We have developed a generic framework for analysing inter-sarcomere dynamics (Denoth et al, 2002). The complexity of a ‘real’ muscle fibre is addressed through rigorous coupling of the sarcomere and myofibril models in a system of differential equations. Our objective is to find an accurate description of (a) a myofibril as a linear motor composed of in series coupled sarcomeres and (b) a fibre as a linear motor composed of parallel coupled myofibrils. Emphasis of this work is put on systematic treatment of sarcomeres and not on the molecular modelling of the active and passive elements in them. With the current method we have found mathematical explanations for mechanisms such as sarcomere popping, homogenisation, extra tension, permanently changed tension or creep phenomena.

METHODS

Properties of the system of differential equations (DE) were examined based on a down-stripped model, which permits the derivation of analytical solutions. The system of differential equations for the complete model was solved by numerical methods, where in contrast to other work in the literature, we confine ourselves to relatively short myofibrils up to 30 sarcomeres. In both cases the inter-sarcomere dynamics in length- and force-controlled experiments were analysed.

RESULTS AND DISCUSSION

(a) Myofibril: In force-controlled experiments the inter-sarcomere dynamics is determined independently for each sarcomere. On the ascending limb and the plateau of the force-length relation of the active element, the sarcomere length resists a perturbation; the mechanical state is stable and is characterized by a relaxation time τ ($\tau \approx 1-5$ s). On the descending limb of the force-length relation of the active element, the sarcomere length will not resist perturbations if the slope of the total force-length function (contractile and passive elements) is negative; the mechanical state is unstable, the relaxation time τ is about 1-5 s.

Length-controlled experiments are governed by a coupling of sarcomeres. The behaviour is much more complex and we have shown that experimentally observed phenomena such as popping or creeping can be explained with the dynamic coupling of the DEs associated with each sarcomere. In mathematical terms the response of such a system can be described by N independent modes, where one mode is a linear combination of the N sarcomeres involved. Similar to simple sarcomeres, the modes are characterized by a stability parameter

Figure 1: Stretch-release experiment of a two-myofibril system. External length control displayed as a length-time curve of the mean sarcomere length (a). Force development in the fibre (b). Length-time curve of the sarcomeres of myofibril 1 (c) and the sarcomeres of myofibril 2 (d). Note: Stable modes in myofibril 1 may not prevent the popping of a sarcomere in myofibril 2.

and the relaxation time, however here unstable modes can affect multiple sarcomeres.

(b) A single fibre: Adjacent myofibrils are mechanically connected through the Z-line scaffold. The cross links are expected to stabilize the system; a local instability will be attenuated by ‘stable’ sarcomeres in neighbouring parallel myofibrils. However, the simulations show that unstable sarcomeres (or modes) in a myofibril may not be stabilized by sarcomeres on the plateau (or stable modes) of the immediate neighbouring myofibril (Figure1).

SUMMARY

A rather simplistic mechanical description of the contractile and passive elements in the sarcomere is sufficient to predict observations from single fibre experiments that are seemingly contradictory. It turns out that the large variability of possible fibre responses is the result from a convolution of multiple rules, each of them defining a certain characteristics of the single sarcomere. With this work we provide a comprehensive model platform for consistent interpretation of single fibre experiments.

LOWER BACK MOMENT AND POSTURAL PARAMETER RELATIONSHIPS DURING ASYMMETRIC LIFTING

Jason C. Gillette¹, Timothy R. Derrick², Nancy E. Quick³, and Robert Shapiro³

INTRODUCTION

Increased risks of injury during asymmetric as compared to symmetric lifting have been predicted by both biomechanical and epidemiological studies [Chaffin, 1999]. The selection of appropriate ergonomic indicators to quantify the effect of asymmetric lifting on lower back loading remains an area of active research. The goals of this study were: a) to determine the effects of asymmetry and object mass on L5/S1 joint moments and b) to examine relationships between L5/S1 joint moments and other postural parameters during lifting.

METHODS

Six subjects (mass 74 ± 12 kg, three males, three females) with no history of back pain volunteered for this study. The subjects lifted a milk crate loaded either with a self-selected, moderate amount of mass (12 ± 2 kg) or half this amount. These subjects lifted the crate free-style from floor level in front of their feet to waist level at 0° , 30° , 60° , or 90° of asymmetry to the right as mapped out on the floor for guidance. In total, three repetitions of two object masses at four asymmetry levels were performed, resulting in 24 lifting trials for each subject. The subjects stood on force platforms (Bertec Corp.) sampled at 960 Hz and wore reflective markers that were tracked by a six-camera video system (Motion Analysis Corp.) at 60 Hz. Centers of pressure (COP) and joint angles were calculated. A three-dimensional model of the human body was utilized to estimate joint moments at the L5/S1 intervertebral disc [Kingma, 1996]. Multivariate ANOVA (SAS Institute, Inc.) was performed to test the dependence of the L5/S1 joint moments on object weight and lifting asymmetry (significance at $p < 0.05$).

RESULTS

Maximum L5/S1 extension moments were significantly greater when lifting the heavier load as compared to the lighter load. Maximum L5/S1 lateral bending moments were greater for 60° and 90° asymmetry than for 0° when lifting the heavier load. In addition, maximum L5/S1 twisting moments were significantly greater for 90° asymmetry with the lighter load and for 60° and 90° asymmetry with the heavier load. Correlation coefficients between the anterior/posterior (A/P) COP and the L5/S1 extension moments averaged above 0.7 (Fig. 1), and correlations between the L5/S1 flexion angle and the L5/S1 extension moments averaged over 0.8 for all lifting conditions. Correlation coefficients between the L5/S1 twisting angle and the L5/S1 twisting moments averaged below -0.5 for 90° with the lighter load and for 60° and 90° with the heavier load.

Correlation of A/P COP and L5/S1 Extension Moments

Figure 1: A representative example showing the relationship between A/P COP and L5/S1 extension moments.

DISCUSSION

Maximum L5/S1 extension moments increased when lifting the heavier load, but were not significantly affected by the degree of lifting asymmetry. Along those lines, studies have found spinal compression forces that have even decreased with lifting asymmetry [van Dieen, 1999]. However, when lifting the heavier load, maximum L5/S1 lateral bending moments significantly increased from 30° to 60° asymmetry. This may suggest that lateral bending effects are of most concern after passing a certain threshold of asymmetry, which becomes more pronounced with increased lifting loads.

The estimation of L5/S1 joint moments requires an elaborate experimental setup that may not be possible to implement in the field. For example, COP could be determined using foot-based pressure sensors, and L5/S1 angle measurements could be measured by a Lumbar Motion Monitor [Marras, 1998]. Both A/P COP and L5/S1 flexion angles were correlated with L5/S1 extension moments and may serve as practical ergonomic measures. For L5/S1 twisting moments, the L5/S1 twisting angle appears promising for the more extreme asymmetry conditions that are of particular concern.

COULD MOBILE BEARING KNEE PROSTHESIS REDUCE STRESS CONCENTRATION UNDER SURGICAL MALALIGNMENT?

Chang-Hung Huang¹, Jiann-Jong Liao¹, Cheng-Kung Cheng¹, Chun-Hsiung Huang^{1,2}

¹Institute of Biomedical Engineering, National Yang-Ming University, Taipei, Taiwan, ckcheng@ortho.ym.edu.tw

INTRODUCTION

Fixed bearing total knee prosthesis (TKP) has been proved to be clinically successful. However, loosening and wear were still the long-term failure in fixed bearing knee prostheses. Mobile bearing TKP is designed to resolve these problems (Buechel F.F. and Pappas M.J.). The polyethylene bearing of mobile TKP can move relatively on the interface between bearing and tibial baseplate, which can decrease constraint force. In addition, the tibiofemoral joint is high conformity in contacting surfaces, so that it could reduce the contact pressure to prevent polyethylene wear. The malalignment of knee prosthesis was hypothesized to accelerate the polyethylene wear. The study was to investigate the difference in contact pressure between fixed and mobile bearing TKP under malalignment condition.

METHODS

At first, we modified the locking mechanism of fixed bearing (U-knee, ROC) to mobile bearing, the polyethylene insert can rotate on the tibial baseplate. These curvatures (moderate conformity) in the tibiofemoral contact surface of the mobile bearing was kept the same as fixed bearing. Malalignment of total knee replacement was simulated and the contact pressure in the tibiofemoral joint was measured by using Fuji prescale film and digital image analysis. The simulated malalignments include the mediolateral translation (0.5 and 1 mm), anteroposterior translation (2 and 4 mm) of the tibial component relative to the normal position. Further, Femoral component was positioned internal/external rotation (1, 3, 5 and 10 degrees) relative to tibial component. The compressive load was 3000 N to simulate the maximum contact force during human gait cycle.

RESULTS AND DISCUSSION

The maximum contact pressure of fixed bearing design was significantly higher than the mobile design when the tibial component was translated anteriorly 4 millimeter (Fig. 1). The maximum contact pressure of fixed bearing design was also significantly higher than the mobile bearing design when the tibial component was translated medially or laterally. In malrotation test, only at the internal or external 10 degrees, the maximum contact pressure of the fixed bearing design was significantly higher than the mobile bearing design. The maximum increase of contact pressure in anteroposterior maltranslation were 7.63 and 7.62 percent relative to the neutral contact situation in fixed and mobile bearing designs respectively. In mediolateral maltranslation, there were 23.3 percent in fixed bearing design and 22 percent in mobile bearing design. However, in the internal/external malrotation, the

increase of maximum contact pressure in fixed bearing design was 27.1 % which was much higher than mobile bearing design (22.4 %). The maximum contact pressure in the fixed bearing design was always higher than the mobile bearing design under malalignment situations. Mobile bearing knee prosthesis could reduce stress concentration because polyethylene insert can internal/external rotate on the metal tibial tray while simulated surgical malalignments occurred. There were some limitations in this study such as: the nonhomogeneous of Fuji pressure film and inaccuracy dimensions of the fixture would influence the measured result of maximum contact pressure.

SUMMARY

The mobile bearing design has smaller maximum contact pressure than the fixed bearing design when the malalignment of tibiofemoral joint of knee prosthesis was simulated. Even though, the design is moderate conformity in tibiofemoral contact surface. The mobile bearing has an advantage to accommodate the surgical malalignment than fixed bearing design. To provide better wear resistance in mobile bearing design, the high conforming design in the tibiofemoral contact surface can be considered.

Figure 1: Contact pressure of fixed and mobile bearing under different surgical malalignments.

T→A 4 mm: Tibial component was translated anteriorly 4 mm.

T→M 1 mm: Tibial component was translated medially 1 mm.

Malrotation 10°: Femoral component was malrotated 10 degree.

MUSCLE FORCES ANALYSIS IN THE SHOULDER MECHANISM DURING WHEELCHAIR PROPULSION

Hwai-Ting Lin¹, Hong-Wen Wu², and Fong-Chin Su¹

¹Institute of Biomedical Engineering, National Cheng Kung University, Tainan, Taiwan, fcsu@mail.ncku.edu.tw

²School of physical therapy, China Medical College, Taichung, Taiwan

INTRODUCTION

Epidemiological studies have shown that there is a high prevalence of shoulder injuries in wheelchair users. The high incidence of upper extremity musculoskeletal problems may be due to the low efficiency of wheelchair propulsion. To lessen the injury probability and to enhance the efficiency of wheelchair propulsion, biomechanical analysis of the contribution of arm- and shoulder muscles to the joint moments during wheelchair propulsion is essential. The purpose of this study was to determine the muscle contraction forces around the shoulder during wheelchair propulsion based on the measured segment motion and the estimated limb mass/inertia property of the wheelchair user.

METHODS

Eleven muscles were included in the shoulder model, while the motion of the entire body was considered in the dynamic analysis of the system. The wheelchair propulsion of a normal subject at level ground with the self-select speed was captured using an Expert VisionTM motion analysis system (Motion Analysis Corporation, U.S.A.) at a 60Hz sampling rate. Using the inverse dynamic problem solution and Newtonian analysis, the joint resultant forces and moments at shoulder were quantified. The indeterminate problem was solved using an optimization technique by minimizing the sum of the squares of muscle stresses. Additional inequality constraints on muscle force and stress output were considered, thus making the present formulation a “mini-max” problem. Sequential quadratic programming and a steepest decent algorithm were used to search for the unique solution. The wheelchair propulsion EMG data reported in the literature were used to qualitatively assess the validity of the theoretically predicted muscle forces and stresses.

RESULTS

We divided the wheelchair propulsion cycle into propulsion and recovery phase for results presentation. Anterior deltoid increased the muscle contraction force at the beginning of the propulsion phase and reached the maximum force 462N at the middle of propulsion phase then decreased to zero at the end of propulsion phase. Pectoralis major also had minor significant contraction force during the propulsion force, whereas the other muscles were relatively quiescent. During the recovery phase, all muscles had smaller contraction forces than in propulsion phase. Posterior deltoid and pectoralis major had larger contraction forces among all muscles (Fig. 1).

DISCUSSION

Direct measurement of muscular forces is invasive and currently impractical. A proper biomechanical model is helpful in understanding the state of muscle contraction in

response to both internal and external loading on the skeletal system. Previous electromyography (EMG) data for the wheelchair propulsion (Chow et al., 2001) showed that the anterior deltoid experiences peak activity in the propulsion phase, and the pectoralis major and posterior deltoid had significant muscle activity in the recovery phase which corroborates with our results. Nevertheless, the triceps brachii had high muscle activity in the propulsion phase in the EMG data that didn't show in our results. That may caused from the EMG data reflected the muscle activity that could not represent real muscle contraction force. The physiological cross-sectional area (PCSA) of the muscle also affected the muscle contraction force. The present study provided the first attempt to quantitate individual muscle contraction during wheelchair propulsion. This model and the analysis technique will aid in elucidating the underlying pathomechanics leading to various overuse syndromes involving the shoulder.

INTRODUCTION

The measurement and assessment of the shape of the human back is an important area of research. Spinal Mouse[®] and Zebris[®] system are now becoming more widely used for the specific purpose of back shape and mobility measurements. In both cases, by tracing the superficial shape of the subjects back, intelligent algorithms, within the systems software, computes information concerning the relative position of the vertebral bodies, of the underlying bony spinal column. To make qualitative judgments about spinal posture by observing surface curvature, is based on the assumption, that the surface curvature consistently reflects the underlying curvature of the vertebral column (Refsauge 1994). This study was therefore designed to test the validity of both systems, by comparing measurements with those of a gold standard, - an Orthopaedic surgeons analysis of Magnetic resonance images. Additionally, with reference to the gold standard measurements, the correlation between back and spinal shape was also investigated.

METHODS

15 male subjects age 19 – 37 were examined in 3 different postures, by 3 different methods – Zebris, Spinal Mouse, and Magnetic Resonance Image analysis. The measurements were conducted with the subject in the lying flat posture (Straight), a posture whose requirement to make the lumbar spine more lordotic (Lordotic), and a posture being used to examine the back/spine curvature, when the lumbar spine is made more kyphotic (Kyphotic). Clinical measurements from the magnetic resonance images, of the surface of the back and the spinal shape, conducted by an experienced orthopaedic surgeon, were also made. From the results, a comparison between the three measurement systems could then be made, as well as the possibility of evaluating the relationship between back shape and spinal curvature. It was essential, to ensure the subject was positioned in exact postures within all measurements. A specially built horizontally aligned bed, to

enable exact repetition of postural stance, was therefore designed and constructed for measurements purposes. The results from Zebris and Spine Mouse system was immediately available in the form of a medical report. However, the MRI radiographs required further examination from an spinal orthopaedic surgeon. The orthopaedic surgeon measured all the required clinical parameters for each subject. The parameters taken from the images were the Cobb angle according to the lumbar and thoracic surface as the gold standard, and the Cobb angle of the bony spine.

RESULTS AND DISCUSSION

Results obtained from each system during patient examinations, are displayed on a clear and easy to understand report sheet. The absolute values of Thoracic kyphosis, and Lumbar lordosis, of both surface and spinal curvatures, from clinical analysis of MRI's obtained, are shown in table (1). Differences in the absolute angles, determined by both Zebris and Spinal Mouse systems, in comparison to the respective gold standard measurements, are small for the Thoracic spine (<2.5°), but higher for the Lumbar spine.

SUMMARY

It is evident from the large standard deviation seen in all measurements obtained, that spine/back shape changes, as a consequence of postural alterations, varies from person to person. Many factors may influence this variation, such as body mass index and poor postural stance. It is clearly evident, that the correlation between surface and spine is an individually determined variable. All surface measurement devices can give acceptable results in the thoracic region of the spine.

VARIABILITY AND STABILITY CHANGE WITH WALKING VELOCITY--WHAT IS THE RELATIONSHIP BETWEEN THE TWO?

Janene Grodesky, M.Ed., Li Li, Ph.D., and Jan Hondzinski, Ph.D.

Department of Kinesiology, Louisiana State University, Baton Rouge, Louisiana, USA, LLI3@LSU.EDU

INTRODUCTION

Researchers have attempted to determine locomotion system stability using variability, such as the standard deviation (SD) of step duration, as an indicator. Furthermore, the increase in variability was related to the decrease in system stability (Brisswalter & Mottet, 1996; Newell & Corcos, 1993; Hamill, et al., 1999). Although variability and stability have been defined in different theoretical frames, the relationship between the two remains unclear. In addition, there is no empirically effective definition of stability. Thus, the purpose of this study was to design a method, based on the Dynamical Systems Theory, to measure stability, identify trends in variability and stability, and examine the relationship between these variables across walking speeds.

METHODS

Five participants of 20.2 ± 0.7 years of age, 63 ± 11 kg, and 1.67 ± 0.08 m were recruited. The participants signed informed consent forms after the testing protocol was discussed in detail. Reflective markers were placed on the anatomical landmarks of the hip, knee, ankle, and 5th metatarsal-phalange joint of the right leg. Lower extremity kinematics was collected at a sampling rate of 100 Hz using a

Qualisys System (Glastonbury, CT, USA). Five trials of 5 minutes were performed at each of 6 different speeds (0.67, 0.80, 0.94, 1.07, 1.21, & 1.34 m/s) randomized within and across subjects. During each trial, a mechanically triggered visual perturbation was introduced when the participants attained a stable stride pattern, which was targeted to be synchronous with heel contact of the right foot. Variability of locomotion was measured by calculating the SD of the knee joint angle ensemble curve across five strides during stable treadmill walking. Stability was calculated as the duration required for participants to resume their normal walking pattern after the gait was affected by the perturbation. A two factor (gait mode and speed) repeated measures ANOVA was used for statistical analysis. Pearson correlation coefficient was calculated to determine the relationship between variability and stability across the various walking speeds.

RESULTS AND DISCUSSION

The perturbations were introduced with a mean absolute latency of .059 s (6% of the gait cycle) after heel contact. The reliability of the variability and stability measurements were reported as reliable in a previous study with an Intraclass Correlation Coefficient (ICC) of 0.80 and 0.83, respectively (unpublished data). The results indicated that stability was insensitive to change in walking speed ($p > 0.9$), while variability decreased as walking speed increased ($p > 0.05$, Figure 1). In addition, no significant correlation between variability and stability was observed ($p > .05$). These data indicate that variability is not a dependable indicator of locomotion stability. Thus, although we cannot conclude that variability and stability measures are separate entities, we suggest that measurement other than variability should be used to describe locomotion system stability.

SUMMARY

The present study showed that trends in variability and stability were different across walking speeds. Also, there was no significant correlation observed between variability and stability. Based on these results we suggest that variability should not be used as an indicator of stability, and stability should be measured directly, independent of variability, when studying locomotion.

Figure 1. The trend of stability and variability changes with walking velocity. Stability was measured as the duration that it takes for the system to recover from a perturbed gait. Variability was measured as the sum of the standard deviation (SD) of the knee joint angle ensemble curve for five non-perturbed cycles.

BIOMECHANICAL INTERACTIONS OF THE PELVIS GIRDLES AND SURROUNDING SOFT TISSUES: TOWARD UNDERSTANDING THE MECHANISM OF PRESSURE SORE ONSET

Eran Linder-Ganz and Amit Gefen

Department of Biomedical Engineering, Faculty of Engineering, Tel Aviv University, Tel Aviv 69978, Israel, gefen@eng.tau.ac.il

INTRODUCTION

Pressure sores, caused by extensive and prolonged loading of tissues, are reported to appear in every 10th hospitalized adult, and are considered one of the most severe complications in geriatric and paralyzed patients. Many studies explored the interfacial mechanical stresses between the recumbent or sitting body and the supporting surfaces (Brosh and Arcan, 2000). However, recent simple biomechanical models of the pelvis indicated that elevated stresses, which could potentially lead to ulceration, are found internally, under the bony prominences of the pelvis (Bosboom et al., 2001). The goal of the present study was, therefore, to develop a realistic, anatomically accurate three-dimensional (3D) model of the pelvis region, in order to apply it for analysis of the mechanical conditions leading to onset of pressure sores.

METHODS

The 3D anatomy of a 5mm-thick cross-section taken around the sacrum was reconstructed from the Visible Human (male) digital database. The bones, cartilage, muscles, colon, ileum, major blood vessels, fascia and skin were segmented and their contours transferred to a solid modeling software package (SolidWorks 2001), for building the solid volumes which described the slice shown in Fig.1. The 3D slice geometry was then transferred to a finite element solver (NASTRAN 2001) for its structural analysis under body loading in the recumbent posture. This far, tissues were assumed to be homogenous, isotropic and elastic materials, with their properties adapted from previous reports (Gefen et al., 2000). Predictions of internal stress distribution were validated experimentally by comparing simulated to measured contact pressures, which were acquired by means of polyester pressure sensitive films (Sensor Products). Simulations of representative stress states in vulnerable populations (elderly and diabetics) were developed by increasing the stiffness of the skin and fascia to 6 times their normal values, in order to mimic the results of aging or disease (Gefen et al., 2001).

Figure 1: Structural model of the pelvis and surrounding tissues (left) and its finite element mesh (right).

RESULTS AND DISCUSSION

The distribution of von Mises stresses (Fig. 2) demonstrated sites of intensified loading in the muscular and soft connective tissues underlying the bony prominences of the pelvis. The maximal internal stresses at these sites (~350 KPa) exceeded the interfacial compression by two orders of magnitude.

Figure 2: The distribution of von Mises stresses (with a region of interest magnified under the bony prominences of the pelvis) during recumbency. A linear path *S* is defined for characterizing the rise in stress in the soft tissues across it, towards the bone surface.

Figure 3: The distributions of pressure under the model's contact area with the supporting surface (left) and of internal von Mises stresses (right) along the path *S* (as marked on Fig. 2) for different stiffness properties of the fascia and skin simulating normal and diabetic tissues.

Distributions of contact pressures under the model's contact area with the surface (Fig. 3) are in agreement with our experimental results. In simulations of the altered distribution of internal and interfacial stresses with the progression of diabetes, where soft connective tissues are stiffened (Gefen et al., 2001), it was shown that maximal stresses may rise by 33% at the surface and by 22% internally, around the sacrum. This indicates the vulnerability of diabetic patients to onset of pressure sores, and the model has the potential of being an aid in design of seats and beds for this and other populations.

VISUAL CONTROL OF LOCOMOTION DURING MOVABLE -OBSTACLE AVOIDANCE

Luiz Santos and Aftab Patla
Gait & Posture Lab, University of Waterloo, Waterloo, Ontario, Canada

INTRODUCTION

Perceiving changes in the environment is very important to implement avoidance strategies during locomotion. Usually avoidance strategies can be planned in advance using visual feedforward information (Patla, et.al., 1991). When there is a sudden change in the environment, however, it is necessary to make on-line adjustments in gait pattern in accordance with the direction and magnitude of the environmental change. This study investigates how visual information about a moving obstacle is used to implement on-line changes in adaptive patterns.

METHODS

Kinematic and kinetic data of seven participants (22-25 yr) was collected using 25 active markers. Participants were asked to walk and step over an obstacle (14 cm high) placed 100 cm in front of a force platform. They were told that the obstacle could move forward or stay static. For half of the trials ($n=40$) the obstacle remained static (V0) and in the other half the obstacle moved forward at one of two velocities (V1= 25, and V2= 60 cm/s). All trials were randomized. The obstacle motion was triggered at the toe off of the lead limb by the force platform. Velocities of toe, heel and Center of Mass (COM) were analyzed at three different points in time: Pos0 (when the foot reached the initial position of the obstacle), Pos1 (when the foot was on the top of the obstacle), and heel contact (HC). Toe Clearance (TC) was measured at Pos0 and at Pos1 (Figure 1a).

Figure 1: (a) Experimental set up; (b) Sample limb profiles.

RESULTS AND DISCUSSION

All subjects were able to step over the obstacle in both static and moving conditions. The sagittal trajectory (XY) of the toe and the heel (Figure 1b) were affected by the obstacle conditions. Vertical displacement of the toe and heel were scaled to obstacle velocity. Displacement was higher for the fastest velocity (V2). Measures of TC, step length (SL), COM, and toe velocity (vertical and horizontal) were significantly affected by obstacle velocity. TC at Pos0 was significantly

affected by the velocity conditions ($F_{(2,12)} = 5.31$, $p=0.022$). Both velocity conditions (V1 and V2) were different from the static condition (V0). The time from toe-off to Pos0 was approximately 250 ms and was not significantly different among the velocities ($F_{(2,12)} = 1.78$, $p=0.20$). This result suggests that there is a common response for the initial toe elevation. Although the magnitude of toe elevation was the same for both velocity conditions, the vertical velocity of the toe was significant scaled to all obstacle velocities ($F_{(2,12)} = 29.14$, $p=0.0001$ - Figure 2a), which suggests on-line acquisition of direction specific visual information.

Figure 2: Significant measures

The values and the time of TC calculated at Pos1 were significant different and were scaled to the obstacle velocity (value: $F_{(2,12)} = 13.84$, $p=0.0008$; time: $F_{(2,12)} = 78.97$, $p=0.0001$, Figure 2a,b). The same result was found for the vertical velocity of COM ($F_{(2,12)} = 70.56$, $p < 0.0001$; V0: -3.56 cm/s; V1: -5.84; V2: -9.54). The horizontal velocity of the toe was only affected by the fast velocity condition (V2), and only at Pos0 ($F_{(2,12)} = 5.11$, $p=0.0247$) and at HC ($F_{(2,12)} = 5.68$, $p=0.0184$). The antero-posterior velocity of the COM was only significantly different at HC ($F_{(2,12)} = 18.79$, $p=0.0002$). Both antero-posterior velocity of COM and SL were scaled to the obstacle conditions (VelCOM - V0: 155.8 cm/s, V1: 166.3 cm/s; V2: 180.2 cm/s; SL - V0: 157.0 cm, V1: 164.6 cm, V2: 172.5 cm).

SUMMARY

The findings suggest that direction and magnitude specific visual information about the moving obstacle were used to control on-line adaptive locomotor patterns.

INJURY RISK FUNCTION FOR THE SMALL FEMALE WRIST

Stefan M. Duma¹, Brian M. Boggess², Jeff R. Crandall², Conor B. MacMahon²

¹Virginia Tech, Impact Biomechanics Laboratory, Blacksburg, VA Duma@vt.edu

²University of Virginia, Automobile Safety Laboratory, Charlottesville, VA

INTRODUCTION

In addition to falls on the outstretched hand, the interaction between a deploying side airbag and the upper extremity has been shown in to result in wrist injuries as the hand becomes entrapped in the handgrip (Duma, 2001). The purpose of this paper is to develop a continuous injury risk function that can be used to predict wrist injuries at any force level from falls or from impact in an automobile crash environment.

METHODS

A total of 17 (n=17) axial impact experiments were performed on the wrists of small female cadavers. Small female cadaver upper extremities were used to develop the wrist tolerance as a conservative estimate of the most vulnerable section of the population. The test configuration was designed to impact the palm and force the wrist into compression. The energy source used to apply the axial loads was a pneumatic impactor. The applied axial pulse from the impactor was configured to match the force onset rate, impulse, and peak force in order to simulate a dynamic load profile. The upper extremities were disarticulated at the mid-shaft humerus and supported by two cables that held the elbow in 90° of flexion. The forearms were kept intact in order to preserve the load distribution through the interosseous ligament. Instrumentation included an impactor load cell (Model 1968, Robert A. Denton Inc., Rochester Hills, MI) to measure applied axial load, accelerometers (Model 7264a, Endevco Inc., San Juan Capistrano, CA) on the impactor mount for mass compensation, and magneto-hydrodynamic angular rate sensors (Model ARS-04E, ATA Sensors Inc., Albuquerque, NM) on the hand and forearm to measure wrist flexion during the event. All tests were recorded with high speed color video at 1000 fps. The bone mineral density of each specimen was determined by using the Osteogram® technique (CompuMed Inc., Los Angeles, CA), and injury analysis was performed using radiographs and detailed necropsy.

RESULTS AND DISCUSSION

Post-test necropsy revealed that 9 of the 17 tests resulted in wrist injuries (Table 1). The injury patterns were consistent to those observed from cases studies of fall data and cadaver tests with side airbags and included fractures of the scaphoid, lunate, distal radius, and distal ulna. The peak impactor force ranged from 344 N to 3616 N and the initial wrist extension angle ranged from 55° to 62°. Analysis of the high speed video showed that the hand remained in contact with the handgrip and did not separate until the end of the impact loading event. Logistic regression analysis showed that the injury outcome was independent of specimen age (p = 0.99), mass (p = 0.31), stature (p = 0.69), and bone mineral density (p = 0.49). The lack of dependence on subject anthropometric parameters was attributed to the narrow sample size in this group of experiments, which consisted only of small female specimens.

Table 1: Specimen mass, test data, and resulting injuries.

T E S T	Subject Body Mass (kg)	Peak Force (N)	Force Onset Rate (N/ms)	Momen- tum Transfer (Ns)	Observed Injuries
1	41	1199	174	12.6	None
2	41	2001	738	17.0	Distal Radius fx Ulna Styloid fx
3	66	1794	352	14.1	None
4	66	2007	508	21.5	Scaphoid fx Distal Radius fx Ulna Styloid fx
5	63	1412	182	14.4	None
6	55	890	140	9.2	None
7	65	1657	435	16.1	Distal Radius fx Ulna Styloid fx
8	91	2708	893	26.8	Scaphoid fx
9	71	2212	242	21.8	None
10	52	3358	430	28.9	Scaphoid fx
11	67	2385	758	28.4	Distal Radius fx
12	55	2653	395	24.0	Distal Radius fx Scaphoid fx
13	65	418	38	5.1	None
14	91	4336	1006	33.2	Distal Radius fx
15	71	4698	1460	36.3	Distal Radius fx Ulna Styloid fx Lunate fx
16	52	2584	571	16.2	None
17	67	1242	269	13.5	None

Using the injury outcome as the binary variable, a logistic regression analysis was performed. The peak impact forces were mass scaled to the 5th percentile female (Eppinger, 1984) to provide an injury risk function suitable for the 5th percentile female test dummy. The analysis produced an injury risk function that predicts a 50% risk of injury at a wrist load of 1700 N (p = 0.0037) where 'x' is the applied axial wrist load:

$$\text{Probability of Wrist Injury (x) = } \frac{1}{1 + e^{(4.40 - 0.00259 \cdot x)}} \text{ For the 5}^{\text{th}} \text{ Percentile Female}$$

Based on the similarities in impact load profile and observed injury patterns between these tests and fall experiments (Chiu, 1998) and side airbag tests (Duma, 2001), it is suggested that the injury risk function will accurately predict the risk of wrist injuries in the both environments.

INTRODUCTION

The essence of human walking is to move the upper body from one place to another with reliable stability. Furthermore, the vertical and lateral pelvic motion plays a crucial role in the stabilization of the upper body and, they are two of the six major determinants of gait. Thus, the study of upper body stability with complex pelvic motion is important (Wu *et al.*, 1998), but has not been studied properly. The challenge is that though the controller can be designed to keep the stability, it often can not produce the responses similar to those from natural systems.

In this work, we develop a mathematical model of human thorax and pelvis moving in the frontal plane during walking. The upper body is modeled as a two-link inverted pendulums. The base point moves freely in the same plane. A continuous controller is designed based on Lyapunov's stability theory to guarantee the system stability. The system response and the control torques are further compared with those based on gait measurement, and we found they match reasonably well.

METHODOLOGY

Figure 1. Two-link Model of the thorax and pelvis

The two-link model is shown in Figure 1. The motion of the base point is described by $\tilde{f}(t)$ and $\tilde{g}(t)$ in the inertial OXY system. The general dynamic equations are shown as follows:

$$M\ddot{\Theta} + C(\Theta, \dot{\Theta})\dot{\Theta} + G(\Theta) + \tilde{F}(\Theta)\ddot{\tilde{f}}(t) + \tilde{G}(\Theta)\ddot{\tilde{g}}(t) = R \quad (1)$$

where $\tilde{F}(\Theta)\ddot{\tilde{f}}(t)$ and $\tilde{G}(\Theta)\ddot{\tilde{g}}(t)$ are vectors related to the effects of base motion. M is the inertia matrix. R is the vector of control torques applied on each link. The controller is designed to stabilize the system at the upright position as:

$$R_1 = -k_1\theta_1 - k_{1d}\dot{\theta}_1 - (m_1a_1 + m_2l_1)\left|\ddot{\tilde{f}}(t)\right|sgn(\dot{\theta}_1) - (m_1a_1 + m_2l_1)\left|\ddot{\tilde{g}}(t)\right|\left|\theta_1\right|sgn(\dot{\theta}_1) \quad (2a)$$

$$R_2 = -k_2\theta_2 - k_{2d}\dot{\theta}_2 - m_2a_2\left|\ddot{\tilde{f}}(t)\right|sgn(\dot{\theta}_2) - m_2a_2\left|\ddot{\tilde{g}}(t)\right|\left|\theta_2\right|sgn(\dot{\theta}_2) \quad (2b)$$

where g is the gravitational acceleration, m_i , and l_i ($i=1,2$) are the mass and length of each link. a_1 is the distance from the base point O to the center of mass of link 1, and a_2 is the

distance from point A to the center of mass of link 2 (see Figure 1). $sgn(\dot{\theta}_i)$ ($i=1,2$) denotes a sigma function.

A Lyapunov function is constructed as follows to prove that the system is stable about the upright position.

$$V = \frac{1}{2}(\dot{\Theta}^T M \dot{\Theta}) + (m_1a_1 + m_2l_1)g(\cos\theta_1 - 1) + m_2a_2g(\cos\theta_2 - 1) + \frac{1}{2}k_1\theta_1^2 + \frac{1}{2}k_2\theta_2^2 \quad (3)$$

where $\dot{\Theta} = \{\dot{\theta}_1, \dot{\theta}_2\}^T$. $k_2 > m_2a_2g$ and $k_1 > (m_1a_1 + m_2l_1)g$. M is the inertial matrix shown in equation (1).

RESULTS AND DISCUSSIONS

To substantiate the capacity of our model towards describing the dynamics of the human thorax and pelvis during walking, the simulations were compared with those from gait measurements. For the sake of brevity, only the pelvic angle and torque are shown in Figure 2, and they match reasonably well.

In this paper, we have demonstrated the development of a dynamic model for human thorax and pelvis during walking with the following important features: (1) the system stability is guaranteed, (2) the effects of translational pelvic motion are included, and (3) the motion and the torques similar to those of humans can still be produced. This model can serve as a framework for further development of more realistic models of human locomotion systems

INTRODUCTION

Detailed investigation of flow patterns in the Left Ventricle (LV) could improve our understanding of heart function and dysfunction. In the present study, the time-dependant structure of the LV was recorded by cine magnetic resonance imaging (MRI) in multiple planes, allowing the reconstruction of a 4D model of the LV cavity. With this information, quantitative intra-ventricular flow patterns were predicted by CFD simulations.

METHODS

Imaging was performed using a Siemens Sonata 1.5T MR system. A multi-slice cine True-FISP imaging sequence was used to acquire 7 short axis slices at 14 phases providing complete spatial and temporal coverage of the LV. All images were acquired within a single 20 second breath-hold so as to minimize registration errors caused by respiratory movement. Segmentation and reconstruction of the LV structure was performed using proprietary software. This allowed the capture of detailed spatial and temporal properties of the endocardial border from reformatted images representing short axis, long axis and M-Mode acquisitions. The LV structure was modelled as the union of a pair of deformed cylinders delineating the inflow and outflow tracts.

Structured numerical volume mesh was generated for the LV cavity at each of 14 phases in a cardiac cycle. B-splines were used to interpolate between measured time points to produce a total of 50 meshes in a cycle. The meshes have the same structure for each model. A finite volume based CFD solver (CFX4) was employed to perform flow simulation from the beginning of systole. During systole, a constant pressure was specified at the outflow plane and no flow was allowed through the inflow plane. During diastole, the outflow plane was closed while the inflow plane was opened with a constant pressure specified. The opening area of the inflow plane was allowed to vary with time. The simulation was carried out for five complete cycles to achieve a periodic solution (where the velocity variation between the last two cycles was less than 3% at test points in the LV model).

RESULTS AND CONCLUSION

CFD simulations were carried out on 3 asymptomatic subjects. For each case, velocity vectors and pressure distributions in the LV models were predicted. Examples of the model geometry, numerical mesh (Figure 1) and velocity vectors in a long axis plane (Figure 2) are shown.

Figure 1. Geometry of the ventricle at (a) mid-systole, (b) mid-diastole and (c) structure numerical mesh.

Figure 2. Velocity vectors in a left ventricular long axis plane at (a) mid-systole and (b) mid-diastole. Vorticity is seen in both cases.

A general feature of intra-ventricular flow as predicted by these methods was large-scale vorticity in the cavity for much of the cardiac cycle. For a given wall geometry, the computed shape, size, location, duration and even directionality of vortices were found to be highly dependent on the size, location and orientation of the inlet orifice representing the mitral valve. Effects of different inlet orifices, and hence inlet boundary conditions, on flow patterns in the models will be presented at the conference.

HEMATOCRIT DETERMINATION IN BLOOD LINE OF DIALYSED PATIENTS BY ULTRASOUND

Michel Y. Jaffrin, Marianne Fenech, Bachar. Kanj and Mahmoud Maasrani
UMR 6600, Biomechanics and Biomedical Engineering
Technological University of Compiègne, BP 20529, 60205 Compiègne, France

INTRODUCTION

Blood volume monitoring during dialysis is important since hypotension, which occurs in about 30% of patients is thought to be related to hypovolemia caused by fluid removal. An ultrasonic technique for blood volume monitoring, proposed by Schneditz and coworkers [1], consists in measuring the sound speed in blood which depends upon blood density and therefore on hematocrit and protein concentration. They proposed an empirical linear relationship between blood water concentration (BWC) and hematocrit.

The purpose of this work is to propose a more accurate method which takes into account patient plasma protein concentration and its variation.

THEORETICAL BACKGROUND

By definition, the BWC is given by

$$BWC = \frac{100M_w}{M_w + M_p + M_{hg}} \quad (1)$$

where M_w is the water mass per liter of blood, M_p the mass of plasma proteins and lipids and M_{hg} the red cell mass including cell membrane. Since a liter of pure water weighs 993 g at 37°C, the water mass in g/l of plasma at a protein concentration C_p in g/l is

$$M_{wpl} = 1012 - 0.913 C_p \quad (2)$$

Since 1 liter of red cells contains 735 g/l of water, we can express the water mass per liter of blood as

$$M_w = (1012 - 0.913 C_p)(1 - H/100) + 7.35 H \quad (3)$$

Assuming that the plasma lipids represent 8.2% of the protein concentration (the average percentage) the plasma lipids and proteins mass per liter of blood is given by

$$M_p = 1.082 C_p (1 - H/100) \quad (4)$$

Finally, since the hemoglobin mass is 340 g/l and the cell membrane 21 g/l we write

$$M_{hg} = (340 + 21) H/100 = 3.61 H \quad (5)$$

Combining eqs 1 to 5 we obtain for BWC

$$BWC = \frac{100[1012 - 0.913 C_p (1 - H/100) - 2.77 H]}{1012 + 0.169 C_p (1 - H/100) + 0.84 H} \quad (6)$$

Assuming proteins and red cells conservation during dialysis, we write

$$C_p(100 - H)/H = C_{p0}(100 - H_0)/H_0 \quad (7)$$

MATERIAL AND METHODS.

Tests were carried out under medical supervision on six patients of the Compiègne Dialysis Center, for a total of 11 runs. The generator used was a Fresenius 4008 H equipped with a blood volume monitor (BVM). Blood samples were sent to a commercial laboratory for measuring hematocrit by a Coulter counter coupled with a spectro-photometer. These measurements were used as controls.

RESULTS AND DISCUSSION

Individual correlations between hematocrits measured by the lab and BWC measured by the BVM are displayed in Fig.1 for each patient. The general correlation obtained by pooling all data for the 11 runs is found to be

$$H_L = 298.9 - 3.1755 BWC \quad (R^2 = 0.7335) \quad (8)$$

The standard deviation was 1.78% and the mean deviation was -0.02%.

Figure 1: Correlation between control hematocrits and BWC in the 11 runs.

Proposed method

The new method consists in calculating in each patient the variation of H and C_p from BWC and the initial protein concentration estimated from the last available blood test. Eqs 6 and 7 are solved for H and C_p respectively as

$$H = \frac{1012(100 - BWC) - C_p(0.169BWC + 91.3)}{277 - 0.913C_p + (0.84 - 0.00169C_p)BWC} \quad (9)$$

$$C_p = \frac{C_{p0}H(100 - H_0)}{H_0(100 - H)} \quad (10)$$

For calculating the hematocrit during each dialysis run from BWC supplied by the BVM we have eliminated C_p in Eq. (9) using Eq.(10). The result is a quadratic equation for H of the form

$$aH^2 - bH + c = 0 \quad (11)$$

where the coefficients a, b, c are functions of C_{p0} and BWC. This equation is solved analytically. The agreement between control hematocrits and those calculated from Eq.(9) for the 11 runs using measured protein concentration is very good. The standard deviation has been reduced to 1.08% (from 1.78% with Eq. 8) with a mean deviation of -0.24%. This precision is equivalent to that of the spectrophotometric method used as control.

THERMAL FINITE ELEMENT ANALYSIS OF OSTEOCYTE KILL ZONES ACHIEVED WITH ACRYO-INSULT PROBE

Karen L. Reed¹ (Email: karen-reed@uiowa.edu), Thomas D. Brown^{2,1}, Michael G. Conzemius³

¹Departments of Biomedical Engineering and ²Orthopaedic Surgery, University of Iowa, Iowa City, IA

³Veterinary Teaching Hospital, Iowa State University, Ames, IA

INTRODUCTION Osteonecrosis remains a major unsolved problem in orthopaedic hip surgery, responsible for about 10% of the primary cases and 20% of the societal cost of total hip arthroplasty (Mont, 1995). To help in devising head-preserving surgeries, we have recently developed a method of creating segmental lesions by using a cryogenic probe (Reed, 2001) in the emu, a large biped which progresses to femoral head collapse (Conzemius, 2000).

In order to parametrically modulate the shape and size of the kill zone (ice ball) produced *in vivo* with the cryogenic probe, a thermal finite element model has been developed, and validated using bench-top surgical simulations. The model has been implemented to guide the intraoperative protocol to determine freezing time to achieve a specified kill-zone.

METHODS A closed-circulation cryo-insult probe, (Figure 1) previously described (Reed, 2001), consists of an outer and inner tube (15 gage and 21 gage 316 stainless steel thin-walled tubing). The outer tube is wrapped in 37 gage high-resistance heating wire, and coated with Teflon for protection. The tip of the probe is thermally isolated from the heated shaft by a small piece of Ultem (polyetherimide). Type T thermocouples are located at the tip and just above the Ultem insulator, so that shaft temperature can be controlled intraoperatively.

Figure 1: Schematic of the closed-circulation cryogenic probe

An axisymmetric thermal finite element model of this probe was developed, using Patran 9.0 for pre-processing (HKS, Pawtucket, RI), and ABAQUS 6.2 for analysis (MSC, Los Angeles, CA). The probe is surrounded by an "infinite" field of a 1% agarose-water gel (whose thermal conductivity matches that of cancellous bone) (Biyikli, 1986). Tip and shaft temperature boundary conditions consisted of curves taken directly from experimental data. Additionally, a far-field boundary condition of room temperature (or emu body temperature, for *in vivo* simulations) was imposed. Model validation consisted of comparing simulated temperature-time curves with those achieved experimentally.

There were three differences between the validation and *in vivo* models: *in vivo* simulations (1) consisted of multiple freeze-thaw cycles, (2) started at emu body temperature (instead of room temperature), and (3) included the warming effects of blood flow in the femoral head.

To simulate blood flow, all substrate (bone tissue bed) elements had a volumetric heat source,

$$q_p = \eta(T_s) \cdot \rho_p \cdot C_{p_p} \cdot \beta \cdot [T_c - T_s]$$

where: q_p = power (W/cm^3); $\eta(T_s)=1$ if $T_s \geq 273$ K, 0 if $T_s < 273$ K; ρ_p =blood density (g/cm^3); C_{p_p} =blood spec. heat ($J/g \cdot K$); β =blood perfusion rate ($g/g \cdot s$); T_c =element temperature (K); and T_s =body temperature (K).

Figure 2: Experimental probe testing setup

The experimental probe testing setup (Figure 2) consisted of 5 type T thermocouples, embedded in the agarose gel at locations ranging from 0 mm to 12 mm from the cryogenic probe. Liquid nitrogen was circulated through the probe using a Cryogun (Brymill Cryogenic Systems, Ellington, CT). Data were collected using LabVIEW (National Instruments, Austin, TX).

Operator control of cryo-insult was via valve attenuation of liquid N_2 flow to the probe, rather than by probe temperature set point. Therefore, time-variant probe temperatures (recorded experimentally) were used to drive the simulation.

Figure 3: Comparison of experimental (dark) and FE (light) temperature histories during a 9-minute freeze

RESULTS Experimental and validation simulations showed close correspondence in temperature-time curves at various radii (figure 3), and similar ice-ball expansion rates. Validation trials were conducted for nine-minute cryo-insults (a time similar to that previously used, empirically, for emu surgeries).

In vivo freeze-thaw cycles showed a decrease in freeze-front expansion, and an increase in thaw rates, due to femoral head blood perfusion. Additionally, as expected, there was a slight increase in ice-ball radius during subsequent freezes, due to a lower "initial" temperature of the surrounding tissue (Figure 4).

Figure 4: Computed *in vivo* ice ball radii for three consecutive nine-minute freeze-thaw cycles

DISCUSSION

This validated FE model has proven invaluable as a means to predictably modulate lesion sizes for our *in vivo* emu surgeries.

SUMMARY A finite element model describing the temperature fields surrounding a cryogenic probe has been developed and validated. This model has been used to estimate the temperature history of bony tissue during local surgical freezing, for the purpose of creating osteonecrotic lesions.

KNEE EXTENSOR TORQUE AND WORK DURING DYNAMIC CONTRACTIONS GUIDED BY PERCEPTUAL SENSATIONS

Paul T. Dixon¹, Alan J. Coelho², and Danny M. Pincivero³

¹Department of Bioengineering, The University of Toledo, pdixon@eng.utoledo.edu

³Department of Kinesiology, The University of Toledo, danny.pincivero@utoledo.edu

INTRODUCTION

The ability to accurately replicate graded levels of knee extensor torque based on subjective feelings of perceived exertion has been shown to be over-estimated during isometric contractions (Pincivero et al, 2000) and lifting tasks (Kumar et al, 1994). The purpose of this study was to examine knee extensor peak torque (PT) and work (W) production during isokinetic contractions guided by perceptual sensations.

METHODS

Fifteen males and 15 females were evaluated for maximum knee extensor strength, via isokinetic testing at $1.05 \text{ rad} \cdot \text{s}^{-1}$. Immediately following 5 maximal-effort contractions, subjects were instructed to “think about the feelings in their quadriceps during the contraction, and to assign a rating of 10 to those feelings”. Following 2 min of rest, subjects were asked to sit quietly and to “think about the feelings in their quadriceps and to assign a rating of 0 to those feelings”.

Subjects performed 3 voluntary knee extensions, separately, at the following perceptual intensities: 1, 2, 3, 4, 5, 6, 7, 8, and 9, in a random order. For each contraction, subjects were instructed to “contract their muscles to a level that feels like a (assigned number)”. During each contraction, subjects were instructed to view a 10-point scale while the investigator pointed to the selected number. During all testing, subjects were blinded to the absolute torque values they were generating. Peak torque, and knee extensor W were determined over the middle 1.22 rad of extension for each contraction. The second 2 contractions were averaged and normalized to the 3 highest values of the maximal efforts.

RESULTS AND DISCUSSION

The results demonstrated a significant increase in normalized knee extensor peak torque ($F_{8,224}=118.87$, $p<0.05$) and work ($F_{8,224}=132.31$, $p<0.05$) across perceived exertion levels 1 to 9 (Figure 1). No significant gender, or gender by perceived exertion interactions for any of the isokinetic variables were noted. Subjects were found to under-estimate their effort at perceived exertion levels 1-2 for PT, and 1-3 for W. In this regard the normalized torque was over-produced (i.e., comparison with expected values of 10% at perceived exertion level 1, 20% at perceived exertion level 2, etc.). Peak torque was found to be statistically similar to the expected values at

perceived exertion levels 3-6, and perceived exertion levels 4-6 for W. At higher perceived exertion levels (7-9), over-estimation was observed as normalized PT and W was under-produced from the expected values.

Figure 1: Normalized knee extensor PT and W across perceived exertion levels 1 to 9.

SUMMARY

The major findings indicate that the ability to accurately replicate PT and W during dynamic knee extension efforts appears to be attenuated at relatively low and high levels of perceived exertion. In concurrence with Kumar and Simmonds (1994), torque replication appeared to be accurate during moderate-level contractions.

INTRODUCTION

Mechanical stimuli play an important role in cellular processes such as growth, adaptation and cellular breakdown. Knowledge of local cell strains can aid in our understanding of these processes. However, defining local cell strains within a tissue is difficult. First, local cell strains are a complex function of tissue strain due to the local microstructural architecture. In turn, tissue strains are influenced by the presence of cells. Moreover, cell and matrix properties vary in time due to remodeling. To incorporate these phenomena, we adopted a finite strain multi-scale finite element approach (Breuls et al., 2002). This approach is used to study the role of the local microstructure's physical and geometrical heterogeneity on resulting cell and tissue strains.

METHODS

In the multi-scale FE approach, the macroscopic tissue is represented by a macroscopic FE model (Figure 1). To each macroscopic integration point, a micro FE model is assigned, representing the underlying local microstructure.

Multi-scale Finite Element Approach

Figure 1: Flow chart of the Multi-scale FE approach.

The macroscopic finite strain FE model supplies boundary conditions for the finite strain microstructural models. These detailed microstructural FE models predict local cell loads. In turn, the microstructural FE models supply the macroscopic stresses and effective stiffnesses using a computational homogenization procedure. Thus, macroscopic behavior is completely determined on the basis of the underlying microstructure – irrespective of its complexity. To deal with the relative large computational times, the approach has been

implemented on a parallel computing system (Beowulf Cluster).

To investigate the effect of microstructural architecture on individual cell loads, we simulated the compression of an engineered muscle tissue construct.

RESULTS

In Fig. 2, the results of the simulations show that:

- 1) Average cell loads highly depend on local architecture.
- 2) Individual cell loads vary a factor 5 due to heterogeneity.
- 3) Cell strains exceed macroscopic tissue strains with an order of magnitude.
- 4) Strain distributions within a cell are heterogeneous.

Multi-scale Simulation

Figure 2: Results of multi-scale simulations with two different microstructural meshes.

SUMMARY

A multi-scale finite element approach, has been adopted to define local cell loads in an engineered tissue construct. The model incorporates a detailed analysis of an arbitrary complex microstructure and contemplates the influences of microstructural properties on the effective macroscopic tissue properties. Simulations indicate that the local microstructural architecture has a profound impact on cell and tissue strains. The multi-scale approach provides a framework to study these cell and tissue strains.

INTRODUCTION

Injury of the interosseous talocalcaneal ligament (ITCL) has been recognized as the most important cause of subtalar instability; however diagnosis of this injury remains difficult due to the lack of an accepted clinical test. We conducted a cadaveric experimental study to identify the appropriate direction for a clinical drawer examination for ITCL injuries. In this investigation, we found the neutral zone laxity of the subtalar joint under applied multi-directional transverse forces, and determined a dominant direction of subtalar joint laxity involved with ITCL sectioning.

METHODS

Four fresh frozen cadaveric specimens were placed in a custom-loading fixture for multi-directional laxity tests. The fixture allowed six tests at 30 degree increments in the transverse plane (**Figure 1**). The anterior direction was defined as 0 degrees, the lateral as 90 degrees, the posterior as 180 degrees, and the medial as 270 degrees. The fixture was mounted in a material-testing machine (MTS-810) that supplies and controls the force. Seven cycles of loading to +/- 60N, using a ramp function with a loading frequency of 0.1Hz, were applied in each test. After four preconditioning cycles, the next three cycles of the load-displacement response were collected. After completing six loading directions in the intact condition, the specimen underwent ITCL sectioning, and the tests were repeated.

RESULTS AND DISCUSSION

The load-displacement relationship was characterized by a sigmoid curve (**Figure 2**). A flat region, where stiffness was near 0, was observed on and about the 0 force. To describe this portion of the load-displacement response, the displacement between +/- 10N of load was defined as the neutral zone laxity. A neutral zone laxity was measured for both positive-to-negative and negative-to-positive drawer forces. The neutral zone laxity portion of the load-displacement curve was characterized by large displacement values that were produced by the application of small magnitude of force. Increases of the neutral zone accompanying sectioning the ITCL serve as an

objective basis for indexing laxity.

The largest increase in laxity occurred in the 300°-120° direction with sectioning of the ITCL (**Table 1**). On average, a 38.3 +/-18.9 % increase was observed in the 300°-120° direction, in contrast, the mean increase among the 0°-180°, 30°-210° and the 60°-240° directions was only 13.7 +/- 14.6 %. Based on these data we believe that clinical assessment of ITCL integrity should be done along an axis roughly defined from the posterior aspect of the lateral malleolus to the anterior aspect of the medial malleolus.

Figure 1 Testing directions of the multi-directional laxity test. The bold line shows the dominant direction of subtalar laxity increasing with ITCL sectioning.

Figure 2 Typical load-displacement relationship (Intact condition, 300°-120° direction)

SUMMARY

Multi-directional transverse laxity tests were studied for the subtalar joint, to identify the appropriate direction for a clinical examination for ITCL injuries. The result suggests that an axis roughly defined from the posterior aspect of the lateral malleolus to the anterior aspect of the medial malleolus is the dominant direction of subtalar laxity increase with ITCL sectioning.

INTRODUCTION

The centre of rotation (COR) of a joint undergoing a specified action has been used to detect movement abnormalities, to estimate musculotendinous moment arms and to predict the loading of a joint and its associated soft tissue structures. The elbow COR has been observed to remain fixed throughout flexion-extension in adults, (For example, Chao and Morrey, 1978). These studies examined the COR in cadavers and therefore it is uncertain whether this COR can be applied to active joint movements. It is also not known whether this COR location can be applied to children, since bone development during and post-puberty may influence the elbow articulation and its consequent movement, (Jaramillo and Waters, 1997). Therefore, the purpose of this study was to derive co-ordinates for the elbow joint COR during active flexion-extension in children, in order to examine whether the COR location remained fixed or moved, and agreed with the adult literature.

METHODS

Thirty one children volunteered to participate in the study. The subject characteristics are presented in Table 1. All children were pre-pubertal according to Tanner's indices of pubic hair.

Table 1. Subject characteristics. Values are means (standard deviations).

	N	Age (y)	Mass (kg)	Stature (m)	Arm length (cm)	Forearm length (cm)
Boys	15	9.7(0.3)	34.11(10.73)	1.39(0.08)	28.9(1.7)	21.1(1.5)
Girls	16	9.5(0.3)	32.39(5.47)	1.37(0.04)	28.3(1.3)	20.3(0.8)
Total	31	9.6(0.3)	33.22(8.34)	1.38(0.06)	28.6(1.5)	20.7(1.2)

To estimate the elbow joint COR throughout the flexion-extension range of motion, the elbow was fixed in 5 positions of elbow flexion (90°, 70°, 50°, 30° and 10°) within the integral body core of a Magnetic Resonance Imager (Philips 0.5 Tesla Powertrak 1000 system). At each angle sagittal plane T1 spin echo images were taken (slice thickness 4mm, slice gap 0.4mm), during isometric elbow flexion. The method described by Reuleaux (1875) cited by Maganaris et al (1998) was used to estimate the COR location. Therefore 4 CORs were derived for the 5 elbow angles scanned. This analysis was performed 6 times for each subject. To compare the COR location throughout the range of motion and between individuals, co-ordinates were derived for each COR by placing axes relative to the long axis of the humerus and also the trochlea, (Figure 1).

To examine whether the COR remained fixed or moved throughout flexion-extension, separate repeated measures

ANOVA tests were performed using each subject's mean x, and y co-ordinates for each COR, respectively. An alpha level of 0.05 was accepted as significant. Since boys and girls were grouped together in the previous ANOVA analyses, non-parametric Mann-Whitney U tests were also used to examine if there were significant sex differences in any of the COR co-ordinates.

RESULTS AND DISCUSSION

There were no significant differences in either the x or y co-ordinates for any of the CORs for the group as whole (boys and girls combined), or between boys and girls. Therefore the mean COR x co-ordinate, and y co-ordinate were determined from the 4 COR locations. This provided a fixed COR position for the children for elbow flexion-extension (Figure 1).

Figure 1. Axes and fixed COR position (x) for active elbow flexion in 9/10 year old children. Scale: 1mm=0.52mm.

The co-ordinate derived for the 9/10 year old boys and girls during isometric elbow flexion positioned the COR approximately on the centre of the trochlea. This is in agreement with the COR positions identified for adult cadavers. In this study, the fixed position of the COR was defined by the co-ordinate (-3.75mm, -1.45mm) relative to the internal axes (Figure 1). This COR co-ordinate can be used for subsequent estimates of muscle-tendon moment arms according to the geometric technique (Pandy, 1999).

IN VIVO ASSESSMENT OF THE INSTANTANEOUS AXES OF ROTATION OF THE LUMBAR SPINE IN SYMPTOMATIC AND ASYMPTOMATIC SUBJECTS

Shawn Farrokhi (farrokhi@usc.edu), Kornelia Kulig, Judy Burnfield, Christopher Powers
Department of Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, California, USA

INTRODUCTION

The location of the instantaneous axis of rotation (IAR) is within the boundaries of a joint in non-pathologic conditions. Pathology, however, may alter joint kinematics, including the location of the IAR. The purpose of this study was to describe the sagittal plane location of the IAR for individuals with and without low back pain. It was hypothesized that a greater number of the IARs would be located outside of the functional spinal unit (FSU) in symptomatic compared to asymptomatic individuals.

METHODS

Eight individuals (four pain-free, four symptomatic; 22-43 y.o.) consented to participate in this study. Symptomatic subjects reported non-specific low back pain that increased with extension. Dynamic imaging of the lumbar spine was performed using a vertically open MR system (0.5 Tesla, Signa SP, General Electric Medical Systems, Milwaukee, WI, USA). Subjects were positioned prone with the lumbar spine centered within the magnet. A surface coil was secured to the anterior and posterior lower torso using cloth tape. Using their arms, each subject was instructed to arch their back as far as they were able to without causing additional pain (Figure 1).

Figure 1. Sagittal view of the resting (left) and final extended (right) position of the lumbar spine for a prone press-up.

Figure 2. The Reuleaux Method
(● = IAR for L5-

MR images of the resting and final extended positions for each individual were used to calculate the IAR for each FSU using the Reuleaux method (Broc 1997; Haher, 1991; Percy, 1988). Due to the clarity of the posterior borders of the vertebrae, the posterior superior and posterior inferior landmarks of the superior and inferior vertebral bodies were chosen to calculate the IAR (Figure 2). Only FSUs L3-L4, L4-L5, L5-S1 were analyzed, as these units are more frequently symptomatic.

RESULTS AND DISCUSSION

Overall, asymptomatic subjects presented with less variability in the location of the IAR for each FSU and, with the exception of one subject, all of the IARs were within the anterior elements of the FSU (Figure 3). The locations of the IAR for symptomatic subjects were more dispersed, and in many cases, were located outside of the anterior elements compared to the asymptomatic subjects. The results of a Chi-square test comparing whether the IAR was located inside or outside the FSU approached significance ($\chi^2 = 3.23$, $p = 0.07$), however, additional subjects are required to clarify these findings. A literature review suggests that these data present the only in vivo evidence of altered IAR location for symptomatic compared to asymptomatic individuals while performing an active movement.

Figure 3. Location of the IAR for L3-L4, L4-L5, L5-S1 for asymptomatic (top) and symptomatic (bottom) subjects. Arrows indicate the direction of linear motion when rotation was not observed.

SUMMARY

These data provide insight into the effects of pathology on lumbar spine mechanics. Changes in the IAR associated with pathology likely alter the length of the moment arms for the lumbar spine musculature and therefore the relative demand imposed upon the musculo-skeletal system.

INTRODUCTION

The drag opposed by a fluid to a moving body is proportional to the drag coefficient, the frontal surface area and the square of the relative velocity between body and fluid (Vogel, 1994). The aim of our study is to determine the relationships between drag coefficient (DC) and the Reynolds number Re for a high level athletic swimmer.

MATERIAL AND METHODS

Within the Kinematic method (Taïar et al., 1999), we defined three most propulsive positions. They were: the end of the external sweep (beginning of the cycle), the end of the internal sweep (middle of the cycle), and the end of the thrust (end of the cycle). These three positions were reproduced using a real size mannequins articulated in real velocity conditions. The mannequins has been fixed on his gravity center, represented by his hip, by the mean of a steel stem. The force measurement is therefore concentrated in this point. The mannequins has been carried during 50 meters at velocity from 1.4 to 2.1 m.s⁻¹, covering the velocity scale from regional to international levels. The tangential contact force measured during the experimentation represents the drag in the moving swimmer's direction.

RESULTS AND DISCUSSION

In our model, for a given swimmer and for the corresponding Re values (fig.1), the DC is more important at the end of the internal sweep (middle of the cycle) than in the beginning of cycle (end of the external sweep) and in the last position of thrust (end of the cycle). In middle of cycle, the superior members are in a vertical plan, perpendicular to the swimmer's displacement, giving a bigger drag coefficient due to an increase of the frontal surface area. We used the theory of turbulence to find the DC as a function of $\log Re$ (see Schlichting et al. 2000) and a very good agreement between the theory and our experimental observations is found. The drag is smallest in the least propulsion positions of the swimming cycle (beginning and end of cycle). In these 2 positions, the superior and lower members are globally at the alignment of the trunk. The swimmer searches a streamline position profiled with a body. The model corresponding to the

fastest swim is the best streamline for the swimming. The best swimmer is characterised by the least resistance along the cycle, compared to the other swimmers. We can say that the drag coefficient depends on the movement adopted by the swimmer. This drag coefficient is principally reduced by the frontal surface area. For the best swimmer the lower members are less bent, his superior members are more lengthened in the beginning of cycle and his head is less raised at end of cycle.

Figure 1: Relation between the drag coefficient and the Reynolds number

ACKNOWLEDGEMENT

We thank Professor Andro Mikelic (a good swimmer) for his advises in applications of the theory of turbulence.

HIGH-SPEED AND CONTINUOUS PRESSURE MEASUREMENTS: A COMPARISON OF ACTIVE PRESSURE SENSORS AND PRESSURE FILM

Joseph M. Cormier, Joel D. Stitzel, William J. Hurst, and Stefan M. Duma
Virginia Tech, Impact Biomechanics Laboratory, Blacksburg, VA. Duma@vt.edu

INTRODUCTION

Obtaining pressure measurements during a high-speed event is a common task. The use of Fuji film may be suitable for low-speed applications, or where the normal pressure remains fairly constant. However, the practicality of Fuji film diminishes in cases where a shear force is present or in cases where a continuous pressure reading is needed. Reed *et al.* (1992) used Fuji film to quantify the normal pressure exerted onto an object in the path of a deploying airbag. Depending on the orientation of the airbag relative to the Fuji film a shear force will exist and may introduce inaccuracies. In this case an active sensor may be more advantageous. Harris *et al.* (1999) compared the area of contact measured by Fuji film to the K-scan sensor. The results showed that the Fuji film measured an area 11-36% lower than the area measured by the K-scan sensors. Both the K-scan and the FlexiForce sensors use the same resistive ink technology; however, the K-scan is limited to a sampling frequency of 127 Hz, which makes it inadequate for recording pressures during a high speed event (Tekscan, South Boston, MA). The purpose of these experiments is to compare the use of Fuji film and FlexiForce sensors to record normal pressures during a high-speed event.

METHODOLOGY

To compare the utility of FlexiForce sensors and Fuji film, a high speed shear test apparatus capable of applying normal pressure was manufactured. The test set-up allowed for an initial pressure to be applied to a stationary, rectangular polycarbonate plate. A pneumatic cannon was used to impact the plate with a projectile, accelerating it to speeds ranging from 86 m/s to 105 m/s. Two types of Fuji film were used: medium, with a range of 10-50MPa and low with a range of 2.5-10MPa (Fuji Photo Film CO., Tokyo, Japan). The Fuji film sheets were placed on top of four FlexiForce sensors which were rigidly mounted to the test stand. This arrangement was held in constant contact with the polycarbonate plate by the initial preload applied to the stand as it traveled under the sensors. A protective sheath was used to limit the shear force exerted onto the Fuji film and sensors. A pressure pulse was created through the use of a raised segment along the short axis of the polycarbonate plate. The pressure exerted onto the FlexiForce sensors was recorded at 28,400 Hz during the event. High speed color video was recorded at 7100 frames per second to track the motion of the polycarbonate block.

RESULTS

A total of 18 tests were conducted, and the peak velocity during the tests was 96.7 m/s with a mean of 78.6 m/s. The peak pressure recorded by the FlexiForce was 4 MPa with a mean of 1.2 MPa. The pressure vs. time graph is shown in Figure 1. The corresponding Fuji film used for the same test is shown in Figure 2. The Fuji film sheets used during the tests were digitized and their resulting pressure was

determined using the color scale provided by the manufacturer. The Fuji film sheets shown in Figure 2 were exposed to the same event. The medium film shows a pressure of approximately 25 MPa, whereas the low film shows a pressure of 10 MPa. There were 9 instances in which the medium scale Fuji film indicated a pressure reading. In none of the tests did the FlexiForce measure a pressure higher than 10 MPa, which is the minimum range of the medium Fuji film.

Figure 1: Pressure measured by FlexiForce sensors

Figure 2: Medium (left) and Low (right) Fuji film results, dotted lines show position of FlexiForce sensors

CONCLUSIONS

The differences in the pressure measurement between the Fuji film and the FlexiForce may be due to shear effects during the event. The FlexiForce sensors are less sensitive to shear forces and therefore would measure a lower pressure than the Fuji film, which is affected by shear. Another source of error arises when considering the deformability of the Fuji film itself. If the film sheets are forced to bend around any type of contour, or if an edge exists, the film becomes more sensitive in that area. In summary, the FlexiForce's ability to sample at extremely high frequency and produce continuous signals make it an ideal sensor for pressure measurements.

DECREASED PROXIMAL AORTIC COMPLIANCE CAUSES SYSTOLIC HYPERTENSION

N. Stergiopoulos, C. Ioannou, I. Startchik¹, A. Kalangos¹, M. J. Licker¹, D. R. Morel¹

Laboratory of Hemodynamics, Swiss Federal Institute of Technology (EPFL), Lausanne, Switzerland.,

INTRODUCTION

Total arterial compliance, principally determined by the elastic properties of the aorta and large arteries, together with peripheral resistance, are the two major arterial parameters that contribute to heart load. Decreased compliance results in an increased pulse wave velocity so that the backward reflected wave contributes to elevation of systolic pressure [1,2]. Acute experiments in intact animals have shown that a decrease in aortic compliance, without a change in peripheral resistance, results in an increased pulse pressure due to elevation of systolic pressure and a reduction in diastolic pressure [3]. Studies on isolated hearts have shown that decreased arterial compliance has little effect on systolic pressure but does affect diastolic pressure. Using a new experimental animal model we aimed to show that systolic hypertension could result from a decrease in arterial compliance without a change in vascular resistance.

METHODS

Fourteen minipigs were divided into two equal groups, a sham operated group and a banding group. All animals had a pressure transducer and a flow probe implanted in the ascending aorta. In the banding group, a Teflon prosthesis was wrapped around the aortic arc. Data were recorded immediately after instrumentation, after banding (only in the banding group), at 2 days postoperatively and at 2 months postoperatively.

RESULTS AND DISCUSSION

After banding, aortic compliance decreased by $52 \pm 13\%$ (\pm SEM) ($p < 0.01$) while systolic pressure increased by $37 \pm 8\%$ ($p < 0.05$) and pulse pressure by $(87 \pm 31\%, p < 0.01)$. Diastolic pressure, mean blood pressure, cardiac output and systemic vascular resistance did not change significantly. Aortic characteristic impedance increased 2.5 times, suggesting a 6-fold decrease in proximal aortic compliance due to the banding. The amplitudes of the forward and reflected pressure waves increased by $96 \pm 41\%$ and $174 \pm 46\%$, respectively, while the time delay between the two decreased by $36 \pm 7\%$.

Figure 1 shows typical recordings of aortic pressure and flow performed in the same animal, before and after banding as well as on the 2nd post-operative day after banding. Immediately

following banding, peak and mean flow were somewhat reduced, recovering to slightly higher values in the post-operative (2-day) period. Immediately following banding, systolic aortic pressure, however, was significantly increased and even increased further in the post-operative period. Following banding, the pressure wave shape was characterized

by a late systolic increase, which is attributed to the early arrival of the reflected wave.

Figure 1: Example of ascending aortic pressure and flow curves taken before and immediately after banding during the day of instrumentation as well as on the 2nd postoperative day. A significant increase in the systolic pressure and rise in pressure is observed after banding, which is maintained post-operatively. Flow is not significantly altered after banding.

SUMMARY

We conclude that decreased proximal aortic compliance results in an increase in systolic pressure, without a change in diastolic pressure or cardiac output, due to an increase in the amplitudes of the forward and reflected waves as well as from an earlier return of the reflected wave. Our model therefore mimics normal ageing, where arterial compliance is decreased and systolic pressure is increased, without changes in peripheral resistance, cardiac output, or diastolic pressure.

A MATHEMATICAL MODEL OF ARTERIAL REGENERATION OVER BIORESORBABLE GRAFTS

Alexander Rachev and Miglena Kirilova
Institute of Mechanics, Acad. G. Bonchev Str., bl 4, 1113 Sofia, Bulgaria
rachev@bgcict.acad.bg

INTRODUCTION

There exists an increasing interest in use of bioresorbable material for fabricating vascular prostheses. The graft dissolves over post-implant time forming a scaffold for tissue ingrowth that leads to development of a neo-vascular conduit. Experimental studies have shown that during resorption process the graft decreases in thickness whereas the newly developed arterial tissue progressively thickens. Geometrical changes are accompanied by softening of the graft material while at the same time the arterial tissue becomes more organized and its elastic modulus increases. The interrelation between the resorption process and factors driving the arterial regeneration are poorly understood. This study aims to test some hypothetical mechanisms of neo-artery formation by comparing the theoretical predictions of a mathematical model with experimental data available in the literature.

METHODS

The artery/graft complex is considered as a two-layered thick-walled tube made of elastic incompressible materials (Fig.1). Under physiological pressure the vessel undergoes finite deformations. The modulus of the graft material is assumed to decay monotonically over post-implant time.

Figure 1: Schematic representation of the artery/graft complex

It was postulated that the rate of change in wall thickness of the neo-artery is driven by the deviation of the current mean circumferential stress from certain “equilibrium” values. Increase of arterial thickness is concomitant with corresponding decrease in thickness of the resorbable graft. The rate of change of arterial modulus depends on the abnormal pulsatile stretch of the arterial wall estimated through the deviation of the current arterial compliance from its baseline value.

Formation of a regenerated artery is described by a system of two non-autonomous first order differential equations for the evolution of the neo-artery dimensions and changes in the mechanical properties of the wall material. The system is coupled to the equation of equilibrium under constant transmural pressure and equations describing changes in the

geometry and mechanical properties of the resorbable prosthesis.

RESULTS AND DISCUSSION

Using data available in the literature the model parameters were specified and the governing equations were numerically solved. The theoretical predictions of the model for time variation of the neo-arterial wall thickness (Fig.2), and time course of the arterial elastic properties (not shown) are in qualitative agreement with the experimental data reported by Greisler H. et al, (1987) for regeneration of rabbit aorta over PGA graft.

Figure 2: Time variation of neo-arterial thickness for different rate of softening of the graft material.

It was shown that a rapid resorption of graft material leads to overloading of the neo-artery tissue before it is sufficiently organized to bear load. This might lead to bursting or aneurismal dilatation, as had been experimentally observed (Greisler H. et al, 1987).

SUMMARY

The results obtained supported the hypothesis that arterial regeneration over a bioresorbable graft is an adaptive process that is influenced and modulated by mechanical factors. If the mean circumferential stress and pulsatile stretch are accepted as major determinants of the vessel wall regeneration, the process is self-limiting and leads to formation of a vessel with dimensions and mechanical properties close to those of a normal artery.

INVESTIGATION OF SKIN ABRASION INJURIES FROM HIGH RATE SHEAR LOADING

Joseph M. Cormier, William J. Hurst, Joel D. Stitzel, and Stefan M. Duma
Virginia Tech, Impact Biomechanics Laboratory, Blacksburg, VA. Email: Duma@vt.edu

INTRODUCTION

Although airbags have been shown to reduce the incidence of life threatening injuries, they have increased the risk of minor injuries such as skin injuries. A study of the National Automobile Sampling System (NASS) found that 66% of front seat occupants exposed to an airbag deployment incur a skin injury, and 47% of these injuries are attributed directly to the airbag itself (Jernigan 2001). It is suggested that there are two general injury mechanisms for airbag induced skin injuries: normal pressure from perpendicular contact of the airbag with the face and thoracic areas, and shear loading as the airbag expands and interacts with the upper extremities. Reed *et al.* (1992) performed studies on human volunteers to elucidate the potential for skin abrasion caused by airbag deployment. Reed concluded that normal loading alone induced enough pressure to cause skin abrasions. The work done by Reed seems applicable only to the perpendicular type loading, and would not accurately predict skin injuries from shear loading. Moreover, a study of airbag induced skin injuries found that the upper extremity is the most often injured body region at 42% of all airbag induced skin injuries (Jernigan, 2001). Given the large incidence of upper extremity airbag induced skin injuries, the shear loading injury mechanism that is likely responsible for these injuries, and the location of the airbag seams in this region. The purpose of the current study is to develop a technique for evaluating skin abrasions caused by shear loading at high velocities.

METHODOLOGY

Airbag fabric with four different seams was obtained and prepared for testing by cutting it into a rectangular shape and mounting to a polycarbonate plate. The mounting was such that the fabric was held in tension along all four directions. Porcine skin was chosen for the current study due to its similarities with human skin. Before the skin was removed from the animal, tension lines were drawn on the skin to facilitate the recreation of the *in vivo* tension of the porcine skin. The test apparatus allowed for the application of an initial normal load to be applied to the skin. A step velocity was applied to the fabric mount by an aluminum projectile released from a pneumatic impactor. Previous research done by Reed (1992) found that airbag velocities above 85 m/s (190 mph) resulted in skin abrasions for normal loading. Based on this criterion, the target fabric velocity for the current study was established at 89 m/s (200 mph). The fabric seam was situated such that it moved over the surface of the skin as the fabric mount was struck by the projectile and was pushed out from under the skin. The tissue stage was prepared with Fuji film sheets, both low and medium sensitivities and Flexi-Force pressure sensors (Tekscan, South Boston, USA). A total of four sensors were used, each with a sensing diameter of 9.5 mm. Data acquisition was configured to record the pressure exerted on the skin by the airbag seam and sampled at a frequency of 28400 Hz. High-speed digital color video was

used to capture the motion of the fabric mount and video was recorded at 7100 frames per second. This frame rate allowed sufficient resolution of the fabric block in motion to facilitate velocity calculations and track the event. Visual examination of the skin was facilitated using ultraviolet black light and orange filters. Based on visually determining which section received the highest degree of abrasion, three sections of skin were removed for histology.

RESULTS AND DISCUSSION

The histology analysis showed that all tests resulted in abrasions with the exception of the control tests (Table 1). The abrasion score indicates depth: 1-2 epidermis, 2-3 transition, 3-4 dermis. In no instance did the abrasion remove the full thickness of the dermis. The abrasions varied from a slight removal of the epidermis, to a partial removal of the dermis (Figure 1). The analysis of the results obtained from these tests shows that it is possible to measure the effects of seam design alone without external effects of airbag inflator design.

Test	Seam Type	Peak Pressure (MPa)	Peak Velocity mph (m/s)	Abrasion Score
1	Control	1.50	210 (93.9)	0.00
2	Control	1.46	215 (96.1)	0.00
3	1	1.88	234 (104.6)	2.16
4	1	1.83	216 (96.6)	2.21
5	2	1.86	197 (88.1)	2.79
6	2	1.89	201 (89.9)	2.81
7	3	1.82	195 (87.2)	3.48
8	3	1.49	202 (90.3)	3.31
9	4	1.61	197 (88.1)	1.65
10	4	1.52	205 (91.6)	1.71

AN ALGORITHM TO QUANTIFY SEGMENTAL LESIONS IN NECROTIC FEMORAL HEADS

Karen L. Reed¹, Robert A. Robinson², Michael G. Conzemius⁴, Thomas D. Brown^{3,1}

¹Departments of Biomedical Engineering, ²Pathology, and ³Orthopaedic Surgery

University of Iowa, Iowa City, IA

⁴Veterinary Teaching Hospital, Iowa State University, Ames, IA

Email: karen-reed@uiowa.edu

INTRODUCTION Approximately 25,000 new cases of femoral head osteonecrosis (ON) present each year in the U.S. To help clarify the pathology, we have recently developed a cryo-insult technique for creating segmental lesions (Reed, 2001) in the emu, a large biped in which osteonecrosis progresses to femoral head collapse (Conzemius, 2000). Osteonecrosis is characterized by the presence of dead osteocytes in histological sections of the affected bone. Quantification of lesion morphology is important in assessing our ability to create reproducible segmental lesions. An automated osteocyte identification and quantification algorithm is here reported to aid in this process.

METHODS Viable osteocytes can readily be identified in haematoxylin and eosin-stained slides by their nuclei, which appear as dark purple spots within a bright local field. Dead osteocytes present as empty lacunae – a small light-colored hole with no

nucleus present – in the trabeculae (Figure 1).

Figure 1 Stained bone showing live (L) and dead (D) osteocyte locations. An automatic detection algorithm to quantify the location of both live and dead osteocytes was written to take advantage of these morphological features. The algorithm, written in PV-Wave (VNI, Houston, TX), reads in eight-bit grayscale images and scans them for features signaturing osteocytes or empty lacunae (Figure 2). The flagged regions are then tested for aspect ratio, size, and contrast relative to the average background color. If a region is identified as an osteocyte or an empty lacuna, its centroid is found and its status is determined by the presence/absence of a dark spot. The algorithm's output is a list of osteocyte-center locations (pairs of x and y coordinates), and a binary value that indicates the osteocyte's status (1=alive, 0=dead)

The algorithm also provides the user with visual feedback, in the form of light and dark circles around the locations identified as live and dead respectively (Figure 3). Thus, the user can verify that the algorithm has correctly identified all points, and he/she can interactively correct any errors.

PERFORMANCE AND VALIDATION Four representative sections of a femoral head slice were chosen for validation purposes. A pathologist (R.A.R.) manually identified all of the live

and dead osteocytes in each section, and their locations and status were recorded. The algorithm then performed the same operation, and the pairs of lists were compared for all four sections. The results, summarized in Table 1, show very good agreement between total detected percentage of viable osteocytes in each section.

DISCUSSION

Until now, assessing the shape and size of segmental

osteonecrotic lesions has been entirely qualitative. However, for the purposes of further developing the emu as a model for osteonecrosis, quantification of lesions now emerges as an important tool in assessing the extent of tissue damage.

As a protection against errors in image analysis, the algorithm relies on a knowledgeable human to verify the completed reads, and make corrections if needed to each file scanned. This strategy of keeping a human in the loop, while allowing the algorithm to perform the bulk of the tedious work, allows necrotic lesions to be (relatively) quickly and accurately mapped.

Fully automated histology analysis tools have been developed for "high volume" production settings, such as identifying abnormal pap smears. To our knowledge, however, such assessments have not previously been coupled with spatial registration of normal/abnormal regions, or to quantify the degree of abnormality.

SUMMARY As development of the emu animal model for osteonecrosis progresses, it has become important to quantify necrotic lesion shape, size, and location. Therefore, an algorithm to identify live and dead osteocytes was developed for the purpose of quantifying these morphological characteristics.

FINITE REYNOLDS NUMBER FLOWS IN THREE-DIMENSIONAL COLLAPSIBLE TUBES

Andrew L. Hazel¹ and Matthias Heil²

Department of Mathematics, University of Manchester, UK

¹ahazel@maths.man.ac.uk

²M.Heil@maths.man.ac.uk

INTRODUCTION

Many biological transport systems consist of elastic tubes conveying viscous fluid: e.g., the cardiovascular, respiratory and renal systems. If the transmural (internal minus external) pressure within such tubes falls below a critical value, the tube buckles and a strong fluid-structure interaction can occur. The interaction is responsible for phenomena such as flow limitation during forced expiration and the development of self-excited oscillations that cause wheezing in the airways and the Korotkoff sounds heard during sphygmomanometry.

MODEL DESCRIPTION

Following the earlier work of Heil (1997), we consider the flow of an incompressible, Newtonian fluid of viscosity μ , density ρ and average speed U through an elastic tube of undeformed diameter D , length L and bending modulus, K . The 3D Navier-Stokes equations, used to describe the fluid flow, are coupled to the equations of geometrically non-linear shell theory, which determine the tube's deformation. The coupled system of equations is solved numerically by a finite element method.

Figure 1: Non-dimensional flow rate, Q , as a function of the pressure drop, Δp , along an elastic tube ($L/D=5$) for a constant upstream transmural pressure. Results are shown for three different values of the parameter H , where $H=0$ corresponds to Stokes flow.

Two dimensionless parameters govern the system: (i) $Re = \rho U D / \mu$, the Reynolds number, representing the ratio of inertial to viscous forces and (ii) $Q = \mu U / DK$, a dimensionless flow rate, that represents the ratio of viscous to

elastic forces. A third dimensionless parameter $H = Re/Q$ depends only upon the material properties of the system and is constant in any experiment involving a given tube and a given fluid.

RESULTS

Results will be presented illustrating the effects of fluid inertia upon the macroscopic behaviour of the system. For example, Figure 1 shows the relationship between the flow rate and the pressure drop along the tube when the upstream transmural pressure is held constant. At finite Reynolds numbers, the Bernoulli effect causes the tube to collapse more strongly than when $Re = 0$, resulting in a lower flow rate at any given pressure drop.

We shall also describe the three-dimensional flow fields and contrast them to those predicted by previous two-dimensional models (e.g. Rast 1994). In 3D, flow separation is open and tends to give rise to structures such as horseshoe vortices, see Figure 2.

Figure 2: Steady flow through an elastic tube at $Re = 255$.

BIOMECHANICAL DIFFERENCES IN SHOULDER LOADING IN POPULATIONS DURING LOAD-BEARING TASKS

Clark Dickerson¹, Kyunghan Kim, Diane Adamo, Bernard Martin, and Don Chaffin
HUMOSIM Laboratory, Center for Ergonomics, University of Michigan, Ann Arbor, Michigan, USA
¹Corresponding Author: cdickers@umich.edu

INTRODUCTION

The role of the shoulder in load-bearing tasks for non-injured populations has been studied extensively (Chaffin et al, 1999). This contrasts to limited examinations of load handling by special populations. However, wheelchair users are highly susceptible to shoulder injuries (Koontz, 1998). This suggests that higher biomechanical tissue loading in the shoulder may occur during task performance by physically limited persons.

METHODS

Three groups of 10 volunteers participated: control (CG), spinal cord injured (SCI), and chronic low back pain sufferers (LBP). Motion capture data was recorded for seated load delivery tasks (25% of extended arm static shoulder strength). Targets were at 3 azimuths (0° [Target #3-10], 45° [#12-20], 90° [#22-30]), 4 heights and 2 horizontal distances. Target numbers increase with height then distance (i.e. 3-5 @ 0° near; 7-10 @ 0° far). Surface electromyography recordings were taken from the upper trapezius (UT), anterior deltoid (AD), infraspinatus (IF), and pectoralis major (PM), and normalized with respect to maximum voluntary contractions (NsEMG). Resultant external dynamic shoulder moments were calculated using a previously described model (Dickerson et al, 2001), and were normalized by subject body weight (NEDSM).

RESULTS AND DISCUSSION

NEDSM values increased both with increased reach distance and increased target height across all three groups (Figure 1). Both target location and subject group had a significant effect in determining NEDSM values (ANOVA, $p < 0.01$). LBP

subjects had significantly higher NEDSM levels than both SCI and CG groups, as identified by Tukey post hoc analysis ($p < 0.01$ for both), though there was no statistical difference between SCI and CG NEDSM values ($p = 0.34$). This may relate to discomfort associated with torso twisting and bending for LBP. Minimizing torso movement may transfer loading to the shoulder via the outstretched loaded arm.

Figure 2 shows a comparison for the anterior deltoid NsEMGs. Pronounced trends existed for NsEMG values with respect to target location and group (ANOVA, $p < 0.01$). For all muscles, LBP NsEMG values were higher than CG ($p < 0.01$). SCI NsEMG values were higher than CG for the AD and PM ($p < 0.01$). This indicates that the groups have different muscle activation patterns.

SUMMARY

This study identified significant differences in biomechanical loading of the shoulder for loaded tasks performed by different populations. It also affirms the necessity for studying injured populations, as they may be at increased risk of injury due to higher tissue loading and muscle use. Interpreting underlying causes of this loading may aid in universal interface design.

Figure 1: NEDSM Group Comparison. LBP NEDSM is significantly higher than CG and SCI NEDSM, possibly due to LBP mechanisms to minimize moments on the lower back.

Figure 2: NsEMG for AD. The SCI had the highest NsEMG values for AD and PM, while the LBP had the highest values for UT and IF, suggesting different motion strategies.

INFLUENCE OF ANGULAR STABILITY OF AN INTERNAL SPINAL FIXATOR ON IMPLANT LOADS

Thomas Zander, Antonius Rohlmann, Georg Bergmann

Biomechanics Laboratory, University Hospital Benjamin Franklin, Free University of Berlin, Germany, rohlmann@biomechanik.de

INTRODUCTION

Several different internal spinal fixation devices are available. Most of them have an angular fixed connection between pedicle screws and the longitudinal rod. Some of the implants act like tension-banding implants thus requiring a stable anterior spinal column and a connection between pedicle screws and longitudinal rod which allows angular motion. Angular movable implants can adapt to different situations, for example graft resorption, thus allowing the bone to take over a great part of the spinal load, which reduces the risk of implant breakage. It is still a matter of debate whether an internal fixator should be flexible or rigid.

