to form thrombosis is low, we are analysing a range of valves for which incidence of clinical thrombosis is known.

METHODS

The technique originated in Edinburgh has been fully described elsewhere (Lewis 1983, Christy 1989). It uses a mixture of milk and cheese makers' rennet as the coagulable fluid in a once-through flow system in which metered, temperature-controlled streams of these components are blended shortly upstream of the valve under test. The chemical and chemical-kinetic resemblances between steps to clotting in this system and the latter stages of thrombus formation in blood have long been established (Jolles 1975). The delay before spontaneous coagulation is chosen to exceed the fluid transit time through the apparatus and the injection of calcium chloride ensures that any coagulum deposited can be made-to resemble thrombus in consistency and adhesiveness. A range of caged ball valves (Starr-Edwards silastic ball and cloth-covered strut valves), monoleaflet valves (Bjork-Shiley Standard, Bjork-Shiley Monostrut, Omniscience, and Ultracor)

and bileaflet valves (St. Jude Medical and Duromedics) have been tested in our artificial heart.

RESULTS AND DISCUSSION

For the valves tested, milk clot forms in the locations for which thrombosis has been reported in clinical practice. There are, however, some instances where additional, thin films of clot form on discs or around the sewing ring which are not reportedly found with blood. However, the extent of clot deposition in such areas is generally low and is usually distinguishable by its appearance.

False positive results for clot formation may be due to a number of factors: the assumption that blood is already activated on passing through the valve, the geometry of our in-vitro test system, effects due to the presence of anticoagulants in blood and differences in properties (eg adhesion) of the two types of clot. Our model heart has a rigid ventricular chamber and the flow pulse is a modified sinusoid. For some valves this may result in modified opening dynamics and, in the case of the mitral position, recirculation zones that would not be present in-vivo. The localised effect of anticoagulants is unknown, but there is the possibility that their effectiveness will be greater around some valves than around others. We have endeavoured to match the properties of the milk clot to those of thrombus, but the relative adhesivity to different surfaces is not amenable to control.