The aim of this study was to determine analytically implant loads for both, angular fixed implants and implants which allow angular motion between screws and rod.

MATERIAL AND METHODS

A three-dimensional, nonlinear finite element model of the human lumbar spine was created. The element mesh of the vertebrae is based on the model used by Smit [1996]. The nucleus pulposus was simulated by an incompressible fluid-filled cavity and the annulus fibrosus by volume elements with superimposed spring elements representing the fibers. The facet joints could only transmit compressive forces. The capsule of the facet joints and the six ligaments of the lumbar spine were included in the computer model. The mainly nonlinear material properties of all tissues were taken from the literature. The lower end-plate of the L5 vertebra was fixed and the model was successively loaded with pure moments of 7.5 Nm acting in the three anatomical main planes. The finite element model is described in detail elsewhere [Zander et al. 2001]. The finite element program ABAQUS was used. After studying the intact lumbar spine, paired bisegmental internal

spinal fixators bridging the L3 vertebra were inserted without a preload. Different angular connections between pedicle screws and longitudinal rod were simulated. Most of the upper bridged disc was replaced by a bone graft (Figure 1).

Figure 1: Outer mesh of the finite element model of the lumbar spine with internal fixators and a bone graft.

RESULTS

An internal fixator considerably reduces the angular motion in the bridged region for flexion and lateral bending (Table 1). For extension, angular motion was higher after insertion of an angular unstable fixator and a bone graft than for the intact spine. The finite element model predicts higher angular motion for implants with an angular movable fixator than for angular fixed ones. This is most pronounced for the loading cases extension and axial rotation.

	Intact spine	Angular fixed	Angular movable
Flexion	8.8°	0.8°	0.9°
Extension	6.5°	5.0°	8.2°
Lateral bending	9.8°	1.6°	2.0°
Axial rotation	6.0°	3.4°	6.5°

Table 1: Angular motion between L2 and L4 vertebrae

Angular stability of the fixator has a marked influence on axial forces on the implant for extension and axial rotation, but a minor one for flexion and lateral bending (Table 2).

	Angular fixed	Angular movable
Flexion	92	85
Extension	-69	-129
Lateral bending	149	140
Axial rotation	3	-20

Table 2: Maximum axial forces (N) on the internal fixators

The resultant bending / torsional moments in the fixators were mostly much higher for the angular fixed than for the angular movable implant (Table 3).

	Angular fixed	Angular movable
Flexion	0.37	0.31
Extension	1.00	0.40
Lateral bending	1.02	0.58
Axial rotation	1.39	0.09

Table 3: Maximum resultant bending / torsional moments (Nm) in the implants

DISCUSSION

An angular movable connection between pedicle screws and longitudinal rod reduces the bending moments on the implants and increases the intersegmental motion in the bridged region. It requires, however, a stable anterior spinal column which has then to transfer the loads. For the implant studied the pedicle screws and the longitudinal rod are not in the same plane. This is the reason why small bending moments were calculated in the longitudinal rod for the angular movable implant.

SIMULATION OF NORMAL WALKING USING 3D MODELING

Dimitar Uzunov¹, Dimitar Tochev¹, Nikolay Zlatov², Yuli Toshev¹

¹Institute of Mechanics and Biomechanics, Bulgarian Academy of Sciences, Canada

²Manufacturing Engineering Center, University of Cardiff, United Kingdom

INTRODUCTION

The human locomotion involves a three-dimensional motion of a multiple linkage system, which demands coordinated control by the central nervous system. The main focus of the present study is simulation of normal walking using 3D modeling. A group of twenty normal male subjects between 18-25 years was studied.

METHODS

Four original force-plates TA-4 (Fig. 1) are used to obtain force and temporal data during walking. The platforms have a minimum resonant frequency of nearly 200 Hz and allow continuous records both of the vertical and the horizontal components of the ground reactions (for every leg) during three gait cycles). Two groups of gait parameters are analysed (Fig. 2). The parameters are defined separately for the right (index *r*) and the left (index *l*) leg. A total of six (*F1r*, *F2r*, *F3r*, *F1l*, *F2l*, *F3l*) force parameters and fourteen temporal parameters are defined in our previous work (Angelova et al., 1998). Six of the temporal variables express the chronological incidences of occurrence of the defined force parameters (*t1r*, *t2r*, *t3r*, *t1l*, *t2l*, *t3l*). The rest eight parameters are the step periods ($T \approx Tr \approx Tl$), the periods of stance phase (*T1r*, *T1l*), the periods of swing phase (*T2r*, *T2l*) and the periods of double support (*Td1*, *Td2*).

Figure 1. Four force-plates TA-4 (I, II, III, IV) for measuring the vertical and the horizontal components of the ground reactions during walking.

HUMAN BODY MODEL

A symmetrical model of the human body with 14 segments is used. Following the model we have to calculate the lengths of 8 segments, to determine their mass, as well as the location of segment mass center on its longitudinal axis. We will also need to determine the main central inertial moments of each segment. We propose an algorithm that enables to determine all necessary geometrical and mass-inertial parameters, using only *L* [cm] and *M* [kg].

Figure 2: The vertical (index *v*) and the horizontal (index *h*) ground reactions of the right (index *r*) and left (index *l*) lower limbs during walking.

RESULTS AND DISCUSSION

One of the most convenient temporal criteria is: $k = (T1r/Td2)/(T1l/Td1)$, due to its sensibility to the walking asymmetry. The 3D simulation (Fig. 3) is based on our experimental results including the criterion *k* and the following whole body parameters: volume=0.076 m³; surface area = 2.119 m²; density=1000 kg/m³; mass=75.954 kg. The principal moments of inertia in the center of gravity during the double support are: *I_x*=1.700 kg.m²; *I_y*=11,334 kg.m²; *I_z*=12,230 kg.m²

Figure 3: Walking simulation using CAD 3D generation

SUMMARY

Using experimental data 3D walking simulation is realized.

MEASURING EFFECTS OF DRUGS ON ARTERIAL MECHANICAL PROPERTIES

Carolien J. van Andel^{1,2}, Marion J. Sierevogel², Gerard Pasterkamp², Peter V. Pistecky¹ and Cornelius Borst²

¹Man-Machine Systems, Delft University of Technology, Delft, The Netherlands, c.j.vanandel@wbmt.tudelft.nl

²Experimental Cardiology, University Medical Center Utrecht, The Netherlands

INTRODUCTION

Many problems in cardiology and cardiovascular research are associated with vascular mechanics. Endothelial cells and smooth muscle cells sense their mechanical environment and respond with metabolic changes (Liu et al, 2000). Restenosis after percutaneous coronary interventions can be a result of these cellular changes (Orford et al, 2000). Drugs that might play a role in the prevention of restenosis are being studied on a cellular level by many researchers. However, the use of drugs might have an effect on the mechanical properties of the vessel wall as a whole. In this study, we used a relatively easy and quick method to determine changes in the circumferential and axial stress-strain relations of isolated coronary arteries. We studied the effects of two drugs, a matrix metalloproteinase (MMP) inhibitor and a collagen synthesis inhibitor on the circumferential and axial mechanical properties of the arterial wall.

METHODS

Animal models. 1) Atherosclerotic Yucatan minipigs, approximately 2 years of age with an average weight of 40 kg were used. Pigs had been fed an atherogenic diet for 9-10 months. Pigs were treated with the MMP-inhibitor BB-2983 for 42 days (n=2) or served as controls (n=2). A proximal and distal part of each right coronary artery was measured within 24 hours after termination. 2) Non-atherosclerotic Yucatan minipigs, approximately 2 years of age and an average weight of 30 kg. Pigs were treated with a collagen synthesis inhibitor for 42 days (n=4) or served as control (n=2). One segment of each right coronary artery was measured within 6 hours after termination.

Measurements of mechanical properties. Axial and circumferential mechanical properties were measured by subjecting arterial segments to inflation and axial tension in vitro. The segments were cannulated and connected to a tensile testing machine in order to regulate lengthening of the segment and to measure axial force. The segments were inflated with and bathed in Tyrode solution at a constant temperature of 37 °C. The external diameter of the artery during inflation was measured with a dual beam laser-micrometer. The measurements were repeated while the vessels were held at different levels of constant axial pre-stretch λ_z . Assuming arterial wall incompressibility, the Green-Lagrange strains (E_θ , E_z) and second Piola-Kirchhoff stresses (S_θ , S_z) in the circumferential (θ) and axial (z) direction can be calculated for the middle surface of the vessel wall.

RESULTS AND DISCUSSION

In the atherosclerotic pigs, the right coronary arteries of the MMP inhibitor group showed a significant reduction in axial stress when increasing the axial pre-stretch ($p=0.02$ at $\lambda_z=1.4$),

Figure 1: Axial stress versus circumferential strain relation of right coronary arteries of atherosclerotic pigs at $\lambda_z=1.4$. The continues line indicates the MMP inhibitor group and the interrupted line the control group, horizontal lines indicate standard deviations.

compared with the control group (fig.1). In the non-atherosclerotic pigs, the collagen synthesis inhibitor group showed a large increase in axial stress at increasing axial pre-stretch ($p=0.06$ at $\lambda_z=1.5$), which was not found in the control group. In both pig models, no differences in circumferential stress were observed among groups.

Clearly, these drugs have an effect on the mechanical behavior of the vessel wall, which can be assessed with a relatively small amount of measurements. Dobrin et al (1984) showed that in canine and human vessels, tensile strength and wall integrity depends on intact collagen. Any disruption of this collagen fiber network causes structural and mechanical alteration of the artery. Axial stiffening due to axial stretch and internal pressure was largely absent in the MMP inhibitor group, which might point to a possible effect of the MMP inhibitor on the mainly axially oriented collagen fibers in the adventitia. The increase in axial stiffening of the vessel wall by the collagen synthesis inhibitor was surprising since this inhibitor is thought to reduce collagen content in the arterial wall. Further research is necessary, but these mechanical experiments could support the testing of long term effects of drugs.

UNIQUE MUSCLE ACTIVITY PATTERNS OBSERVED DURING GAIT TRANSITIONS

Lorna Ogden and Li Li

Department of Kinesiology, Louisiana State University, Baton Rouge, Louisiana, USA, lli3@lsu.edu

INTRODUCTION

Often the approach to investigating gait related variables, including muscular function, at transition speeds entailed conducting tests at speeds held constant from one test to the next (Prilutsky & Gregor, 2001). Estimated transition speeds would be included within these tests; few did the protocols call for testing while transition was in progress. In a study on the response of vertical ground reaction force (VGRF) to gait transitions, Li and Hamill (in press) reported that VGRF exhibited transition specific patterns several steps before gait transitions. In order to produce these transition specific VGRF patterns, muscles might act accordingly with transition specific coordination. This study investigated muscular activity during continuously changing speeds, which may better resemble the transition process, in order to further detail and quantify neuromuscular changes during gait transitions.

METHODS

Twelve healthy adults, 18-41 years of age, were recruited as participants. Informed consent was obtained. Experiment was conducted on a treadmill with embedded force platforms (Kistler, Amherst, NY, USA). Gait transitions were induced by the speed of the treadmill changing with constant acceleration. Walking was identified by double stance phases where running was identified by double flight phases. Reflective markers were placed on the anatomical landmarks of hip, knee, ankle, heel, and 5th metatarsal joint. Bipolar surface electrodes were positioned on the subjects' skin over the muscular bellies of the gluteus maximus (GM), rectus femoris (RF), vastus lateralis (VL), biceps femoris (BF), tibialis anterior (TA), gastrocnemius (GAS), and soleus (SOL). Electromyographic (EMG) data were collected at 960 Hz. Five transition trials were conducted for both progression modes: walk-to-run (WR) and run-to-walk (RW), and five interval trials were collected for both walk and run at constant speeds. The mean of recorded transition speeds (MTS) was calculated from the preceding transition trials.

The experimental protocol includes four conditions: WR and RW transitions, as well as walking and running at different but matched constant speeds. Five trials were included in each condition. For the transition conditions, each trial refers to one step. Five steps proceed the gait transitions were analyzed. The mean speed of each of these steps (trials) was different since they led to gait transitions with a constant acceleration. There were five different constant speed trials for both walking (WC) and running (RC), the speeds were MTS - 0.6, MTS - 0.3, MTS, MTS + 0.3, and MTS + 0.6 mph. EMG data of one step from each trial was selected for further analysis. Peak magnitude and duration of EMG activities were examined across trials and conditions. Two factor (condition and trial) repeated measures ANOVA was employed for statistical analysis ($\alpha = .05$).

TREND ANALYSIS OF GAS PEAK

Figure 1: Condition/trial interaction graph for the relative peak magnitude of the GAS. Peak magnitude increased with speed in a linear fashion for all conditions but one condition. Peak magnitude increased quadratically with speed in the WR condition.

RESULTS AND DISCUSSION

A significant condition/trial interaction (see Figure 1 for example) for burst peak magnitude was observed for GM, RF, VL, TA, GAS, and SOL. EMG activity intensity in some of the muscles changed with the locomotion speed in a quadratic fashion (for example, GM and RF in WR). However these quadratic changes with locomotion speed were only observed in transition related trials but not in interval trials even though the range of speed was comparable. Significant condition/trial interactions for muscle burst duration were also observed. Similar as to the EMG activity intensity, quadratic response to speed change was also observed with EMG activity duration. Again, these quadratic trends were only observed in transition related trials (GAS in RW) but not in locomotion at constant velocity. These results indicate that preparation for gait transition occurs before observed kinematic changes and triggers of gait transitions should be studied accordingly.

SUMMARY

Transitional specific muscular activity was observed in the study. Neuromuscular changes occur steps before the observed gait transition. These results suggest that gait transition related studies should be conducted with changing speed rather than constant velocity in the same range.

THREE-DIMENSIONAL MOTION TRACKING OF THE FOREARM USING SURFACE MARKERS

Eding Mvilongo^{1,2}, Carolyn F. Small^{1,2}, David Pichora²

¹Queen's University, Kingston, Ontario, Canada, mvilongo@me.queensu.ca

²Human Mobility Research Centre, Kingston General Hospital, Kingston, Ontario, Canada

INTRODUCTION

Rheumatoid arthritis is a systemic inflammatory disease. When affecting the wrist joint, it generates pathological changes causing a decrease in the range and consistency of motion and leading to joint instability and loss of hand function (Taleisnik, 1989). Restoration of strength and motion by means of a complete wrist replacement, known as arthroplasty, is a preferred treatment option for severe cases of rheumatoid arthritis (Swanson, 1973; Swanson, 1981). In order to set objective criteria for evaluating motion with wrist implants, normal motion, or kinematics, of the wrist joint therefore needs to be defined. Studies of upper limb 3D kinematics including forearm pronation-supination have been done *in vivo* statically, but not yet dynamically using skin markers. The goal of this project is twofold. First, we want to validate a testing protocol that would enable us to characterize, from skin markers, dynamic forearm pronation-supination both *in vitro* and *in vivo*. Secondly, we want to establish if skin motion patterns can be used to describe bone motion during *in vivo* pronation-supination for an asymptomatic subject.

METHODS

A mechanized model of a human forearm (Sawbones, Pacific Research Laboratories, Inc.) was initially used with a custom-built apparatus to validate motion analysis software developed in-house for pronation-supination kinematics. Upon validation, we used a cadaver arm for standard optoelectronic motion tracking (OPTOTRAK, Northern Digital Inc.) of the wrist and the forearm during dynamically induced flexion-extension, radioulnar deviation and pronation-supination. Surface markers were placed on the forearm and at the elbow (Figure 1). Position data was collected during 3 different testing cycles. Three sets of CT scans (GE Light Speed Plus) with our specimen in different semi-static positions were also done for later work involving the computation of a skin motion artefact correction algorithm.

Figure 1: Surface markers on the upper limb specimen

RESULTS AND DISCUSSION

We were successful setting up a testing apparatus and protocol for dynamic pronation-supination motion. We used the collected position data in our in-house motion analysis software to measure the Euler angles and the Screw Displacement Axis parameters resulting from motions of the hand, the radius and the ulna. Table 1 displays sample results of kinematic data collected following a validation experiment.

Table 1: Sample results for Euler angles; flexion-extension (θ), radioulnar deviation (ϕ) and pronation-supination (ψ)

Trial number	Wrist position	Euler angles (degrees)		
		ϕ	θ	ψ
1	45° flexion	-9.09	-46.05	4.74
2	neutral	1.37	8.29	13.47
3	45° extension	-4.32	47.10	4.12

We are now looking at the skin motion artefact created following the utilization of surface markers during optoelectronic data acquisition by relating position data of anatomical landmarks to that of the markers. We are estimating the motion relative to the ulna during testing by using skin motion data from CT images of the upper limb in the different semi-static positions. We are also in the process of verifying if a valid correction algorithm can be developed so that skin motion artefact could be expressed in terms of a transformation matrix applied to the underlying bones, relating the surface markers to the bony landmarks.

SUMMARY

Normal kinematics of the forearm need to be defined so as to quantitatively determine the extent of altered motion due to the presence of rheumatoid arthritis and to set objective criteria for evaluating motion with forearm implants. This project aims to validate a testing protocol that would enable us to describe the three-dimensional kinematics of forearm pronation-supination from skin markers, and establish if skin motion patterns can ultimately be used to accurately describe bone motion during *in vivo* pronation-supination for an asymptomatic subject.

TEMPORAL PATTERN RECOGNITION TECHNIQUES CAN DETECT EMG DIFFERENCES BETWEEN MODERATE KNEE OSTEOARTHRITIS PATIENTS AND HEALTHY CONTROLS DURING WALKING

C.L. Hubley-Kozey¹, K.J. Deluzio², J.W. Kozey³, J. McNutt¹, J.J. Chu⁴, G.E. Caldwell⁴, W.D. Stanish⁵

INTRODUCTION

Early detection of mild to moderate knee osteoarthritis (OA) may assist in the development of effective therapeutic strategies to slow down or possibly reverse disease progression. There is strong evidence that mechanical factors play a role in the pathogenesis of OA. Since the muscles surrounding the knee joint produce forces for movement, stability and impact attenuation, identifying muscle activation patterns unique to OA may assist in developing particular therapies that focus on altering neuromuscular control strategies. The purpose of this study was to quantitatively compare temporal electromyographic (EMG) profiles of the knee muscles during walking between those who have been diagnosed with moderate OA and those with healthy knees (CON). In an attempt to stress the system normal and a fast walking speed conditions were compared. Although motion and force data were collected simultaneously with the EMG data, this paper will focus on the EMG results.

METHODS

EMG data were collected from CON and patients with moderate OA (scored 1 or 2 on the Kellgren and Lawrence scale). Subjects gave informed consent (approved by Ethics Committee), completed the SF-36 health survey and the OA subjects completed the WOMAC. After skin preparation, Ag/Ag Cl surface electrodes were attached in standard locations over the vastus lateralis (VL), vastus medialis (VM), rectus femoris (RF), lateral hamstring (LH), medial hamstring (MH), medial (MG) and lateral gastrocnemius (LG) muscles of the affected limb for the OA group, and a randomly selected limb for the CON. EMG signals were amplified (BP 10 - 1000 Hz, CMRR 115dB, input impedance ~ 10 Gohm) using an AMT-8 EMG system (Bortec Inc., Calgary, Al) and were digitized at 1000 Hz using the analogue data capture feature of the QualysisTM motion analysis system. Each subject performed, in random order, five trials of their normal selected speed (C1), and a fast walk (C2) (150% of the normal speed). Following the test trials, subjects performed six standardized maximal voluntary isometric contractions (MVIC) for each muscle site. Raw EMG signals were full-wave rectified, low pass filtered at 6 Hz, and for the test trials were amplitude normalized to %MVIC and time normalized (% gait cycle) from heel strike to heel strike on the measured limb. The Karhunen-Loève Expansion was applied to the data set of all time-normalized profiles. The weighting coefficients for each muscle derived for each principal component pattern (PC_{*i*}) were the main dependent measures in the mixed model ANOVAs. For each muscle, trial effects were tested followed by group and speed main effects and interactions ($\alpha = 0.05$) using Minitab statistical software package (11Xtra).

RESULTS

The mean age for the CON was 44 ± 9 and 57.8 ± 14 years for the OA. The WOMAC score ranged from 89-113. No differences were found between groups for walking speed. Ninety eight percent of the variance in the profiles for the seven muscles was contained in 10 PCs. There were no significant trial effects ($p > 0.05$) for any muscle or speed, indicating consistency in the temporal patterns. Significant group by speed interactions ($P < 0.05$) were found for all three quadriceps sites and for the two hamstring muscles. Post hoc analysis revealed that the statistical differences occurred in the higher speed, C2, trials rather than the slower, C1, trials. The quantitative EMG similarities for C1 and differences for C2 identified by the statistical analysis for VL is evident in the ensemble average profiles in Figure 1.

Figure 1 %MVIC versus % gait cycle for VL.

DISCUSSION AND CONCLUSION

The EMG waveform data revealed differences in muscle activation patterns between the two groups primarily at the faster walking speed condition. The differences in the PCs for VL captured the double peak and the high amplitude at heel strike in the temporal waveform for the OA group for C2. For the MH and LH, the significant PC corresponded to the high amplitude of activity at heel contact and a burst of activity during late stance for the OA group in particular for C2. The disproportionately higher amplitude of knee flexor coactivity at heel strike may reflect a guarded response to pain, whereas the burst during the weight transfer phase may reflect a stabilizing response as the knee moment changes from a flexor moment to an extensor moment. These data support that at normal walking speeds the temporal activation patterns were similar between groups. However, differences were exaggerated when the system was stressed at higher speed. The higher activity from both knee flexors and knee extensors and the differences in patterns need to be further explored, in particular given the trend for lower external flexor moments for the OA group at the fast walking speed. These data support that the neuromuscular control patterns are different for those with moderate OA compared to healthy knees.

CFD MODELING OF CAROTID BIFURCATION BLOOD FLOW USING 3D ULTRASOUND

Alexander D. Augst¹, Dean C. Barratt², Alun D. Hughes², Simon A.McG. Thom², X. Yun Xu¹
Departments of ¹Chemical Engineering, ²Clinical Pharmacology, Imperial College, London, UK, a.augst@ic.ac.uk

INTRODUCTION

Computational Fluid Dynamics (CFD) flow simulation techniques have the potential to enhance our understanding of how haemodynamic factors are involved in atherosclerotic plaque formation. In order to model blood flow and predict wall shear stress for individual patients using CFD, an accurate description of vascular geometry is necessary. 3D X-ray angiography and magnetic resonance angiography (MRA) have been used for gathering this information in vivo, but recently 3D ultrasound imaging has emerged as an alternative. We describe the application of a novel 3D ultrasound imaging system to extract vessel geometry for CFD studies of the human carotid artery bifurcation.

METHODS

3D ultrasound scans of human carotid artery bifurcations were carried out on 8 subjects. The 3D ultrasound system used in this study is based on a standard 2D ultrasound scanner (HDI 5000, ATL-Philips Ltd, Bothell, MA, USA), and an electromagnetic position and orientation measuring (EPOM) device (Ascension Technology Inc, Vermont, USA) (Barratt 2001a and b). During the scan, the transducer probe is swept slowly over the subject's neck and images are acquired on the peak of each ECG R-wave. Two separate data sets were recorded on detection of a trigger pulse: a set of 2D images from the scanner and the orientation and position of the ultrasound probe from the EPOM device. The digital images were stored on the scanner and later downloaded onto a PC to be analyzed off-line. The EPOM data was used to accurately determine the location of each acquired ultrasound image within a 3D volume. Blood velocity information was also acquired in the proximal common and external carotid artery (CCA and ECA, respectively) using pulsed Doppler ultrasound. Time-dependent center-stream velocities were used as input data for the CFD simulations. The acquired transverse images were then segmented using purpose-built software, which allowed points on the vessel wall to be manually defined. A smooth cubic spline or ellipse was fitted to these points, as appropriate. Thus, a series of cross-sectional contours were produced that define the geometry of the vessel. In order to reduce spatial reconstruction artefacts in the reconstructed vessel, a cubic smoothing spline was fitted to the centroids of the contours. Each contour was then realigned so that its centroid coincided with the fitted centerline curve. The vessel surface was reconstructed by fitting smoothing splines to successive contour points.

The surface splines were used by a commercial CAD/CAE package (ICEM-DDN) to produce the input file for the grid generator (ICEM-Hexa). Using the CAD tool, the internal

carotid artery (ICA) was extended linearly in order to move the outflow boundary far enough away from the carotid bulb. This was deemed necessary as relevant flow features were expected to occur in this region which might have been affected by a nearby boundary. The semi-automatic Hexa tool allows the generation of a fully structured hexagonal cell grid for the designated solver CFX-4.4.

Flow simulations were carried out under pulsatile flow conditions using a non-Newtonian fluid. Fully developed flow was assumed at inlet while time-varying outflow divisions between ICA and ECA were determined from Doppler data. The oscillatory shear index (OSI) and time averaged wall shear stress magnitude (TAWSS) were calculated.

RESULTS AND DISCUSSION

Figure 1: OSI shown for sample bifurcation.

It can be seen in Fig.1 that particularly high values of OSI occur in the carotid bulb and at the bifurcation region proximal to the ECA where the CCA starts to increase in diameter. Analogous patterns were observed on all subjects.

SUMMARY

It has been demonstrated that 3D ultrasound is a viable alternative to other established vascular imaging techniques for generating accurate 3D geometric input data for CFD simulations. Future work will include evaluation and improvement of the methods described in this paper using phantom and in vivo studies.

INFLUENCE OF INTERFERENCE-FIT ON THE INITIAL STABILITY OF CEMENTLESS PROXIMAL FEMORAL STEMS

A.S.Wong¹, A.New¹, G.Isaac² and M. Taylor¹

¹Bioengineering Sciences Group, University of Southampton, Southampton, SO17 1BJ, United Kingdom, asw@soton.ac.uk

²DePuy International, St. Anthony's Road, Leeds, LS11 8DT, United Kingdom

INTRODUCTION

Cementless press-fit stems have become a common design concept in present hip joint replacement. Cementless stems are pressed into a canal that is slightly smaller than the femoral stem to create an interference-fit to provide greater initial stability and bone contact. A number of finite element (FE) studies have modelled cementless hip stems, but they have neglected to model the interference-fit. The influence of interference on the initial stability, bone strain and contact area has yet to be quantified. This preliminary study will address these issues.

METHOD

A FE model was constructed based on computer-tomography (CT) scans of a male human femur and implanted with a proximally porous coated IPS stems (DePuy). This stem was designed to be implanted into an under-reamed cavity to produce an interference-fit of up to 0.375mm. The elastic modulus of the bone was assumed to have a relationship with apparent density in the form $E = 2875 \rho^3$ [Carter and Hayes, 1977]. The elastic modulus of the titanium stem was 116 GPa.

Initially, two models were analysed, with (model EI) and without (model E) a modest interference of 0.1mm, and assuming elastic material properties for bone. On observing significant bone strains, the analyses were repeated assuming elastic-perfectly plastic bone properties with a yield strain of 1.5% (models EP and EPI). For all models, a coefficient of friction of 0.6 was assumed at the bone-implant interface and loads were applied as suggested by Bergmann [Hip 98 cd]. The micromotions and bone strains are reported at the bone-stem interface at six cross-sections from the proximal (L1) to distal (L6) portion of the porous-coated area.

RESULTS AND DISCUSSION

The minimum principal strain at the bone interface was significantly higher in the interference-fit models (Fig. 1). The elastic-plastic model showed significant plastic deformation, which suggests greater bone damage. However, the addition of plasticity to the models did not influence the micromotion values (Table 1.).

Axial micromotions were smaller in the models with interference-fit due to residual stresses at the interface. The micromotion values are large in comparison to similar studies. The inclusion of an interference-fit reduced the peak micromotions by only 10-30 μm .

Contact areas in the interference-fit models were significantly higher as compared to the no interference-fit models. When

loaded, greater contact with the stem was maintained due to elastic recovery of the interference-fit.

Figure 1. Mean minimum principal strain of L1, L3 and L6. Error bars showed the minimum and maximum minimum principal strain values at the cross-sections.

Model	Maximum axial micromotion, μm					
	1	2	3	4	5	6
E	183.1	228.0	198.8	189.1	163.7	194.7
EP	183.2	228.1	198.9	189.4	164.1	194.8
EI	150.2	205.8	167.2	171.3	150.6	177.4
EPI	148.4	205.7	166.8	169.4	148.6	177.6

Table 1. Maximum axial micromotions

SUMMARY

The predicted micromotions were high in this study, particularly around the anterior and posterior regions of the stem. The application of multiple load cycles may reduce the magnitude of the micromotions, by allowing the stem to 'bed in' [Kuiper and Huiskes, 1996], particularly for the elastic-plastic models. The results suggested that the inclusion of an interference-fit only marginally improved the stability of the stem, although the contact area was increased. The strain distribution was dominated by the interference-fit and this lead to significant bone damage (in some areas up to 1.5% minimum principal plastic strain). This may result in adverse bone resorption, in the early post-operative period. This raises the question, is there an optimum degree of interference, which minimises the degree of bone damage, but provides adequate initial stability and bone contact? Further work is required to study this in greater details.

INTRA-UTERINE TRANSPORT PATTERN DURING EMBRYO TRANSFER

Sarit Yaniv¹, Osnat Eytan², Ariel J. Jaffa² and David Elad¹

INTRODUCTION

Embryo transfer (ET) is the last stage of extra-corporal fertilization better known as in vitro fertilization (IVF). The ET procedure is performed 1-2 days after fertilization with a thin catheter, which is filled with 2-3 embryos in a fluid medium. The catheter is inserted into the uterus with its tip near the fundus at the top of the uterus (Schoolcraft et al., 2001). While fertilization in the laboratory occurs with relatively high success rates (>90%), the overall success of take home baby is still very low (<25%). Once the embryo enters the uterus, the ultimate goal is implantation at a fundal area to ensure a successful pregnancy. It has been demonstrated that intrauterine fluid motions, which are induced by myometrial contractions, may transport the embryo towards its implantation site (Eytan & Elad, 1999). In the present study, we analyzed the transport characteristics of ET by utilizing a model of a fluid-filled thin catheter inserted within a two dimensional (2D) channel with oscillating walls.

METHOD

The transport phenomena during the procedure of ET are simulated by a thin fluid-filled catheter inserted within a 2D channel which represents the intrauterine cavity (Fig. 1). Uterine peristalsis is simulated by a sinusoidal wall motility on both sides of the channel. The fluid that contains the embryos is injected into the channel via the catheter in either a constant or time varying speed. The initiation of the injection is synchronized with the position of the channel wall at the cross-section that coincides with the catheter tip. The time-dependent nonlinear governing equations for laminar flow of an incompressible fluid with constant viscosity are solved in a discrete form by FIDAP. Mesh points are clustered around the catheter and along the walls, where large gradients of velocity were expected. A total of 64,500 quadrilateral elements are used for the present simulation. The transport patterns of embryos during embryo transfer are analyzed for various parameters of the catheter and the channel.

Figure 1: Schematic description of ET in the sagittal cross-section of the uterus.

RESULTS

Simulations of intrauterine fluid flow pattern during the process of ET show that the higher the injection speed, the smaller the dependence of axial propagation on the peristaltic motion. As the injection stops, the trajectories of massless particles that represent potential embryos are determined entirely by the peristalsis and the channel characteristics. When the magnitude of injection velocity is of the same order as that of wall motility, the axial displacement of the particles is significantly affected by the synchronization of the onset of fluid injection with the wall motility. At higher injection velocities the trajectories of these particles are independent of the onset timing of the injection.

DISCUSSION

The presence of the catheter in the uterine cavity changes the normal intrauterine fluid flow. The speed of injection of the embryos from the catheter controls their dispersion within the uterine cavity. At high injection speeds the embryos are transferred forward and may reach the fundus (end of the channel) within one time period. When the magnitude of the injection speed is of the same order as that of the peristaltic wave speed, the embryos trajectories are mostly dominated by the peristaltic motion of the uterine walls, which may resemble to the natural process. This study may explain some of the biomechanical aspects involved in techniques of ET that may be responsible for the low rate of implantation after successful procedures of fertilization in the laboratory.

STUDY OF POSTURAL STABILITY BY CHAOS THEORY

Sandro Fioretti (fioretti@bioma.ee.unian.it) and Alessio Scattolini
Dipartimento di Elettronica ed Automatica – University of Ancona – Ancona - Italy

INTRODUCTION

In the present research, the problem of characterizing postural stability is approached from the perspective of nonlinear dynamics and chaos theory (Yamada, 1995). “Chaotic” is a term assigned to a deterministic non-linear process which is strongly sensitive to the initial conditions and system’s parameters. Particularly, the dominant (largest) Lyapunov exponent λ_1 quantifies the exponential divergence of initially close state-space trajectories and gives an estimate of the amount of chaos in a system (Wolf et al, 1985). The goal of this study was to verify if the dominant Lyapunov exponent relative to the center of foot pressure (CoP) time series is able to characterize the degree of postural stability when different bases of support and different vision conditions are considered.

METHODS

Five normal, healthy adult volunteers (25 ± 3 years) participated in this study. We collected CoP data for 120 s using an extensimetric platform (Bertec) at a sample frequency of 100 Hz; the subjects stood barefoot, looking straight ahead at a fixed point in a quiet room with their arms relaxed at the sides. The CoP data were filtered by a 4th order Butterworth low-pass filter (cut-off frequency 5 Hz). For each subject we performed six different acquisitions, one for each experimental condition: (1) eyes-open, feet together (*FT*), (2) eyes-closed, feet together, (3) eyes-open, feet 30° (*F30°*), (4) eyes-closed, feet 30°, (5) eyes-open, right foot forward 10 cm (*F_{dx}A*), (6) eyes-closed, right foot forward 10 cm. Starting from a single-dimensional measurement vector (y_i), $i=1, N_s$, \mathbf{x}_i -trajectory points in an m -dimensional embedding phase-space can be defined according to the time-delay method (Takens, 1981):

$$\mathbf{x}_i \equiv (y_i, y_{i+\tau}, \dots, y_{i+(m-1)\tau}) \quad i=1, N_s - (m-1)\tau$$

where y_i are CoP (AP or ML) data, τ is the time delay, m is the embedding dimension. Parameters τ and m have been calculated by mutual information (Fraser et al., 1986) and false-nearest-neighbors method (Kennel et al., 1992) respectively. The computation of the dominant Lyapunov exponent was performed using the algorithm proposed by Wolf et al.(1985).

RESULTS AND DISCUSSION

The optimal values for τ and m resulted 30 and 3 respectively. Table 1 shows the largest Lyapunov exponents computed for the mediolateral component (ML) of the subjects. A similar behavior was obtained for the anteroposterior component (AP) too. Repeatability has been verified on one subject

(Subject-5) that performed the experimental protocol three times in three different days.

Table 1: Largest Lyapunov exponent (λ_1) for the ML component of the CoP. Subject-5 was tested three times in three different days to verify repeatability.

ML m = 3, τ = 30	<i>Eyes-open</i>			<i>Eyes-closed</i>		
	<i>FU</i>	<i>F30°</i>	<i>F_{dx}A</i>	<i>FU</i>	<i>F30°</i>	<i>F_{dx}A</i>
Subject-1	0.299	0.161	0.194	0.354	0.168	0.267
Subject-2	0.292	0.168	0.289	0.317	0.225	0.306
Subject-3	0.125	0.098	0.124	0.175	0.138	0.152
Subject-4	0.138	0.114	0.247	0.274	0.168	0.318
Subject-5.1	0.243	0.169	0.208	0.331	0.221	0.314
Subject-5.2	0.212	0.183	0.196	0.298	0.241	0.269
Subject-5.3	0.229	0.174	0.189	0.281	0.197	0.225

The eyes-closed condition and the precariousness in the base of support resulted in an increment of the largest Lyapunov exponent λ_1 . Being λ_1 proportional to the instability of a process, results shown in Table 1 confirm that this parameter can be assumed as an index of postural instability. Besides, the experimental condition characterized by the lower λ_1 value was relative to the eyes-open and *F30°* task, that is the most stable posture.

SUMMARY

Because of the nonlinearity of the posture system, the CoP oscillation during quite standing is a good candidate to measure the chaotic movement of stance. Since the largest Lyapunov exponent λ_1 resulted positive, the postural system can be assumed to be chaotic. With respect to other parameters of the chaos theory (like f.i. the Lyapunov spectrum) the computation of the dominant exponent is a robust procedure resulting in a parameter that is repeatable and strictly connected to the stability of the system. With respect to classical posturographic parameters the dominant exponent together with other quantifiers of chaos theory can be more directly connected to the posture control mechanisms.

TEMPORAL ACTIVATION PATTERN DIFFERENCES BETWEEN THOSE WITH AND THOSE WITHOUT CHRONIC LOW BACK PAIN

Cheryl Hubley-Kozey¹ and M. Johanne Vezina²

¹ School of Physiotherapy, Dalhousie University, NS clk@is.dal.ca ² Physiotherapy Department CFSU(0) HCC Ottawa ON

INTRODUCTION

Trunk stabilization through appropriate neuromuscular responses to external perturbations (McGill, 1999) and the association between decreased trunk stability and mechanical low back pain (LBP) (Cholewicki and McGill, 1996) has provided the impetus to improve therapeutic LBP exercises. Concepts such as synergistic and antagonist coactivation are deemed important neuromuscular control strategies for stabilization (Granata and Wilson, 2001). Since the electromyographic (EMG) signal is a time-varying waveform of muscle activity, quantifying the temporal activation patterns in response to a sequence of perturbations should improve our understanding of muscle coactivation. This study compared (between those with LBP and those without) EMG waveforms recorded while subjects performed a task that challenged the neuromuscular system to respond to a sequence of perturbations while maintaining a neutral spine. Karhunen-Loève (KL) Expansion reduced the waveforms and two hypotheses were tested: all muscle sites were activated with the same temporal pattern and the temporal patterns were the same between the two groups.

METHODS

Twenty-four men without LBP (CON) and 14 men with chronic LBP (> 7 weeks) gave informed consent (approved by Ethics Committee). LBP subjects filled out Roland-Morris, Oswestry and six-point pain scales. Meditrace Ag/Ag Cl surface (Graphics Control, Ca) electrodes were attached in standard locations over 7 muscle sites: right lower (LRA) and right upper rectus abdominus (URA); right (REO) and left external oblique (LEO); right erector spinae ES; right (RMT) and left multifidus (LMT). EMG signals were amplified (BP 10 - 1000 Hz, CMRR 115dB, input impedance ~ 10 Gohm) using an AMT-8 EMG system (Bortec Inc., Calgary, Ab). Subjects repeated 5 trials of an exercise performed in supine which incorporated an abdominal hollowing maneuver, followed by leg-lifting and lowering tasks, while maintaining a neutral spine position (Vezina and Hubley-Kozey, 2000). The EMG signals were digitized at 1000 Hz using a Tecmar Lab Master A to D board (12-bit resolution, Scientific Solutions Inc., Oh) and a General Basic Software Program on an IBM PC. EMG signals were full-wave rectified, low pass filtered at 6 Hz, amplitude normalized to the average amplitude (%AVG) over the exercise and time normalized to 100% from start to end of the exercise (%Time). The KL Expansion was applied to the data set of all time-normalized profiles ($X=101 \times 1330$) and the weighting coefficients (WC_i) derived for each principal component pattern (PC_i) were the main dependent measures. Trial effects were tested, then two-factor (muscle and group) mixed ANOVA models tested interactions and main effects for each WC_i separately ($\alpha =$

0.05) using Minitab statistical software package (11Xtra). Post hoc analyses were performed on significant results.

RESULTS

The mean age for the CON was 32 ± 8 and for the LBP was 39 ± 5 years. The mean Roland, Oswestry, pain scale scores and number of years with LBP were 4.3 ± 4 , 19.4 ± 14 , $1.6 \pm .6$ and 7.7 ± 4.8 , respectively. Ninety-six percent of the variance in the waveforms was contained in 3 PCs. There were no significant trial effects ($p > 0.05$). There was significant ($p < 0.05$) group and muscle main effects for WC_1 and group by muscle interactions for both WC_2 and WC_3 . The RMT was the only muscle site that produced significant differences between the two groups for WC_2 , whereas significant differences for all muscles except ES and LMT were found for WC_3 . There were no significant differences among muscle sites for the CON for either WC_2 or WC_3 , whereas numerous differences were found among muscles for the LBP. The statistical differences captured the qualitative differences illustrated in the group ensemble average profiles for each muscle illustrated below.

DISCUSSION AND CONCLUSION

Moderately disabled LBP subjects used different temporal activation patterns than CON subjects. The LBP subjects had greater variation in amplitude over time. As well, the differences among muscles for the LBP subjects demonstrated a lack of synergistic and antagonistic coactivation, whereas the CON group recruited all seven muscles in a coordinated manner as illustrated in the ensemble average profiles. These data provide a quantitative basis for developing a diagnostic classifier of neuromuscular control impairments associated with LBP, and in future could help direct therapeutic interventions in particular those aimed at muscle reeducation.

ERRORS ASSOCIATED WITH CFD MODELS RECONSTRUCTED FROM 3D ULTRASOUND DATA

Alexander D. Augst¹, Dean C. Barratt², Alun D. Hughes², Simon A.McG. Thom², X. Yun Xu¹
Departments of ¹Chemical Engineering, ²Clinical Pharmacology, Imperial College, London, UK, a.augst@ic.ac.uk

INTRODUCTION

Computational fluid dynamics (CFD) is widely being used to gain insight into the complex flow patterns in human arteries. This can be done using idealized or realistic vascular geometries. For the latter an appropriate imaging technique is required to generate an accurate representation of the blood vessel. 3D X-ray angiography and magnetic resonance angiography (MRA) have been used for gathering this information in vivo, but recently 3D ultrasound (3DUS) imaging has emerged as an alternative. This study assessed the reproducibility of this procedure from image acquisition, to reconstruction to CFD simulation. A carotid artery bifurcation phantom was used for this purpose.

METHODS

An anthropomorphic carotid artery phantom (R.G. Shelly Ltd, Ontario, Canada) (Smith 1996) constructed from a set of silicon tubing in a tuning fork shape embedded in agar solution was scanned three times using 3D ultrasound. The lumen of the phantom was filled with a glycerol solution with a similar acoustic velocity to blood.

The 3D ultrasound system used was based on a standard 2D ultrasound scanner, and an electromagnetic position and orientation measurement (EPOM) device (Barratt 2001a and b). During the scan, the transducer probe was swept slowly over the open surface of the phantom. Two separate data sets were recorded: a 2D image from the scanner and the orientation and position of the ultrasound probe from the EPOM device. These sets were acquired on detection of a trigger pulse at a fixed time interval of 800ms. Digital images were then stored on the scanner and later downloaded to a PC to be analyzed off-line.

The acquired images were segmented using purpose-built software. The software was used to manually define points on the vessel wall to which a smooth cubic spline or ellipse was fitted, as appropriate. Thus, a series of cross-sectional contours was produced which define the geometry of the vessel. In order to reduce spatial artifacts in the reconstructed vessel, a cubic smoothing spline was fitted to the centroids of the contours. Each contour was then realigned so that its centroid coincided with the fitted centerline curve. The vessel surface was reconstructed by fitting smoothing splines to successive contour points (Barratt 2002). The surface splines were used by a commercial CAD/CAE package (ICEM-DDN) to produce the input file for the grid generator (ICEM Hexa). The semiautomatic Hexa tool allows the generation of a fully structured, multi-block hexagonal cell grid for the designated solver CFX-4.4.

Four CFD models were generated for the carotid bifurcation phantom studied, one from the corresponding CAD data describing its true geometry, and one based on each of the three 3D ultrasound scans.

Flow simulations were carried out for all four models under pulsatile flow conditions using a non-Newtonian, blood-mimicking fluid model. A 60:40 outflow ratio between the internal and external vessels was used which was determined from the ratio of the exit diameters of these vessels. Time-integrated parameters such as the oscillatory shear index (OSI) and time averaged wall shear stress magnitude (TAWSS) were calculated as well as instantaneous values of wall shear stress (WSS) magnitude and corresponding WSS vectors.

RESULTS AND DISCUSSION

Figure 1: OSI for CAD, Scan 1, Scan 2, Scan 3.

There was good agreement between the localization of areas of high OSI in the CAD generated set (left) and the three scans. This was also true for other wall shear stress indices. This may be attributed to the high geometric accuracy of 3D ultrasound reconstructions (Barratt 2002).

RMS errors for OSI calculated along a contour at location 1.75mm proximal to the apex of the bifurcation were found to be 0.0623, 0.0262 and 0.0314 (the full range of OSI values was 0 to 0.43 (CAD)).

SUMMARY

3D ultrasound has proved to be a highly accurate imaging method. It allows the reconstruction of blood vessels suitable for highly significant CFD-modeling.

INTRODUCTION

Osteoarthritis is the most frequent joint pathology throughout the world. Obtaining objective, dynamic and quantified data allowing the evaluation of patients' progress before and after hip arthroplasty is crucial. Gait analysis can be used for evaluating improvement in such patients, since walking is the principal human physical activity. Comprehensive gait analysis usually includes kinematics, kinetics, and electromyography. A complex instrumentation is thus required that only can be installed in a dedicated laboratory. These techniques are valuable to support clinical decisions and to evaluate the results. However, in several instances, a simplified analysis, concentrated on few selected gait parameters, can be valuable as well. Recently, we have proposed a new ambulatory system for gait analysis (Physilog) and validated its performances for normal and abnormal walking (Aminian et al., 2002). The aim of this study is to show the efficacy of Physilog system for clinical gait analysis in orthopaedics.

METHODS

Lower limbs movement during walking was measured using four miniature gyroscopes attached on each shank and thigh. Each sensor measured the angular rotation rate parallel to the mediolateral axis. The signals were digitized (12 bit) at a sampling rate of 200 Hz by a very light portable data logger (Physilog, BioAGM, CH), and stored for off-line elaboration. Spatial-temporal parameters of gait were determined according to a kinematic model. Measurements were taken from 7 patients with hip coxarthrosis (60±9 yrs old), 6 patients with total hip prosthesis (69±4 yrs old) and 8 aged-matched healthy subjects as controls (63±4 yrs old). In addition, the quality of life score (SF36) was used to evaluate pain and function in patients and control subjects. Each subject was asked to perform 10 walking trials at his/her habitual pace.

RESULTS AND DISCUSSION

A total of 106, 80 and 83 gait cycles were obtained from patient with hip coxarthrosis, patients with total hip prosthesis and control subjects, respectively. Lower performances were obtained for patient with coxarthrosis compared to patient with hip prosthesis and control subjects. In particular, the range of shank, thigh and knee rotation in sagittal plane were significantly lower for coxarthrosis patients compared to other subjects. As it can be seen in Figure 1, the range of shank

rotation in coxarthrosis patients was significantly different than control group ($p<0.001$). However SF36 score can not clearly discriminate between these two groups. Among the temporal parameters, the difference between initial and terminal double support showed a significant change between control and coxarthrosis patients ($p<0.01$), as well as between control and hip prosthesis patients ($p<0.05$). Moreover, stride velocity and stride length were significantly lower for coxarthrosis patients than other subjects ($p<0.05$).

Figure 1: Range of shank rotation angle for coxarthrosis (o), hip prosthesis (□) and control (◆) subjects compared to SF36 score.

The proposed method reveals a promising monitoring tool for functional evaluation of gait improvement. It allows measuring temporal and spatial parameters of gait (stance, swing, single and double support, stride velocity, stride length, range of knee, shank and thigh rotation) during a long period of walking and supplying in this way the stride-to-stride variability. Because of its portability and its low weight, this new device interferes minimally with the usual activity of the subjects. Therefore, contrary to other devices that require laboratory setting, Physilog allows to monitor the subjects in their usual environment and provides information that is probably as close as possible to the “real-world”.

COMPARISON OF BILATERAL AND UNILATERAL INDUCED ACCELERATION ANALYSES OF GAIT KINETICS

Patrick O. Riley¹ and D. Casey Kerrigan²

¹Department of PM&R, Harvard Medical School, Boston, MA, USA

²Department of PM&R, U. of Virginia, Charlottesville, VA, USA

INTRODUCTION

Induced acceleration analysis is an extremely useful tool for understanding coupled dynamics of posture control and gait. Meglan (1991) stated that a whole body model was required for an induced acceleration analysis. Kepple (1997) employed such a model to analyze propulsion and support functions during single support. We have performed induced acceleration analyses using a single limb model (Riley 1999, 2001a, 2001b). In doing so, we presumed that a single limb model is complete if all external forces are taken into account. While this assumption is common in analysis of dynamic systems, it is appropriate to test its validity. We do this by comparing the stance limb hip, knee, and ankle moment contributions to propulsion and support derived from bilateral models to the results of our unilateral analysis. We hypothesize that the analysis is sensitive to constraint formulation. We further hypothesize that with appropriate use of constraints, unilateral and bilateral models will provide similar.

METHODS

Ten subjects (5 female) from our database of healthy young control subjects were selected for analysis. The average subject age, height and mass were 26.6 ± 3.9 years, 1.7 ± 0.1 m, and 65.0 ± 12.9 kg, respectively. Kinematic data were sampled at 120 Hz. Force plate data were sampled at 1080 Hz. Subject specific seven segment bilateral models (right and left thigh, leg and foot segments and a pelvis/upper-body segment) were developed. Two versions of the models were developed, one with pelvic motion constrained and the second with the pelvic motion unconstrained during the model kinematic assembly process and inverse dynamic analyses. For both origin constraint formulations, two different foot constraints were imposed during the induced acceleration analyses. First, the foot position was constrained at the center of pressure during stance. Second, the foot rotation was also constrained. Thus, four different bilateral models (two forms of origin constraint and two forms of foot constraint) were evaluated. The trunk was assumed to be rotationally stabilized in space. The contributions of each limb's ankle, knee, and hip moments to propulsion and support were compared to the corresponding contributions defined by the unilateral model.

RESULTS

The models with the origin unconstrained yielded relatively poor agreement between kinematic accelerations and the summed induced accelerations. Of the two origin-constrained models, the model with both foot position and rotation constrained in foot-flat yielded better acceleration correlations than the model with only the foot position constrained. For the foot position constrained model the Pearson correlation coefficient was 0.63 for the foot position and rotation constrained model $r=0.79$. Qualitatively, acceleration agreement was excellent during single support, and marginal in double-support

The stance limb joint moment contributions to anterior/posterior and vertical origin accelerations of the constrained bilateral and unilateral models are comparable (Figure 1). For example, all models indicate that the hip moment contribution to anterior/posterior acceleration of the model origin is positive in early-stance and in late-swing, and negative in late-stance. Similarly, there is agreement on a strong positive late stance ankle moment contribution to origin anterior/posterior. The magnitudes of the contributions are, however, very sensitive to model formulation.

DISCUSSION

As hypothesized, the analysis was sensitive to model formulation. While the question of how complete a complete model needs to be, remains unanswered. Constraints can, it appears, be used effectively to represent unmodeled segments and forces. However, quantitative results are very sensitive to model formulation. The fundamental principle of induced acceleration analyses is that each degree of freedom influences every other degree of freedom. In seeking to validate a model for quantitative application of induced acceleration analyses, it will be best to begin with a model that represents as many of the body's degrees of freedom as possible (Riley 1990, Meglan 1991, Krebs 1992, Hutchinson 1994).

SONOMICROMETRIC MEASUREMENTS OF EYE DISPLACEMENTS

William J. Hurst, Joseph M. Cormier and Stefan M. Duma
Impact Biomechanics Laboratory, Virginia Tech, Blacksburg, VA Duma@vt.edu

INTRODUCTION

Every year there are over 2.4 million reported cases of eye injuries in the United States, and of these injuries, 30,000 result in permanent vision loss in at least one eye (Luder, 2000). While many researchers have attempted to investigate the fundamental injury mechanisms of eye trauma, there is a void of research that accurately quantifies the amount of stress and strain experienced by the eye during an impact event. Many different approaches have been attempted to measure the response of the eye to impact loading, including high-speed photography, scanning laser tomography, and ultrasound biomicroscopy; however, these methods do not accurately measure the response of the eye to deformation in both time and three-dimensional space.

Sonomicrometry allows for real-time three-dimensional measurements to be obtained. This technique allows for sampling frequencies of over 6.5 kHz with a 0.015mm resolution. Also, the piezoelectric transducer crystals used may be as small as 0.7mm in diameter. Sonomicrometric transducers have been used in various other types of medical biological studies including: length measurements of operating skeletal muscles, tendons, cardiac muscle, and respiratory tissues (Kamel, 2001). The purpose of this study is to determine the if sonomicrometry may be used to measure the dimensions of the eye.

METHODS

For this study two transducer configurations were tested: an equatorial configuration and a cornea to optic nerve configuration. In both configurations piezoelectric transducers were placed on diametrically opposite ends of the globe (Figure 1). Two compression plates were used to compress the eye along the axis being measured. Attached to these plates was a linear voltage differential transformer (Mitutoyo, Japan), which measures the distance between the plates, and two sonomicrometer transducer crystals (Sonometrics, London, Ontario, Canada), which measure the axial length of the eye.

Figure 1: Test setup for equatorial configuration.

The eye was compressed to different levels ranging from 0% to 36% of the original axial length. At each level, measurements were recorded from both sources.

RESULTS AND DISCUSSION

Comparing the data shows that there are small errors (maximum error of 0.82%) that occur with the use of sonomicrometry in this experiment (Table 1). Although these errors exist, they are very small and do not significantly effect the precision of the measurements. The results do not indicate any significant increase in error based on the configuration. This study was conducted using simplified configurations that may be used to measure distortions of the eye. Future research will be done to evaluate the ability to perform three-dimensional measurements.

Table 1: Summary of error data obtained from comparing the linear voltage differential transformer data and the sonomicrometry data. The maximum error values are indicated in bold type.

IS ACTION OF MEDIAL QUADRICEPS ALONE ADEQUATE TO STABILIZE THE KNEE AGAINST VALGUS LOADS?

INTRODUCTION

Upon examination of knee joint geometry, the medial moment arms of the vastus medialis obliquus (VMO) and longus (VML) in the coronal plane create an expectation for both muscles to generate adduction moments in the joint. Such actions in the coronal plane have implications in medio-lateral joint stability. However, this simple assumption has never been tested analytically or experimentally. We sought to determine the torque resulting from activating each of these muscles independently.

METHODS

A mathematical model of the patello-femoral joint was introduced using a basis-function method to accurately represent the contact surfaces as C^2 continuous functions. In the model, which was derived from the Visible Human right knee joint (Visible Productions, Ft. Collins, CO), the quadriceps were represented as five separate forces (figure 1) (Dhaher et. al, 2000 and Dhaher & Kahn, 2001). As the model solves patellar equilibrium for a given tibio-femoral joint orientation and relative quadriceps forces, we examined the resulting joint torques when VMO and VML were independently activated with no force contribution from the other vasti (Thiranagama, 1990).

Corroboration of the computational results was achieved *in vivo* by stimulating the same muscles. Four subjects participated and had their shanks fixed to a beam at the end of a 6-axis load cell. The VMO and VML were selectively stimulated using intramuscular electrodes and the resulting joint torques were recorded.

Figure 1: Graphical representation of the contact surfaces, coordinate systems, and muscle and tendon forces in the

model.

RESULTS AND DISCUSSION

Contrary to what was expected, independent activation of the VML and VMO in the model produced abduction moments at the knee. The abduction moment ranged increased from approximately 15% to 40% of the extension moment with increasing knee flexion angle (figure 2). Similar results were obtained *in vivo*, as shown in the figure.

Figure 2: Ratio of abduction torque to extension torque created by the VMO in the model (solid) and *in vivo* (dashed) at multiple flexion angles

SUMMARY

The effect of the individual medial quadriceps muscles on tibiofemoral joint torques was examined in a novel 3-D computational model. Our model results were validated by *in vivo* stimulation of the same muscles. In both model and experimental data, the medial extensors produced torque to abduct the shank (~20% of flexion torque), which is contrary to what should happen according to simple examination of the joint. It is likely that this counterintuitive result arose from the complex interaction between the patellar and femoral contact surfaces. Although significant, the selective role of the medial extensors in generating the appropriate stabilizing torque in secondary directions is questionable. Our data suggest that in the presence of an abduction torque applied to the knee, the individual medial quadriceps cannot produce the necessary adduction torque to stabilize the knee. Co-activation of all muscles (medial and lateral) with medial muscles exhibiting larger responses is an alternative strategy that may be mechanically more favorable (Dhaher et al, 2002).

ULTRASOUND WAVE PROPAGATION IN POROUS MEDIUM. APPLICATION TO CANCELLOUS BONE.

Luis Cardoso¹, Frédéric Teboul², Christian Oddou¹, and Alain Meunier²

CNRS ESA 7052, Biomécanique et Biomatériaux Ostéo – Articulaires,

INTRODUCTION

Bone pathologies such as osteoporosis lead to drastic changes in the architecture, mineral content and mechanical properties of cancellous bone. Non invasive characterisation of such tissues can be performed using ultrasonic methods. Indeed, the acoustic waves properties are affected by the spatial orientation, complexity and polyphasic nature of this material. Biot's theory of propagation of elastic waves in a fluid saturated porous solid (Biot 1956), has been used in order to evaluate the ultrasound propagation in bovine cancellous bone (Williams 1992). In such media, acoustic waves were shown to propagate following two modes with different velocities (Hosokawa and Otani 1997-98). This parametric study, leading to the variation of the two waves velocities as function of both porosity and orientation of the structure, is shown to be in fair agreement with experimental in vitro tests associated with attenuation measurements.

MATERIALS AND METHODS

14 bovine and 60 human trabecular bone samples were tested in vitro, using an immersed transmission method with a pulsed excitation. The parallel-faced cubic samples of about 1cm³ volume, were machined from different cancellous specimens of bovine or human femoral heads and from femoral and tibial human condyles. Broadband ultrasound transducers at central frequency of 2,25MHz (6mm OD) were used. Wave velocities were measured using a conventional transmission technique.

EXPERIMENTAL RESULTS

Figure 1.

The two predicted longitudinal propagation modes were observed in both human and bovine cancellous bone. Due to the limited size of the available samples, both waves generally superimposed and were separated in the frequency domain using digital filtering. Figure 1 shows the measured fast and slow waves in three orthogonal directions obtained when testing 38 human femoral head specimens as a function of bone porosity. It is clear that for a single homogenous specimen (with a unique porosity) the measures of acoustic velocities are orientation dependant. Therefore, the elastic

properties of cancellous bone cannot be accurately predicted with the sole value of the local porosity. For this reason, a theoretical model based on Biot's Theory was developed and applied to these data. This model takes into account a Structural Parameter (SP) based on trabecular orientations. From the model, this parameter was computed for each specimen and each measured direction. Figure 2 shows the fast and slow wave velocities measured on bovine specimens as a function of both porosity and Structural Parameter. The figure clearly show that each direction corresponds to a well defined value of SP that is independent from the specimen's porosity. Solid lines presented in figure 1 corresponds to the same theoretical model, using an averaged SP value for each direction.

Figure 2.

DISCUSSION AND CONCLUSION

In such in vitro tests, the two longitudinal propagation modes predicted by the model were clearly observed and quantified in both human and bovine cancellous bone. The measured slow wave velocities were always of the same order of magnitude as the sound velocity in the aqueous fluid phase alone. On the contrary the measured fast wave velocities demonstrated a high range of variation depending upon both the degree of porosity and the orientation of the trabecular structure with respect to the ultrasound beam direction.

Either in the experimental measurements or in the theoretical data for highly porous samples, the slow wave attenuation could be lower than the attenuation of the fast wave. This finding may be a cause of concern when considering in-vivo measurements of very osteoporotic specimens for which the only measurable velocity could be related to the propagation of the slow wave mode, thus characterising more the fluid phase than the solid one.

BACKPACK LOADS CARRIED BY SCHOOL CHILDREN

Jeffery Morley, Mary C. Verstraete and Shawn Robinson

Department of Biomedical Engineering, The University of Akron, Akron, OH 44325-0302

mary@biomed.uakron.edu

INTRODUCTION

The popularity of backpacks among school age children in the United States has increased significantly over the past few decades. Public media (USA Today 2000, US News & World Report 1999, Business Week 1999), in addition to several scholarly sources (Negrini, et al. 1999, Grimmer, et al. 1999, Hong and Brueggemann 2000, Pascoe, et al. 1997, Wang, et al. 2001), have recently highlighted the possible risks to children carrying heavy loads in their backpacks to and from school. The adolescent spine differs from the adult spine in that it represents structures in variable stages of growth. Chronic conditions may predispose children to further problems later in life. The purpose of this study was to determine the average load carried by children aged 12-13 during a typical school day.

METHODS

Six junior high/middle schools in the greater Akron area were contacted to assist in evaluating the loads carried in backpacks to and from school. Letters were sent home to parents requesting their permission to weigh their child, their child's backpack and to allow their child to answer a few questions about their age, potential back and shoulder pain, and participation in sports. Once permission was received, the investigators made an appointment with the principal of the school to visit the school on an unannounced day to measure these variables.

A physicians scale, accurate to 0.5 lb, was brought to the school to ensure that all weights were consistently measured. The investigators set up the scale in a private setting designated by each school to avoid the effects of peer pressure and other potential psychological factors. Each student was then brought to this location with their backpack loaded with a "typical" amount of books and materials that they would normally carry to and from school. The child was weighed and their height was measured without their backpack and then the pack was weighed separately. The child was then asked several questions: 1) their age, 2) their gender, 3) whether they experience any pain in their back or shoulders (if they answered "yes", they were asked to discuss the frequency and type), 4) if they participated regularly in type of sports or exercise. All data were recorded anonymously.

RESULTS AND DISCUSSION

Of the six schools that agreed to participate, 111 students were included in the study. Of these students, 69 were female (mean weight 52.5 kg and mean height 157.0 cm) and 42 were male (mean weight 53.8 kg and mean height 160.1 cm). Table 1 presents the results of comparing the weight of the student and

the weight of their backpack. Table 2 lists the results of the questions regarding existing pain in the shoulders or back.

Table 1: Percent of Body Weight Carried in Backpacks

	0%-10%	10%-20%	20%-30%	30%-40%
Girls	11	42	15	1
Boys	12	21	10	1
Total	23	63	25	2

Table 2: Pain Reported by the Subjects

	Pain	Neck Pain	Shoulder Pain	Back Pain	Other
Girls	43	2	34	17	2
Boys	21	1	14	12	1
Total	64	3	48	29	3

Of the 111 children studied, 21% of them carried between 0 and 10% of their bodyweight, 57% carried between 10 and 20%, and 23% carried between 20 and 30%. A total of 58% of these students also reported some type of existing pain in their neck, shoulders or back. These numbers indicate that a potential connection exists between the amount of load carried in the backpack and the occurrence of pain in these students.

SUMMARY

The results of this study show that school children, age 12-13, are carrying between 0 to 40% of their body weight in their backpacks to and from school on an average day. Most of the students also indicated that they typically wore their backpacks using only one of the two shoulder straps, thus distributing this weight in an asymmetric manner to primarily one shoulder. The results of this study will be used to provide input to an ongoing research project investigating the actual forces and moments incurred on the lower back due to this applied load.

PATTERN OF ARTICULAR CONTACT AT THE TIBIO-TALAR JOINT IN PASSIVE FLEXION

Federico Corazza^{1,3}, Rita Stagni^{2,3}, Alberto Leardini³, Vincenzo Parenti Castelli¹

¹ DIEM - Università degli Studi di Bologna, Italy, federico.corazza@ior.it

² DEIS – Università degli Studi di Bologna, Italy

³ Movement Analysis Laboratory, Istituti Ortopedici Rizzoli, Bologna, Italy

INTRODUCTION

The knowledge of the articular contact patterns at the human tibio-talar joint (Ti-Ta) is fundamental for the understanding of the joint kinematics and mechanics and to enhance biomechanics-based clinical treatments. Most of the contact area estimates from the literature are limited by the invasive measuring techniques. Studies have also rarely reported areas on the tibial mortise, and no studies have been performed in unloaded conditions. Motion analysis has successfully been used to assess these areas without any interference with the frictionless articulation (Kura et al., 1998). Clinical treatments, such as arthrodesis, arthroplasty and ligament reconstruction, would benefit from the results of this work. In the present study, the pattern of contact of the Ti-Ta joint during passive flexion is reported using a novel technique based on Roentgen Stereophotogrammetric Analysis (RSA) and a 3D digitiser.

METHODS

Passive flexion tests (Leardini et al., 1999) were performed on three anatomical preparations from amputation. RSA was used to reconstruct the position of four tantalum balls embedded in the tibia and in the talus, at several different positions of unconstrained passive flexion. This provided a discrete representation of the ankle joint neutral path (Leardini et al., 1999). After RSA, each specimen was dissected, and a large number of points was digitised on the trochlea tali (TTa) and on the tibial mortise (TiM). Digitisation also of the tantalum balls allowed the reconstruction of these points in a common reference coordinate system, at each of the different flexion positions. The articulating surfaces were then modelled by thin plate splines, delimited by standard B-splines interpolating the border points. The distance between the modelled points of the TTa and TiM was mapped on the two articular surfaces, for each reconstructed joint position. A distance threshold was set to detect the closest areas for each specimen. The position of the contact area centroid was calculated with respect to the three principal axes of inertia of each modelled surface.

RESULTS AND DISCUSSION

The contact area moved anteriorly on both articular surfaces with dorsiflexion (Do). Taken x as the posterior-anterior principal inertia axis, and y as the medio-lateral (see Fig. 1), the contact area was located in the most posterior part of the surfaces at maximum plantarflexion (PI) (mean TiM x: -60%). For increasing angles of Do, the contact area moved to the lateral zone in all the specimens, and reached its most anterior position at maximum Do (mean TiM x: +29%). These findings are partially supported by the literature (Kura et al., 1998;

Driscoll et al., 1994), although obtained in different conditions. The area was clearly found to be smallest at 50% Do (mean TiM CA: 3%), largest at 50% PI (mean TiM CA: 13%) (see Tab. 1), whereas more variable results have been reported previously (Kura et al., 1998).

Figure 1: Contact areas on the articular surfaces, both seen from above, for five flexion positions in one typical specimen.

Do+/- (%)		Specimen A			Specimen B			Specimen C		
		CA%	x%	y%	CA%	x%	y%	CA%	x%	y%

Table 1: Normalized values of contact area (CA) and contact centroid in the principal axis coordinates (x,y).

SUMMARY

These findings provide a useful characterization of the contact pattern at the Ti-Ta articulation. A well defined pattern of anterior motion of the contact area on the tibial mortise supports the hypothesis that the ankle behaves as a mechanism in passive flexion.

CROSSLINKING DENSITY INFLUENCES CHONDROCYTE MORPHOLOGY AND METABOLISM IN MECHANICALLY LOADED PEG HYDROGELS

INTRODUCTION

From a tissue engineering perspective, photopolymerizable hydrogels based on poly(ethylene glycol) are attractive for their ability to be gelled *in situ* with controlled architecture and desired macroscopic properties. However, in designing an *in situ* forming cell-scaffold, it is important to understand the impact of mechanical loading on cells within the scaffolds. During normal activity, articular cartilage is subject to mechanical loading, which causes cell deformation and alters biosynthesis within the tissue. Therefore, this study tests the hypothesis that changes in hydrogel properties, in the form of the crosslinking density, can influence the morphology and the metabolism of seeded chondrocytes in response to loading.

MATERIALS AND METHODS

Construct Preparation. Bovine articular chondrocytes were isolated from the metacarpalpalangeal joints of 18-month old steers via a sequential enzyme digestion with pronase (700 U/ml, Sigma) and collagenase (300 U/ml, Sigma). Poly(ethylene glycol) dimethacrylate (PEGDM, MW=3000) was synthesized [Sawhney,1993] and the PEGDM macromer was dissolved at concentrations from 10-20% (w/w) in PBS or water. Cytocompatible photoinitiating conditions 0.05% (w/w) and 0.012% (w/w) (I2959, Ciba Geigy), for 10 and 20% PEGDM gels, respectively, were employed [Bryant,2000]. The isolated chondrocytes were suspended in the macromer/initiator solution to a final concentration of 50×10^6 cells/ml and polymerized using 365 nm light at an intensity of ~ 2 mW/cm² for 10 minutes.

Cell Morphology. A confocal laser scanning microscope was used to visualize and measure cells embedded in PEG hydrogels following previously described techniques [Knight,1996]. Briefly, chondrocytes in cell-hydrogel constructs of rectangular shape (4x4x3 mm³) were stained with 5 μ M Calcein-AM (Molecular Probes), a viable fluorescent probe. Using a fabricated test rig [Knight,1996], the cell-hydrogel constructs were compressed from 0% to 20% strain and 50 cells/construct (4 constructs) were visualized at 0 and 20% gel strain. A horizontal image through the center of the cell was obtained, and the cell diameters were measured parallel (X) and perpendicular (Y) to the axis of compression. The deformation index (DI) is defined as X/Y.

Cell Metabolism Cell-hydrogel constructs of cylindrical shape (4 mm diameter, 5 mm height) were incubated in culture for 24 hours. The constructs were placed in a specially designed cell-straining apparatus [Lee,1997] and subjected to compressive strains from 0% to 15% in a sinusoidal waveform at a frequency of 1 Hz for 48 hours. The constructs were removed and digested in a papain solution (5 μ l/ml papain (Sigma, P3125), 10 mM l-cysteine-HCl, 100 mM phosphate, and 10mM EDTA at pH 6.3) for 15 hours at 60°C, and the glycosaminoglycan content [Farndale,1982] and total DNA content [Rao,1992] were measured. Statistical analysis was performed using a Student's t-test with a confidence level of 0.05 unless otherwise specified.

RESULTS AND DISCUSSION

By varying the PEGDM macromer concentration, a range of crosslinking densities (ρ_x) is obtained to yield gels with the same chemistry but different network structures. PEGDM gels were prepared from solutions containing 10 and 20%

PEGDM macromer, which produced gels of different ρ_x values. In addition, ρ_x influences many of the macroscopic gel properties. For example, an increase in ρ_x results in a decrease in water content, but an increase in gel mechanics.

The DI of chondrocytes was measured in the unstrained and strained states of the two seeded PEG gels (Table 1). At 0% gel strain, the mean DI for both systems was approximately unity, suggesting rounded morphology characteristic of differentiated chondrocytes. When the gels were subjected to 20% strain, the DI decreased in both systems, but interestingly, the cells embedded in the more tightly crosslinked gel deformed more ($p < 0.001$) than the cells within the more loosely crosslinked gel. These data suggest that the overall macroscopic differences, which exist between the gel systems, may lead to variations in the local strain adjacent to the cells.

Table 1. DI for chondrocytes seeded in PEG hydrogels with two crosslinking densities after a 24 hour culture period (mean \pm SD (N=200)).

	10% PEGDM	20% PEGDM
DI _{0% gel strain}	0.99 \pm 0.08	0.99 \pm 0.08
DI _{20% gel strain}	0.80 \pm 0.10	0.72 \pm 0.11

Table 2. GAG content (μ g GAG / μ g DNA) for constructs subjected to a 15% dynamic strain at 1 Hz (mean \pm SE (N=24)).

	10% PEGDM	20% PEGDM
Unloaded	3.6 \pm 0.2	1.7 \pm 0.09
Loaded	3.4 \pm 0.1	1.5 \pm 0.06

Figure 1. The percentage change from unstrained controls for GAG content in PEG gels (mean \pm SE (N=24)) * $p < 0.05$

When the cell-scaffolds were dynamically loaded for a 48 hour period during 72 hours of culture, the GAG content was statistically lower in the more highly crosslinked system in both the unloaded and loaded state. In addition, GAG production was inhibited in both systems by the application of strain, but the percentage change from unloaded to loaded was statistically greater in the more crosslinked gel. Therefore, during the first three days of culture when limited matrix has

been produced, crosslinking density appears to play an important role in the mechanotransduction pathways in chondrocytes photo-encapsulated in PEG hydrogels.

MUSCULAR RESPONSE OF THE SWING LIMB AND ARMS DURING AN UNEXPECTED SLIP

Daniel S. Marigold¹, Allison J. Bethune², and Aftab E. Patla²

¹Rehabilitation Research Lab, Graduate Program in Neuroscience, University of British Columbia, Vancouver, British Columbia, Canada, dsmarigo@interchange.ubc.ca

²Gait and Posture Lab, Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada

INTRODUCTION

Falls among the elderly are a major source of death and morbidity (Hsiao & Robinovitch, 1998). Slipping is a common cause of these falls (Pai & Iqbal, 1999). Reactive recovery responses are crucial in maintaining dynamic stability following unexpected destabilizing events such as a slip and accordingly, it is important to understand the nature of these responses. The role of the swing limb (i.e. the unperturbed limb) in the recovery response to an unexpected slip is not well known. The importance of this limb is reflected in the recent finding that the critical time for regaining stability following the onset of slip is during the first double support phase of the gait cycle (You et al., 2001).

The purpose of this study was to investigate the role of the swing limb in the reactive recovery response following an unexpected slip. The muscular activity of this recovery response is described here.

METHODS

Ten (6 female and 4 male) healthy, young adults from the University of Waterloo participated in this experiment. A slip was induced when participants stepped directly on a set of steel rollers with their right foot. The rollers (static & dynamic coefficient of friction equal to 0.04 & 0.03, respectively) were mounted on a force plate, sat flush in the middle of a 6.5 m long, 3.8 cm elevated wooden walkway and were visible at all times. Each participant travelled along the walkway a total of 20 trials. In each trial, participants were not aware of the rollers' surface (locked/no slip or unlocked/slip). At a random trial after the initial 10, 6 consecutive slips were induced.

Bipolar surface electromyography (EMG) electrodes were used to record the muscle activity of the unperturbed limb (i.e. the swing limb that did not make contact with the rollers) including rectus femoris (RF), biceps femoris (BF), tibialis anterior (TA), and the medial head of gastrocnemius (MG). In addition, bilateral gluteus medius (RGM and LGM), erector spinae (RES and LES), and deltoid (RD and LD) muscles were recorded. All raw EMG analog signals were sampled at 1200 Hz for 6 seconds. For analysis, the raw EMG signals were full-wave rectified and low-pass filtered at 10 Hz with a custom program. Each muscle response profile for a slip trial was determined by subtracting the ensemble average profile of the control trials from the slip trial. The control trials used were the unperturbed trials prior to the first slip. A one-way (Muscle) repeated measures ANOVA on muscle onset latency was performed for the first slip trial. Post hoc analysis consisted of Tukey's HSD test with significance set at $p < 0.05$.

RESULTS AND DISCUSSION

The ten muscles showed a significant difference in onset

latency (Figure 1) in response to the first slip trial ($F_{9,79} = 5.103$, $p < 0.001$). Post-hoc analysis revealed that MG was significantly delayed compared to all muscles except LGM and RGM. Furthermore, RGM was significantly delayed compared to all muscles except MG and LGM. The remainder of the muscles were activated in the range of 140 – 162 ms following the onset of the first slip trial (see Figure 1).

Figure 1: Muscle onset latencies in response to an unexpected slip during locomotion. FC = foot contact on rollers. Significant at $p < 0.05$ compared to all muscles except LGM & RGM (*) and to all muscles except MG & LGM (**).

The muscle onset latencies for the swing limb were slower than previously found in responding to an unexpected slip during locomotion (Tang et al., 1998). However, it is evident that interlimb coordination is crucial in maintaining dynamic stability following an unexpected slip (Marigold & Patla, 2002; Tang et al., 1998). The pattern of muscle activity observed serve specific functions: the musculature is activated rapidly to allow the limb to quickly land and provide stability. This was demonstrated by 70% of the participants as they briefly terminated swing before continuing the limbs' trajectory. Furthermore, the fact that the arm muscles responded quickly suggests they are vital in recovering balance as supported by recent data (Marigold & Patla, 2002). The arms serve to control body center of mass by shifting it more anteriorly after it is forced backwards by the slip.

CHANGES IN PLANTAR FORCE, AREA AND PRESSURE WITHIN A SINGLE SESSION USING AN IN-SHOE MEASUREMENT SYSTEM

Timothy A. Hanke and David Tiberio

Department of Physical Therapy and Department of Kinesiology - Human Performance Laboratory
University of Connecticut, Storrs, CT, USA, timothy.hanke@uconn.edu

INTRODUCTION

Evaluating a variety of in-shoe pressure-relief materials with the F-Scan System (Tekscan Inc., Boston, MA, USA) revealed decreased peak plantar forces over subsequent trials during a single experimental session. This could not be explained by subject performance as all subjects used different sensors and were paced at their preferred walking speed on a treadmill. To further understand the consistency of in-shoe sensors and their plantar force measurements during walking (cf., Rose et al, 1992), we describe changes in force, area and contact pressure using a set of in-shoe sensors for one experimental session.

METHODS

One healthy 49 y/o male performed treadmill walking at a self-selected speed (2.8 miles/hr.). F-Scan sensors were equilibrated using an air bladder system and calibrated using the F-Scan software (v.4.21). Eleven trials were collected: s1 with sensors (baseline); m2-9 walking with sensors and a PORON® material (Rogers Corp., Rogers, CT, USA) replaced each trial with a new set of the same material to avoid temperature or wear-related changes; s10 with sensors only; and s11 with sensors after re-calibration. Data was collected for 15s at 100Hz after 30-45s of walking.

RESULTS AND DISCUSSION

Figure 1: Plantar force and area decrease with time.

There was a significant decrease in the peak of the average total plantar force (contact + push off) (repeated measures ANOVA, $F(7,63) = 52.78$, $p < .001$) as well as sensor reporting

area ($F(7,63) = 9.06$, $p < .001$) across m trials (Figure 1). There was a trial effect for the peak of the average total contact pressure for m trials ($F(7,63) = 2.29$, $p = .038$). However, post hoc analysis revealed only the m2m8 comparison to be significant ($p = .005$). Comparisons m2m7 and m2m9 were not different ($p > .07$). See Figure 2.

Figure 2: Total contact pressure across trials.

Force and area measurements decreased with subsequent trials within a single session. The decrease in force and area resulted in the total contact pressure remaining relatively stable across trials. Additional calibration at the end of the session significantly altered total contact pressure (compare s10-s11).

SUMMARY

Although additional observations would strengthen the results, plantar pressure may be a more prudent variable over force when studying in-shoe materials across trials within a single session. Additional calibrations may not aid in comparing early and late trials. Finally, an “extended calibration” procedure (F-Scan manual) may require validation in studies examining effects of different in-shoe materials across trials.

PERICARDIUM-MEDIATED EQUALIZATION OF LEFT AND RIGHT VENTRICULAR OUTPUTS

Carol A. Gibbons Kroeker¹, Nigel G. Shrive², and John V. Tyberg¹

Departments of Physiology & Biophysics¹ and Civil Engineering²,

University of Calgary, 3330 Hospital Dr. NW, Calgary, Alberta, T2N 4N1; kcagibbo@ucalgary

INTRODUCTION

Although it is generally accepted that the pericardium plays an important role in equalizing left ventricular (LV) and right ventricular (RV) outputs, the mechanism has never been clearly demonstrated. The pericardium may mediate this equalization because of its stress-strain relationship, which is very distensible at low strains, but much stiffer at higher strain levels. Hence, at low strains (and low pericardial pressures), the size of the heart can increase relatively easily within the pericardium and there is little to no interaction between the ventricles. At higher strains, however, where the pericardium is stiff, the size of the heart will change very little with any further increase in load. Hence, any increase in the area of one ventricle must be accompanied by a decrease in the area of the other. The aim of this study was to show that the pericardium is important in equalizing LV and RV outputs on a beat-to-beat basis. We produced large, sudden changes in atrial volume and assessed the effects in terms of pericardial and ventricular pressures, dimensions, and outputs.

METHODS

Experiments were performed on 8 open-chest anaesthetized dogs. Aortic, left and right ventricular, atrial, and pericardial pressures were recorded, as well as LV and RV dimensions. Aortic and pulmonary flows also measured, from which LV and RV outputs or stroke volumes (SV) were calculated. To effect changes in atrial volumes, a reservoir was designed which allows rapid (~300 ms, during systole) infusion or withdrawal of 20-25 mL blood into or out of either the left or right atrium (LA or RA). Haemodynamic parameters were recorded for several beats before and for several beats after an infusion or withdrawal. LVEDP was decreased by a vena caval occlusion, or increased by volume loading. Inflations and deflations were repeated several times at various LVEDP's. This protocol was then repeated with the pericardium removed.

RESULTS AND DISCUSSION

With LA or RA infusions, there was a rise in ipsilateral transmural pressure, diameter and output (SV). With the pericardium present, there was also a compensatory decrease in transmural pressure, diameter, and SV on the contralateral ventricle. Further, the sum of the ipsilateral increase and contralateral decrease in outputs closely matched the initial infused volume (see Figure 1A). With LA or RA withdrawal, the opposite changes were observed, with the overall sum again closely corresponding to the initial withdrawal. In all cases, the response was quick (75-85% of complete response in the first beat post-infusion or withdrawal), with LV and RV SV's returning to control values within 3-4 beats. With the pericardium removed, there was again an increase in the ipsilateral ventricular output with LA or RA infusions. However, there was no compensatory decrease in SV seen in the contralateral ventricle. Similar results were observed with

LA or RA withdrawals. With the pericardium removed, the sum of the excess and deficit SV's did not match the infused or withdrawn volume (see Fig. 1B). These results show that the pericardium is essential for rapid biventricular equalization of the LV and RV outputs.

Figure 1: LA infusions with and without the pericardium.

To assess the accuracy of the biventricular compensatory response, with and without the pericardium, the sum of the cumulative changes in LVS SV and RVS SV are plotted as a fraction of the infused or withdrawn volume and shown against pericardial pressure (Figure 2). With the pericardium intact, the ratio was very close to one, indicating excellent equalization of LV and RV outputs and compensation for the initial infusion or withdrawal. Once the pericardium was removed (pericardial pressure equal to zero), however, LV and RV outputs were not equalized and, within the observation interval, compensation was not achieved. When the EDP's and pericardial pressures were lowered, there appeared to be a reduced ability to equalize the LV and RV outputs. At these low pressures, the data approached that seen with the pericardium removed. That is, the sum of the excess and deficit stroke volumes did not equate so well with the infused or withdrawn volumes.

Figure 2: The effect of pericardial pressure on the accuracy of the biventricular compensatory response $((\Delta LVS SV + \Delta RVS SV) / \text{infused or withdrawn volume})$. Filled squares, pericardium closed; open squares, pericardium open.

SUMMARY

This study clearly demonstrates that the pericardium is necessary to effect precise and rapid equalization of LV and RV outputs. When the pericardium was intact and its pressure at least 5 mm Hg, a sudden increase in atrial volume caused an ipsilateral increase in ventricular output and a compensatory contralateral decrease. Likewise, a decrease in atrial volume caused an ipsilateral decrease in SV and a contralateral increase. In all cases, the sum of the excess and deficit stroke volumes closely matched the infused or withdrawn volume. This interaction was lost when the pericardium was removed. With low pericardial pressures, the interaction diminished. We have demonstrated strong beat-to-beat equalization of ventricular outputs mediated by the pericardium. These results may be important in exercise when lung throughput is greater, and with orthostatic hypotension.

TORSO POSITIONS OF MINIMUM PASSIVE TISSUE STRAIN –WHERE DO WE SIT, STAND AND WALK?

Scannell, J.P.¹ and McGill S.M.

Faculty of Applied Health Sciences, University of Waterloo, Ontario, N2L 3G1.

¹ Communicating Author: jscannell@sympatico.ca

INTRODUCTION

The purpose of this study was to quantify the lumbar spine position of minimal strain and to investigate the posture related differences in the lumbar passive tissue strain levels endured during sitting, standing and walking trials.

Passive tissue strain is a recognized cause of mechanical low back pain (MLBP) (Kumar 2001). Yet to date the position of least lumbar passive tissue strain (elastic equilibrium) has not been quantified and it is not known if, without training, we assume the position of elastic equilibrium in ADL. Elastic equilibrium was identified following which the lumbar passive tissue strain in ADL was calculated by comparing the lumbar position in ADL to the position of elastic equilibrium.

METHODS

Eighteen female participants (6 hypolordotic, 6 hyperlordotic and 6 controls) were recruited from a pre-screened group of 150 undergraduate university students (without a history of LBP). Lumbar elastic equilibrium, the resting position of the lumbar spine in the absence of muscle activation, was identified after bending moments were applied by an assistant to the lumbar torso while the participant lay on a frictionless jig and simultaneous angular displacements of the T12 relative to S1 were recorded. Angular displacements of the lumbar spine were recorded during sitting, standing and walking trials and compared to the position of elastic equilibrium to identify the level of passive tissue strain. One-way ANOVA was used to perform statistical analysis.

RESULTS AND DISCUSSION

A 'zone' (neutral zone), rather than a specific lumbar position, of low tissue strain was found. The size and location of the neutral zone was not significantly different ($p > 0.5$) between different postural groups.

Regardless of their natural lumbar posture all participants sat in lumbar elastic flexion and walked with lumbar spine positions within their neutral zone. Both the hypolordotic group and the control group also stood within their neutral zone but the hyperlordotic group stood in elastic extension. Lumbar spine positions assumed during walking were consistently within the neutral zone indicating the absence of passive tissue strain during walking (Figure 1)

Positions either flexed (as found during sitting) or extended (as the hyperlordotic group were during standing) of the neutral zone imply that some passive tissue is beyond elastic strain and the tissue safety margin is reduced. The passive tissue strain was found to be specific to the hypolordotic and hyperlordotic classification.

Posture related differences in lumbar passive tissue strain

Figure 1: The neutral zone of each group, indicated by the black bars, is the zone of lumbar positions of least passive tissue strain. The average group lumbar spine position (50% level of the APDF) during the sitting, standing and walking trials in the pre-training test are shown relative to the group NZ. Positions outside the neutral zone are indicative of passive tissue strain and are indicative of a greater risk of tissue failure. The hypolordotic group sat significantly further from (more flexed of) their NZ than the hyperlordotic group.

SUMMARY

A 'zone' of lumbar spine positions where the passive tissue strain is low was found. Depending on an individual's natural lumbar posture, sitting and standing impose greater passive tissue strains than walking.

LOWER EXTREMITY SUPPORT DURING TODDLER GAIT

S. Potoczny¹, D.G.E. Robertson¹ and H. Sveistrup^{1,2}

Motor Control Laboratory, University of Ottawa, Ottawa, Ontario, Canada

¹School of Human Kinetics, ²School of Rehabilitation Sciences

INTRODUCTION

A net support moment of the lower limb, M_s , is defined as the sum of the moments at the hip, knee and ankle during the stance phase of walking. For adults, the net support moment during stance prevents collapse and brings about push-off (Winter 1980, 1991). It has been proposed (Breniere & Bril, 1988) that children within their first few months of independent walking actually “walk while falling”, whereas adults “fall while walking.” For children this implies that the vertical acceleration of the centre of gravity remains negative through single support and becomes positive only during double support. The purpose of this study was to characterize the M_s patterns of toddlers in their first year of independent walking and to determine if the proposed “walk while falling” is reflected by a negative M_s .

METHODS

Four toddlers aged 12, 16, 21 & 22 months with 2, 3, 7 & 12 months of independent walking, respectively, participated in this study. Surface markers were placed on the ASIS, sacrum, greater trochanter, lateral condyle, tibial tuberosity, lateral malleolus, heel and fifth metatarsal head. Toddlers walked independently at their own speeds across two AMTI force plates. A minimum of nine trials were analyzed for each toddler. Kinematic data were collected using three VHS cameras and processed using the Ariel Performance Analysis System. Force and kinematic data were analyzed and combined using Biomech software (Robertson, 2002) to calculate net joint and support moments. All moments were normalized to body weight.

RESULTS AND DISCUSSION

Support and lower limb moment curves during the stance phase for all trials from one toddler along with corresponding data (mean \pm st. dev.) from adults are plotted in Figure 1 (extensor moments being positive). This toddler's M_s s are much smaller and lack the double hump profile of adults. In 6 of 11 trials, the M_s were negative during the first 20% of stance of toddler gait corresponding to the period of weight transfer. In adults, the M_s at contact was always positive. The negative support moments lend credence to the suggestion that toddlers do not anticipate foot contact and are less stable on the lower limb at contact. The toddlers were able to provide an extensor M_s for the rest of stance bringing about push-off. Toddler ankle and hip joint moments followed similar patterns as those recorded for adult gait. Knee joint moments were negligible suggesting that toddlers may lock their knee creating a rigid segment. Regulation of stance phase seems to occur at the ankle and hip joints.

Figure1: Support and joint moments of force for a 2-month walker and averaged adult data (the latter from Winter, 1991).

SUMMARY

Early walking is characterized by a negative support moment of the lower limb during the first 20% of stance as the toddler attempts to position the body to create the support necessary to prevent a fall. Toddlers are less stable throughout stance and are therefore more susceptible to falls due to their reduced support moments.

INTRODUCTION

Previously, in vivo kinematic studies have determined that axial rotation patterns are quite variable between implant type and specific subjects. Previously, kinematic studies have determined that subjects having a mobile bearing TKA experience axial rotation, but it was unknown as to whether the bearing was rotating. (Stiehl, 1997) Therefore, the objective of this present study was to analyze the in vivo kinematics for subjects having a mobile bearing prosthesis to determine if the polyethylene rotates relative to the femoral and/or the tibial components.

METHODS

Femorotibial contact positions for ten subjects having a mobile bearing TKA, implanted by a single surgeon, were analyzed using video fluoroscopy. Each subject, while under fluoroscopic surveillance, performed a weight-bearing deep knee bend to maximum flexion. Video images were downloaded to a workstation computer and analyzed at varying degrees of knee flexion. Each polyethylene component had four metallic beads, inserted at known positions. Using a 3D model-fitting process, the femoral, tibial and polyethylene insert components were overlaid onto the fluoroscopic images. Initially, the polyethylene insert was made transparent, allowing visualization of the four metal beads. Then, the polyethylene insert was made viewable and analyzed relative to the metal femoral and tibial components.

Figure 1. Example of overlay progression used in this process. First the femoral component and polyethylene were fit to the image. Second, the tibia relative to the existing femoral component was fit. Finally, the polyethylene was inserted with respect to the tibia.

Figure 2. Axial rotation of the femur on the polyethylene was negligible in most subjects. However, the poly rotation on the tibial tray proved that the bearing rotates throughout increasing flexion.

RESULTS AND DISCUSSION

All of the subjects experienced polyethylene bearing rotation relative to the metal tibial base and minimal rotation relative to the metal femoral component. On average, relative to the tibial base, the subjects experienced 4.7° (2.1 to 7.9°) of polyethylene bearing rotation. The subjects experienced a similar amount of femoral component rotation, relative to the tibial base. On average, the subjects experienced 4.0° (-0.7 to 10.0°) of rotation of the femoral component relative to the tibial base. Therefore, on average, subjects experienced only 0.7° of rotation for the femoral component relative to the polyethylene bearing. Also, on average, from full extension to 90° of knee flexion the subjects experienced -2.9 mm of posterior femoral rollback of their lateral condyle and -0.4 mm of their medial condyle.

SUMMARY

This is the first study to determine the in vivo rotation of the polyethylene bearing for subjects having a mobile bearing TKA. The results from this study determined that the polyethylene bearing was rotating relative to the metal tibial component, but little motion of the femoral component relative to the polyethylene bearing was discovered relative to the metal. Therefore, as the femoral component axially rotated the polyethylene bearing was rotating a similar amount in the same direction. Since bearing rotation occurs under in vivo conditions, subjects' knees implanted with a mobile bearing prosthesis may be subjected to lower amounts of contact stress.

IN VIVO FORCES AND MOTIONS FROM FLUOROSCOPY AND MATHEMATICAL MODELING

Richard D. Komistek¹, Thomas R. Kane², Mohamed Mahfouz¹, Douglas A. Dennis¹, Brian D. Haas¹

¹Rocky Mountain Musculoskeletal Research Laboratory, Denver, Colorado: rkmositek@rmmrl.org

²Stanford University, Stanford CA

INTRODUCTION

Understanding the forces across the human lower extremity joints are of considerable interest to the clinician and implant manufacturers. In the past, telemetric hip implants have been used to determine the forces across the hip joint, but the forces at the knee joint have yet to be validated. Recently, video fluoroscopy has been utilized to accurately determine the in vivo kinematics of human joints during various activities. The objective of this study was to predict muscle and joint forces from a mathematical model utilizing fluoroscopy as the input motion data. (Komistek, 1998)

METHODS

Utilizing Kane's Dynamics, a mathematical model of the human lower extremity was developed. Using Autolev®, a symbolic manipulator soft-ware package, 18 equations of motion were explicitly derived using $F_r + F_r^* = 0$, $r=18$. Eighteen auxilliary generalized speeds were modeled in the velocity and angular velocity equations and were then constrained after the system kinematic equations were derived. While under fluoroscopic surveillance, one subject was asked to perform gait and deep knee bends at various speeds. The kinematic data, derived using fluoroscopy, was then used as input to a mathematical model and the predicted knee joint, quadriceps muscles and patellar ligament forces were plotted with respect to time, percent gait cycle and knee flexion angle.

RESULTS AND DISCUSSION

While walking at a normal speed, femorotibial force just after heel-strike was 1.9 times body weight (x BW) and 2.2 x BW just before toe-off (Figure 1). The patellofemoral force ranged from 0.3 to 0.5 x BW. The force in the quadriceps and patellar ligament ranged from 0.9 to 1.2 x BW, in the opposite direction of each other. The A/P forces in the knee were 0.1 and 0.4 (0.3 to 0.5) x BW at the femorotibial and patellofemoral joints, respectively. During a deep knee bend, the femorotibial force ranged from 0.5 to 1.8 x BW and the patellofemoral force increased from 0.1 x BW at full extension to 3.2 x BW at 90° of knee flexion (Figure 2). During a deep knee bend, the quadriceps force (0.1 to 2.3 x BW) was greater than the patellar ligament force (0.1 to 1.4 x BW). The model was very sensitive to the angle between the patellar ligament and the tibia. Varying this angle increased the femorotibial force during gait to 3.5 x BW.

Figure 1. Interaction forces during stance-phase of gait.

Figure 2. Interaction forces during a deep knee bend.

SUMMARY

Although we have not been able to validate the derived knee forces using a subject having a telemetric knee, the predicted hip forces using the model were very similar. Therefore, it can be assumed that the knee forces should also be accurate, or our modeled system would have predicted inaccurate hip forces. In the future, we hope to validate the model using a subject having a telemetric knee. The results from this study have revealed that patellar motion does influence the forces throughout the lower extremity. Simultaneous kinematic (fluoroscopy) and kinetic (mathematical model) data for subjects having a total knee replacement will provide valuable information for implant testing and future development.

OBSTACLE AVOIDANCE STRATEGIES ARE ALTERED FOLLOWING TOTAL KNEE ARTHROPLASTY

Jeannette M. Byrne and Stephen D. Prentice

Gait and Posture Laboratory, University of Waterloo, Waterloo, Ontario, Canada

jmbyrne@ahsmaail.uwaterloo.ca

INTRODUCTION

As locomotion involves coordinated movement of all lower limb joints, the effects of total knee arthroplasty (TKA) on function can be fully understood only by investigating bilateral lower limb function. Such research, by defining the bilateral motor changes resulting from TKA, will assist in the design of treatment programs for use with this population and also provide a deeper understanding of plasticity in the neuromuscular system. The primary purpose of the current study will, therefore, be to determine how TKA alters not only surgical knee function, but also how kinetic patterns in the remaining lower limb joints are affected. To accomplish this goal an obstacle avoidance task will be examined.

METHODS

Six individuals, an average of 20 months post right TKA (2 male, 4 females, mean age 73 years) and a group of 6 healthy participants (3 males, 3 females, mean age 76.6 years) were studied. Participants performed a total of 48 walking trials, divided equally among 3 conditions – unobstructed walking and clearing a 6cm and 18cm obstacle. Sixteen trials were performed at each height (8 right limb lead; 8 left limb lead). An Optotrak motion analysis system was used to collect kinematic data from both the right and left limbs. Bilateral ankle, knee and hip moments and powers were calculated using an inverse dynamics analysis. These results were used to determine rotational ankle, knee and hip work and translational hip work. Statistical analysis consisted of two separate two-way repeated measures ANOVAs to determine if surgical and non-surgical limb function differed from that of healthy, control limbs ($\alpha = 0.01$).

RESULTS AND DISCUSSION

Qualitatively, most patients exhibited decreased surgical knee flexion moments during early swing (Fig 1a). Deficits in surgical knee flexor work were also observed (obstacle x limb interaction $P=0.009$; Fig 1a). Post-hoc analysis of this interaction demonstrated differences between surgical and healthy limbs were significant at both heights ($\alpha < 0.01$). As knee flexor work during elevation (toe off to toe over obstacle) primarily flexes the knee (MacFadyen & Winter 1991), this decrease in knee work would account for deficits in active surgical knee flexion previously reported in these same individuals (Byrne 2001). Knee flexor work during early swing also passively flexes the hip and ankle via intersegmental dynamics (Patla & Prentice 1995). Deficits in surgical knee work would, therefore, result in members of the TKA group having less passive hip flexion and potentially less overall surgical hip flexion. As such a decrease in hip flexion would have deleterious effects on toe clearance, members of the TKA group increased surgical hip work (18cm height) (Fig 1a). This increase approached significance ($p = 0.0328$) and occurred in conjunction with greater surgical hip flexor

Figure 1: a) knee, hip moment and work (18cm obstacle) b) translational hip work (* significant difference between surgical and control limbs)

moments (Fig 1a). Although not significant, it is felt the increase in hip work was sufficient to ensure hip flexion was maintained. Surgical limb translation hip work increased at both obstacle heights ($P = 0.0024$; Fig 1b). Post-hoc analysis revealed this increase was significant only at the 18cm height. This increase can be understood by examining lower limb kinematics during swing. While members of the TKA group exhibited normal hip and ankle flexion, surgical knee flexion decreased, resulting in an overall decrease in surgical limb flexion (Byrne 2001). Despite this decrease, toe clearance was maintained. As translational hip work represents the stance limb's contribution to toe elevation, increases in translational hip work during surgical limb lead provided additional swing hip elevation, thereby, enabling members of the TKA group to maintain toe clearance despite decreased surgical knee flexion.

SUMMARY

The results demonstrate that while surgical knee function is clearly deficient following TKA, kinetic changes also occur at the surgical hip. These changes help compensate for surgical knee deficits, enabling these individuals to successfully negotiate obstacles.

IN VIVO DETERMINATION OF HIP JOINT SEPARATION IN SUBJECTS HAVING VARIABLE BEARING SURFACES

Richard D. Komistek¹, Douglas A. Dennis¹, Laurent Sedel², Curt D. Hammill¹, Eric J Northcut¹, Pascal Bizot²

¹Rocky Mountain Musculoskeletal Research Laboratory, Denver, Colorado, rkomistek@rmmrl.org

INTRODUCTION

Previous in vivo kinematic analyses of the hip joint have determined that femoral head separation from the medial aspect of the acetabular component occurs in metal-on-polyethylene THA (Dennis, 2001). The present study analyzes subjects having either an alumina-on-alumina (AOA), alumina-on-polyethylene (AOP), metal-on-metal (MOM) or metal-on-polyethylene (MOP) THA during gait and an abduction/adduction leg lift to determine if the incidence of hip joint separation (femoral head sliding on the acetabular cup insert) varies based on articular surface material.

METHODS

Forty subjects were analyzed in vivo using video fluoroscopy. Ten subjects had a AOA THA, ten an AOP THA, ten a MOM THA, and ten had a MOP THA. All THA subjects were implanted by two surgeons and were judged clinically successful (Harris hip scores >90.0). Each subject performed normal gait on a treadmill and an abduction/adduction leg lift maneuver while under fluoroscopic surveillance. The two-dimensional (2D) fluoroscopic videos were converted into 3D using a computer automated model-fitting technique. Each implant was analyzed at varying flexion angles to assess the incidence of hip joint separation.

RESULTS AND DISCUSSION

During gait and the abduction/adduction leg lift, no separation was observed in subjects having an AOA THA or in subjects having a MOM THA (Figure 1). Similar to our previous studies pertaining to subjects having a THA with a polyethylene acetabular insert, all ten subjects having a MOP THA and 6/10 subjects having an AOP THA experienced hip joint separation. The maximum amount of separation was 7.4 mm for a subject having an AOP THA and 3.1 mm for a subject having a MOP THA. The maximum amount of separation occurred during mid-stance to toe-off (Figure 2).

Figure 1. Fluoroscopy images of final fit overlay and component positioning of a subject having an alumina-on-

alumina THA. Images are shown during gait activity at heel-strike, 33%, 66% and toe-off.

Figure 2. Fluoroscopy images of final fit overlay and component positioning of a subject having an alumina-on-polyethylene THA. Images are shown during gait activity at heel-strike, 33%, 66% and toe-off.

SUMMARY

This study shows femoral head separation from the medial aspect of the acetabular component can occur in the presence of a polyethylene liner. The femoral head often remains in contact with the liner, hinging superolaterally. Previous studies have only reported hip separation (femoral head sliding) to occur during non-weightbearing conditions. The presence of hip separation during stance-phase of gait may suggest that the inertia of the contra-lateral leg induces the acetabular cup to separate away from the femoral from mid-stance to toe-off. Potential detrimental effects resulting from hip joint separation include premature polyethylene wear, component loosening (secondary to impulse loading conditions) and hip instability. Wear may be enhanced due to creation of multidirectional wear vectors or excessive loads due to eccentric femoral head pivoting. The absence of separation observed in AOA and MOM THA designs may be related to increased wettability of these materials and tighter radial tolerances resulting in a cohesive lubrication film. This data may be of value in hip simulation studies to better duplicate wear patterns observed in retrieval analyses and assist in the understanding of the lubrication regime and wear rates in AOA and MOM designs, allowing for the synthesis of prosthetic components that minimize wear and optimize kinematics.

NORMALIZATION OF SURFACE EMG SIGNALS - COMPARISON AMONG EFFORT, JOINT POSITION AND PROCESSING METHOD

Nigel Zheng, Ph.D., Brian Ragan, Paul Marvar, Glenn Fleisig, Ph.D., Steve Barrentine, M.S.
American Sports Medicine Institute
1313 13th Street South, Birmingham, Alabama 35205, USA, nigelz@asmi.org

INTRODUCTION

EMG signals have been used for diagnosis of disease, evaluation of different exercises, and estimation of muscle forces (Zheng, N et al, 1997). EMG results are affected by numerous factors during data detection and processing (De Luca, C. 1997), however these factors are often ignored and/or not reported when normalizing EMG. The objective of this study was to evaluate the effects of contraction effort, joint angle, and data processing method during isometric contraction of the quadriceps muscles.

METHODS AND MATERIALS

Ten healthy subjects (5 male, 5 female) with no history of knee injury volunteered as subjects. The dominant leg was tested with the subject seated. Three pairs of surface electrodes (Medicotest Marketing, Inc. Ballwin, MO) were placed on the muscle belly of the vastus medialis (VM), vastus lateralis (VL), and rectus femoris (RF). A load cell (Omega Engineering) was installed to directly measure force applied by the dominant leg near the ankle. The force signal was collected at 1000 Hz. Synchronized EMG signals from the three muscles were recorded at 1000 Hz with a Myosystem 2000 (Noraxon USA, Inc., Scottsdale, AZ). Signals were converted from analog to digital data and stored with an ADS system (Motion Analysis Corp., Santa Rosa, CA). Tests were conducted at 30, 60 and 90 degrees of knee flexion with maximum, 75% and 50% effort voluntary isometric contraction for 3 seconds. Each test was repeated three times. Subjects were allowed to take a 2-minute break between tests.

Data were passed through a high-pass 4th order butter filter and rectified. Four different processing methods were then used: integration (INT), low-pass filter with cut-off frequency of 25 Hz (LPS), root-mean-square (RMS) and average rectified value (ARV). For each processing method, the mean value of the middle second was calculated and averaged for the three tests each subject performed for each condition. The coefficient of variability (COV) among the three tests was also calculated. Repeated measures analysis of variance (ANOVA) was used to identify significant ($p < 0.05$) differences in mean EMG and COV among effort, knee angle, and data process for each muscle (SPSS Inc, Chicago, USA).

RESULTS AND DISCUSSION

EMG data is commonly scaled by the EMG magnitude of maximum voluntary isometric contraction (MVIC). While

this is a common approach, Lawrence and De Luca (1983) suggested that the variability of EMG during maximum effort was high to make it a poor choice for normalization. As expected, the current study showed that mean value of EMG and force both were highest with maximum effort and lowest with 50% effort. However their COV were not significantly different among effort levels. Thus, the choice of effort for normalization trials would affect the magnitude but not the consistency of scaled data.

The mean values of EMG for the VM and VL muscles varied significantly with knee flexion angle, and were highest with 90° knee flexion and lowest with 30°. COV varied with knee angle, and were lowest at 60°. For the RF muscle, mean values and COV for different knee angles showed no significant differences. Thus, the choice of isometric position should be considered and reported when isometric data are used for normalization, as the magnitude and consistency of scaled data may be affected.

EMG results varied significantly among the different data processing methods. Mean values were greatest with the INT method and least with the ARV method. COV was the least with INT and no differences among others. Each of these methods has virtue and has been used in EMG analysis. The current study does not suggest that one method is superior, but that the choice of method can affect the results and should therefore be reported.

SUMMARY

Normalization is often used in EMG data analysis. MVIC has the highest magnitude and the choice of using MVIC is no better or worse than 75% or 50% effort level. The choice of joint position and processing method should also be considered and reported. Different joint angles should be considered for different muscles to obtain MVIC or other level VIC. Because of variability, multiple trials are always a good idea. The choice of result parameter (e.g., global peak of 3 seconds, peak of the middle second and average of the middle second) also affects results. The choice of effort, position, and processing method is important not only for the quality of an individual study, but also for comparison of various studies and clinical application of EMG testing.

ON NOT TIPPING A STEPLADDER SIDWAYS

Bing-Shiang Yang and James A. Ashton-Miller
Biomechanics Research Laboratory, Department of Mechanical Engineering
University of Michigan, Ann Arbor, MI, U.S.A. bsyang@umich.edu

INTRODUCTION

Falls from ladders are the second most frequent cause of injury involving falls from elevation. A fall caused by tipping a stepladder over sideways is the most common cause of stepladder accidents (and the second most common cause involving ladder accidents) (Björnstig et al., 1992). Faergemann et al. (2001) suggested that overreaching laterally is the most common cause of falls from stepladders. In the elderly, standing on a raised surface is considered as one of the three most-challenging activities of daily living (Powell et al. 1995). The purpose of this study, therefore, was to use a biomechanical model, validated by experiment, to analyze in the frontal plane, the factors determining the stability of an individual during the lateral weight shift associated with climbing or descending a stepladder. We examined the effect of (a) altering the height of stance step, H , as a percentage of body height (BH), (b) altering the bipedal foot separation distance, and (c) the velocity with which the individual shifts his/her weight laterally from bipedal to unipedal stance.

METHODS

A stepladder was modeled as a rigid, planar, inverted “U” structure of variable height with 10% body mass (representing step height, expressed as a % of body height) and of fixed width resting on flat ground. We modeled a human shifting from double support to single support at the middle of the step as an inverted pendulum. The torque acting at its pivot joint represented the moment applied about the midpoint of the step by the stance foot-step reaction force. Its magnitude was constrained by the value of the product of body weight times foot width, and by the average ankle inversion/eversion strengths for young males (Ottaviani, 1995). The length and mass of the inverted pendulum corresponded to the average young male (Winter, 1990). Simulation inputs at contralateral foot lift-off included initial inclination angle of the pendulum center of mass (COM) from the vertical, initial COM angular velocity. A fourth-order Runge-Kutta method was used to solve the equations of motion in this MATLAB® simulation and a ‘Bang-Bang’ control strategy to control the joint torque. The controller objective was to bring COM over the stance foot width, or base of support (BOS), with zero residual COM velocity. When the total torque applied to the stepladder exceeded the torque required to lift one leg of the stepladder, then the ladder was deemed ‘unstable’. The feasible phase plane operating region was then found. To validate model predictions, five healthy young males were each asked to transfer weight in 7 trials from bipedal stance onto one foot at the middle of a step located at 0 and 22% of body height (BH). Kinematic measures on pelvic, torso and leg motions were obtained at 100 Hz using an Optotrak 3020 system, while foot

reaction forces were measured at 100 Hz using two AMTI force plates under the stepladder legs and an F-Scan pressure distribution system under the stance foot.

RESULTS AND DISCUSSION

The stability region was found to be strongly dependent on height of step on which the subject stood, the initial COM displacement related to BOS given by the initial foot separation distance, and velocity of the weight shift (Fig. 1). The stable region was 80% smaller when the human stood on a step at 22% of body height than when the human stood on the ground. Moreover, the higher the step was, the narrower the feasible range of COM velocities was. These model predictions were supported by the experimental data. This simplified model generally identified the feasible region of stepladder stability under lateral weight shift conditions. EMG analyses of gluteus medius activity supported the ‘bang-bang’ control strategy assumption.

Figure 1: Model-predicted region of stability (lines). Experimental data points are also shown (*: successful (no ladder tilt) recovery trials for $H=0\%BH$; o: failed (ladder tilt) recovery trials for $H=0\%BH$; +: successful recovery trials for $H=22\%BH$; Δ: failed recovery trials for $H=22\%BH$).

SUMMARY

The model provided a reasonable prediction of the circumstances under which a human can cause a stepladder leg to inadvertently lose ground contact. The higher the step, the narrower the bipedal base of support should be, and the slower the COM should be moved.

VERIFICATION OF THREE-DIMENSIONAL JOINT KINEMATICS DETERMINED USING FLUOROSCOPY: AN ERROR ANALYSIS

Mohamed Mahfouz^{1,2}, William Hoff², Richard Komistek¹, Douglas Dennis¹

¹Rocky Mountain Musculoskeletal Research Laboratory, Denver, Colorado, mmahfouz@rmmrl.org

²Colorado School of Mines, Golden Colorado

INTRODUCTION

A method was developed to analyze the accuracy of a 3D-to-2D image registration system that has been used successfully in joint kinematics studies (Dennis, 1996; Mahfouz, 2002). This system, determines the relative pose of femoral and tibial knee implant components from single plane X-ray fluoroscopy images. The accuracy analysis method used cadaver images very similar to “in vivo” clinical X-ray fluoroscopy images, and a completely independent method for determining the ground truth poses based on the use of an optical sensor. The objective of the study was to conduct an unbiased characterization of the accuracy of the 3-D to 2-D registration method.

METHODS

The sensor used in this study was an Optotrak 3020 system (Northern Digital Inc., Waterloo, Canada), which is a position-tracking device that tracks infrared LED's by using three fixed linear array CCD cameras. Shallow registration holes (5/64”) were drilled into the femoral and tibial components of a posterior cruciate retaining knee implant. The holes were distributed throughout the components in a non-collinear arrangement. These holes were used to establish a reference frame for each implant component using the optical sensor. The implants were laser scanned and a polygonal surface model was created for the femoral, the tibial component.

Figure 1 The Optotrak probe was used to determine the

location of the registration points.

The locations of the registration holes on the surface models were found by manually placing virtual beads (balls) of the same size as the probe tip in the holes located on the surface of the generated models. The coordinates of the beads were recorded in the implant model coordinate reference frame. The 3D-to-2D registration system operated fully autonomously, after initial model placement by the operator. The optimization process in the 3D-to-2D-image registration system was allowed to converge, and the pose results were

recorded without any adjustment or intervention.

Table 1 Differences of poses derived from our method and those derived from Optotrak sensor (Sagittal plane).			Table 2 Estimated standard deviation of errors due to our process only in the Sagittal plane.	
	Mean	SD	SD	
X trans (mm)	-0.338	0.323	X trans (mm)	0.001
Y trans (mm)	0.130	0.472	Y trans (mm)	0.429
Z trans (mm)	-0.494	1.640	Z trans (mm)	1.622
X rotation (deg)	-0.125	0.550	X rotation (deg)	0.427
Y rotation (deg)	-0.351	0.592	Y rotation (deg)	0.501
Z rotation (deg)	-0.006	0.971	Z rotation (deg)	0.727

A surgeon implanted both components into a fresh cadaver. The Optotrak probe was used to measure the (x, y, and z) coordinates of the registration holes in the femoral and tibial components while simultaneously video recording the X-ray fluoroscopy (Figure 1).

RESULTS AND DISCUSSION

With the exception of the Z (out of plane) translation, the mean difference in translation was less than 0.34 mm in all directions, and the standard deviation of translation errors was less than 0.50 mm in all directions. Error is higher for translation along the Z axis (the direction perpendicular to the image plane) because the registration method is much less sensitive to displacements in that direction. The mean difference in rotation was less than 0.50 degrees about any axis, and the standard deviation of rotation is less than 0.70 degrees about any axis (Table 1 and 2).

SUMMARY

The accuracy analysis method in this study is unique in that it used data very similar to “in vivo” clinical X-ray fluoroscopy images, unlike other work that uses clean laboratory images or synthetic data. Also, a completely independent method for determining the ground truth was developed, unlike some previous work that uses ground truth derived from X-ray data. This gives a true characterization of the accuracy of our 3-D to 2-D registration method. This approach could be used for determining ground truth for testing other registration methods.

ASSESSMENT OF CUSHIONING MATERIALS: WHAT'S THE APPROPRIATE MEASURE?

David Tiberio and Timothy A. Hanke

Department of Physical Therapy & Human Performance Laboratory, University of Connecticut, Storrs, CT, USA

david.tiberio@uconn.edu

INTRODUCTION

Assessment of cushioning insoles / materials is often performed using plantar pressure measurements. Regardless of which measurement system is used, investigators must decide what dependent variable / measure provides the most appropriate insight into the cushioning properties of different materials. Mechanical testing of impact g-force does not take into account the interaction between the material and the human neuro-musculo-skeletal system.

METHODS

Twelve subjects hopped repetitively on one leg for 5 seconds on a force platform (AMTI, Watertown, MA, USA) with a F-Scan sensor (Tekscan, South Boston, MA, USA) in their sport shoe. The force plate data was sampled at 200Hz and the F-Scan data at 100 Hz. There was a 3 minutes rest between material conditions. The sequence of the tested materials was the same, but the starting order was changed for each subject. Each 5 - second trial resulted in 10-12 hopping cycles.

The peak vertical force (FZ) for each hop was averaged to produce a mean for each material for each subject. The peak value for the total contact pressure (TCP) from the F-Scan was averaged in the same manner. Five "box pressures" (BP) were determined using the F-Scan software for the hallux and 4 metatarsal head regions. The box with the highest pressure values was selected for each subject.

Inspection of the data revealed intra-subject variability across materials. There were substantial differences in FZ for the different materials, possibly due to the subjective comfort assessment of each participant. In order to minimize this effect, the FZ was divided by the subject's body weight to produce a body weight unit (BWU) for each material. This BWU was then used to evaluate both the TCP and the BP data.

RESULTS AND DISCUSSION

Figure 1. FZ for different materials normalized by BW.

Since the subjects were landing on the force plate with different BWU values, the TCP was normalized (Figure 2). This substantially changes the relative cushioning efficacy of the materials.

Figure 2. Effect of normalizing TCP by BWU on the relative rankings of cushioning effectiveness.

Figure 3 shows a comparison of the TCP and the BP for the different materials. The relative rankings of materials from lowest to highest pressure are different for the BP compared to TCP. Material E had the highest BP / BWU, but the third lowest TCP / BWU.

Figure 3. Materials ranked in order of TCP, compared to BP.

Even when normalized by BWU, the materials differed in effectiveness. This would suggest that, for hopping, materials do not have the same cushioning efficacy in high pressure areas of the foot when compared to the total contact pressure.

SUMMARY

We contend that the use of BWU to normalize FZ and pressure measures is important when testing different materials. TCP and BP are different measures of cushioning.

ASSESSING THE ACCURACY OF DOPPLER VELOCITY WAVEFORMS USING A STRING PHANTOM

Andrew Zambanini, Nicholas W. Witt, Dean C. Barratt, Simon A. McG Thom, Alun D. Hughes

Department of Clinical Pharmacology, National Heart & Lung Institute, Imperial College, London, UK
a.zambanini@ic.ac.uk

INTRODUCTION

Non-invasive techniques such as magnetic resonance and Doppler ultrasound imaging are popular methods used to determine flow velocity waveforms in arteries. These data are subsequently used for clinical applications such as wave intensity analysis, computational fluid dynamics modelling and the determination of volumetric flow. Previous work has suggested that peak velocities may be over-estimated using pulsed wave Doppler ultrasound (Hoskins, 1999). Real-time automated peak and mean frequency tracing algorithms have therefore been developed and are less variable than manual measurements (Rickey & Fenster, 1996). The aim of our study was to determine which of these two algorithms is most accurate for determining the flow velocity waveform.

METHODS

A string phantom (Gamex RMI, Middleton, USA) with an O-ring rubber filament was immersed in a tank containing degassed water at a temperature of 36°C (acoustic velocity 1522 m s⁻¹) and used as a moving target. The string was rotated using a stepper motor controlled by an electronic waveform generator programmed with 4 types of waveform; a constant speed of 35cm/s (P1), a single phase positive waveform with a peak velocity of 100cm/s (P2), a two phase positive waveform with peak velocities of 75 cm/s (P3), and a triphasic waveform with both positive and negative velocities with peak velocity of 90 cm/s (P4). The speed of the drive wheel on the string phantom was determined over successive periods of 17ms using a shaft encoder linked via a microcontroller to a PC.

An L12-5 linear-array transducer and HDI5000 ultrasound scanner (ATL, Bothell, USA) were used to acquire signals from the string phantom. This system provided real-time automated peak and mean frequency tracing algorithms and allowed digital data to be transferred to a PC for further analysis. Following simultaneous acquisition of the Doppler and shaft encoder data (5s for P1, 10 waveforms for P2-P4), ensemble averaging was performed to generate velocity waveforms from the shaft encoder (S) together with peak (Pk) and mean (M) Doppler for each string phantom program. Pk and M were compared with S by determining the root mean square (RMS) errors.

RESULTS

Pk overestimated the true velocity (S) in all cases. Figure 1 illustrates the differences between Pk, M and S for the triphasic waveform P4. The RMS errors are summarized in table 1 and confirm that there was very little difference between M and S for all generated waveforms.

Figure 1: Peak (bold) & Mean (dashed) Doppler waveforms compared with the shaft encoder waveform for P4

SUMMARY

In the Doppler ultrasound system tested, the mean Doppler tracing algorithm was found to be more accurate than the peak for determining the velocity waveform for a string phantom. In order to avoid significant errors in velocity measurements, it is recommended that the accuracy of other ultrasound systems should be assessed using this method.

HAND IMPACT FORCE REDUCTION IN FORWARD FALLS IN YOUNG MALES: A PROSPECTIVE, CONTROLLED, 3-MONTH INTERVENTION TRIAL

J. Lo, G.N. McCabe, H. Okuizumi, and J.A. Ashton-MillerBiomechanics Research Laboratory,
University of Michigan, Ann Arbor, MI USA. E-mail: joshualo@umich.edu

INTRODUCTION

Fall-related injuries of the upper extremities are common at any age because of the magnitude of the impact force acting on the limb (Myers et al. 1993). Accordingly, a reduction of impact forces is key to reducing fall impact-related injuries. It has recently been shown that after a brief, 10 minute, instructional intervention, healthy subjects can volitionally reduce the impact force on the upper extremity by 27% during standardized forward falls (DeGoede, 2002). Using this paradigm, we explore two hypotheses in young males using forward falls: (1) the reduction in impact forces obtained after the 10 minute instructional intervention during the baseline visit was not due to self-learning; (2) in a prospective, controlled, trial conducted without practice, the impact forces in the intervention group would not differ significantly from the untrained controls at 3 or 12-week follow-up.

METHODS

20 young males, without previous fall trainings, participated in the study (mean±SD: age=25±2 years, body weight=69±8 kgf, and height=173±3 cm). Subjects were leaned forward, restrained by a waist harness until a cable supported them with a tension of 30% body weight. Both shoulders were then lowered to 1 meter from the ground. Upon cable release, the subject was instructed to arrest the fall with both hands, and body segment kinematics were measured at 200 Hz using an Optotrak 3020 system. The impact forces on both hands were collected at 2 kHz using dual AMTI force plates. The subjects were divided randomly into two groups, 10 in the intervention and 10 in the control. At the baseline visit, each subject in the intervention group was asked to perform 5 falls without instruction (termed “natural falls”). The subjects were then given a 10-min intervention consisting of instructions on how to reduce impact by minimizing the hand-ground relative velocity at impact. After intervention, the subjects performed another 5 falls (termed “reduced-impact falls”). They were then asked to perform, without practice or instructions, 5 reduced-impact falls at the 3-week and 12-week follow-up visits. The control group followed a similar experimental protocol to that of the intervention group, except that they received no instructions during the intervention period and merely repeated their natural falls after the 10-min break and at the follow-up visits. A two-way repeated-measures analysis of variance was used to test the hypotheses using $p < 0.05$.

RESULTS AND DISCUSSION

The first hypothesis was supported in that, during the baseline visit, the intervention group volitionally reduced the impact forces by 11.4% ($p=0.0024$) over initial values, whereas the subjects in the control did not decrease their impact forces significantly (0.3%, $p=0.96$, Figure 1). The second hypothesis

was supported in that, at 3 and 12 weeks follow-up, the mean impact forces of both groups were not different ($p=0.62$). Interestingly, across all subjects, impact force at 12 weeks follow-up was significantly less than that at baseline($p=0.007$).

Figure 1: Top: Average impact forces at the baseline visit, by group. Bottom: Learning curves by group. (Bars denote standard error; forces are normalized by the mean of the five first ‘natural’ falls at baseline).

SUMMARY

Healthy young males can volitionally reduce impact forces after 10-minute instruction, and the control group data show this was not due to self-learning. The challenging nature of this fall-arrest task did induce, without practice, self-learning in the 3 months study period.

THE ROLE OF TRANSVERSUS ABDOMINIS IN SPINE STABILITY

Sylvain G. Grenier, Stuart M. McGill

Occupational Biomechanics Laboratory, University of Waterloo, Waterloo, Ontario, Canada

Contact: sggrenie@ahsmaail.uwaterloo.ca

INTRODUCTION

There is a perception in clinical circles that recruitment of transversus abdominis (TA) through abdominal hollowing (drawing in the navel) is advantageous because it increases stability without augmenting the compressive load on the spine. The abdominal hollowing recruitment technique was originally conceived to re-train TA recruitment and not to directly improve stability. This was thought to be important because TA has been found to be deficient in those with a previous low back injury (Hodges, 1998). The purpose of this research was to evaluate, through a model, the mechanical contribution of TA to spine stability.

METHODS

Over a period of twenty-five seconds a 10Kg bilateral weight was held in a neutral standing posture: relaxed for five seconds, abdominal hollow for five seconds, relax for five, abdominal brace for five and relax for the final five seconds. Lumbar spine kinematics were recorded in 3D and EMG was recorded from 7 channels bilaterally.

The model used in this experiment has been fully described by Cholewicki and McGill (1996). Some modifications were made to include TA. Ten fascicles were added bilaterally, five originating on the tip of the spinous process where the supraspinous ligament attaches, the others originating from the transverse process of the lumbar vertebrae. The ten fascicles converge on a point 60cm directly lateral of L5. This arrangement was conceived to reproduce the coronal plane action of TA on the lumbar spine while minimizing its moment generation potential.

The abdominal activation levels were artificially adjusted to imitate “ideal” hollowing (HLW) and bracing (BRC) strategies. The extensor activation levels were left untouched. For HLW, transversus abdominis and internal oblique were activated at 20% of maximum voluntary contraction (MVC) while the rectus abdominis and external oblique were activated at 1% MVC. The BRC strategy required all abdominals activated at 20%. Two additional trials were simulated one where rectus abdominis and external oblique were activated at 20% while TA and internal oblique were activated at 1% (NoIO/TA) and another where TA was deactivated (NoTA). The change in compression and stability between bracing and reference trials was expressed as a percentage change.

$$\%change = \left(\frac{BRC - REF}{BRC} \right) \times 100$$

RESULTS AND DISCUSSION

As a means of increasing stability in the lumbar spine HLW is not as effective as BRC. BRC improved stability over HLW by 95.43% with only a 18.98% increase in compression. NoIO/TA decreased stability by 88.5% relative to BRC with a 8.3% decrease in compression (Table 2). Removing only TA from the BRC pattern decreased stability by 55%.

The mechanical effect of TA on stability has not, to our knowledge, been reported in the literature. The force generated by our TA equivalent was on the order of 10 N for a 20% MVC contraction. This compares Tesh et al.'s (1987) reported thoracolumbar fascia tissue tolerance of 335N. They also report that IAP may contribute as much as 40% of the restorative moment in lateral bending. Our own work shows that IAP contributes significant stiffness especially in the neutral posture. However for comparison purposes this can be safely neglected because a hollowing strategy is unlikely to generate greater IAP than bracing. Others have also suggested that general cocontraction balanced against the load is most effective in attaining and maintaining stability (Granata and Orishimo, 2001).

CONCLUSION

General bracing of the abdominal girdle should be advocated where greater spine stability is required. This is not say that abdominal hollowing is not a valid training tool for TA activation. Under conditions of surprise perturbation prompt recruitment of TA countering increased IAP may be critical until the remaining torso muscles can be recruited, once the CNS has determined the nature of the perturbation. It might be useful to compare the maximum load that could be stabilized by TA against the load generated by unexpected perturbations.

Table 1: The percent increase in stability with a minimal increase in compression (CMP) of BRC over every other strategy in the simulation is clear. The muscle compression (MCMP) values reported are the reference values.

% Δ from BRC	Stability	CMP	MCMP
BRC vs. HLW	95.43	18.98	316N
BRC vs. NoIO/TA	88.50	8.36	351N
BRC vs. NoTA	55.47	8.32	354N

MUSCLE RECONSTRUCTION AND MODELING FROM MRI-SCAN

Mohamed Mahfouz^{1,2}, Richard Komistek¹, Scott Walker¹, Douglas Dennis¹

¹Rocky Mountain Musculoskeletal Research Laboratory, Denver, Colorado, mmahfouz@rmmrl.org

²Colorado School of Mines, Golden Colorado

INTRODUCTION

Medical imaging techniques such as Magnetic Resonance (MR) can noninvasively capture patient information specifics about the geometric and material properties of bone and muscle. Hence, MRI makes it possible to measure physiological cross-sectional area (PCSA) of leg muscles of healthy human subjects, which are much larger than PCSAs of cadaveric leg muscles that have been used in biomechanical simulation. The objective of this study was to use MRI to construct 3D models of human bone and soft-tissues and to compare the accuracy of the models with CT images.

METHODS

The entire lower limb of a healthy 30-year-old male subject was imaged using a fat-suppressed three-dimensional sequence (SPGR; 1.5T). Multiple overlapping MRI scans were required to complete the entire lower limb. Markers were attached to the subject skin and distributed throughout the leg in a non-collinear arrangement. These markers were used to register (3D-to-3D rigid transformation) the MRI volumetric data segments after the data sets have been geometrically corrected, due to gradient field nonlinearities and magnetic field inhomogeneities (using a specially designed calibration phantom). After correction of MR inhomogeneities, morphological operators were used to finally segment the muscle and bone. Bone segmentation was performed using a method based on deformable contours models (Terzopoulos, 1991; Terzopoulos, 1987). The segmentation methods used were mainly automated. Manual segmentation was performed only when the automated methods failed to separate a muscle, and in this case, the bone at the articular cartilage of the knee joint. More than sixteen muscles were segmented including all the knee flexors and extensors and the major ankle joint muscles.

RESULTS AND DISCUSSION

Muscle and bone segmentation results from MR scanning were successful (Figure 1). Good quality surface model for each muscle was created from the segmented volumes and the entire flexors and extensors muscles of the knee joint were created. The interfaces between the muscles and tendons were created as well (Figure 2). The results for this initial in vivo analysis were encouraging for 3D model development of muscles and bone models. Bone models created were similar in accuracy to the models constructed using CT images.

Figure 1. Selected muscles of the lower extremity.

Figure 2. Muscle –Tendon interface Soleus.

SUMMARY

The objective of this study was to develop a 3-dimensional muscle model that is capable of predicting and simulating loads acting on knee, hip or ankle joint. The simulation method will employ modern finite element analysis techniques such as real muscle geometries, appropriate constitutive behavior and muscle interaction. Finite element models will provide appropriate computations required for evaluation of muscle and joint loads of a patient preoperatively.

A UNIQUE METHOD TO DETERMINE DYNAMIC *IN VIVO* ARTICULAR SURFACE INTERACTION

William J. Anderst and Scott Tashman

Motion Analysis Lab, Bone and Joint Center, Henry Ford Hospital, Detroit, MI

Email:anderst@bjc.hfh.edu

INTRODUCTION

This paper describes a unique method to calculate and visualize the proximity of articular bone surfaces during movement. This information may be useful in the study of osteoarthritis, in biomechanical modeling, and in identifying normal and pathological joint mechanics. As an example of this technique, the distances between tibia and femur articulating surfaces during hopping in uninjured and anterior cruciate ligament (ACL) reconstructed knees are presented.

METHODS

Kinematic Data: Under IRB approval and after acquiring informed consent, three 1.6mm tantalum spheres were implanted into both tibias and femurs during ACL reconstructive surgery. Data was acquired during one-legged hopping and treadmill running 6 months after surgery. Kinematic data was collected using a biplane radiographic system capable of tracking implanted radiopaque markers in 3D at a rate of 250 frames/s with a dynamic accuracy of $\pm 0.1\text{mm}$ (Tashman, 1995). 3D marker coordinates were determined using previously described techniques (Tashman, 1999).

Computed Tomography Data: Computed tomography (CT) data was collected after marker implantation (1mm slices, 0.5859mm x 0.5859mm resolution). The CT scans were reconstructed into 3D solid figures (Treece, 1999). The locations of the vertices in the solid figure mesh were used to calculate the area and centroid of each triangle in the solid figure.

Implanted tantalum marker locations were identified in the CT scans and combined with vertex information from the bone surface mesh to determine the relationship between implanted markers and bone surface centroids. This information, combined with the tracked radiopaque marker data, made it possible to calculate the minimum distance between bone

surfaces on the tibia and femur at each instant. Surface polygons were color-coded according to the minimum distance between bones at each polygon centroid. The color-coded joint surfaces were displayed and animated using the freely available Geomview (www.geomview.org) software package.

RESULTS AND DISCUSSION

Figure 1 shows the color-coded surfaces of the uninjured and ACL reconstructed femur and tibia after landing from a one-legged hop.

Differences are evident between the uninjured and reconstructed joints. The uninjured joint shows an asymmetric distribution in medio-lateral contact patterns on the tibia, indicating the tibia was internally rotated relative to the femur. The reconstructed joint, however, showed a symmetric distribution of contact on the tibia. This difference could indicate that ACL reconstruction did not restore normal internal-external rotation of the tibia relative to the femur for this subject.

This tool for calculating and visualizing bone surface motion *in vivo* during dynamic movements may provide insight into cartilage deformation and damage. Additionally, it can provide information on the dynamic interaction between articular surfaces such as rolling and sliding contact and areas of close contact. It also can identify changes in joint surface motion over time. None of this information can be obtained using conventional 3D motion analysis.

INTRODUCTION

The purpose of this study was to examine the effects of relative inertial load on QF muscle activation and perceived exertion during single-leg, knee extension exercise.

METHODS

Fifteen males and 15 females were evaluated for the maximum amount of weight they could lift once (1-RM) with their right leg during knee extension (Power Systems Inc.). Subjects performed 2 repetitions at loads equivalent to 20-90% (10% increments) of their 1-RM, in a random order. Subjects were instructed to: 1) lift the weight and achieve full knee extension (concentric phase), 2) hold the weight in the knee extended position for approximately 2 s (isometric phase), and 3) lower the weight in slow and controlled manner (eccentric phase).

Immediately following the 1-RM, subjects were instructed to “think about the feelings in their quadriceps during the contraction, and to assign a rating of maximal to those feelings”. Following 2 min of rest, subjects were asked to sit quietly and to “think about the feelings in their quadriceps and to assign a rating of 0 to those feelings”. Immediately prior to the sub-maximal contractions, subjects were instructed to “think about the feelings in your quadriceps during the contractions, and give a number from the scale about how your quadriceps feel”, via a modified Borg (1982) category-ratio scale.

Muscle activation was assessed through surface EMG for the VM, VL, and RF muscles (sampling rate=1000 Hz, bandpass filtered 20-500 Hz). Pre-amplified, bipolar circular electrodes were placed on each muscle with a fixed 2 cm inter-electrode distance. Raw EMG activity was full-wave rectified and integrated over the concentric phase of the exercise, and at each sub-maximal lifting level, was converted to a 1 s average, and normalized to the recorded activity during the 1-RM.

RESULTS AND DISCUSSION

The results demonstrated a significant load effect as VM, VL and RF muscle EMG increased from 20-90% 1-RM ($F_{7,196}=156.72$, $p<0.05$) (Figure 1). Rectus femoris EMG was found to increase significantly more than the VL from 30-40%, and 50-60% 1-RM. The results revealed a significant intensity main effect ($F_{7,189}=195.49$, $p<0.001$) for the perceived exertion responses. The findings demonstrated that perceived exertion was significantly ($p<0.05$) lower than the specific expected

values on the CR-10 scale from 10-60% 1-RM, and was not different from 70-90% 1-RM. The results also revealed that the perceived exertion response was fit to the following power function: $R=9.998 \cdot S^{1.467}$, where R=predicted perceived exertion response, and S=relative lifting load.

Figure 1: Normalized QF muscle EMG activity during the concentric phase of knee extension from 20-90% 1-RM.

SUMMARY

The major findings indicate that as a function of relative inertial load during dynamic knee extension exercise, RF EMG appears to increase more than the VL at moderate loads. Equivalent activation of the superficial QF muscles, however, appears to predominate throughout the range of lifting loads, while the perceptual sensation (i.e., perceived exertion) is more sensitive at relatively higher lifting intensities.

STRATEGY IN REDUCING ELBOW LOADING DURING FALL ON AN OUTSTRETCHED HAND

Paul Pei-Hsi Chou¹, You-Li Chou², Shen-Kai Chen¹, Yung-Chin Shi², Gwo-Feng Hung², Tun-Chin Wu²

¹Department of Orthopedic Surgery, Kaohsiung Medical University, Kaohsiung, Taiwan, chou0626@ms3.hinet.net

²Institute of Biomedical Engineering, National Cheng-Kung University, Tainan, Taiwan.

INTRODUCTION

Approximately 75% of all fractures sustained by children occur in the upper extremities during a fall onto an outstretched hand. The majority of these injuries involve the wrist and forearm, but the elbow alone accounts for approximately 10 percent of all fractures in children. Clinically, there are far more extension type of supra-condylar fractures of the elbow than flexion type. Furthermore, posterolateral instability of the elbow can be reproduced with forearm supination and mild elbow flexion. These evidences stress the importance of elbow flexion in the upper extremity trauma. Therefore, the purpose of this study is to investigate the effect of different initial elbow flexion angles on joint loading during a fall on the outstretched hand.

METHODS

Twenty male subjects volunteered in this study. Their average age was 23.8 years, with an average height of 171.7 cm, and average weight of 62.9 Kg. A hinge elbow brace was used to limit the elbow extension without interfering the elbow flexion. A suspension system was designed to release the subject from 5 cm above the ground. Simulating a fall on the outstretched hand, each subject fell on the force plate with his elbow in four elbow flexion angles: 0°, 20°, 40°, and unlimited degree. A Motion Analysis System (Motion Analysis Inc., Santa Rosa, CA, U.S.A.), two Kistler force plates (Model 9281B, Kistler Instruments AG, Winterthur, Switzerland), and a workstation computer were used to collect data.

RESULTS AND DISCUSSION

The ground reaction force curve was characterized by a high frequency peak F_1 at the moment of impact. The second low frequency peak F_2 occurred soon after F_1 (Fig. 1).

Figure 1: This is a ground reaction force (GRF) curve.

T_0 : release of subject from the suspension system.

T_s : the moment of impact. T_e : the end of impact.

At the moment of impact, the F_1 was significantly different

among various initial elbow flexion angles ($p < 0.001$). The impact force F_1 decreased significantly with increased elbow flexion (Fig. 2).

Figure 2: Peak ground reaction force F_1 , F_2 (y-axis), vs. degree of initial elbow flexion angle (x-axis).

In a study by Chiu and Robinovitch, a fall height greater than 60 cm was predicted to be hazardous in producing distal radial fracture of the wrist. However, only the motion of shoulder and wrist were considered in their two-mass model to simulate a fall on the outstretched hand. In addition to the effective dampers and springs of wrist and shoulder, the elbow played a very important role of energy dissipation. Taking the effect of elbow motion into consideration, our three-mass-model was more precise in simulating the motion of upper extremity during a fall.

CONCLUSION

In conclusion, the loading biomechanics of the elbow joint differs with various initial flexion angles. With the increasing elbow flexion at the moment of impact, the impact force (F_1) decreases but the elbow extension moment (M_1) increases. On the contrary, the impact force (F_1) is at maximum when the elbow is fully extended upon impact. Therefore, fall on the outstretched hand with elbow in full extension should be avoided. Additionally, a forward fall with mild elbow flexion maybe a better strategy to reduce impact force and to reduce injury.

COMPARISON OF STEP VARIABILITY DURING GAIT ON FLAT AND IRREGULAR SURFACES IN PATIENTS WITH POLYNEUROPATHY

Sibylle Thies, James K. Richardson¹, and James A. Ashton-Miller

Biomechanics Research Laboratory, Department of Biomedical Engineering, and ¹Physical Medicine and Rehabilitation, University of Michigan, Michigan, USA. sthies@umich.edu

INTRODUCTION

Patients with a diffuse polyneuropathy (PN), which is characterized by a distal-to-proximal gradient decrement in lower extremity sensation and strength, have a 20-fold higher risk for falls and 6-fold higher risk for fall-related fractures than matched controls (Richardson, 1992). PN patients report difficulty when walking on uneven surfaces, particularly in low-light conditions. We are not aware of studies of how humans, whether impaired or healthy, adjust their gait on uneven ground. We tested the primary (null) hypothesis that elderly PN patients would not alter their stepping pattern when walking on an uneven surface under low-light as compared to a flat surface under normal light. Similarly, secondary hypotheses were tested that the uneven surface would not affect (a) step time, or (b) average gait speed.

METHODS

Twenty PN patients (64.1 ± 10.3 yrs; 15 males), in a full-body safety harness and identical walking shoes, were asked to walk a 6-m walkway at their comfortable speed under two conditions: on flat linoleum-tiled floor under normal lighting (> 600 lux, 10 trials), and on a standardized uneven surface (1.5 cm-high, multiple randomly-arranged triangular wooden prisms located under industrial carpeting) under low lighting (< 90 lux, 10 trials). Kinematic measures of step width and step length were obtained during double support at 100 Hz using optoelectronic markers placed over both ankles (via Optotrak 3020 system), while two pairs of foot switches (heel, metatarsal) indicated dual support times. The standard deviation served as the measure of variability. A marker over the umbilicus was used to determine the average gait speed. Two-sided, paired t-tests ($P < 0.05$) were used to test the hypotheses.

RESULTS AND DISCUSSION

The primary hypothesis was rejected in that the patients demonstrated an increased step width (7.7%, $p = 0.003$) and increased step width variability (16.8%, $p < 0.001$) on the uneven surface. The secondary hypotheses were also rejected in that significantly increased step time variability (42.0%; $p < 0.001$), decreased step length (4.1%, $p = 0.004$) and gait speed (6.5%, $p = 0.004$) were found on the uneven surface. On the uneven surface, 8 patients exhibited a total of 34 steps that crossed the midline (defined as “cross-over” steps, Figure 1). Significantly fewer cross-over steps were observed on the flat

surface: 3 patients exhibited a total of 4 cross-over steps. Cross-over steps are dangerous because they increase the risk for a trip via swing foot toe contact with the stance foot heel, particularly when the prior step is shortened. A detailed kinematic analysis of three cross-over steps on the uneven surface revealed that, following an unexpected stance foot perturbation, the torso marker veered laterally for about 0.5 second prior to alteration of the swing leg trajectory. In all three cases the next step was shorter (~ 3 cm) and wider (~ 4 cm), than average for the subject. This seemed to be part of the recovery strategy for mediolateral plane balance. This is the first quantification of human stepping patterns on an uneven surface.

Figure 1: Top-view of sample kinematics of cross-over step (left foot crossing in front of the right while walking in the direction of the arrow on the uneven surface). Squares and circles show position of left and right ankles, respectively, at “foot-flat”.

SUMMARY

An uneven surface and low lighting caused PN patients to significantly increase their step width and step time variability, and increase the number of unintended ‘cross-over’ steps, despite decreased step length and gait speed.

A LOSS OF BALANCE IS A LOSS OF CONTROL: THE 3σ HYPOTHESIS

Alaa A. Ahmed¹, M.S. and James Ashton-Miller^{1,2}, PhD.

Biomechanics Research Laboratory

Departments of ¹Biomedical and ²Mechanical Engineering

University of Michigan, Ann Arbor, MI, U.S.A.[aaahmed@umich.edu]

INTRODUCTION

Happily, not every ‘loss of balance’ results in a fall, yet every fall is preceded by a ‘loss of balance’ (LOB). Surprisingly, a precise, physical description of a LOB is lacking. We propose that a LOB is the fundamental requirement for the CNS to initiate a compensatory response aimed at preventing a potential fall and/or subsequent injury. We posit that a ‘loss of balance’ is a loss of control (LOC) in engineering terms, causing the system to become temporarily unstable about the current operating point. In the event of a perturbation during gait, such as a trip, the controller must compensate for the temporary LOC through a change in control strategy in an attempt to regain stability about a new operating point. As long as this new operating point does not involve a fall, the event is classified as a ‘temporary’ LOC, else we define it post-hoc as a ‘terminal’ LOC. Our goal was to identify LOC in a challenging balancing task, and then to examine the reliability of this algorithm in predicting an impending compensatory response. We tested the primary hypothesis that the instant of loss of control (T_{LOC}) can be identified by using a 3σ threshold criterion on the controller error signal (see below). The secondary hypothesis, that any compensatory response will lag the instant of LOC by at least 100ms, was also tested.

METHODS

Twenty healthy, young adult volunteers (10 females) aged 18-25 years were tested. They were seated in a sturdy, four-legged experimental chair with a rigid back and head rest (Fig.1a). The subjects were asked to use only their dominant leg forefoot to push themselves slowly backwards until they (and the chair) were perfectly balanced for as long as possible over its rear legs, P, with no foot-ground contact. Each subject performed ten trials with their eyes open. A 200 N force transducer under the dominant foot, sampled at 100 Hz, recorded the vertical and horizontal reaction forces (Fig.1b). The position of three LEDs on the head and two on the chair were tracked using an Optotrak 3020 system at 100 Hz. An error signal was formed from the difference between the expected system output due to the given force input and the actual output, chair acceleration. LOC was defined to have occurred once the error signal crossed a threshold level set at three standard deviations (3σ) above the mean value in a 2-second-wide moving window that trailed the current time instant, t , by 100 msec. The mean and standard deviation of these data were used to calculate the threshold at time t (Fig.1c). Terminal LOC was confirmed by impact of the chair rear frame, F, with the ground after it had rotated 30° within 2 sec. The occurrence of a natural righting response, a large

acceleration of the head in flexion (relative to the chair), was defined as a compensatory response, and evidence of LOC perception. Reaction time (RT) was defined as the latency of this response following LOC (Fig.1d).

Figure 1: Single subject data (see text)

RESULTS AND DISCUSSION

The 3σ algorithm successfully identified LOC in 98.0% of 197 trials and was supported by the presence of a compensatory response an average of 451 msec later in 95% of the trials. Short RTs were associated with large angular accelerations at T_{LOC} , and vice versa. No gender effects were observed. The optimal threshold level was found to be 3σ ; lower levels resulted in more false positives, while higher levels resulted in delayed LOC detection times. It is noteworthy that the 3σ hypothesis does not depend on a vertical angular reference.

SUMMARY

The results support the definition of a loss of balance as being a loss of control. LOC was successfully identified, as was the latency of the following righting response.

INTRODUCTION

Blood flow under pathological conditions, such as atherosclerosis, involves a narrowing of the artery lumen, referred to as a stenosis, which together with flow pulsatility can result in periodic generation of turbulence despite relatively low Reynolds numbers. Laminar flow chambers have frequently been used to subject cells to known shear stresses (Frangos, 1988). However, the shear stresses are typically inferred from idealized theory for two-dimensional fully developed laminar flow between infinite parallel plates. We have measured the velocity fields within a typical laminar flow cell to examine how uniform the velocity and shear stress field is across the apparatus and how well it is predicted by theory. Application to turbulent stenotic flows is underway.

METHODS

Velocity fields within the flow chamber were obtained using micro-Particle Image Velocimetry (μ -PIV). The μ -PIV system consists of a pulsed Nd:YAG laser, a fast interline transfer CCD camera, and an epifluorescent microscope which captures two consecutive images of a fluorescent particle seeded flow illuminated by the laser. A 0.00038% concentration of 1 μ m diameter seed particles and a 20X microscope lens were used to image a 300x300 μ m area within the flow cell. The flow cell was a narrow channel 330 μ m deep, 34.2 mm wide, and 74.1 mm long. Water (20C) was pumped through the chamber by a gear pump at a flow rate of 37.3 ml/min. One hundred image pairs were taken at each measurement volume within the chamber and temporally averaged to obtain the velocity.

RESULTS AND DISCUSSION

The spanwise velocity profiles at the inlet and in the center of the flow cell chamber are shown in Fig. 1. Each vector within the flow channel is an average of 1280 vectors in the μ -PIV interrogation region. A typical μ -PIV vector field is shown in the upper left part of Fig. 1. This is an average of five instantaneous realizations, from which a single vector is obtained. Additionally, three near-wall μ -PIV images are presented with average velocity profiles overlaid on the two images along the chamber centerline. The overall spanwise profile shows an interesting asymmetry about the streamwise centerline. The fluid near the bottom wall (opposite to the injection port) has a lower velocity than the fluid near the opposing wall. Also, near the injection slot wall, the velocity

vectors are angled down towards the wall. This is because the injection slot does not span the entire channel.

These measurements show that even in a carefully designed and constructed flow apparatus, slight dimensional variances result in differences in the flow to which the cells are subjected. This illustrates the importance of measuring the velocity and associated shear stress field directly.

IMPACT ATTENUATION OF LANDING ACTIVITIES IN BAREFOOT AND SHOD

Songning Zhang and Yeonjoo Yu

Biomechanics/Sports Medicine Laboratory, The University of Tennessee, Knoxville, Tennessee, USA, szhang@utk.edu

INTRODUCTION

Impact loading is tremendous during the landing phase of sports activities. It can be dissipated through footwear, various connective tissues and skeletal muscles in the body. Effects of footwear on protection of the body from impact loading have been researched extensively in walking and running (Cavanagh et al., 1981; De Wit et al., 2000). However, few studies addressed its effects on impact and shock attenuation during more vigorous sport activities such as landing. Therefore, the purpose of this study was to investigate effects of shod and landing heights on impact force and shock attenuation during landing activities.

METHODS

Ten healthy and physically active male subjects (age: 20.4 ± 2.9 yrs, body mass: 77.0 ± 9.5 kg, 182.9 ± 5.6 cm) volunteered to participate in the study. A video camera (60 Hz, Panasonic) was used to obtain kinematic data of the right sagittal view; a force platform (AMTI) was used to measure ground reaction force (GRF) during the testing trials. Two miniature (1.7 g) accelerometers (A353B17, PCB) were used to measure accelerations (ACC) at the forehead and the distal tibia. Signals from the accelerometers and the force platform were sampled at 1200 Hz. The subjects performed 5 trials of step-off landings in each of eight testing conditions that are combinations of 4 landing heights (30, 45, 60 and 75 cm) and 2 surfaces (barefoot and athletic shoe). The subjects were instructed to land the right foot on the force platform with the left foot on the adjacent floor. The order of the surface conditions was randomized at each height; the landing height was increased from 30 to 75 cm. The raw coordinates of the reflective markers were smoothed using a fourth-order and zero-lag Butterworth digital filter. The cutoff frequency was individually chosen for the each x and y coordinate of the reflective markers using an optimized algorithm. A Shannon algorithm was used to reconstruct the video signal from 60 Hz to 240 Hz (Hamill et al., 1997). A 4 x 2 (height x surface) repeated measures analysis of variance was used to evaluate selected GRF, ACC and kinematic variables ($p < 0.05$).

RESULTS

The GRF results showed that the forefoot peak GRF (F1) in the shod landing was significantly greater than that in the barefoot landing at 45, 60 and 75 cm. The rearfoot peak GRF (F2) in the barefoot landing was significantly greater than that in the shod landing at 30, 45 and 75 cm levels. The impulse integrated from contact to 100 ms only showed a significant difference at 30 cm. Meanwhile the peak head ACC (Hmax) for the barefoot was smaller than that for the shod at two higher heights; the peak tibia ACC (LMax) for the barefoot

was significantly greater than that for the shod at all landing heights. The shock attenuation index (Index) was calculated as:

$$Index = (1 - \frac{HMax}{LMax}) \times 100$$

Its result also demonstrated significantly greater values across all heights for the barefoot landing. The kinematic data showed that a greater contact angle for the ankle and a lesser contact angle for the knee joint at two lower heights in the barefoot landing.

Table 1. Mean values of selected GRF and ACC variables

Surface	Height	F1	F2	Impulse	HMax	LMax	Index
Shod	1	13.4	54.3	2.5	2.6	18.3	84.4
	2	21.5	59.3	2.7	3.3	23.8	85.2
	3	29.6	65.4	2.9	3.6	28.5	87.0
	4	36.9	75.9	3.1	4.5	38.2	88.1
Barefoot	1	13.1	65.2	2.3	2.3	30.1	90.6
	2	19.4	76.2	2.6	2.7	37.7	91.7
	3	26.0	81.0	2.8	3.0	47.5	92.1
	4	30.9	91.2	2.9	3.2	63.9	94.0

F1 & F2: N/kg, Impulse: Ns/kg, HMax & LMax: g, Index: %.

DISCUSSION

The results from this study showed significantly attenuated impacts at the forefoot contact in the barefoot landing. This may be due to conscious and active neuromuscular intervention because of increases in the perceived threat to the body. In the shod conditions, the impact experienced by the body was actually greater indicating a reduced conscious effort due to decreases in the perceived threat. The result indicates the importance of the material and construction at the forefoot area of footwear used in landing related sport activities. At the heel contact, greater impact forces were observed in the barefoot landing; the shoe provided additional cushion to the body. Therefore, it also indicates the importance of the midsole material and construction in the rearfoot region of sport footwear. In addition, the kinematic results suggest that there may be a neuromuscular adaptation at the two lower heights.

HAMSTRING LENGTH DURING GAIT DOES NOT CHANGE AFTER SURGICAL HAMSTRING LENGTHENING

Michael Orendurff

Gait Analysis Lab, Center of Excellence for Limb Loss Prevention and Prosthetic Engineering,
Veterans Hospital, Seattle, Washington, USA. morendurff@hotmail.com.

INTRODUCTION

When individuals walk in crouch and have tight hamstrings, surgical muscle lengthening may be undertaken in an effort to increase knee extension during gait. Several studies have evaluated hamstring length in children with cerebral palsy crouch gait, and suggested that their hamstring musculotendinous units are often of normal length (Delp, et al., 1998; Thompson, et al., 2001). Nevertheless, improvements in knee extension are seen following surgical hamstring lengthenings (Rethlefsen, et al., 1999), suggesting that the treatment is effective in increasing knee extension in gait despite the normal length of these muscles. The goal of this study was to evaluate joint kinematic changes, muscle length and muscle velocity after surgical hamstring intervention.

METHODS

Twenty-three individuals (40 sides) with cerebral palsy who underwent computerized gait analysis and hamstring lengthening surgery were reviewed retrospectively. All individuals underwent medial and lateral hamstring lengthenings; 22 sides also underwent adductor lengthenings, 9 sides had distal femoral derotational osteotomies, 5 sides had iliopsoas lengthenings, 4 sides underwent rectus femoris transfers, 4 sides had triceps surae lengthenings and 2 sides had subtalar fusions at the time of their hamstring surgery. Nine sides had hamstring surgery only. Gait data was collected with a 6-camera Vicon 370 system prior to and about one year following surgery. Three dimensional kinematics and kinetics were calculated in vicon clinical manager. Kinematic measures included maximum knee extension in single limb stance, maximum knee flexion, maximum hip extension in single limb stance, maximum hip flexion. Biceps femoris, rectus femoris, and vastus lateralis muscle lengths were calculated from the kinematic data using the methods of Visser, et al., (1990). Muscle velocity data was calculated using a 3-point finite difference algorithm. Maximum and minimum muscle lengths and velocities were extracted preop and postop. Variables were compared preop to postop using repeated measures ANOVAs. An alpha level of $p < 0.05$ was chosen a priori.

RESULTS

Table 1. Sagittal knee and hip kinematics before and after surgical hamstring lengthening. n = 40 sides (23 individuals). * indicates significance at $p < 0.05$.

	Preop	Postop	p-value
Knee			
Maximum Extension	30.1 ± 13.1°	7.6 ± 13.0°	<0.0001*
Maximum Flexion	57.8 ± 10.2°	45.5 ± 12.6°	<0.0001*
Hip			
Maximum Extension	13.7 ± 14.7°	11.2 ± 15.9°	0.1575
Maximum Flexion	49.3 ± 10.1°	54.5 ± 11.7°	0.0033*

Table 2. Muscle lengths (%anatomic neutral length) and velocities (%anatomic neutral length / %gait cycle) before and after surgical hamstring lengthening. n = 40 sides (23 individuals). * indicates significance at $p < 0.05$.

	Preop	Postop	p-value
Biceps Femoris			
Maximum Length	15.2 ± 3.6	16.1 ± 4.1	0.0989
Minimum Length	3.1 ± 4.7	2.8 ± 5.4	0.6356
Shortening Velocity	0.58 ± 0.20	0.60 ± 0.17	0.4540
Lengthening Velocity	-0.35 ± 0.13	-0.43 ± 0.10	0.0207*
Rectus Femoris			
Maximum Length	7.9 ± 2.3	6.2 ± 4.2	0.0053*
Minimum Length	2.2 ± 2.4	-2.5 ± 2.4	<0.0001*
Shortening Velocity	0.22 ± 0.13	0.35 ± 0.20	<0.0001*
Lengthening Velocity	-0.34 ± 0.14	-0.46 ± 0.20	<0.0001*
Vastus Lateralis			
Maximum Length	11.1 ± 1.8	8.9 ± 2.2	<0.0001*
Minimum Length	5.9 ± 2.6	1.2 ± 2.9	<0.0001*
Shortening Velocity	0.25 ± 0.11	0.35 ± 0.12	<0.0001*
Lengthening Velocity	-0.32 ± 0.12	-0.42 ± 0.14	<0.0001*

DISCUSSION

Despite surgical lengthening, hamstring length did not significantly change during gait from preop to postop, consistent with Delp, et al., (1998) and Thompson, et al., (2001). However, subjects showed a marked increase in knee extension in single limb stance, supporting the effectiveness of this intervention in improving crouch gait. Hamstring muscle-tendon length is much more dependent upon hip flexion than knee flexion, and hip flexion increased only in late stance, and then by just 5° from preop to postop. It is likely that hamstring tension is much lower postop, and that preop the individuals reached similar lengths with much greater tension. This reduction in tension at the functional length may account for the improvements observed, but in vivo tension measurements during gait were not made in this study. Hamstring shortening velocity did not change, but lengthening velocity did, suggesting that at the new tension level, eccentric contraction of the hamstring in single limb stance did not elicit spasticity as readily as was the case preop. The quadriceps showed improvements in all parameters, indicating that their function may have been improved. The results help to explain why hamstring length may be normal in individuals with crouch gait both preop and postop despite improvements in knee extension following surgical intervention.

EFFECTS OF MIDSOLE DENSITY AND HEIGHT ON IMPACT ATTENUATION IN LANDING

Songning Zhang, Kurt Clowers and Charles Kohstall

Biomechanics/Sports Medicine Laboratory, The University of Tennessee, Knoxville, Tennessee, USA, szhang@utk.edu

INTRODUCTION

Effects of shoe properties on impact attenuation have been researched extensively with mixed results. Lafortune and Hennig (Lafortune et al., 1992) reported significantly lower initial peak tibia acceleration and acceleration transient rate in the athletic shoes and street shoes compared to the barefoot during walking. Nigg et al. (Nigg et al., 1987) found no significant effects of running shoes with different midsole densities on peak vertical ground reaction forces (GRF) in running. Therefore, the purpose of this study was to examine effects of shoe midsole densities on impact shock attenuation during a landing activity.

METHODS

Nine healthy and intercollegiate male athletes (age: 20.2 ± 1.9 yrs, body mass: 77.4 ± 5.1 kg, 1.82 ± 0.07 m) participated in the study. Instrumentation. A digital video camera (120 Hz, JVC) was used to obtain right sagittal kinematic data; a force platform (AMTI) was used to measure GRF during the testing trials. Two miniature (1.7 g) accelerometers (A353B17, PCB) were used to measure accelerations (ACC) at the forehead and the distal tibia. Signals from the accelerometers and the force platform were sampled at 1200 Hz. An electrogoniometer (Penny and Gile) was placed on the left knee joint to monitor consistency of the maximum knee flexion during landing performance. Subjects wore three pairs of basketball shoes (adidas) that have identical construction and are differed only by the midsole density: soft (Shore C: 40), normal (Shore C: 55), and hard (Shore C: 70) midsole. The subjects performed five step-off landing trials in each of nine test conditions that are a combination of three different shoes and three different pre-determined heights. The three jump heights were determined individually based upon the potential energy (PE) of a subject. A "mid-size" person of 80 kg landing from 0.60 m with a potential energy of 470.9 J was chosen as a 100% PE condition. A 70% and 130% PE were computed accordingly; three heights were then determined based on the body mass of individual subjects. A Shannon algorithm was used to reconstruct the video signal from 60 Hz to 240 Hz. A 3 x 3 (surface x height) repeated measures analysis of variance was performed on selected GRF and ACC variables with the significance level set at $p < 0.05$.

RESULTS

The GRF results showed that the first peak GRF (F1) in the normal and hard midsoles was significantly greater than that in the soft midsole at the low and median PEs (Table 1). The difference of the second peak GRF (F2) was significant between the normal and hard midsoles and between the soft and hard midsoles at the median PE, and between the soft and

hard midsoles at the high PE. The accelerometer data indicated that the peak head ACC (HMax) of the normal and hard midsoles were significantly greater than that of the soft midsole at the median and high PEs (Table 1). A greater peak tibia ACC (LMax) for the hard midsole was observed compared to the other midsoles at the median PE. At the high PE, the peak tibia ACC of the hard midsole was also significantly greater than that of the soft midsole. A higher shock attenuation index (as a ratio HMax and LMax) was also observed for the hard midsole at both median and high PEs compared to the soft shoe.

Table 1. Mean values of selected GRF and ACC variables

PE	Midsole	F1	F2	HMax	LMax	Index
Low	Soft	19.4	57.5	3.49	24.6	86.2
	Normal	20.9	58.7	3.5	26.7	87.1
	Hard	21.6	63.9	3.6	30.6	88.1
Med	Soft	29.3	67.1	4.0	34.5	88.5
	Normal	30.6	66.5	3.8	35.4	89.0
	Hard	30.7	81.0	4.4	46.4	90.6
High	Soft	41.2	78.2	4.7	49.2	90.0
	Normal	42.4	81.4	5.0	52.6	90.1
	Hard	42.6	87.6	5.1	59.8	91.2

Unit: F1 & F2 - N/kg, HMax & LMax - g, Index - %.

DISCUSSION

Gross and Nelson (Gross et al., 1988) found no significant differences in peak GRF and ACC values across three different surfaces in barefoot landings. Our results are also different from that of Nigg et al. (Nigg et al., 1987). On the other hand, Lafortune and Hennig (Lafortune, &Hennig, 1992) were able to detect significant effects of more compliant shoe on shock attenuation. The results from this study indicated that the forefoot (F1) and rearfoot (F2) impact forces were attenuated with the softer shoes, but occurred at the different PE levels. The peak head and tibia shock waves were also attenuated to certain extents. The results from this study suggest that shoes with more compliant midsole provide better cushion in the landing activities.

CORRELATION OF MECHANICAL FACTORS WITH INTIMAL HYPERPLASIA IN THE MILLER'S CUFF AND ITS APPLICATION TO OPTIMIZATION OF ANASTOMOTIC DESIGN

Xue-Mei Li¹ and Stanley E. Rittgers²

¹Department of Biomedical Engineering, Duke University, Durham, NC, USA

²Department of Biomedical Engineering, The University of Akron, Akron, OH, USA

INTRODUCTION

Mechanical factors are believed to be among the primary causes implicated in stimulating the formation of anastomotic intimal hyperplasia (IH). Although these factors have been analyzed by several groups employing computational simulations [Hofer (1996), Ballyk (1998)], none of these studies were based on a realistic large strain model for wall stress analysis nor did these studies attempt a direct correlation of the amount of IH with mechanical factors. Furthermore, optimizations of anastomotic designs to diminish IH formation have only considered the hemodynamic factors which were present in the physiologically loaded anastomotic geometry. Therefore, the purposes of this study were to: 1) simulate the mechanical environment by using a large strain finite element analysis (FEA) and a pulsatile computational fluid dynamics (CFD) analysis, 2) establish a regression relationship between IH and mechanical factors, 3) to provide an insight to the reduced IH formation in the venous cuffed anastomosis, and, 4) optimize the anastomotic design by altering the mechanical factors present in the regression relationship obtained above.

METHODS

An ePTFE cuffed distal end-to-side anastomosis was constructed for computational analysis in accordance with clinic procedures described by Kissin et al. (2000). A large strain and deformation FEA was used to analyze the wall strain and stress distribution in the anastomosis under the application of physiological loading. The deformed anastomotic geometries were then used as the wall boundaries for pulsatile CFD analysis. The maximal principle wall strain, wall shear stress, and oscillatory shear index (OSI) were calculated. Multiple linear regression analysis was employed in an effort to establish relationships between the amount of IH obtained by Kissin et al. (2000) in a chronic (4 wk.) porcine implant and these mechanical factors. The regression relationship was applied to biomechanical factors in similarly constructed venous cuffed anastomosis in order to explain the reduced amount of IH as also obtained by Kissin et al. (2000). Finally, an optimized design has been performed of a single component ePTFE anastomosis to control the mechanical factors involved in the regression relationship for the purpose of facilitating surgery and reducing IH.

RESULTS AND DISCUSSION

A distinct feature of the FEA derived wall mechanics was that the expansion of the cuffs caused elevated strains and stresses along the artery floor as well as at the heel and toe regions in the anastomosis. The hemodynamics were characterized by a

large central vortex in the cuff region during most of the cardiac cycle, which was suppressed by a forward stream motion during the acceleration phase and then divided by a backward stream during the reversing phase. The multiple linear regression equation for IH vs. strain, ϵ , and oscillatory shear index, OSI, was:

$$IH(\mu\text{m}) = -1397 + (2765 \times \epsilon) + (1034 \times \text{OSI}) \quad (1) \\ (R^2=0.999, p<0.05)$$

with a standardized regression equation of:

$$IH = (0.91 \times \epsilon) + (0.80 \times \text{OSI}) \quad (2)$$

Taking the values for ϵ and OSI calculated for the venous cuff simulation and substituting them into Eqn. (1) predicted values of IH of 527 μm , 616 μm , and 213 μm at the heel, middle floor, and toe, respectively. Compared to the values of IH obtained by Kissin et al. (2000) at four weeks implantation (13 μm , 10 μm , and 9 μm at the heel, middle floor, and toe, respectively), these predicted IH amounts were much greater (>20X) than those actually present. This implies that unaccounted for biological factors may work against the stimulating effect of the mechanical factors. The optimized anastomotic design showed that a laterally constrained, donut shaped, single component ePTFE graft/cuff generated a uniformly reduced wall strain and a partially reduced OSI under physiological loading which, thus, should suppress the IH formation at the heel, toe and middle artery floor.

CONCLUSIONS

A large strain model is necessary to resolve important biomechanical features in the vascular anastomotic analysis. Maximal principle wall strain and OSI account for the formation of intimal hyperplasia directly proportionally and equivalently in an ePTFE cuffed anastomosis. Based on our model, the reduced amount of intimal hyperplasia in the venous cuffed anastomosis is not due to the extensibility of the cuff material nor to a beneficial influence of its unique shape on the hemodynamic environment. A clipped, donut shaped, single component ePTFE anastomosis uniformly reduced the wall strain and partially reduced the OSI compared to the traditional approach.

A REPRODUCIBLE METHOD TO DEFINE A COORDINATE SYSTEM FOR 3D KINEMATICS EVALUATION OF THE KNEE

Maxime Van de Putte^{1,2} maxime.vandeputte@etsmtl.ca, Nicola Hagemeister¹, Gerald Parent¹, Nancy St-Onge^{1,4}, J.A. de Guise^{1,3}
¹Laboratoire de recherche en imagerie et orthopédie (LIO), CHUM Hôpital Notre-Dame, Montréal (Québec), ²Université de Montréal, Montréal (Québec), ³École de Technologie Supérieure, Montréal (Québec), ⁴Institut de réadaptation de Montréal, Montréal (Québec)

INTRODUCTION

When 3D kinematics are recorded, parameters are generally represented in a local coordinate system for a clinically sound interpretation of the data (calibration). The difficulty in defining a correct joint coordinate system in the knee, without the use of medical imaging (Rx) resides in the precise positioning, in space, of anatomical landmarks (i.e.: The femoral condyles, antero-superior iliac spine and the postero-superior iliac spine). Techniques described in the literature generate errors of a significant nature. Our research group (LIO) has developed a technique based on a functional approach already proposed by Cappozzo (1984) and using less anatomical landmarks. The proposed technique includes a postural approach to define the neutral position of the knee (0° of flexion and extension). The hypothesis is that errors incurred by the definition of the anatomical landmarks would be diminished through a more functional approach.

METHODS

In this experiment, reproducibility of both techniques (LIO and Cappozzo 1984) was evaluated in 5 subjects by three observers. The 3D kinematics of the subjects were recorded while they were walking on an instrumented treadmill after 5 minutes of habituation. Mean kinematic parameters (knee flexion/extension, abduction/adduction, tibial rotation, antero-posterior, medio-lateral and vertical translations) were calculated from 30 gait cycles using the two different calibrating methods (5 calibrations per technique per observer for the same sample of gait).

Evaluation of mean error for each observer and for all observers were then carried out to evaluate the results obtained for each calibrating technique. Repeatability was assessed through intra class correlation coefficient (ICC) (Kadaba 1989). A Student t test was then used to determine if the discrepancies discovered between the two calibrating techniques were of a significant nature.

RESULTS AND DISCUSSION

On the 5 subjects that have been recorded to date, our calibration technique has given results that suggest an equal or higher reproducibility of the calibrating technique, compared to the one proposed by Cappozzo (table1). The Student t test analysis as shown that errors yielded by our calibrating technique were smaller than those produced by Cappozzo's technique in abduction/adduction and tibial rotation for the intra-observer study. The inter-observer study has shown that our calibrating technique generated errors that were

statistically smaller from Cappozzo's in all parameters except for flexion/extension (fig.1). The proof of a higher reproducibility of our technique could diminish the possibility of error due to the difficulty to locate the anatomical landmarks.

SUMMARY:

The goal of this study is to develop a new technique for the precise positioning of the local coordinate systems necessary for the 3D knee kinematic analysis. Our technique, which is based on a functional approach for the determination of local coordinate systems, has yielded results that are more reproducible than those obtained using Cappozzo's method.

FRACTURE TOUGHNESS OF CARTILAGE BY MICROINDENTATION

Jack L. Lewis¹ and Narendra K. Simha²

¹Department of Orthopaedic Surgery, University of Minnesota, USA

²Department of Mechanical Engineering, University of Miami, USA

INTRODUCTION

Cartilage strength is important as a measure of cartilage function; reduction of strength reflects degradation of the matrix. Although important, there are few methods for measuring cartilage strength. Tensile tests are the most common method, but they do not reflect the failure mode of cartilage and it is difficult to fabricate the small specimens needed for these tests. An alternative method for strength measurement is microindentation, in which an indenting tip penetrates the surface. Small tissue volumes can be tested without the need to prepare regularly shaped small specimens. However, traditional nanoindentation methods¹ used with metals and other hard materials do not work with soft time dependent materials. Methods are proposed for overcoming these limitations and deducing a fracture toughness value for cartilage from microindentation tests.

METHODS

Cartilage from bovine patella was indented using a NanoindenterXP (MTS, Inc.). Bone/cartilage specimens approximately 10 x 10 x 4 mm were adhered to a holder and bathed with PBS. Indents were made with a conical indenter with diamond tip of included angle of 67°. After finding the surface, the tissue was loaded at a rate of 4 mN/sec to a maximum load. To assess penetration, in test Group 1 indents with maximum loads of 75, 100, 150, 200, 300, and 400 mN were performed. After testing the cartilage was bathed in India Ink and examined in a dissecting microscope. In each of Groups 2 and 3, 3 indents each of maximum load of 300 mN and 400 mN were performed. In group 4, 3 indents of 300 mN and 3 indents of 400 mN were performed and the specimen prepared for histology and depths of the indents measured from the slides.

Depth of penetration was predicted by assuming that the rate of work done, the power, increases rapidly whenever penetration occurs. After an initial penetration, as determined from the power rate, all displacement that occurs during elevated power rate was considered penetration displacement. These were summed to give the total penetration. The penetration, or fracture work, done was the sum of work done during the penetrating displacements. Fracture toughness was defined as the work during penetration divided by one-half the penetrated surface area of the conical tip.

RESULTS AND DISCUSSION

Comparing the power and India Ink stain images suggests that rapid change in the power is a reliable indicator of penetration. The predicted depth of penetration was not different from the depth

measured by histology ($p > .5$). The predicted fracture toughness for the 300 mN indents was identical with the predicted fracture toughness for the 400 mN indents, for both Groups 2 and 3. The pooled results for Group 2 is different from the results for Group 3, probably reflecting variation over the patella surface². The fracture toughness of Groups 2 and 3 are compared with the fracture toughness for bovine cartilage measured by Adams et al³ using a modified single edged notch test. There was no difference between the Adams results and the present results (Figure 1).

SUMMARY

A value of fracture toughness of cartilage can be

measured by microindentation. The predicted penetration depth agrees well with direct measurement by histology. The predicted fracture toughness agrees well with values measured by a macroscopic test. The microindentation method is promising as a new tool for measuring failure properties of cartilage and other soft tissues.

EFFECT OF SHOE MASS ON SOCCER KICKING VELOCITY

Mike Amos and Erez Morag
Nike Sports Research Laboratory, Nike, Beaverton, Oregon, USA
michael.amos@nike.com

INTRODUCTION

Foot speed is an important trait of skilled soccer players. It assists them in maneuvering the ball past opposing defenders and enables them to make first contact with the ball in a 50/50 challenge. It is generally recognized that changes in shoe characteristics which improve foot speed are advantageous.

Increases in shoe mass have been shown to require increased energy expenditure. In steady-state running Frederick (1983) predicts an increase of 1% VO_2 for every 100 grams of additional shoe mass. During an activity such as soccer where rapid changes in speed and direction occur which require large foot accelerations this energy cost may be even higher.

The purpose of this study was to evaluate the influence of shoe mass on soccer kicking velocity.

METHODS

Fourteen skilled male soccer players performed 3 maximal effort kicks in each of 5 shoe mass conditions; 215, 344, 381, 431, and 482 g. The dominant foot and a 2-step approach were used in each kick. The ball was kicked straight forward. Ball pressure was 12 PSI.

High speed video (1000 Hz) recorded the motion of markers placed on the lateral fibula, the lateral malleolus, and the 5th metatarsal head. Foot velocity was calculated from these markers and the ball was treated as a marker to measure ball velocity.

EMG (1000 Hz) was collected and used to measure activation in 5 muscles in the kicking leg (tibialis anterior, lateral/medial quadriceps, and lateral/medial hamstrings). The signals were bandpass filtered (10-350 Hz), rectified, and low-pass filtered (20 Hz) to create linear envelope curves and expressed as a percentage of maximal voluntary contractions for each muscle. Mean activation levels were calculated for i) 50 ms before ball contact (BC), ii) during BC, and iii) 100 ms after BC.

RESULTS AND DISCUSSION

Shoe mass had a significant effect on peak foot velocity ($p=0.002$); as shoe mass increased foot velocity decreased.

There was no significant difference in the resulting ball velocity between shoe conditions ($p=0.510$). Striking the ball with added shoe mass seems to have compensated for the reduced foot impact velocity to create an equivalent ball velocity.

Figure 1: Peak foot velocities during maximal effort kicks. Note the reduction in velocity with increased shoe mass.

Figure 2: Peak ball velocities resulting from maximal effort kicks. Ball velocity is unchanged by varying shoe mass.

No differences were detected in EMG activity between shoe conditions for any of the muscles or time intervals monitored ($p=0.534-0.992$). It may be that any existing differences in muscle activation between shoe conditions were masked by the natural variability in kicking technique.

SUMMARY

Increases in foot velocity were observed during kicking in lighter shoes. This was accomplished without detectable change in muscle activation level or resulting ball velocity. Therefore, potential advantages from increased foot speed and agility can be attained with lighter shoes while maintaining ball kicking velocity.

NEUROMUSCULAR RESPONSES TO KNEE OSTEOARTHRITIS DURING STAIRWAY LOCOMOTION

Paul DeVita, Jill Moody, Stacey Beam, Jovita Jolla, Kim Smith, Chris Mizelle, Joe Garry, and Tibor Hortobagyi
Biomechanics Laboratory, East Carolina University, Greenville, NC, USA

INTRODUCTION

While pain due to knee osteoarthritis (OA) limits movement capabilities (Hurwitz et al 2000), secondary muscle deficits including less quadriceps activation and strength (Hurley et al 1993) also affect movement. Knee OA subjects had reduced knee extensor torques in level walking and in stair ascent compared to healthy controls (Fisher et al 1997, Kaufman et al. 2001). Although other populations with reduced knee muscle function (i.e. ACL injured and healthy older adults) have shown increases in either hip and/or ankle muscle function (DeVita et al, 1998, 2000), compensatory functional increases have not been reported in knee OA patients. We hypothesized that knee OA is associated with a neuromuscular reorganization during gait such that reductions in knee extensor function will be compensated by increases in other lower limb muscles. The purpose of this study was to identify the effects of knee OA on lower extremity joint torques and powers during stairway locomotion.

METHODS

Eleven knee OA and 12 healthy subjects (mean ages: 57 & 49 yr) were tested in stair ascent and descent on a 4-step stairway instrumented with a force plate. Presence of OA was verified by a physician and with X-rays. Steps were 20 cm high and 27 cm deep. Floor reactions and sagittal plane kinematics were obtained during ascent and descent and combined with inverse dynamics to calculate hip, knee, and ankle joint torques and powers. Support torque and total power curves were calculated as the sum of the individual joint torques and powers. Extensor angular impulse and work at each joint were derived from these data and compared between groups with t-tests, $p < 0.05$.

RESULTS AND DISCUSSION

While support torque and total power were not different between groups, OA increased the hip extensor angular impulse 250% to offset the 25% reduced knee extensor angular impulse compared to healthy subjects in ascent. These torques produced 220% more work at the hip and 19% less work at knee in the OA group. Peak hip torques were similar between groups but the phase of extensor torque lasted longer in OA. Ankle torque and power were nearly identical between groups in ascent. Descent torques and powers had fewer differences than ascent.

Healthy subjects had 8% more plantarflexor impulse that did 36% more work compared to OA subjects in stair descent.

Our knee torque results were similar to those of Kaufman et al for ascent but not descent. They reported ~77% higher peak knee torque in healthy vs. OA and we had a ~75% difference (see figure). Kaufman et al also had higher knee torque in descent vs. ascent while we had the opposite result. Since subject and stairway characteristics and subject kinematics (not reported here) were similar between studies, we cannot explain these differences at this time.

We concluded that knee OA caused a reorganization of the neuromuscular control strategy in stair ascent such that ascent was performed with greater effort from the hip extensors and less effort from the knee extensors. We found less support for our hypothesis in descent since only the ankle muscles performed differently between groups.

INTRODUCTION

The diagnostic of foot ailments is still based on qualitative assessment often neglecting compensatory actions observed in the lower limbs and pelvis (Morag and Cavanagh, 1999). There is a need for systems that can quickly and clinically provide quantitative clinical information on foot ailments while considering other body posture parameters. This paper reports on the use of a color-coded video-based system for foot disorders assessment. Before this system can be used for the diagnostic of foot ailments, the number of trials required for an evaluation needs to be established and the intra-tester reliability determined.

METHODS

Seven females and three males young healthy adults (21.1 ± 1.8 years old age) participated in this study. A color-coded video-based system was developed to assess the postural attitude of the whole body, body segments such as the trunk, lower limbs or parts like the foot. This system consists of a black and white digital camera connected to a film grabber operating in a PC environment. The subject stands inside an open ended, three-sided black structure facing the camera. Normally, the subject uncovers the body parts to be analyzed. Fluorescent lights ensure a uniformly lit body surface and appropriate contrast of the exposed flesh.

Fourteen camera images consisting of the anterior and posterior views of the lower limbs, the anterior view of the knee, the posterior view of the pelvis and the anterior, posterior, medial and lateral views of the feet as well as posterior views of the feet in flexion in weight-bearing position were taken of each subject. These 14 digital pictures formed a single set data from which 43 parameters were measured (3-5 angles on each image) and calculated for two, three and four trials. The intra-class correlation coefficient (ICC) was used to estimate the number of trials. This was followed by ANOVAs ($p < 0.05$) to determine of significant difference between all the calculated ICCs. Intra-tester reliability was tested with three evaluators using data collected from data previously collected on one of the 10 subjects.

RESULTS

The average ICC values for all 43 parameters measured from 14 camera images and calculated for two, three and four trials was 0.84. There was not significant difference between the sets of trials. Data from both feet were combined and reported according to the images taken. For example, the lateral foot image includes all the parameters taken on this view for both feet. Average ICC values for the lower limbs and pelvis were 0.90 ± 0.09 . The foot parameters had ICC values ranging from

0.74 to 0.95 with an average of 0.82 ± 0.10 . The medial, postero-anterior and foot views had mean ICCs of 0.80 and above. The antero-posterior view ICC was close to 0.80 at 0.79 while the lateral foot parameters had the lowest mean ICC at 0.68 ± 0.24 . The average intra-tester reliability was 0.86 with 35 postural parameters having ICC value 0.7. Eight parameters had a mean ICC of 0.51.

DISCUSSION

This system was evaluated because of the good quality of the numerical photographs and its ability to apply a color code to the images. From the numerical pictures, the patient's morphology was immediately recognizable thus making a qualitative comparison with previous images easy.

Our mean ICC value (0.84) did not increase significantly with additional trials. Overall, the measured parameters had an excellent reliability, which do not warrant additional trials so that a single set of images can be used for clinical evaluations. The mean of intra-tester reliability was excellent except for 8 angles that displayed poorer reliability. Their reliability can be improved by defining more precisely how these angles should be measured.

CONCLUSION

These results support the idea that a color-coded video-based system can be reliably used for assessing patients with foot ailments.

SUMMARY

There is a need for a system that can quickly and clinically provide a relevant body posture evaluation as well as information on foot ailments. This paper reports on the use of a color-coded video-based system for assessing foot disorders. More specifically the number of trials required for a clinical evaluation and the intra-tester reliability were determined. The average ICC values for 43 angles measurements taken from 14 camera images and calculated for two, three and four trials was 0.84. The intra-tester reliability was good to excellent on 35 of the 43 measured postural parameters. These results support the idea that a color-coded video-base measurement system can be reliably used for assessing patient with foot ailments.

BIOMECHANICS & HYDRODYNAMICS OF DECELLULARISED PORCINE AORTIC HEART VALVES

Sotiris Korossis¹, Cath Booth², Helen Wilcox², Kevin Watterson³, John Kearney⁴, Eileen Ingham², John Fisher¹

¹ School of Mechanical Engineering, University of Leeds, Leeds, UK menskoro@leeds.ac.uk, ² Division of Microbiology, University of Leeds, Leeds, UK, ³ Leeds General Infirmary, Leeds, UK, ⁴ Yorkshire Regional Tissue Bank, Pinderfields Hospital, Wakefield, UK

INTRODUCTION

There is no adequate heart valve substitute for long term implantation for the majority of patients (Korossis 2000). For elderly patients bioprosthetic tissue valves with a life expectancy of 10-15 years provide a satisfactory solution. The heart valve substitute of choice for patients with a greater life expectancy is the mechanical heart valve. However, these valves require long-term anticoagulation therapy. For young adults and children there is a need to deliver a heart valve that will develop with the patient. Homograft valves have been used in this patient group, but they do not retain viability following transplantation. Tissue engineered heart valves coupled with recellularisation have the potential to grow with the patient. An approach is to use natural tissue matrices, either of xenograft or allograft nature. The major challenge in this approach is to develop effective decellularisation techniques to remove foreign cellular elements while retaining the biomechanical integrity of the valvular matrix. This study investigated the effect of sodium-dedocyl-sulfate (SDS), as a decellularisation treatment, on the biomechanical integrity and hydrodynamics of porcine aortic heart valves.

METHODS

Left coronary leaflets were dissected from fresh porcine aortic valves within 4 hours of slaughter. The leaflets were divided into 6 groups and treated according to the protocols listed in Table 1. Haematoxylin and eosin histological staining was performed to all the groups to assess the degree of decellularisation. Circumferential and radial specimens were cut from each of the 6 leaflet groups and tested under uniaxial tensile loading to failure. Whole porcine aortic roots were also treated with 0.1% (w/v) SDS in hypotonic buffer and their functionality was assessed by pressurising them to physiological pressures (120 mmHg) and by subjecting them to simulated pulsatile flow.

Table 1: Leaflet treatments used in the biomechanical study.

Fresh (control)
Isotonic buffer (control)
Hypotonic buffer (control)
Isotonic buffer + 0.03%(w/v) SDS (control)
Hypotonic buffer + 0.03%(w/v) SDS
Hypotonic buffer + 0.1%(w/v) SDS

RESULTS AND DISCUSSION

Isotonic buffer or isotonic buffer with SDS did not alter the biomechanical properties. However, they were not effective decellularisation treatments. Treatment with 0.03% and 0.1% (w/v) SDS in hypotonic buffer produced complete accellularity while retaining the network of elastin, collagen and glycosaminoglycans (Booth 2002). These protocols produced modest changes in the biomechanics of the leaflets

by reducing their elastin and collagen phase slopes, as well as by increasing their transition and failure strains. However, the treatments did not affect the strength of the leaflets (Korossis 2002). Whole porcine aortic roots treated with 0.1% (w/v) SDS in hypotonic buffer and pressurized to 120mmHg presented complete leaflet competence, whereas, when they were subjected to pulsatile flow showed reduced transvalvular pressure gradients (Figure 1) and similar regurgitation volumes compared to fresh, untreated roots. Regarding leaflet kinematics, the treated roots exhibited similar levels of leaflet free edge bending strains compared to the fresh control, as well as physiological opening and closing actions (Figure 2).

Figure 1: Pressure difference vs. root mean square forward flow for fresh and SDS-treated aortic roots (mean \pm 95% C.I.).

Figure 2: Leaflet kinematics of SDS-treated aortic valve.

SUMMARY

The decellularisation protocol used in this study, incorporating SDS in hypotonic buffer, produced complete accellularity of porcine aortic leaflets, causing modest changes in their extensibility. The absence of dead cells as foci for calcification, the retention of the elastin, collagen and glycosaminoglycans, as well as the promising leaflet kinematics and the retention of the leaflet matrix compliance and strength, form a promising platform for further studies. Further work will investigate whether the treated leaflets have adequate durability and will consider *in vitro* recellularisation and penetration of the cells in the leaflet matrix.

ON THE CORRELATION BETWEEN NEGATIVE NEAR-WALL SHEAR STRESS IN HUMAN AORTA AND VARIOUS STAGES OF CHF

M. Gharib¹ and M. Beizaie²

¹Aeronautics and Bioengineering, California Institute of Technology, Pasadena, CA 91125, USA, mory@caltech.edu

²Orqis™ Medical, 20914 Bake Parkway, Suite 112, Lake Forest, CA 92630, USA, masoud@orqis.com

INTRODUCTION

The critical effect of NYHA Class III and IV CHF is the reduced blood flow in descending aorta that results from mild to severe reduction in cardiac output, which usually accompanies low EF. In these patients the heart tries to compensate by beating faster, but reduced blood flow combined with increased heart rate can lead to a retrograde flow adjacent to the wall and thereby a negative shear stress along the vessel walls during each cardiac cycle. Our studies show that near-wall negative shear stress can result from the existence of either an entire-retrograde flow at normal heart rates or a Womersley type phase delayed near-wall retrograde flow at high HR and low EF conditions. Previous studies suggest a number of possible harmful responses of the blood-vessel endothelial linings to the reversal of shear stress along the vessel walls. In this study, we try to map the correlation between the level of retrograde flow in descending aorta and the severity of CHF.

METHODS

A compliant aortic loop with appropriate pressure and flow instrumentation, was used. A Harvard pulsatile blood pump (HP) generated the aortic flow and the descending aorta model was totally immersed in water. In the first set of experiments, we used two liters each of three mixtures of distilled water and glycerin with a kinematic viscosity of 1, 2, and 4 cS, respectively. In the second, we used two liters of property filtered, anti-coagulated diluted bovine blood with an effective kinematic viscosity of 4 cS. The flow field was mapped using a GE-Vingmed System 5 platform with a 10 MHz probe. The resulting images were analyzed with Caltech's Digital Ultrasound Speckle Image Velocimetry (DUSIV) technique.

Figure 1: Orqis™ Medical's compliant descending aortic model (left) and typical DUSIV results from bovine-blood experiments, showing near-wall retrograde flow during diastole (center) and its absence during systole (right); mean flow was always positive at about 2.25 lpm, 110 bpm, giving $Re = 470$, $Wo = 21.5$.

RESULTS AND DISCUSSION

We have shown that near-wall retrograde flow does indeed happen under certain conditions of aortic flow rate and frequency. We have charted these conditions via an empirical relationship between Reynolds and Womersley numbers. Also, we have demonstrated a strong correlation between the level of retrograde flow and the transition from Class II to III in CHF patients.

Figure 2: Variation of near-wall retrograde threshold as a function of cardiac output and heart rate, compared to clinical data from previous investigators.

We also have shown that the retrograde conditions can be reduced or eliminated by increasing the aortic flow

Figure 3: Frequency of occurrence of near-wall retrograde as a function of heart rate.

VELOCITY OF THE RECTUS FEMORIS MUSCLE AFTER TENDON TRANSFER SURGERY

Deanna Schmidt Asakawa^{1,3,4}, Silvia Blemker¹, Garry Gold^{2,3}, and Scott Delp¹
Depts. of ¹Mechanical Engineering and ²Radiology, Stanford University, Stanford, California
³Diagnostic Radiology Center, VA Health Care System, Palo Alto, California ⁴djasakawa@stanford.edu

INTRODUCTION

Rectus femoris transfer surgery is performed to improve knee flexion in persons with cerebral palsy who walk with a stiff-knee gait (Perry, 1987). In this surgery, the rectus femoris muscle is detached from the patella and reattached to a tendon that inserts posterior to the knee in an attempt to convert the muscle from a knee extensor to a knee flexor. However, outcomes of the surgery are variable. The purpose of this study was to gain insight into the action of the rectus femoris muscle after tendon transfer surgery using dynamic magnetic resonance imaging. Cine phase contrast magnetic resonance imaging (cine-PC MRI) accurately captures the anatomy and the velocity of tissues during joint motion (Drace and Pelc, 1994; Sheehan *et al.*, 1998). Based on the direction of the muscle tissue velocity, one can identify a muscle's action (e.g., as the knee extends, the knee extensors move superiorly and the knee flexors move inferiorly). We used cine-PC MRI to test the hypothesis that the transferred rectus femoris muscle acts as a knee flexor and therefore moves inferiorly with knee extension.

METHODS

We acquired axial plane cine-PC MR images in the proximal thigh of 5 control subjects (5 limbs) and 6 subjects (10 limbs) with cerebral palsy who had undergone rectus femoris transfer surgery. Each subject was positioned supine in the 1.5T GE scanner with the lower limb between dual radiofrequency coils. Subjects were imaged as the investigator moved their knee passively through 100 repeated cycles of knee extension/flexion at a rate of 35 cycles/min. Images were acquired with a 17ms TR, 36x27cm FOV, 256x128 matrix, and 20 cm/s encoding velocity with 24 time frames representing a motion cycle. On the velocity images we prescribed 0.25-cm square regions in the rectus femoris (RF), vastus intermedius (VI), and semitendinosus (ST) and the average superior-inferior velocity within these regions was computed for each time frame using MATLAB.

Figure 1. Average (lines) and standard deviation (shaded regions) of superior-inferior muscle velocities measured from cine-PC MR images acquired during knee extension.

RESULTS

In the control subjects, the RF and VI, knee extensors, had velocities in the superior direction and the ST, a knee flexor, had velocity in the inferior direction during knee extension (Fig. 1). In the RF transfer subjects, the RF also had velocities in the superior direction during knee extension despite its insertion posterior to the knee. The RF/VI velocity ratios (Table 1) demonstrate that the control subjects had maximum RF velocities greater than the maximum VI velocities; in contrast, the RF transfer subjects had RF velocities less than VI velocities. These results indicate that RF transfer surgery does not convert the RF to a knee flexor, but the surgery does diminish the muscle's capacity for knee extension.

Table 1. Maximum Muscle Tissue Velocities¹ in cm/s

Limb	RF Velocity	VI Velocity	RF/VI Ratio
1	1.4	1.6	0.9
2	1.5	2.5	0.6
3	1.1	1.6	0.7
4	2.0	3.3	0.6
5	0.1	3.0	0.0
6	1.1	2.7	0.4
7	1.9	2.5	0.8
8	2.9	4.4	0.7
9	1.6	3.0	0.5
10	2.3	2.5	0.9
Controls	3.8 ± 0.2	2.1 ± 0.8	1.9 ± 0.3

¹Positive values indicate velocity in the superior direction

DISCUSSION

The rectus femoris muscle did not move in the direction of the knee flexors in any of the 10 limbs that had undergone a rectus femoris transfer. This result is surprising considering that its path is surgically altered to insert into a knee flexor muscle or tendon. One possible explanation is that scar tissue may form after surgery, constraining the motion of the muscle and diminishing the force transmitted to its distal tendon. Our results indicate that the mechanism for improved knee flexion in some subjects following rectus femoris transfer is unlikely to be a knee flexion moment generated by the rectus femoris.

STIFFNESS OF THE HUMAN ARM IN THREE DIMENSIONAL SPACE

Mark C. Pierre and Robert F. Kirsch

Biomedical Eng. Dept., Case Western Reserve University, 10900 Euclid Ave, Cleveland, OH 44106

E-mail:mcp6@po.cwru.edu

INTRODUCTION

The goal of this work was to measure the dynamic characteristics of the arm, including its endpoint mass, viscosity, and stiffness. These dynamic characteristics depend on inherent musculo-skeletal properties, skeletal geometry and neuromuscular interactions. Previous studies of posture and movement focusing on single muscles, single joints, or movements in the horizontal plane may not have revealed critical features of natural neural control. In this study, we have added the capability to measure the endpoint stiffness of the arm in three dimensions while the subject isometrically exerts forces in three-dimensional space.

METHODS

The dynamic stiffness of the human arm is the relationship between a displacement imposed at the endpoint of the arm and the forces that result from that displacement. The endpoint stiffness was estimated using data obtained during stochastic displacement perturbations applied to the hand by a robotic manipulator (Acosta, et al. 2000). The subject's trunk and wrist were constrained so that only the arm was free to move. The dynamic input-output relations between the three displacements and three forces were determined using a frequency domain non-parametric system identification technique (Bendat & Piersol, 1986, Perreault et al 1999). This technique identifies a set of nine transfer functions that assume linearity for small displacements about a particular posture.

RESULTS AND DISCUSSION

It has been shown that second order models using inertial (I), viscous (B), and stiffness (K) parameters can be used to accurately represent endpoint transfer functions (Perreault et al 1999). The inertial, viscous, and stiffness properties are dependent on the direction of the input. We characterized these directional properties by representing the endpoint stiffness as an ellipsoid, created by plotting the force responses to a unit displacement applied to the identified stiffness values. This is the extension of a previous two-dimensional method used to plot ellipses (Mussa-Ivadi, et al. 1985)

Figure 1 shows an ellipsoid as the central figure surrounded by three two-dimensional projections that aid in visualizing the three dimensional content of the ellipsoid. This figure is shaded to highlight the varying stiffness. Areas with the highest stiffness are shaded lightly and areas of low stiffness are dark. Relative to the figure, the subject would be oriented with their shoulders parallel to the X-axis facing the positive Y-direction. The endpoint of the hand would be located in the center of the ellipsoid at location (0, 0,0).

Three-Dimensional Stiffness Ellipsoid

Figure 1. The three-dimensional stiffness ellipsoid is the center most object. The three surrounding ellipses are projections of the ellipsoid onto each plane. Shading correlates to the stiffness magnitude; lighter being stiffer.

SUMMARY

This abstract outlines a non-parametric method for characterizing three-dimensional arm dynamics in response to stochastic perturbations. The method assumes no prior knowledge about the system dynamics except linearity in the presence of small displacements. In addition, this technique differs from previous techniques because it includes all three dimensions, a much more meaningful evaluation for arm postures. Thus, this test can be used to more fully determine system structure under natural three-dimensional conditions.

Preliminary results show that this method is suitable for characterizing changes in three-dimensional endpoint stiffness. In addition, the graphical ellipsoid is an important tool to help visualize the complex dynamic properties of the arm. Future work will concentrate on testing the dynamic properties of the arm in functional positions. Ultimately, this technique will be used to quantify stiffness changes due to functional neuromuscular stimulation of paralyzed muscles in individuals with spinal cord injury.

BIOLOGICAL AND BIOMECHANICAL RESPONSE OF RAT DORSIFLEXORS TO ECCENTRIC EXERCISE

David Peters, Ilona Barash, Michael Burdi, Phillip Yuan, Jan Fridén, Gordon J. Lutz and Richard L. Lieber

INTRODUCTION

Eccentric contraction (EC) of skeletal muscle can result in tissue injury and decreased force output (Proske and Morgan, 2001). Reported structural changes after EC include Z-disk streaming (Fridén *et al.* 1981), extreme sarcomere length changes (Talbot and Morgan, 1996), loss the intermediate filament protein desmin (Lieber *et al.* 1996), inclusion of plasma fibronectin (Fridén *et al.* 1991), and expression of embryonic myosin heavy chain (Lieber *et al.* 1994). However, the relative timing of these events is not known. Such information would permit development of a mechanistic hypothesis that explains muscle response and remodeling after EC, especially in a rat model, where a plethora of antibodies and gene sequences are available.

METHODS

The experimental subjects for this study were young, male Sprague-Dawley Rats with an average size of 433.9 ± 4.2 g (mean \pm SEM, $n = 30$). All procedures were approved by the University of California and V.A. Medical Center Committees on the Use of Animal Subjects in Research. To induce eccentric contractions, rat dorsiflexors were activated at 100 Hz by placing a nerve cuff around the peroneal nerve while actively plantarflexing the foot using a dual-mode servo motor (Cambridge Tech, Model 6650) similar to that previously reported for the rabbit model (Lieber *et al.* 1994). Ankle angle was rotated 38° over 400 ms corresponding to a fiber length change of about 10% and a sarcomere length change from 2.48 ± 0.069 μ m to 2.87 ± 0.048 μ m in the extensor digitorum longus (EDL) muscle. Thirty ECs, at two minute intervals, were imposed upon the muscle and then joint torque and tissue were analyzed 6, 12, 24, 48, 72 and 168 hours later. Muscle tissue was snap frozen and sectioned for immunohistochemical staining with monoclonal antibodies against desmin (an intermediate filament protein; DER-11, Novocastra), fibronectin (signaling increased membrane permeability; EDA, Sigma), embryonic myosin heavy chain (MHC, expression signaling regeneration; 1.652, Novocastra) and vimentin (an intermediate filament protein expressed in infiltrating macrophages; VIM-V9, Novocastra). The number of fibers showing a positive immunostain were directly counted by light microscopy at 25X magnification.

Figure 1: Dorsiflexion torque prior to (Pre-) and at various times after 30 eccentric contractions separated by 2 minutes.

RESULTS

Initial dorsiflexion torque was $.053 \pm .00095$ Nm, decreased to $.030 \pm .00082$ Nm immediately after the eccentric exercise bout and recovered monotonically to control levels after 168 hours ($0.055 \pm .00026$ Nm; Fig. 1). In contrast, cellular events were staggered in time and resolved over varying time courses (Fig. 2). For example, the most rapid structural change was loss of immunostaining for the intermediate filament protein, desmin (Fig. 2, solid bars), which was maximal at 12 hours and resolved within 72 hours. Changes in vimentin and fibronectin paralleled one another, peaking 24 hours after EC and being nearly resolved after 7 days (Fig. 2, open bars and hatched bars respectively). Finally, expression of the MHC protein became significant 48 hours after exercise and was still increasing 7 days later (Fig. 2, stippled bar).

Figure 2: Number of fibers showing change from control for the protein shown at various times (hours) after the EC bout.

DISCUSSION

These data reveal an injury/repair process whereby loss of desmin immunostaining signifies the first stage of the process. Such loss may be due to depolymerization of the intermediate filament system, loss of the desmin antibody's epitope or even selective proteolysis. In any case, this change is followed by a transient increase in cellular permeability as indicated by fibronectin labeling and infiltration of macrophages as indicated by vimentin staining. Finally, the embryonic MHC is upregulated, which may lead to the observed functional recovery. The relationship among these events as well as their necessity (if any) to muscle hypertrophy remain unclear.

ASYMMETRIC DYNAMIC KNEE LOADING IN ADVANCED UNILATERAL HIP OSTEOARTHRITIS

Najia Shakoor¹, Debra E. Hurwitz^{1,2}, Rohita Shah², Susan Shott³, Joel A. Block¹, John P. Case^{1,4}

INTRODUCTION

Dynamic joint loading has been shown to be an important factor in the pathogenesis of lower extremity osteoarthritis (OA). For instance, the peak external knee *adduction moment* during gait has been correlated with radiographic OA severity (Sharma et al., 1998) and may be predictive of subsequent radiographic progression (Wada et al., 2000; Hong et al., 2001). It is likely that abnormal loading of one lower extremity joint due to pain, disease or deformity will result in altered loading in the other joints (either on the same or contralateral side of the body).

We recently investigated the sequence of lower extremity total joint replacements in OA patients and showed that the evolution of endstage lower extremity OA is *not random*. Patients who have an initial unilateral total *hip* replacement (THR) for OA require a subsequent *contralateral* total knee replacement (TKR) significantly more frequently than they do an *ipsilateral* TKR (Shakoor et al., 2001). The objective of the present study was to relate the evolution of endstage OA to dynamic joint loading. The hypothesis tested was that patients with unilateral endstage *hip* OA have higher dynamic knee loads at the *contralateral knee* relative to the *ipsilateral knee*.

METHODS

The knee joint loads during gait on the ipsilateral and contralateral sides of 49 preoperative THR patients with unilateral hip OA were compared. All patients had gait analysis using an optoelectronic camera system and a multi-component force plate (Andriacchi et al., 1997). Walking trials at a speed of approximately 1 m/s were chosen for analysis. Three dimensional moments were calculated using inverse dynamics. The peak medial compartment force at the knee was also estimated using the gait data in conjunction with a statically determinate model (Schipplein and Andriacchi, 1991).

The Friedman test was used to identify differences in the peak external knee adduction moment and peak medial compartment load at the knee ipsilateral and contralateral to the preoperative hip.

RESULTS

Dynamic loading in these patients with endstage hip OA differed between the extremities. The peak knee adduction moment and the peak medial compartment load were both *significantly higher* at the *knee contralateral* to the

preoperative hip relative to the knee ipsilateral to the preoperative hip (see Table 1).

Table 1: Adduction Moment and Medial Compartment Load

	Adduction Moment (%BW*Ht)	Medial Compartment Load (BW)
Contralateral Knee	1.7 (±1.0)*	1.9 (±0.6)**
Ipsilateral Knee	1.3 (±0.9)	1.1 (±0.5)

*p=0.003 **p<0.001

DISCUSSION

Previous studies have also suggested the clinical importance of asymmetric loading in the evolution of lower extremity OA. An investigation of traumatic amputees found a significantly higher incidence of radiographic knee OA at the non-amputated limb when compared to age-matched healthy controls (Melzer et al., 2001). Biomechanical evaluations of such amputees revealed higher load-bearing on the knee of the non-amputated limb (Eberhart et al, 1954). The results from the current study extend the concept of asymmetric knee loading and OA evolution to a non-amputee population.

These are the first data to reveal a relative loading differential between the knees of preoperative THR patients, which may explain the asymmetric development of endstage knee OA (TKR requirement) in these subjects. Further investigation is necessary to discern how early in the course of hip OA differential loading develops, and its relationship to alterations in neuromuscular limb control.

MICRO- AND MACRO-LEVEL 3D STRAINS MEASURED IN MICROSTRUCTURALLY VARIED COLLAGEN ECMS

INTRODUCTION

In vivo, cells reside in a three-dimensional (3D) framework known as the extracellular matrix (ECM). The structure and composition of the ECM conveys to cells biochemical as well as biomechanical information critical to maintenance of tissue form and function. Mechanical loads applied to tissues have been shown to affect many fundamental cellular processes; however, little is known regarding how loads are transmitted through the ECM to cells and how those load ultimately affect cellular function. A model ECM consisting of a 3D matrix of type I collagen fibrils was used to further understand how mechanical loads are transmitted from a macro (tissue) level to the a micro (cellular) level. Specifically, collagen ECMs with different microstructures were loaded in tension and both 3D macro- and micro-level strains were measured and compared.

METHODS

Collagen ECMs were manufactured by neutralizing an acid solution of collagen type I (Sigma Chemical Co.) to desired concentration and pH. Collagen content and polymerization pH were varied to create micro-structurally varied collagen ECMs (Roeder et al., 2002). The neutralized solution was polymerized in a “dog-bone” shape by incubating the ECM at 37°C in a humidified environment for at least 18 hours before testing. Combined confocal-mechanical experiments (Voytik-Harbin et al., 2002) acquired 3D images of collagen ECM microstructure and images of the ECM cross-section (width & thickness), as specimens were incrementally loaded in tension (1.0 mm/min). 3D images tracked a specific location (an approximately 150×150×35 μm volume) inside the collagen ECM. Digital volume correlation was then used to measure 3D tensorial strains in microstructure of the collagen ECM (Roeder et al., 2001). Macro-level strains were derived from cross-sectional area images (ϵ_{22} & ϵ_{33}) and applied strains (ϵ_{11}). Shear strains were not measured at the macro-level.

RESULTS AND DISCUSSION

Previously, alterations in microstructural properties such as fibril length, diameter and density were found to substantially change macroscopic material properties such as modulus and failure strength of collagen ECMs (Roeder et al., 2002). Here, micro-level strains were determined and correlated with macro-level strains in mechanically loaded collagen ECMs with varied microstructure. For example, the means of six independent components of the lagrangian strain tensor measured in the microstructure of a 1.0 mg/ml, pH 7.4 collagen ECM are compared to macro-level strains, as tensile loads (1-direction) were applied to the specimen (Figure 1). Error bars indicate the standard deviation of the strains measured in the image volumes. In the loading direction,

macro-level strains applied to the sample increased linearly, while the micro-level strains initially paralleled this behavior but leveled off at higher loads. Similarly, transverse strains (ϵ_{22} & ϵ_{33}) decreased substantially as loads were applied, but the micro-level strains were lower in magnitude than the macro-level strains at higher loads. Understanding how the micromechanical behavior of collagen ECMs is related to their macroscopic behavior will help elucidate how the ECM microstructure acts to functionally transmit loads from the tissue (macro) level to cellular (micro) level. Such relevant information regarding micromechanical loads at the cellular level will prove invaluable in the design of future tissue engineered devices.

Figure 1: 3D strains measured at the micro- and macro-level in a 1.0 mg/ml collagen ECMs as the specimen was stretched in the 1-direction.

BIOMECHANICS OF CERVICAL SPINE SURGERY: COMPARISON OF FUSION AND NONFUSION INSTRUMENTATION

Denis J. DiAngelo¹, Kevin T. Foley², Champ Davis¹, and Bobby J. McVay¹

¹School of Biomedical Engineering, The University of Tennessee Health Science Center, Memphis, TN, ddiangelo@utmem.edu

²Department of Neurosurgery, The University of Tennessee Health Science Center, Memphis, TN

INTRODUCTION

Anterior cervical discectomy or anterior cervical decompression is an acceptable surgical method for the treatment of cervical spondylosis or other spinal disc diseases. The gold standard for surgical treatment is fusion and can include spinal instrumentation. However, clinical studies have shown that motion at spinal segments adjacent to a fused region increases over time and may cause adjacent segment disease. Multiple factors have been implicated, including number of levels fused, health condition, post-operative alignment, and rigid fixation. An alternative approach to fusion surgery of the cervical spine is to restore motion to the diseased joint using an artificial cervical joint (ACJ). The objective was to compare the biomechanical stability of two single-level cervical procedures: graft fusion with anterior cervical plate (GAP) versus an artificial cervical joint (ACJ).

METHODS

Five human cadaveric cervical spines (C2-T1) were procured and screened with AP and lateral radiographs to exclude those with disease. Three different spine conditions were analyzed: i) harvested (H), ii) implanted ACJ, and iii) instrumented GAP. The ACJ spine consisted of a single level discectomy with subsequent disc replacement using the “Bristol” disc. An Orion™ anterior cervical plate (Medtronic-Sofamor Danek, Memphis, TN) was used for the graft-plated constructs. The specimens were nondestructively tested in flexion/extension, lateral bending, and axial rotation. Measurements included overall spine motion, individual vertebral motions, and applied load and moment. Global (C2-T1) rotational stiffness was calculated and normalized to the harvested condition to control intrinsic differences in the specimens. The relative rotations at the superior (S), operated (O) (C5-C6), and inferior (I) motion segment units (MSU) were normalized with the respect to the overall rotation of those three (S+O+I) MSUs. Paired t-tests ($p < 0.05$) were used to statistically analyze the normalized motion and stiffness data.

RESULTS

There was no significant difference ($p < 0.05$) in the stiffness values between the H and ACJ spines for all modes of testing. There were significant differences between GAP and both the H and ACJ conditions. The normalized rotations at the operated and adjacent segments for flexion/extension and lateral bending are shown in Figure 1. Similar results occurred in axial rotation. There was no significant difference in the normalized motion between the H and ACJ conditions at all three levels and loading modes. There was a significant difference between the GAP and ACJ spine conditions at all three levels for all three loading modes.

MSU Rotations

Figure 1: Relative MSU Rotations. A) Flexion, B) Extension, C) Right Lateral Bending, and D) Left Lateral Bending. (Mean + one standard deviation.)

DISCUSSION

Clinical studies have reported increased loading at adjacent segments following fusion surgery. Lost motion at the fusion site may increase adjacent segment motion, that overtime, may lead to degenerative wear of the adjacent discs. In this study, the GAP did significantly alter the motion and at the operated and adjacent MSUs compare to the H and ACJ spine conditions. Additional surgery may be required. The ACJ did not significantly alter motion at the superior, implanted, or inferior MSUs relative to the harvested spine condition, nor did it change the stiffness. There are two differing viewpoints on adjacent segment disease: i) the disease is part of the natural aging process and ii) the MSUs adjacent to a fused level experience a significant increase in motion that enhances the disease. We found that the single-level plated procedure caused a significant increase in motion at the adjacent segments, which clinically may contribute to the advancement of adjacent segment disease. Use of the artificial cervical joint did not alter the adjacent segment motion patterns and is less likely to promote adjacent segment disease.

KINEMATICS OF THE CERVICAL SPINE: PATH OF THE INSTANT AXIS OF ROTATION IN FLEXION AND EXTENSION

Denis J. DiAngelo¹, Keith A. Vossel¹, and Kevin T. Foley²

¹School of Biomedical Engineering, The University of Tennessee Health Science Center, Memphis, TN, ddiangelo@utmem.edu

²Department of Neurosurgery, The University of Tennessee Health Science Center, Memphis, TN

INTRODUCTION

Two-dimensional motion of a joint can be described by the Instant Axis of Rotation (IAR). Calculation of the IAR depends on the experimental set-up, anatomical structure, mathematical reduction technique, and accuracy of the measurement equipment. For the cervical spine, no accurate calculations of the IAR path exist; typical vertebral measurements only include the rotational components. The objective of the study was to determine the IAR of the cervical spine for flexion-extension loads *in vitro*.

METHODS

Six human cadaveric cervical spines (C2-T1) were procured and mounted in a programmable testing system. A previously developed *in vitro* testing protocol that replicated physiologic flexion and extension motion (DiAngelo et al., 1997) was used (see Figure 1). Measurement of the vertebral motions were made using a custom-built optical joint measurement system (JMS) that had an improved resolution (10 microns). The motion data were then used to calculate the IAR coordinates of each motion segment unit (MSU). Several statistical tests were performed to analyze the IAR data, including comparison between the experimental IAR and a theoretical IAR zone (anterior half of subjacent body). Using the JMS, the theoretical error in calculating the coordinates of the IAR was less than 1 mm. However, using a conventional system (100 to 500 micron resolution), the IAR error increased 7 to 10 mm.

Figure 1: Relative MSU Rotation of the Harvested Spine. Mean + one standard deviation of the combined flexion/extension rotations for the *in vitro* harvested spine compared to published *in vivo* data. (Ameco et al, 1991; Dvorak et al, 1998; Lind et al, 1998; White and Panjabi, 1990)

RESULTS AND DISCUSSION

The average location of the IAR positions of the harvested cervical spine on an upright representative spine model is shown in figure 2 for flexion and extension loading. The shift in the position of the IAR between extension and flexion was significant (paired t-test, n=6, p<0.05). The standard deviations of the IAR positions (comparing between different spines) averaged ± 9 mm along the anterior/posterior axis of the spine and ± 8 mm in the dorsal/ventral direction. A two-way ANOVA test was also performed to determine the fraction of local IAR points that laid in the theoretical zone (i.e., anterior half of subjacent body). In extension, 10% of the IAR points were within the predefined zone. During flexion, 14% of the IAR points laid within the theoretical IAR zone. The combined flexion/extension motion of an individual, intact cervical MSU varies between 5° and 15°. To calculate their IAR path, smaller angular measurements (2°) were needed. Using the improved JMS, the IAR of the cervical spine was found to lay in the subjacent body near the facet joints during extension and moved towards the center of the subjacent vertebral body during flexion. This change was significant.

BIOMECHANICAL STABILITY OF MULTI-LEVEL CERVICAL SPINE INSTRUMENTATION: COMPARISON OF CONSTRAINED VERSUS SEMI-CONSTRAINED ANTERIOR CERVICAL PLATES

Denis J. DiAngelo¹, Kevin T. Foley², W. Liu¹, and Christine M. Olney¹

¹School of Biomedical Engineering, The University of Tennessee Health Science Center, Memphis, TN, ddiangelo@utmem.edu

²Department of Neurosurgery, The University of Tennessee Health Science Center, Memphis, TN

INTRODUCTION

Recent clinical experience has shown that anterior cervical plating does not prevent construct failure in multi-level cervical corpectomy (Vaccaro et al, 1998). We have also shown that anterior cervical plating reverses the load transfer through multi-level strut-grafts and may promote pistoning of these grafts (DiAngelo et al, 2000). The design of the anterior cervical plate (ACP) may contribute to this phenomenon. The purpose of this study was to compare the graft loading mechanics of two different anterior cervical plating systems; one with a constrained screw-plate interface versus another with a semi-constrained, translational screw-plate interface.

METHODS

Ten cadaveric cervical spines (C2-T1) were harvested and mounted in a programmable tester and loaded in flexion and extension. Five spine conditions were evaluated: harvested (H), (C4-C6) corpectomy (C), strut-graft alone (GA), strut-graft with constrained anterior cervical plate (CACP), and strut-graft with translational anterior cervical plate (TACP). The Orion™ cervical plating system was used for the CACP conditions and the Premier™ plating system was used for the TACP condition (Medtronic – Sofamor Danek, Memphis, TN). Five spines were tested with each plating system. Following harvested and corpectomy testing, the spine was decompressed and a force sensing strut-graft (FSSG) was inserted into the corpectomized region and lengthened to achieve a 20N pre-load. Graft loads were measured prior to and after plate application. A previously developed *in vitro* testing protocol was adopted, i.e., target moment at T1 of 3Nm with limit checks of 40° total spine rotation, 5Nm maximum bending moment, 75N actuator load, or 200N maximum graft load (DiAngelo et al, 2000). Measurements included vertebral motion, applied load and moment, and load transferred through the FSSG. Global (C2-T1) rotational stiffness was calculated and normalized to the harvested condition to control intrinsic differences in the specimens. Output from the FSSG and mean relative rotations were compared at nondestructive end limits of flexion and extension. A one-way ANOVA ($p < 0.05$) was used to determine the statistical differences between the strut-graft pre-load and end-load of the CACP and TACP conditions in flexion and extension, and the normalized motion data of the graft-alone, TACP, and CACP conditions.

RESULTS AND DISCUSSION

Application of either anterior cervical plate increased the global (C2-T1) stiffness and decreased the local (C3-C7) motion. Values of the FSSG pre-loads, end-load, and change in load are shown in Table 1. Flexion of the SG spine loaded the FSSG; extension unloaded the FSSG. With both plates,

these load transfer patterns were reversed. The CACP construct produced significantly higher graft loads in extension than the TACP construct ($p < 0.001$) and GA spine ($p < 0.001$), which may promote graft pistoning and lead to construct failure. Importantly, there was no significant difference in graft loads in extension between TACP and GA constructs. In flexion, there were no significant differences in graft loads amongst the three constructs. The CACP construct produced significantly higher pre-load than the TACP (in both extension ($p < 0.001$) and flexion ($p = 0.003$)) and the GA constructs (in both extension ($p < 0.006$) and flexion ($p < 0.005$)). However, there were no significant differences in pre-load between TACP and GA constructs in both extension and flexion. There were significant differences between the change in pre-load and end-load values for the CACP and TACP spines, in both extension ($p < 0.001$) and flexion ($p = 0.025$). However, no significant differences occurred between the TACP and GA constructs in both extension and flexion. Values of the normalized local (C3-C7) motion are shown in Table 2. During flexion, there were no significant differences between the GA, CACP, or TACP conditions. During extension, there were significant differences between the CACP versus GA ($p < 0.001$) and CACP versus TACP ($p < 0.03$). In summary, the semi-constrained, translational plate did not produce significant changes in strut-graft loads, which would be considered biomechanically advantageous in this setting.

Table 1: FSSG Loads in Extension and Flexion

Measurement Condition		FSSG Load (N)		
		GA	TACP	CACP
Preload	Flexion	23(3)	21(11)	59(21)
	Extension	18(3)	7(5)	40(13)
Max Load at 8°	Flexion	33(9)	15(16)	15(19)
	Extension	15(3)	24(6)	140(48)
Change in Preload	Flexion	10(7)	10(11)	44(27)
	Extension	2(2)	16(7)	101(39)

Table 2: (C3-C7) Motion Normalized to Harvested

Measurement Condition	Normalized Motion Relative to H		
	GA	TACP	CACP
Flexion	0.84(0.23)	0.68(0.25)	0.47(0.37)
Extension	1.0(0.14)	0.67(0.34)	0.27(0.18)

INTRODUCTION

Different lower extremity exercises can be used to improve, retain, or restore functional independence in older adults. Two such exercises are the squat (SQ) and the box squat (BS), an activity where one squats down onto a stable surface before rising. We hypothesized that these activities would invoke different lower extremity demands and that they could be used to preferentially target specific muscle groups in elders. Thus, the purpose of this investigation was to characterize the contributions of the hip extensors, knee extensors, and ankle plantar flexors during two functional squatting activities in older adults

METHODS

Twenty healthy, older adults (ages 70-85) performed SQ to a self-selected depth and BS onto a stool at a standardized height of 43.8 cm. Each subject completed three trials of each exercise, and both exercises were performed during the same session. Joint kinetics were obtained using inverse dynamics techniques. The angular impulse of each joint was obtained by integrating the hip, knee, and ankle moment curves over an entire repetition. A support impulse was calculated as the sum of the three joint impulses. The contribution of the lower extremity extensor muscle groups was determined by dividing the individual joint impulses by the support impulse. Results were averaged across the three trials. Comparisons between SQ and BS were made with paired t-tests.

RESULTS AND DISCUSSION

SQ generated a 51.2% greater knee extensor impulse ($p < 0.01$), a 157.9% greater plantar flexor impulse ($p < 0.01$), and a 31.3% greater total support impulse ($p < 0.01$) than BS (Table 1). Conversely, BS generated a 8.1% greater hip extensor impulse than SQ ($P = 0.50$). Results are expressed as a percentage of the total support impulse in Figure 1.

Findings suggest that SQ and BS activities require different lower-extremity motor programs that may preferentially target different muscle groups in older adults. SQ generates greater knee extensor and ankle plantar flexor impulses; thus, this

Figure 1. Relative contributions of the hip extensor, knee extensor, and ankle plantar flexor impulses.

activity may be preferred by clinicians prescribing exercise for elders with knee and ankle weakness. Conversely, BS generates a greater hip extensor impulse and a greater hip contribution to the total support impulse. This exercise may be most beneficial for elders with hip weakness. In older adults without identified lower extremity weakness, the SQ appears to be the preferred exercise because it generates the greatest total support impulse.

SUMMARY

This study demonstrates statistically significant differences in the generated joint impulses associated with SQ and BS activities in older adults. Future investigations should characterize the muscle recruitment patterns, joint powers, joint work, and relative participant preference associated with these activities.

INTRODUCTION

The human cervical spine can be sub-divided into four units, each with a unique morphology that determines its kinematics and its contribution to the functions of the complete cervical spine. While literature delineating the biomechanical characteristics of the atlas, axis and the typical cervical spine abound, there remain a dearth of studies with regards to the biomechanics of the C2-C3 junction, from which the typical cervical spine commences. The present study of developing and exercising a finite element (FE) model of the C2-C3 segment was undertaken to partially fill the gap in the literature by quantifying its gross behavior under various physiological loads.

MATERIALS AND METHODS

A 3-dimensional FE model of the C2-C3 segment based on a 68-year old male cadaveric spine was developed. The model was developed based on previously reported digitizing techniques, modeling methodology and material models. The C2-C3 segment was subjected to bending moments in the anatomic sagittal, frontal and transverse planes. Five incremental loads of 300 Nmm each were applied uniformly across the superior articular surfaces of C2, while the inferior vertebral body of C3 was rigidly constrained in all directions. The rotational components of relative motion between the C2 and C3 segments under increment moment to maximal moments of 1500 Nmm were computed.

RESULTS AND DISCUSSION

The FE model of the C2-C3 segment (Fig.1) comprised 4580 "8-noded" solid elements for the definition of the bony structures and the intervertebral disc, and 181 tension cable elements represented the spinal ligaments. Surface-to-surface contact elements were used to simulate the joints between the C2 inferior and C3 superior articulating surfaces.

Figure 1: The FE model of C2-C3

The gross biomechanical response of the C2-C3 segment displayed varying non-linear and stiffening characteristics under different loads (Fig 2).

Under applied moments in the sagittal plane, the C2-C3 model exhibited greater stiffness in the extension direction at high loads (>400 Nmm), but at low loads (0 – 400 Nmm), the spinal segment was stiffer under flexion. The variation in stiffness was insignificant for flexion, but the increase in

stiffness was discernable between 200 – 400 Nmm in the extension direction.

Figure 2: C2-C3 Responses under various loads.

Under axially applied incremental torsion loads, the model exhibited gradual stiffening. Coupled motion – in the form of lateral bending in the frontal plane – was observed. In lateral bending exertions, the model predicted a maximum angular motion of 3° at 1400 Nmm, and no variation in stiffness was noted throughout the loading history. The model also predicted coupled motion in the transverse plane.

The simulation of the 45°-inclined facet joints via moving contact elements greatly influenced the kinematics of the C2-C3 segment, while the spinal ligaments and the intervertebral disc controlled the range of motion in all the body planes considered in the present study.

SUMMARY

A 3D FE model of the C2-C3 spinal segment was developed and reported for the first time based on previously published methodology and materials for the lower cervical spine. As such, appreciable levels of confidence in the aforementioned results are expected. The non-linear response and range of motion of the C2-C3 segment were observed to be the concerted efforts of all spinal components and the orientation of articular facets. The model has the potential to supplement various *in vitro* and *in vivo* studies to further the understanding of human cervical spine biomechanics under different load-displacement vectors.

SUBTLE EFFECT OF WALKING SPEED ON MEDIO-LATERAL CENTER OF MASS MOTION IN YOUNG ADULTS

Michael E. Hahn and Li-Shan Chou

Department of Exercise and Movement Science, University of Oregon, Eugene, OR, USA

E-mail: chou@oregon.uoregon.edu

INTRODUCTION

Adequate dynamic stability during gait may be demonstrated by a controlled COM displacement or a well-modulated COM velocity profile. A greater and faster COM motion in the frontal plane, with a slower walking speed, was demonstrated in older adults and individuals with balance disorders (Kaya et al., 1998; Chou et al., 2000). It is not clear how much if any of this increased COM motion is due to a slower walking speed alone. Recent studies showed peak M-L velocity of the COM to be invariant in healthy children (~9 yrs) walking at three different speeds (Cherng, 2001; Hughes et al., 2001). However no data have been reported for the effect of walking speed on COM motion in adult population. The purpose of this study was to quantify the effect of walking speed on COM motion in young adults. It was hypothesized that frontal plane COM motion is not affected by the walking speed.

METHODS

Sixteen young adult subjects (eight per gender; mean age, 24.6 yrs) without neurological or musculoskeletal impairment were asked to walk barefoot, over level ground, in three conditions of chosen speed. The first condition was their preferred gait, and then a noticeably faster condition followed by a noticeably slower condition. Trajectory data were collected using a six-camera HiRes™ system (Motion Analysis Corp., Santa Rosa, CA). Position of the whole-body COM was then calculated using a 13-segment link model, and linear velocities were calculated using the GCVSPL algorithm. A two-way ANOVA with repeated measures of walking speed was used to test for significant effects of gender and/or walking speed on COM displacements and peak velocities.

RESULTS AND DISCUSSION

There were no significant gender effects for any of the variables tested. Significant effects of walking speed were found for all variables tested (Table 1). The M-L COM

displacement decreased as walking speed increased, however the peak M-L velocity was significantly less for both the fast and slow walking speeds when compared with the normal pace. Although these differences were significant, they are relatively small (~1cm in displacement and ~1cm/s in peak velocity), which reflects a robust and precise control of COM motion in the frontal plane of healthy young adults. Furthermore, these walking speed-induced differences are much less than those differences reported between healthy young and elderly (Chou et al., 2000) or between healthy elderly and patients with vestibular dysfunction (Kaya et al., 1998) during level walking.

SUMMARY

Findings of this study demonstrated that, in young adults, walking with a faster/slower speed causes a subtle but significant change in the frontal plane COM motion. This information provides more insight into the use of COM motion as an objective measurement of dynamic stability. It remains to be seen what effects walking speed may have on COM motion in elderly adults.

A PARAMETER TO DESCRIBE COORDINATION OF HIP AND KNEE FLEXION DURING OBSTRUCTED GAIT

Michael E. Hahn and Li-Shan Chou

Department of Exercise and Movement Science, University of Oregon, Eugene, Oregon

E-mail: chou@oregon.uoregon.edu

INTRODUCTION

During obstacle crossing, healthy adults increase toe-ground/obstacle clearance from an average of 3 cm during level walking to approximately 10-15 cm over an obstacle (Chen et al., 1991; Patla et al., 1996; Chou et al., 1997) to minimize the risk of tripping. The hip, knee and ankle joints of the swing limb are modulated for phase and amplitude of flexion to ensure appropriate elevation of the swing foot over the obstacle (Patla et al., 1996). Due to a different proximity of the swing foot at the time of toe-off with the location of the obstacle, strategies with emphasis on different joints are adopted to elevate the swing foot to clear the obstacle (McFayden and Winter, 1991; Patla et al., 1996; Chou et al., 1997). The purposes of this study was to define a parameter that could describe different coordination strategies of hip and knee flexion of the leading and trailing limbs during obstacle crossing and to examine its relationship with the obstacle height in healthy young adults.

METHODS

Six healthy young adults (mean age, 24.8 years) were recruited for this study. Whole body kinematic data were collected using a six-camera HiResTM system (Motion Analysis Corp., Santa Rosa, CA) during unobstructed walking and when stepping over an obstacle of height corresponding to 2.5%, 5%, 10%, or 15% of the subject's body height (BH). All trials were conducted at a comfortable self-selected walking speed while barefoot. The order of obstacle height was randomly selected. Flexion angles of the hip and knee joints were plotted one against the other, from toe-off to heel-strike for each limb. A coordination slope was then calculated to represent the overall trend of joint coordination for each limb (Fig. 1). Graphical midpoints were calculated between toe-off (LTO, TTO) and heel-strike (LHS, THS). For each limb, the slope of the line between the midpoint and the apex of the coordination curve represented the overall hip/knee coordination during the obstacle-crossing stride. A one-way ANOVA with repeated measures for obstacle height was used for each limb to test the effect of obstacle height on coordination of the hip and knee.

RESULTS AND DISCUSSION

During unobstructed walking, the coordination slope between knee and hip flexion had an average value of 0.181, which implies a favor of flexing knee joint to the swing foot with the floor. This can be explained from the aspect of energy efficiency. During obstacle crossing, the coordination slope of the leading limb demonstrated a value from 0.447 ± 0.09 for the lowest obstacle to a value of 0.602 ± 0.06 over the highest obstacle. A significant effect of obstacle height on the joint coordination slope of the leading limb was identified

Figure 1. Representative joint coordination plot of the 15% BH obstacle condition, defining the slope of each limb.

($p=0.001$). These greater values of the coordination slope reflect that a relatively greater contribution from the hip flexion, as compared to the knee flexion, is required to safely step over a higher obstacle. The coordination slope of the trailing limb increased slightly from that of unobstructed walking to an average value of 0.247 ± 0.06 across all obstacle heights. This indicated that the joint coordination strategy of the trailing limb remains unchanged regardless of obstacle height, with foot elevation being achieved primarily through knee flexion

SUMMARY

The joint coordination slope provides us information on the overall strategy adopted by the swing limb when walking on different terrains. Inability to coordinate motion of hip and knee joints may result in obstacle contact, increasing the risk of tripping and falls. Results of this study could potentially serve as a baseline for comparing the functional strategies adopted by patients with joint pathology, muscular strength deficits or post-surgical complications.

BIOMECHANICAL PROPERTIES OF TOTAL ANKLE ARTHROPLASTY AND ANKLE ARTHRODESIS

Victor Valderrabano¹, Beat Hintermann¹, Benno M. Nigg², Darren Stefanyshyn², Pro Stergiou²

¹ Clinic of Orthopaedic Surgery, University of Basle, Kantonsspital, 4031 Basel, Switzerland; v.valderrabano@bluewin.ch

² Human Performance Laboratory, Kinesiology, University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

Ankle arthrodesis and total ankle arthroplasty are the surgical treatment possibilities for severe ankle arthritis. The ankle arthrodesis is a well-established and accepted method, but has a few biomechanical and clinical disadvantages: Gait abnormality, degeneration of adjacent joints, pseudoarthrosis, stress fractures. The new total ankle replacement (TAR) generation shows encouraging clinical results and represent nowadays a valuable alternative to the ankle fusion. Although biomechanical comparison studies could provide important data for determination of the future development in this field, they are still extremely rare. The purpose of this in vitro study was therefore to determine the biomechanical characteristics of the ankle before and after ankle arthrodesis and after implantation of three currently used total ankle prostheses. The ankle range of motion (ROM), ankle movement transfer and the talar coupled movement were investigated.

METHODS

A 6 degrees-of-freedom device (Fig. 1) with an axial load of 200 N, and a camera high speed video system (Motion Analysis Corporation, Santa Rosa, CA, USA) were used. Data collection was performed on 6 fresh frozen cadaveric leg specimens after insertion of reflective hindfoot bone markers and performance of the different ankle surgeries. All five conditions (normal ankle, ankle fusion, AGILITY [AGILITY™ Total Ankle System, DePuy Inc., USA],

S.T.A.R. [Scandinavian Total Ankle Replacement, Waldemar Link, Hamburg, Germany], HINTEGRA [HINTEGRA®, Newdeal SA, Vienne, France]) were performed in each case on the same foot. Three-dimensional bone marker positions were calculated using a direct linear transformation (DLT) procedure (EVA software, version 6.0). The 3-D co-ordinates of the markers were transferred into other software for analysis (Kintrak, version 6.0, The University of Calgary, Calgary, AB, Canada). Relative joint angles and translations were calculated as rotations or shift between the bones of interest for a specific movement. The input movements were performed dynamically and statically (100N). Significant condition effects were detected using ANOVA and paired student t-tests.

RESULTS

ROM: Compared to the normal condition, the ROM for dorsi-plantarflexion had the highest change for the ankle arthrodesis.

The total ROM for eversion/inversion was slightly decreased by the fused ankle, not changed by the three-component prostheses (HINTEGRA, S.T.A.R.) and increased by the two-component prosthesis (AGILITY). The ROM for internal and external tibial rotation was not altered by the AGILITY and HINTEGRA ankle, but it was significantly reduced by the ankle arthrodesis. S.T.A.R. showed a significant shift of the total ROM towards internal tibial rotation.

Movement Transfer: While dorsi-/plantarflexion of the foot, ankle joint fusion increased the movement transfer to tibial rotation by a 2.4 factor and to eversion-inversion by a 18.5 factor; whereas, this movement transfer did not change for all prosthesis conditions. The movement transfer between foot eversion and tibial rotation was found to decrease for all ankle prostheses.

Talar movement: In the normal ankle, dorsi-plantarflexion movement was coupled with rotation of the talus about its longitudinal axis and medio-lateral talar shift. While the three-component prostheses (HINTEGRA, S.T.A.R.) did not show no changes to the normal condition, AGILITY was significantly decreased and therefore constrained in both coupled movements.

DISCUSSION AND SUMMARY

Physiological range of motion and intact coupled movements of the ankle are very important for natural human foot function. A pathological ROM or movement transfer result in abnormal gait kinematics and high rate of second degeneration and injuries. The ankle fusion alters the normal biomechanics with a decrease of ROM and an increase of movement transfer leading to an overstress of neighboring joints. The total ankle prostheses changed the kinematics parameters of the ankle joint complex less than the ankle arthrodesis. The three-component total ankle prostheses were shown to replicate the normal ankle joint closer as the two-component design. In the surgical treatment of severe ankle arthritis an anatomical shaped, three-component total ankle replacement can be seen as the biomechanical “gold-standard”.

FINITE ELEMENT MODEL OF THE EPIDERMIS-DERMIS INTERFACE

Nelson Morales^{1,2}, Dongbu Cao², Yan Chen², Brian L. Davis²

¹NASA Glenn Research Center

²Department of Biomedical Engineering - Cleveland Clinic Foundation

INTRODUCTION

Usually, when the skin is represented using finite element models, the interface between the epidermis and dermis is shown as a flat line. In reality, this interface is not flat, but rather consists of so-called “rete ridges” (Figure 1). Neglecting the ridges can yield to incorrect results because of the large difference in stiffness between the two layers (one order of magnitude). These irregularities could prevent relative slipping between layers when the skin is subjected to shear loads. Thus the purpose of the current study was to obtain a quantitative effect of different epidermal-dermal (E-D) configurations and compare these with the flat configuration.

Figure 1: Epidermis-dermis beneath first metatarsal head

METHODS:

A 3D finite element model of a small section of the skin was created to compare the effects of the ridges and their frequency. Four different configurations were investigated: one flat and three others with sinusoidal ridges at the epidermal-dermal interface. The model was initially created in a 2D plane (x-y plane) and later extruded in the z-direction. The overall size of each model was 3mm x 1mm x 0.2 mm. Each model had approximately 140,000 elements and 155,000 nodes. The model was preprocessed in PATRAN® and analyzed using the commercial finite element model code, ABAQUS®. All the models were analyzed separately.

The ridge sizes were compared to real sample data obtained from the skin of the soles of cadaver feet. Ridge spacing was measured using ResView 3.0. The ridge spacing obtained was 65 μm . This is similar to the width used in the finite element model, 56 μm (high frequency). The other two configurations, mid-frequency (100 μm), and low frequency (252 μm), are variations that may simulate other skin regions or skin conditions. The material properties given to the model were linear elastic. The elasticity moduli used were 20 MPa for the dermis, and 200 MPa for the epidermis. Vertical and shear loads were applied in the x-z plane. The loads consisted of a compressive load of 200 kPa (to simulate the body weight on the foot) and a shear stress of 20 kPa (to simulate the friction forces when walking). Constraint boundary conditions

were applied on the top nodes to prevent free body motion.

RESULTS

All the configurations were compared on the basis of their Von Mises stress. The table below shows a summary the Von Mises (VM) stresses for all the configurations. These stress values occur at the interface region and represent local peak values. Also, since VM stress does not indicate whether the stresses are compressive or tensile, principal stresses were examined. It was found that the values given below are associated to compressive (negative values) stresses at the interface. The overall peak stress of the model was very similar in all the configurations (550 kPa), but it occurred at the constrained region, away from the epidermis-dermis interface. Also, the models stress distribution in the regions away from the epidermis-dermis interface was very similar in all the configurations.

Table 1: VM Stress at E-D interface for all configurations

Configuration	VM Stress Range in Dermis (kPa)	VM Stress Range in Epidermis (kPa)
Flat	246-283	250-273
Low frequency	400-480	75-90
Mid frequency	400-520	64-75
High frequency	380-504	55-73

DISCUSSION

As shown above, representing the epidermis-dermis interface as a flat interface can yield inaccurate results. These results neglect the peak stresses at the interface. Including rete ridges in the model reveals that the interface stress are approximately twice as much as a model without the ridges. Although models like these can be computer intensive, submodeling can be used to obtain results of a larger region, such as the entire foot, relatively faster without using excessive computing resources. Also, it can be noticed that the models with the three different ridges yielded very similar results.

INTRODUCTION

The objective of this study is to examine the load distribution in the knee joint between the articular cartilage and the meniscus and the role of the interstitial fluid in stress distribution in the tissues.

METHODS

An axisymmetric finite element model of the knee joint was developed, based on geometric approximations obtained from the literature for the menisci and the articular cartilage. The solid phase of the meniscus was modeled with anisotropic material properties, being much stiffer circumferentially than radially. The joint was studied under an axial load of approximately double the average human body weight (1400 N) applied in 0.34 seconds using a commercial FEM package (ABAQUS 6.1). The initial gap between the articular cartilage surfaces was varied from 0mm to 1mm in 0.25mm steps. The meniscus and the articular cartilage were modeled as saturated biphasic materials consisting of solid and interstitial fluid. Stress states in the meniscus were compared with the locations of the different meniscal cell phenotypes identified earlier^(Hellio Le Graverand, 2001).

RESULTS AND DISCUSSION

Load deflection curves obtained from our model for different initial gaps between the cartilage layers are similar to the experimental results obtained from porcine and human knee joints^(Shrive, 1974). The vertical loads between the femur and the tibia are mainly carried by the interstitial fluid. The presence of the meniscus decreases the magnitude of the pore water pressure and the stresses in the articular cartilage compared to the meniscus deficient knee. The meniscus carries 50-75% of the load depending upon the initial gap between the articular cartilage surfaces.

The state of stress in the meniscus varies tremendously from inner to outer radius. At the inner periphery, there are high hydrostatic fluid pressures and low circumferential tension, whereas the opposite occurs at the outer periphery (Fig. 1, 2). Interestingly, these different stress states correspond with the varying cell phenotype detected in the rabbit meniscus⁽¹⁾. Chondrocytic cells are observed towards the inner periphery, with increasing cellular networks and

processes to the outer edge where the cells are fibrocytic and aligned predominantly circumferentially.

Fig. 1. Circumferential stress in the meniscus at 1400 N.

Fig. 2. Pore Pressure Distribution in the meniscus at 1400 N.

SUMMARY

Modeling soft tissues as a biphasic mixture of a solid and a fluid phase demonstrates the behavior of those tissues under compression as a nearly incompressible material with very low shear properties. The results obtained also show how the morphology of the meniscus is well adapted for transmitting load across the knee.

INTRODUCTION

Ligaments are composed of solid matrix and fluid phases. When ligaments are stretched, an increase in volume would be expected to lead to a negative pore pressure inside the tissue. This pressure would, in turn, cause an inward flux of fluid. However, experiments have shown that when the ligaments are stretched, there is an outward flux of fluid^(Hannafin, 1994) suggesting a decrease in volume. We have investigated this unique behaviour and have found three mechanisms which may contribute to the expected observations: the slackness of the fibres before stretching can lead to a decrease in volume upon straightening; a poisson's ratio higher than 0.5 from the axial to the lateral direction (as recorded in the literature^(Hewitt, 2001)) due to the very high level of anisotropy of the tissue; and a constant osmotic pressure that causes the swelling of the tissue before loading^(Thornton, 2001), together with a certain level of anisotropy. These mechanisms may not be the only ones to cause the observed fluid exudation on tensile loading.

METHODS

Each mechanism was studied separately. For the case of fibre slackness, a simple mathematical model was used with a parabolic curve for the outer fibres (a barrel shaped ligament). The value of the volume change after straightening of the fibres was calculated and shown to be lower than the initial volume (**Fig. 1**). For the case of high poisson's ratio in anisotropy, a finite element model of a ligament was constructed and analysed through poro-elastic theory. The ligament was taken to be 12 mm long and 2 mm in diameter. Axisymmetric elements were used. A high level of anisotropy was implemented with three values for the ratio of lateral strain to longitudinal strain taken 0.3, 0.5 and 0.7. The same finite element model was used with a smaller poisson's ratio (0.3). To assess osmotic swelling a constant positive pore pressure was imposed on the surface simulating an osmotic pressure which caused the tissue to swell with time. The ligament was then stretched for different levels of anisotropy measured by the values of E_2/E_1 (Longitudinal stiffness/horizontal stiffness) and G/E_1 (in plane shear stiffness/horizontal stiffness). The ligament was considered to exude fluid when—at one point during the stretching process—all the values of the fluid pressure inside the ligament were higher or equal to the imposed osmotic pressure.

RESULTS AND DISCUSSION

Results of the simple mathematical model show that for curved fibres, very small strains are required to straighten the fibres. However, these strains cause a tremendous decrease in volume, depending upon the slackness of the fibres. For the finite element model with different poisson's ratio, results show that for a poisson's ratio higher than 0.5, the ligament tends to exude fluid. Finally, the osmotic pressure that tends to swell the ligaments is another cause for the phenomenon of fluid exuding from ligaments. Results show that the value of the imposed osmotic pressure that would cause fluid exudation depends on the anisotropy of the material. For high stiffness in the longitudinal direction and low shear stiffness, the value of the osmotic pressure required to exude fluid is less than that required for a ligament with less longitudinal stiffness and higher shear stiffness.

Fig. 1. (a) The assumed barrel shape of the ligament before stretching. (b) Ligament shape after stretching.

SUMMARY

Ligaments tend to exude fluid upon stretching. This phenomenon was investigated and was related to one or more of three mechanisms: Slackness of fibres; high poisson's ratio; and the osmotic pressure that causes ligament swelling.

THE “MINIMUM CRACKLE” HYPOTHESIS FOR MANIPULATING MASS-SPRING OBJECTS SMOOTHLY

Jonathan B. Dingwell¹, Christopher D. Mah², and Ferdinando Mussa-Ivaldi²

¹Department of Kinesiology and Health Education, The University of Texas, Austin, TX

Email: jdingwell@mail.utexas.edu Web: <http://www.utexas.edu/education/kinesiology/motorbe/dingwell.html>

INTRODUCTION

Humans make “smooth” movements during point-to-point reaching tasks, adopting optimal “minimum jerk” trajectories (Flash & Hogan, 1985), defining in effect the lowest order polynomial (5th) to satisfy the boundary conditions (BC) imposed by the task. Tasks where the end-point of a non-rigid object is controlled impose additional BC on reaching, requiring new optimal solutions. Indeed, humans adopt very different kinematics when manipulating mass-spring objects (Dingwell et al., 2002). This study determined if these kinematics are also optimally smooth in the same sense as minimum jerk.

METHODS

The task studied was reaching to a target with a mass-on-a-spring attached to the hand. The object’s dynamics were:

$$M_O \ddot{r}_O = -K_O(r_O - r_H) \quad (1)$$

where M_O =object mass, K_O =object stiffness, r_O =object displacement, and r_H =hand displacement. Both the hand and object were to be stationary (i.e. $\dot{r}_O = \dot{r}_O = \dot{r}_H = \dot{r}_H = 0$) at the beginning ($t = 0$) and end ($t = T$) of the movement. Minimum jerk trajectories cannot satisfy all of these BC. Therefore, we propose a cost function for this task that minimizes the mean squared “crackle” (5th derivative of displacement) along r_O :

$$C[r_O(t)] = \frac{1}{2} \int_0^T \left\{ d^5/dt^5 [r_O(t)] \right\}^2 dt = \frac{1}{2} \int_0^T [\ddot{r}_O]^2 dt \quad (2)$$

Solving the Euler-Poisson equation (Flash & Hogan, 1985) subject to this cost function gives a general 9th order polynomial solution for $r_O(t)$. Applying the appropriate BC gives:

$$r_O(t) = L \left[70 \left(\frac{t}{T} \right)^9 - 315 \left(\frac{t}{T} \right)^8 + 540 \left(\frac{t}{T} \right)^7 - 420 \left(\frac{t}{T} \right)^6 + 126 \left(\frac{t}{T} \right)^5 \right] \quad (3)$$

Hand trajectories are obtained by substituting (3) into (1) and solving for $r_H(t)$. Contrary to minimum jerk predictions, the minimum crackle hypothesis predicts that faster movements or movements made with objects of lower resonant frequency (f) will require bi-phasic hand movements (Fig. 1B).

To test these predictions, 12 young healthy subjects (6M+6F; age = 28.7±3.0 yrs) made targeted reaching movements with their dominant arm using a robot (Fig. 1A) that imposed forces simulating various mass-spring objects. Subjects were given 1-2 days (2-4 hours) to become skilled at the task, but were not told *how* to solve the task. Subjects were then tested under a variety of task conditions to compare their movements with those predicted by the minimum crackle model.

RESULTS

All subjects exhibited uni-phasic or bi-phasic hand movements under task conditions where the minimum crackle hypothesis predicted that they should (e.g. Fig. 2). Furthermore, all subjects switched from uni-phasic to bi-phasic hand movements

(and back again) when the task conditions changed accordingly. Subjects exhibited behavior generally consistent with all predictions made by the minimum crackle model.

Figure 1: A: 2-DOF robot used to simulate mass-spring objects. B: Predicted hand velocity profiles for (left) different total movement times (T) and (right) different object resonant frequencies (f).

Figure 2: Predicted (“ideal”) and actual hand velocity profiles for a typical subject reaching with 3 different mass-spring objects.

DISCUSSION AND SUMMARY

These results demonstrate that the ability of humans to generate smooth movements extends beyond simple reaching, to manipulation tasks involving non-rigid objects that impose additional degrees-of-freedom on the system being controlled (i.e. the arm). This does *not* necessarily mean that the brain is explicitly computing “crackle”, but it does provide further evidence that “smoothness” in this sense is a general principle that guides movement planning and control.

ECHO-PIV®: A NOVEL METHOD FOR THE NON-INVASIVE MEASUREMENT OF VELOCITY VECTORS USING ULTRASOUND IMAGING

Hyoungh-Bum Kim¹, Jean Hertzberg¹, and Robin Shandas^{1,2}

¹Dept. of Mechanical Engineering, University of Colorado, Boulder, CO, USA

² Cardiovascular Flow Research Laboratory, The Children's Hospital / University of Colorado Health Sciences Center, Denver, CO USA shandas.robin@tchden.org

INTRODUCTION

The inherent angle-limitation of current ultrasound Doppler imaging techniques precludes the ability to quantify parameters such as fluid stress, vorticity, or complex velocity profiles. Such information should allow clinicians to develop a more comprehensive picture of cardiovascular hemodynamics non-invasively. We have recently developed a novel method to measure multiple-components of velocity using high frame rate (>100 fps) echocardiography coupled with contrast imaging. This method, Echo-PIV®, is an *in vivo* equivalent of laser-based particle image velocimetry methods used *in vitro* for flow quantitation.

METHODS

The utility of Echo-PIV® to quantify various flow conditions was tested in a series of *in vitro* flow phantoms ranging from simple steady and pulsatile flows (0.5 – 3 L/min) through a tube, to complex pulsatile flow (30 – 80 cc/beat; 50 – 80 bpm) through a bileaflet mechanical heart valve. High frame rate echocardiography (>100 fps) and contrast imaging (Optison®) was used to image the flow patterns from both short and long axis views. Each image frame was digitally stored without compression and transferred to an off-line analysis system. A two-dimensional spatial cross-correlation algorithm was used to extract mean spatial shift of contrast particles within smaller sub-windows (16X16 pixels; 32X32 pixels) of the image frame. The local 2D velocity vector was then obtained by dividing the spatial shift vector by the time difference between consecutive frames.

RESULTS AND DISCUSSION

Figures 1 and 2 show velocity vector plots from the steady-flow tube studies (1) and the bileaflet mechanical valve (2). Figure 1 shows that Echo-PIV can measure velocity profiles across an arterial or venous cross-section; this information can be used to compute wall and fluid shear stresses. Figure 2 shows the two side jet flows issuing obliquely from the valve as well as the central jet.

Figure 1: Velocity vectors for steady flow through an arterial model as measured by Echo-PIV®.

Figure 2: Velocity vectors immediately distal to a bileaflet mechanical heart valve (S,C,S: side, central, side orifices).

SUMMARY

Echo PIV® appears to be a promising method for the non-invasive measurement of multiple velocity vectors *in vivo* without angle limitations, and should raise the accuracy of hemodynamic information that can be obtained using echocardiography.

DERIVING ROWING COORDINATION PATTERNS AND BOAT RIGGING FROM OPTIMIZATION OF A SIMPLE MODEL

David Cabrera and Andy Ruina

Human Power and Robotics Laboratory, Theoretical and Applied Mechanics, Cornell University, Ithaca, NY, USA
<http://www.tam.cornell.edu/~ruina/hplab/index.html>

INTRODUCTION

Trusting that the rowing stroke has been nearly optimized by the evolution of the sport, we attempt to explain current competitive rowing techniques by optimizing the performance of a simple model. The model is thus verified by its ability to predict various kinematic and force data found in actual rowing.

Once such realism has been achieved, the model can be used to check the advantages of various possible design changes for racing boats. It is hoped, for example, that the ideas could help test changes in rigging on a person-by-person basis, for upwind or downwind races, making use of work by the coxswain, etc.

More generally, however, finding which optimization criteria make for the best matches with used-technique validates the overall modeling strategies for better understanding of other human and animal activities.

METHODS

We develop a mathematical model of the mechanics of the rowing stroke that is quasi-one-dimensional. Momentum balance only in the fore-aft direction is considered. Mass is distributed in two places, the boat and the rower's gut. The controlled degrees of freedom are leg length, back angle, and arm length as functions of time. The arc-like motion of the oar blade and handle is considered when calculating the fore-aft mechanics. That is, we allow the oar to sweep through large angles instead of assuming small angular motion as is done in some other simple models. The oar is flexible and the oar blade has wing-like lift and drag properties in the water. Hand raising is assumed to be timed so that there is zero-splash and hand lowering is timed just when the bending of the oar is relieved. We use computer optimization of the coordination (leg length, back angle, and arm length as functions of time) to maximize the boat speed (or minimize race time) with given rower performance limitations. In the simplest model the rower's average rate of metabolic cost is bounded and metabolic cost is proportional to the joint work of the leg, back, and arm actuators (counting negative work as slightly costly). In this optimization we can also leave free to optimize the oar length and oarlock position (fore-aft and outboard).

We parameterize the control functions of the body part motions in time using periodic cubic splines. The splines

consist of knots which are evenly spaced in time and, thus, the body displacements at the knot times are the parameters over which we optimize. The knot values, as well as a few rigging parameters, determine, through the simulation, both the metabolic cost and the boat speed. In addition to the metabolic work limitation, we place upper and lower bounds on the amount the various body parts can displace. Matlab®'s nonlinearly constrained optimization routine, 'fmincon', is used to determine the optimal coordination strategy as well as the optimal boat rigging parameters. The model and optimization criteria are evaluated in terms of how well they predict present rigging practice and present popular rowing technique as determined by available kinematic and force data.

RESULTS AND DISCUSSION

We have been able to "derive" both rowing technique and common rigging as well as might be hoped with a simple model. Due to the flatness of the objective function, once constrained, near the optimum, we see very little change in the average boat speed when searching in this neighborhood of the parameter space. Therefore, we find multiple coordination strategies which produce similar average boat speeds at a given metabolic cost. However all of these strategies have some common features, the most conspicuous of which is the near absence of negative-work by all of the body parts.

SUMMARY

Our quasi 1D model, with 2D oar mechanics, with an energy based model of human performance, is surprising predictive of some aspects of rowing coordination. That is, even without putting any bounds on the strengths of any muscles, or indeed any information about the muscles at all, much of rowing can be explained. Overall this predictive ability adds some credence to the view that energetics has an important role in explaining human and animal coordination patterns.

THE FINITE ELEMENT ANALYSIS OF DIFFERENT FIXATIONS FOR MANDIBULAR FRACTURE

Chih-Hung Chuang¹, Ming-Yih Lee¹, Lun-Jou Lo² and Chun-Li Lin¹

¹Department of Mechanical Engineering, Chang Gung University, Tao-Yuan Taiwan, d9022003@stmail2.cgu.edu.tw

²Craniofacial Surgery, Chang Gung Memorial Hospital, Tao-Yuan, Taiwan

INTRODUCTION

Plates and screws fixation system is commonly used to fix the bone segments for craniofacial trauma fracture and malformation orthopedics. The long-term success of surgery is influenced by biomechanical aspects, such as stress concentration and bone remodeling that related to the insecure fixation philosophies. However, quantification guideline cannot identify by clinical experiences and experimental approaches. Therefore, computer analysis is needed to use as a complementary tool to understand the mechanical interactions between fixation system and surrounding bone.

METHODS

Medical image software (MIMICS 6.3) was employed to process coronal CT data of a healthy male mandible. A 3D FE model included cortical and cancellous bone was constructed in FEA package (ANSYS 5.6) through self-developed program that transformed CT data to ANSYS. Reducing Young's modulus procedure was used to simulate for mandibular fracture volume and four types of fixation philosophies were then designed to model different fixation system. The mandibular condyle and coronoid process was constrained as the boundary conditions. Vertical occlusive forces were applied as the loading conditions at premolar and molar symmetrizing to the symphysis. The peak von Mises stresses and the displacements for all designs were calculated to investigate the mechanical responses.

RESULTS AND DISCUSSION

The peak stress and displacement of fixation type A were lower than B, C and D (Table 1). However, considered about the anatomy and parasymphysis location of mandible that

fixation type D might be the better chose among four designs. This was because the higher bending moment acted on the B and C fixation that might cause the excessive stress concentration and displacement. These biomechanical interactions could lead the bone surrounding screws damage and malocclusion during healing. After bone healing, the stresses distribution and displacements of the bone surrounding screws was observed no significantly.

Figure 1: (a) The mandible FE model; (b) The von Mises stress patterns for D fixation type.

SUMMARY

Based on the limited data, the results indicated that fixation philosophies might influence the stress redistribution near the screws and surrounding bone.

TANGENTIAL FORCE SHARING AMONG FINGERS DURING STATIC GRASPING

Todd Pataky¹, Vladimir Zatsiorsky, and Mark Latash

Department of Kinesiology, The Pennsylvania State University, University Park, Pennsylvania, USA

¹tcp120@psu.edu

INTRODUCTION

Multi-finger grasping is statically indeterminate; the number of unknown finger forces exceeds the number of equilibrium equations. As such, normal force sharing has received substantial attention in the literature (e.g. Santello and Soechting, 2000). Far fewer studies exist in the literature regarding tangential finger forces (e.g. Flanagan et al., 1999). Tangential force sharing for “natural” prismatic grasping (4 fingers opposing the thumb) has not been addressed. The purpose of this study was to examine the tangential (load sustaining) force sharing at the fingertips as a function of both load magnitude and load direction.

METHODS

Eight subjects (age: 28.1 ± 5.9 years) were required to grasp a handle “as lightly as possible, while keeping the handle stationary”. The handle was free to rotate about a central axis (Figure 1) to tightly prescribe a zero net moment. Three loads (250, 750, 1250 g) were applied to the handle in both the downward and upward vertical directions. Upward loading was achieved with a leveled steelyard mechanism (Figure 1). Fingertip forces were registered with multi-axis force transducers (ATI, North Carolina, USA).

Figure 1: Rotating handle to prevent moment production (left); steelyard mechanism to achieve upward loading (right).

RESULTS AND DISCUSSION

Load sharing (% of the total tangential force) was evidently not constant (Figure 2). The mean sharing pattern changed more notably with load direction than with load magnitude. Notably, the thumb decreased its tangential force by about 15% of the total load when required to resist the applied load by pushing in a downward direction. The index finger conversely increased its tangential force by about 15% of the total load. The standard deviations associated with these percentages were less than 4% for the majority of conditions. Note that subjects were free to choose any tangential force sharing pattern desired provided that the sum of these forces was equal in magnitude and opposite in direction to the load. It may be expected that individual subjects select distinct sharing patterns because of the large number of possible patterns, but this was not observed. Another trend that was observed was the fact that the thumb did not produce 50% of the total tangential force. This indicates that the tangential forces contributed to a supination moment (for downward loading) and a pronation moment (for upward loading) despite constant hand posture.

SUMMARY

- 1) This is the first study to examine tangential force sharing, and patterns of this sharing have been presented.
- 2) The tangential force sharing pattern was more markedly affected by load direction than by load magnitude.
- 3) The subjects selected quite similar tangential force sharing patterns despite the high degree of redundancy in the task.

The current line of work will be important for understanding object manipulation, where the gravitational field can change with respect to the hand.

EVALUATION OF SPINAL IMPLANTS - VERTEBRAL BONE DENSITY IS AN IMPORTANT FACTOR

Juay-Seng Tan, Brian K. Kwon, Dinesh Samarasekera, Marcel F. Dvorak, Charles G. Fisher and Thomas R. Oxland
toxland@interchange.ubc.ca

Department of Orthopaedics, University of British Columbia, Vancouver, British Columbia, Canada

INTRODUCTION

The current ASTM standard for spinal implant constructs uses synthetic elements as vertebral surrogates and therefore does not address bone-implant interface issues. Presumably, this interface is important since it is a frequent site of clinical failure. Variation in implant designs could result in different degrees of trabecular bone failure at the interface and by testing implants in synthetic materials, this important factor is not evaluated. Therefore, devices tested using ASTM test standards may give clinicians and regulatory bodies a false sense of security with respect to implant performance due to their limited scope. The purpose of this study was to contrast the mechanical behaviour of pedicle screws in cadaveric vertebrae versus synthetic surrogates.

METHODS

Short-term physiologic axial compression and bending moment were cyclically applied to pedicle screws inserted in lumbar vertebrae and UHMWPE. The maximum applied load consisted of a 300N vertical force and a moment arm of 35mm resulting in a 10.5Nm bending moment (Figure 1). These loads were based on *in vivo* measurements (Rohlmann 1997). Loads were applied to a hinged PE block superiorly and the inferior vertebrae and PE were rigidly clamped. An optoelectronic system (Optotrak 3020, Northern Digital Inc., Waterloo, Canada) was used to detect motion of the screw with respect to the bone and PE in each test. Motion of the inferior pedicle screws with respect to vertebrae and PE at the end of 100 cycles were compared. Eight lower lumbar vertebrae (L3, L4, L5) were tested and one PE was tested 8 times. One side of each vertebra was overdrilled so as to compare between motion of pedicle screws in normal insertion and loosened pedicle screws. The vertebrae were from a previous indentation test and the pedicles were all intact. Lateral DEXA bone mineral density of these specimens ranged from 0.30 to 1.04 g/cm² with a mean of 0.70 g/cm². An unpaired t-test was used to determine if there was any difference between the translation and rotation ranges between screws in UHMWPE and screws in bone inserted in the normal fashion. A paired t-test was used to compare between pedicle screws in normal and in overdrilled holes.

RESULTS AND DISCUSSION

Motions of pedicle screws in PE were significantly smaller than in vertebrae (Figure 2). There was a trend that specimens with higher bone mineral densities had lower translation and rotation ranges. The kinematics of the screw was affected by bone mineral density. Screws inserted in high-density bone were pivoting about a point between screw head and screw tip, whereas screws inserted in low-density bone underwent a translation and a rotation under each cycle of load. It was clear that bone mineral density affects the kinematics of the screw and the bending points on it.

Figure 1: Test setup used to compare motion of pedicle screw in bone and in UHMWPE.

Figure 2: Motion of pedicle screw in UHMWPE was significantly lower than motion in vertebrae ($p < 0.005$). There was no significant difference for screw motion in the vertebrae between normal insertion and after overdrilling.

CONCLUSION

The kinematics of pedicle screws in bone and in PE are different in terms of the range of motion, pivoting and bending points of the screws and in terms of the effects of bone mineral density. The kinematics of the screws in bone is more relevant to clinical modes of failure. The fixation at the bone-implant interface can be quantified during short-term cyclic testing when an appropriate model is used, as demonstrated in this study.

EFFECTS OF AGE AND TIME PERIOD ON JOINT KINEMATICS AND KINETICS DURING A SINGLE STEP RESPONSE

INTRODUCTION

Aging increases the frequency of injurious falls in the elderly (Tinetti, 1989). Taking a step is a strategy often used to arrest an impending fall when balance disturbances are encountered during activities of daily living. The generation of rapid, coordinated muscle actions about lower extremity joints is believed to be an important biomechanical component underlying successful stepping responses. The purpose of this study was to investigate the effect of age and time period (double stance, single stance, and landing) on the kinematics and kinetics at the ankle, knee, and hip joints used to execute a single step in response to a posterior waist pull.

METHODS

The performance of using a single step for balance recovery in response to a posterior waist pull was measured in 11 young adult (mean age 23.7, $SD = 4.1$ yrs) and 11 old adult (mean age 69.6 yrs, $SD = 5.2$ yrs) healthy female participants. Each participant gave her informed written consent as approved by the institution's review board on human experimentation. The posterior waist pulls were produced using an electronically released weight and cable system (Luchies, 1999). Foot-support surface reactions (AMTI) and body segment kinematics (Optotrak, NDI) were measured and analyzed using an inverse dynamics model (Vaughn, 1999) to determine the ankle, knee, and hip joint kinematics and power time histories during three time periods: double stance, single stance, and landing (Figure 1). Step foot liftoff and landing times, step length, height, and average speed were also determined. A two-way MANOVA was conducted on the dependent variables. Significant main effect findings ($p < 0.05$) were followed up with an ANOVA on each variable. Type I error was controlled for by using the Bonferroni Method.

RESULTS AND DISCUSSION

The old adults, compared to young adults, had earlier liftoff times ($p < .05$), earlier landing times ($p < .01$), shorter step lengths ($p < .001$), shorter in step height ($p < .005$), and slower average step speeds ($p < .001$). The old adults, compared to young adults, had significantly smaller flexion/extension joint excursion angles at the step leg ankle ($p < .005$), knee ($p < .05$), and hip ($p < .001$).

The landing period, compared to the double stance period, resulted in significantly larger flexion/extension joint excursion angles at the step leg ankle ($p < .05$), knee ($p < .001$), and hip ($p < .001$); larger power generation for the step leg knee ($p < .001$); and larger power absorption for the step leg ankle ($p < .001$) and hip ($p < .001$).

The landing period, compared to the single stance period, resulted in significantly larger joint excursion angles at the step leg ankle ($p < .001$); larger power generation in the step leg ankle ($p < .001$), knee ($p < .05$), and hip ($p < .001$); and larger power absorption in the step leg ankle ($p < .001$), knee ($p < .005$), and hip ($p < .05$).

Figure 1: Foot forces, step leg joint powers and torques.

SUMMARY

Significant age and time period effects were found in the kinematics and kinetics in the step leg for a single step taken in response to a posterior waist pull. Older adults, compared to younger adults, stepped earlier and with a smaller step, resulting in smaller joint excursion angles. Despite the differences in kinematics, the underlying joint powers were similar between the two groups. Step landing resulted in larger joint powers than step initiation or swing. Thus, the landing period may represent the most challenging period of the stepping response in terms of joint kinetics, especially for those with limited capacity to generate muscle power quickly.

INTRODUCTION

The shape of a curved line that passes through thoracic and lumbar vertebrae is often used to study spinal deformity with measurements in “auxiliary” planes that are not truly three-dimensional (3-D). Here we propose a new index, the geometric torsion (3-D intrinsic property of a curve), which could uniquely describe the spinal deformity. In this study we assessed whether geometric torsion could be effectively used to predict spinal deformity with the aid of multiple linear regression.

MATERIALS AND METHODS

Anatomical landmarks (6 points per vertebra) were obtained from multi-view radiographic reconstruction and used to generate 3-D model of the spine and rib cage of 28 patients. Fourier series best fitted to the vertebral centroids approximated the spinal shape. For each patient, spinal deformity indices were computed. Torsion was calculated (Frenet formulas) and 20 derived parameters were recorded. Torsion inputs were used in a multiple linear regression model for prediction of key spinal indices.

RESULTS AND DISCUSSION

The primary clinical Cobb angle (mainly thoracic) was predicted well, with $r=0.89$ using all 20 inputs of torsion or $r=0.83$ (Figure 1) using just two (maximal value and range of torsion in curve).

Figure 1: Actual vs. predicted Cobb angle. Data points are plotted for the 28 primary curves with the regression best-fit line ($y=0.8456x$).

Torsion was also well related (Figure 2) to the orientation of plane of maximal deformity ($r=0.87$). Torsion was less accurate but still significant in predicting maximal vertebral axial rotation ($r=0.77$).

Figure 2: Actual vs. predicted orientation of plane of maximal deformity. Data points are plotted for the 28 primary curves with the regression best-fit line ($y=0.9208x$).

SUMMARY

This preliminary study showed promising results for the use of geometric torsion as an alternative 3-D index of spinal deformity. As expected, the orientation of the plane of maximal curvature, a quasi 3-D measure based on the overall lateral and sagittal curvature of the spine, correlated closely to the geometric torsion. The use of various input variables tended to improve predictive accuracy, though usually only slightly. Careful selection and combination of input indices, therefore, is essential to provide appropriate information and further improve the linear regression model predictive capacity.

Future work will focus on more patients and subgroups, and use of an artificial neural network, a high-order non-linear system, to improve correlations and study the reliability of geometric torsion as an accurate marker of scoliosis progression.

INTRODUCTION

The aim of this research was to explore the biomechanics of two types of partial foot amputation: hallux amputation (HA), and transmetatarsal amputation (TMA) before and after the intervention of the newly designed total contact foot prostheses. The prosthesis was designed based on a total contact insole with filler at the amputation site. The plantar stress distributions before and after the intervention of foot prostheses were quantified using finite element analyses.

METHODS

Three different foot models (normal, HA and TMA) were created in the SolidWorks2000 CAD software and finite element models were created in the Patran2000 FEA software. The prostheses were modeled as total contact insole with filler and the thickness were ranging from 2 to 5mm. Young's moduli and Poisson's ratios for the bone, cartilage and soft tissue were adopted from literature. The prosthesis was made of Microcelpoff and Softsponge. The loading condition for the analysis was assumed that the foot be pushed by a rigid plane vertically from plantar side in 20mm/sec and continued for 1 sec (Fig. 1). Loading was divided into 20 increments.

Figure 1: The boundary conditions used for analysis.

The maximum stress and strain values were calculated when the reaction force at the constrained tibial surface was equal to 600N simulating single leg stance condition. Plantar foot is divided into 5 different regions as M1 to M5 (Fig. 2), for comparison before and after footwear intervention.

Figure 2: Five plantar regions: M1 to M5.

RESULTS AND DISCUSSION

Results showed that total contact prostheses could contribute over 60% of the plantar pressure reduction (Fig. 3), excluding M4 area of TMA foot. Peak plantar pressure was found to be higher in amputation feet than normal ones. Excluding M5 (plantar calcaneus) area, total contact prosthesis can reduce the peak pressure value to under 100kPa. This proves the effect of plantar pressure reduction by the special geometry and material combination of the total contact prostheses. Maximum von Mises strain also decreased 10% after wearing total contact footwear for normal foot, but increased for amputation feet. This may be resulted from the different load transfer path due to skeletal structure changes.

Plantar Pressure Reduction With footwear

Figure 3: Peak Plantar Pressure(PPP) reduction in 5 plantar regions (M1 to M5) after wearing total contact prosthesis.

SUMMARY

This study can be a reference on the plantar pressure and skeletal stress distributions in foot amputation and prosthetic design. It is possible to evaluate different material and geometry combinations to design a more optimal prosthesis for patients with partial foot amputation.

INTRODUCTION

Stemless-type prostheses, such as, surface replacement have been used during the early developing stage of hip arthroplasty. However, the high stresses occurred at the femoral head and the acetabulum jeopardized its development. A new stemless prosthesis was designed for solving the stress-shielding effect and the osteolysis caused by the wear debris often seen in stem-type prostheses. The objective of this study is to investigate the biomechanical performance of the newly designed Cervico-Trochanteric (C-T) stemless prosthesis by comparing the stress distributions with the traditional stem-type PCA (porous-coated anatomic) prosthesis using three-dimensional finite element models.

METHODS

Four finite element models were created for the intact femur, C-T implanted (with two fixation screws) femur, C-T implanted (with three fixation screws) femur, and PCA implanted femur. The geometry of the femur was based on a standardized composite femur. The finite element models for the C-T prosthesis, two screws, three screws and PCA prosthesis were created and shown in Fig. 1. The element type used was 10-node (2nd order) tetrahedral element. Material properties for each different material (cortical bone, cancellous bone, titanium alloy, Co-Cr alloy) were considered to be linear, elastic. Loading condition of single-legged stance was considered.

RESULTS AND DISCUSSION

The von Mises stress distributions on the medial side of the femur for the four models are shown in Fig. 2. and Fig. 3. The results can be summarized as:

1. Von Mises stress in the proximal, medial femur for the C-T implanted model was higher than that of the intact model and the PCA-implanted model.
2. Stress-shielding effects were significantly eliminated for the C-T-implanted models (with 2 or 3 fixation screws) as compared with PCA-implanted model.
3. No significant difference in von Mises stress distribution for the C-T-implanted model with 2 or 3 fixation screws.
4. There is no significant stress concentration around the fixation screws.

CONCLUSIONS

Based on the results, we found that the C-T implanted femur has more physiological stress distribution on the proximal

femur than that of PCA prosthesis. C-T prosthesis can prevent the osteolysis caused by the wear debris. It can provide immediate stabilization of the implant and the preservation of endosteal vascularity.

MUSCLE ACTIVATION AND THREE-DIMENSIONAL KINEMATICS OF UPPER EXTREMITY IN TENNIS VOLLEY

Lin-Hwa Wang¹, Kuo-Cheng Lo³, Chia-Ching Wu² and Fong-Chin Su²

¹Department of Physical Education & ²Institute of Biomedical Engineering, National Cheng Kung University, Tainan, TAIWAN
³Physical Education Section, Kun Shan University of Technology, Tainan, TAIWAN

INTRODUCTION

Volley is one of important techniques in tennis competition. There are two distinctly different volley types: the punch volley and the drop volley. Understanding of three-dimensional (3D) kinematics and muscle activities in upper limb in four phases of volley, introductory backswing, forward acceleration, impact and follow through, would provide the basic guidelines of the tennis training and the tennis evaluation. The purpose of this study was to investigate the kinematics and EMG signals of the trunk and upper extremity during punch volley and drop volley.

METHODS

12 male tennis players with right hand dominant were recruited in this study. A full 3D kinematic model of trunk and upper extremity was developed for studying tennis volley. 21 markers were placed on selected anatomic landmarks unilaterally to define the coordinate system of the trunk, pelvis, upper arm, forearm and hand. The HiRES motion system with six cameras (Motion analysis Corp., Santa Rosa, CA, USA) was used to collect the position of the reflective markers at sampling rate of 240 Hz. Ten trials were sampled for each subject. Euler angles were used to describe the 3D joint movements of trunk and upper extremity with respect to their neutral posture.

Muscle activities were determined using a surface EMG system (Motion Lab Systems, Inc., USA). 8 surface electrodes were attached to the flexor carpi radialis (FCR), extensor carpi radialis (ECR), brachioradialis (BRR), biceps and triceps brachii (BIB & TRB), antero-middle and postero- middle deltoids (AMD & PMD), and pectoralis major (PCM) muscles of the dominant arm. The maximum effort 5-sec isometric contraction was performed for each muscle/muscle group before the experimental trials to obtain maximum EMG level of the selected muscles for normalization.

RESULTS AND DISCUSSION

Each joint movements of upper extremity of dominant arm and trunk during the forehand volley were showed in Fig. 1. In punch volley, more trunk and shoulder movements were used to generate more kinetic energy and with less movement in wrist joint to stabilize and cause more reflection the kinetic energy of ball. However, the drop volley had more movements in wrist joint to absorb the kinetic energy and control the reflection angle and position of ball. The same results pattern were showed in backhand volley between punch and drop

types.

Fig. 1: Joint movements of shoulder and wrist joints in forehand punch and drop volley.

Punch volley required more muscle activation than drop (Fig. 2), especially for backhand punch trials. All muscles showed strong activity during the acceleration phase except the biceps. For forehand volley, the FCR, BBR and PCM were the dominant muscle that compare to the ECR, TRB, AMD and PMD muscles in backhand volley.

Fig. 2: Normalized maximum EMG levels

Understanding of the 3D joints movements and muscle activities of upper extremity during the different types of tennis volley will allow the tennis player and coach to improve the performance of tennis technique.

EFFECTS OF DIFFERENT LEVELS OF TRANSTROCHANTERIC ROTATIONAL OSTEOTOMY ON THE STRESS DISTRIBUTIONS IN THE PROXIMAL FEMUR

Jean-Bue Chen^{1,2}, Weng-Pin Chen², Shiuann-Sheng Lee³

¹Department of Orthopaedic Surgery, Tao-Yuan General Hospital, Department of Health, Chungli, Taiwan

INTRODUCTION

Transtrochanteric rotational osteotomy (TRO) is an alternative solution besides total hip arthroplasty (THA) for relatively younger avascular necrosis (AVN) patients. The concept of the TRO is to move the weight-bearing necrotic area to a non-weight-bearing region by rotational osteotomy. The objective of this study is to investigate the effects of four different transtrochanteric rotational osteotomy levels on the stress distributions of bone and fixation devices using finite element analysis. Dynamic hip screw (DHS) fixation system was used. We hoped that through this research a guideline for the osteotomy level for the TRO can be established.

MATERIALS AND METHODS

CT image data of a standardized composite femur was used to create a 3-D finite element intact femur model. Based on the intact model, four models simulating four different levels of osteotomy line together with the implanted DHS fixation system were created and shown in Fig. 1. The four models were defined as DHS-1 (normal transtrochanteric line), DHS-2 (0.5cm distal), DHS-3 (1cm distal) and DHS-4 (1.5 cm distal). The total numbers of elements used for the four models were: 28430 (DHS-1), 28555 (DHS-2), 29139 (DHS-3), and 30666 (DHS-4). A vertical loading of 2000N was applied on the femoral head and finite element analyses were performed using a FEA software (MARC2000).

RESULTS

The von-Mises stress distributions of the four different TRO models are shown in Fig. 1. The peak von Mises stresses on each component of the DHS devices (screws, plates and lag screw) for the four different models are shown in Fig. 2. The stresses increased on the osteotomy interface and the fixation devices as the osteotomy line moves distally. There was a significant stress rise when the osteotomy line moves from DHS-2 to DHS-3 as seen from Fig. 2. The stiffness value for the femur-implant complexes were found by calculating the 2000N loading divided by the longitudinal displacement at the loading point. each model was calculated respectively (Intact: 3086 N/mm, DHS-1: 2989 N/mm, DHS-2: 2753 N/mm, DHS-3: 2113 N/mm, and DHS-4: 1165 N/mm).

DISCUSSION AND CONCLUSION

Results concluded that the osteotomy line should be carefully designed and limited to no more than 0.5 cm distal to the intertrochanteric line because high stress concentration and loss of lateral cortical buttress will possibly lead to early mechanical failure. The DHS-1 model has a stiffness value (2989 N/mm) closer to that of the intact femur (3086 N/mm) than other models. Therefore, DHS-1 is suggested from the stability consideration.

AIR FLOW AND TEMPERATURE DISTRIBUTION IN A NEONATAL INCUBATOR

Sang-Ho Yun, Chi-Ho Kwon, Young-Ho Kim

Department of Biomedical Engineering, Research of Medical Engineering,
Research Institute for Medical Instrumentation & Rehabilitation Engineering,
Technology Innovation Center for Medical Instruments, Yonsei University
yhkim@dragon.yonsei.ac.kr

INTRODUCTION

Careful considerations of temperature, airflow, and humidity should be made for an effective control of neonatal incubator. The temperature differences inside an incubator lead to neonate heat loss, hypothermia and apnea, which are closely related to air flow and air velocity (Libert et al, 1997). Many studies have been performed to visualize major airflow patterns in many different fields other than inside a commercial incubator (Yamaguchi et al, 1996). However, the turbulent airflow characteristics in the incubator were not considered in their studies. In the study, flow visualizations, hot-wire velocity measurements and computational fluid dynamics were performed to determine the airflow characteristics inside a neonatal incubator.

METHODS

The incubator chamber had a long inlet at the right side of the neonate and an exit of similar size and shape at the left side of the neonate so that the major airflow in the incubator chamber would be of a transverse directional nature. An anatomically correct neonate model is designed using a three-dimensional laser scanner system and a rapid prototyping machine.

The flow visualization system consisted of a flood light, a digital video camera, a slit light system and a smoke generator. Hot wire measurements along the contour of neonate 0.2cm distant from the neonate's body, were employed to measure local airflow velocities and fluctuations.

A three-dimensional steady-state convective heat transfer in the incubator with a neonate model was computed using a pressure-based finite-volume software, CFD-ACE (CFD Research Corporation, U.S.A.).

RESULTS AND DISCUSSION

Motion pictures of smoke particles have demonstrated that flow in the incubator was turbulent, unsteady and three-dimensional. Flow was separated at the wall near the inlet, which resulted from the interaction between the air stream and vortex layers springing from the corners of the incubator (Figure 1(a)). Disturbances from the corners of the incubator chamber and the sharp angle of entry of the incubator might affect the airflow instability. Computational fluid dynamics provided more detailed information on the airflow fields in the incubator. As shown in Figure 1(b), airflow from the inlet formed a large-rotating vortex near the middle of the incubator chamber and partly moved towards

the exit, similar to airflow visualization results.

Figure 1: Flow pattern on the neonate's transverse plane.

Skin temperature distributions of the neonate were observed uniform temperatures of about 34°C on the neonate's anterior aspect. Convective heat transfer increased where air velocity was large. Temperatures at the right armpit and the crotch were 36.1°C, and the temperature at the left surface of the neck was 35.3°C. Temperatures at the medial aspects of both thighs were high, where weak stationary vortices were found. Results from computational fluid mechanics showed that a warmer temperature was maintained on the neonate's right aspect, especially near the neck, the armpit and the crotch, where air was relatively stationary. Heat losses were larger at the forehead region, but smaller in the extremities, which was similar to a previous study (Sarman et al, 1992).

SUMMARY

Flow fields from flow visualizations, hot-wire measurements, and computational fluid dynamics inside a neonatal incubator were very similar both qualitatively and quantitatively. The small eddies produced between the neonate and the mattress might interfere with convective and evaporative heat transfers from the neonate. Therefore, it is important to eliminate eddies around the neonate for future designs of neonatal incubators.

INFLUENCES OF GENDER AND EXERCISE ON ACL LAXITY

Christine Pollard, Elizabeth Devine, Barry Braun, Joseph Hamill
Biomechanics Laboratory, University of Massachusetts, Amherst, Massachusetts, USA

INTRODUCTION

Numerous investigators have reported a higher incidence of anterior cruciate ligament (ACL) injury in women than in men (Arendt et al., 1995). Multiple factors have been associated with this disproportionate incidence of injury. It has been suggested that females may be at greater risk of injury due to greater ACL laxity. Investigators have also suggested an increase in ACL laxity following exercise (Steiner et al., 1986). In addition to these changes in laxity associated with exercise, changes in ACL laxity across the menstrual cycle phases have also been reported (Heitz et al., 1999). The purpose of this study was to determine if there were differences in the effect of exercise on ACL laxity between males and females. In addition, the influence of exercise on ACL laxity across the menstrual cycle phases was investigated.

METHODS

Subjects consisted of six females (age: \bar{x} = 26 years, mass: \bar{x} = 64 kg) with a history of a normal menstrual cycle lasting 28-32 days and six males (age: \bar{x} = 24 years, mass: \bar{x} = 82 kg). All subjects had intact knee ligaments bilaterally and exercised on average at least five times a week for thirty minutes. Female subjects were assigned to start data collection at either the onset of menses or the onset of ovulation depending on which event came first after signing the informed consent to participate. Ovulation was determined by a positive test on an ovulation kit. Serial estrogen levels of the female subjects were measured via radioimmunoassay procedures.

Knee laxity was measured with a KT-1000 knee arthrometer at 20 degrees of knee flexion with a displacement force of 89N. Displacement was recorded to the nearest 0.5mm. Estrogen levels and ACL laxity were measured for the female subjects at specific times to represent the three menstrual cycle phases. These times were at onset menses (menstrual phase), days 10 and 12 post onset menses (follicular phase), and days 7 and 9 post ovulation (luteal phase). ACL laxity of the male subjects was measured on three different days with 10-12 days between each measurement.

For each data collection session, ACL laxity was measured just prior to an exercise protocol and immediately following the exercise protocol. The exercise protocol consisted of fifteen minutes of treadmill running at a self-selected pace, two minutes of weaving, two minutes of cutting and twenty-five jump downs from a twelve-inch surface.

A repeated measures ANOVA (gender x laxity x subjects) was used to test for significant differences in the change in knee laxity values between females and males and across the different menstrual cycle phases ($p \leq 0.05$).

RESULTS AND DISCUSSION

There were no significant differences in the effect of exercise on ACL laxity between males and females (Figure 1). In addition, the effect of exercise did not differ across the menstrual cycle phases (Figure 2). However, there were significant differences in ACL laxity between genders both pre-exercise and post-exercise.

Figure 1: Influences of Gender and Exercise on ACL Laxity.

Figure 2: Influences of Exercise on ACL Laxity Across the Menstrual Cycle Phases.

SUMMARY

These results suggest that ACL laxity is increased in both genders following an exercise protocol. This increase in laxity due to exercise does not appear to differ in females across the menstrual cycle phases. However, females demonstrate greater ACL laxity than do males both pre and post exercise.

VISCOELASTIC STRESS RELAXATION DURING ACUTE PASSIVE STRETCHING AND ITS INFLUENCE ON MAXIMUM VOLUNTARY STRENGTH

Derek Weir, Geoff Elder, and Jill Tingley

School of Health & human performance, dalhousie university, halifax, nova scotia, canada, [HTTP://WWW.DAL.CA/HAHP](http://www.dal.ca/HAHP)

INTRODUCTION

Increased muscular compliance following a bout of acute passive stretching (APS) could potentially modify the length-tension characteristics of the stretched muscle, thereby altering its maximal force-generating capacity at any given joint angle. Two recent studies investigated the effects of 30 (Fowles, Sale, & MacDougall, 2000) and 60 min (Avela, Kyrolainen, & Komi, 1999) of APS on the isometric maximum voluntary contraction (MVC) of the plantar flexors and decreases of 28 and 24%, respectively were reported. Whether less extensive stretching regimes would have similar detrimental effects on MVC however, remains in question. In addition, the exact nature of any such MVC decrement has not yet been clearly established. The purpose of this study was to investigate viscoelastic stress relaxation in the human plantar flexors *in vivo* during APS, to establish whether this response would reduce maximal strength, and if so, to determine the mechanisms responsible for the decrease.

METHODS

Fifteen female subjects underwent a series of five plantar flexor stretches, where the ankle was passively extended to within 2° of their maximum dorsiflexion (D) range of motion and held for 120 s. MVC, with twitch interpolation, and the electromyographic (EMG) and torque output of the mechanically induced stretch reflex (SR) were assessed before (Pre) and immediately following (Post-test₁) APS at 20° D, along with the electrically induced maximal Hoffmann reflex (H_{\max}) and maximal mass compound action potential (M_{\max}). MVC, SR, and M_{\max} measures were then assessed again (Post-test₂) at an increased angle ($26 \pm 1^\circ$ D), to test if the length-tension relationship had been altered. EMG was recorded from the soleus (SOL), medial gastrocnemius (MG), and tibialis anterior (TA) using bipolar surface electrodes.

RESULTS

During APS there was a significant decrease in passive torque with time (120 s) and stretch (1-5) but the decrease was less as more stretches were performed (Figure 1). Following APS, there was a 7% reduction in MVC torque ($P < 0.05$) and a 13% reduction in SR torque ($P < 0.05$). SR EMG recorded from SOL and MG was also reduced by 27% ($P < 0.05$) and 22% ($P < 0.05$), respectively. The ratio of H_{\max} to M_{\max} EMG did not differ significantly at Post-test₁, nor did the H_{\max} and M_{\max} torque responses. At Post-test₂, MVC and SR EMG (SOL and MG) recovered to pre-stretch values, while the SR and M_{\max} torques increased to 19 and 13% above Pre, respectively ($P < 0.05$). There were no significant changes in motor unit activation between any of the tests.

Figure 1: Data recording of APS for one subject. *Top:* passive torque record. *Middle:* raw EMG recorded from SOL, MG, and TA. *Bottom:* ankle angle displacement. The torque record indicates stress relaxation in the absence of any significant EMG activity.

DISCUSSION

The results of this study provide new evidence to suggest that decreases in maximal strength following shorter bouts of APS are the result of mechanical changes in the stretched muscle, rather than reduced neural drive. The decrease in MVC was associated with a marked decrease in passive torque at any given joint angle and the fact that MVC was restored with the application of additional stretch indicates that the decrease was most likely caused by an alteration in the length-tension properties of the plantar flexors. Although APS reduced SR excitability in a resting state, it is not believed that changes in afferent drive and/or motoneuron excitability influenced these findings, as the decrease and subsequent increase in MVC was not associated with any change in motor unit activation.

FLUID VELOCITIES WITHIN A VENTRICULAR ASSIST DEVICE ARE HIGHLY SENSITIVE TO PNEUMATIC DRIVE CONDITIONS

Allen Nugent and Chris Bertram

Graduate School of Biomedical Engineering, University of New South Wales, Sydney, Australia , (www.gsbme.unsw.edu.au)

INTRODUCTION

Both bulk flow performance and valve-generated water hammer are strongly affected by the drive conditions of a pulsatile ventricular assist device (VAD) (Umezumi et al. 1989). Indeed, these considerations influence the design of VADs as well as the control algorithms of their actuators. However, little attention has been paid to small-scale effects of drive conditions, such as the influence on the time-varying fluid velocity at particular locations within the VAD.

The Spiral Vortex (SV) VAD was designed to minimise undesirable fluid-mechanical phenomena and haemolysis. With a tangential inflow tract and an axial outflow tract, flow stasis and prolonged residence are eliminated. Previous investigations of the device have revealed highly organised flow patterns and good washout of peripheral surfaces (Umezumi et al. 1991).

METHODS

From 3-inch cast acrylic sheet, a model of the SV VAD was fabricated with flat, polished, orthogonal exterior walls. This was connected to a mock circulation consisting of a Windkessel model of the aorta and a blood bag for the left atrium. A blood-analogue fluid formulated from NaI and glycerol gave dynamic similarity with blood while matching the refractive index of the acrylic to better than 4 decimal places, essential for making LDA measurements within the complex shape of the VAD interior.

At each of nearly 700 nodes in a 5mm-spaced Cartesian measuring grid, 2-component LDA data were taken until 10,000 samples were accumulated or 5 minutes had elapsed. Between 25 and 360 cycles (model heart beats) were required, and these were overlaid in the correct phase prior to statistical analysis of the ensembles.

Velocity components parallel to the projection of the inflow tract onto the equatorial plane (U) and parallel to the outflow tract (W) were measured. The pneumatic drive pressure (DP), mock aortic and left atrial pressure, and aortic flow-rate were sampled simultaneously.

Model heart rate was 68 min^{-1} and systolic fraction was 35 %. Drive pressure and vacuum were adjusted for physiological systemic parameters within the mock circulation.

During the investigation, it was discovered that the vacuum setting on the pneumatic driver was marginally excessive, resulting in what appeared as a small downward spike on the DP waveform immediately prior to systole. Close inspection of this feature, which arises from stretching of the diaphragm, suggested that the magnitude and duration of excess negative DP might be sufficient to affect flow velocities within the VAD, and the reality of this effect was examined by

comparison of data from certain locations with new data obtained after reducing the vacuum.

RESULTS AND DISCUSSION

Waveforms of the W-component of velocity at sites within the outlet tract were found to be most affected by excess vacuum, displaying a sigmoid perturbation, with a peak-to-peak amplitude of 0.6 to 0.9 m/s, coinciding with the unwanted feature on the DP waveform. U-component waveforms at these sites were less affected. Velocities within the inflow tract were apparently unaffected, as were those nearer the diaphragm.

Figure 1: Drive pressure and outflow tract W-velocity in the presence of excess drive vacuum.

It is likely that velocities at sites near the diaphragm are indeed perturbed, but that the amplitude is small relative to the data scatter. The cross-sectional area in the neck of the outflow tract of the SV VAD is only 6 % of that at the equatorial plane (diaphragm-housing junction), so that a small perturbation distributed over the latter region is effectively magnified by the convergent geometry.

The required adjustment of vacuum that restored normal drive conditions was barely palpable, and too small to observe on the vacuum gauge. This observation highlights the sensitivity of pneumatic VADs to drive conditions, while the findings above reinforce the importance of optimising drive conditions.

SUMMARY

Deleterious flow behaviour within a blood pump may result from very fine misadjustments of pneumatic drive conditions.

THE ASSOCIATION OF ESTROGEN CHANGES ACROSS THE MENSTRUAL CYCLE PHASES WITH ACL LAXITY IN ACTIVE FEMALES

Christine Pollard, Elizabeth Devine, Barry Braun, Joseph Hamill
Biomechanics Laboratory, University of Massachusetts, Amherst, Massachusetts, USA

INTRODUCTION

Women have been reported to experience four to eight times the number of anterior cruciate ligament injuries (ACL) as men (Arendt et al., 1995). Researchers have investigated a variety of factors that may affect this disproportionate incidence rate. Recent work has focused on potential hormonal influences on injury due to the difference in estrogen levels between genders. More specifically, investigators have focused on the influences of high estrogen levels during specific times of the menstrual cycle. These authors have suggested that changes in circulating estrogen levels across the menstrual cycle phases may contribute to this higher incidence of injury. This potential factor has stemmed from recent *in vitro* work that has reported that physiologic levels of estrogen may significantly reduce ACL fibroblast proliferation and rate of collagen synthesis (Liu et al., 1997). This reduction may be associated with changes in ligament laxity.

Within the normal menstruating female, serum estrogen typically fluctuates from low levels during the menstrual phase to high levels during the follicular phase and then decreases to moderately high levels during the luteal phase. The purpose of this study was to determine if there were changes in ACL laxity associated with estrogen changes across the menstrual cycle phases in active females.

METHODS

Subjects consisted of six females (age: \bar{x} =26 years, mass: \bar{x} =64 kg) with a history of a normal menstrual cycle lasting 28-32 days and intact knee ligaments bilaterally. All subjects exercised on average at least five times a week for thirty minutes. Subjects were assigned to start data collection at either onset menses or at onset ovulation depending on which event came first after signing the informed consent to participate. Ovulation was determined by a positive test on an ovulation kit.

Knee laxity was measured with a KT-1000 knee arthrometer at 20 degrees of knee flexion with a displacement force of 89N. Displacement was recorded to the nearest 0.5mm. Serum estrogen levels and ACL laxity were measured at specific times to represent the three phases of the menstrual cycle. These times were at onset menses (menstrual phase), days 10 and 12 post onset menses (follicular phase), and days 7 and 9 post ovulation (luteal phase). Serial estrogen levels were measured via radioimmunoassay procedures.

A repeated measures analysis of variance (laxity x phase x subjects) was used to test for the presence or absence of significant differences in knee laxity values across the

different menstrual cycle phases ($p \leq 0.05$).

RESULTS AND DISCUSSION

There were no significant differences in ACL laxity between the menstrual cycle phases (Figure 1). However, there was a significant increase in estrogen between the menstrual and the follicular phase (Figure 2). The estrogen level in the luteal phase was similar to both the menstrual and follicular phase levels. These findings suggest that ACL laxity in females is not associated with changes in circulating estrogen levels.

Figure 1: ACL laxity across the menstrual cycle phases.

Figure 2: Estrogen levels across the menstrual cycle phases (phases with like letters are not significantly different).

SUMMARY

Although *in vitro* investigations have suggested that the ACL may be at greater risk of injury when exposed to higher levels of circulating estrogen, there does not appear to be a clinically significant association between ACL laxity and changes in serum estrogen across the menstrual cycle phases. However, it is important to consider that this study focused on knee laxity and did not address lower extremity dynamics. Future studies are necessary to begin to investigate the effects of circulating hormones on lower extremity dynamics.

INTRODUCTION

Parkinson's disease is a debilitating neurological condition that affects over 1 million people in the US. Previous work has found significant differences in the kinematic walking patterns and increases in variability in parkinsonian gait (Murray, 1978). However, these changes in the variability of parkinsonian gait and their underlying nature have received little attention. The purpose of this study was to examine the underlying organizational dynamics of parkinsonian gait.

METHODS

Six subjects suffering from idiopathic Parkinson's disease (age=66.0±7.7 yrs) and six healthy controls (age=63.5±7.0 yrs) participated in the study. Parkinson's subjects undergoing dopamine therapy were asked to refrain from taking their medication the morning of data collection. Kinematic data from 30 continuous footfalls (avg=2378 data points/trial) were collected using two cameras (60Hz) while the subjects walked on a treadmill at their self-selected pace. Sagittal 3D angles of the right hip, knee, and ankle were calculated. Lyapunov exponents (LyE) and correlation dimensions (COD) of the angles were calculated for both groups and were analyzed using the Chaos Data Analyzer (Sprott & Rowlands, 1992). LyE is a measure of the stability of a dynamical system and its dependence on initial conditions. COD describes the geometric dimension of a dynamical system in state space. All calculations were performed using 5 embedded dimensions. The embedded dimension is the number of dimensions needed to unfold the structure of a given dynamical system. It was calculated using a Global False Nearest Neighbor analysis (Abarbanel, 1996). All data were also surrogated using a phase randomization technique (Theiler et al., 1992). Surrogation removes the deterministic structure from the original data set, generating a random equivalent. LyE of the surrogate data set (S-LyE) is then calculated. If significant differences are found between the LyE and S-LyE, then the original is not a randomly derived data set. Lastly, the approximate entropy (ApEn), a measure of the regularity of a data series was computed for all data sets (Pincus, 1991). Small ApEn values (≈ 0) indicate less complexity (greater periodicity) in the data, while higher values (≈ 2) indicate greater complexity

(increased randomness). Mean group values for ApEn, LyE, S-LyE and COD of both groups were analyzed using t-tests ($p<0.05$).

RESULTS AND DISCUSSION

All LyE values for both groups were significantly different from their surrogate counterparts indicating that variability in all time series may be deterministic in nature. Knee and ankle COD values were significantly higher for the Parkinson's group. No significant differences were found between groups for the hip COD, or for the LyE and ApEn for any of the joints. However, all values for the Parkinson's group at all joints were higher suggesting a more random (noisier) behavior in comparison with the control group. Increased noise in the Parkinson's group may be attributed to changing constraints as a consequence of pathophysiological changes in the brain. Previously reported changes in gait kinematics in the Parkinson's patients may result from adjustments by the neuromuscular system to compensate for the increased noise.

SUMMARY

Variability in parkinsonian and healthy gait was found to be deterministic in nature suggesting that the inherent variability generated by the neuromuscular system may still be intact in this pathological group. If the basal ganglia is the neuro-source of this disorder (Conley & Kirchner, 1999), then it can be speculated that the mechanisms that are responsible for the deterministic nature of variability in gait are not housed there. The higher values reported in all variables for the parkinsonian gait, indicated that changing constraints associated with the disease may lead to increased behavioral noise during gait.

BILE CANALICULI REFORMED BY RAT SMALL HEPATOCYTES, AND ITS DYNAMIC MOVEMENT

Ryo Sudo^{1,2}, Hiroshi Kohara¹, Toshihiro Mitaka², Mariko Ikeda¹, Kazuo Tanishita¹

¹Department of System Design Engineering, Keio University, Yokohama, Kanagawa, Japan, sudo@tani.sd.keio.ac.jp

INTRODUCTION

Small hepatocytes, which are known to be hepatic progenitor cells, can be isolated from an adult rat liver (Mitaka et al., 1999). They can rapidly proliferate with maintaining hepatic functions such as albumin secretion, and formed a monolayer colony consisting of 20 to 30 cells within 10 days. About 10 days after plating, many colonies were surrounded by hepatic nonparenchymal cells such as liver epithelial cells and stellate cells, and, several days later, rising/piled-up cells appeared in the colonies. In such colonies, translucent belts are formed between the piled-up cells under phase-contrast microscopy. As time in culture, they developed into anastomosing network, which seem to be bile canalliculi (BC). We investigated whether this BC-like structure has ability to be functionally active and how it works as a pump to transport components.

METHODS

Hepatic cells, including small hepatocytes, were isolated from an adult rat liver and cultured. Double fluorescent immunocytochemistry for BC proteins (MRP2: multidrug-resistance-associated protein 2, 5NT: 5'-Nucleotidase, ectoATPase) and actin was carried out. Phase-contrast images of BC formed in a colony were digitally recorded at the 20-second intervals for 2 hours. To observe flux within BC, CellTracker™, which is fluorescent dye and secreted into BC, was microinjected into one of the piled-up cells in a colony. Then, time-lapse fluorescence images were recorded at the 5-second intervals for 5 minutes. We also assessed the effects of calcium ionophore A23187 and Endothelin-1 on BC contractions to investigate the mechanism of contractile motion. Before and after the dose of these reagents, time-lapse images were recorded at the 20-second intervals for 3 hours.

RESULTS AND DISCUSSION

Immunostaining of BC proteins showed that BC proteins were distributed in the intercellular space that coincided with the translucent belts formed in the piled-up cells. In addition, actin was intensively positive around BC-like structures corresponding to the expression of BC proteins.

Figure 1A shows phase-contrast images of the piled-up colony in which anastomosing BC network developed well. The calculated light intensity of each segment in figure 1A is graphically shown in figure 1B. Contraction and dilatation of reformed BC occurred in the experimental period (Fig. 1C-E). This contractile motion may have a relation to the intracellular Ca²⁺ level, because the treatments of A23187 and Endothelin-1

resulted in the enhancement of BC contraction. We also found that reformed BC contract synchronously through the adjacent cells.

Microinjected CellTracker™ was metabolized and fluorescein was secreted into BC. Soon after the injection, bright fluorescence was observed in the cytoplasm and a line of fluorescence extended in the direction of the tip of the colony. A few minutes later, the tracer was clearly detected in 4 cells distant from the injected cell.

Figure 1: Phase-contrast images and graphical representation of BC contraction. Scale bars, 50 μ m (A) and 20 μ m (C).

SUMMARY

This is the first experiment that demonstrates tubular structures of BC *in vitro* have a motility to transport the components. The results in this study suggest that reformed BC by rat small hepatocytes may be functionally active and have a contractile activity in a synchronized manner.

COMPUTATIONAL FLUID DYNAMICS MODEL ANALYSIS OF THE BLOOD FLOW IN THE CIRCLE OF WILLIS

Makoto HARAZAWA, Takami YAMAGUCHI

Department of Mechatronics and Precision Engineering, Graduate School of Engineering,
Tohoku University, Sendai, Japan., harazawa@pfs1.mech.tohoku.ac.jp

INTRODUCTION

Blood is supplied to the brain via four arteries: two internal carotid arteries and two vertebral arteries. To increase the reliability of the supply of blood to the brain, these arteries are interconnected at the base of the brain, where they form a closed arterial circle, called the circle of Willis. However, their anastomoses vary considerably. If some of the anastomoses are very small, or absent, the safety of the blood supply is jeopardized. This is particularly important in diseases such as cerebral thrombosis when the blood flow is obstructed unilaterally. In such cases, redistribution of the blood supply is thought to be strongly affected by the geometric configuration of the anastomoses. Cerebral aneurysms, which may induce serious cerebrovascular disease, preferentially occur at the circle of Willis, and the complex blood flow pattern is suspected of influencing the development of aneurysms. Again, this is dependent on the complex geometry of the circle. Therefore, we conducted a computational fluid dynamics (CFD) simulation of the blood flow in the circle of Willis, focusing on the relationship between the geometric configuration and the redistribution of blood flow under changing inlet flow conditions.

Fig. 1: Typical variations of the circle of Willis. (Adachi, 1928)

METHODS

The circle of Willis consists of multiple inlet and outlet vessels. They have a complex 3D geometry, with a very wide variety of atypism (Adachi, 1928). We built a generic 2-dimensional model of the circle of Willis (Fig. 2).

Fig. 2: CFD model and the circle of Willis.

The CFD computation used SCRYU ver. 1.9 (Software Cradle, Osaka, Japan). The governing equations were the Navier-Stokes equations for an incompressible Newtonian fluid with the properties of water. The boundary conditions at every inlet consisted of a steady uniform inflow velocity perpendicular to the cross section. The Reynolds numbers of inflow velocity are listed in Table 1. At the outlet, the boundary conditions were zero pressure and zero velocity gradient. No-slip walls were assumed.

Table 1: The Reynolds number of inflow velocity.

TYPE	1-1	1-2	1-3	1-4	1-5	2-1	2-2	2-3	2-4	2-5	3-1	3-2	3-3	3-4	3-5
Inlet 1	500	375	250	125	0	500	375	250	125	0	500	375	250	125	0
Inlet 2	500	500	500	500	500	500	500	500	500	500	500	500	500	500	500
Inlet 3	500	500	500	500	500	250	250	250	250	250	0	0	0	0	0

RESULTS

Representative results are shown in Figs. 3 and 4. Fig. 3 shows the velocity vectors, and Fig. 4 shows the pressure distribution. Fig. 5 shows the change in flow at other outlets that resulted from changing the inflow conditions at inlet 1. At outlet 1, which is close to inlet 1, the change in the flow was proportional to the change in the inlet flow at inlet 1. At outlets 3 and 5, on the contralateral side, relatively little change in the flow was observed. In contrast, there was little change in the flow of outlet 1, on the contralateral side. The outflow from outlet 1, which is directly connected to inlet 1, was significantly affected. However this effect was diminished by bypass flows from inlet 3. Therefore, the outflow from outlets 4 and 6 was spared relatively.

Fig. 4: Pressure distribution.

(a) I3; Re=500.

(b) I3; Re=250.

(c) I3; Re=0.

Fig. 5: Flows by changing inflow conditions.

CONCLUDING REMARKS

This study found that geometrical factors, such as mode of connection and proximity of inlets and outlets, significantly affected the redistribution of the blood flow when unilateral alterations of the flow occurred in the circle of Willis. This was not shown in previous studies using one-dimensional simulations equivalent to an electric circuit analogy (Hillen et al., 1988; Lodi and Ursino, 1999). This clearly shows the need for true fluid dynamical studies using a more realistic three-dimensional model based on real data obtained from both healthy and diseased subjects.

EXPERIMENTAL STUDY ON AIR FLOW IN A TWO-DIMENSIONAL CHANNEL WITH AN OBSTRUCTION OSCILLATING AT 10 HZ TO 100 HZ

Yuji Matsuzaki, Masateru Watanabe, Tatsuya Aomatsu and Tadashige Ikeda
Department of Aerospace Engineering, Nagoya University, Chikusa, Nagoya, Japan
matsuzaki@nuae.nagoya-u.ac.jp

INTRODUCTION

In a human body, flows of blood, air and body fluids in flexible vessels such as blood vessels, air ways, etc., produce many kinds of static and dynamic phenomena, which are mostly very complex from mechanical view points. To understand physiological and pathological aspects of such phenomena, it is essential to observe them in vivo as well as perform both related experiments on artificial conditions and analytical studies. In the case of the flexible tubes the dynamic behaviors of the flow and the tube are very complicated due to an interaction between flow pressure and tube deformation (Matsuzaki & Matsumoto, 1989; Matsuzaki, et al., 1994). To produce phonetic sounds, a pair of vocal chords oscillate over 200 to 1,000 Hz with very small amplitudes (Ikeda & Matsuzaki, 2001). One of difficult issues is to evaluate the fluid pressure distribution on the oscillating wall experimentally and analytically (Matsuzaki & Fung, 1976; Matsuzaki & Ikeda, 1998; Ikeda & Matsuzaki, 1999). In this paper we present experimental results on flow pressures in a two-dimensional flow channel with an obstruction oscillating at low to high frequencies up to 100 Hz in order to provide quantitative information on the flows passing through the oscillating narrow passage.

METHOD

The flow channel is shown in Fig. 1 and a magnified view of the test section is given in Fig. 2. The air was sucked from the atmosphere to a vacuum. The flow was obstructed by a trapezoidal block modeling a vocal chord. Static pressures were measured at the center of the narrowed passage, and its 10mm upstream and downstream, that is, $p(0)$, $p(-10)$ and $p(10)$, respectively. The level surface of the trapezoid was periodically moved in a vertical direction with amplitude of 0.05mm at given frequency and clearance to the wall. The pressure was measured for several sets of Reynolds and Strouhal numbers, changing the flow rate, the frequency of the level surface and the initial clearance.

RESULTS AND DISCUSSION

In a frequency range less than 10 Hz the flow behaved quasistatically. The narrower the obstructed passage became, the smaller the static pressure $p(0)$ was. Above 30 Hz, the moving effect of the block surface was clearer with increasing frequency. For instance, the pressure amplitudes of $p(0)$ and $p(10)$ became smaller, but the amplitude of $p(-10)$ larger. At 70 Hz, the phase relationship between the passage clearance and the static pressure changed clearly in an opposite way to that of 10 Hz. At 100 Hz, the amplitude of $p(0)$ showed two peaks.

SUMMARY

The static pressure was measured around the oscillating obstruction at low frequencies to 100 Hz. The high frequency oscillation of the obstruction in the air flow channel has strong influences on the static pressures and their phase difference.

BIOMECHANICS OF THE KARATE FRONT KICK

D. Gordon E. Robertson, François Beaulieu, Carlos Fernando and Michael Hart
Biomechanics Laboratory, School of Human Kinetics, University of Ottawa, Ottawa, Ontario, Canada

INTRODUCTION

The front kick (*mae geri*) in karate is one of the strongest and most easily mastered kicks. This project examined the powers produced by the lower extremity joints of the kicking leg of two elite (fourth dan) martial artists performing both closed and open stance front kicks. The purpose was to determine the contributions and sequencing of the ankle, knee and hip moments.

METHODS

The subjects (one a specialist in Tae-kwon-do, the other in Karate) kicked against a padded board held by an assistant while filmed by a VHS camera. The subjects performed several trials each using both an open stance (kicking leg back) and closed stance (legs beside each other). The video was digitized with the Ariel Performance Analysis System and analyzed with the Biomech Motion Analysis System (Robertson, 2002). Inverse dynamics were used to compute the net moments and their associated powers for the ankle, knee and hip joints.

RESULTS AND DISCUSSION

The powers produced by the ankle moment of force were too small to warrant analysis. Figure 1 shows the angular velocities, moments of force and their powers for the knee and ankle of a typical trial. Notice that the moments of force of the hip and knee reverse direction at precisely the same instant just prior to contact with the board (right arrow). This was common to all trials and both subjects.

The powers produced by the closed stance kicks, as expected, always produced larger moments and powers than the closed stance kicks. Obviously, the added range of motion enabled the subjects to generate greater impulses and foot velocities.

The sequencing of the moments were consistent across all trials and both subjects. The motion began with almost simultaneous flexing of the hip and knee joints. The hip flexors were responsible for flexing both joints as shown by the burst of positive work done by the hip flexors while the knee moment of force was relatively inactive.

After the hip reached its maximum velocity, the hip moment of force became extensor (presumably due to eccentric contraction of the gluteals) causing the hip to slow its flexion and begin knee extension. Not surprisingly, based on similar research on the mechanics of sprinting (Lemaire & Robertson, 1989) the knee extensor moments did not contribute to increasing knee extension. Instead, the knee moment was flexor producing negative (eccentric) work to presumably protect the knee from hyperextension at the end of the kick.

SUMMARY

Peak powers were greater for the open stance than the closed stance. The hip extensors and flexors were the prime movers of both the hip and knee actions. The knee moments were primarily used to reduce knee flexion and extension during the kick.

CLINICAL APPLICATION OF A KNEE-JOINT-CONTROLLED ELECTRO-MECHANICAL KAFO FOR POLIO PATIENTS

Sung-Jae Kang and Young-Ho Kim

Department of Biomedical Engineering, Institute of Medical Engineering,
Research Institute for Medical Instrumentation & Rehabilitation Engineering,
Technology Innovation Center for Medical Instruments, Yonsei University
yhkim@dragon.yonsei.ac.kr

INTRODUCTION

The ideal knee joint of KAFO (Knee-Ankle-Foot Orthosis) should provide the stability in stance and the foot clearance in swing. To achieve these two important functions, many researches have been performed on the control of the knee joint in KAFO (Long and Ross, 1972; Yang, 1975; Suga et al, 1998; Lehmann, and Stonebridge, 1978). However, clinical evaluations on patients with those KAFOs have not been successful yet. In the present study, an electro-mechanical KAFO to satisfy both the stability in stance and the knee flexion in swing was developed and evaluated in eight polio patients with the motion analysis.

METHODS

A knee joint control algorithm suitable for eight polio patients who are lack of stability in pre-swing was developed and various control systems and circuits were also designed. Knee flexion angles and knee flexion moments were measured on those polio patients with the developed KAFO using electrogoniometers and the three-dimensional motion analysis system. Temporal gait parameters in the controlled-knee gait with the developed KAFO were also compared with the locked-knee gait as well as the normal gait

RESULTS AND DISCUSSION

The designed foot switch system successfully determined the gait cycle of eight polio patients to control the knee joint of KAFO, resulting in the passive knee flexion or foot clearance during swing phase. From the three-dimensional gait analysis for polio patients, it was found that the controlled-knee gait with the developed electro-mechanical KAFO showed the knee flexion of $40^{\circ} \sim 45^{\circ}$ at an appropriate time during swing phase and maximum knee flexion moment of $6.07\text{N}\cdot\text{m}$. In addition, the developed electro-mechanical KAFO revealed the possibility to correct toe drag and circumduction in an involved limb that are frequently found in polio patients.

Vertical movements of COG in controlled-knee gait (gait with the developed electro-mechanical KAFO) were significantly smaller than those in locked-knee gait (gait with the locked knee joint), and correspondingly controlled-knee gait reduced approximately 40% less energy consumption during horizontal walking.

More efficient gait patterns could be obtained, when various rehabilitation training and therapeutic programs as well as the developed electro-mechanical KAFO were applied for polio patients

Figure 1: Knee flexion angles in the locked-knee gait and the controlled-knee gait

SUMMARY

In this study, an electro-mechanical KAFO which an improved clutch control algorithm was developed and clinically evaluated on eight polio patients. From three-dimensional gait analysis, the maximum knee flexion angle in controlled-knee gait was $40^{\circ} \sim 45^{\circ}$. The temporal parameters and knee flexion pattern for controlled-knee gait showed a good agreement with those in the normal gait. The developed KAFO system with the automatic knee joint control could be a useful tool for polio patients.

SHOCK ABSORBING CROSS-COUNTRY SKI POLE FOR DRYLAND SKIING

Andrew Post and D. Gordon E. Robertson

Biomechanics Laboratory, School of Human Kinetics, University of Ottawa, Ottawa, Ontario, Canada

INTRODUCTION

Some research has gone into the forces that are produced during the pole plant phase of cross-country roller skiing (Street & Frederick, 1995; Komi, 1988; Millet et al., 1998a,b,c). Due to the hard surface (usually asphalt) into which the roller skiers plant their poles there are much higher forces travelling through the pole than with ordinary snow skiing. These high ground reaction forces have been identified as a possible cause of injuries to the wrists, elbows and shoulders of roller skiers.

To date few studies have tried to resolve this problem by inserting a shock absorbing mechanism into the ski pole. In the present experiment pole forces were examined before and after a shock absorbing mechanism (a spring) was inserted into a normal Nordic ski pole. The spring was inserted into the shaft of a carbon fibre cross-country ski pole between the handle and the shaft.

METHODS

To simulate the load created by the arm, a 1.13 kg mass was attached to the handle above the spring. The ski pole was dropped from a support that was set up over a force platform (Kistler). The pole was dropped five times for each of the four pole/height conditions: 20 and 40 cm with and without the modification. The pole was suspended by a fish line and the drop height was measured by an anthropometer to ensure repeatable impulses. The force platform was covered with a steel plate to protect it from the carbide tips of the ski pole. The resonant frequency of the force platform was measured to be approximately 780 Hz.

RESULTS AND DISCUSSION

The peak vertical forces for the 20 cm trials were 458 ± 66 N and 404 ± 45 N for the standard versus modified poles, respectively. The peak vertical forces for the 40 cm trials were 766 ± 49 N and 615 ± 64 N for the standard versus modified poles, respectively. Thus, the spring reduced the peak vertical force by 11.8% for the 20 cm drop height and 19.8% for the 40 cm drop height. Figure 1 shows vertical force histories for the normal and modified poles for the 40 cm drop. Notice that the spring dissipates the impact forces by spreading the forces over a longer duration and creating negative vertical forces.

The reduced peak forces are comparable to those reported by Wells (1988) for cross-country skiers on snow. Presumably, the spring has reduced the peak forces low enough to prevent stress related injuries.

SUMMARY

In summary, the trials to test the modified ski pole successfully simulated a standard pole plant on a harder than snow surface. The results showed that the forces were reduced by the shock absorbing system that was installed on the ski pole. While the modified pole was successful in a laboratory environment it is essential to estimate its durability and its functionality in a field setting for its use by the general public and athletes.

EFFECTS OF A COMPLETE BYPASS GRAFT ON THE FLOWFIELDS IN A HOST ARTERY WITH DIFFERENT SEVERITY OF STENOSIS

Tzu-Hsiang Ko

Department of Mechanical Engineering, Lunghwa University of Science and Technology, Taiwan, R.O.C
Associate Professor, thko@mail.lhu.edu.tw

INTRODUCTION

When moderate or severe stenosis occurs in the coronary arteries, the coronary bypass surgery will be operated. The effects of the bypass graft on the flowfields are closely relevant to the severity degree of stenosis. In the earlier studies, the end-to-side anastomosis flow model which assumed 100%-area severity stenosis was most frequently used (Hofer et al., 1996; Ethier et al., 1998). The flowfields obtained from the model could be very different from the realistic cases with only partially obstructed host arteries. To implement the flow characteristics in the host artery with different severity degree of stenosis, the present paper focuses on the anastomosis flows in tubes with different degree obstructions, and investigates the bypass effects on the flowfields.

METHODS

The geometry of the model is shown as Fig. 1. The flow is assumed as three dimensional, incompressible, laminar and steady. The continuity equation and the Navier-Stokes equation are solved numerically by SIMPLEC scheme. The grid layout is also shown in Fig.1. Uniform velocity distributions are assumed at the inlet and the fully developed condition is assumed at the outlet.

RESULTS AND DISCUSSION

Three different obstructed degrees, including 70%, 80% and 90%-area obstructed cases were studied in the present paper. Figs. 2(a), (b) and (c) showed the flowfields on the symmetric plane for the three cases respectively. The highest velocity appeared at the contracted area in all three cases. The highest velocity in 90%-area obstructed cases was about twice of the inlet velocity, and in the 70%-area obstructed case, the highest velocity was only about 1.75 times of the inlet velocity. The difference might induce different shear stresses at the contracted region. Four low velocity zones appear in three cases similarly. They distributed at the entrance of the bypass, the lower zone upstream of the contracted region and the upper and lower zones downstream of the contracted region. When three different cases were compared, the low velocity zone at the bypass entrance was widest in the 70%-area obstructed case, and the low velocity zones occurring at the other three regions were widest in the 90%-area obstructed case. There were recirculations on the low velocity regions, and were prone to accumulate the damaged particles and substances. Fig. 3 compared the mass fractions entering the bypass. The mass fractions entering the bypass in the three cases were about 60%, 73% and 86% respectively. Though the mass fraction directly flowing through the contracted region was the smallest in the 90%-area obstructed case, the velocity was

highest in three cases as mentioned previously. The high velocity fluid entering the downstream of the contracted area would induce high shear stresses which were believed to be an important factor relevant to the success of the bypass graft surgeon.

Fig. 1 The geometry and grid layout of the model

Fig.2 Velocity distributions for (a)70% (b)80% and (c) 90%-area obstructed cases (normalized by inlet velocity)

Fig. 3 Mass fraction entering the bypass graft for different obstructed cases

SUMMARY

The flow characteristics in a 70%, 80% and 90%-area obstructed host tube with a complete bypass graft were investigated. The flowfields in three cases showed very different features. The results were also different from those in the earlier studies which used the end-to-side model. The present study provided more realistic simulations as for preliminary design information.

MEASUREMENT DIFFERENCES BETWEEN TWO WRIST GONIOMETERS DURING PRONATION & SUPINATION

Peter W. Johnson¹, Per Jonsson² and Mats Hagberg²

¹ Department of Environmental Health, University of Washington, Seattle, WA, petej@u.washington.edu
² Section of Occupational Medicine, Göteborg University, Göteborg, Sweden

INTRODUCTION

Pronation and supination has been shown to affect the measurement accuracy of wrist goniometers. The purpose of this study was to determine whether there were differences in measurement accuracy between two different goniometers, over a wide range of pronation and supination (P/S).

METHODS

Eight subjects moved their wrist between -40° and 40° of flexion/extension (F/E) and -10° and 20° of radial/ulnar (R/U) deviation in four different P/S positions: 90° pronation (90 P); 45° pronation (45 P); 0° neutral (0 N) and 45° supination (45 S). Crosstalk and offset errors were compared between the goniometer systems and across the various P/S positions.

Two electrogoniometers were tested: System A consisted of a biaxial, single transducer goniometer (Biometrics; model XM-65; Gwent, UK), System B consisted of a biaxial, two-transducer goniometer integrated into a fingerless glove. (WristSystem, Greenleaf Medical, Palo Alto, California, USA). The sensing elements in System B were the exact same design as System A's and manufactured by the same company (Biometrics; Gwent, UK).

A tiltable, adjustable-height table (Part 50642, Förbandsmaterial AB, Partille, Sweden) combined with a calibration fixture (Greenleaf Medical; Palo Alto, CA) was used to repeatedly position each subject's forearm and wrist in known pronation/supination, flexion/extension and radial/ulnar angles. The goniometers were calibrated in 90° of pronation.

RESULTS AND DISCUSSION

As shown in Figure 1, offset errors in F/E were encountered during P/S and both systems experienced similar F/E offset errors. R/U offset errors were also encountered with both systems during P/S; however, the trends in R/U offset errors between systems were roughly equal but opposite in direction. As shown in Figure 2, System A was prone to more R/U crosstalk than System B and the amount of R/U crosstalk with System A was dependent on the P/S position. F/E crosstalk was present with both goniometer systems and dependent on P/S. Movement from 90 P to 45 S caused a synchronous twist/rotation in both the F/E and R/U signal with System A, whereas with System B, there was virtually no twist/rotation with the F/E movements and a small amount of P/S twisting/rotation with the R/U movements.

Figure 1: The effects of pronation and supination on measurement accuracy [n=8]. The bold black identity lines indicate the actual movements.

Figure 2: The effects of pronation and supination on F/E and R/U crosstalk grouped by goniometer system [n=8]. Offset errors in the various P/S positions from Figure 1 have been adjusted so the origins of each P/S position are aligned.

SUMMARY

Goniometer crosstalk is an important source of measurement error and results from a twisting of the goniometer transducer. System B demonstrates that design changes can reduce transducer twist and the resultant crosstalk. The calibration position will affect wrist angle measurements and the magnitude and direction of measurement errors. To minimize offset errors, goniometers should be calibrated/zeroed in the most common P/S position or in the mid-range of anticipated P/S positions. When possible, goniometers should not be calibrated in one P/S position and used another P/S position, otherwise offset error will result.

HEAD TURNS INDUCE ALTERED LOADING DURING STANDING IN STROKE PATIENTS

Anouk Lamontagne, Nicole Paquet and Joyce Fung

Jewish Rehabilitation Hospital Research Center & McGill University, Montreal, Canada.
(Anouk.Lamontagne@mcgill.ca)

INTRODUCTION

Stroke patients have difficulties maintaining balance while walking with voluntary head turns (Kairy et al. 2000). How postural adaptations to fast head turns in stroke patients differ from those of healthy individuals, however, is unclear. Our objective was to compare postural adaptations to horizontal head turns during standing between stroke patients and healthy subjects by examining the loading forces (GRF), body center of mass (CoM) and center of pressure (CoP).

METHODS

Eight patients (aged 56-79 yrs) with a hemiparesis (right=4, left=4) secondary to a first ischemic stroke and 4 healthy controls (aged 54-76 yrs) were evaluated during standing with their feet apart at shoulder width. An illuminated arrow panel located in front of the subjects indicated the direction for voluntary head turns. Head turn directions were randomly delivered in the right and left directions (3-6 trials per direction), interspersed with catch trials (6-12 trials) with no head turn. Subjects were instructed to turn the head as fast and as quickly as possible in the direction indicated by the arrow and to keep the head turned for 3s. A Vicontm 3-D motion analysis system with six infrared cameras was used to record body segment displacements at 120 Hz. Body CoM was calculated based on kinematics using a 9-segment model. Two AMTI (OR6-7) force plates, embedded in the floor, were used to record GRF under each foot and the net displacement of the body CoP was calculated. Changes in GRF with respect to baseline values were calculated using integrals over sequential time windows (see Figure). In addition, maximum displacement of the body CoM and CoP, as well as the mean absolute difference between CoP and CoM, were analyzed.

RESULTS

Patients performed amplitudes of head turn similar to controls, but at slower velocities. Mean peak head turn velocities were 335 (± 124) deg/s for the controls and 237 (± 63) deg/s for the patients. In the controls (Figure), GRF were characterized by an unloading-loading pattern of the limb ipsilateral to the direction of the head turn. In the patients (Figure), head turns ipsilateral to the paretic side caused the same unloading-loading pattern of the paretic limb, but this was immediately followed by an unloading of the paretic limb. During contralateral head turns, a systematic unloading of the paretic limb was observed. Note that very little if no changes in GRF

took place before the onset of head turns in both groups. CoM and CoP in patients and controls were shifted toward the side of the head rotation. The shifts in body CoM were small and similar between groups and directions of head turn (range: 3.5 - 4.1 mm). CoP displacements, however, were larger in the patients (ipsilateral=11.6mm, contralateral=11.9mm) than in the controls (8.0 mm), resulting in a larger CoP-CoM difference. These shifts in CoM and CoP represented more than 3 times the peak-to-peak displacements observed in trials with no head turns for the controls. In the patients, peak-to-peak displacements of CoM and CoP were similar between trials with and without head turns.

Changes in vertical ground reaction forces (GRF) during horizontal headturns

DISCUSSION AND CONCLUSIONS

GRF patterns indicate that stroke patients minimize loading of the paretic limb during horizontal head turns, in contrast with healthy subjects who show a typical unloading-loading pattern of the limb ipsilateral to the direction of the head turn. The inability to load the paretic limb likely explains the lack of increase in CoM and CoP excursions during trials with head turns as compared to trials without head turns. The larger CoP-CoM differences and the slower head turn velocities in patients suggest the maintenance of a larger safety margin due to postural instability (Corriveau et al. 2000).

EFFECTS OF AGE AND GENDER ON MAXIMUM HIP FLEXION POWER AT LOW AND HIGH VELOCITIES

¹Biomechanics Research Laboratory, University of Michigan, Ann Arbor, MI, USA

²Bio Logic Engineering Inc., Dexter, MI, USA

³Communicating author cecile.smeesters@gme.usherb.ca

INTRODUCTION

The ability to complete a compensatory step in time to arrest an on-going forward fall can require the hip flexor muscles to maximize power (Schultz et al., 1997). Mean step velocity of older males in single-step recovery from their maximum forward lean is approximately 350°/sec (Wojcik et al., 1999). However, age and gender effects on maximum hip flexion strengths have only been reported for isokinetic velocities up to 210°/sec (Cahalan et al., 1989). The literature contains reports showing significant gravitational and inertial measurement artefacts as well as narrowing isokinetic windows at higher isokinetic velocities. We used a custom dynamometer that made corrections for these effects. Our null hypothesis was that neither age nor gender would significantly affect the maximum hip flexion power (torque x angular velocity) developed in healthy adults.

METHODS

The custom dynamometer had a stiff, low rotational inertia lever arm providing a smooth, adjustable, passive resistance throughout the range of motion (ROM); visual feedback of results; and dedicated angular position and torque sensors. From the measurements obtained, velocity, acceleration, rate of torque and power were calculated, and corrections for the leg lever inertia and gravity were made. The subject's upper body was secured so that the dominant leg hip joint was aligned with the center of rotation of the lever arm. The tested leg was secured to the lever arm at the ankle with the tested knee near full extension. Twenty-four young (18-26yrs) and 24 older (65-84yrs) healthy adults, with equal numbers of males and females, were tested at five randomly ordered resistance levels spanning the range of achievable velocities for each subject. Except for the maximum resistance level or zero velocity isometric test where the angle was maintained at 0°, the ROM was from 0° to 90°. The subjects were instructed to swing their leg "as fast and as hard as possible" until it was decelerated by a soft stop. Maximum instantaneous hip flexion power, velocity and torque over the ROM were measured (Figure 1). Linear curves were fitted to each subject's maximum torque over the ROM versus maximum velocity over the ROM data. Quadratic curves were fitted to each subject's maximum power over the ROM versus maximum velocity over the ROM data. Age and gender effects on maximum achievable hip flexion kinetic power, torque and velocity were assessed with repeated measures analyses of variance (rm-ANOVA).

Figure 1: Average (N=48) normalized angle, velocity, torque and power versus time from low (LR) to high resistances (HR).

RESULTS AND DISCUSSION

Age and gender significantly affect the maximum achievable kinetic power, torque and velocity (all $p < 0.005$). Maximum achievable hip flexion power decreased 21% and 16% with increasing age for males and females, respectively, due to a decrease in both maximum torque and velocity (Table 1). The maximum achievable kinetic velocities ranged from 244°/sec to 508°/sec. The substantial age-related reduction in older adult hip flexor muscle power may underlie the diminished ability, especially in older women, to take a sufficiently rapid step to arrest a forward fall (Wojcik et al., 1999).

Table 1: Percentage Decrease With Age of Torque (T), Power (P) and Velocity (V) at the Maximum (Max) Points

	TMax	PMax			Vmax		
	T	T	V	P	T	V	P
Female	25%	31%	21%	49%	44%	21%	50%
Male	17%	20%	16%	37%	30%	14%	39%

INTRODUCTION

Small airways consist of tapered, curved, branching tubes with various length and diameter, and their geometry influence mechanical dynamics in airways (airflow structure, surfactant transport and particle deposition). In the previous studies, the cast models and the fixed preparations were available to analyze large airway geometry⁽¹⁻³⁾. However, the airway geometry, especially small airways, may be changed in the stage of preparations and it varies during respiration. In this study, we propose the new technique to visualize the small airways at high resolution without requiring fixed preparation.

METHODS

We visualized small airways of the excised rat lungs without fixed preparation. The radiopaque solution was induced into blood and stained to lung tissue without airways by the permeability. In our technique, lung tissue without air, for example pulmonary arteries and airway wall, exhibits a higher intensity than airway lumens.

Animal Preparation

After male Wister rats (300 ± 30 g) were anesthetized with pentobarbital sodium (50 mg/kg ip), they were exsanguinated and cardiac arrest was induced by 0.2 g/ml KCl solution. The water mixed this a radiopaque media, Sodium diatrizoate (Sigma Chemical, St Louis, MO) in the quantity 0.8 g/ml, was induced into an inferior vena cava. After the solution was stained to lung tissue for 1 h, the lungs were removed.

Imaging

The small airways were visualized by a microfocal X-ray CT system (MCT-CB100MF, Hitachi Medical Corp., Japan, Tokyo). This system consisted of microfocal cone-beam X-ray source (spotsizes: 7 μ m), X-Y-Z- θ rotation stage, an image intensifier and 12 bit CCD camera. The Resolution was 480×480 pixel and 1 voxel size was 13 μ m. In one rotation, the number of slice images was obtained 200 images.

The excised rat lung induced by the radiopaque solution was placed into a Plexiglas cylinder in. It was mounted on the rotation stage, and it took 2.5 min to rotate around 360°.

RESULTS AND DISCUSSION

Fig. 1 shows the example continuous micro-CT images (slice pitch: 52 μ m). The radiopaque solution was stained to lung tissue, and so airway lumens had a lower intensity. Using our technique the continuous and complex branching airways were visualized in detail physiologically.

The edge lines of target airways could be identified using a threshold method. Fig. 2 shows the three dimensional structure, which was reconstructed from the continuous edge lines.

Fig. 1: The continuous images of micro-CT (Scale bar = 500 μ m). From image (A) to image (F), airway (1) and airway (2) were branching, otherwise airway (2) and airway (3) were merging.

Fig. 2: Three dimensional reconstruction image from the continuous edge lines (width: 6.24 mm and height: 2.59 mm).

SUMMARY

We stained the radiopaque solution to lung tissue by the permeability and visualized by a microfocal CT system, and so we visualized small airways physiologically in detail. Using this new visualization technique, the geometry of small airways, diameter and length as well as branching angle and curvature, can be analyzed in detail when lung volume is variable.

FLOW IN A REALISTIC MRI-BASED VASCULAR BRANCH

Mehran Tadjfar and Ryutaro Himeno
Advanced Computing Center
Institute of Physical and Chemical Research (RIKEN)
2-1, Hirosawa, Wako-Shi, Saitama, JAPAN

INTRODUCTION

Many researchers use CFD to study the mechanics of blood flow in the human vascular system. The emphasis is shifting from averaged, idealized geometric models into realistic patient-specific models taken from MRI images or other advanced imaging techniques (Taylor et al. 1998). In order to use the results of CFD for clinical diagnoses or surgical planning, one needs to have fairly accurate representation of the given patient's vascular system or at least in the region of interest. This involves fairly smooth geometrical model of the region and an accurate description of the inlet and outlet flow conditions. Here, we use CFD methods to study the flow based on an accurate grid representation of a realistic MRI-based arterial branch (Fig. 1).

METHODS

The unsteady, three-dimensional, incompressible Navier-Stokes equations are solved using a fast, parallel, and time-accurate finite volume solver (See Tadjfar 2002). The solver is capable of dealing with moving boundaries and moving grids. It is designed to handle complex, three-dimensional vascular systems. The computational domain is divided into multiple block subdomains. At each cross section the plane is divided into twelve sub-zones to allow flexibility for handling complex geometries and, if needed, appropriate parallel data partitioning. A second-order in time and third-order upwind finite volume method for solving time-accurate incompressible flows based on pseudo-compressibility and dual time-stepping technique is used.

RESULTS AND DISCUSSION

We have developed tools to convert arterial branches from MRI-images to solid surface geometries. A structured grid is generated from these solid surfaces for the use in the flow simulation. We can obtain all the flow properties for both steady and unsteady flow simulations (see Fig. 2). From the simulation data, we can obtain the shear and normal stresses on the arterial walls. The intention is to use the results of these simulations based on the MRI-images obtained from a patient base for the study of arterial diseases.

INTRODUCTION

Cerebral oxygen demand is very large and normal brain function depends on continuous oxygen delivery. One of the most important parameters in the oxygen delivery process is a microvascular structure where the oxygen is mainly supplied through to tissue. Regional differences in the microvascular networks and density are generally known (Duvernoy, H.M.). However, the quantitative differences in the microvascular structure are not clear, and whether the regional varieties of the microvasculature respond a subsistent oxygen demand in tissue is subsequently unclear. To clarify the quantitative differences in the microvasculature in the local cerebral regions, we developed a quantitative evaluation of the microvascular structures by means of a resin injection method with fluorescent dye. In addition, to confirm whether the microvascular structure is influenced by the oxygen demand, we investigated the relationships between the regional microvasculature and Po₂ distribution in both the different function areas and their laminar regions in rat somatosensory cortex.

MATERIALS AND METHODS

The experiments were performed on male Wistar rats (290-320 g) anesthetized with sodium pentobarbital (50 mg/kg bw, i.p). To visualize the microvascular structure in the brain, prepolymerized methacrylate resin mixed with fluorescent dye (Lumogen® F Red 300, BASF) was perfused through the left ventricle. After the fixation of the blood vessels, the whole brain was removed and then its coronal sections were developed (Fig. 1A). The microvascular structure, within the functional areas in the primary somatosensory cortex (S1HL: hindlimb region, S1FL: forelimb region, and S1Tr: trunk region) based on the brain map (Paxinos and Watson), was observed by a laser scanning confocal microscope (Oz, NORAN). Analysis of the vascularity was performed by the isolating regions of interesting (ROI) in each functional area (Fig. 1B). To produce the binary ROI of the selected regions, a threshold of discrimination was applied. Then, to estimate the number density of the blood vessels in the ROI, we calculated the number density of the black pixels skeletonized from the casting molds of the vessels in the ROI (Fig. 1C). Po₂ distribution in the functional areas was measured by micro-coaxial oxygen electrodes (Lübbers Type) penetrating vertically from the brain surface by 20-μm step intervals.

RESULTS AND DISCUSSION

The high vascular density region was found in the middle cortical layers (III-V) in all functional areas we observed (Fig. 2). This agrees with the human cortical microvascularization (Torre, F. R. 1998) and this suggests that the large vascularity reflects the high oxygen demand, because the highest cerebral glucose utilization was found in the layer IV (Wress, A. 1990) where the neural inputs from thalamus directly connect.

Figure 1: Visualizations of vascularity in rat brain (300-μm thickness)
(A) Coronal section of the left hemisphere
(B) Selected region of interesting (ROI) in a functional area.
(C) Skeletonized section of the binary ROI (from Fig. 1(B))

Figure 2: Number density of black pixels (vascularity) in ROI

Figure 3: Comparison of the vascularity and Po₂ distribution in the area S1HL (Layer I-VI)

Some inconsistent points between the vascularity and Po₂ distribution was found in the superficial layers (I-II). Such as the vascularity increased from the surface, in contrast, the Po₂ decreased (Fig.3). This implies that disproportion of the oxygen supply to the oxygen demand may exist in the cerebral superficial regions.

EVALUATION OF SHAPE ACCURACY IN CT BASED FEMUR MODEL FOR PROSTHETIC STEM DESIGN

Jiro Sakamoto¹, Tanzo Sugimori², Ayumi Kaneuji², Mitsuru Nishino², Juhachi Oda¹ and Tadami Matsumoto²

¹ Dept. Human and Mechanical Systems Engineering, Kanazawa University,
Kanazawa, Ishikawa, Japan, sakamoto@t.kanazawa-u.ac.jp

INTRODUCTION

Three-dimensional CAD model of hip joint is required for development of total hip prosthesis and stress analysis by finite-element method. The authors have been classified proximal femur canal shape of Japanese osteoarthritis (OA) patients by using 3D models based on CT images to develop total prosthetic stem fitting specially for Japanese OA (Hasegawa, et al., 2000). Although shape accuracy of the 3D model is very important to develop the total hip stem, it has not ensured sufficiently. In this study, a 3D femur model constructed from CT images was compared with corresponded real femur, and accuracy of the model was evaluated.

MATERIALS AND METHODS

A femur of 50 years-old female with OA was subjected to evaluate accuracy of the 3D model. The right leg was resected because of a malignant tumor. CT images of the femur were obtained before the resection. The CT images were inputted into image processing software (MedVision, Evergreen Technologies Inc.), and cortical outlines and canal lines were extracted in each section. These lines were transferred to CAD software (Unigraphics, Unigraphics Solution Inc.), and then 3D model was constructed by interpolation based on the lines. On the other hand, the resected femur was embedded in resin mold, and parallel sliced specimens were prepared. Photographs of the cross sections were taken from the specimens as same as CT scan. The 3D model based on the real femur was constructed in same way to make the 3D model based on CT images. These models are comparable each other by overlapping operation of CAD. Overlapping image of the real and CT based model is shown in Fig. 1. Bone axis, lesser trochanter and center of femoral head are matched up each other in the overlapping.

RESULTS AND DISCUSSION

The outlines and canal lines of the real and CT based model in frontal plane are shown in Fig.2. Gap between each canal line of the real and CT based model was measured in some horizontal plane. In the figure, "level" denotes distance from the lesser trochanter level. The gap value means shape error of the CT based model related to the real femur. The canal lines corresponded well each other in distal part below the level of +15mm. Maximum gap is 1.5mm at the medial side

of lesser trochanter level. If the CT based model is used to design the prosthetic stem shape, we have to pay attention that error of the model can be over 1mm.

Figure 1: 3D overlapping image of the real and CT based model of proximal femur.

Figure 2: Gap of the canal line between the real and CT based model in frontal plane.

SUMMARY

Shape accuracy of 3D femur model created by CT images was evaluated in comparison with precise model based on cross section images of the real femur. Proximal canal surfaces of the two models were compared each other by overlapping in CAD software. Over 1mm error was observed in the CT based model. We have to consider such error range when the CT based model is used to design of prosthetic stem fit to proximal femur canal.

FLOW BETWEEN A CLOT MODEL AND A STENOSIS

A. Sarkar¹ and G. Jayaraman

Center for Atmospheric Sciences, Indian Institute of Technology Delhi,
Hauz Khas, New Delhi – 110016, INDIA.

¹Present Address : Bioengineering, University of Washington, Seattle. USA. anamika@bioeng.washington.edu

INTRODUCTION

A pathological condition is encountered when some blood constituents deposited on the artery wall get detached from the wall, join the blood stream again and form a clot which can lead to complete blockage of the blood vessels. Doffin and Chagneau (1981) set up an experiment and showed that the velocity profiles, of the steady component of the flow, experience considerable changes in the unsteady flow field by the steady streaming, especially for low values of the frequency parameter. We analyse the model proposed by them, to study the effect of the height of the clot model and frequency parameter on the physiological parameters of the flow.

MATHEMATICAL MODEL

We model the artery as a rigid tube with radius R_0 . Fig.1 shows the schematic diagram of the stenosed artery in the presence of a clot model in the cylindrical coordinate system (R, θ, Z) . The flow is axi-symmetric and oscillatory in nature. It is assumed that the development of the stenosis is axisymmetric over the length of the artery. It is also assumed that the clot model is axisymmetric.

Fig. 1 The schematic diagram of the stenosed artery with a clot model inside.

The equations of motion in non dimensional form become,

$$\frac{\partial u}{\partial r} + \frac{u}{r} + \frac{\partial w}{\partial z} = 0$$

$$\begin{aligned} \alpha^2 \frac{\partial w}{\partial \tau} + R_{en} \delta \left(u \frac{\partial w}{\partial r} + w \frac{\partial w}{\partial z} \right) &= -R_{en} \frac{\partial p}{\partial z} \\ + \left(\frac{\partial^2 w}{\partial r^2} + \frac{1}{r} \frac{\partial w}{\partial r} \right) + \delta^2 \frac{\partial^2 w}{\partial z^2} \\ \delta^2 \alpha^2 \frac{\partial u}{\partial \tau} + R_{en} \delta^3 \left(u \frac{\partial u}{\partial r} + w \frac{\partial u}{\partial z} \right) &= -R_{en} \frac{\partial p}{\partial r} + \\ \delta^2 \left(\frac{\partial^2 u}{\partial r^2} + \frac{1}{r} \frac{\partial u}{\partial r} - \frac{u}{r^2} \right) + \delta^4 \frac{\partial^2 u}{\partial z^2} \end{aligned}$$

where R_{en} is the Reynolds Number, u and w are the velocities in the radial and axial directions respectively, p denotes the pressure, $\alpha = R_0 \sqrt{(\omega/\nu)}$ is the Womersley number (ω = angular velocity and ν = kinematic viscosity) and δ is the geometric parameter. The no slip boundary conditions give $w = u = 0$ at $r = r_s(z)$ and $r_c(z)$, where $r_s(z)$ and $r_c(z)$ describe the non dimensional stenotic wall and geometry of the clot model. Also, we assume constant volume flux say, $Q = \cos(\tau)$ at every instant along the tube. Using lubrication theory, we develop a series solution in powers of δ for frequency parameter, α , either small or very large. Asymptotic analysis is done to study the flow field separated into three regions (i) region near the clot model (ii) core region and (iii) region near the stenotic wall.

RESULTS AND DISCUSSIONS

The solutions are obtained for two different geometries of stenosis. *Geometry 1*: $r_s(z) = 1 - \delta_1 e^{-\pi^2(z-0.5)^2}$, which is a Gaussian curve with peak (δ_1) at $z = 0.5$ and *Geometry 2*: A fitted curve based on data after coronary angioplasty PTCA (Back and Denton (1992)) The clot model is described by the function $r_c(z) = k + \delta_2 e^{-\pi^2(z-zd-0.5)^2}$ where δ_2 is the maximum height attained by the clot at $z = zd + 0.5$, k is the radius of the inner tube which keeps the clot model in position and zd represents the axial displacement of the clot. The table shows the comparison of induced mean pressure gradient at the end of the stenosis, p_s , and maximum absolute value of shear stress, T_s , for different values of δ_2 for *Geometry 1* and 2 ($\alpha = 5$, $zd = 0$).

Table : Comparison of mean pressure gradient, p_s and maximum absolute value of shear stress, T_s

Geometry	p_s			T_s		
	1		2	1		2
	$\delta_2=0.2$	$\delta_1=0$ $\delta_1=0.16$		$\delta_1=0$ $\delta_1=0.16$		
	0.05	-0.29 -0.087	1.12	0.067 0.094		0.201
	0.1	-0.51 -0.329	0.76	0.106 0.195		0.329
	0.15	-0.70 -0.528	0.48	0.393 0.396		0.456
	0.2	-0.85 -0.696	0.25	0.474 0.842		0.874

The streamline patterns show distinct boundary layer characteristics at both the stenotic wall and the wall of the clot when the frequency parameter is small. Results are sensitive to not only the geometries of the stenotic wall but also to the position of the clot model.

INTRODUCTION

The mechanical properties of hard tooth tissues are considerable interest in the field of dental research. The hardness of dentine and enamel has been studied by a number of researchers who have used spherical (Renson and Braden, 1971), Knoop (Meredith et al., 1996) and Vickers (Ryge et al., 1961; Curry and Brear, 1990) indenters. Evans and Wilshaw (1976) have used a microindentation test to obtain the fracture toughness of ceramic materials. Hassan et al. (1981) utilized a similar technique to determine the fracture toughness of human enamel. However, this technique was difficult to detect cracks developed by the wedge-shaped corners of the Vickers' indenter. In this study, we investigated the fracture toughness and hardness of human enamel utilizing a microindentation method with a laser scanning microscopy.

MATERIALS AND METHODS

Forty-eight enamel specimens were obtained from sixteen human molars. Enamel specimens were transversely sliced into thin layers 1.0 mm thick from upper, middle and lower positions of teeth. The perpendicular direction of specimen was aligned with the tooth axis. Each specimen was polished with a buffing machine. After being polished, specimens were stored in saline. The specimens were tested on a Vickers microhardness tester (MVK-H1, Akashi, Japan), equipped with a diamond pyramid indenter, using 1.96, 2.94 and 4.9 N applied loads for 30 seconds. The surface of specimen was covered with a wet tissue between indentation. The indentation diagonal and crack size were measured with a laser scanning microscopy (OLS1100, Olympus, Japan). Vickers microhardness, H_V , is defined applied load divided by the surface area of the indentation. The fracture toughness, K_{IC} , is defined as (Lewis et al., 1981):

$$K_{IC} = \frac{1.4}{\pi^{3/2} \tan \phi} \cdot \frac{P}{c^{3/2}} \quad (1)$$

where c is length of crack developed by the wedge-shaped corners of indentation, P is applied load and ϕ is half-angle of Vickers indenter at 74 degrees.

RESULTS AND DISCUSSION

Mean values for Vickers hardness and fracture toughness of enamel with confidence intervals at the 95% level were calculated for different positions and applied loads, and are presented graphically in Figs. 1 and 2. No significant differences were observed for hardness. The fracture toughness at the middle position was higher than that at the upper position. The value of fracture toughness was found within the range of 0.8 to 1.1 $\text{MN/m}^{3/2}$. The advantages of the microindentation method lies in its ability to provide fracture

toughness measurement not only on small specimens, but in localized areas as well. Further studies can be performed using this method to determine the anisotropic and inhomogeneous effects on the fracture toughness of enamel.

STRESS DISTRIBUTION ON A LEUKOCYTE FLOWING THROUGH A NON-UNIFORM MICROVESSEL WITH AN ENDOTHELIAL SURFACE LAYER

Masako Sugihara-Seki

Faculty of Engineering, Kansai University, Suita, Osaka, Japan, sekim@kansai-u.ac.jp

INTRODUCTION

It is well known that cells in the circulation respond to stresses exerted by the blood flow in various circumstances. Recently, an important response of circulating leukocytes to fluid stresses has been reported in physiological and inflammatory states (Moazzam et al 1997; Fukuda et al 2000). In the present study, we numerically examine the fluid stresses acting on the surface of a freely floating leukocyte, in the presence of an irregularity of the vessel lumen and an endothelial surface layer (ESL). Interior surfaces of blood vessels are lined with a layer of bound or adsorbed macromolecules, named as ESL, whose physiological implications are discussed (Vink, Duling 1996; Secomb et al 1998; Pries et al 2000; Feng, Weinbaum 2000). Here, the effect of the ESL on the stresses acting on a flowing leukocyte is examined.

METHODS

We consider the motion of a leukocyte freely floating in a non-uniform microvessel with or without an ESL. For simplicity, the leukocyte is modeled as a rigid sphere, and the ESL is approximated as a porous medium with a constant Darcy permeability K_0 and a constant thickness w . The particle is suspended in an incompressible Newtonian fluid (viscosity μ) flowing through a circular cylinder whose wall has a protrusion with a sinusoidal shape into the lumen with height h , as shown in Fig. 1. In the present analysis, penetration of the particle into the ESL is not treated.

Figure 1: Configuration.

Assuming that the inertia of the fluid and the particle can be neglected, the resultant force and moment on the particle vanish at each instant, and the motion of the fluid obeys: $\nabla \cdot \mathbf{u} = 0$ and $-\nabla p + \mu \nabla^2 \mathbf{u} - K\mathbf{u} = 0$, where p and \mathbf{u} denote the pressure and the velocity vector of the fluid, respectively, and $K = K_0$ in the ESL and $K = 0$

otherwise. These equations are solved numerically by a finite element method, under the non-slip boundary condition at the surfaces of the particle and the vessel wall.

RESULTS AND DISCUSSION

Straight uniform vessel ($h = 0$): The thickness of the ESL is estimated to range from $0.5 \mu\text{m}$ to more than $1 \mu\text{m}$ (Pries et al 2000). Estimates of K_0 showed at least $\approx 10^8 \text{ dyn} \cdot \text{s} / \text{cm}^4$ for microvessels (Secomb et al 1998), indicating that flow penetrates only a short distance (approximately $0.1 \mu\text{m}$) into the ESL. This implies smaller effective cross-sectional area of the microvessel compared to that with no ESL, so that the presence of the ESL enlarges the flow velocity (and the shear rate) at constant flow rates. Thus, a suspended particle experiences higher stresses on its surface when the ESL is present. This tendency is enhanced as the gap distance between the particle surface and the edge of the ESL is decreased.

Non-uniform vessel: Figure 2 shows examples of the computed flow velocity, the pressure contours and the distribution of the shear stress on the particle surface, in the presence of both ESL and protrusion of the vessel wall. This corresponds to the case of a leukocyte with $8 \mu\text{m}$ diameter flowing through a $16 \mu\text{m}$ microvessel with a protrusion of $1.6 \mu\text{m}$ height and an ESL of $1 \mu\text{m}$ thickness with $K_0 = 1.56 \times 10^8 \text{ dyn} \cdot \text{s} / \text{cm}^4$. Compared to the cases when one or both of the ESL and the protrusion are absent, much larger variations of the shear stress and the pressure are observed on the particle surface near the gap region. When the mean flow velocity across the vessel cross-section $U_m = 1 \text{ mm} / \text{s}$ and $\mu = 0.01 \text{ dyn} \cdot \text{s} / \text{cm}^2$, the variation of the pressure over the particle surface is approximately $106 \text{ dyn} / \text{cm}^2$ and that of the shear stress is approximately $63 \text{ dyn} / \text{cm}^2$, in the case shown in Fig. 2. Due to the rotation of the particle, its surface always experiences these variations as it translates.

TIME-DEPENDENT STRESS-STRAIN ANALYSIS OF UNCONFINED COMPRESSED ARTICULAR CARTILAGE USING COMFOCAL LASER SCANNING MICROSCOPY

Maki Ihara¹ Teruo Murakami² and Yoshinori Sawae²

¹Dept. of Intelligent Machinery and Systems, Graduate School of Engineering, Kyushu University, Fukuoka, Japan, maki@tribo1.mech.kyushu-u.ac.jp

INTRODUCTION

Articular cartilage has viscoelastic property based on high water content, and the flow behavior of water concerns the deformation of articular cartilage under compression state. In addition, its depth-dependent complicated structure causes complex stress-strain field. In this study, we investigated the structural response of time-dependent stress-strain behavior under unconfined, axial and static compression.

METHODS

Full depth rectangular blocks of articular cartilage including subchondral bone were prepared from the medial femoral condyle in knee joints of 4 -5 months porcines, and hemi-cylindrical test specimens which has a radius of 3 mm were cut from them. None of the joints exhibited any visible signs of degeneration.

For fluorescent microscopy, cells within articular cartilage are stained with the viable fluorescent probe, 5- Chloromethyl fluorescein diacetate. The direct observation of depth-dependent deformation of articular cartilage became possible by taking fluorescent stained chondrocytes as marker.

Test specimens were compressed at ramp period of 1.0 s to strains of up to 15% using a specially designed test rig whose indenter was controlled by a micrometer head. And the indentation alumina plate was impermeable. It was mounted on the stage of confocal laser scanning microscope which was used to visualize the cells within the articular cartilage. Test specimens were kept hydrated in a bath of PBS.

We took the time-dependent successive images during 120 s immediately after compression. After that, the scanning was executed at 300 s, 900 s, 1200 s.

RESULTS AND DISCUSSION

We observed time-dependent strain of articular cartilage by monitoring stained chondrocytes within articular cartilage. We confirmed viscoelastic stress relaxation under compression. Results indicated that the zone-specific changes of articular cartilage under compression predicted that the strain of the upper part in the middle layer immediately after compression

may be larger than equilibrium and mechanical environment around chondrocytes in this layer changed largely than equilibrium. These processes are important to elucidate the deformation mechanism of articular cartilage in the osteoarthritis.

Figure 1: Time-dependent displacement of chondrocyte in cartilage at (a)5s, (b)30s, (c)120s, (d)300s after unconfined compression

SUMMARY

Articular cartilage has viscoelastic property and it is impossible to explain its mechanical environments easily. We made the special test rig to compress articular cartilage up to constant strain, and using the confocal laser scanning microscopy we could make it possible to monitor time-dependent and depth-dependent strain of articular cartilage.

INTRODUCTION

Many studies in aging have demonstrated the mechanisms for regulating balance in standing and walking interact with high level cognitive systems and may share similar attention resources (Teasdale 1993, Shumway-Cook et al. 1997). Research on children also shows that attention is related to learning and fine motor control. Whether attention affects the children's postural and balance control is less investigated. The purpose of this study was to investigate the effect of a concurrent attentional task on the standing balance performance in children and young adults.

METHODS

Ten children (age, 9.4 ± 3.5 range 5-13 years; height, 141.2 ± 20 range 116-158.5 cm; mass, 34.8 ± 11.8 range 20.5-48.5 kg) and ten young adults (age, 20.8 ± 0.7 range 20-22 years; height, 165.7 ± 5.1 range 157-171 cm; mass, 56.7 ± 7.3 range 50.5-74 kg) participated in this study. The effect of a concurrent attentional task (tone detection) on standing balance was investigated under four sensory conditions: (1) eyes open, fixed foot support, (2) eyes close, fixed foot support, (3) eyes open, compliant foot support, and (4) eyes close, compliant foot support. The fixed foot support was the metal force plate surface and the compliant foot support was a medium-density foam (40.5-cm x 40.5-cm x 7.5-cm section) placed on top of the force plate. The tone-detection task involved playing an auditory signal (a 250 Hz pure tone) to the right or left of the subjects every two seconds. The subjects were required to press a left or a right button as soon as they heard the tone. The task varied at two levels of difficulty: easy (stimulus and response were spatially compatible, e.g., left tone left button) and hard (where stimulus and response were spatially incompatible, e.g., left tone right button). A force platform (Kistler 9284) was used to collect the ground reaction force at a sampling rate of 500 Hz for 20 s. The sway area of center of pressure was calculated and used to represent the subject's standing balance.

RESULTS AND DISCUSSION

Figure presents the subjects' standing balance under three attentional conditions (no concurrent task, low-demand task and high-demand task) and four sensory conditions. Results showed that children generally presented greater COP sway area than adults did ($F_{1,18} = 30.01$, $p < .0001$). The effect of attentional task was also significant. Subjects showed smaller COP sway area with concurrent attentional task than without concurrent attentional task ($F_{2,36} = 19.05$, $p < .0001$).

The effect of the attentional task was not different in children than in adults ($F_{2,36} = 1.65$, n.s.).

The results showed that the concurrent attentional task did not negatively affect the balance performance. Rather it improved the standing stability of both children and young adults. The effect was not different in low demand and high demand attention tasks. Although these results are not the same as those reported in the literature with elderly subjects, they are not different from the results of Vuillerme et al (2000). Vuillerme et al. showed that postural stability was better while concurrently performing a reaction time task than while maintaining balance alone condition. The discrepancy between our results and those studies based on the elderly subjects may be explained as follows. Aging caused deterioration of the peripheral system. As a result, a task (such as standing) which normally is taken to be easy and automatic by children and young adults will require attention in the elderly. This renders the elderly especially vulnerable under a divided-attention situation. By contrast, children and young adults apparently cope with the situation with a different strategy. In our study, it appeared that the effect of the concurrent attentional task was an increase of the subjects' alertness and their body stiffness, thereby an increase in their standing stability.

INTRODUCTION

We have been developing a computational fluid dynamic modeling of left ventricle hemodynamics for a purpose of clinical application. In our previous model, velocity boundary conditions at aorta- and mitral valve in left ventricle were defined using measured physiological data with pulse Doppler method. With consideration of non-invasive assessment of left ventricle function, a multi-scale modeling of combined lumped model and detailed 3D model can be of great significance. In this study, we aim at coupling of the previous 3D model with a recently developed lumped model for cardiovascular system, in which the influence of left atrium and aorta are accounted for in terms of resistance, compliance, and inductance⁽¹⁾ (Fig. 1).

Figure 1: A multi-scale computational model for left ventricle hemodynamics.

METHODS

In the two-chamber-view modeling⁽²⁾ method that we developed for numerical analysis of blood flow in a left ventricle, we reconstruct the anatomic model of a human left ventricle by applying two-chamber-view modeling to two phase echocardiogram images. In the unsteady solutions to the 3D incompressible Navier-Stokes equations, fluid is assumed to be homogeneous and Newtonian. The governing equations are discretized and solved in a manner of finite volume method. A 0D model for circulation system is expressed by a lumped constraint model, which is constituted with resists, compliances, and inductances. A combined computational system of the 0D and 3D models is hereby established for simulation of hemodynamics in left ventricle. The 0D model is used to provide boundary conditions for the detailed 3D model at inlet, the mitral valve and outlet, the aortic valve, in terms of pressure and flow flux. Therefore, the lumped model can provide time-varying flow boundary conditions at the mitral valve.

RESULTS AND DISCUSSIONS

Fig. 2a-d illustrates the morphological modeling of a left ventricle computer model based on ultrasonic images recorded in two mutual perpendicular cross sections, and shows flow pattern at early diastole when the mitral valve opens. Note that an asymmetric vortex ring is detected. Right after the closure of the mitral valves the vortex flow inside the left ventricle are observed and a rapid rise in pressure is also detected, which eventually results in a steep pressure gradient when approaching to the systole before the aortic valve opens.

Figure 2: Morphological and CFD modeling of left ventricle

ACCURACY OF PATELLOFEMORAL JOINT CONTACT AREA PREDICTIONS USING MR IMAGING

Rebecca Moss and Janet Ronsky

Department of Mechanical and Manufacturing Engineering and Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada. jlrnsky@ucalgary.ca

INTRODUCTION

Abnormal joint contact mechanics are commonly speculated to be an initiating factor in cartilage degeneration. Magnetic resonance imaging (MRI) provides a non-invasive technique for evaluating cartilage contact. However, specific evaluation of the sources and magnitudes of error are limited. This study evaluates the error sources in surface reconstructions and predicted joint contact area in a loaded patellofemoral (PF) joint obtained with MRI.

METHODS

A fast spin echo pulse sequence (T2 weighting, 90° flip angle, TR = 5400 ms, TE = 80 ms, bandwidth = 15.63 kHz, 1 NEX, 140 mm FOV, 512x512 readout matrix, echo train length = 9) and an anterior neck coil were used to image five fresh porcine knees. The joint was loaded in a custom loading apparatus prior to imaging. The Non-Maxima Suppression (Devernay, 1995) semi-automated technique of edge detection was used to identify articular cartilage profiles. The Thin Plate Spline technique (Boyd et al., 1999) was used for surface reconstruction and data smoothing. PF joint contact region was determined by measuring the distance along surface normals projected from regular intervals on one (base) articular surface to its intersection with the opposing (target) surface. All points where this distance was less than a threshold value were defined to be in contact. In the absence of a gold standard, a comparative measure with staining and multi-station digital photogrammetry (MDPG) (Ronsky et al., 1999) was used to evaluate the accuracy and repeatability of the joint surface and contact modeling procedures based on MRI (Figure 1). Sensitivity of the contact area to: image digitization repeatability, surface smoothing, resampling interval, base surface and proximity threshold was analyzed.

RESULTS AND DISCUSSION

The perimeter of the contact pattern obtained from MR images is accurate within approximately 2.5 mm, as measured radially from the centroid of the stained contact area. The uncertainty in the calculated contact area is approximately 16%. Intra-user variability (based on 3 repeat trials) resulted in contact area differences of 1% or less, while inter-user digitization errors increased the differences in contact area to as much as 10%. Introduction of surface smoothing did not result in a consistent increase or decrease in contact area across the five specimens. The difference in contact area between the smoothed and original surfaces ranged from -6.1% to 6.0%. For all specimens the difference in calculated contact area resulting from changes in the smoothing factor (ranging from 0.25 to 1.45) was less than the difference between any of the

smoothed surfaces and the original surface. A 0.32 mm grid size, applied to all specimen images, provided the optimal trade off between accuracy and computational time. Selection of base surface resulted in mean differences in contact area ranging from 0.2%-2.7%. The patella was the most appropriate base surface based on contact area calculations on analytical surfaces. A contact proximity threshold of 0.2 mm was determined as optimal, based on comparison with the staining technique.

Figure 1: Comparison of contact area perimeter from staining, MRI and MDPG techniques for porcine specimen #5, using a proximity threshold of 0.2 mm. Solid lines indicate regions used for inter-technique comparisons.

SUMMARY

These study findings illuminate factors that influence the accuracy of joint contact predictions based on MR imaging in fresh joints. The largest sources of error were MR image quality, repeatability of edge detection and the sensitivity of the contact area to proximity threshold. Image digitization error is minimized with a single user, even with semi-automated edge detection algorithms. Some smoothing of the surface data is required due to MR image noise and distribution of digitized surface points. This technique is suitable for an assessment of contact area trends associated with joint motion or major injury, where changes in contact area of greater than roughly 20% are anticipated.

MECHANICAL ENERGY TRANSFER BY TWO-JOINT LEG MUSCLES DURING SNATCH LIFT

Tadao Isaka¹, Boris I. Prilutsky², Robert J. Gregor², Nobuyuki Matsumoto¹ and Sadao Kawamura¹

¹Human Robotics Laboratory, Ritsumeikan University, Shiga, JAPAN, isaka@se.ritsumeik.ac.jp

²Center for Human Movement Studies, Georgia Institute of Technology, Atlanta, GA, USA

INTRODUCTION

Weight lifting and especially the snatch lift is one of the most power-demanding sport events. The lifters are required to generate a great deal of muscular power and to effectively transfer this power to the barbell. Therefore, the analysis of mechanical power and energy generation and transfer in weight lifting is important for the understanding and improving the athletic performance. It has been suggested that the performance in explosive movements can be improved due to the energy transfer by two-joint muscles between adjacent joints (Bobbert, van Ingen Schenau, 1988). The purpose of this study was to analyze the mechanical energy transfer by two-joint muscles during the 'pull phase' of the snatch lift.

METHODS

Experiment: Five healthy male subjects participated in this study. One subject was a competitive weightlifter (skilled) and the other ones were American football players who had some experience in the snatch lift (unskilled). Each subject performed two to three snatch lifts of each of the three barbell weights: 50, 70 and 80% of their best current result. A high-speed video system was employed to record subject and barbell's displacement data during the snatch lift. At the same time, two force platforms were recording the ground reaction forces under each foot. Surface EMG during the snatch was sampled from the following muscles: gastrocnemius, vastus medialis, rectus femoris, semitendinosus, biceps femoris, gluteus maximus, erector spinae and rectus abdominals. The EMG signals were low-pass filtered, normalized to the peak EMG in the 80%-snatch lift, and then used to estimate muscle forces. Only the pull phase of the snatch (from the barbell lift-off to the feet lift-off) was analyzed.

Estimation of energy transfer by two-joint muscles: First, muscle forces during the snatch were calculated as a function of the activation and muscle velocity using a muscle model. Parameters of the model were optimized by minimizing the difference between the calculated joint moments and the joint moments found using inverse dynamics. Trials where no reasonable agreement between predicted and experimentally obtained total joint powers occurred were not considered. Power of individual muscles, power produced by individual muscle moments at the joints, and joint power were calculated. The amount and direction of energy transfer by two-joint muscles were determined as described earlier (Prilutsky, Zatsiorsky, 1994, Prilutsky et al, 1996).

During the pull phase of the snatch lift, peaks of joint power (up to 1200 W) occurred in the second part of the pull in all subjects. During this period of the maximum power production, the direction of energy transfer by two-joint muscles in unskilled subjects was from the knee to the hip (by the hamstring, HA) and from the knee to the ankle (by the gastrocnemius). This energy transfer and the EMG results indicate the primary contribution of the one-joint knee extensors in power generation in unskilled subjects. During the same period, the skilled subject demonstrated in addition a substantial energy transfer from the hip to the knee by the rectus femoris (RF; 22% of work done at the knee; Fig. 1). This energy transfer was the consequence of the high activation of the RF in late pull. A simultaneous energy transfer from the knee to the hip by the HA and from the hip to the knee by the RF was suggested to assist extensions in both the knee and hip joints (Lombard, 1903). A further analysis is needed to fully understand the significance of the found energy transfer mechanisms for the snatch performance.

Figure 1: Power of HA and RF and power produced by moments of these muscles at the knee and hip (characters 'kn' and 'hi', respectively). Skilled subject; 83%-snatch. The two vertical lines indicate approximately the last third of the pull phase. During this period, the HA transported from the knee to the hip 38 J (26% of work at the hip); the RF transported from the hip to the knee 5.6 J (22% of work at the knee).

RESULTS AND DISCUSSION

DOES ORBICULARIS ORIS MAKE UPPER AND LOWER LIPS COMPRESS EACH OTHER?

Itaru Kourakata¹, Tomokane Kurosawa², and Toshiaki Hara²

¹Graduate School of Niigata University, Niigata, Japan, itaru@tmbio7.eng.niigata-u.ac.jp

INTRODUCTION

Because of the complexities of its anatomical layout and physiology, functional correlation between lip-closing force or movement and each individual perioral muscle is not cleared. Although some “mouth robots” have been recently presented, which generates lip configuration like human speaking typical vowels, another adopting two rubber tubes imitating upper and lower lips plays brass instruments, and so forth, it is hard to say they are well modeled on the basis of musculo-skeletal aspects. Thus in this paper authors present the experimental results comparing bilabial closing force, puckering force, and contact pressure distribution on teeth buccal surface between human and artificial lip developed.

MATERIAL AND METHODS

Modeling: To create the shape of dental arch and oral cavity easily acrylic pipe with 64 mm in outer diameter was used. The material was once cut and bonded with approximately 120 degree of crossing angle. For soft tissue surrounding dental arch very soft two silicon rubber sheets with a few millimeter thickness was processed and attached on to the pipe by straps. Three wires were liken to muscles considering levator anguli oris (LAO), depressor anguli oris (DAO), and buccinator (BUCC). One wire as LAO ran from its starting point of one side to modulus node fixed on rubber surface, piercing through lower lip, and led to another side. Modeling DAO was similar to LAO but upside down. BUCCs were connected to modulus nodes in both sides respectively. These three wires were pulled anteriorly by independent three pneumatic cylinders.

Measurements: A new force transducer for measuring bilabial closing force and its distribution on lip aperture was prepared, which had five measuring arms on which strain gages were attached and the thickness of one arm was only 2.6 mm, so that the closing force could be measured in natural and neutral form

of lip. Contact pressure sensor using electric conductive rubber was also thin enough less than 1 mm and it was inserted between silicon rubber and pipe. Tensions of wires were changed from 0 to 36N in stepwise, however, strengths of LAO and DAO were set in same value. Lip configurations and bilabial forces obtained are shown in fig. 1. The same items by five young adult subjects were also measured. In this case subjects were ordered to close lip, pucker, pull POM meter adjusting to designated %MVC with observing output values from transducers. Simultaneously SEMG of orbicularis oris superior and inferior (OOS, OOI), LAO, DAO, and mentalis were recorded. Measured SEMG signals were analyzed to reveal strength of correlation between their amplitudes and mechanical parameter obtained by transducers. Besides zero-lag correlation coefficients between two of four signals, which were all rectified and low-pass filtered.

RESULTS AND DISCUSSION

EMG analysis showed statistically strong coordination of LAO and DAO than any other muscle combinations and linearities of these two muscles' activities to almost all mechanical parameters (two-way ANOVA with Fisher's LSD test). Further more it is very interesting that lip model without orbicularis oris that shortens lip itself demonstrated to produce bilabial closing forces. Distribution pattern of bilabial forces in the model was similar to the human subjects; however, its magnitude at the center was so much less than at distal region. Thus modeling the function of orbicularis oris will be the key to replicate human lip movement and mechanics.

EFFECTS OF CIRCUMFERENTIAL RESIDUAL STRESS ON THE CIRCUMFERENTIAL STRESS DISTRIBUTION OF THE ARTERIAL WALL BY FINITE ELEMENT MODELING

INTRODUCTION

Stress distribution of the arterial wall is an important factor in biomechanics of arteries. It has been suggested that excessive stress leads to arterial degeneration and lesion formation. Mechanical stress in arterial wall consists of two components, the first one is caused by external load (blood pressure) and the second is residual stress. If a ring of an artery is cut in radial direction it opens. The degree of opening is determined by the opening angle (Figure 1) which is a determinant of circumferential residual stress. This investigation aimed to study effects of circumferential residual stress on the total circumferential stress distribution with the differing mechanical parameters.

METHODS

Finite element modeling was used to evaluate circumferential residual stress in a typical model of cross section of human aorta. The modeling was performed through introduction of different opening angles to models. Then an internal pressure equivalent to a typical mean arterial pressure (100 mm Hg) was applied and stress results were obtained. The residual stress values were compared to the stress caused by blood pressure. The models consisted of lamellar structures with lamellar and interlamellar layers with different values of Young's modulus of elasticities of two types of layers (E_1 and E_2). The appropriate boundary conditions were introduced to the model to allow radial expansion. The average number of elements were 3000 (depending on the θ value), with 8 node quadratic 2D element and plane strain conditions.

RESULTS AND COCLUSION

Circumferential residual stress along arterial thickness consists of two components. A compressive component with a maximum value on intima side and a tensile component with a maximum value on adventitia side. When an artery is exposed to blood pressure a tensile stress profile will be resulted with a maximum value on the luminal side and a minimum value on the adventitia side. Then the effect of compressive residual stress on luminal side is to compensate part of maximum tensile stress, and therefore decreases severity of tension on endothelial lining.

Results show that residual stress values are influenced by structural and mechanical parameters. An increase in θ results in an increase in residual stress values (Figure 2). The maximum compressive residual stress compensates 17.3% of maximum tensile stress for $\theta=50^\circ$, and 32.6% for $\theta=90^\circ$. The stiffening of arterial wall resulted in an increase of residual stress. Results showed that for all models the circumferential residual stress profile is nonlinear and the neutral location (zero stress) is dependent on mechanical parameters, but

approximately is close to the middle of wall thickness on luminal side.

It was concluded that arterial circumferential residual stress plays an important role in stress analysis of arterial wall. The amount of residual stress is a function of mechanical and structural parameters. Depending on the situation, the circumferential residual stress can compensate part of maximum tensile stress on endothelial lining. The evaluation of arterial residual stress is recommended for different arteries, ages, and geometrical locations, such as bifurcations and curvatures. Also it can be applied in pathological situations such as presence of atherosclerotic

INTRODUCTION

Recent investigation of the one-year post-op. migration of the femoral component of Total Hip Replacement (THR) using Radio Stereometric Analysis (RSA) demonstrated increased migration into retroversion at one year with lower post-op. anteversion as measured by CT scan (Hermann, 2000). Early migration of the femoral stem into retroversion is reported to be predictive of early failure (Alfaro-Adrian *et al.* 1999).

Heller *et al.* (2001) reported an increase of up to 28% in Hip Joint Reaction (HJR) force by increasing anteversion up to 30° in patient-based musculo-skeletal models. They did not report the effect upon the moment about the prosthesis long axis, which is important for the stability of the implant.

This study investigated the effects of changing anteversion on the moment acting around a femoral prosthesis stem.

METHODS AND MODELS

A Vicon gait analysis system with five cameras was used to capture the gait kinematics of a subject with anteversion of 18°. These data were then used as input for a standard scaled musculoskeletal model with an implied anteversion of 18°. Data collection and modelling were based upon Davis *et al.* (1991) and muscle force distribution on Crowninshield (1978).

Changes in the anteversion of the model were simulated by two methods. The first accommodated the change by a rotation of the entire lower limb distal to the femoral neck, as in Heller *et al.* The second method maintained the attitude of the lower limb while changing the rotation of the femoral neck. The anteversion angles were chosen to vary from -5° to +30°.

A simplified sensitivity study was performed, calculating the HJR moment about the prosthesis stem and muscle moments about the hip joint with changing anteversion. Force data for maximum stem torsion during stair climbing, muscle attachments and femoral neck orientation were obtained from HIP98 (Bergmann, 2001). An anteversion of 18° was used.

RESULTS AND DISCUSSION

The HJR moment about the stem was -1.5 %BWm, tending to decrease anteversion. This decreased to -2.2 %BWm at -5° anteversion and increased to -1.0 %BWm at +30°. The largest transverse plane muscle moments about the joint centre were due to the abductors (-1.1 % BWm), vastus lateralis (-1.1 % BWm) and vastus medialis (-0.6 % BWm). The moments with the largest changes using method 1 are reported in Table 1.

Table 1: Transverse muscle moment changes with anteversion of -5° and +30°. itb is iliotibial band, tfl is tensor fasciae latae.

	abductor	proximal itb	proximal tfl
-5°	+76%	-35%	+14%
+30°	-41%	+15%	-10%

Method 2 predicts slightly larger changes, opposite in sign to those predicted by method 1.

The increased rotational migration of a prosthesis may be explained simplistically by the change in moment arm of the HJR. However the changes in muscle moments show that the anteversion will have a large effect upon the system of forces acting on the proximal femur. Further, this effect depends upon how the change in angle is accommodated, a question which has yet to be addressed.

Of necessity the effect of changing anteversion from an average or “normal” value was investigated. Representing the clinical situation of correction of abnormal anteversion would be complicated by the variation of other morphological parameters related to the anteversion.

SUMMARY

Reducing the anteversion angle increases the magnitude of the peak moment of the HJR, tending to decrease anteversion, about a femoral stem. Assumptions about the accommodation of the change of angle determine the muscle moment changes.

INTRODUCTION

The medial supporting structure of the patellofemoral joint (MSS) is ligament complex that restrains lateral patellar displacement. Injury to the MSS ligament complex has been described as the result of a blow to the lateral aspect of the knee in flexion or extension motion. When MSS ligament complex deficiency is present with patellofemoral instability, reconstruction of MSS is required. Graft insertion site is one of the important factors that affect the results of reconstruction of MSS ligament complex. Theoretical reconstructive procedure to restore the function of the MSS ligament complex has not been established. The purpose of this study was to locate and describe the possible ligament insertion sites for surgical reconstruction of MSS ligament complex that satisfied normal motion of intact cadaver knee.

METHODS

The three dimensional geometry of the articular surface of the femur, tibia and patella were constructed from successive cross sectional plane CT images in normal knee from fresh cadaver. The three dimensional position and angular orientation of the knee during active knee flexion and extension were recorded with magnetic position sensor (3SPACEFASTRAK, Polhemus, U.S.A.). The motions of patella were recorded and compared while knee was flexed and extended under conditions of MSS ligament complex retained and MSS ligament complex dissected, respectively.

RESULTS AND DISCUSSION

From these data, MSS ligament complex restrained lateral patellar displacement near full extension position, but had little effect for knee flexion (Fig.1). Computer search technique was adopted to determine the length of graft route that traced through articular surface. The distance between femoral and patellar ligament insertion sites were calculated as a function of the knee flexion angle. All the ligament insertion sites, where the graft became tight near full extension and non-tensioned during knee flexion of the intact knee motion, were determined.

The optimum graft insertion sites were determined. The distance of graft route was calculated from clinically popular medial apex on the patella to any location on the femur. The

proximal to the medial femoral condyle was obtained for the femoral graft insertion site (Fig. 2). This site nearly coincided with the femoral attachment site of medial patellofemoral ligament (MPFL), which worked as primary stabilizer against lateral patellar displacement.

Fig.1 Patellar motion in simulated active knee extension before and after sectioning the medial supporting structure

Fig.2 Femoral insertion site

SUMMARY

Optimum femoral ligament insertion site of the graft was found to be located proximally to the medial femoral condyle and the optimum patellar ligament insertion site was located at the central medial surface of patella.

INTRODUCTION

Postural perturbations are often used to investigate human balance and postural control. The Clinical Test for Sensory Interaction in Balance is one of the method which has been proposed for clinically assessment of the influence of sensory interaction on postural stability in the stance .The purpose of this study was to develop a new dynamic balance assessment system with multi-direction perturbations and to study the muscle synergy difference between genders and dynamic balance mechanism after sudden perturbation.

METHODS

A new designed perturbation-balance system consisted of three modulus, center of gravity (COG) measuring system, motor driven system, and pneumatic inflation system. The COG measurement system consisted of 60cm x 60cm square platform with a load cell at each corner and having it's bottom freely attached to a ball and socket base. The motion of the platform was controlled by a motor driven system with two main linkages driven by two servomotors. The platform could be rotated in anterior-posterior (AP), medial-lateral (ML), and circumgyration (CC).

Six-female and six-male healthy young subjects with average ages of 23.8 old were participated. Each subject performed anterior-posterior (AP), medial-lateral (ML), and counter-clockwise (CC) perturbations at the frequency of 0.3Hz and 0.6Hz with eyes closed and opened. Each trail had two perturbed amplitudes 5 and 10 degrees. The total experiment consisted of 22 trails. Ten channels EMG (MA300, Motion Lab. Inc, USA) were attached on the major flexor and extensor of lower extremities. The loci of center of foot pressures were recorded by insole type pressure sensors (Fscan, Tekscan, USA). Maximum displacement in X-Y directions, loci of COG, and balance score, plantar pressure, and muscle synergies corresponding to the perturbation orientation were analysed.

RESULTS AND DISCUSSION

The results showed that the balance score of female subjects was significantly higher than male subjects, 17 out of 22 trails had significantly differences (Fig. 1). The rest items were also comparable but there was no difference between male and female at 0.6Hz, ML, 5/10 degrees. The perturbation phase and foot pressure change showed that subjects had a better motor synergy at 0.3Hz for non-precaution perturbations, but at 0.6Hz

had the better synergy once got used to the perturbation sequence. The EMG data revealed that the erector spinae was acting at all perturbation tests. In the anterior perturbation, gastrocnemius and biceps femoris of both legs were acting (Fig 2), while in the posterior perturbation, tibialis anterior and rectus femoris of both legs were firing. At the counter clockwise rotation, right gastrocnemius, left gastrocnemius, right tibialis anterior, left tibialis anterior were acting in order. Besides, the EMG signals of lower extremity and foot pressure were significantly related to the motions of AP/0.6Hz / 5 degrees, ML/0.6Hz /5 degrees and CC/0.3Hz/5 degrees.

SUMMARY

Female in general shows better synergy ability than male
The lower extremity muscles were alternative firing in sequence according to the direction of perturbations.

KINEMATIC AND KINETIC ANALYSIS OF WHEELIE ACTIVITY

Po-Chou Lin¹, Jyh-Jong Chang^{1,2}, Chien-Chih Chen^{1,2}, Fong-Chin Su¹

¹Institute of Biomedical Engineering, National Cheng Kung University, Tainan, TAIWAN

²School of Rehabilitation Medicine, Kaohsiung Medical University, Kaohsiung, TAIWAN

INTRODUCTION

A wheelie is executed when the user pops the front casters off the ground and balances on the rear wheels, and it is useful in many situations, just as climbing a curb, turning in confined spaces, or negotiating uneven terrain. To maintain the balance, the position of the center of mass (COM) must be within the base of support (BOS). In the case of wheelie performing, the performer keeps the COM in the small BOS with integrating hand and trunk strategies. McInnes et al. reported that vision played an important role in the maintenance of a stationary wheelie. Kirby et al. found the new wheelie aid provided stability and wheelie-like function with maneuverability. Bonaparte et al. suggested wheelie performers appear to use a proactive balance strategy in maintaining a stationary wheelie. However, how the hand push and pull and trunk movements play their roles in maintaining the stability of wheelie performing is not clear. Therefore, the purpose of this study was to investigate the hand push force and center of pressure of the user-wheelchair system in wheelie activity

METHODS

Ten normal subjects (age 20.6 ± 1.5 years, weight 64.7 ± 6.3 kg, height 171.3 ± 5.2 cm) participated this study. They had learned this skill for about one month before test. A six-camera Expert Vision™ video-tracking system (Motion Analysis Corp, CA, USA) was used to collect the three-dimensional trajectory data of the markers placed on the wheelchair. A standard type manual wheelchair with an instrumented wheel consists of a six-component load cell was used to collect the forces and moments applied on the hand-rim by users. Two force plates were used to collect the ground reaction forces of the wheelchair. Subjects were requested to keep both wheels of the wheelchair on two force plates, respectively, during tests. Every subject was asked to perform 5 trials from level to wheelie up for 10 seconds.

RESULTS AND DISCUSSION

When performing wheelie, subjects had to strike backward slightly for preparing to push forward. The first forward striking was used to pop the front casts off ground, so this pushing would result in the maximum tangent force (Ft), axial moment (Ma), and pitch (tilt) angle (Ap). The maximum Ap was occurred after the maximum Ft and Ma. Then, the second backward striking was applied to pull the trunk back for balance. Forward tilting moment caused by backward striking was used to react the backward tilting moment caused by body weight and first backward tilting moment to prevent back falling. Therefore, second backward striking played an important role in performing wheelie. In the stable balance, the magnitudes of Ft and Ma on the pushrim were small. Instead, the trunk movement was used for balance control. The Ap was 23.7 ± 0.6 degrees, and it was greater than previous study, 13.6 ± 2.3 degrees, by Bonaparte (2001). The difference of wheelchair COM and

sitting position would affect Ap. The maximum forward displacement of center of pressure during wheelie activity was only 5.4 ± 6.3 cm in order to keep the wheelchair on the force plate. In stable state, the displacement of center of pressure was very small. The total normal force (Fn) of force plates was decreased during first backward pushing because body forward tilting made a forward moment of wheel axle. After that, the Fn was increased during first forward pushing and reached to the maximum value when attaining to the maximum Fn and Ma.

Table 1. Push force of the hand and pitch angle in wheelie activity

	Ft (N)	Ma (N-m)	Ap (deg)
1 st Backward ^{Max}	72.2±9.7	35.9±6.1	
1 st Forward ^{Max}	125.4±7.5	71.7±4.2	29.2±1.8
2 nd Backward ^{Max}	63.4±7.5	36.7±4.8	23.6±0.9
Balance	3.0±9.0	0.01±5.2	23.7±0.6

Figure 1. Tangential pushrim force and pitch angle of the wheelchair in performing wheelie.

CONCLUSION

Subjects needed a backward pulling to easily perform wheelie. The body backward tilting reacted with the first forward pushing which brings the maximum pitch angle. In stable state, the Ft and Ma were small because of good trunk control. Results of this study would help the wheelchair user in learning the wheelie skill.

INTRODUCTION

Hip fracture is frequently observed among the elderly. It is mainly caused by fall and impairs the ability of the patient to stand and walk. Because of the increase in the population of elderly age, this fracture is one of the most serious clinical problems in the field of orthopedics.

Hence we evaluate the effects of dynamic loading and shock absorption by padding on hip fracture using finite element analyses. Firstly, we evaluated the stress distribution in femur neck during fall. Then we discussed the effects of soft tissue of thigh and material properties of hip protector on the prevention of hip fracture.

METHODS

A finite element model of thigh for dynamic analysis with body segments was constructed by modifying our previous model. The morphology of the femur model was determined based on the data from cadaveric femur of 8 Japanese elderly females. The mechanical properties of femur were identified on the basis of bone density referring to Snyder and Schneider, Peacock et al. and Lotz et al. Hip pads of a hard and a soft type were also modeled. Falls on concrete ground were simulated. The impact velocity was taken from van den Kroonenberg et al. The Analyses were performed by LS-DYNA Version 950 (Livermore Software Technology).

RESULTS AND DISCUSSION

Simulation results showed that stress concentrations were observed in the basicervical region in every case. An example of

Figure 2: Time variations of minimum principal stress in basicervical region of femur neck (against concrete ground)

SUMMARY

The effects of soft tissue and hip pads on the prevention of hip fracture were evaluated by using dynamic finite element analyses. The results showed that the fracture risk in the basicervical region was reduced by soft tissue and hip pad but there was no difference between the protection effects of two materials of hip pad. The optimal design and material of hip pad for fracture prevention will be discussed in detail in the next step.

the minimum principal stress distribution in the femur neck is shown in Fig. 1. Against concrete ground, the fracture risk in this region was reduced by soft tissue and hip pad but there was no difference between the protection effects of two materials of hip pad as shown in Fig. 2.

PREDICTORS TO DISCRIMINATE REACH MOVEMENT IN CEREBRAL PALSY

Jyh-Jong Chang^{1,3}, Tong-I Wu¹, Jer-Hao Chang^{1,2}, and Fong-Chin Su¹

¹Institute of Biomedical Engineering, ²Department of Occupational Therapy,
National Cheng Kung University, Tainan, Taiwan

³School of Rehabilitation Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan

INTRODUCTION

Reach and grasp movements involve basic and important motor control in the independence of daily living activities. Learning skills and control of electronic aids to daily living are also affected by the control ability in reach movement for children with cerebral palsy (CP). However, few kinematic studies were involved in reach movement for children with CP. This study used a kinematic model to assess the quantity and quality of reach movement in children with CP compared with normal control, and to establish a predictive model for the discrimination of reach movement.

METHODS

Twenty-eight subjects, 14 normal children (Mean Age (SD) = 11.41(2.57)) and 14 children with CP (Mean Age (SD) = 9.88(2.75)), were assigned to control and experimental groups. Each subject was positioned in a restrictive seat and in front of a height-adjustable table to normalize his/her relative posture and asked to reach a button (1.6 cm in diameter, located at a sternal level and arm-length away from the subject) with his/her dominant hand in a self-natural pace method. Retroreflective spherical markers were placed on the fingertip, wrist joint, lateral epicondyle of the elbow, and acromion process. The trajectories of the reaching movements were collected using a 6-camera motion analysis system. The movement duration (MD), time to maximum velocity (TMV), time to maximum acceleration (TMA), and normalized jerk score (NJS) were computed for comparison. Descriptive statistics, GLM multivariate procedure and discriminative analysis were utilized to examine the data.

RESULTS AND DISCUSSION

The results show children with CP group had prolonged MD, delayed TMV and TMA, and higher NJS in the index tip movement than the control group (Table 1). In the velocity profiles, children with CP showed increased rate during the acceleration phase and demonstrated multiple drops (oscillations) during the deceleration phase when compared with the normal control (Figure 1). Feedback control is important for children with CP in reach movement. Discriminative analysis revealed NJS and TMA could discriminate the reach movement between normal children and children with CP with 89.3 % total correction rate (Table 2). Two diplegias and one left hemiplegia with nearly normal dominant hand function were misclassified to the normal group and all the normal controls were correctly classified. These results showed NJS and TMA were sensitive to changes in reach movement and useful in the assessment of control in reach movement.

SUMMARY

This study suggests that NJS and TMA are good predictors to

discriminate reach movement between normal and children with CP. These predictors are also useful indexes to present the treatment effect and quality of control in reach movement.

Fig. 1. Typical reach movement velocity profiles between normal and CP children.

Table 1. Group differences between CP and control on temporal-distance variable

Para-meters	Mean (SD)		F-value	Effect Size
	Normal	CP		
MD	0.69(0.14)	0.97(0.35)	11.13	0.31
TMA	0.10(0.03)	0.21(0.10)	14.96	0.37
TMV	0.27(0.05)	0.36(0.12)	4.86	0.16

COMPUTATIONAL HEMODYNAMICS AND ITS APPLICATION TO SURGERIES FOR TWO CONGENITAL HEART DISEASES

Tony W. H. Sheu¹ and S. F. Tsai¹

¹Scientific Computing and Cardiovascular Simulation Laboratory, National Taiwan University
73, Chou-Shan Rd., Taipei, Taiwan 106, R. O. C., sheu@sccs.na.ntu.edu.tw

INTRODUCTION

Numerical investigation into the total cavopulmonary connection (TCPC) blood flow and arterial switch operations (ASO) were conducted by solving the three-dimensional Navier-Stokes equations. We consider the total cavopulmonary connection (TCPC) operation, which is specifically used to treat hearts with essentially a single ventricular chamber. The operation ends with construction of a right atria lateral tunnel that connects the IVC to the transected end of the SVC, which is anastomosed to the right and main pulmonary arteries. Transposition of the great arteries (TGA) is a congenital heart disease. The abnormality is that the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. A septal defect, another congenital abnormality of heart development in the fetus, permits abnormal blood circulation from the left (high pressure) side of the heart to the right (low pressure) side. This may result in excessive blood flow through the lungs and can cause pulmonary hypertension and heart failure.

METHOD

The blood under investigation is a Newtonian fluid, which is treated as being homogeneous and incompressible. Based on the above assumptions, the working equations for non-pulsatile flow simulation of the vascular system, Ω , are made dimensionless as follows:

$$\frac{\partial u_i}{\partial x_i} = 0, \quad (1)$$

$$\frac{\partial}{\partial x_m}(u_m u_i) = -\frac{\partial p}{\partial x_i} + \frac{1}{\text{Re}} \frac{\partial^2 u_i}{\partial x_m \partial x_m}. \quad (2)$$

RESULTS AND DISCUSSION

Throughout this TCPC study, we presented for three cases with different offset values. The offset is defined as the distance between the centers of two caval anastomoses. In view of the importance of wall shear stress, we show its distribution on the entire vessel wall. It is seen that the wall shear stresses are smaller in magnitude on the outer wall of the bifurcated pulmonary arteries. This zone is clinically very risky since it is susceptible to atherosclerotic lesions.

To provide theoretical evidence that the SRGA (Spiral relationship of the normally related Great Arteries) arterial switch operation outperforms that of the Lecompte procedure, we evaluate the pressure on the vessel surface and compute the wall shear stress from the computed velocities. It is found that SRGA surgery has lower pressure and higher shear stresses, compared with those obtained from the Lecompte operation. Evidence is also provided in verifying that the SRGA manoeuvre is less susceptible to stenosis. We also show that SRGA is the operation of choice for the ASO from the point of view of energy. Assessment of two anatomies is done by computing the total energy loss coefficient and the hydraulic dissipated power index.

SUMMARY

In this study, the three-dimensional Navier-Stokes equations for incompressible blood flow have been solved in order to numerically assess two ASO and TCPC surgeries. From the hemodynamic point of view, the ASO surgery with the spiral manoeuvre outperforms the Lecompte operation based either on the shear stress distribution or the pressure distribution. Our three-dimensional calculations reveal that regions with low shear stresses are located at the nondivider walls of bifurcation. Particle tracers reveal that the blood flow is featured by spiraling motion. Through this study, we could depict a clear flow structure. The complexity of the flow field results from the axial velocity shifting towards the inner walls and the rapidly developing secondary flow. To accurately indicate where blood flow separates and then reattaches, we have applied the theoretically rigorous topology theory to find critical lines based on the computed limiting streamlines.

AORTIC LEAK SEVERITY DETERMINES ARTERIAL ELASTANCE AND HEART-ARTERIAL COUPLING IN AORTIC REGURGITATION

Patrick Segers¹, Philippe Morimont², Philippe Kolh², Nikos Stergiopoulos³, Nico Westerhof⁴ and Pascal Verdonck¹

¹Hydraulics Laboratory, Institute Biomedical Technology, Ghent University, Belgium; ²Hémoliège, Centre Hospitalier Universitaire, University of Liège, Belgium; ³Biomedical Engineering Laboratory, EPFL, Lausanne, Switzerland; ⁴Laboratory for Physiology, ICar-VU, Vrije Universiteit Amsterdam, The Netherlands

INTRODUCTION

Effective arterial elastance (E_a ; mmHg/ml), introduced as a measure of the arterial load on the heart, is approximated by the ratio of left ventricular end-systolic pressure and stroke volume, and combines steady and pulsatile load components. E_a can be combined with E_{max} (mmHg/ml; the slope of the left ventricular end-systolic pressure-volume relation) to form the heart-arterial coupling parameter E_a/E_{max} . The E_a/E_{max} parameter is extensively used in studies considering mechanico-energetic aspects of heart-arterial coupling. In aortic valve regurgitation (AR), the normal heart-arterial interaction is disturbed by the leaking aortic valve with the severity of the aortic leak being an important modulator of cardiovascular hemodynamics. Although E_a and E_{max} can still be calculated from measured pressure-volume (P-V) loops, the pattern of these P-V loops is in part determined by the aortic regurgitation itself, and aortic leak severity should therefore interfere with the E_a/E_{max} concept. The aim of this study is to assess (i) how E_a relates to arterial properties and leak severity, and (ii) the validity of E_a/E_{max} as a heart-arterial coupling parameter in AR.

METHODS, RESULTS AND DISCUSSION

The study is based on human data obtained from a study on vascular adaptation in chronic AR (Devlin et al., 1999). These data allowed us to assess the parameters of a computer model of heart-arterial interaction (Segers et al., 2000). In particular, total peripheral resistance (R ; in mmHg/(ml/s)) and aortic leak severity - expressed as leak resistance ($R_{L,ao}$; in mmHg/(ml/s)) - were quantified for different patient subgroups (Table 1)

Table 1: Computer model parameters assessed for 3 patient groups (Devlin et al., 1999)

	group I	group IIa	group IIb
E_{max}	2.15	0.62	0.47
E_a	1.24	0.66	0.90
R	1.90	0.60	0.85
$R_{L,ao}$	0.35	0.05	0.20

A parameter study demonstrated that $R_{L,ao}$ was the main determinant of E_a (Figure 1). With all other parameters constant, valve repair would increase E_a to 2.81, 1.08 and 1.54 mmHg/ml in groups I, IIa and IIb, respectively.

It has been shown theoretically that for a given preload and inotropic state of the left ventricle (LV), stroke work (SW) is determined by E_a/E_{max} and maximal when $E_a/E_{max} = 1$. This relation was derived under the assumption that SW can be approximated by the product of stroke volume and end-

systolic pressure which, obviously, is an assumption violated in AR. We found no straightforward relation between E_a/E_{max} and SW, not even after normalization of the data, and SW is not maximal for $E_a/E_{max} = 1$.

For a given E_a/E_{max} , LV pump efficiency (estimated as the ratio of SW and LV systolic pressure-volume area) was lower than the theoretical predicted value, except for the simulations with intact aortic valve.

Figure 1: Contribution of total peripheral resistance (R), total arterial compliance (C) and leak severity to arterial elastance in conditions of AR, and for identical cardiac and arterial conditions, but with an intact aortic valve (closed symbols).

SUMMARY

In summary, we have shown that in AR, effective arterial elastance (E_a) is determined not only by arterial mechanical properties, but mainly by the severity of the aortic leak. In these conditions, it seems more appropriate to characterize the arterial system by specific system properties (total peripheral resistance, arterial compliance, valve leakage) rather than by a global parameter such as E_a . Furthermore, in AR, the assumptions leading to the conceptual heart-arterial coupling framework linking E_a/E_{max} to mechanico-energetic parameters, are violated. As such, the use of E_a/E_{max} as a coupling parameter in general or as a mechanico-energetic regulatory parameter in particular, is questionable in these conditions.

INDIVIDUAL STRESS ANALYSIS OF THE HUMAN MANDIBLE UNDER BITING CONDITIONS

Norio INOU¹, Michihiko KOSEKI¹ and Koutarou MAKI²

¹Graduate School of Science and Engineering, Tokyo Institute of Technology, Tokyo, Japan, inou@mech.titech.ac.jp

²Department of Orthodontics, Showa University, Tokyo, Japan

INTRODUCTION

The purpose of this study is to examine biomechanical characteristics of the human mandible in occlusion. The mandibular body has a complicated shape and receives various masticatory forces under biting conditions. To obtain the exact mandibular model, an automated modeling method based on CT images was developed. Stress analyses were performed under bilateral and unilateral bitings. This research proposes a synthesized method to evaluate mechanical rationality of the bone using these computational results.

METHODS

The modeling method is composed of four processes. The first provides a voxel space of a bone from the CT images. The second distributes nodal points in the space. The third generates tetrahedral elements with the nodal points by use of Delaunay triangulation. The fourth finishes accurately the model by removing excessive elements.

For stress analysis in the biting condition, we consider four kinds of masticatory muscles. The masticatory forces were assumed to be proportional to sectional area of muscles. The muscular directions were determined from the reconstructed 3D image of the mandible.

The boundary conditions were set as follows. Condyles can turn in any direction like a pivot. One side of condyle can also move along the X-axis. The moments around the X-axis produced by reaction forces and muscular forces should adjust the balance as following equations.

Figure 1: Boundary conditions

RESULTS AND DISCUSSION

Stress analyses were performed under bilateral and unilateral biting conditions. Reaction forces at the teeth in the bilateral biting conditions were measured by a pressure sheet. Reaction forces under the unilateral biting conditions were given to half side of the dental arch so that the total value of the reaction forces is nearly equal. Stress analyses were performed by CAEFEM (Concurrent Analysis Co.).

The analytical results were synthesized by choosing the highest value among the stresses for each nodal point. The obtained stressed map covers the wide area of the mandible. This suggests the mechanical rationality of mandible.

Figure 2: Calculated Stress distributions under several biting conditions and stressed map synthesized with these results

CONCLUSION

An individual simulation method of the human mandible based on X-ray CT data was proposed. An evaluation method to synthesize analytical results under multi-loading conditions was also proposed. The computational results showed that the mandible could be explained from biomechanical viewpoints. The proposed method will be applicable to other bones.

Ca²⁺ RESPONSES AND ITS PROPAGATION IN CULTURED ENDOTHELIAL CELLS TO CYTOSOLIC MECHANICAL STIMULATION BY LASER TWEEZERS

INTRODUCTION

We have hypothesized that the cytoplasmic micro-mechanical strain and its associated cytoskeletal structures are playing major roles in mechano-sensing mechanism of endothelial cells. To test this hypothesis, the cytosolic Ca²⁺ responses of endothelial cells to the mechanical stimulus by laser tweezers without direct contact, were investigated.

METHODS

Bovine aortic endothelial cells (ECs) were cultured on a glass bottom cell culture dish until confluent. ECs were loaded with Fura red (40μM) and Fluo-4 (20μM) for 30min. The laser beam (1064nm, SIGMA KOKI, Japan) was focused on the nucleus of a single EC. The nucleus was moved slightly without any contact, and the fluorescent images were taken every 1 sec with a real time confocal laser microscope (CSU-10;YOKOGAWA, Japan). The stored images on a computer (PowerMac G4, Apple Computer, USA) were decomposed in the RGB format and the changes of the cytosolic Ca²⁺ of ECs were estimated with the ratio images of the Fluo-4 image (Green) to the Fura red images (Red) (Budel S. et al. 2001).

RESULTS AND DISCUSSION

After the laser beam focus was moved, the cytosolic Ca²⁺ gradually increased in the EC (Fig.1(A)). In contrast, in EC which were irradiated by the laser beam without any movement of the laser beam focus, the cytosolic Ca²⁺ did not increase (Fig.1(B)). The Ca²⁺ wave was propagated from the stimulated EC to the surrounding ECs non-uniformly (Fig.2). The Ca²⁺ wave propagation time between ECs in the visual field was within 10-20 sec, indicating cell-to-cell electrical coupling. Thus, the micro-strain induced by the micro-movement of the nucleus can be a trigger of the cytosolic Ca²⁺ increase and bring about the Ca²⁺ wave propagation.

Figure 1: Typical traces of the change of the cytosolic Ca²⁺ in EC stimulated by a laser tweezers. (A) with the laser beam movement and (b) without the laser beam movement.

SUMMARY

When the nucleus of one EC was slightly moved by laser tweezers, the cytosolic Ca²⁺ increased immediately in the same EC and the Ca²⁺ wave was propagated from the stimulated EC to the surrounding ECs non-uniformly. The micro-strain induced by the micro-movement of the nucleus can be a trigger of the cytosolic Ca²⁺ increase and the Ca²⁺ wave propagate probably by an electrical communication.

INTRODUCTION

We have developed a real-time monitoring system of the femorotibial joint motion during total knee arthroplasty (TKA)¹. Nine knee motions in eight patients have been measured intraoperatively. The motion data was evaluated as movement of contact point between the femorotibial articular surfaces (Figure 1). Consequently, two different types were observed with respect to anteroposterior translation of the contact point: (a) roll-back pattern and (b) paradoxical pattern relative to the tibial surface during knee flexion¹). In order to validate the significance of these patterns, post-operative knee motion was measured, and then intra- and post-operative knee motions were compared.

MATERIALS AND METHODS

Post-operative knee motion was measured using a six degree-of-freedom electro goniometer set on the lateral side of thigh and shank²). Radiographic marker was mounted on each end of the goniometer. By bi-planar radiography, three-dimensional position of the marker was detected. Three-dimensional position of the TKA component on the radiographic image was estimated by using the matching technique³) between the projective image of the component and its three-dimensional computer model. From these position data, positional relationship between the marker and the component was estimated. By combining the positional relation data with the motion data obtained from the goniometer, the motion of the femoral component relative to the tibial one was obtained. The motion data was expressed the movement of the contact point. Seven knees in six patients after TKA, who measured the motion intraoperatively (movement pattern (a) in five knees and pattern (b) in two knees), were studied at six months after TKA. As total knee system, three different types were used: (1) Genesis I cruciate retaining (CR) type; (2) Genesis II CR type and (3) Genesis II posterior stabilized (PS) type (Smith & Nephew, Richards, USA). Knee motion was measured with and without body-weight bearings. In order to evaluate the laxity of the knee, the hyperextension angle was evaluated from the sagittal radiographic image.

RESULTS AND DISCUSSION

Average hyperextension angle was 2.6 degrees in pattern (a) and 6.1 degrees in pattern (b). At maximum extension angle, the contact point in pattern (b) was located posteriorly by comparison with one in pattern (a). Difference between the post-operative knee motion in pattern (a) and one in pattern (b) was observed with regard to amount of anteroposterior translation of the contact point with and without body-weight bearings. Difference between the knee motion in CR type and one in PS type wasn't detected. These seemed to be related to difference of the joint tightness. Therefore, the intraoperative knee-motion monitoring system was verified to be potentially acceptable to predict the post-operative knee motion.

THE EFFECT OF A SHEAR FLOW ON THE UPTAKE OF LDL BY AN EC-SMC BILAYER IN CULTURE

Takeshi Karino¹, Tatsunori Kado and Koichi Niwa
Research Institute for Electronic Science, Hokkaido University, Sapporo, Japan
karino@bfd.es.hokudai.ac.jp

INTRODUCTION

It is suspected that wall shear stress plays an important role in the pathogenesis and localization of atherosclerosis in the human arterial system. Thus the effects of a shear flow on the transport of low density lipoprotein (LDL), known to be an atherogenic substance, from flowing blood to an arterial wall has been studied by many investigators by using a monolayer of cultured vascular endothelial cells, and measuring the effects of wall shear stress on the uptake of LDL and its analogues by the endothelial cell (EC). However, it is questionable whether a monolayer of ECs can be used as a model of an arterial wall where ECs are forming only the inner surface of a thick wall consisting of the internal elastic lamina and layers of smooth muscle cells (SMC), fibroblasts, and various matrix fibers. Therefore we prepared EC-SMC bilayers which we considered a model closer to an arterial wall by seeding ECs directly over the SMCs and co-culturing them, and tested whether the EC-SMC bilayers behave in the same manner as monolayers of ECs in the uptake of LDL and microspheres.

MATERIALS AND METHODS

Bovine aortic SMCs were seeded on the inner surface of a 35-mm diameter Falcon culture dish at a cell density of 5×10^4 cells/cm² and cultured for 5 days in an Iscove's modified Dulbecco's medium (IMDM: Sigma Chemicals) containing fetal calf serum at 20% by volume, 100 U/ml penicillin, 100 µg/ml streptomycin, and 50 µg/ml ascorbic acid in a 95% air and 5% CO₂ humidified atmosphere at 37°C. Then bovine aortic ECs were seeded directly over the SMCs at a cell density of 5×10^4 cells/cm² and they were co-cultured for 5 days until the ECs became confluent and completely cover the SMCs, forming an EC-SMC bilayer.

The effects of a shear flow on the uptake of macromolecules were studied using three different substances, that is, DiI-LDL (Biomed. Tec., Stoughton, MA) as a model of LDL, DiI-Ac-LDL (Biomed. Tec.) as a model of oxidized LDL, and fluorescent polystyrene latex microsphere (FluoSpheres: Molecular Probes, Eugene, OR) whose diameter was approximately the same as that of LDL (20 nm).

The effects of a shear flow on the uptake of these substances were tested as follows. A 35-mm diameter culture dish in which an EC-SMC bilayer was prepared was filled with 2 ml of IMDM containing fetal calf serum at 20% and either DiI-LDL (4.0 µg/ml) or microspheres (1.35×10^{14} particles/ml) or DiI-Ac-LDL (4.0 µg/ml). The culture dish was then set to a 32-mm diameter rotating-disk shearing apparatus keeping a distance of 0.5 mm between the EC-SMC bilayer

and the disk, and exposed the ECs to a mean wall shear stress of 0 and 10 dynes/cm² for 2 hours at 37°C in a cell culture incubator in a 95% air and 5% CO₂ humidified atmosphere.

After finishing the flow experiment, the EC-SMC bilayer was rinsed with a phosphate buffer solution (PBS) and then removed from the dish by using 2 ml of PBS containing a surfactant (0.2% Triton-X100). The ECs and SMCs dispersed in the PBS were lysed by the addition of collagenase (Sigma Chemicals, St. Louis, MO) at a final concentration of 0.1% and incubating the solution for 15 minutes at 37°C. The amount of the LDL, microsphere, and Ac-LDL taken up by the EC-SMC bilayer was assessed by measuring the fluorescence intensity of the solution using a spectrofluorometer (FP-750, Jasco, Japan) and converting it to the concentration of the substance. The results were compared with those obtained with a monolayer of ECs prepared from the same stock of cells as those used to prepare the EC-SMC bilayer.

RESULTS AND DISCUSSION

The uptake of LDL and microspheres by an EC-SMC bilayer was much greater than that by a monolayer of ECs. A shear flow which imposed a mean wall shear stress of 10 dynes/cm² to the ECs augmented the uptake of both LDL and microspheres by a monolayer of ECs but not by an EC-SMC bilayer. The uptake of Ac-LDL was almost the same by both a monolayer of ECs and an EC-SMC bilayer, indicating that it was taken up only by ECs forming the luminal surface of the EC-SMC bilayer. However, as shown in Figure 1, in both the cases, the uptake of Ac-LDL was significantly reduced by the imposition of a shear flow, suggesting that the mechanism of the uptake of Ac-LDL by ECs is very different from that of LDL.

Figure 1: Effects of a shear flow on the uptake of Ac-LDL.

MECHANICAL PROPERTIES AND PERMEABILITY OF POLYELECTROLYTE MICROCAPSULES (PEMC)

Hans Bäumler¹, R. Mitlöhner¹, M. Hin¹, G. Artmann², R. Georgieva¹, S. Moya³, H. Kieseewetter¹

¹Institute of Transfusion Medicine, Humboldt University of Berlin, D-10098 Berlin, Germany

²Dept. of Applied Biophysics, TFH Aachen, D-52428 Jülich, Germany

³Max Planck Institute of Colloids and Interfaces, D-14424 Potsdam-Golm, Germany

INTRODUCTION

Microcapsules in the 100nm to 10µm size range are of both scientific and technological interest, since they have potential applications as nano- and micro-containers. Liposomes represent a well-known example of spherical closed thin films, which in addition to their numerous applications as model biological membranes, have already been employed as drug delivery systems in pharmaceuticals and cosmetics [Lasic 1993]. Their limited stability and low permeability for polar molecules, however, imposes serious limitations for general use. Microcapsules fabricated from polyelectrolytes offer advantages in that they are permeable to small polar molecules and are extremely stable against chemical and physical influences [Caruso et al. 1998, Klitzing and Möhwald 1995, Bäumler et al. 2000]. Both types of closed films are, however, limited by their spherical shape, which precludes producing capsules with anisotropic properties. Biological cells possess a wide variety of shapes and sizes, and thus using them as templates allows producing capsules with a wide range of morphologies [Neu et al. 2001].

METHODS

Polyelectrolyte microcapsules (PEMC) were prepared on decomposable/dissolvable biological templates like red blood cells. The PEMC were prepared by consecutive multiple adsorption of the polyanion poly(styrene sulfonate) [PSS], dextran sulfate and human serum albumin and the polycation poly(allylamine hydrochloride) [PAH] as well as chitosan/chitosansulfate onto glutardialdehyde treated red blood cells as template, which was decomposed after completing the coating by a hypochlorate solution.

Deformability properties of PEMC were studied by means of micropipette technique and confocal laser scanning imaging. The morphological and permeability properties of the PEMC were characterised by atomic force microscopy, confocal laser scanning microscopy, transmission electron microscopy, and electrophoretic mobility.

RESULTS AND DISCUSSION

The diameter of the PEMC increased in dependence on the composition of the polyelectrolyte shell by up to 2/3 of the original size. Due to the elastic behaviour of the shell the PEMC recovers to the original shape and size.

The wall thickness as well as the bending modulus (BM) of the PEMC was depended on the number of layers and the used polyelectrolytes. The thickness was in the range between 7 and

28 nm and the BM was between $3.5 \cdot 10^{-15}$ and $1.8 \cdot 10^{-14}$, 4 to 5 magnitudes larger than the BE of red blood cells [Evans 1973]. If lipids were added to the polyelectrolyte layers the capsules cannot be visibly deformed by micropipette suction up to 10^4 N/m².

The PEMC are permeable for salt ions and charged macromolecules. The permeability depends on the salt concentration, the used polyelectrolytes and the number of layers.

SUMMARY

PEMC are a new type of microparticles, permeable to small polar molecules and are extremely stable against chemical and physical influences. They show elastic behaviour and the bending modulus depends on the number of polyelectrolyte layer as well as on the kind of polyelectrolyte. The permeability of the PEMC can be varied in the M_w range of a few Dalton up to some kDa.

FINITE ELEMENT ANALYSIS OF CARDIAC FUNCTION IN HYPERTENSIVE HEART DISEASE

Masakazu Tsutsumi, Akiyoshi Shiomi, Tadashi Inaba, Yutaka Sawaki and Masataka Tokuda
Department of Mechanical Engineering, Mie University, Tsu 514-8507, Japan, tsutsumi@bio.mach.mie-u.ac.jp

INTRODUCTION

In order to estimate quantitatively the mechanical functions of the left ventricle, the authors have constructed a fundamental numerical simulation system based on a finite element ventricle model connected with both an electric stimulus transmission model and a blood circulation system model. In this research work, the biomechanical cardiac functions supposed the heart with hypertensive heart disease (HHD) are analyzed by using the proposed numerical simulation system.

MATHEMATICAL MODEL OF LEFT VENTRICLE AND FINITE ELEMENT SIMULATION

The mathematical models of the left ventricle are composed of the mechanical model of the myocardial fiber, the electric stimulus transmission model and the blood circulation system model. As the circulation system model, a simplified electric circuit analogy model (see figure 1) is employed in the present numerical simulation. The installation of the fiber orientation into the finite element model is realized by transforming the standard element in the local coordinate system to the real element in the global coordinate system. The 3-dimensional geometry of the left ventricle is here assumed to be a prolate spheroid for simplicity. The isoparametric parallelepiped finite elements (198 elements in total) are arranged along the ventricular wall. The mechanical properties of the myocardial fiber and the other various material constants are not determined for a specific individual, but chosen on the basis of studies up to the present as well as the experience and knowledge of medical doctors.

Figure 1: Schematic representation of blood circulation system model.

RESULTS AND DISCUSSIONS

In the present study, the analysis of the cardiac functions supposed the heart with HHD was performed with the following process.

- (1) By decreasing the aortic compliance (Ca in afterload system shown in figure 1), the cardiac functions in the elevated blood pressure conditions were estimated.

- (2) In the elevated blood pressure condition, by increasing the initial (end diastole) wall thickness, the cardiac functions in the hypertensive hypertrophic conditions were estimated.

Figure 2 show time courses of circumferential strain during systole and stroke volumes in a cardiac cycle for several Ca values. From figure 2, it is recognized that both of the circumferential strain and the stroke volume decrease together with a decrease of the Ca value, that is, an increase of the blood pressure. Figure 3 show time courses of circumferential strain and stroke volumes for several wall thicknesses. From figure 3, it is confirmed that both of them increase together with an increase of the wall thickness. From these simulated results, it is considered that the an amount of contraction of the myocardium decreases when the heart becomes the elevated blood pressure condition. It is also considered that the hypertrophy of the myocardial wall in HHD is one of acclimatization developments to compensate a reduction of the stroke volume.

Figure 2: Cardiac functions for several Ca values.

BIODYNAMIC DATA SET FOR MODELLING CAR DRIVERS

Barbara Hinz, Helmut Seidel, Gerhard Menzel, Jürgen Keitel, Ralph Blüthner
Federal Institut for Occupational Safety and Health, Berlin, Hinz.Barbara@baua.bund.de

INTRODUCTION

The examination of the transmission of vibration to drivers and their reduction is an essential task for occupational biomechanics.

The ISO 5982 (2001) describes the biodynamic data of seated individuals subjected to z-axis whole-body vibration. A human model is derived. The range of the data in this ISO is determined from the results in 18 publications. The defined values considered special conditions (posture, exposure, hard seat without backrest) for drivers of off-road, heavy road and industrial vehicles. However this ISO mention the lack of a data base for the condition car driving. A new item of the International Standard Organization (ISO) will tackle that problem and this paper provides a relevant data set.

METHODS

23 voluntary male subjects (body masses (BM) 58.2 kg – 106 kg; body heights (BH) 160 cm – 186.9 cm) and 22 female voluntary subjects (BM between 51.5 kg and 84.1 kg; BH 154 – 175 cm) were selected. Anthropometric parameters were determined in the standing and sitting posture. The test subjects sat in an relaxed, leaned and subjectively comfortable posture, the hand on the legs on three different car seats and on one lab seat with a rigid seat pan and with the backrest of a car seat. They were exposed to three vertical exposures: E1 – broad-band random vibration with a frequency weighted (ISO 2631, 1997) r.m.s. value (aw_z) of 0.3 ms^{-2} ; E2 – car typical signal for driving of a main road, $aw_z = 0.7 \text{ ms}^{-2}$; E3 – car typical signal for driving of a main road, $aw_z = 1.4 \text{ ms}^{-2}$. The accelerations (a) were measured at the seat basis in z-direction (z) (B200, HBM), at the seat- and backrest-cushion in z- and x-directions (Type 4322 mounted in a rubber disc, B&K). The resulting force at the interface between the test subject and the seat was measured using three force cells (KWH 100, Mess-elektronik) for the rigid seat. Markers on relevant body points were acquired (Motion Analysis System, Qualysis) to quantify the posture. The transfer functions (nondimensional ratio of the response at the cushions to the forced vibration at the basis) to the backrest were determined for all seats, to the seat cushion for the car seats only. The impedance and the apparent mass were calculated for the rigid seat (ISO 5982, 2001, 3.1 and 3.2).

RESULTS AND DISCUSSION

Rigid seat: The mean values (MV) of the peaks of the moduli of the impedance and apparent mass were lower during E3 and occurred for men and women at the lower frequency. For the men higher values of moduli were registered. The mean apparent mass for car seat conditions exhibited lower values range below 4 Hz than in ISO 5982 (Fig.1). The peaks of the mean absolute values of the transfer functions from the seat basis to

Figure 1: MV (N=55) of the modulus of the apparent mass

the acceleration in x-direction at the backrest shows higher values at the lower frequencies for E3. The mean absolute values were higher for men up to 6.5 to 8 Hz with the lower frequency at E3. In the upper frequency range the women showed higher mean absolute values.

Car seats: Two transfer functions were calculated: az at the seat basis to az at the seat cushion (STF) and to the ax at the backrest cushion (BTF). A dependence of the mean absolute values of STF and BTF from the intensity was found, slightly modified by the used seat, in a similar way as for the hard seat. This dependence is more distinctly for STF than for BTF. The mean absolute values of STF and BTF were higher for men up to 6 Hz, above that frequency the values of women were higher. The individual STF and BTF show a great variability.

SUMMARY

Based on the presented results an amendment of the ISO 5982 for car seats should consider the following aspects: the transmission to the backrest, the transmission properties of soft seats, the intensity dependence of the transmissions, the gender as an essential factor for the transmission, and the range of the interindividual variability. Further experimental research work is needed in order to find a represent range of biodynamic values for car seats.

EFFECTS OF ELECTRO-ACUPUNCTURE STIMULATION ON SYSTEMIC AND MESENTERIC MICROVASCULAR HEMODYNAMICS IN ANESTHETIZED RATS

Kentaro Takagi, Shinjiro Yamaguchi, Momoyo Ito and Norio Ohshima¹
Department of Biomedical Engineering, Institute of Basic Medical Sciences, University of Tsukuba,
Tsukuba Science City, Ibaraki, Japan. ¹ ohshima@md.tsukuba.ac.jp

INTRODUCTION

Electro-acupuncture therapy has recently been recognized as a complementary treatment for various diseases and symptoms. Electro-acupuncture stimulation (EAS) is known to evoke various reflex responses by activating afferent nerve fibers. A number of reports have indicated that EAS affect autonomic functions via somato-autonomic reflex. However, little has been known about the effects of EAS on the hemodynamics in the target organ particularly from the viewpoints of the microcirculation (Yamaguchi *et al.*, 2001). We therefore intended to assess the effects of the EAS on microvascular and systemic hemodynamics by using an intravital microscope-television system.

MATERIALS AND METHODS

Experiments were performed using adult male Wistar rats (250-300 g) anesthetized with urethane (1.1 g/kg). Respiration was maintained using a ventilator. Blood pressure and heart rate (HR) were continuously recorded throughout the experiments. Rectal temperature was monitored and maintained at 37-38°C using a temperature control system. An intravital microscope-television system was used throughout the experiments. The mesentery was exteriorized on a stage designed for intravital microscopy. During each experiment, an arteriole was continuously visualized by a CCD camera, and recorded by a video cassette recorder. Inner diameter of the arteriole was measured on a replayed standstill TV frame by use of an image processor. The red blood cell (RBC) velocity was measured by the dual-sensor method developed by the authors (Sato and Ohshima, 1988). Two acupuncture needles inserted through the skin up to the underlying muscles of the hindpaw. EAS was performed by passing current between these two needles for 30 s at differed current intensities using an electrical stimulator.

In the first series of experiments, to investigate stimulus intensity-response relationships, in term of systemic hemodynamics and microvascular RBC velocity, were examined. EAS was applied to a hindpaw at current intensities of 1.0-10.0 mA.

In the second series of experiments, to identify the peripheral neural pathway of hemodynamic reflex response evoked by EAS, pharmacological studies using several vasoactive substances, such as local anesthesia (lidocaine), α -adrenergic receptor antagonist (phentolamine), β -adrenergic receptor antagonist (propranolol), and cholinergic receptor antagonist (atropine), were administrated. Systemic and microcirculatory hemodynamic changes accompanying administration of these drugs were analysed. EAS was applied at current intensities of 5.0 mA.

RESULT AND DISCUSSION

The EAS of intensity over 3.0 mA applied to the hindpaw evoked intensity-dependent increase response in mean arterial pressure (MAP), HR, and arteriolar RBC velocity. Thus, it indicated a quantitative relation existed between current intensity of EAS and these hemodynamic changes. In some cases of the experiments, localized vasoconstriction of the arteriole was induced by EAS. These results suggested that effect of EAS on the mesenteric microhemodynamics was mainly attributable to increase of the systemic blood pressure, but partly due to vasoconstrictive effect.

The EAS-induced increase responses in MAP, HR, and arteriolar RBC velocity were abolished after somatic afferent blockade by subcutaneous injection of local anesthesia to the stimulated site. Such increase responses in MAP and RBC velocity were also abolished by the intravenous injection of α -adrenergic receptor antagonist, while these responses were not abolished by the intravenous injection of β -adrenergic receptor antagonist or cholinergic receptor antagonist. While, increase response in HR was abolished by the administration of β -adrenergic receptor antagonist. These results suggested that these responses were induced by somato-sympathetic reflex mediated via α -adrenergic receptors in the vascular smooth muscles.

SUMMARY

In the present study, effects of EAS on systemic and mesenteric microvascular hemodynamics were directly observed. EAS evoked the intensity-dependent response of stimulus in systemic and microvascular hemodynamics. It was clarified that the increase response in RBC velocity in the mesenteric arteriole by EAS depends mainly on arterial pressure but partly is affected by localized vasoconstriction of the arteriole as well. Pharmacological experiments using several vasoactive substances indicated that the pressor response by EAS was induced by somato-sympathetic reflex mediated via somatosensory nerve and α -adrenergic receptors in the vascular smooth muscles.

FOOT FUNCTION AFTER THE SHORT TERM USE OF CUSTOM MADE FOOT ORTHOSES

Craig Payne

School of Human Biosciences, La Trobe University, Melbourne, Australia

c.payne@latrobe.edu.au

INTRODUCTION

Foot orthoses (FOs) are widely used in clinical practice for what is assumed to be biomechanical dysfunction. Many studies have previously investigated the immediate kinematic effects of FOs, but little is known about the longer term effects of FOs on foot function. The aim of this project was to determine foot function when custom FOs were first used and then again at 4 weeks.

METHODS

Consecutive patients needing rigid custom FOs at a podiatry teaching clinic were recruited for this project. Custom made FOs were made over a negative plaster cast of the foot in its defined neutral position. When orthoses were first issued, foot function was determined using the Pedar in-shoe pressure measuring system. Subjects were measured walking for approximately 10 steps in canvas shoes with and without their FOs. This was repeated again at approximately 4 weeks after the subjects had been using the FOs. Using the NovelWin software, 6 steps of each trial were averaged. Masks were created over the hallux, first metatarsal head, lateral forefoot, arch and heel areas to calculate mean pressure and the pressure time integral in each masked area. Contact time for the averaged steps to check if velocity was consistent between trials.

RESULTS AND DISCUSSION

36 subjects were recruited (10 were lost to follow-up). The left foot of 26 subjects was used for the analysis. Mean time between baseline and follow up was 29.5 (± 10.3) days. Repeated measures ANOVA showed that the velocity within subjects of each trial were consistent enough for further analysis ($p=0.31$). The results of the pressure variables are reported in Tables 1 & 2. Post hoc analysis showed, as expected, differences between the use of FOs and no FOs both at baseline and at follow up. However, no differences were found between foot function at baseline and at follow up without the use of FOs. Similarly, no differences were found in foot function at baseline and follow up with the use of FOs, indicating that no adaptation or changes occur to foot function in the parameters we measured over a 4 week period of using FOs.

SUMMARY

This study has shown that there are no adaptive changes in foot function in the short term in the parameters used. This does not rule out the possibility of longer term changes.

BIOMECHANICAL ANALYSIS OF THE DESIGN OF ENDOVASCULAR STENTS: INFLUENCE OF COIL-PITCH ON INTRALUMINAL FLOW BEHAVIOR

INTRODUCTION

Neointimal hyperplasia is considered partly responsible for the restenosis after treatment with indwelling interventional endovascular stents. From the biomechanical viewpoints, it is expected that if the design of endovascular stents is optimally modified as to control blood flow velocity close to the vessel wall, such stents could prevent development of neointimal hyperplasia. The objective of the present study is, therefore, to examine whether adjusting coil-pitch of the coil stents is able to regulate blood flow condition near the vascular wall.

MATERIALS AND METHODS

To analyze the changes of detailed flow pattern caused by the indwelling endovascular stents, the flow was visualized in an *in vitro* mock perfusion circuit. A single-coil endovascular stent (SUS316L; wire diameter = 0.5 mm, coil diameter = 4 mm; coil-pitch = 2.5, 5, or 10 mm) was placed at the center of a glass tube (4 mm i.d., 6 mm o.d.), and a physiological saline containing a diluted suspension of rat erythrocytes chosen as tracer particles (adjusted at a value of hematocrit of 0.1%, viscosity of 1.0 mPa) was perfused at a flow rate of 30-90 mL/min.

The behavior of the erythrocytes within the glass tube was video-recorded at 250 frames/s under a microscope, and was subjected to off-line image analysis. Video images obtained by observing focused planes parallel to the longitudinal axial section in the glass tube were scanned at an interval depth of 0.4 mm, and the velocity were measured by tracing trajectories of erythrocytes from the frame-by-frame analysis.

RESULTS AND DISCUSSION

A complex and three-dimensional spiral flow pattern due to the secondary flows was observed in the vicinity of the stent. Figure 1 shows the flow velocity profiles in the glass tube indwelt with coil stent. The reduction of the velocity near the vessel wall was linearly correlated with the decrease in coil-pitch significantly ($p < 0.01$), particularly at the higher flow rates (correlation coefficient with the volumetric flow rate of 60 mL/min, $r = 0.56$; with the volumetric flow rate of 90 mL/min, $r = 0.55$).

The conventional endovascular stents have been considered to work by resisting mechanically to inwardly protruding vascular wall. Whereas, the present study pointed out a possibility of a new design concept of suppressing neointimal hyperplasia by adjusting intraluminal blood flow.

It now has been widely accepted that region of the low shear stress ($< 0.4 \text{ N/m}^2$) exposed to the vascular wall was localized at atherosclerosis-prone site. Based on the results of the present study concerning the relationships between the flow velocity near the wall and the coil-pitch of the indwelling stent, we can estimate the wall shear stress of any given stented vessels. In the case of human abdominal aorta indwelt with coil stents, therefore, the coil-pitch should be over 6 mm in length in order to exceed the lowest level of shear stress of 0.4 N/m^2 .

SUMMARY

To analyze blood flow behavior, we constructed an *in vitro* perfusion system. The flow velocity near the vessel wall was affected by the coil-pitch of the indwelling endovascular stents, which fact suggests a possibility to improve the stent design.

COMPUTER INVESTIGATION OF CRUCIATE LIGAMENTS ORIENTATION DURING THE PASSIVE RANGE OF MOTION OF NORMAL KNEES

S. Zaffagnini, S. Martelli, F. Acquaroli
Rizzoli Orthopaedic Institutes, Biomechanics Lab., Bologna, Italy
Contact author: s.martelli@biomec.ior.it

INTRODUCTION

Cruciate ligaments of the knee have been extensively studied for anatomical and surgical reasons. Several authors have reported data on ligaments elongations, stress and strain, but no quantitative data are reported in the literature regarding the orientation of anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL) fibers during passive range of motion (1,2,3,6). The goal of this study is to start filling this gap of information for normal knees.

METHODS

In this study we examined, qualitatively and quantitatively, 8 normal cadaver knees. The passive range of motion of each defrosted and intact joint was recorded using the 6-degrees-of-freedom electrogoniometer FARO Arm (Faro Technologies, Lake Mary, USA). Then the joint was exposed to digitize the articular surfaces of tibia and femur, ACL and PCL insertion boundaries, couples of 9 fibers insertions on ACL and PCL. Computer elaboration of the recorded data enabled the reconstruction of the joint and ligaments relative position during the passive range of motion. This method has been previously used for anatomical or kinematic studies (Martelli 2000) and is currently under patent process (E.P. 00128769.7, Dec 30, 2000).

The 3D orientation of single ligaments' fibers was measured reporting the angle between the line joining each fiber insertions with following three planes :

- a plane fitting the tibial plateaux, computed using a least square algorithm, named "tibial plateaux plane" (I);
- a plane fitting the femoral ACL insertion area, computed using a least square algorithm, named "femoral notch plane" (II);
- a plane perpendicular to the tibial plateaux directed in the medio-lateral direction, named "third plane" (III).

Figure 1 reports the planes used for ACL orientation in knee 2.

The ACL 9 fibers were split into antero-medial and postero-lateral ones, in order to evaluate bundles orientation. The PCL 9 fibers were classified as postero-lateral and antero-medial. Then we computed the average orientation of the two bundles in all knees.

RESULTS AND CONCLUSIONS

The inclination of ACL with respect to the tibial plateaux decreases with flexion from 56° to 33° . Orientation of ACL with respect to the femoral notch increases with flexion from 4° to 58° . The ACL orientation in a medio-lateral direction changes from 24° to 52° . The postero-lateral and the antero-medial bundle have different angular variations, mainly with respect to the tibial plateaux and medio-lateral direction.

The inclination of PCL with respect to the tibial plateaux decreases with flexion from 43° to 28° . Orientation of PCL with respect to the femoral notch ranges from 36° to 51° . The PCL orientation in a medio-lateral direction decreases with flexion changes from 45° to 25° . The postero-lateral and the antero-medial bundle have different angular variations, mainly with respect to the medio-lateral direction.

This quantitative and qualitative information not only increases the anatomical knowledge of the ACL and PCL, but could also be important in developing or improving the

surgical strategy for their reconstruction.

Figure 1: Reference planes used for computing ACL fibers orientation.

INTRODUCTION

Wear is one of the main reasons of failure of the artificial knee joint (AKJ) fixation into the host bone, due to the biological reaction against wear debris. In the modified design of the AKJ, proposed by Iwatsubo et al. (2001), a poro-elastic hydrated layer covers the tibial plateau and micro-pockets are machined on the surface of the femoral head (Fig. 1). Taking as reference the case of a smooth femur, theoretically was found that the friction coefficient reduces in the presence of the micro-pockets. In order to check this result, first (present work) we intend to perform wear tests for a smooth femur. Further on we plan to compare the wear data, obtained with and without micro-pockets on the femoral component.

Figure 1: Modified design of the AKJ

MATERIALS AND METHODS

Femoral head is considered as a circular plate of 25 mm diameter (surface roughness, $R_a = 0.02 \mu\text{m}$), made in stainless steel. The artificial cartilage material is polyvinyl alcohol hydrogel (PVAH), prepared using the cyclic freezing/thawing method (Stammen et al. 2001). The PVAH layer has a water content $w = 77\%$ and a thickness $t = 2, 3, 4 \text{ mm}$. In the creeping test (Fig. 2.a), due to the water exudation, the residual

increases with the strain increasing (Fig. 2.b) but does not depend on layer's thickness. Fig. 3 illustrates the wear test rig. AC servomotor drives the ball-screw. The ball-nut translates together with the slider of the LM guide and the water tank, following the ISO-14243 anterior-posterior displacement pattern. The PVAH is bonded on the tibial substrate and immersed in the water tank. The loading screw produces a force, which is applied on the femoral head via lamella spring. It is possible to measure the displacement, load and wear volume (e.g., by using a spectrophotometer we measure the absorbance of the solution in which wear debris were dissolved). Tests on a smooth femoral head against PVAH reveals a wear factor on order of $10^{-4} \text{ mm}^3/(\text{Nm})$ and a friction coefficient about 0.1-0.2.

Figure 3: Photo of the wear test rig

SUMMARY

The prepared PVAH can operate up to 1.5 MPa pressure. The elastic modulus increases with the strain and does not depend on layer's thickness. The wear and friction measurements for a smooth femur against PVAH represent the reference data for the further studies of a femoral head with micro-pockets.

INTRODUCTION

Several materials (non-absorbable prostheses, collagen, synthetic biodegradable polymers, natural biodegradable materials) have been used for scaffolds in tendon or ligament tissue engineering. The scaffold should provide adequate sites for attachment and growth of enough cells to survive and function in vivo.

Recently, it has been reported that alginate and chitosan, natural biodegradable materials, have been good potential for biocompatible and biodegradable scaffold. Chitosan has various biological functions such as wound healing, antibacterial activity. Moreover, chitosan and alginate are easily prepared and a natural biopolymer available in plenty. On the other hand, the strength of these materials has been required to be improved. We developed new hybrid fibers consisted from Alginate and Chitosan. The aim of this study was to evaluate feasibility of novel Alginate-Chitosan Hybrid fibers as potential biomaterials.

METHODS

Biomechanical Study. Tensile tests for five samples of each material, Polyglactin 910 (Vicryl[®]), Alginate, Alginate-0.05%Chitosan Hybrid fibers (Cos-Y 0.05), Alginate-0.1%Chitosan fibers (Cos-Y 0.1), were performed at a cross-head speed of 20 mm/min. The cross-sectional area was determined with the non-contact method using microscope and video dimension analyzer.

Cell Attachment. Fibroblasts were isolated from the patellar tendon of Japanese White rabbit under sterile conditions. Cells were maintained in culture using standard procedures and used at passage 2. The concentration of fibroblasts suspension was 1.4×10^7 cells/ml. Cell adhesion study was performed as follows, (Nishimura 1985. Int. J. Biol. Macromol, 7, 100-104). Briefly, the fibrous samples were cut into 7mm length, and packed in small Teflon tubes (30mm length, 7.0 mm inner diameter). Then, fibroblasts suspension (0.1mL) was loaded on the column for 15minutes, and then washed out with phosphate-buffered saline (1mL) after loading. The number of fibroblasts retained on the fiber was estimated by the microscopic observation of washing solution. Results were analyzed using One-way Factorial ANOVA and Fisher's PLSD test. Difference was considered significant for $p < 0.05$.

RESULTS AND DISCUSSION

Biomechanical Study. Tensile strength in hybrid polymers was significantly lower than that in the alginate polymers. The guluronic acid chains of alginate ionically bind each other via the calcium ions. That may be replaced by chitosan in the Alginate-Chitosan Hybrid fiber. This may explain the mechanical inferiority in hybrid polymers.

Cell Attachment The number of washed out fibroblasts in Vicryl were significantly higher than that in the other polymers. The adhesivities in Cos-Y 0.05 and Cos-Y 0.1 were better than that in Vicryl and Alginate. On the other hand, the total amount of adhered fibroblasts was not affected by the increase in degree of content of chitosan. Zielinski (1994 Biomaterials, 15, 1049-1056) reported a cationic hydrogel such as chitosan provides a matrix necessary to maintain anchorage-dependent cell attachment and spreading. Our results were consistent with those reports.

In conclusion, novel Alginate-Chitosan Hybrid fiber showed great potential as desirable biomaterials for tendon or ligament tissue engineering.

INTRODUCTION

Severe ligament and tendon injuries are frequently treated with autograft transplantation. However, biological grafts are not ideal replacements. The use of autografts will necessarily results in donor site morbidity. Furthermore, the grafts initially undergo necrosis after the implantation. This is the main reason why the biological grafts often do not provide adequate mechanical strength until a long term remodeling process is done.

Resorbable scaffolds seeded with cells are potential alternatives to biological grafts. Currently, most of these constructs for tissue engineering have been based on collagen scaffolds. On the other hand, the major limitation is that collagen scaffolds are allogenic. Also, collagen scaffolds suffer from batch-to-batch variability, making consistent reproduction of these constructs difficult. To solve this problem, we developed new hybrid materials consisted from chitosan and hyaluronan (HA). It was reported that chitosan could promote the healing of skin wound. Moreover, chitosan is not immunogenic. HA has been shown to improve healing of a variety of tissues by means of trophic effects through binding, delivery of growth factors, cell adhesion, and anti-inflammatory effects. The purpose of this study is to investigate material properties and fibroblasts adhesion behavior of chitosan-based HA hybrid polymer.

METHODS

Polymer fibers of Polyglactin 910 (vicryl®, Ethicon Co, NJ) were used as a control material. Chitosan polymer fibers and chitosan-based HA hybrid polymers (Chitosan/0.05HA: Chitosan:HA = 8%:0.05%, Chitosan/0.1HA: Chitosan:HA = 8%:0.1%) were originally developed in our laboratory.

Measurement of Material Properties

Tensile tests for five samples of each material were performed at a cross-head speed of 20 mm/min. The cross sectional area was determined with the non-contact method using microscope and video dimension analyzer.

Cell Adhesion Study

Fibroblasts were isolated from the patellar tendon of a Japanese white rabbit under sterile conditions. Cells were isolated and maintained in culture using standard procedures and used at second passage. The fibroblasts suspension was concentrated to 1.4×10^7 cells/ml using a hemocytometer. Cell adhesion study was performed according to our previous study (1985, Int. J. Biol. Macromol, 7, 100-104). Briefly, the fibrous samples were cut into 7 mm pieces and packed in Teflon tube (30 mm length, 7 mm inner diameter) and then 0.1 ml of fibroblasts suspension was loaded on the column. The cells were allowed to adhere in a humidified incubator for 1 hour. Each column was gently rinsed with 1 ml of phosphate-buffered saline and the number of

unattached cells was quantified by the microscopic observation of rinsed solution. Five parallel samples were used for each polymer fibers. Statistical comparison was performed using one-way ANOVA and Fisher's PLSD test. Difference was considered significant for $p < 0.05$.

RESULTS AND DISCUSSION

Mechanically, new materials were significantly weaker than control polyglactin fibers. On the other hand, strain at failure in new polymers showed significantly stiffer than control fibers. This strain characteristic of new polymers may be beneficial for ligament scaffold. HA significantly increased chitosan polymer strength (Table 1). This may be attributable to water binding affinity of HA during manufacturing process of air-drying. The current study showed that the adhesivity of fibroblasts was significantly higher in the new polymer materials. Moreover, HA significantly increased cell adhesion to the polymers (Fig. 1).

SUMMARY

Material properties and cell adhesivity were investigated in newly developed chitosan polymer fibers and chitosan-based HA hybrid polymers. Chitosan-based HA hybrid polymers showed great potential as a desirable biomaterials for use in a tissue scaffold. Further in vivo study should be conducted.

Table 1: Material properties of scaffolds

Material	Tensile Strength (MPa)	Strain at Failure (%)
Vicryl®	886.2 +/- 7.7	28.1 +/- 0.6
Chitosan	128.1 +/- 4.9*	4.3 +/- 0.4*
Chitosan/0.05HA	152.6 +/- 5.4***	6.1 +/- 0.7*
Chitosan/0.1HA	217.6 +/- 8.5***	3.2 +/- 0.3*

INTRODUCTION

Our long-term goal is to utilize therapeutic ultrasound (TUS) as a stimulus for angiogenesis and vascular regeneration. Stimulation of new capillary growth under ischemic conditions is crucial in preventing large damage following major events such as acute infarction, and kidney or liver dysfunction. It has been demonstrated that TUS induces cell proliferation and migration, collagen synthesis, stimulation of growth factors, production of cytokines, regeneration of skeletal myofibrils, migration of smooth muscle cells and angiogenesis. The physical interaction of TUS with tissues is complex and intensity (and frequency) dependent. Cavitation erosion of surfaces due to bubble collapse and high velocity jet formation as well as thermal effects are associated with the high range of intensities of TUS. The relevant mechanisms for the lower range of TUS intensities, which are used in this investigation, are associated with bubble pulsation and micro streaming, and transverse (shear) waves.

Regarding TUS and angiogenesis, this study concerns TUS and its effect on blood vessels in general and on the endothelium in particular. We hypothesize that low intensity TUS induces localized shear stresses on the endothelial cell (EC) layer. This is based on evidence for TUS-induced intercellular spaces between the first two outermost cell layers of fish epidermis (Frenkel et al. 1999), and on the physical similarities, in relation to ultrasound, between the epithelium and endothelium at the tissue/liquid interfaces.

It is known that biomechanical forces act on endothelial cells to modulate their structure and function. For instance, shear stresses induced by the flowing blood, influence permeability to macromolecules and accumulation of lipoproteins. They affect angiogenesis and lately were found (unpublished) to regulate the level of expressed receptors such as VEGFR-1 and VEGFR-2 (Vascular Endothelial Growth Factor Receptors) and angiopoietin receptors (e.g. Tie-1 and Tie-2). VEGFR-2 (Flk-1) receptor is known to enhance the proliferation of endothelial cells, mediate chemotaxis (migration), and increase the vascular permeability. VEGFR-1 (Flt-1) is connected with communication between the endothelial cells. Tie-2 involves in expansion of the endothelium, matrix association and pericyte recruitment and Tie-1 involves in capillary development and endothelial cell integrity. Both Tie-1 and Tie-2 play a role in the late phase of angiogenic capillary growth and in survival of the endothelium.

The following study is about sonication of endothelial cells *in vitro*. It describes the changes of viability, the variations in

level of angiogenic molecules and the morphological changes in the EC after exposure to TUS.

METHODS

TUS was applied to confluent Bovine Aortic Endothelial Cells (BAEC), kept in DMEM low glucose 10% calf serum under 5% CO₂/95% air in a humidified incubator at 37°C. The medium contained also 2mM L-Glutamin, 1 µg/ml Gentamycin, 20 µg/ml Streptomycin, and 20U/ml Penicillin. The EC were exposed to TUS (frequency 1.5MHz, intensity 1W/cm², continuous mode) for time durations that vary from 5 to 30 minutes. Western blot analysis and immunoblotting were used to test the expression of VEGF receptors Flk-1 and Flt-1, and angiopoietin receptors Tie-1 and Tie-2. Viability was tested using XTT kit, Hocht and direct counting.

RESULTS AND DISCUSSION

The expression of Flk-1 was increased significantly after 30 minutes of exposure to ultrasound. At the same time no change was observed in Tie-2 levels. Preliminary data indicates that TUS induces changes in Tie-1 and Flt-1. These regulations of the angiogenic factors correspond with the results of shear stress stimulation of EC obtained in a cone-and-plate apparatus (unpublished). Hours after treatment we observe that in comparison to control sonicated EC have fewer and smaller extensions, and their boundaries appear more round and monotonous. This might be the result of disconnected adhesion sites and may serve as indirect indication of TUS-induced shear stresses. Also, treated BAECs show no preferred orientation as expected from the random nature of bubble's micro streaming and the localized shear stresses, which are generated by bubble pulsations near a surface. No sign of cavitation erosion is found in this study as indicated by the fact that EC viability is not at all reduced by the TUS.

We conclude that low intensity TUS influence angiogenic mechanism in BAEC *in-vitro* and might have an effect on the functioning of the cardiovascular endothelium *in-vivo*. The regulating effect of TUS on angiogenic factors in BAEC point to the possibility that shear stresses are involved.

A REGRESSION MODEL FOR PREDICTING PERCEIVED LOAD

Masaru Hotehama¹, Jeff Janert², and Toshikazu Takemori¹

¹R&D Department, Osaka Gas Co., Ltd

²Visiting Researcher R&D Department, Osaka Gas Co., Ltd

INTRODUCTION

The purpose of this research is to develop a regression model between torque and perceived load, which will be integrated with commercial software called "Digital Human" or "Computer Mannequin".

The paper describes a best-fit regression model and its comparison with other types of regression models.

METHODS

Ten subjects performed biceps MVC on a biceps isolation bench (isolation MVC) and again while seated and without any back support (non-isolation MVC). The subjects then curled a bucket of unknown weight but between 1kg and 10kg for 15 trials and reported what percentage of their biceps MVC the weight represented each time. Afterwards to validate the algorithm derived from the previous 15 trials; the same ten subjects then moved the unknown weight from the floor to a 10 centimeter platform again while seated and without back support (living scene).

RESULTS AND DISCUSSION

Table1 shows regression models (linear and nonlinear) and the population R² values for the torque normalized with the Max torques on non-isolation MVC movement and isolation MVC movement, and average of prediction error on living scene. The best fit function for the isolation MVC is (Perceived Load)%=43.593*(Normalized reported torque percent of Max Torque)+80.886. The algorithm validation error between the isolation normalized algorithm and the real application data is 11.91%. The average error of each subject's perceived load between 1st time and 2nd time is 9.23%, and standard deviation is 9.28. So prediction error is small enough to predict a perceived load on bicep.

Figure1 shows the living scene data normalized by isolation MVC and nonlinear regression line. The variation in data is seen between 0.5 and 1. But almost all data is close to nonlinear regression line.

Figure 1: Living scene “real-life” validation of biceps isolation bench MVC normalized data and nonlinear regression line for all 10 subjects.

SUMMARY

We developed a regression model for predicting perceived load based on biceps maximum voluntary contraction. The best fit function for the isolation MVC is (Perceived Load)%=43.593*(Normalized reported torque percent of Max Torque)+80.886. The algorithm validation error between the isolation normalized algorithm and the real application data is 11.91%. The error is small enough to predict a human sensation on bicep.

If we develop other parts model and integrate these functions to computer mannequin, we will be able to predict a personal perceived load by measuring max torque.

INTRODUCTION

It is well known that rigid metal plates induce bone atrophy during the healing of fractured bone. This phenomenon is widely recognized as stress shielding and the problem is the large stiffness mismatch between metal plates and human cortical bone. Hence primary objective of this research project is to design and develop a less rigid and biocompatible braided carbon fiber fabric reinforced PEEK composite osteosynthesis plate for the treatment of long bone fractures.

FABRICATION METHODS OF BIOCOMPATIBLE OSTEOSYNTHESIS PLATES USING BRAIDING TECHNIQUES

In this study, braiding techniques were adopted to fabricate composite bone plates. Firstly, a new type of commingled yarn, called micro-braiding yarn (*Figure 1 [a]*) was made. This yarn was made by inserting three reinforcing carbon fiber yarns (diameter = $7\mu\text{m}$, 1000 filaments) into a tubular braid of 10 matrix PEEK fiber yarns (230 dTEX, 30 filaments). The feature of this yarn is such that the reinforcing and matrix fibers were mixed uniformly, which results in good impregnation of PEEK matrix into carbon fibers. Moreover, PEEK fibers wrap carbon fibers effectively and reduce the possibility of release of broken fibers. The micro-braiding yarn was used to make the flat braided fabrics with braiding angle θ (*Figure 1 [b]*). The braided carbon/PEEK composite osteosynthesis plate (*Figure 1 [c]*) was fabricated using optimized compression molding conditions, an average pressure of 5.6MPa and temperature of 400C° for 60 minutes.

RESULTS AND DISCUSSION

As shown in *Fig.2*, bending moment and stiffness of the composite bone plates decreased with increasing braiding angle and the specimens showed $7.07 \sim 8.14$ [Nm] maximum moment and $0.316 \sim 0.359$ [Nm/deg.] stiffness with varied braided angles. These values correspond to $38.2 \sim 44.0\%$ of the maximum moment and $26.6 \sim 30.2\%$ of the stiffness of stainless-steel bone plate values. These mechanical properties can be varied with different size of the micro-braiding yarn or braiding structure of composite. That means braided composite osteosynthesis plates offer the desirable and suitable mechanical design for each patient regardless of sex and age. It is considered that braided composite plates are holding promise of a better bone fixation as compared with conventional metal plates.

INTRODUCTION

Total hip arthroplasty (THA) has proven to be a successful surgical technique in the past thirty years due to the improvement of prosthetic design, biomaterials and surgical technique. However, the complication of local bone loss still remains an unsolved problem during the long-term application. No femoral prostheses were free of such complications. Stress-shielding effect was thought to be the main factor that result in local bone loss after prosthesis implantation. In order to eliminate the stress shielding effect that traditional prosthetic femora encounters in long-term application, we developed a new designed stemless prosthesis (Cervico-Stemless prosthesis, C-S prosthesis), Figure 1. An integral and systematic biomechanical experiment was conducted by using this C-S prosthesis, and the results were compared with that of traditional femoral prosthesis.

METHODS

We measured the surface strains of proximal femora *in-vitro* on conditions of one-leg stance using synthetic femora and MTS testing machine under 1,000 Newtons loading. The surface strains of implanted femora are compared between C-S and traditional PCA prosthesis after insertion of C-S prosthesis in cases of (A) Two screws fixation; (B) Three screws fixation and (C) Cement fixation. The experimental set-up was shown in Figure 2.

RESULTS AND DISCUSSION

The percentage of surface strains as compared to intact femora for C-S and traditional prosthetic femora was shown in Figure 3. The results was summarized as follows:

1. The stress shielding phenomena of C-S prosthetic femora were significantly eliminated in all insertion conditions as compared to the PCA case.
2. As for C-S prosthetic femora, there exists similar stress distribution between each insertion condition. No significant difference of surface strains was found.

SUMMARY

Based on the results of this current study, we concluded that the newly designed C-S prosthesis possess the following superiority:

1. More physiological stress distribution on the proximal femur;

2. Prevention of endosteal femoral osteolysis;
3. Immediate stabilization of the implant;
4. Preservation of endosteal vascularity; and
5. Capacity for later femoral revision.

SIMULATION OF THE SHAPE CHANGE OF A RED BLOOD CELL AT THE ENTRANCE OF A CAPILLARY

Shigeo Wada and Ryo Kobayashi

Research Institute for Electronic Science, Hokkaido University, Sapporo, Japan

wada@bfd.es.hokudai.ac.jp

INTRODUCTION

It is well known that a red blood cell (RBC) has an ability to pass through a capillary with a diameter smaller than that of the cell by changing its shape flexibly. The flexibility of an RBC arises from the mechanical properties of the cell membrane consisting of a lipid bilayer and an underlying skeletal network (Mohandas and Evans, 1994). However, it also depends on the shape of an RBC taking a shell structure. Therefore, in order to understand the flexibility of an RBC, it is necessary to describe the behavior of an RBC which deforms 3-dimensionally into various shapes based on the properties of the membrane. In this study, we simulated the shape change of an RBC passing through a capillary using our elastic network-model of an RBC (Wada et al., 2000).

METHODS

The whole membrane of an RBC was divided into small triangular elements (4484 elements with 2244 nodes). Each edge of the element was expressed by a linear spring with an elastic resistance, k_s . An element was connected with the neighboring elements by a plate spring having an elastic resistance, k_b , which resisted to the change of the contact angle between them. It was assumed that the element also resisted to the change in both the area of each element and the total surface area of the membrane, and it had an expansion modulus for the local area change, k_a , and for the global area change, k_A . Furthermore, the resistance to the change in volume of an RBC was expressed by a bulk modulus of the cell, k_V .

When an external force is applied to an RBC to cause a shape change, elastic energies are generated as the results of stretching of the linear spring, bending of the plate spring, area expansion of the element and the membrane, and volume change of the cell. Here, these elastic energies were mathematically expressed as a function of position vector at each node of the elements. Based on the energy principle, the shape of an RBC was determined by finding nodal positions that minimized the sum of the elastic energies. Since the derivative of the total energy with respect to the position vector at a node provides an internal force acting on the nodal point, this was accomplished by solving the equation of motion of mass points assigned to the nodes which were moved by the internal force and an external force applied.

The values of elastic resistances were chosen to be $k_s = 1.5 \times 10^{-2}$ dyn/cm and $k_b = 1.0 \times 10^{-6}$ dyn, which were equivalent respectively to a shear modulus and a bending stiffness of an RBC membrane shown in literatures (Mohandas and Evans, 1994; Hansen, 1996). The expansion modulus for local area change, k_a , was determined to be 0.5 dyn/cm based on

experimental data obtained by an aspiration test (Mohandas and Evans, 1994). The expansion modulus, k_A , and bulk modulus, k_V , were set to be 5.0 dyn/cm and 1.0×10^{-6} dyn/cm², respectively, so that the calculations could be carried out successfully keeping the surface area of the membrane and the volume of the RBC almost constant.

RESULTS AND DISCUSSION

It was assumed that the shape of an RBC in a natural state (stress free state) was a biconcave disc with a diameter of 8.30 μm , a minimum thickness of 1.01 μm , a maximum thickness of 2.18 μm , a surface area of 138 μm^2 , and a volume of 122 μm^3 . Simulation was carried out from a state where the RBC was approaching the entrance of a capillary with a diameter of 6 μm by aligning its axis with the axis of the capillary.

Figure 1 shows the shape change of an RBC as the cell was drawn in the capillary by a suction pressure of 50 dyn/cm². The total elastic energy generated in the RBC increased until the cell was completely drawn in the capillary. The internal force acting on the membrane which increased with increasing the elastic energy resisted to the shape change of the RBC. However, in going deeper in the capillary, the shape of the RBC gradually changed in such a manner that it decreased the total elastic energy and pass through the capillary easily.

ADJUSTMENT OF INDIVIDUAL STIMULATION PATTERNS FOR FES CYCLING

Margit Gföhler¹, Thomas Angeli¹, Peter Lugner² and Winfried Mayr³

INTRODUCTION

By Functional Electrical Stimulation (FES) of leg muscles paraplegics can coordinate the movement pattern of pedaling. As paralyzed muscles are mostly weakened and only a limited number of effective leg muscles can be reached by surface electrodes it is important to convert the generated muscle forces into drive power with high efficiency. Therefore, before the test person starts cycling on a mobile tricycle, tests are performed on a test bed (Gföhler et al., 2001) for determination of the optimal individual stimulation pattern.

METHODS

The paraplegic test person is seated on a specially adapted wheelchair, the relative position of crank and chair and also the angle of the backrest can be adjusted (Fig. 1). A four bar linkage allows the pedal to rotate on an optimized noncircular pedal path (Angeli et al., 1999). A specially developed measuring crank allows measurements of the three orthogonal forces applied to the crank. The knee angle is measured by a goniometer. For the pedaling experiments the gear motor can either fix the crank at a given angular position (static measurements) or drive the crank with a given angular velocity (dynamic measurements).

Figure 1: Scheme of the test bed.

The geometry of the rider-cycle system (vertical and horizontal distance between hip joint and crank axis, backrest inclination) and the influence of the stimulation parameters (threshold / max. stimulation voltage, stimulation frequency) are tested by variation of the different parameters. The generated crank loads and drive torque are measured, and

optimal stimulation intervals are determined for each stimulated muscle individually. Afterwards dynamic measurements at a given crank angular velocity with all muscles stimulated together show which power output can be achieved during one full rotation of the crank.

RESULTS AND DISCUSSION

Figure 2 shows the results of dynamic measurements with stimulation of the hamstrings.

Figure 2: Measurements with stimulation of the hamstrings at crank angular velocity 25 rpm in the individually optimized stimulation interval: stimulation voltage and resulting active drive torque (due to active muscle forces) applied to the crank during one full rotation

SUMMARY

As paralyzed muscles are mostly weakened and only a limited number of effective leg muscles can be reached by surface electrodes it is important for FES cycling to convert the generated muscle forces into drive power with high efficiency. This study describes how to optimize the stimulation patterns for FES cycling with static and dynamic tests on a test bed for an individual paraplegic test person.

A BIPHASIC CONSTITUTIVE LAW FOR PASSIVE CARDIAC TISSUE

D.-E. Bakman, Y. Loosli, P. Schmid, P. Niederer

Institute of Biomedical Engineering, University and ETH Zurich, Zurich, Switzerland

bakman@biomed.ee.ethz.ch

INTRODUCTION

Myocardial tissue consists of a variety of different components, among them, muscle fibres, collagen, coronary vessels, blood and interstitial fluid. The pronounced anisotropy of the tissue is characterized by the architecture of the highly crosslinked muscle fibres (Schmid 1997). Passive myocardial tissue has furthermore non-linear viscoelastic constitutive characteristics (Fung 1981). The intravascular fluid flow, in turn, is influenced by the contraction (systole) and relaxation (diastole) processes, such that an effective compressibility may be simulated by an unbalanced fluid exchange.

In order to simulate the redistribution of coronary blood in the ventricular wall during the deformation (passive filling phase), a biphasic formulation (fluid + solid) has been developed for the myocardium to be applied during the diastolic phase.

CONSTITUTIVE EQUATIONS

In this study the myocardial tissue is considered as a mixture of an incompressible inviscid fluid phase (representing the coronary blood) and a nearly incompressible anisotropic solid phase. Each phase is homogeneous and no material exchange occurs between the two constituents.

The stress tensor of the fluid (σ^f) is calculated by the relation

$$\sigma^f = -p \frac{\phi^f \rho_T^f}{\rho} \mathbf{I} \quad (1)$$

whereas the stress on the solid phase (σ^s) is given by

$$\sigma^s = -p \frac{\phi^s \rho_T^s}{\rho} \mathbf{I} + \sigma^E \quad (2)$$

Thereby, ρ_T^α is the true density, $\rho_T^\alpha(\underline{x}, t) = \frac{dm^\alpha(\underline{x}, t)}{dV^\alpha(\underline{x}, t)}$, and ϕ^α is

the local volume fraction of the α th constituent:

$$\phi^\alpha(\underline{x}, t) = \frac{dV^\alpha(\underline{x}, t)}{dV(\underline{x}, t)}, \quad \alpha = s : \text{solid}, \quad \alpha = f : \text{fluid} \quad (3)$$

$$\rho \text{ is the density of the mixture, } \rho = \rho^s + \rho^f \quad (4)$$

$$\text{with } \rho^\alpha(\underline{x}, t) = \frac{dm^\alpha(\underline{x}, t)}{dV(\underline{x}, t)} \quad (5)$$

σ^E is the solid stress which in general is derived from the strain energy function, W. Huyghe (1991) proposed a formulation for this function for use in a passive heart model:

$$\sigma^E(\underline{\epsilon}, t) = \frac{\partial(C(J-1)^2)}{2 \cdot \partial \underline{\epsilon}} + \int_0^t G(t-\tau) \cdot \frac{\partial \sigma^{el}(\underline{\epsilon}(\tau))}{\partial \tau} \cdot d\tau \quad (6)$$

Here, C is the bulk modulus, J the Jacobian, σ^{el} the anisotropic elastic response of the material and G(t) the scalar reduced relaxation function

$$G(t) = \left[1 + \int_0^\infty \Psi(s) \cdot e^{-\frac{t}{s}} ds \right] \cdot \left[1 + \int_0^\infty \Psi(s) \cdot ds \right]^{-1} \quad (7)$$

with $\Psi(s) = \frac{d}{ds} + \Psi^0$ if $s_1 \leq s \leq s_2$ and $\Psi(s) = 0$ elsewhere.

$$\sigma^{el} \text{ is given by: } \sigma_{ij}^{el} = \frac{1}{2} \left(\frac{\partial W^{el}}{\partial \epsilon_{ij}} + \frac{\partial W^{el}}{\partial \epsilon_{ji}} \right) \quad (8)$$

$$W^{el} = c^n \left\{ \sum_{i=1}^3 (\exp(a^{cf} \epsilon_{ii}) - a^{cf} \epsilon_{ii}) + \sum_{i \neq j} \sum_{j \neq i} \left(\frac{1}{2} (\exp(a^b \epsilon_{ii}) - a^b \epsilon_{ii}) (\exp(a^b \epsilon_{jj}) - a^b \epsilon_{jj}) \right) - 6 \right\} + c^s \left\{ \exp\left(\frac{a^s}{2} \sum_{i \neq j} \sum_{j \neq i} \epsilon_{ij} \epsilon_{ij}\right) - 1 \right\}$$

The fluid flux into the biphasic medium is defined as

$$\underline{J} = \phi^f (\underline{v}^f - \underline{v}^s) \quad (9)$$

where \underline{v}^f and \underline{v}^s are the fluid and solid velocities, respectively.

The constitutive equation for the momentum supply $\underline{\pi}$, representing the internal force between the two phases, reads

$$\underline{\pi} = \frac{\mathbf{K}}{\phi^f} \underline{J} - \frac{p}{\rho} \underline{u} (\underline{v}^s \cdot \underline{\nabla} \rho^s + \underline{v}^f \cdot \underline{\nabla} \rho^f) \quad \text{with } u_i = \frac{1}{3(v_i^f - v_i^s)} \quad (10)$$

where \mathbf{K} a positive definite diagonal tensor whose terms describe the diffusive resistance coefficients.

DISCUSSION

The equations ((1), (2), (6) and (10)) describe the constitutive behavior of the myocardial tissue. The effective compressibility of the heart, due to the intravascular fluid flow, as well as its anisotropic structure and its non-linear viscoelastic behaviour are also considered. In this formulation the time dependence of the blood flux was not taken into account, however, a pulsatile coronary blood flow can be implemented. The biphasic formulation (equations (1), (2) and (10)) presented here is not limited to the myocardium and can also describe the mechanical behaviour of other soft tissues.

CELL SEEDED PLASMA-TREATED POLYESTER LIGAMENT UNDER CYCLIC TENSILE LOAD- COMMISSIONING OF METHODOLOGY

Mostafa Raif¹, Toyoda Takashi¹ and Bahaa Seedhom²

Division of Bioengineering, Rheumatology and Rehabilitation Research Unit, Leeds Medical School, Leeds, UK

1 Postdoctoral Research Fellow, 2 Reader and Director of Research

INTRODUCTION

Plasma treatment of polyester ligament structures has been shown to render the material hydrophilic and increase cell adhesion to it (Rowland et al (2000)). In this work we describe methodology, apparatus and report early results of an investigation into the cell proliferation and morphological changes of cells when seeded on a plasma-treated polyester ligament scaffold, which is then subjected to cyclic tensile strains.

METHODS

Cell culture: Primary cultures of Synovial fibroblasts were prepared from Metatarsophalangeal bovine joints by enzymatic digestion with collagenase.

Mechanical load application: A special apparatus was designed which allowed the application of a cyclic tensile load, of varying amplitude at a frequency of 1 Hz, on the cell seeded ligament scaffolds while being gripped and placed in culture medium within an incubator at 37°C. The design allowed visual monitoring of the cell seeded ligament scaffold with light microscopy, during prolonged tests

Cytotoxicity test: The cytotoxicity of scaffold grips was investigated using synovial fibroblasts in cell monolayer culture. The scaffold grips were partially immersed and partially projecting out of the culture dish. The grips materials tested were 303 and 316 stainless steel, Titanium (Ti) and Delrin.

Cell proliferation: The ligament scaffolds were seeded with synovial fibroblasts. After four days in culture, the scaffolds were incubated in a serum free medium for 24 hours. Subsequently, a cyclic tensile load of amplitude of 150N (producing 5% cyclic tensile strain) was applied for a period of 6 hours. The cell-seeded scaffolds were then incubated for a further 24 hours. Effect of cyclic strain on cell proliferation was assessed using Blue Trypan. The controls (unloaded cell seeded scaffolds, both **within** and **without** the grips) were carried out under the same conditions.

Optical microscopy analysis

The loaded and unloaded cell seeded scaffolds (one of the two control groups) were fixed with 3.7% formaldehyde for 5 minutes. They were then washed with PBS and stained with Toluidine Blue O for 5 minutes.

RESULTS AND DISCUSSION

Efficacy of the apparatus: A mechanical test was carried out to examine the capacity of the grips to hold the implant whilst applying cyclic tensile load. The test demonstrated that these grips could successfully hold the implant in place after the application of a tensile load of 150N amplitude, at a frequency of 1 Hz throughout 300,000 load cycles.

Toxicity: contrast optical microscopy and the cell cytotoxicity studies showed that the 316 stainless steel was the most biocompatible of the alloys tested when partially immersed in the culture medium and partially projecting out of the culture dish.

Cell proliferation: The application of cyclic strain for 6 hours was associated with an increase in the number of cells of some 8% observed in the loaded ligament scaffolds, above those observed in seeded but unloaded scaffolds.

Morphological changes: In the *unloaded control* group the cells are randomly oriented, Figure 1-a, and although cellular morphology varied from one cell to another, a fibroblastic shape is the most typical. In the *loaded scaffolds* most of the cells are oriented in the direction of the load (scaffold filaments), Figure 1-b, and most of the cells acquired a spindle-shape typical of ligament fibroblasts, Figure 1-c.

Figure 1: Morphology of bovine synovial cells seeded on plasma-treated polyester ligament scaffold, (a): Controls, (b): Cells on loaded scaffold, (c): higher magnification of b.

CONCLUSION

We have developed a viable methodology for seeding fibroblasts onto plasma treated polyester ligament scaffolds and subjecting these, for prescribed periods, to cyclic loads at a physiological frequency in order to investigate and monitor cell proliferation; morphology and metabolism.

INTRODUCTION

It is becoming increasingly important to develop accurate mathematical models of human tissue for use in finite element analysis. For modeling the impingement of bone fragments on the spinal cord during fracture, mechanical properties of the spinal cord are required but only limited data is available. The viscoelastic behaviour over 1 minute has been studied (Bilston, 1996), but no authors have investigated extended relaxation. The aim of this study was to investigate the time-dependent characteristics of spinal cord and fit mathematical models to both loading and stress-relaxation data obtained.

METHODS

Experimental - Samples of intact bovine spinal cord (80mm-120mm) were taken from their dural sheath and placed in a sealed container of preheated isotonic saline solution (37°C). Individual specimens were then fitted with two clips around the central section to mark the gauge length and the specimen ends were placed into fixation devices loaded with dry ice to hold the sample firm. Care was taken not to stretch the specimen as the fixations were attached to the lower base and upper load cell of a bench top tensile testing machine (Shimadzu, JN). A preload of 0.5N, representing a strain of approximately 3-5% was then applied to each specimen. A videoextensometer (Messphysk ME-46) was used to identify the gauge length and determine the extension caused by the uniaxial load on the specimen. For each test, 15 conditioning cycles were performed before samples were elongated to a maximum nominal strain at a preset strain rate (0.023s⁻¹) and held for 15 minutes.

Mathematical Models – A quasilinear model developed by Fung (1993) was used to model the cord behaviour during loading. Using the same elastic response function as Bilston (1996), the following expression for the stress response was obtained:

$$\sigma(t) = AB\epsilon_0 \sum_i G_i \left[\frac{1}{\frac{1}{\tau_i} + B\epsilon_0} (e^{B\epsilon_0 t} - e^{\frac{-t}{\tau_i}}) \right] \quad 0 < t < t_1$$

It was also attempted to fit the quasilinear model to the stress-relaxation data but this was deemed unsuccessful due to the extended relaxation period tested.

A Maxwell-Kelvin four-element model was therefore used to model the cord behaviour during relaxation. Substituting the elastic and viscous elements in the relaxation response of a four-element viscoelastic model gives:

$$\sigma(t) = E_1 e^{(t_1-t)\tau_1} + E_2 e^{(t_1-t)\tau_2}$$

RESULTS

A total of 10 tests were successfully carried out, and data from each test were fitted to the models using a generalised reduced gradient non-linear optimisation algorithm (Microsoft Excel Solver, Microsoft, WA) to obtain values for each of the parameters. The results of each model are summarised below:

Figure 1: Typical Stress-Time Plot during Loading

Figure 2: Typical Stress-Time Plot during Relaxation

DISCUSSION

The results of the experimental tests show a non-linear ‘J-shaped’ stress-strain response during loading and clear viscoelastic properties upon relaxation. The quasilinear model developed to describe the behaviour of the spinal cord was found to describe the material behaviour adequately during loading, but was deemed unsuccessful for modelling the extended relaxation. The 4-element model appeared to fit the relaxation behaviour well. The parameters from both models are therefore useful for finite element simulations of the spinal cord under different loading conditions.

INTRODUCTION

This study was focused on the relationship between the compressive modulus of cartilage and its deformation under cyclic loading conditions – particularly those arising during level walking, which is the most predominant of human activities. Other parameters that influence cartilage deformation under these conditions are the duty cycle parameters including: the frequency of load application, the amplitude of the applied load, the ratio of the loading duration to that of recovery within a loading cycle and the number of loading cycles applied. It is likely that effects of these parameters on cartilage deformation have not been investigated because of the limited variation in them. It is interesting, however, that no study has so far investigated the effect of the large range of modulus (1- 20 MN/m²), on the deformation of cartilage and this may well be because of the expectation that this relation would be a simple inverse one. This study has focused on this aspect because of both the intrinsic viscoelastic nature of cartilage and the influence of flow of the interstitial fluid during the application of cyclic load on cartilage that naturally occurs during locomotion.

METHODS

Twenty-four osteochondral plugs were harvested at eight specific sites from 3 fresh cadaveric knees. The cartilage tested thus had the widest possible range of compressive modulus as that observed across the knee in previous studies. Cartilage specimens were immersed in Hanks balanced salt solution, which was maintained at 37°C, and were subjected to the same cyclic loading regime representative of a typical walking cycle, for over 1 hour using a specialized indentation apparatus (Barker and Seedhom (1997)). The viscous and elastic components of matrix strain and the creep rate were measured throughout the entire experiment. The cartilage ‘instantaneous’ compressive modulus of each osteochondral plug was determined using methodology developed in our laboratory (Shepherd and Seedhom (1997)).

RESULTS AND DISCUSSION

The values of ‘*instantaneous compressive modulus*’ ranged from 1 to 19.5 MN/m². *Elastic strain decreased exponentially* with the compressive modulus; specimens with a modulus less

than 4 MN/m² experienced elastic strains in the range 0.18 and 0.36, whereas stiffer specimens experienced strains between 0.05 and 0.13. *Viscous strain increased linearly* with cartilage compressive modulus and was as low as 0.02 at the lower values of the modulus but increased to 0.22 for a compressive modulus of 18 MN/m².

The rate of creep under cyclic load had an inverse linear relationship with the cartilage stiffness. The strain response of soft specimens approached steady state by 200 cycles but that of stiff specimens approached it by 1300 cycles. Subsequent experiment corroborated the view that this difference in the viscous behavior of stiff and soft cartilage is mostly related to the interstitial fluid flow rather than to intrinsic viscoelasticity of the cartilage matrix.

The total strain (sum of elastic and viscous strain components), had a bimodal relationship with the compressive modulus, and had a minimum that corresponded to the midrange value of the modulus (10 MN/m²). A hypothesis is proposed that cartilage adapts its matrix components so as to minimize the total strain in response to the most prevalent loading regime that it is subjected to.

INTRODUCTION

Although a great number of total joint replacements have been carried out particularly for diseased hip and knee joints, in certain cases, serious tribological problems such as loosening and wear occurred. Therefore authors investigated another rubbing surface as joint replacement, namely, artificial cartilage material by using PVA (polyvinyl alcohol) hydrogel. And in a condition of walking motion at knee joint simulator, PVA hydrogel showed low friction by fluid film lubrication. However, in thin film lubrication like mixed lubrication the wear of PVA hydrogel was increased against the zirconia ceramics.

In this study to investigate the possibility of clinical use of PVA hydrogel, the pair of PVA hydrogel as lower specimen and PVA hydrogel or natural articular cartilage as upper specimen was examined.

METHODS

PVA hydrogel was made by repeated freezing method (degree of saponification: 99.4-99.8mol%, EWC: 79%, repeating process: 5 cycles).

Friction and wear properties of PVA hydrogel as artificial cartilage was investigated in a reciprocating tester. In the test a elliptical surface of PVA hydrogel or natural articular cartilage was used as upper specimen and PVA hydrogel plate was used as lower specimen. The sliding speed was 20mm/s, the total sliding distance was 3km, the stroke was 35mm (rectangular wave) and the load was 9.8, 4.9, 2.94 N. The lubricants were saline solution containing protein and hyaluronic acid (HA). The wear was evaluated by the wear grade based on difference of surface structure observed by microscopy or naked eye.

The film thickness was calculated to confirm that mixed lubrication occurred. The equations proposed by D.Dowson et al. was used.

RESULTS AND DISCUSSION

Figure 1 shows surface structure images after reciprocating test (lower specimen: PVA hydrogel, upper specimen: natural articular cartilage, load: 9.8N, lubrication: saline + 0.5wt% HA). In PVA hydrogel as lower specimen the wear was mild. In natural articular cartilage as upper specimen, however, the severe wear was observed. The addition of proteins, i.e., albumin and globulin could reduce the wear of articular cartilage as shown in figure 2. The boundary film of protein is effective for the natural articular cartilage.

Figure 1: Surface structure images after reciprocating test (lubricant: saline + 0.5wt% HA, left: lower PVA hydrogel, right: upper natural articular cartilage)

Figure 2: Surface structure images after reciprocating test (lubricant: saline + 0.5wt% HA + 0.7wt% globulin, left: lower PVA hydrogel, right: upper natural articular cartilage)

In the rubbing pair of PVA hydrogel against itself, although the upper PVA specimen showed significant wear, the addition of albumin and globulin could reduce wear. In PVA hydrogel the lubricant containing protein was effective to make boundary layer. Therefore, the artificial cartilage of PVA hydrogel is expected to be clinically applicable in biological environment in low loaded joint replacement.

SUMMARY

To evaluate the tribological behavior of PVA hydrogel, the simplified reciprocating test was conducted for sliding pairs of PVA hydrogel against natural articular cartilage or PVA hydrogel. In both pairs of PVA hydrogel and natural articular cartilage or PVA hydrogel, the lubricant containing protein effectively reduced wear.

INTRODUCTION

In previous studies, we determined the topographic variation in cartilage compressive modulus on the entire articular surfaces of knee and ankle joints (Swann and Seedhom (1993), Yao and Seedhom (1993), Shepherd and Seedhom (1999). These studies showed that the compressive modulus (whether measured as a 'creep' or 'instantaneous' modulus) was related to the regional variation in the prevalent stresses occurring in these two joints. Thus cartilage was stiff (had a high modulus) where the prevalent stress was high, whereas cartilage subjected to predominantly low stress was soft, (had a low modulus). These data supported the hypothesis that cartilage responds to the predominant mechanical stress and so adapts its mechanical properties. These data provide necessary (but not sufficient) evidence in support of our mechanical conditioning hypothesis of articular cartilage. Because the knee and ankle joints used in the previous studies were from different populations it was not possible to extrapolate from the data obtained so far whether it was viable to propose the hypothesis that properties of cartilage of joints in the lower limb were also related to the prevalent stresses acting in these joints i.e. those arising during locomotion. To test this hypothesis it was necessary to survey the properties of cartilage on the entire articular surfaces of groups of hip, knee and ankle joints where each set is from the ipsilateral side. In this presentation we report some of the findings of this investigation.

METHODS

Eleven sets of fresh human lower limb joints, obtained from the ipsilateral side from eleven cadaveric donors, were used in this study. The 'instantaneous' modulus was determined using a specially developed indentation apparatus (Shepherd and Seedhom, 1997) that allowed application of load on articular surfaces at a physiological rate, and so from the measured indentation and cartilage thickness at a particular site, the modulus was calculated for a specific geometry of contact. Measurements were made at some 50 sites in each hip, 70 sites in each knee and 35 in each ankle. The average modulus for the entire joint surface of each joint and the topographical variations in the modulus within each joint were examined for all eleven sets, and subjected to statistical analysis.

RESULTS AND DISCUSSION

Within each set of joints (hip, knee and ankle) the ankle *always* had a significantly greater mean compressive modulus than the hip and knee ($p < 0.001$ - $p < 0.05$). In seven sets of joints there was no significant difference between the mean compressive moduli of the knee and hip joints. In three sets of joints the compressive modulus of the knee was significantly greater than that of the hip ($p < 0.001$ - $p < 0.01$), while in only one set of joints was the compressive modulus of the hip significantly greater than that of the knee ($p < 0.01$). The topographical variations in the cartilage instantaneous compressive modulus over the surfaces of the lower limb joints were matched by differences in the prevalent stresses occurring in different areas of each joint. The results of the present study corroborate previous findings and show that the site specific stresses and corresponding values of the instantaneous cartilage compressive modulus over the surfaces of lower limb joints were correlated ($r = 0.82$ at $p < 0.01$), thus adding credence to the conditioning hypothesis of cartilage by prevalent stress.

STUDY OF LV FILLING: COMPARISON OF HYDRAULIC AND NUMERICAL MODELING

Stefaan De Mey, Jan Vierendeels and Pascal Verdonck
Institute of Biomedical Technology, Ghent University, Ghent, Belgium.

INTRODUCTION

The aim of this study is to compare the findings in a hydraulic LV filling model with numerical simulations in a 2D axis-symmetric LV filling model.

METHODS

The left heart model (De Mey et al, 2000) consists of an atrium (LA) connected to a truncated ellipsoidal left ventricle (LV). Hydraulic model experiments of LV filling were done for varying relaxation ($\tau = 45, 60$ and 90 ms), LA pressure (LAP = $3, 10$ and 30 mmHg) and compliance ($C = 0.45$ and 1.35 ml/mmHg). Flow propagation of LV filling (v_p) is calculated from measured color M-Mode (CMD) images. The hydraulic experiment results are fitted to a multiple linear regression model (General Linear Model, GLM) with v_p the dependent variable to test for significant variables. Hydraulic experiment results are compared to numerical simulations derived from a 2D axis-symmetric numerical LV filling model (Vierendeels et al, 2000).

RESULTS AND DISCUSSION

Figure 1 compares CMD images obtained in the hydraulic model experiment and the according numerical model simulations corresponding for varying settings. Overall, a good qualitative agreement is observed. The GLM modeling the hydraulic experiment results has a F-value of 82.9 (adjusted $r^2 = 0.82$, $p < 0.001$). A significant ($p < 0.001$) influence of τ , C and LAP is found. Overall, a moderate, but significant correlation is found ($r = 0.67$, $p < 0.01$) between numeric and hydraulic experiment results. Numerical model results are however consistently lower.

In the numerical model an ambiguous influence of compliance is noticed. Visual inspection of CMD images shows a curved isovelocity contour that can be approximated in a bilinear way. Close to the base, the front is steeper (higher v_p) than further into the LV (lower v_p). The slower v_p , obtained when using the isovelocity contour that goes deeper in the LV can be explained by a stagnation point of the traveling vortices, occurring in the stiff LV, but not in the compliant LV. As can be verified in figure 1 (A) and 1 (B), this stagnation point moves towards the apex with decreasing τ . Because the closer to the apex a stagnation point is situated, the less influence it has on calculated v_p values, this mechanism possibly explains the merging of v_p values for low τ values in the computer

model.

Figure 1: Calculated CMD images using the numerical model (top) and corresponding measured CMD images in the hydraulic model experiments (bottom) for varying time constant of relaxation (τ), LA pressure (LAP) and compliance (C).

SUMMARY

The interaction between v_p and LV diastolic variables is studied in a numerical model and compared to corresponding hydraulic model results. Overall a good agreement is found. v_p increases with increasing LA filling pressure and decreases with increasing τ . A decrease in compliance augments v_p in the region of the LV base but decreases v_p due to stagnation of the vortex at the mid-level of the LV.

A BIOMECHANICAL ANALYSIS OF TRIANGULATION OF ANTERIOR VERTEBRAL DOUBLE-SCREW FIXATION

Ching-Lung Tai¹, Shih-Hao Chen¹, Tsung-Jen Huang¹, Weng-Pin Chen² and Robert Wen-Wei Hsu¹

¹Department of Orthopaedic Surgery, Chang Gung Memorial Hospital, Kweishan, Taiwan, ortholab@adm.cgmh.org.tw

INTRODUCTION

Anterior spinal instrumentation of the thoracic and lumbar spine has gained in popularity since Dwyer et al developed the cable system in 1964. However, implant loosening, screw breakage and cut-throughs have been noted clinically when using Dwyer or Zielke's Ventrals Derotations Spondylodese (VDS) instrumentations. To avoid these complications, one may use an anterior vertebral screw to penetrate the second cortex, or even a double-screw instrumentation using two parallel and penetrated screws to provide a stronger fixation. Bi-cortical screw purchase of vertebral body in anterior spinal fixation is well recognized to achieve optimal stabilization of implants. However, the potential hazards of penetration of anterior vertebral cortex screws that might cause neurovascular or organs injuries.

METHODS

Single-screw with bi-cortical purchase and various modes of double-screw fixation in anterior vertebral bodies were done using Trifix vertebral screws (San Andrio, CA, USA, Fig. 1.A) to assess the biomechanical stability of each fixation mode. The pullout forces of two parallel or triangulated anterior double-screw fixation with uni-cortical or bi-cortical purchase, were compared with that of single-screw with bi-cortical purchase. Four porcine spines were used for biomechanical analysis and bone mineral density was measured on each individual specimen before test. Single-screw with bi-cortical purchase and double-screws with 4 different modes of fixation which includes group A: triangulated with one screw penetration; group B: triangulated with no screw penetration; group C: two parallel with two screws penetration; and group D: two parallel with no screw penetration, were sequentially allocated into T11-L6 (totally 31 vertebrae) vertebrae. The experimental set-up were shown in Fig. 1.B and Fig. 2

RESULTS AND DISCUSSION

The results (Figure 3) demonstrate that the magnitudes of pullout force for various double-screw fixation modes are significantly higher as compared to the mode of single-screw bi-cortical purchase ($p < 0.05$). However, in pullout tests of double-screw fixation, there is no statistically significance between group B and group C ($p = 0.144$).

SUMMARY

In anterior vertebral double-screw fixation, the triangulated with no screw penetration mode can achieve ideal stability as those of two parallel with two screws penetration mode that is commonly advocated clinically. Therefore, the risks of placing anterior vertebral screws with cortical penetration can be avoided.

BIODYNAMIC CHARACTERISTICS OF TOP SPRINTERS

Milan Coh, Bojan Jost, Milan Zvan
Faculty of Sport, University of Ljubljana, Slovenia, milan.coh@sp.uni-lj.si

INTRODUCTION

Sprinting velocity is the product of stride rate and stride length. Both parameters are interdependent and individually conditioned with the processes of central regulation of movement, morphologic and physiologic characteristics, motor abilities and energy factors. Sprint, as a motor stereotype of human locomotors, consists of repetitions of strides. The length of the stride depends mainly on body height or leg length and the force developed by the extensors of the hip, knee and ankle joints in the contact phase. On the other hand, stride rate depends on the functioning of the central nervous system on the cortical and sub-cortical level and is strongly genetically determined. The ratio between both parameters is individually defined and automated. Increasing stride rate results in shorter stride length and vice-versa. Maximal sprinting velocity is actually the result of an optimal relation between the stride length and stride rate of the athlete. The aim of our study was to find which morphologic and kinematic characteristics most differentiate sprinters in the competitive 100m sprint results. The flying 20m test was used to measure the kinematic parameters of maximal velocity and the low start 20m run for the kinematic characteristics of the starting acceleration.

METHODS

Twenty-four sprinters participated in the experiment. They were divided into two groups of twelve subjects according to their competitive 100m sprint time. In the first, better group (Group A), the average age was 23.9 ± 3.88 years, average 100m sprint time 10.52 ± 0.19 s, the best athlete's time 10.21s. In the second, worse group (Group B) the average age was 22.7 ± 4.05 years, average 100m result 11.09 ± 0.12 s, the best 100m time 10.92s. Measurements of the 100m sprint were performed on a track with a tartan surface. The two 20m tests were performed indoors on a tensiometric carpet (Ergo tester - Bosco) of length 20m and width 0.80m. Each subject performed four runs. Specially written software (Sprint) was used to obtain the following kinematic parameters: stride rate and frequency, contact times and flight times. The flying start and low start 20m times were measured with a system of infrared photocells. The morphologic characteristics of the sprinters were assessed with a battery of seventeen measures, obtained by the procedures proposed in the International Biologic Programme (IBP) and measured by a professionally trained medical team. The SPSS statistical package was used for data analysis.

RESULTS AND DISCUSSION

The results show that elite sprinters do not differ significantly in the morphological parameters in connection with their 100m time. Only the diameter of the knee measure is on the verge of statistical significance. The athletes are equal in body height, leg length, body mass, thigh and calf circumferences. The differences in skin-folds are somewhat more noticeable but not statistically significant. Sprinters in the better group have in general a little less subcutaneous fat in the stomach, thigh and forearm areas. This can be seen also from the proportion of fat, which is 0.4% larger in group B than in group A. The better sprinters group has 1.59% more muscular mass than the group with worse sprinting times. They differ significantly ($p < 0.01$) in the starting acceleration ability and in maximal velocity. The contact time of maximal velocity and starting acceleration is that factor which significantly ($p < 0.01$) differentiates between better and worse sprinters. The maximal stride rate parameter is on the verge of statistical significance ($p = 0.05$). Better sprinters have a 4 cm longer stride than worse ones, but this difference is not statistically significant, nor is the difference between the groups in stride length and rate in the starting acceleration. The results show that the most important generator of differences ($p < 0.01$) in sprinting quality among the kinematic parameters is contact time. Luhtanen and Komi (1980) divide the contact phase of the sprinting stride into two parts: braking phase and propulsion phase. The sum of both is total contact time, amounting for elite world-class sprinters to 80 – 85ms. (Mero, Komi & Gregor, 1992). The most important role in economical sprint running goes to the ratio between the braking phase and the propulsion phase, which should be 40:60. The shorter the braking phase, the lesser the reduction in horizontal velocity of the body centre of gravity – BCG. The average contact time of the better group of our sprinters is 89.7ms, the worse group 95.6ms.

FLOW DISTRIBUTION IN A RIGHT ANGLE BRANCH DURING OSCILLATORY FLOW

Gaku Tanaka, Eiji Sakai and Makoto Hishida
Department of Electronics and Mechanical Engineering
Chiba University, Chiba, Japan
tanaka@meneth.tm.chiba-u.ac.jp

INTRODUCTION

The presence of unidirectional flow in the avian lung is thought to be effected by aerodynamic valves (Scheid et al., 1972). Previous studies suggest that the aerodynamic valves may be largely attributable to the flow distribution in a airway branch in a steady inspiratory flow (Wang et al., 1988). In this study, the flow distribution in a right angle branch during oscillatory flow was studied to clarify the flow unsteady effects on the aerodynamic valves.

METHODS

Figure 1 shows the experimental apparatus. The working fluid is water and three straight acrylic tubes (primary, main, and side branch, i.d., 22mm; length, 1m) function as the right angle branch. A pulse generator installed at one end of the primary tube generates sinusoidal oscillatory flow. The main and side branches terminate in large reservoirs. Reservoirs connect by connecting duct (i.d. 110mm). The temporal variation of flow rate in each tube was measured by a laser-Doppler velocimeter, and pressure differences by a pressure transducer. Flow patterns at the bifurcation were visualized with a tracer method. The experimental conditions were characterized by the dimensionless tidal volume V_T/a^3 and the frequency parameter $\alpha (= a(\omega/v)^{0.5})$, and were chosen to match the conditions corresponding to the high frequencies of avian panting.

RESULTS AND DISCUSSION

Based on the flow rate measurements in the main and side branches (Q_m , Q_s), we found the three different flow regimes (Fig. 2). When V_T/a^3 or α^2 is relatively small, Q_m and Q_s are the same at all times during an oscillation (zone 1). When V_T/a^3 and α^2 increase, asymmetrical flow distribution causes the net flow between the main and side branches (zone 2). Zone 3 is the transition regime between zone 1 and 2.

Figure 3 shows typical flow rate waveforms in zone 2 in (a) the main branch and (b) the side branch. Q_m and Q_s are normalized by the amplitude of the flow rate in the primary tube $Q_{p, \max}$ and time t is normalized by the oscillation period T . $t/T = 0-0.5$ corresponds to the inspiratory dividing flow and $t/T = 0.5-1.0$ corresponds to the expiratory merging flow. The temporal variation of Q_m and Q_s agree well with a sine curve, but the mean flow rate ($Q_{m, \text{mean}}$, $Q_{s, \text{mean}}$) deviate from zero. Since the flow rate waveform in the primary tube is a purely oscillatory flow, this mean component indicates the net flow from the side branch to the main branch.

The occurrence of the net flow is related to the direction-dependent flow separation at the bifurcation. The magnitude of the net flow was correlated with the mean pressure difference between the main and the side branches. The results also show that the net flow is further enhanced by the constriction installed at the entrance to the bifurcation.

SUMMARY

Oscillatory flow in a right angle branch causes a steady net flow from the side branch to the main branch. The net flow magnitude increases with the increase of the amplitude of flow rate in the primary tube.

CERVICAL RANGE OF MOTION IN ASYMPTOMATIC SUBJECTS FOLLOWING SPINAL MANIPULATIVE THERAPY: A DOUBLE BLINDED RANDOMISED CLINICAL TRIAL.

René Fejer, Kari Skovmand Petersen, Frederik Gothen Rolschau, Jacob West and Niels Grunnet-Nilsson
Institute of Sports Science and Clinical Biomechanics, University of Southern Denmark, Odense, Denmark, RFejer@Health.sdu.dk

INTRODUCTION

Patients often express increased flexibility following spinal manipulative therapy (SMT) of the cervical spine. Most studies seem to show that SMT increases range of motion (ROM) of the cervical spine (Cassidy 1992, Nansel 1989, Nilsson 1996), and recently a study has demonstrated a significant increase in ROM following SMT on patients with cervicogenic headache (Whittingham 2001). The question remains, though, whether SMT improves cervical ROM in asymptomatic subjects with lower normal ROM.

METHODS

Twenty-three females (age ranging 20-29 years) with lower normal active cervical ROM - but otherwise asymptomatic - volunteered for this study. After one-week baseline the subjects were randomised into two groups. One group received a placebo treatment (using an Activator locked to 'zero amplitude'), and the other group received cervical SMT (toggle recoil for upper cervicals and diversified for lower cervicals). Both groups were treated 6 times over a 3-week period. Each group then had a one-week follow-up period. Recordings on active cervical ROM were made once a week using the CROM device giving a total of 6 recordings for the treated group and 7 recordings for the placebo group (see below). All recordings were calculated as mean-of-three in rotation and lateral flexion. Flexion-extension was not recorded.

All subjects had prior to the randomization been told that the study was a comparison of two different treatment techniques; hence no subject was aware that a placebo treatment was used. Due to ethical considerations the placebo group was offered the same treatment as the other group and additional recordings were made.

RESULTS AND DISCUSSION

The mean active ROM for rotation and lateral flexion are shown in figures 1 and 2. There are no statistical significances in any of the recordings except for the placebo group receiving the additional treatments. This was only true for rotation ($P=0.009$) but not for lateral flexion. However, at that point of time the subjects knew they received true SMT. Therefore, bias cannot be ruled out.

CONCLUSION

Spinal manipulative therapy does not significantly alter the active cervical range of motion on asymptomatic females.

TIME-LAPSE OF CELLULAR STIFFNESS MEASURED WITH SCANNING PROBE MICROSCOPY DEPENDING ON CELL MIGRATION

Masafumi Nagayama*, Hisashi Haga and Kazushige Kawabata
Division of Physics, Graduate School of Science, Hokkaido University, Sapporo, Japan
*masafumi@skws.sci.hokudai.ac.jp

INTRODUCTION

Cell migration plays an important role in phenomena ranging from healing of wounded tissue to self-organizing of the early embryo. Many kinds of molecular components involved in cell migration have been identified. Recently, various studies of their functions are investigated at a rapid rate. However, it is not still clear how these components work harmoniously as an integrated system. Then, we have focused on the relation between mechanical properties of migrating cells and rearrangement of biomolecular components such as actin filaments and focal adhesions. In this study, to clarify the cooperative mechanism for cell migration, we measured the time dependence of the local stiffness distribution of living fibroblasts with Scanning Probe Microscopy (SPM).

METHODS

The SPM measures topography by scanning a cantilever, which has a tip at its end, over the surface of a sample. This has been used to image a wide variety of biological samples in liquid environment. Furthermore, the SPM has been also applied to measuring such mechanical properties as stiffness since the tip is directly in contact with the sample.

Stiffness imaging was carried out using force modulation mode. This mode has higher temporal and spatial resolution than any other method. In this mode, we can obtain a 128×64 pixels image only for 6 minutes. So, this is quite effective to examine relation between temporal change of stiffness and cell migration. The viscoelasticity of the sample was estimated from a sample strain against an external periodic stress by the method based on the linear viscoelastic theory. The experiments were performed under the physiological condition (34°C HEPES-buffer).

RESULTS AND DISCUSSION

Sequential images of the local stiffness distribution in living fibroblasts (NIH3T3) were captured every 10 minutes using force modulation mode (Fig. 1). The measurements were carried out over 60 minutes, which corresponds to the average time period of the intermittent cell migration. We found the following relations: Once the cells started to move, the stiffness in the nuclear portion was drastically reduced. On the other hand, while the cells were staying at one position, the stiffness distribution was quite stable. Previous immunofluorescence observations with chemical doping

strongly suggest that the local elasticity is mainly attributed to actin filaments rather than microtubules. We propose a model that change of tensional force acting along the stress fibers induces the cell migration. To verify this assumption, we examine temporal variations of the local stiffness when actin-myosin interaction is controlled with antagonist or growth factor.

Figure 1: Topography and stiffness image measured with SPM simultaneously. Sequential pair of identical cell is shown.

SUMMARY

We measured the sequential images of the topography and the local stiffness distribution of living fibroblasts by SPM. We discovered a clear correlation between the change of the local stiffness distribution and the intermittent cell migration. To explain this correlation, we propose that the tensional force acting along the stress fibers would change with the cell migration.

THE INFLUENCE OF BODY MASS ON THE FLIGHT PATH IN SKI JUMPING

Bernhard Schmölzer and Wolfram Müller

Institute of Medical Physics and Biophysics, Karl-Franzens University Graz, Austria

Communicating author, b.schmoelzer@aon.at

INTRODUCTION

A recent anthropometrical study has shown that all ski jumpers are very light. 15 of 92 investigated athletes were in thinness class I according to the WHO classification, the lowest body mass index (BMI) was 16.6 kg m^{-2} , the BMI mean value was 19.6 kg m^{-2} (Müller, 2002). However, within this group of low weight athletes no correlation between body weight and World Cup ranking has been found indicating that some of the athletes go beyond the limits of reason.

The earliest analytical model of ski jumping was made by Straumann (Straumann, 1927). Here, a computer model that is based on the equations of motion and that considers the positional changes of a ski jumper during the flight phase is used for the analysis of the effects associated with low body weight. The effects have to be seen in the context of other factors that affect jump distance (Müller et al., 1995; Müller et al., 1996; Schmölzer, Müller, 2002).

METHODS

The computer model is based on the equations of motion and uses tabulated functions for the lift $L=L(t)$ and drag $D=D(t)$ areas corresponding to the athletes positions during the flight. A reference jump based on sets of wind tunnel measurements with 1:1 models of ski jumpers in current equipment (2001/2002) formed the basis for the computer simulation studies discussed here. For all simulations the new profile of the jumping hill in Innsbruck ($K = 120\text{m}$) has been used. The modelling approach and the wind tunnel measurements have been described in detail recently (Schmölzer, Müller, 2002).

RESULTS AND DISCUSSION

Figure 1a shows the decrease of jump length with increasing weight of the athlete with his equipment. The jump length l was 120 m when the mass was set to 65 kg, the approach velocity to $v_0 = 26.0 \text{ m s}^{-1}$, and the take off velocity perpendicular to the ramp v_{p0} to 2.5 m s^{-1} (Virmavirta, 2001). The mass m profoundly influences the jump length l and the velocity of motion along the flight path. The jump length l was only 106.1 m with $m = 80 \text{ kg}$ and increased to 133.2 m with $m = 50 \text{ kg}$. One kg less mass increased the jump length by 0.9m (linear approximation). Additionally, with a lower body mass the landing is eased due to a pronounced reduction of the landing speed. Filled circles in Figure 1b indicate pairs of m and v_0 values required to obtain a given jump length of 120 m. The advantage associated with 1 kg less mass can be compensated by a 0.05 m/s increase in the approach velocity. Possible changes to the regulations that would make it less attractive to be extremely underweight are being discussed.

Figure 1: a) Influence of body mass m on the jump length l .
b) Pairs of values m and v_0 that result in an unaltered jump length of 120m.

Beside a higher v_0 value also an increased v_{p0} would compensate higher weight. Aerodynamically advantageous equipment components for heavier athletes (e.g. larger skis) could provide a tool to solve the underweight problem in ski jumping.

AUGMENTED LONGITUDINAL DIFFUSION IN OSCILLATORY FLOW ALONG A LATERAL GROOVED TUBE IMITATED OF TRACHEA WITH UNEVEN INNER SURFACE BY CARTILAGE

Akihiro Shimizu¹, Kosuke Miyahara², Masashi Shimizu² and Saburo Ryumae²

INTRODUCTION

Respiration is attained despite small tidal volume breathing and large dead space in the trachea. Uneven inner surface configuration by cartilage of trachea may influence on the effective diffusivity. Ye had reported augmentation of diffusion by oscillatory flow of water in a lateral grooved tube. Measurements of CO₂ concentration in the oscillatory flow in tubes with several groove widths have been carried out.

METHODS

Inner diameter of the test tube was 18mm, and inner surface configuration was composed by combination of aluminum rings with rectangular cross section as shown in figure 1. Depth of the groove of each configuration was 2mm and Bottom width and top width of it are described in table 1. Total length of the test tube was 3025mm, consisting of the part from the entrance to injecting point of 1260mm and from there to sensing point of 500mm, and further 1265mm to the open end. Oscillatory flow was generated by piston($\phi 50$) connected with a reciprocating block double slider-crank mechanism driven by AC servomotor. CO₂ gas was injected simultaneously with the lower dead point of the piston. Non-dispersive infrared analyzer measured CO₂ concentration.

Figure 1: Inner surface configuration along the grooved tube.

RESULTS AND DISCUSSION

Values of $(D_{eff}/D_{mol}-1)/(V^2/a^6)$, where D_{eff} is effective diffusivity, D_{mol} is molecular diffusivity, V is stroke volume and a is the inner radius of the tube, are shown in figure 2. The difference between the effective diffusivity obtained and the theoretical one in the oscillatory flow in a straight tube is

increasing with the increase of Womersly number. As for the bottom width of the groove, wide width of groove gives relatively large augmentation on the effective diffusivity.

Figure 2: Evaluation index derived from non-dimensional effective diffusivity and non-dimensional stroke volume. Solid curve indicates the theoretical value for laminar flow in a straight tube.

SUMMARY

The effective diffusivity of CO₂ in oscillatory flow along tubes with the lateral grooves has been measured. The difference between the effective diffusivity through the lateral grooved tube and one through the smooth straight tube is increasing with the increase of Womersly number. The effective diffusivity is more augmented by each inner surface configuration with the increase of the width of the groove within the region of the present experimental condition.

COMPUTATIONAL FLUID DYNAMICS IN HEMODIALYSERS

Sunny Eloit, Dirk De Wachter, Ilse Van Tricht and Pascal Verdonck
Hydraulics Laboratory, Institute of Biomedical Technology, Ghent University, Belgium
Sunny.Eloit@rug.ac.be <http://navier.rug.ac.be/>

INTRODUCTION

Hemodialysis is a renal replacement therapy during which blood of a patient is circulated through an extracorporeal hollow fiber or packed membrane sheets module. Blood and dialysis fluid are circulated countercurrently on opposite sides of a porous membrane which permits the passage of waste metabolites and water but restricts the transfer of blood proteins and blood cells from the blood towards the dialysis fluid. In a hollow fiber dialyser, blood flows inside the capillaries while dialysis fluid flows around them.

AIM OF THE STUDY

While other studies [Nordon,1997] only provide information about macroscopic flow patterns in dialysers, product optimisation should be based looking more in detail at transport processes and fluid properties inside the dialyser. Therefore, this study aims to investigate the effect of flow, blood viscosity and dialyser dimensions on flow in a hollow fiber dialyser using computational fluid dynamics.

METHODS

A three-dimensional finite volume model of the blood-dialysate interface over the complete length of the dialyser is developed (Fluent 5.4). Assuming the fibers spaced in a hexagonal lattice and based on symmetry, one twelfth part of a single fiber can be isolated (Figure 1), characterised by an

Figure 1 : Hexagonal lattice of the hollow fiber dialyser

axial to radial dimension ratio of 1000.

Different equations govern blood and dialysate flow (Navier-Stokes and continuity) and transmembrane water transport (Darcy). Blood is modelled as a non-Newtonian fluid with a viscosity varying in radial and axial direction because of the influence of the local cell concentration, the small diameter of the capillaries (Fahraeus-Lindqvist effect) and the local shear rate. Based on in vivo measurements, the dialysate flow is assumed to be an incompressible, isothermal laminar Newtonian flow with a constant viscosity. The permeability

characteristics of the membrane, produced of modified or regenerated cellulose or synthetic polymers, are obtained from laboratory tests for forward and backfiltration [Eloit,accepted]. The oncotic pressure, which is exerted by the plasma proteins and opposes the hydrostatic transmembrane pressure, is implemented as a function of cell concentration. Moreover, the reduction of the overall permeability caused by the adhesion of a protein layer on the membrane, is implemented as a series of resistances.

RESULTS

Assuming a constant blood and dialysate inlet flow of 250 and 500ml/min respectively, outlet pressures of 10kPa and 5Pa respectively, the pressure distribution renders an overall water filtration flow of 45ml/min as expected theoretically and in vivo, while no backfiltration occurs. As blood

Figure 2 : Radial viscosity distribution at inlet (x) and outlet (+).

flows through the dialyser, the water removal causes hemoconcentration and, as a consequence, the mean viscosity increases with 50%. Figure 2 demonstrates the radial viscosity variation caused by a plug flow of blood cells at the axis and a plasma layer near the membrane wall. The pressure distribution in the blood compartment deviates only slightly from linearity (0.3% at blood in and outlet) due to the water removal.

CONCLUSION

The presented model allows to investigate in detail the impact of hemodialyser dimensions and transmembrane flow on the blood flow and blood viscosity.

BIOMECHANICAL EFFECTS OF THE DESIGNS ON POSTERIOR RESIN-BONDED PROSTHESES

Chih-Han Chang¹, Ting-Sheng Lin¹ and Chun-Li Lin²

¹Institute of Biomedical Engineering, National Cheng Kung University, Tainan, TAIWAN

²Department and Graduate Institute of Mechanical Engineering, Chang Gung University, Tau-Yuan, TAIWAN

INTRODUCTION

Resin-bonded (RB) prosthesis has become an alternative to replace missing teeth in clinical dentistry in recent years. However, the retention rate of RB prostheses was still unsatisfied especially when it is applied to the posterior region. Many studies have focused on the improvement of adhesion and enhanced the bonding strength between metal and abutment teeth. The investigations of in the biomechanical aspect of RB prostheses, on the other hand, were insufficient due to the difficulties in experimental setup and clinical observation. Unlike conventional fixed partial dentures, the guidelines of posterior RB prostheses, such as retainer thickness, occlusal rest seats and retention grooves were still unclear and needed further investigation. Finite element (FE) analysis provides more complete information than traditional experimental approaches and its reliability has been validated by several researches. The objective of this study is to investigate the biomechanical effects of posterior RB bridges with different design parameters by 3D FE analysis.

METHODS

The replicas of the abutment teeth (a second premolar and second molar) and metal bridgework were fabricated based on the actual teeth. The structure was embedded in an epoxy block. Low speed saw was used to obtain the biopsy of this posterior RB prosthesis serially. An in-house image processing system was employed to track the contour of each slice and transferred into finite element packages (ANSYS 5.6). A mesh model of posterior RB prosthesis was constructed by isotropic 8-node brick elements. Five levels of retainer thickness, reduced gradually from 1.0mm to 0.2mm, were adopted. The designs with and without occlusal rest seats and retention grooves were also investigated. In order to study the effects of the direction of functional cusp in posterior mandible, the loadings were decomposed into vertical and horizontal (buccal direction) forces respectively. The abutment teeth were assumed with only one material (dentin) for simplification. The mechanical properties of metal (Ni-Cr alloy, $E=188000\text{MPa}$, $\nu=0.28$) and abutment teeth (dentin, $E=18600\text{MPa}$, $\nu=0.31$) were referred from other studies. All nodes below cemento-enamel junction were fixed in all directions as the boundary condition. Peak tensile stress at the interface between metal and abutment teeth was selected as the judgment index to predict the failure probability quantitatively.

RESULTS AND DISCUSSION

The effect of horizontal force has greater effect than vertical force. Peak tensile stress reduced exponentially as the retainer thickness increased. Occlusal rest seats help to decrease interface stresses slightly when vertical force was applied but this phenomenon did not observe for horizontal loading. The retention groove design has the ability to resist buccal displacement and deformation, but the interfacial tensile stresses tend to concentrate on the edge of distal grooves and raise the probability of interface debonding.

Figure 1: Finite element mesh mode of posterior RB prosthesis

Figure 2: Relation of retainer thickness and peak tensile stress in second molar under horizontal force

General questions, contact: Prof. Chih-Han Chang email: cchang@mail.bme.ncku.edu.tw

SUMMARY

Retainer thickness was the most effective support in the framework designs. The effects of occlusal rest seats and retention grooves were not significant in this study.

CALIBRATION OF AN ARTERIAL APPLANATION TONOMETER FOR IN-VIVO PRESSURE TRANSDUCTION

Andrew Zambanini¹, Ashraf W. Khir², Kim H. Parker², Simon A. McG Thom¹, Alun D. Hughes¹

¹ Clinical Pharmacology, National Heart & Lung Institute, St. Mary's Hospital, a.zambanini@ic.ac.uk

Imperial College, London, UK

INTRODUCTION

Non-invasive methods for determining the arterial pressure waveform at peripheral sites have become increasingly popular for use in wave intensity analysis, computational fluid dynamics modelling and pulse wave analysis. Although applanation tonometry has been shown to accurately represent the pressure wave morphology, current methods calibrate the amplitude of the waveform at sites other than the brachial artery using brachial diastolic and mean arterial pressures. We have developed an alternative approach using an in-vitro calibration of the tonometer.

METHODS

A pressure phantom was constructed using 1cm diameter latex tube placed within a similarly sized Dacron graft. An intravascular pressure catheter (8F SVPC-684A, Millar Instruments, Houston, USA) was introduced into the phantom and the system was filled with saline to achieve a static pressure of 50 mmHg. A high fidelity strain gauge tonometer (SPT 301, Millar Instruments, Houston, USA) was placed externally 1cm distal to the catheter and attached to a stand for hands-free measurements. Rapid active filling and passive drainage of the phantom using saline and a syringe achieved variations in pressure. Pressure data from tonometry and invasive catheter measurements were sampled simultaneously at 250Hz. A series of pressure waveforms were generated over three different applied applanation pressures and provided the data needed to develop a calibration algorithm.

Using the same tonometer, pressure waveforms were obtained from the right brachial artery in 30 resting human subjects [10 normals, 10 treated hypertensives and 10 untreated hypertensives, 27 men, mean (\pm SD) age 52 (\pm 14) years] with simultaneous measurement of the blood pressure in the left arm using a semi-automated sphygmomanometer [mean BP 143/85 mmHg (range 98-221/65-128)]. Following use of the calibration factor and correcting for mean arterial pressure, comparisons were made between pressures determined by tonometry and sphygmomanometry.

RESULTS

There was a linear relationship between the intraluminal catheter and tonometry pressure measurements in the phantom.

However, the slope of the linear regression line increased linearly with increased applanation pressure (figure 1).

Figure 1: The relationship between tonometric and catheter pressures in a phantom. The applanation pressures were 12.3 mmHg (Study 1), 119.9 mmHg (Study 2) and 167.8 mmHg (Study3) respectively and the tonometry pressures plotted were corrected for these.

The slopes and intercepts from these linear regression lines were used to develop the correction algorithm for tonometry pressures (P) taking into account applanation pressure (P_a) and measured tonometry pressure (P_t):

$$P = 0.04P_a P_t + 0.60P_t - 0.32P_a + 34.2$$

When applied to brachial tonometry waveforms in vivo, there was a significant correlation between the calibrated tonometry and sphygmomanometry pressures ($y = 0.93x + 6.90$, $r = 0.996$, $p < 0.0001$). The mean difference (\pm SD) in sphygmomanometry and tonometry pressures was 1.4 (± 9.9) mmHg.

DISCUSSION

By calibrating a tonometer in-vitro, we have developed a non-invasive method for determining the pressure waveform accurately in the peripheral arteries of man. This method can be applied to other sites such as the carotid artery where direct non-invasive measurement of systolic and diastolic pressure is not feasible.

A 2-D ANALYSIS OF TEMPOROMANDIBULAR JOINT LOADING GENERATED DURING BILATERAL BITING AT THE MOLARS AND PREMOLARS

INTRODUCTION

In order to clarify the control mechanism during static bilateral biting, we have been analyzing the controllability of TMJ loading achieved by coordinative activities of the masticatory muscles. In the present study, we estimated TMJ loading in actual biting by applying subject's data of bite force and EMG activity into a static 2-D jaws model, in an attempt to validate to what extent TMJ loading was optimized.

METHODS

A 2-D jaw model consisted of a rigid-body model of the jaws and a rigid-body spring model of TMJ (Itoh, K. and Hayashi, T., 2000). The jaw model incorporated the masticatory muscles such as the masseter (including the internal pterygoid), the temporalis and the lateral pterygoid. The bite force was assumed to be applied at a point of either the molars or premolars. The muscle force was estimated firstly from its cross-section area, normalized EMG data and the intrinsic muscle strength (Prium, G.J., et al, 1980). Then, the estimated muscle forces were corrected in order that the bite force estimated from the muscle forces agreed with the actual bite force measured by means of a pressure sensitive film (Dental Prescale 50HR), under the assumption that the intrinsic muscle-strength of the masseter and temporalis muscles can be corrected proportionally. Three male subjects with a set of bilateral acrylic splints mounted on the lower molars or premolars were asked to generate the maximal voluntary bite force. EMG activity of the superficial masseter muscle, the anterior and posterior portions of the temporalis muscle were recorded bilaterally by means of a bipolar surface electrode with a diameter of 12 mm and the inter-polar distance of 15 mm. Our previous papers reported that the magnitude of TMJ loading can be minimized under the same bite condition merely by adjusting the forces of the masseter and temporalis muscles (Itoh, K., et al, 1997). Then, such minimum TMJ loading was computed in each experiment.

RESULTS AND DISCUSSION

Figure 1 demonstrates a typical result of the estimated TMJ-loading (f_j) and the minimum TMJ loading ($f_{j,min}$), and corresponding load distribution in the disk under the two biting conditions. In the molar bite, TMJ-loading f_j was not necessarily minimized, while it was nearly minimized in the premolar bite. Such remarkable results were also observed in all other subjects. In the molar bite, the ratio of the TMJ loading versus the bite force was relatively small (0.47 on average), and the load was concentrated primarily in the intermediate zone of the disk. In the premolar bite, on the

contrary, the ratio was relatively large (0.90 on average), and the load was distributed throughout the disk. This suggested that TMJ loading is optimized to some extent even in actual biting in accordance with the bite condition.

SUMMARY

The present study assessed the optimization of TMJ loading in actual biting by applying subject's data of bite force and EMG activity into a static 2-D jaws model. Results were summarized as follows: 1) in the molar bite, TMJ loading was not necessarily minimized, and was focused primarily on the load-bearing portion of the disk; and 2) in the premolar bite, TMJ loading was nearly minimized, and was distributed throughout the disk.

INTRODUCTION

Since the pioneering work of C.R. Taylor and colleagues (1970) it has generally been acknowledged that humans are uneconomical runners compared to animal species of the same mass. More ambiguous, however, is how humans' energy cost of transport (J/kg/m) compares to similar size species during other shared locomotor tasks where the mechanical basis of movement is different from that of steady-speed level running. To address this issue we chose to compare the energy costs of transport of humans and a more economical bipedal runner of similar mass, the ostrich (Taylor et al, 1982), during level running, incline running and walking. These locomotor tasks were chosen because each depends on a different mechanism for generating the mechanical work of locomotion; during level running much of the mechanical work is supplied via the release of elastic strain energy stored in tendons; during incline running by the muscles themselves; and during walking by a 'pendulum-like' exchange between kinetic and gravitational potential energy of the body's center of mass (Dickinson et al, 2000).

METHODS

Four elite human runners (66.1 ± 5.1 kg; mean \pm S.D.) and four ostriches (66.1 ± 6.1 kg; mean \pm S.D.) were trained to run and walk on a motorized treadmill over a range of speeds both on the horizontal and on a 5% and 10% incline. The humans' and birds' rates of oxygen consumption were measured at rest and during treadmill locomotion using the same open-flow metabolic system.

RESULTS AND DISCUSSION

The rate of oxygen consumption during level running in humans, and hence energy cost of transport, exceeded that of ostriches by nearly 40% (Fig. 1a). However, during walking and incline running the difference in energy cost of transport disappears (Fig. 1 a,b). This finding supports the earlier view that human walking may not be exceptionally economical (Alexander, 1991). Our data also indicates that the additional vertical work of running up-hill may be relatively inexpensive in humans. Possible mechanisms for these observations are discussed.

Figure 1: The mass-specific rate of oxygen consumption ($\dot{V}O_2$; means \pm S.E.) in humans and ostriches as a function of (a) speed and (b) incline.

SUMMARY

Despite level running being more expensive for humans than for ostriches this difference disappears when running on steep inclines or during walking. This raises the intriguing question of whether the difference in the cost of transport among animal species of similar mass may be, in general, largest for level running and smallest for walking and incline running, an important consideration given that walking is the preferred mode of locomotion for many terrestrial animal species and that several live in a heterogeneous landscape.

INTRODUCTION

The purpose of this study was to develop a technique for monitoring the effect of spinal instrumentation on the range of motion occurring within the spine. The method was then applied to a pedicle screw system inserted into a lumbar spinal section to determine the behavior of various spinal constructs under loading.

METHODS

The technique was based on a method developed for the study of human gait (Holt et al, 2000), using infrared cameras to view the movement of marker clusters attached to the body segments to be studied. The Soderkvist and Wedin (1993) approach is used to define three interrelated coordinate sets defined within the marker cluster, body segment, and the laboratory measurement volume. The relative motion of one body segment to the other is defined through manipulation of these transformation matrices.

The technique was used to determine the effect of cross-linked pedicle screw systems on the behaviour of calf spine sections loaded in vitro. Five calf lumbar spine sections consisting of the L3-L5 vertebrae had a fracture simulated at the L4 level. They were then loaded with 2Nm moments to cause flexion/extension, left & right lateral bending and left & right axial rotation. Each section was tested with four implant arrangements: unimplanted, pedicle screws & rods only, pedicle screws & rods with one or two cross-links. At each load and implant arrangement the motion of L3 relative to L5 was calculated to determine the range of motion (ROM).

The ROM mean values and standard deviations were checked for significance using paired two tailed T tests (significance level $p=0.05$).

RESULTS AND DISCUSSION

The results showed that pedicle screws and rods, used on their own, have a significant effect on the rotation occurring within the section ($p=0.008$, $p=0.022$, $p=0.02$ for flexion/extension, lateral flexion and rotation respectively). When compared to using screws and rods alone, the only significant improvement found by the introduction of cross-links was a reduction in the amount of axial rotation. In this case the addition of one cross-link showed a significant improvement over just screws & rods ($p=0.017$). Two cross links showed a further significant

improvement over one ($p=0.04$). The results for axial rotation are shown in figure 1.

Figure 1: Axial range of motion with various combinations of implant

The technique originally used to analyze knee movement has been successfully applied to the study of the motion of the spine and has confirmed results found in a previous study (Dick et al 1997). The advantage of this approach is that it allows simultaneous determination of the motion of the spine in all six degrees of freedom. This allows an enhanced understanding of the coupled movement of the spine and will be of great benefit in determining the effect of spinal implant systems.

SUMMARY

A new technique has been developed which has advanced the understanding of the effect of instrumentation on the behaviour of the spine in vitro. It has shown that the use of cross-links in pedicle screw implant systems reduces the amount of axial rotation and that using two cross-links has a greater effect than one.

PULLOUT STRENGTH OF PEDICLE SCREWS IMPROVES WITH PALACOS OR CORTOSS AUGMENTATION

*Sam L Evans¹, Sashin Ahuja² and Chris M Hunt¹

¹Division of Materials and Minerals, School of Engineering, Cardiff University,

INTRODUCTION

Spinal instrumentation is used extensively in the treatment of the spine. Pedicle screw implants systems use screws driven into the pedicles to provide a mounting point for a structure that runs between two or more vertebrae. It has been found that in some conditions (such as at the ends of long span fixations, or in the presence of osteoporosis) the pedicle screws can lose purchase in the bone and pull out, leading to failure of the treatment.

This work aimed to test whether the pullout strength of pedicle screws could be improved by augmenting their fixation with either low viscosity bone cement or a bioactive bone-substitute.

METHODS

The experiments were carried out using Cortoss (a bone substitute produced by Orthovita) and Palacos LV (a low viscosity cement produced by Schering-Plough). Five-calf lumbar vertebra were used to test each of the materials. Each vertebra had a cement or bone-substitute augmented screw inserted into a randomly selected pedicle, and a non-augmented screw inserted into the other. In this way each augmented pedicle screw had its own paired, non-augmented screw mounted in the same vertebra. Bone cement was used to provide a flat surface for a loading plate attached to the posterior of each pedicle. The shafts of the screws were coated with PTFE tape to prevent the cement adhering to them and affecting the results. Once the vertebrae had been prepared the pedicle screws were pulled out using a tensile testing machine and the load at pullout recorded.

The tests produced paired results for augmented and non-augmented pedicle screws. After testing, means and standard deviations were calculated for the augmenting material and their non-augmented pairs. Paired, two-tailed T-tests with a significance level of $p=0.05$ were then used to compare the augmented results with the paired non-augmented results. Two-tailed unpaired T-tests were also used to compare the two types of augmenting material and also the two control groups.

RESULTS AND DISCUSSION

Both Palacos LV and Cortoss significantly increased the pullout strength ($p=0.0213$ and $p=0.0029$ respectively). Comparison of the Palacos and Cortoss results suggested no significant difference between them ($p=0.79$). There was no significant difference between the spines used ($p=0.41$).

Figure 1: Mean pullout strengths and standard deviations for the paired Cortoss and Palacos LV tests

The results suggest that augmentation with bone cement or bone-substitute can increase the pullout strength of pedicle screws. No significant difference was found between the two augmenting materials. In the long term the bone-substitute may stimulate bone growth, increasing bone density in the vicinity of the pedicle screw and increasing the pullout strength further. This test did show that even without the formation of new bone, the bone-substitute is as effective at increasing pullout strength as the low viscosity cement.

SUMMARY

- Augmentation with Cortoss or Palacos significantly increased pullout strength of pedicle screws.
- There was no significant difference between Cortoss and Palacos.

EXPERIMENTAL AND FINITE ELEMENT ANALYSIS OF THE EFFECT OF MUSCLE FORCES ON FIXATION OF CEMENTED HIP PROSTHESES AT HEEL STRIKE

B. Afsharpoya¹, T. Stewart¹, D. C. Barton¹, J. Fisher¹, B Purbach², M. Wroblewski²

2. Wrightington Hospital, Appley Bridge, Wigan UK.

INTRODUCTION

The bending, or strain, in a cemented hip prostheses is shielded by the increased stiffness of the implant and cement, and further restricted by actions of the muscle forces acting to stabilise the joint throughout the range of complex physiological motions. Due to anatomical complexity in-vitro studies of cemented hip fixation have either been simplified experimental models in the stance phase of gait with only limited use of muscle forces, or complex finite element models which lack validation [1,2,3]. Consequently a clinically relevant in-vitro model which reproduces the cement mantle fracture seen in-vivo is required. It is postulated that at heel strike where high bending moments exist, incorporating the actions of the Glutei and Vastus muscle groups will cause increased bending strains within the cement mantle and a more physiological model of fixation. The purpose of the study was to develop an experimental and finite element model of femoral stem fixation at heel strike and to determine the effects of muscle forces on the resulting strain produced.

MATERIALS AND METHODS

Depuy C-stem femoral stems were cemented into Sawbone composites femurs by an orthopaedic surgeon. Each femur was rotated into the heel strike position of the gait and fixed distally. Muscle force positions and vectors at heel strike [4,5] were applied by means of springs and pulleys with their forces measured by load cells as shown in Table 1. Eight uni-axial strain gauges were applied to the lateral, medial, anterior and posterior surfaces of the femur. Strain gauge and load cell outputs were monitored by a PC data acquisition system.

Table1. Joint and muscle forces

Force	F _x (N)	F _y (N)	F _z (N)
Joint	520	203	-1711
Gluteus maximus	498	-479	630
Gluteus medius	350	-0.53	398
Gluteus minimus	218	-55	325
Vastus medialis	-5	-22	-243
Vastus lateralis	14.7	-20	-294

IDEAS software was used to build a solid model of the Sawbone and hip prosthesis. Isotropic 20-node parabolic elements were used to mesh the solid model. The Young's moduli of stem, cement, epoxy and polyurethane foam were 210, 2.28, 11.5 and 0.41 GPa respectively.

RESULTS

Figure 1 shows predicted and measured surface strains for the implanted femur without muscle forces. Results show good agreement indicating that the FE model is valid. Predicted surface strains with and without muscle forces are shown in Figure 2. Tension was decreased anteriorly (b) and increased

laterally (h) while compression increased medially (c,d) and decreased posteriorly (e,f,g) by the addition of muscle forces.

Figure 1: Measured vs. predicted surface strains without muscle forces

Fig. 2: Predicted surface strains with/without muscle forces

DISCUSSION

The experimental and predicted strains within the femur at heel strike were in close agreement both with and without muscle forces. The addition of the glutei and vastus muscles reduced the strain anteriorly and posteriorly, while increasing the strain medially and laterally. The increased medial/lateral bending produced at heel strike increases the stresses at the implant/cement/bone fixation interfaces. With the addition of proximal debonding of the cement mantle, it is predicted that this loading will lead to high torsional stresses and reproduce the cement mantle failure as seen *in vivo*.

THE EFFECTS OF AGE AND FEEDBACK ON ISOMETRIC KNEE EXTENSOR FORCE CONTROL ABILITIES

Jeff M. Schiffman¹, Carl W. Luchies², Lorie G. Richards⁴, Carole J. Zebas³

⁴Department of Occupational Therapy Education, University of Kansas Medical Center, Kansas City, Kansas.

INTRODUCTION

Mixed results exist regarding the effects of age on force variability during a force control task (Enoka, 1999; Graves 2000, Hortobagyi, 2001). While past research used continuous feedback designs, most ADLs require the monitoring of internal feedback for submaximal forces. The purpose of this study was to investigate the effects of age, feedback, and force level on isometric knee extensor force control ability.

METHODS

Twenty young (YA, 25.8 ± 2.7 yrs) and 20 older (OA, 71.8 ± 2.0 yrs) adult healthy male participants maintained a steady force in knee extension (knee joint set at 60 degrees flexion) at two levels of force (20% and 60% MVC) with and without visual bandwidth feedback for 8 seconds. The upper and lower bandwidth limits were defined as ± 6.1 Nm. The on-screen feedback consisted of a green light with "Push more" and a red light with "Push less" above it which illuminated whenever force production fell below or rose above the bandwidth limits. Variables examined were force variability, bias, and time in bandwidth.

Strength was measured using the Cybex 6000 isokinetic dynamometer system (Lumex, Inc.) interfaced with a computer data acquisition system. The voltage output from the dynamometer was sampled at 200 Hz and filtered. A three-way MANOVA (age x force x feedback) was performed on the 3-trial average of the variables. p values less than 0.05 were considered significant. Significant findings were followed up with ANOVAS and pair wise testing.

RESULTS AND DISCUSSION

As force increased, variability increased for both groups, with YA having greater increases in variability (Table 1). Variability was significantly higher for the YA at the 60%, though the actual difference was small (1 Nm), suggesting that the two groups performed quite similarly which would be consistent with past research (Graves, 2000; Tracy, 2000). The main effect of feedback on variability was not significant. The variability from the feedback condition may be more similar to our no feedback condition in contrast to continuous feedback conditions of other studies.

Table 1. Age x force (%MVC) effects on Force Variability

	YA, 20%	OA, 20%	YA, 60%	OA, 60%
Mean	0.863	0.7255	3.1262	2.1003
SD \pm	0.357	0.4752	1.2814	1.1397

Increase in age, decrease in force level, and presence of feedback resulted in significantly less bias away from bandwidth midline. Bias was larger with an increase in force for the feedback condition and for the feedback removed condition (Figure 1). At 60% MVC, bias was significantly larger for the feedback removed condition. It has been suggested that OA have a larger safety margin because of age-related impairments in tactile and proprioceptive sensation. Therefore we expected, consistent with the results, that the OA would use more force in our task than the YA. The YA produced just enough force to be within the bandwidth, while the OA produced more force than required, even when feedback was removed. Both OA and YA spent more time within the bandwidth at 20% compared to 60% MVC and with feedback than without (figure 1). Time in bandwidth decreased as force increased with feedback and without. Time in bandwidth decreased in the feedback removed condition at 20% MVC and at 60% MVC.

Figure 1. Feedback x Force Interaction Effect Means and Standard deviations for Time in Bandwidth and Bias

SUMMARY

Both groups were fairly accurate at accomplishing the task, though the higher force was harder to control. The visual feedback improved performance in terms of time spent in bandwidth and safety margin but had little affect on force variability. Older adults performed with a higher safety margin and statistically less variability. Further study is needed to examine the effects of feedback paradigms (intermittent versus continuous feedback) on submaximal force control ability.

MODEL BLOOD CONSISTING OF DENSE SUSPENSION OF NATURAL POLYMERIC GEL PARTICLES

K. Ohba¹, T. Ando¹, I. Yoza¹, A. Onoue¹, T. Uragami² and T. Miyata²
Kansai University, Suita, Osaka, 564-8680 Japan, ohbak@ipcku.kansai-u.ac.jp
¹Dept. of Mechanical and Systems Engrg., ²Dept. of Applied Chemistry

INTRODUCTION

Simulating blood flow in experiments *in vitro* are very important to derive effective and precise results in the studies of the pathogenic mechanism of cardiovascular diseases, such as arteriosclerosis, and the development of artificial organs. However, it was difficult to make a similar flow pattern to the actual blood with a simple fluid, such as glycerol solution, because the actual blood is a non-Newtonian fluid, and obeys the Casson's diagram. These complicated flow properties are mainly caused by the motion of the red blood cells. Therefore, we have developed a tiny particle of natural polymeric gel as a model of human red blood cell (RBC), and have made a high concentration suspension of these particles in water and physiological salt solution as a realistic model of human blood [1].

MATERIALS AND METHODS

The model RBC (MRBC) was made of alginic acid calcium gel, and was of a spherical shape and very soft and elastic. Its average diameter was about 10 μm , which was very similar to human RBC, although its shape was not so-called biconcave. Shear rate $d\gamma/dt$ and shear stress τ of the human blood with 45% hematocrit (volumetric concentration) of the RBC at the temperature of 37°C and the model blood with 45% hematocrit of the MRBC at the temperature of 15°C were measured by using a cone-plate viscometer. The motion of each MRBC in the various range of shear rate was observed using a rheoscope system consisted of an inverted microscope, a cone-plate viscometer, and a high-speed video camera. The elasticity of the MRBC was also visualized and measured using a micromanipulator.

RESULTS AND DISCUSSION

Figure 1 shows the Casson's diagram, i.e. $\sqrt{d\gamma/dt}$ versus $\sqrt{\tau}$ obtained from the present model blood and the human blood. It can be seen from Fig. 1 that the present model blood obeys the Casson's diagram and agrees very well with that of real blood. All the curve of this model blood obey the Casson's diagram regardless of various concentrations and temperatures, although the yield stress and the gradient of the curves for the model blood shows a little dependence on concentration and temperature, which is considered to be partly due to the variation of the viscosity of water with temperature. The coefficients of viscosity calculated from the above curves in the case of four different concentrations and six different

temperatures show clear shear thinning, and agree very well with that of the human blood in the case shown in Fig. 1. Furthermore, in the region of low shear rate less than about 100/sec, visualization of the MRBC motion revealed formation of aggregates of the MRBC, which is a very similar phenomenon as real RBC forms a rouleaux when shear rate is lower than about 100/sec. The relationship between the deformation of the spherical MRBC and the force applied on it obeyed the Hertz's contact theory, and the total Young's modulus of the MRBC was 0.075MPa for $\nu = 0.5$ and 0.10MPa for $\nu = 0$, where ν is the Poisson's ratio.

Fig. 1 Casson's diagram of human blood and model

SUMMARY

The above experimental results show that the present model blood has almost same rheological characteristics as actual human blood, and that it can be used as a powerful substitute of actual human blood to make a precise experiments *in vitro*.

INTRODUCTION

Routine gait analysis is critically limited by skin motion artefact (SMA). The analysis of this artefact on patients with external fixators (Cappozzo et al., 1996) and on volunteers with percutaneous pins (Manal et al., 2002) is limited by the restrictions to skin sliding. Moreover, only a small number of markers has been analysed. The knowledge on the amount and direction of the SMA is therefore limited. It is necessary to better characterize this artefact in order to achieve higher accuracy in gait analysis data. In the present study the SMA was characterized non invasively collecting data from a patient with a total knee replacement by means of stereophotogrammetry and 3D fluoroscopy simultaneously.

METHODS

One patient operated of total knee replacement was analysed during stair climbing (SC) and sit-to-stand/stand-to-sit (STS) activities with fluoroscopy and stereophotogrammetry. Nineteen reflecting markers were uniformly attached laterally on the skin of the thigh, ten on the shank, and one reflecting/radiopaque on the patella for temporal synchronization. Moreover, three reflecting/radiopaque markers were placed in the fluoroscope field of view for spatial registration. The marker trajectories were reconstructed by means of a stereophotogrammetric system with 5 TV cameras (e-Motion, Padova, Italy). The accurate 3D pose of the prosthesis components was reconstructed from each 2D fluoroscopic projection with an iterative procedure using a CAD model based shape matching technique (Banks et al., 1996). The skin marker trajectories on the thigh and shank were reported in the corresponding prosthesis component reference frames. The displacements were calculated with respect to the initial frame.

RESULTS AND DISCUSSION

Markers on the thigh exhibited a much larger movement with respect to markers on the shank, particularly during STS (Figure 1 and 2). In particular, the markers located posteriorly on the thigh were more affected by SMA. In SC the displacement involved in the thigh and in the shank were comparable (Figure 2). The maximum amount of displacement of the markers located posteriorly on the thigh during STS was 40.0, 51.5, and 55.3mm along the antero/posterior, medio/lateral and vertical direction, respectively. In the shank, the maximum displacements were 31.4, 32.4 and 32.4 mm along the antero/posterior, medio/lateral and vertical direction, respectively. These displacements enable a rationale identification of the optimal location of markers depending on

the segment and on the motor task under analysis. This technique can be applied to a large number of subjects.

Figure 1: Skin markers trajectories in the femoral (left) and tibial (right) component reference frame during a trial of STS.

Figure 2: Root mean square value of the three components of the marker displacement vector, during the execution of SC and STS.

SUMMARY

Displacement as large as about 50mm was observed in markers attached on the thigh. The extension of this novel technique to a larger number of subjects will allow to identify the optimal location of markers in order to study with higher accuracy knee kinematics in gait analysis.

CHARACTERISATION OF A SUBSTITUTE MATERIAL TO MODEL CANCELLOUS BONE IN *IN VITRO* IMPLANT MIGRATION STUDIES

Vinu Palissery, Mark Taylor and Martin Browne

Bioengineering Sciences Research Group, School of Engineering Sciences, University of Southampton,
Highfield, Southampton, SO17 1BJ, UK. vinu@soton.ac.uk

INTRODUCTION

Progressive fatigue failure of supporting cancellous bone with inadequate bone remodelling has been suggested as a possible cause of implant migration [Taylor et al., 1997]. There is no preclinical migration test that has accounted this factor. An analogue material with uniform and consistent properties similar to cancellous bone would provide a simplified idealised model for a preliminary *in vitro* analytical and experimental migration studies simulating the worst-case scenario. Wide variation in the properties of cancellous bone will affect the reproducibility of experimental results. Substitute materials to cancellous bone used in *in vitro* studies are normally chosen based on a similar structure and static compressive behaviour to that of cancellous bone [Szivek et al., 1993], and no comparison of fatigue behaviour has been reported. In this study a rigid closed cell polymer foam (HEREX C[®]70.55) of density 60 kg/m³ was tested to assess its fatigue behaviour for use as a cancellous bone substitute in migration studies.

EXPERIMENTS AND METHODS

Reduced section cylindrical specimens of foam were tested under static and cyclic loads. Strength and modulus of the material, calculated from five specimens each in tension and compression, were consistent though the material was stronger in tension (strength = 1.45MPa, modulus = 48.9MPa) than in compression (strength = 0.64MPa, modulus = 39.9MPa). Fatigue tests in tension and compression, conducted under load control, were carried out at various stress levels at a frequency of 2Hz. Secant modulus and translation of hysteresis loop along the strain axis (creep) at various cycles were determined for each test. Secant modulus determined from a preconditioning test, prior to each fatigue test, was used to normalise the stress.

RESULTS AND DISCUSSION

Qualitatively, the static behaviour of HEREX C[®]70.55 was similar to cancellous bone. Strength and modulus, which fall in the lowest range of cancellous bone, were consistent with a standard deviation less than 10%. Under compressive cyclic loading with a non-zero mean stress cancellous bone shows accumulation of strain and modulus degradation with number of cycles [Bowman et al., 1998], where the number of cycles to failure and secondary state creep rate are related to normalised stress by means of power law relationships. There are no tensile fatigue tests reported for cancellous bone. Similar findings were observed for the analogue material. Figure 1 shows creep and modulus reduction of the foam against life fraction in compression fatigue. Numbers of cycles to failure and creep rate were related to normalised

stress by a power law relationship in both tension and compression (Figure 2). The degree of creep and modulus reduction was low compared to that of cancellous bone in compression fatigue. Generally there was more creep and modulus reduction in compression than in tension for the analogue material. This is probably because the material was stronger in tension than in compression, which is normally the reverse in the case of bone. This research does not intend to replicate the mechanical behaviour of cancellous bone quantitatively; however the methods may be used to propose a protocol that could be used for the selection of suitable analogue *in vitro* test medium for assessing implant performance under cyclic loading.

Figure 1: Creep and modulus degradation against life fraction in compression fatigue

Figure 2: Power law relationship between number of cycles to failure (N_f) and creep rate with normalized stress (Logarithmic plot)

ROTATIONS OF THE HUMAN KNEE

Clementina D. Mladenova

Institute of Mechanics, Bulgarian Academy of Sciences
Acad. G. Bonchev Str., Block 4, Sofia 1113, Bulgaria
Email: clem@bgcict.acad.bg

INTRODUCTION

It is necessary to display the kinematic data of the knee in a suitable parameter space, so that the diagnostic test reacts with sensitivity to the respective damage (cf Gillner 1999 and Mannel 1999). In this connection a mathematical description of the knee rotations is presented through an efficient parameterization of the rotation group already used by the author in multibody systems for modeling and control, i.e. using vectors of rotations 'c' which are elements of a Lie group and have clear and simple composition law.

KNEE GEOMETRY

The knee is the intermediate joint of the lower limb. It is mainly a joint with one degree of freedom which allows the end of the limb to be moved towards or away from its root. The knee has an accessory, i.e. second degree of freedom: rotation of the long axis of the leg, which only occurs when the knee is flexed. The first degree of freedom is related to the transverse axis XX' around which occur movements of flexion and extension in a sagittal plane. This axis XX' , lying in a frontal plane, runs through the femoral condyles horizontally. The second degree of freedom of the joint is related to rotation around the long axis YY' of the leg with the knee flexed. The axis ZZ' (broken line) is running anteroposteriorly and at right angles to the other two axes. This axis does not represent a third degree of freedom but, owing to a measure of 'play' at the joint, side-to-side movements occur. In full extension these movements disappear and if they still persist they must be considered, as a rule, as abnormal.

KNEE ROTATIONS

The present paper breaks the standard frames of considering multibody systems motion and presents a unified treatment of robot dynamics using the ideas from Lie groups and differential geometry (see Mladenova 1990, Mladenova 1991). Since the properties of the parameterization of the rotation group in three dimensional space $SO(3)$ more or less influence over the efficiency of the dynamic model, we use vector - parameters c , which make a Lie group with a clear geometrical sense and a simple composition law, they are linear and

symmetrical with respect to all components, and play role of new generalized coordinates, different from the standard joint displacements.

We introduce :

rotation angle - α (around X axis), β (around Y axis), (around Z axis) and the vectors c_1, c_2, c_3 which are the vector-parameters describing the rotations around X, Y, Z axes respectively.

The basic rotations are:

- Flexion (rotation around Z axis)

$$c_1 = (0, 0, \tan(\gamma/2));$$

- Rotation (rotation around Y axis)

$$c_2 = (0, \tan(\beta/2), 0);$$

- Adduction (rotation around X axis)

$$c_3 = (\tan(\alpha/2), 0, 0);$$

- Rotation + Flexion = $\langle c_2, c_1 \rangle$ - this means the composition law of the group

- Flexion + Rotation = $\langle c_1, c_2 \rangle$ - this means the composition law of the group, where the composition (group) law of the vector-parameters is:

$$c' = \langle c_1, c_2 \rangle = (c_1 + c_2 + c_1 \times c_2) / (1 - c_1 \cdot c_2)$$

$$c'' = \langle c_2, c_1 \rangle = (c_2 + c_1 + c_2 \times c_1) / (1 - c_2 \cdot c_1).$$

SUMMARY

The present approach allows efficient presentations of the basic kinematic and dynamic relations so that the last to be successfully applied in the virtual dynamic simulations, for the control and mechanics of human movement systems, for biomechanical investigations and motor control of human gait.

3D FINITE ELEMENT ANALYSIS OF AN INTRAVASCULAR STENTING PROCEDURE USING AN NIROYAL STENT

Caitriona Lally¹, Patrick J. Prendergast¹ and Finbar Dolan²

¹Department of Mechanical Engineering, Trinity College, Dublin 2, Ireland, calally@tcd.ie

²Medtronic AVE, Parkmore Industrial Estate, Galway, Ireland

INTRODUCTION

Coronary heart disease may be treated by the deployment of a stent within the stenosed artery, however, in-stent restenosis occurs in 20-50% of stented vessels (Grewe *et al.*, 2000). Tissue prolapse and high stresses within a stented vessel have been hypothesised to increase the probability of in-stent restenosis. This study aims to quantify the stresses induced within an idealised cylindrical vessel, by deploying an NIROYAL stent within the vessel using the Finite Element Method (FEM). We wish to establish if stresses in the vessel wall and tissue prolapse within the stent repeating units could play a role in the initiation of the restenotic process.

The ultimate objectives of this study are to generate a computational model of restenosis using the stress distribution within the vessel wall as a stimulus and subsequently determine the probability of restenosis within various stent designs.

METHODS

The geometry of one repeating unit of a fully expanded 2.5 mm diameter NIROYAL stent was determined using a coordinate measurement technique (Prendergast *et al.*, 2002). A full 3D segment of the stent, with a radial thickness of 0.1 mm and an inner diameter of 2.5 mm, was generated based on the geometry of the repeating unit.

To describe the stress-stretch behaviour of the artery wall a reduced 9-parameter Mooney-Rivlin hyperelastic constitutive equation was used. Experimental stress-stretch data, obtained from uniaxial and equibiaxial tensile tests conducted on human femoral arterial tissue, was used to determine the specific hyperelastic constants in the constitutive equation (Prendergast *et al.*, 2002). The coronary artery was modelled with a thickness of 0.5 mm and a diameter of 2 mm.

The analysis was carried out in two load steps. Initially the stent elements were deactivated and the vessel was expanded beyond the stent by applying a luminal pressure of 70 kPa. The stent elements were then activated in the second load step and the luminal pressure removed. Due to the nature of the vessel material, which was modelled as a hyperelastic material and is therefore completely elastic, the vessel attempted to return back to its original configuration upon removal of the pressure. However, contact surfaces defined on the outer surface of the stent and on the inner lumen of the vessel ensured that the vessel was scaffolded open by the stent.

The stent was assumed to be rigid and therefore completely restrained during the analysis, whilst restraining the proximal

and distal faces of the vessel simulated longitudinal tethering of the vessel.

RESULTS AND DISCUSSION

Tissue prolapse (i.e. narrowing of the lumen as a result of elastic deformation of the vessel wall) was observed between the struts of the stent to a maximum of 0.1 mm within each stent unit, see Fig. 1 (a).

Von Mises stress magnitudes of up to 460 kPa were observed to be induced in the arterial vessel where the stent struts contacted the lumen of the vessel, see Fig. 1 (b).

Figure 1 (a) Deformation of a cylindrical vessel after deployment of an NIROYAL stent, (b) Von Mises stress distribution within the vessel wall for one repeating stent unit

CONCLUSION

From this study it is clear that the stress distribution, as well as the degree of tissue prolapse, within stented vessels may be determined using FEM. Tissue prolapse observed within the stented vessel contributes to lumen loss and also induces high stresses within the vessel which may act as a stimulus for in-stent restenosis. An analysis to determine the effect that elastic recoil of the stent has on the stress distribution within the vessel, where the stent is allowed to deform elastically, will be carried out in a future study.

TRAJECTORY ANALYSIS OF CATCHING MOTION BY A HAND USING THREE-DIMENSIONAL POSITION SENSOR

Nobuo Sakai, Teruo Murakami and Yoshinori Sawae

Department of Intelligent Machinery and Systems, Kyushu University, Fukuoka, Japan.

Bionic Design Laboratory, sakai@mech.kyushu-u.ac.jp

INTRODUCTION

The application of robots to the human-care system for elder or disabled people is required, but the direct application of existing industrial robot has difficult problem. Namely human-care robots or machines encounter a minor collision with human body directly. Machines coexisting in human livings must be designed with a lot of consideration about soft and smooth touch to human body. In robotics research field, the structure of human body and human motion has served as an inspiration to propose a design that could be used to build more useful system. A situation that a human touches directly to another person in a hand may be found in a daily life. In such situation, a condition of human mind largely affects the feeling impression of another person. In this study we set up the following scenario to investigate the catching motion within humans: The subjects were asked to support a human body falling backward by placing their hand on the falling person's back either gently or without limits. The purpose of this study is to speculate how to generate and to control a trajectory for robots or machines touching to human directly.

METHODS

When we measure a human voluntary motion, the first question we have to consider is how subjects have consciousness or peculiar effort. We evaluated the dependence of the trajectory and contact force on the subject's consciousness in a catching motion for a falling person. Subjects were sufficiently instructed to have the mind in which subjects catch a falling human softly. To discuss the difference for subject's mind, another situation was arranged so that the subject push back to escape a falling person.

A trajectory of subject's hand was measured by three-dimensional position sensor using an electromagnetic signal. Position sensor was attached on metacarpal bone. A tactile sensor was attached on a back of falling person to estimate contact force. Experimental process is as follows;

(1) Subject stands in a person's back within an area of reaching by subject's hand; (2) Subject puts one's hand to tactile sensor attached on person's back to give a cue for falling backward; (3) Person falls backward with fixing knee and hip joints straight; (4) Subject reaches out a hand to the back of falling person to support him or her in a medium position; (5) Subject pushes the falling person to the starting state; (6) Subject settles a hand in the starting position. Measured position data were translated to a coordinate system having X-axis along a linear motion line and a coordinate origin at starting position of a hand. The data were recorded at 120 Hz and filtered using Savitzky-Golay method to estimate the velocity directly.

RESULTS AND DISCUSSION

An example of measured trajectory and contact force with the mind for softly touching is shown in Fig.1. Each number in figure corresponds to each action stated above. At a time of action near (4), velocity transition was different from that in

Figure 1: Trajectory and touching load for supporting a human with the mind for softly touching.

Figure 2: Trajectory and touching load for supporting a human without the mind for softly touching.

Fig.2, in which

the data were measured by a subject without the mind for softly touching. In the situation that subject supported a falling human softly in mind, velocity profile was smooth transition at early touching time. As to the touching force profile, estimated maximum force in Fig.1 was the same as in Fig.2. But it is clear that integration of time dependent force transition was evaluated to be larger in soft touching. This result implies that the comfortable contact action required more energy than simple escaping motion evaluated in this experiments.

SUMMARY

The experimental result indicated that in the supporting motion for a falling person the direct contact action considering a feeling of satisfaction required not only energy evaluation but also special time-depending force transition profile or trajectory profile.

EFFECT OF LOADING RATE ON THE DURAL-SAC OCCLUSION

Young Eun Kim¹ and Jae Yong Ahn²

¹Dept. of Mechanical Engineering, Dankook University, Seoul, Korea, yekim@dankook.ac.kr

²Samsung Cheil Hospital, Dept. of Orthopedic Surgery, Sungkyunkyun University, Seoul, Korea

INTRODUCTION

Spinal stenosis has been defined as a narrowing below the lowest limit of the ranges for normal vertebral canal size. For static loading condition, disc and ligamentum flavum were the main causes for generating stenosis. Among the various types of loading conditions, impact loading, which induces spinal fractures, leases energy rapidly over a short time period. In this case, fractured vertebral bony segment pose a great treat to the spinal cord. In this study therefore improved the previously developed finite element model (Kim et al. 2001) of the spinal motion segment to reflect the response of the dural-sac occlusion by the bony fragment under varying impact durations

METHODS

A finite element model of L3/L4 lumbar spinal motion segment which consist of all ligament, dural-sac and bone fragment was developed. The ligamentum flavum was modeled by four-node shell element in order to be able to analyze the slackening. By performing the modal analysis of the ligamentum flavum, the third mode, which is closed to the slackened shape, was chosen and small amount of initial displacements were assigned to create desired deformed shape. Occlusion of dural-sac was modeled by utilizing the surface contact scheme. The contact between two surfaces assigned slave and master elements was restricted not to penetrate the master side. Figure 1 shows the developed FE model including bony fragment. To simulate the damping phenomena in the motion segment, structural damping was assigned to the disc element. The impact load applied to the top of the L3 vertebral body was assumed to be a triangular impulsive force with variable impact duration. A maximum compressive force of

Figure 1: Developed 3-D FE motion segment model including dural-sac and bony fragment
6kN was chosen for this study to simulate the actual situation of initial fracture in the human spine.

RESULTS AND DISCUSSION

High loading rate(short impact duration) produced relatively large dural-sac occlusion compare to low loading rate(large impact duration) as shown in figure 2. In this case, impinged bony fragment resulted dural-sac occlusion. In comparison, at the low loading rate, very small dural-sac occlusion was calculated and main causes of occlusion were disc bulging and slackened ligamentum flavum similar to the static loading case. Experimental study with post injury radiography (Tran et al. 1995) showed bigger spinal canal encroachment at high loading rate than at low loading rate. This encroachment difference was due to the total volume of the generated burst fracture. Contrast to previous experimental study, we used only one fragment for this analysis, but similar results were calculated for different loading rates.

Figure 2: Cross sectional area variation of dural-sac for different impact duration

SUMMARY

Use of the finite element technique to address the role of impact loading rate in producing dural-sac occlusion is presented. Fractured bony fragment at the posterior wall of the cortical shell produced different amount of occlusion according to impact duration(loading rate) changes.

EFFECTS OF TENDON SHEATHS ON THE TENSILE PROPERTIES OF MOUSE TAIL TENDON

Noritaka Yamamoto and Eiji Ikawa

Biomechanics Laboratory, Department of Mechanical Engineering, Faculty of Science and Engineering,
Ritsumeikan University, Kusatsu, Shiga, Japan, noritaka@se.ritsumei.ac.jp

INTRODUCTION

Tendons and ligaments have such hierarchical structures as fascicles, fibers, and fibrils. They were enveloped by sheaths. The basic knowledge of their structure and mechanical properties is essential to the biomechanics of tendons and ligaments.

A rat tail tendon was composed of several fascicles enveloped by a sheath (peritenon, epitenon, or reticular membrane) (Kastelic et al., 1978; Rowe, 1985; Strocchi et al., 1985). In this study, we developed a new method by which tensile tests were performed observing the microstructure of a tendon and its fascicles with a light microscope, and studied the effects of tendon sheaths on the mechanical properties of mouse tail tendon.

METHODS

Male DD-y mice age 4 weeks weighing 18.5 ± 0.5 g (Mean \pm S.E.) were used. Tendons having the length of 35 mm were resected from mouse tails (Figure 1). They were divided into two portions in the direction of the length. The distal portions were stretched to failure. In the proximal portions, fascicles were resected from a sheath and stretched to failure.

For mechanical testing, a specially designed micro tensile tester was mounted on a microscope stage. Small acrylic blocks were attached to both ends of each specimen with cyanoacrylate adhesives. One of the blocks was fixed to a load cell, and the other one was fixed to the crosshead of a linear actuator. The specimen was immersed in a saline solution and stretched to failure by moving the actuator at the speed of 0.1 mm/sec. The microstructure of the specimen was observed using a differential interference microscope, and the images were recorded on a video recorder.

We confirmed that there were no significant differences in the mechanical properties of fascicles between the proximal and distal portions.

RESULTS AND DISCUSSION

In each specimen, the maximum load of a tendon (distal portion) was larger than the sum of that of its fascicles (proximal portion) (Figure 2). There were statistically significant differences between these mean values. The differences might be attributable to mechanical interaction between fibers as well as between fibers and ground substance induced by binding fascicles with the sheath.

In conclusion, tendon sheaths are a basic microstructural component to determine the tensile properties of mouse tail tendon.

Figure 1: Resection of a tendon and its fascicles from a mouse tail.

Figure 2: Maximum load of a tendon and its fascicles in each specimen (A ~ E).

ANTICIPATORY BEHAVIOUR DURING RECOVERY FROM UNEXPECTED PERTURBATIONS: YOUNGER VERSES OLDER ADULTS

Shirley Rietdyk and Kasey Wiley

Biomechanics Laboratory, Purdue University, West Lafayette, Indiana, USA (srietdyk@sls.purdue.edu)

INTRODUCTION

Research on young adults indicates that during unexpected perturbations, the response was based on an anticipation of the perturbation magnitude (Rietdyk et al., 1999). The purpose of this research was to examine the anticipatory component of the older adult's response to determine the effect of age-related delays and degenerations.

METHODS

To date, three healthy older adults (mean age: 69) have participated in the study. The subjects received unexpected trunk perturbations in different directions and at different sites. The centre of pressure (COP) was determined from the forceplate (AMTI), and the centre of mass (COM) was determined from a 10-segment model (14 IREDs, Optotrak, NDI). Anticipatory behaviour was measured as the phase relationship between the COM and COP (determined from the cross-correlation, Winter et al., 1998). Corrections to the COP were documented by the third time derivative of the COP (Hogan, 1984). Responses were compared to data for 10 younger subjects (mean age: 26; Rietdyk et al., 1999).

RESULTS AND DISCUSSION

For both young and older participants, the COP acts to corral and decelerate the COM (Fig. 1). The average phase lead of the COP for the older adult was almost twice as long (elderly: 198 ± 51 ms (mean correlation at 198 ms = 0.951); young: 109 ± 37 ms (mean correlation at 107 ms = 0.976)($p < 0.01$)). This increased phase lead can be interpreted two ways: (1) the system takes longer to respond in the elderly or (2) that the nervous system has anticipated the age-related delays and attempts to provide greater time for the response. The first possibility is addressed by comparing the COM acceleration and the difference between the COP and COM displacement (Winter et al., 1998); no differences were found between the young and elderly. Therefore, the nervous system appears to be compensating by providing more time.

The extended phase lead can be problematic if the COM displacement is predicted incorrectly: The subject must detect errors and make corrections in COP displacement (see A in Fig. 1). Multiple corrections are evidenced by the third time derivative (jerk) of the COP (Hogan, 1984): the elderly show peak jerk values which are 25 times greater than the young subjects (elderly: 848.2 m/s^3 ; young: 33.8 m/s^3)($p < 0.01$). If the error is not detected, balance is compromised, as demonstrated in Fig. 1 (bottom panel). At time 0.8 s, the COM is still moving towards the edge of the foot, but the COP turns around, and heads back to correct for any overshoot (B in Fig. 1). The nervous system anticipated that the peak COP

displacement was adequate to decelerate and turn around the COM in the immediate future. However, the COM does not decelerate and is heading for the edge of the base of support. It takes another 0.9 s to detect the mistake, decelerate and turn around the COP (C in Fig. 1) in an unsuccessful attempt to corral and decelerate the COM. The participant had to take a step in order to prevent a fall.

SUMMARY

During recovery from an unexpected perturbation the nervous system appears to compensate for age-related delays by anticipating the magnitude of the disruption, and providing a COP-COM phase lead almost two times longer than younger adults. This adaptation appears to put the older adult at increased risk of losing balance because they need to rely more extensively on feedback, and degenerations in the feedback system may compromise their ability to anticipate the excursion or to detect errors.

BONDING STRENGTH OF PLASMA SPRAYED HA COATING ON Ti6AL4V ALLOY SUBSTRATE: THE EFFECT OF RESIDUAL STRESS

Yung-Chin Yang¹ and Edward Chang

Department of Materials science and engineering, University of Cheng-Kung, Tainan, Taiwan

¹fatchin@cubic.mat.ncku.edu.tw

INTRODUCTION

For the durability of the system to succeed in application, the residual stress of plasma-sprayed HA coatings on a titanium substrate for orthopedic use might be very important, but was seldom considered. In this study, we investigated the influence of residual stress in HACs on the bonding strength of plasma-sprayed HA on titanium substrates.

EXPERIMENTAL

Seven HACs were plasma sprayed on Ti-6Al-4V substrates by varying the cooling effect and the coating thickness (Table 1). To evaluate the residual stress of the HACs, the " $\sin^2\psi$ " technique of XRD method [1] was used. The Young's modulus value $E = 16.2$ GPa [2] was instead of the value 110 GPa for residual stress calculation. The bonding strength of HAC/Ti was tested using a standard adhesion test (ASTM C-633).

RESULTS AND DISCUSSION

The thicker 200 μ m HAC exhibited higher residual stress than that of thinner 50 μ m HAC coating (Table 1). The Table 1 also showed the residual stresses of the HACs with the various substrate temperatures. The max. temperature of HA5 without cooling during the plasma spraying was above 500 °C and it revealed the highest residual stress (26 MPa, compressive). This was due to the higher thermal expansion mismatch between coating and substrate during cooling from an elevated temperature to room temperature. In contrast, the max. temperature of the substrates were lower when cooling media were used. For the HA1, the lowest residual stress (18.0 MPa) was obtained due to a lower thermal expansion mismatch.

Fig. 1 shows the variation in bonding strengths of the HACs with the corresponding residual stresses. The HA1 with the lowest residual stress exhibited a higher bonding strength than the others; the HA5 displayed the lowest bonding strength apparently due to its high residual stress. The observation that the specimen with higher residual stress exhibited lower bonding strength can be explained in term of the compressive residual stress in the HAC, which could cause the coating to delaminate from the substrate [3].

CONCLUSION

Compressive residual stress weakened the bonding at the interface of the HA and the Ti-substrate. Then, in turn, the weakened bonding at the interface of the HA and the Ti substrate resulted in a decrease in the bonding strength.

NUMERICAL AND EXPERIMENTAL MEASUREMENTS OF THE FLOW IN PULSATILE VENTRICLE ASSIST DEVICE

I. Avrahami¹, M. Rosenfeld¹, S. Einav¹, U. Zaretsky¹ and K. Affeld²

¹Departement of Biomedical Engineering, Tel Aviv University, Israel. idita@eng.tau.ac.il

²Humboldt University Berlin, Germany.

INTRODUCTION

Some of the most important factors that affect the longevity of the ventricle assist devices (VADs) are their hemodynamic properties. Interaction of blood with the moving components, stagnation regions or high shear stresses may promote thrombosis and hemolysis with detrimental effects on the operation of the VAD. The study of the flow field inside the VAD is, therefore, is of great importance both for optimising existing designs and for developing new ones. In the presented study, the Berlin Left Ventricle Assist Device (LVAD) [1], with the improved energy converter unit, has been investigated both numerically and experimentally.

METHODS

For the investigation of the flow field in the blood chamber of the Berlin LVAD, an experimental Continuous Digital Particle Imaging Velocimetry (CDPIV) was combined with a computational fluid dynamics (CFD) analysis in moving boundaries. These tools complemented each other to result into a comprehensive description of the complex 3D, viscous and time-dependent flow field inside the artificial ventricle.

For the numerical analysis, a commercial finite element package was used to solve the Navier-Stokes equations (FIDAP, Fluent Inc., Evanston).

For the experimental analysis, an optically clear elastic model of the LVAD was placed inside the CDPIV system. The CDPIV system is capable of sampling 15 velocity vector fields per second, based on image-pairs intervals lower than 0.5 millisecond.

RESULTS

Figure 1 shows typical vector plots as obtained from the numerical and experimental analyses.

Figure 1: Velocity vector plots at central cross-section at peak diastole as obtained from (a) the numerical analysis and (b) the experimental analysis.

The flow inside the blood chamber was characterized with high velocity jet through the mitral valve in the beginning of diastole, a rotation flow filling the chamber during diastole and a complete washout during systole. No permanent stagnation regions were found in the mid-section of the blood chamber. High shear stresses (in the order of 2000dyne/cm²) were found for a short duration (0.05 sec) at peak diastole near the walls and during peak systole (up to 1000dyne/cm²).

Continuous sequences of experimental images, followed by their calculated velocity and vorticity transient fields, are given as animated presentation of the distensible VAD. The experimental results of both groups (German and Israeli) were similar and were used for validating the CFD simulations. The results obtained from the experimental and numerical simulations were also in good agreement with previous works (Rosenfeld et al, 2002).

Once validated, the CFD results provided a detailed 3D and time dependent description of the flow field, allowing the identification of stagnation or high shear stress regions.

SUMMARY

CDPIV method had some limitations in analysing high velocities, wall shear stress and 3D flow field. However, After the validation of the numerical model, the detailed numerical simulation were very useful providing valuable information that was hard or even impossible to obtained experimentally such as shear stresses or 3-D flow.

The simulation of the membranes motion was essential for demonstrating the exact flow behaviour during systole. Modelling the S-shape valves in their fully open phase is recommended to extract the accurate circulation dynamic during diastole.

ANALYSIS OF WEAR PERFORMANCE IN TOTAL HIP REPLACEMENT

Richard M Hall

School of Mechanical Engineering, University of Leeds & Musculoskeletal Services
St James's University Hospital, Leeds, UK, r.m.hall@leeds.ac.uk

INTRODUCTION

One of the most crucial issues facing total hip arthroplasty is socket loosening and its relationship to wear. Whilst considerable research has focused on the acquisition of wear data from radiographs and retrieved samples, little attention has been paid to the most appropriate data analyses. Indeed, two articles (Lewis 2000, Pedersen et al 2000) have incorrectly indicated that a non-normal distribution of the wear data is a barrier to the use of appropriate parametric statistics, in particular, regression or associated methods. Using the bootstrap method this paper explores the errors that may arise in deviations from the regression assumptions for such analyses.

METHOD

Most calculations of the penetration rate are based on ordinary least squares (OLS) regression including studies that evaluate the mean. OLS regression is most efficient if four assumptions are found to be true (Hamilton 1992):

1. The independent variable has fixed values.
2. The errors have a mean equal to zero.
3. The errors have constant variance (homoscedastic).
4. The errors are not correlated with each other.

The standard errors (se) of the coefficients are unbiased if these assumptions hold. The incorporation of a non-normal error assumption is unnecessary for OLS unless the t and F distributions are used in subsequent analyses. This is, in itself, only true if the central limit theory (CLT) does not apply. Two data sets are used to explore these underlying assumptions, 1) wear data from retrieved metal backed acetabular components and 2) from retrieved Charnley sockets. In both cases the penetration was determined using shadowgraphic techniques and the service life from clinical records. The penetration rate was determined using traditional parameter estimation and the bootstrapping technique (Efron et al 1986). Three regression models were used:

1. Simple linear model with no residual weighting.
2. As in 1 with residual weighting equal to $(\text{time})^2$.
3. As in 2 but with the regression constant = 0. Here, the mean penetration rate is identical to that gained from calculating the mean from individual penetration rates.

The bootstrap technique resamples the data with replacement and provides an improved estimate of the se in settings where the traditional method is untrustworthy.

RESULTS

Using model 1 each of the data sets displayed heteroscedastic residuals and as such violated assumption 3. The results gained for data sets 1 are displayed in Table 1. The parameters 'a' and 'b' indicate the constant term and the coefficient, which is the penetration rate, from the regression. The prefix 'se' indicates the standard error gained from standard regression analyses whilst * indicates that derived from the bootstrap distribution. Both data sets 1 and 2 are

large ($n > 30$) and it is probable that the central limit theorem (CLT) will apply. Indeed two of the plots (Figure 1), which indicates the variation in the penetration rates, are approximately normal. Estimate b3 using model 3 indicated a mild deviation from normality although the effect may not be serious. Of the two good models, 2 is the most efficient. Similar results were gained for data set 2.

Figure 1: The bootstrap distributions for the penetration rate estimation (b1, b2, b3) using each of the models 1, 2 and 3 respectively (data set 1).

Parameter	Model 1	Model 2	Model 2
a	0.233	-0.131	-
se(a)	0.254	0.075	-
se(a)*	0.207	0.069	-
b	0.166	0.206	0.184
se(b)	0.022	0.018	0.014
se(b)*	0.022	0.015	0.014

Table 1: Results from the bootstrap method (data set 1).

DISCUSSION

The different models produce differing parameter estimations together with their standard errors, with Model 1 being less efficient than Model 2. Evidence here suggests that the penetration rate sampling distribution, determined from the traditional analyses (Model 3), departs from normality which may invalidate results gained from using the t or F test. It is recommended that penetration data be analysed using model 2 with regression diagnostic routinely undertaken to check the underlying assumptions. The use of inferential statistics may become problematic in situations where the CLT does not hold, that is in small samples less than 30 data points with extreme outliers.

AORTIC VALVE STENOSIS – NUMERICAL STUDY ON THE ACCURACY OF NONINVASIVE AND INVASIVE DIAGNOSTICS

Yael Danai¹, Shmuel Einav¹, Moshe Rosenfeld², Heinrich Schima³

Department of ¹Biomedical Engineering and ²Fluid Mechanics, Faculty of Engineering
Tel Aviv University, Tel Aviv 69978, Israel. danai@eng.tau.ac.il

³Department of Cardiology, Vienna General Hospital, University of Vienna, Vienna, Austria

INTRODUCTION

The assessment of aortic valve stenosis is of great clinical significance. In the present study the evaluation of the flow field factors on valve area calculation and the accuracy of Doppler Ultrasound and Cardiac Catheterization in the determination of valve area, is done by studying computer models of the flow in the immediate neighborhood of the valve, varying systematically the flow rate and the valve area. For Doppler measurements the flow rate is evaluated using the PISA (Proximal Isovelocity Surface Area) technique, and the effective valve area is determined using the continuity equation based on the velocity field. For Catheterization technique the Gorlin equation is applied based on the measured volumetric flow rate and the pressure gradient. The numerical results were compared with the in-vitro results of Schima *et. al.* (1999).

METHOD

An axisymmetric numerical model was constructed to simulate the aortic valve flow using a time-dependent CFD analysis to predict the flow characteristics during the cardiac cycle through axisymmetric straight channel with diameter of 3.0 cm. Disk type plates (2 mm thickness) with central orifices of 0.5, 1.0 or 1.5 cm² were used to model stenosis of various degree of severity. The pulse rate was held constant at 60 bpm, with an ejection time of 0.37 sec. The Navier-Stokes equations were solved using FIDAP (Fluent Inc., Evanston) for incompressible, laminar flow with constant viscosity.

The PISA method uses the velocity field proximal to the orifice to estimate the flow rate (see Fig.). Clinically and experimentally the velocity field is obtained through the use of 2-D CDFM (Color Doppler Flow Mapping) that is capable of extracting only the velocity components aligned with the signal of the transducer beam. It is therefore less accurate in contrast with computational simulations where the velocity components can be obtained at every node. This set of equations and the appropriate boundary and initial conditions determine the velocity and pressure drop in the analyzed domain.

The flow field was analyzed for several phases of the cardiac cycle, for varied orifice size and for different flow rates. The calculated flow rate was compared to the real flow values as given by the initial conditions of the model, and the calculated valve areas were compared to the in-vitro findings, using both Doppler and Catheterization techniques.

RESULTS AND DISCUSSION

Numerical simulations provide knowledge on the instantaneous velocity and pressure fields throughout the cardiac cycle therefore enables accurate valve area calculations at any chosen time. The PISA approximation of flow rate was found to yield accurate results near the peak flow for small orifice sizes, allowing accurate calculation of the effective orifice area.

The in-vitro measurements uses volumetric flow rate during the entire ejection time, mean pressure drop and mean velocity. The measurements show significant overestimation of the valve area, both by Doppler and by Catheterization techniques, due to incorrect use of continuity and Gorlin equations. Correction factors were set using computer simulations: the Gorlin formula was modified by the addition of ‘discharge coefficient’, the continuity equation was modified by setting a correction factor that compensated on using measured velocities (maximum velocities instead of average velocities), according to the flow profile. The incorporation of these correction factors enables accurate calculations (error<5%) of the valve area.

SUMMARY

Numerical analysis of the aortic valve is very complicated by the large 3-D motion of the highly flexible leaflets in a compliant system of fluid and structure. Using simplifications in the numerical study enabled its solutions and provided an insight on the flow characteristics, and on noninvasive and invasive methods for calculating the effective valve area.

The current work employs Fluid-Structure Interaction (FSI) simulations, which simulated flow through rigid channel with flexible leaflets, using an arbitrary Lagrange-Euler (ALE) formulation. The objective is to analyze the leaflets movement during the cardiac cycle and to characterize the flow field through it.

DISINTEGRATION AND DEFORMATION OF CELLS AND MICROCAPSULES USING SHOCK WAVES AND GAS BUBBLES FOR DEVELOPING DDS

Masaaki Tamagawa¹ and Ichiro Yamanoi²

INTRODUCTION

Recently shock wave phenomena in living tissues are being widely applied in the fields of medical and chemical engineering, such as extracorporeal shock wave lithotripsy or bioprocess for environmental protection (Genenger,1997). In the bioprocess, a bubble inside the cell is broken by shock waves to rise efficiency of disintegration of cells. In the same mechanism, we propose a Drug Delivery Systems (DDS) using shock waves (Tamagawa, 2001). In this system, a microcapsule including a gas bubble is flown in the blood pipe, and finally broken and drug is reached to the affected part in the body as same as traditional DDS(Fig.1). In these process, the mechanism for deformation and disintegration of cells depend on the parameter of elasticity of cells or microcapsules, diameter of bubbles and position of the bubbles. It is necessary to investigate these fundamental mechanism for design of the capsule in DDS and bioprocess. This paper describes the trial making of microcapsules and observation of deformation of a bubble near the curved elastic wall.

EXPERIMENTAL MODELS AND METHODS

In order to investigate possibilities to make microcapsules in small scale, the prototype capsules in mm scale are produced using alginic acid-sodium (0.3-0.7 %), small gum Arabic, and calcium chloride. By pouring liquid and bubbles into these capsules using injector, the three-layer experimental model (membrane, liquid and bubble) can be made as shown in Fig.2. In the next step, to observe deformation process of a bubble in a cell or microcapsule, the bubble near the curved elastic wall made of Gelatin is observed when plane shock wave works on it in the shock tube apparatus. Here silicone oil is used as the surrounding liquid.

RESULTS AND DISCUSSION

Taking high-speed photograph of bubble deformation using framing tube, time histories of bubble radius are obtained in case of various curvatures of gelatin wall and distance from the wall. Figure 4 shows the maximum radius of a bubble with changing distance from the wall and the curvature. R_0 , R_{max} , b_0 mean initial radius, maximum radius, initial distance respectively. From the result, it is found that by controlling the curvature of the wall and initial position of a bubble there is a point to have large deformation, which tends to be collapsed easily. This is one of the results to aid design of DDS or bioprocess for cell-integration.

INTER-GROUP COMPARISON OF EMG RESPONSES OF THIGH AND LEG MUSCLES DURING GAIT IN TREADMILL

Isabel C.N. Sacco^{1,2}; Alberto C. Amadio².

¹ Physical Therapy, Speech and Occupational Therapy dept.- School of Medicine – University of São Paulo, Brazil, icensacco@usp.br

² Laboratory of Biomechanics – School of Physical Education and Sport – University of São Paulo, Brazil.

INTRODUCTION

Biomechanical changes in neuropathic patient's gait have been reported, as well motor strategies created to compensate their somatosensorial deficits (Cavanagh et al. 1992; Abboud et al., 2000, Sacco et al., 2000). The present investigation aims at comparing the EMG activity in the leg and thigh muscles during treadmill locomotion between a neuropathic patients group (DG) and a non-diabetic group (CG).

METHODS

Thirty-six voluntary adults of both sexes from the University Hospital were assigned to 2 groups: DG- with neuropathy confirmed, and a healthy non-diabetic group (CG). We used a Gaitway treadmill (Kistler) and six surface EMG electrodes (Delsys) that were placed on the motor point of the gastrocnemius lateral, tibialis anterior, and vastus lateral of both legs. CG subjects achieved an average walking velocity in a treadmill of 4.6 ± 0.4 km/h and DG subjects, 3.8 ± 0.4 km/h. EMG signals were acquired 3 times at 1000 Hz, acquisition time of 12 s, resulting in 30 supports for each foot. The EMG signal were rectified, filtered, integrated and normalized by the mean value and by support time. Inter-groups comparisons of each electromyographic variable were made through the use of the t test and Mann-Whitney test. The Ethical Committee of the University Hospital approved the protocol.

RESULTS AND DISCUSSION

The EMG pattern of the DG was expressively different from the CG (fig. 1). We observed significantly inter-groups differences in the activation of the right vastus lateral ($P=0.032$), its first activation peak in CG subjects was at 7.4% of support time and in DG it was at 10.3%. The activation beginning and the peak activation of the right gastrocnemius

lateral in the DG subjects were delayed. The right and left tibialis anterior activation was also significantly different between groups (R: $P=0.042$, L: $P=0.022$). The first activation peak of right tibialis anterior in CG subjects was at 1.4% of support time and in DG it was at 8.2%. The first activation peak of left tibialis anterior in CG was at 3.0% of the support time and in DG it was at 9.7%. And we also observed lower EMG magnitudes for the vastus lateral in DG subjects.

Figure 1: Mean curve of linear envelopes of the right vastus lateral, tibialis anterior and gastrocnemius lateral of DG.

Another important aspect to detach is the lower coefficient of variation of the EMG of both groups. This fact was also observed by Dingwell et al. (2000) and it is discussed that the restrictive treadmill environment impose a locomotor pattern extremely reproductive with lower variability.

MUSCULAR ACTIVITY AND STRENGTH TESTING OF TRUNK AND HIP EXTENSORS: A REPRODUCIBILITY STUDY

Ruhleder M., Segieth C., Vogt L., Banzer W.

Johann Wolfgang Goethe-University, Institute of Sports Sciences, Frankfurt/Main, Germany
Dept. of Sports Medicine, ruhleder@sport.uni-frankfurt.de

INTRODUCTION

Methods have been developed to evaluate the strength of hip surrounding muscles and to examine the effects of rehabilitation measures following implantation of endoprotheses (Shih et al. 1994; Horstmann et al 1995). The purpose of this study was to evaluate the test-retest reproducibility of SEMG activity of selected lumbopelvic muscles and their amount of activity during the “lateralflexion” maneuver, which has been described and already used in clinical practice (Stutz & Schreiber 1999).

METHOD

In a standardized testing procedure 11 healthy subjects ($f=4$, $m=7$, age 26.7 ± 3.0 years, range 22-32 years) without a history of hip pain performed three maximal isometric contractions (MVC) in three randomized positions: leg abduction (supine lying), trunk extension (from prone position) and “lateralflexion” (supine lying, body side was randomly selected). During the “lateralflexion” maneuver the subjects were instructed to rotate their pelvis in the frontal plane in order to reduce the distance between the iliac crest and the rib cage. The “lateralflexion” maneuver against an invincibly resistance is thus characterized by the attempt of a left- respectively right-concave curve of the low back in the frontal plane. Maximal isometric strength and bilateral SEMG activity of the gluteus medius and the lumbar erector spinae muscles were recorded with 1000Hz/channel (Biovision®, Wehrheim, Germany). The electrode placement was oriented on international standards (Frericks et al. 1999). MVC was performed over a period of five seconds with a rest of three minutes between trials. All measurements were taken from the neutral position on one day (1h-intervall) within one electrode application. MVC with the highest force peak was determined and the mean SEMG activity was calculated. The average SEMG activity during the “lateralflexion” maneuver was analyzed in relation to the maximum voluntary contraction which was considered as 100% muscle activity. For the verification of normality of sampling distribution the Kolmogorov-Smirnov test was carried out. Students t-test for paired samples were calculated for differences of relative myoelectrical activity during the “lateralflexion” maneuver between test and retest.

RESULTS AND DISCUSSION

Students t-test showed no significant differences for the average SEMG activity between test and retest for both muscles (figure 1). Correlation coefficient ranged from $r = 0.78-0.97$ ($p < 0.05$). In relation to the MVC the results revealed a higher muscle activity of the gluteus medius muscle than the lumbar erector spinae during “lateralflexion”. It seems that the erector spinae muscle had

a more stabilizational function during the “lateralflexion” maneuver (figure 2).

Figure 1: Test retest activity during the “lateralflexion” maneuver in relation to the maximum voluntary contraction (MVC was considered as 100% muscle activity) ($p > 0.05$)

Figure 2: Muscle activity during the “lateralflexion” maneuver in relation to the maximum voluntary contraction (MVC was considered as 100% muscle activity)

SUMMARY

The findings of this study encourage the implementation of the proposed method for strength testing in clinical practice and rehabilitation.

INTRODUCTION

Three-dimensional (3D) task analysis is an important part of biomechanics studies. Kinematics data is obtained by reconstruction of spatial motion of markers on all mobile segments (Veldpauss et al. 1988). Typically, joints between biomechanical segments are used as anatomical points and skin markers are chosen to provide simple relations with those joints. Analysis are frequently contaminated by missing coordinates (Muijtjens et al. 1997) and some trials end up being rejected because of the missing markers (Nussbaum et al. 2000).

The purpose of this paper is to present a simple mathematical formulation that can be used to retrieve the coordinates of markers hidden during a task. A strategy based on the smoothness of the variation of distance between points is devised, which leads to an automated computer procedure for retrieving hidden skin markers or missing joint coordinates (missing 3D points). This approach has the advantage of not being restricted to the frequent rigid-body assumption.

METHODS

The mathematical formulation does not require a specific biomechanical model except that all skin markers on a segment are considered to be attached to the joints of that segment.

Let assume that A, B and C are three points in the laboratory space and that point B is some time missing. Let dL_{ab} be the distance between points A and B. One can compute the distances dL_{ab} , dL_{bc} and dL_{ac} using a frame where all three points are present. Let also the distances dL_{ab} and dL_{bc} vary monotonically with time in such a way that they can always be interpolated over time with quintic splines. There is no restriction on dL_{ac} except that points A and C should be present when computing the coordinates of missing point B.

Point B is on a sphere of radius around point A and, simultaneously, on a sphere of radius around point C. The intersection of the two spheres is a circle which lies in a plane with its normal passing through the coordinates of A and C. Let point E be at the centre of the circle. The distance of the plane and point A is then given by a proportion which is a function only of the length dL_{ab} , dL_{bc} and dL_{ac} , which can be calculated using the Pythagorean theorem.

$$dL_{ae} = \frac{(dL_{ab}^2 + dL_{ac}^2 - dL_{bc}^2)}{2.0(dL_{ac})} \quad (1)$$

Vectors in the laboratory reference frame can also represent points A, B and C. Thus the equation of a plane containing point B is given by:

$$\frac{\vec{C} - \vec{A}}{dL_{ac}} \cdot \vec{P} = \frac{\vec{C} - \vec{A}}{dL_{ac}} \cdot \vec{A} + dL_{ae} \quad (2)$$

where \vec{P} is the vector in the laboratory reference system associated with the coordinates of a point lying in the plane.

To retrieve point B, let assume that there are other points monotonously linked to B. For each pair of monotonously linked points a plane is expressed using equation 2. Note that these points do not need to be on the same segment; for example, for a human elbow two points close to the wrist and two others close to the shoulder can be used. Because the coordinates of point B are common to all planes, the set of plane equations is used to calculate these coordinates borrowing the common solution of linear algebraics with the singular-value decomposition technique.

RESULTS AND DISCUSSION

A mathematical procedure that can retrieve missing coordinates of a point in a 3D volume has been presented. This procedure is easy to implement in an automatic algorithm. It is based simply on the ability to determine the distances of the missing point (e.g. B) from its neighbours (e.g. A and C). This means that the two distances dL_{ab} and dL_{bc} have to be known or interpolated at all times during the trial.

SUMMARY

It was found that a set of four non-coplanar monotonously linked points, always gives the coordinates of a missing point.

EFFECT OF INTERFRAGMENTARY SHEAR AND COMPRESSIVE STIMULATION ON BONE HEALING

Nicholas Bishop, Maarten van Rhijn, Ivan Tami, Erich Schneider, Keita Ito
AO Research Institute, Davos, Switzerland, keita.ito@ao-asif.ch

INTRODUCTION

Mechanical deformation of the callus modulates fracture healing, i.e. tissue proliferation and differentiation. Clinically, shear has been associated with delayed- and non-unions. In a rabbit model, transverse shear first led to non-unions (Yamagishi & Yoshimoto, 1955), but then oblique shear stimulated healing (Park *et al*, 1998). Although both studies applied interfragmentary (IF) shear, local deformations and their deviatoric/volumetric components, as implicated in mechanotransduction theories (Pauwels 1980), may not have been similar. In this study, the effect of torsional IF deformation, (pure deviatoric), axial IF deformation (deviatoric and volumetric), and rigid fixation on fracture healing was compared in an *in vivo* ovine model.

METHODS

In 3 groups of 6 Swiss Alpine sheep each, a 2.4 mm mid-diaphyseal tibial transverse gap osteotomy was created and stabilized with a custom unilateral external fixator. The fixator was rigidly locked or accurately applied axial or torsional motion. 120 sinusoidal loading cycles were applied daily with 25% minimum (compressive) principal peak IF strain at 0.5Hz. IF displacements were 0.6 mm axially and 7.2° in torsion with load limits of 360 N and 1670 Nmm, respectively. After 8 weeks, the sheep were sacrificed. Transverse CT scans were made to measure gap density and osteotomy stiffness was measured by 4-point bending in and out of the pin plane. This study was approved by the Animal Experimentation Commission of the Veterinarians Office of the Canton Graubünden.

RESULTS AND DISCUSSION

Circumferential analysis of CT scans around the bone axis indicated that highest density tissue formed caudally, where the soft tissue coverage is greatest (Fig 1). Mean density of gap tissue was highest in the torsional group around the entire bone. The rigid and axial groups had similar mean density of gap except caudal-laterally where the former was denser. Analysis of consecutive radial rings indicated higher gap tissue mean density in torsional vs. axial group for the medullary and intracortical regions, but externally their values converged (Fig. 1). The torsional group produced denser callus than the rigid group in the medullary and external regions but was similar intracortically. Stiffnesses were similar in the torsional and rigid groups, 69±29% and 64±26% (of intact contralateral tibia) respectively, and lower in the axial group (41±25%).

Figure 1: Mean angular (left) and radial (right) tissue density distribution.

In general, healing in the torsion group was most advanced. This is contrary to the view that shear deformation compromises fracture healing. Since there is relatively little volumetric deformation in the torsion group (or related fluid flow), it would appear that volumetric stimuli (including fluid flow) are less stimulatory than the deviatoric deformations. This is in contradiction with recent theories which involve fluid flow (Lacroix and Prendergast 1999).

It would also appear that the axial group has less advanced healing than the rigid group. This is the only group with significant volumetric deformation so this parameter may therefore be responsible for the retarded healing.

SUMMARY

These results indicate that interfragmentary shear is not detrimental to fracture healing. They are consistent with the concept that shear deformation stimulates and compressive hydrostatic pressure retards bone healing (Carter et al 1988). Future histological evaluation may indicate further differences between groups and will be compared with finite element analysis of local mechanical conditions to explore mechanotransduction mechanisms in more detail.

MOVEMENT BEHAVIOUR IN CHRONIC NECK PAIN PATIENTS

C. Segieth¹, Y. Moshref¹, L. Vogt¹, K. Pfeifer² and W. Banzer¹

Johann Wolfgang Goethe-University, Institute of Sports Sciences, Frankfurt/Main, Germany

¹ Dep. of Sports Medicine, c.segieth@sport.uni-frankfurt.de

² Otto-von-Guericke University, Institute of Sports Sciences, Training and Health, Magdeburg, Germany

INTRODUCTION

Although back pain is the most costly musculoskeletal problem affecting industrialized nations (Van Tulder et al.1997), a general lack of knowledge exists concerning the etiology and specific symptoms related to chronic neck pain (CNP).

Some studies already described the importance of cervical motion analysis (Highland et al. 1992) and examined the kinematics in patients with neck pain (Hagen et al. 1997), but it still remains unclear how adaptations to muscle pain accommodates the coordination and interaction of neck and shoulder movements.

The purpose of this study was to investigate how pain modulates the kinematic of the cervical spine in a defined sample of chronic neck pain sufferers compared to healthy control subjects.

METHODS

Sixteen chronic neck pain (CNP) patients (f = 10, m = 6, mean age 55.8±2.8 yr), who had cervical pain on at least half the days in the past 12–18 months, and eighteen age matched controls (f = 10, m = 8, mean age 56.6±3.5 yr) performed ten repetitive maximal cervical movement cycles (flexion /extension, axial rotation, lateral flexion) at a self-determined velocity (patients: 39.9±14.4°/s; controls: 37.5±15.6°/s).

To collect the kinematic data of the cervical spine a three-dimensional ultrasonic movement analysis system (Zebris CMS 70[®], Germany) was used. Maximum oscillation angles (ROM, degrees) of the various movements were calculated for amplitude analysis. To describe the movement variability in the maximum oscillation amplitudes the intra-subject coefficients of variation (CV %) were determined. The computed maximum difference was characterized by the absolute differences between the minimum and maximum oscillation amplitudes of iterated movement cycles (Figure1). Pain intensity was obtained by visual analogue scales (VAS).

Figure 1: Maximum difference of ten repetitive cervical spine movements in the frontal plane for one patient.

RESULTS AND DISCUSSION

The average pain rating of the CNP patients indicated moderate neck pain intensity (mean 37±8).

The independent t-test revealed a significant decreased range of motion (ROM) in the CNP group for all anatomic planes ($p<0.05$), except for the lateral flexion to the right. The maximum differences and variability parameters showed significantly increased values in the CNP group in all directions ($p<0.001$)(Table 1).

SUMMARY

This study confirmed that CNP patients compared to healthy subjects show a typical restriction in the max. range of motion (ROM) and significant differences in variability parameters (CV, max. difference) calculated for the repeated movement cycles.

EFFECT OF GLYCOPROTEINS ON FRICTION COEFFICIENT OF NATURAL AND ARTIFICIAL JOINT SURFACES

Toshio Kitano, Yoshinori Kadoya, Kentarou Inui, and Yoshiki Yamano

Department of Orthopaedic Surgery, Osaka City University Graduate School of Medicine
1-4-3 Asahimachi Abenoku OSAKA, 545-8585 JAPAN
tkitano@med.osaka-cu.ac.jp

INTRODUCTION

Failure in lubrication mechanism causes Orthopaedic complications, Osteoarthritis for natural joint and loosening of artificial joint. When Hydrodynamic lubrication breaks down, boundary lubrication becomes dominant. In this condition, boundary lubricating molecular e.g., Glycoproteins or Phospholipid becomes important. Synovial fluid of natural joint and Periprosthetic fluid after total joint arthroplasty mainly contains Glycoproteins in addition to Hyaluronic acid. It has been hypothesized that constituents and conditions of Glycoproteins affect the lubrication properties in natural and artificial joint. The purpose of this study is to test this hypothesis, comparing the effects of Glycoproteins on friction coefficient between natural and artificial joint

METHODS

Four lubricants were tested in this study: L01; 0.033M Tris buffer + sodium hyaluronate (HA) 3 mg/ml, L02; L01 + bovine albumin (ALB) 12 mg/ml, L03; L01 + bovine Gamma-globulin (GLB) 8 mg/ml, L04; L01 + ALB 12 mg/ml + GLB 8 mg/ml. Each lubricant was tested at 8 different pH values varying from 6.5 to 8.6. CF of cartilage against cartilage and ultra-high molecular weight polyethylene (UHMWPE) against Co-Cr-Mo alloy (CoCrMo) were measured with a mechanical spectrometer using the cylindrical joint surface model. Normal stress 150kPa was applied to the natural joint surface model and 250kPa was applied to the artificial joint surface model.

Fig.1 Angular Velocity - CF Curve (Ca-Ca)

RESULTS AND DISCUSSION

Addition of GLB decreased CF of cartilage against cartilage (Ca-Ca) while the addition of ALB did not decrease CF (Fig.1). Addition of ALB or GLB increased CF of UHMWPE against CoCrMo (PE-CoCr) at the low velocity range independent of lubricant viscosity while addition of ALB or GLB decreased CF at the middle and high velocity range in lubricant viscosity dependent manner (Fig.2).

The difference of boundary lubrication properties between artificial and natural joint has been observed. Addition of GLB decreased CF in natural joint model at the entire range of speed under boundary lubrication condition. On the other hand, addition of ALB or GLB increased CF in artificial joint model at the low speed at which boundary lubrication is dominant. Failure of joint lubrication produces many problems in natural synovial joint as well as in the artificial joint. The boundary lubrication plays an important role in joint lubrication after the failure of fluid film lubrication. The results obtained in this study support that surface modification of artificial surface might improve boundary lubrication properties by affecting the adsorption ability of boundary lubricant layer and that the regulation of synovial fluid might improve Osteoarthritis conditions of natural joint.

INTRODUCTION :

Interactions of lymphocyte function-associated antigen-1 (LFA-1) with intercellular adhesion molecule-1 (ICAM-1) play an important role in a number of cellular events, for example, the leukocyte adhesion and transendothelial migration in inflammation. The aim of this work was to investigate the adhesion mechanism of LFA-1 and ICAM-1 interaction by a newly developed micropipette method (Chesla et al., 1998) and a commonly used flow chamber technique.

METHODS :

A normal human RBC was coated with soluble ICAM-1 by an improved chromium chloride coupling method. This RBC interacted either with a SKW-3 cell (human T cell leukemia) or with a normal human lymphocyte (HLC), both of these two cells expressed LFA-1 on their surface. The two interacting cells were respectively held by a pair of micropipettes with negative pressure and brought into contact using a computer-controlled micromanipulator system. The contact area was kept constant and the contact duration was varied over a range from 1 to 16 seconds. Using the RBC as a force transducer through its deformation for judging the happening of adhesion, an adhesion probability (Pa) was obtained. In parallel, a flow chamber system was also used in this work. Human umbilical vein endothelial cells (HUVEC) were cultured on glass coverslips coated with 1% gelatin and these slides were assembled to a commonly used rectangular flow chamber for shear experiments. A syringe pump generated steady flows corresponding to values of shear stress of 0.17 and 0.7Pa at the surface of endothelial monolayer. A suspension of SKW-3 ($1 \times 10^6/\text{ml}$) would be injected into the flow chamber. The number of firmly adhered SKW-3 cells (Nad) was counted with the help of an image acquisition and analysis program (Visilog 5.1).

RESULTS AND DISCUSSION:

Phytohemagglutinin (PHA) stimulation resulted in a significant increase in the adhesion probability of lymphocytes compared with nonstimulated ones ($P < 0.001$)

(Table 1). But Tetramethylpyrazine (TMP) treatment could significantly inhibit such increase. These effects were confirmed by experiments on firm adhesion of SKW-3 on HUVECs under low shear conditions (Figure 1). It was found a significant positive correlation between the Pa and Nad obtained by the two methods.

Figure 1 : Number of firmly adhered lymphocytes to endothelial cells in different groups at two shear stresses (0.7 and 0.17 Pa).

SUMMARY:

This study demonstrates that the interaction between ICAM-1 and LFA-1 plays an important role in cell adhesion. The experiments on the changes of cell adhesion induced by TNF- α , PHA or TMP show a good concordance between the results obtained by the two techniques used.

INTRODUCTION

Biomechanical models can be used in surgical planning to assess the outcome of an operation, and are particularly useful in performing sensitivity analyses. This aspect of computer assisted surgery (CAS) requires sophisticated models that are accessible to clinicians and are sufficiently fast in operation. Inverse-dynamic models suffer from two main problems. The first of these is that the kinematics of the simulation must be known in advance and the second is that the optimisation of muscle forces makes the models slow. Forward-dynamic models assume no prior knowledge of kinematics, but do require a neural input. The aim of this study was to develop a large-scale, forward-dynamic model that is fast in operation and could be used in CAS. The success of the model was assessed by its ability to reproduce measured movements.

METHODS

An inverse-dynamic model including an inverse dynamic muscle model of the upper limb (Happee and van der Helm, 1995) was used to calculate the required neural input for a recorded movement (forward flexion of the humerus - from -15° to $+15^\circ$ in the sagittal plane), sample time 0.012s. A set of optimised muscle forces was calculated based on a quadratic cost function (sum of squared muscle stresses weighted by muscle volume), and these muscle forces were converted into neural inputs by use of a muscle model. This model was a Hill-type muscle model with a contractile element, series and parallel elastic elements and three state variables (length of contractile element, activation and excitation). The model was then rewritten to allow forward-dynamic simulations, and the same neural input used to try to recreate the measured kinematics.

RESULTS AND DISCUSSION

Figure 1 shows the combination of muscle forces used by the model to generate the movement. Acceleration of the humerus into forward flexion is primarily achieved by the supra- and infraspinatus muscles, and deceleration is then produced by deltoideus posterior and triceps. Although this seems to be a reasonable combination of muscle forces, the resulting motion (Fig. 2) deviates considerably from the desired pattern (-15° to $+15^\circ$). Given the number of steps between the neural input and the kinematic output, and the complexity of the model this result is surprisingly good - a smooth anteflexion of the humerus has been simulated. In a complex multiple DOF system muscle forces must balance each other for each DOF in order to obtain a stable solution. Discretization of neural

inputs, linear interpolation and the three-step time-delay in an inverse dynamic muscle model result in modelling noise. Future work will focus on improving the estimates of neural input. Using the forward-dynamic and inverse-dynamic models together and feeding the error in predicted kinematics back into the inverse-dynamic loop, the calculated neural inputs can be optimised.

DESIGN AND ASSEMBLY OF A STERILE NANOSCALE ORTHOPEDIC BIOMATERIAL

John Longworth, Steven Eppell
Case Western Reserve University
Department of Biomedical Engineering
jrl22@po.cwru.edu

INTRODUCTION

An ideal biomaterial bone substitute should facilitate bone healing and be resorbed by the body. Although they have been proven to facilitate bone healing, hydroxyapatite ceramics cannot be resorbed in vivo or in vitro due to their highly crystalline structure (Yuasa et al. 2001). It is also questionable whether more current bone cements that better mimic the crystallinity of bone minerals will be completely resorbed by the body (Yuasa et al. 2001). It has been postulated that the size of the crystals may influence their resorbability by the body, as shown by the fact that nanocrystalline hydroxyapatite grains are readily degraded by osteoclasts (Webster et al. 2001). This could be due to the fact that the smaller crystals have a larger surface area to volume ratio, resulting in a larger surface area per gram of the crystal being exposed. It has been theorized that the size of the mineralites in bone may be determined by the spacing between the collagen monomer repeats in the collagen fibrils (Hodge 1989). By using collagen fibrils as a scaffold, our lab has succeeded in making a synthetic bone biomaterial composed of collagen fibrils and nanometer-sized apatites that closely resemble the dimensions of bone apatites. The objective of this current project was to create a sterile collagen composite using aseptic technique for further testing in osteoclast cell cultures.

MATERIALS AND METHODS

The protein content of collagen monomer in acid (Vitrogen), was verified by trypsin digestion followed by SDS-PAGE in the manner described by Bruckner and Prockop (1981). Trypsin digests collagen polypeptides that are not in the form of intact monomers, thus it can be used to test that a solution contains triple helical collagen monomers. All composite assembly steps were done in a laminar flow hood. Solutions were sterilized using 0.2-micron bottle top filters. Fibril assembly in vitro was achieved using the simultaneous neutralization warming method (Holmes et al. 1986). After fibril self-assembly, the pH of a mineralization solution, which simulates the ionic concentrations of body fluid, was raised from 7.4 to 8.2 to initiate precipitation of calcium. The fibrils were added to the mineralization solution and allowed to incubate for 24 hours. After mineralization, the fibrils were

washed multiple times with ethanol to remove excess solution and macro-sized minerals. Some samples were prepared for SEM imaging by progressive ethanol dehydration. These samples were then coated with palladium and imaged in an environmental SEM in full vacuum mode. Samples were loaded into cell chambers to hold down the collagen and create a well-defined surface. The composites were incubated in α -MEM at 37° C for 14 days.

RESULTS

SDS-PAGE showed that the protein was still intact after trypsin digestion, indicating that the starting solution was composed of triple helical collagen. The results exhibited bands for the α 1 and α 2 chains (the alpha band), a band for two crosslinked α chains (beta band) and a band for three crosslinked α chains (gamma band), identical to literature from results [4]. As shown by the SEM, fibers were successfully assembled sterilely in vitro, and no large crystals were found. After incubating the composites for 14 days no signs of infection were detected.

DISCUSSION

The results of the trypsin digestion show that the collagen we are working with is composed of primarily triple helical monomers, rather than individual polypeptide chains. Analysis by SEM shows that the self-assembly protocol we utilize results in a meshwork of collagen fibrils several microns in length. The resulting material has also shown to be sterile, since incubating the samples for several days does not result in any kind of infection. Further cell based work with this material is now possible.

NONLINEAR DAMAGE THEORY APPLIED TO TWO-STEP FATIGUE FAILURE PREDICTION OF BONE

John R. Cotton¹, Peter Zioupos², Keith Winwood², and Mark Taylor¹

¹Bioengineering Science Research Group, School of Engineering Sciences, University of Southampton, Highfield, Southampton, SO17 1BJ, UK. Email: j cotton@soton.ac.uk

²Department of Materials & Medical Sciences, Cranfield University, Shrivenham, SN6 8LA, UK

INTRODUCTION

Fatigue failure prediction in bone is desirable for orthopedic implant design. Load cycle magnitude varies during normal function. Also, fatigue-induced creep and stiffness loss redistributes stress with time. Thus, to predict failure *in vivo*, a theory accommodating variable stress magnitudes must be generated and validated.

Zioupos and Casinos (1998) tested femoral cortical bone from a 44 year-old male, *in vitro*, in two-step loading fatigue. Predictions based upon linear Palmgren-Miner theory produced a systematic error: high/low stress steps overestimate life and low/high steps underestimate life. A possible improvement on this theory ties damage accumulation to stiffness loss. We have been collecting data on the reduction of Young's modulus during uniform cyclic fatigue (Winwood, et al. 2001). Herein, we use modulus degradation relationships from current work to formulate a nonlinear damage theory and predict the published two-step fatigue test results.

METHODS

Fatigue (0-tension) was performed, as published (Zioupos, et al. 1996), on 10 samples from a 55 year-old male. Damage, defined as the modulus loss $(1-E/E_0)$, was taken from the crosshead movement of the testing system. The tangent modulus, E_0 , was calculated from a low-stress pretest. Data was fitted to the most appropriate of the three damage laws identified by Zioupos, et al. (1996),

$$D = 1 - (E/E_0) = 1 - \left[1 - (n/N_f)^{(1-\alpha)^{-1}} \right]^{(1+\beta)^{-1}} \quad (1)$$

Parameters $(1-\alpha)$ and $(1+\beta)$ were determined from a non-linear regression analysis and fitted as functions of normalized stress, σ/E_0 . These relationships for α and β , were combined with uniform cyclic S-N data (Zioupos and Casinos, 1998) to predict failure for the published two-step experiments. The nonlinear prediction method is shown graphically in figure 1.

RESULTS

From mechanical tests, damage was seen to accumulate according to equation 1, with parameters α and β fitting

$$\begin{aligned} \text{Log}(1-\alpha) &= -2300 \sigma/E_0 + 19. \\ \beta &= -31000 \sigma/E_0 + 205. \end{aligned} \quad (2)$$

To relate intrinsic differences between individuals, σ/E_0 values in equation 2 were multiplied by a correction factor of 0.80. This was the ratio of σ/E_0 values needed to predict the same cycles to failure between the two individual's S-N curves. No other tuning was used between the two data sets. Model predictions are presented in figure 2.

Figure 1: Prediction of failure in two-step loading with a nonlinear damage theory. Damage, D_1 , was calculated from the first-step values σ_1 and $(n/N_f)_1$. Then, the equivalent life fraction $(n/N_f)_{1-2}$ was calculated. The second-step life fraction is $(n/N_f)_2 = 1 - (n/N_f)_{1-2}$.

Figure 2: Prediction accuracy for cycles to failure, n_2 . Scatter around the dashed line, $y = x$, using the nonlinear theory is less than linear Palmgren-Miner theory (r^2 of 0.71 and 0.39 respectively).

SUMMARY

The nonlinear theory shown here improved prediction of remaining life despite using modulus data from a different individual. The stress-step order dependency (high/low vs. low/high) is not seen in the nonlinear theory, removing the systematic error seen in Palmgren-Miner theory.

INTRODUCTION

Ultrasound imaging of laminar flow towards the regurgitant orifice has been widely used for valvular regurgitant flow rate assessment¹. Nevertheless, the behavior of flow distribution in this zone is not exactly described by ultrasound techniques, even using 3D color Doppler reconstruction, due to technical and fundamental limitations²⁻⁴. This study was designed to characterize the pulsatile flow behavior in an in vitro model of mitral prolaps using a 3D particular velocity imaging (3DPVI) technique

METHODS

Our experimental heart model is represented by two cylindrical chambers simulating ventricular and atrial cavities separated by a perforated wall between two half cylinders placed symmetrically in opposition as shown on fig 1. The cylinder diameter was 40mm. Physiological pressure conditions have been provided by a pump governed by a synthesizer signal generator. The viscosity of the fluid was designed to mimic blood (3.6 cp at 20°). The velocity measurements were made by PVI method, using silica particles illuminated with a 1 mm laser light plane. Each plane in longitudinal and transversal plane was separated by 5 mm (fig1). We obtain velocity fields every 50 ms all over the cardiac cycle (600 ms). Based on orthogonal 2D vectors, we calculated the 3D velocity field.

Fig 1: experimental model and PVI reconstruction method

RESULTS

This 3D reconstruction method gave us exact representation of flow dynamics in the convergent region.

Figure 2 show 3D PVI velocity fields upstream the orifice at peak ejection time. In this particular model of mitral regurgitation, we note that 3D isovelocity profiles are complex and the hemispheric assumption usually used in clinical setting for flow rate calculation is not accurate in this configuration.

Fig 2: Orthogonal views of velocity field in the convergent region

SUMMARY

This study was designed to characterize the pulsatile flow behavior in an in vitro model of mitral prolaps using a 3D particular velocity imaging (3DPVI) technique. We generate a complex pulsatile flow convergent field using a mitral prolaps regurgitant model. Bi-dimensional velocity vectors were calculated using particular velocity imaging. Flow is lighted by a 1mm thickness laser plan and particular velocity vectors are measured by PVI software. Based on orthogonal 2D vectors, we calculated the 3D velocity field.

Conclusion. Perfect knowledge of the 3D velocity vectors distribution is crucial for developing new tools for flow regurgitant rate quantitation. Our model gives us exact characterization of flow in a complex pulsatile mode of mitral regurgitation.

A BLACK BOX APPROACH TO MODELING THE EQUINE BACK AS A FLEXIBLE BEAM

Schobesberger H, Peham C

Clinic for Orthopedics in Ungulates, Veterinary University Vienna, Austria

christian.peham@vu-wien.ac.at

INTRODUCTION

Back pain and diseases of the spine constitute significant problems in equine sports and veterinary medicine. Mathematical models have become one of the basic and renowned methods for examining the biomechanical behavior of the back. Han et al. (1995) have formulated such a model for the human spine using kinematic and EMG data. Van den Bogert et al. (1989) have built models of the whole horse with rigid segments, but they are not realistic enough for in-depth analysis. In our study we propose a novel approach to define a biomechanical model of the equine back.

METHODS

We have measured the EMG of the long back muscle of 15 horses without back pain during lateroflexion and extension, while simultaneously recording the motion of the back by a kinematic tracking system. Out of these data sets, we derived a linear transfer function (TF) for two positions on the back (spinous process of thoracical vertebra T16 and T12) relating the EMG to the actual movement of the back (equation (1)).

$$TF(s) = \frac{X(s)}{F_{EMG}(s)} \quad (1) \text{ with } s \text{ denoting the complex frequency.}$$

We evaluated the transfer function by computing the correlation coefficient (CC) between the output of the TF and the actual kinematic measurement.

Consequently we related the transfer function to the general motion equation in the frequency domain. Equation (2) shows the general motion equation in its canonical form in the time domain and its corresponding description in the frequency domain,

$$f_{EMG}(t) = m \cdot \ddot{x} + D \cdot \dot{x} + K \cdot x \Leftrightarrow \\ \Leftrightarrow F_{EMG}(s) = m \cdot s^2 \cdot X(s) + D \cdot s \cdot X(s) + K \cdot X(s) \quad (2)$$

$$\text{with } F_{EMG}(s) = \frac{X(s)}{TF(s)} \Rightarrow TF = \frac{1}{m \cdot s^2 + D \cdot s + K} \quad (3)$$

with s denoting the complex frequency, and m as coefficient for inertia, D for damping and K for the spring constant. By comparison of the coefficients we obtained relevant parameter estimates equating the filter polynomial to the general motion equation in the frequency domain (equation 3). The derived parameters were used for the simulation of the back as a flexible beam. The mathematical parts of our work were done using MATLAB™ (Mathworks, Inc.), the flexible beam was simulated in ADAMS™ (Mechanical Dynamics, Inc.).

RESULTS

During lateroflexion to the left, we achieved a pooled correlation coefficient (CC) of 0.711 for position T16 and a pooled CC of 0.701 for position T12. Lateroflexion to the right resulted in a pooled CC of 0.731 for T16 and a pooled CC of

0.695 for T12, and extension in a pooled CC of 0.878 for T16 and a pooled CC of 0.852 for T12. We obtained the coefficients of the polynomial of the transfer function by a least squares fit to the measured frequency response data. In the ensuing step we modeled the equine back as a flexible beam using the advanced simulation software ADAMS™.

DISCUSSION

We now propose a novel approach to model the equine back. Using EMG and locomotion data from 15 horses, we have derived the transfer function (TF) in the frequency domain for certain positions on the back. The high correlation achieved between calculated and measured data show that a linear black box model can be sufficient to derive a simple mathematical relation (TF) between EMG input and position output. This enabled us to identify necessary material characteristics (m , D , K) to simulate the equine back as a flexible beam, and in preliminary experiments we were able to demonstrate the similarity of the motion of the real and the simulated back. Once this correspondence has been proven statistically valid, we will be able to subject the modeled equine spine to all kinds of load and vibration stress regimes, and explore its dynamical behavior during physiological and pathological scenarios, as well as its contribution to general locomotion at different gaits. This will greatly enhance the insight into the nature of the motion of the equine spine. Furthermore, the model will be of great potential value for clinical practice in providing a new means of diagnosing equine back problems.

SUMMARY

The aim of our work was to establish a biomechanical model of the equine back, based on kinematic and surface electromyographic data of horses without back pain. Our approach in order to do so, consisted of four essential steps: Step 1) to measure the horses kinematically and electromyographically, 2) to identify the mechanical system by computing a linear transfer function relating the EMG to the kinematic data, and determining the validity of the linear transfer function, 3) to relate the transfer function to the general motion equation to acquire relevant parameter estimates, and 4) to model the equine back as simple flexible beam.

STRESS TRANSFER TO CORONARY VASA VASORUM AFTER STENTING: A FINITE ELEMENT MODEL

Mark E. Zobitz¹, Michael S. Rosol³, Mario Goessl², Malyar M. Nasser², Kai-Nan An¹, Birgit Kantor³

¹Biomechanics Laboratory, Department of Orthopedics, ²Department of Physiology and Biophysics,

³Department of Internal Medicine and Cardiovascular Diseases

Mayo Clinic/Mayo Foundation, 200 First Street SW, Rochester, MN 55905, e-mail: zobitz.mark@mayo.edu

INTRODUCTION

In-stent restenosis is a major health issue in the US. It is characterized by excessive cell proliferation. The underlying mechanisms are not well understood. Vasa vasorum are nutrient vessels in the outer wall of coronary arteries (Kantor, 1999; Kantor, 2000). Damage and manipulation to vasa result in neointimal proliferation and subsequent artery stenosis. We hypothesized that stents damage vasa during balloon inflation and through sustained compression by the individual stent struts. The aim of this study was to develop a finite element analysis (FEA) model of stented coronary arteries to determine stresses induced in the vessel wall in order to predict vasa compression by the stent, which could initiate the restenotic process.

METHODS

A 3D FEA model of the coronary artery wall was developed using ABAQUS (HKS, Inc., Pawtucket, RI) finite element software. The model was created for half of the artery using 8-node brick elements and consisting of 19,000 nodes and 15,500 elements (Fig. 1). The outer diameter was 7.3mm and the final expanded lumen diameter 3.3mm. Vasa were modeled in the wall at a location 70% of the wall thickness. The vessel wall was modeled as isotropic, linear elastic, and incompressible ($E=1.0\text{MPa}$ (7501mmHg), $\nu=0.49$). Boundary conditions were applied to the symmetry plane while the outer wall of the vessel was free to expand radially. An internal pressure of 95mmHg was applied to simulate the mean blood pressure. Two sizes of vasa were modeled; 50 and 150 μm diameter. Two degrees of stent diameter expansion were considered (16% and 34%). The expanded 3D stent geometry was simulated from 3D microscopic-CT images (Jorgensen 1998). Stent expansion was simulated by applying radial displacements to the nodes of the vessel wall surface where stent contact would occur. Data were analyzed through a plane in the midsection of the model with a radial path chosen from the lumen through the vasa vasorum to the outer wall. All stresses are reported as Von Mises equivalent stress in mmHg.

Figure 1: FEA model after 34% stent expansion.

RESULTS

Fig. 2 shows the stress contours through a plane in the midsection of the model. On the luminal stented side, stresses were greater than 1,500mmHg with a maximum of 4,000 and 10,000mmHg for 16% and 34% expansions, respectively. The stress decreased in a non-linear manner with increased distance from the lumen (Fig. 3). In the region where vasa are located, stresses exceeded 500 and 1,000mmHg for the two expansions. In comparison, prior to stenting, stresses in the wall induced by the blood pressure were lower ($<30\text{mmHg}$).

Figure 2: Stress contours following 34% stent expansion.

Figure 3: Von Mises stress as a function of distance from lumen before and after stent expansion.

DISCUSSION

This study demonstrates a dramatic increase in stresses within the vessel wall in response to stent implantation including the region where vasa vasorum are located. Therefore, it would be expected that these stresses are sufficient to compress the vasa and impair vessel wall perfusion. The subsequent hypoxia can lead to increased release of growth factors and to cell proliferation and restenosis. This model can be used to predict stresses induced by various stent types and to optimize stent design to minimize impact on vasa vasorum.

SUDDEN LOADING OF THE UPPER BODY LEADS TO MOVEMENT OF BOTH THE LUMBAR SPINE AND PELVIS.

Henrik Naesborg, Christian T. Hye-Knudsen and Jorgen Skotte.
National Institute of Occupational Health, Denmark, Department of Physiology
hen@ami.dk

INTRODUCTION

In laboratory setups studying sudden loading of the upper body pelvic fixation is often used. Both semi-seated (Cholewicki et al 2000) and standing (Stokes et al 2000, Skotte et al 2001) procedures have been used to immobilize the pelvis. A pilot study by Andersen (2001) has indicated that pelvic rotation occurs when the pelvis is tightly fixed by a non-elastic belt. Ignoring pelvic rotation may tend to overestimate lumbar flexion. This could lead to errors in biomechanical modeling. The aim of this study was therefore to describe and quantify the movement of the pelvis and the lumbar spine when healthy subjects are fixed at the pelvis and exposed to a sudden perturbation of the upper body.

METHODS

Ten subjects participated in the study. The experimental set-up is illustrated in Figure 1. The external force on the subject was momentarily increased from 3 N to 60 N through a steel wire attached to the subject via a shoulder harness. A Peak Motus video system (50 Hz) was used to collect the 2D coordinates of reflective markers placed on C7, T2, T4, L1, L3, L5, midpoint between right and left posterior superior iliac spine (PSIS), anterior superior iliac spine (ASIS) and the great trochanter (see fig. 1). The combination of 2 different body postures (erect and 30° of trunk forward inclination) and loads (no load and 15% of body weight (BW) in a box held in the hands) was randomly applied to the subjects. The pelvis was firmly fixed to a wooden plate by a non-elastic belt. Pelvic rotation and lumbar flexion was defined as change in pelvic angle (P_{angle}) and lumbar angle (L_{angle}) respectively according to Figure 1. A two-Way Repeated ANOVA ($p < 0.05$) was used to test the effect of body position and load. If interaction was

found One-Way Repeated ANOVA was used.

RESULTS AND DISCUSSION

Movement caused by the perturbations resulted in less forward

Figure 2. Mean (SE) pelvic rotation (A) and lumbar flexion (B) in degrees. * indicates significance

pelvic rotation in the inclined position compared to standing erect ($p=0.004$). No difference was seen between the two load conditions ($p=0.085$) (fig.2A). For lumbar flexion interaction was seen between position and load ($p=0.021$). Less flexion of the lumbar spine was observed in the inclined position compared to standing erect despite load level ($p \leq 0.005$). Less lumbar flexion was also detected in the erect position with a load ($p=0.031$) while in the inclined position an extra load did not affect the degree of lumbar flexion ($p=0.091$) (fig. 2B). The significant pelvic rotation caused by a sudden perturbation indicates that lumbar flexion is overestimated if not corrected for pelvic rotation. The overestimation seems to be larger in inclined postures were smaller movement of the lumbar spine was distinct. The smaller lumbar flexion and pelvis rotation in the inclined position indicates an increased stiffness in both the lumbar spine and around the hip joint.

SUMMARY

After a sudden perturbation of the upper body both lumbar flexion and pelvic rotation are seen even if the pelvis is firmly fixed. In future experiments the pelvis and spine should to some degree be considered as a combined movable unit even when the pelvis is fixed.

STARTING FRICTION OF ARTIFICIAL CARTILAGE MATERIALS IN HYALURONATE SOLUTIONS

Teruo Murakami, Ryo Kinoshita, Yoshinori Sawae and Kazuhiro Nakashima

Dept. of Intelligent Machinery and Systems, Faculty of Engineering, Kyushu University, Fukuoka, Japan

tmura@mech.kyushu-u.ac.jp

INTRODUCTION

To improve the longevity of artificial joints, the authors have investigated the application of compliant artificial cartilage. In the previous knee joint simulator tests for walking motion, the improvement of lubrication mode was confirmed in knee prosthesis with PVA (polyvinyl alcohol) hydrogel layer lubricated with hyaluronate solution containing protein. For various daily activities, however, the high friction at starting motion after long standing is another problem in compliant rubbing materials. In this study, the influence of lubricants on the starting friction in sliding pair of compliant material of PVA hydrogel and polyurethane as artificial cartilage against hard material.

METHODS

Test apparatus to measure the starting friction was constructed, in which the upper stainless steel cylindrical roller of 30 mm radius is rubbed against the lower flat plate specimen of PVA hydrogel or segmented polyurethane of 2 mm thickness. PVA hydrogel of 79 % water content was prepared by repeated freezing-thawing method. Elastic modulus of PVA hydrogel is 1 MPa and that of polyurethane is 19.9 MPa. After the definite loading time with constant load of 37 N for 5 s, 1 min, 5 min, 15 min, 30 min and 60 min, the lower plate and moving support was driven at 4 mm/s by means of linear motor. The frictional behavior was observed by the signal from strain gauges on leaf spring with upper stationary specimen. Three kinds of 1.0 wt% solutions for sodium hyaluronate (HA) of different molecular weight, i.e., 0.58×10^6 , 1.00×10^6 and 1.98×10^6 were used as lubricants. Higher molecular weight corresponds to higher viscosity.

RESULTS AND DISCUSSION

After the lower specimen started to move, the friction increased gradually to the maximum value and then decrease to steady value as coefficient of friction of about 0.04 to 0.05. The maximum friction value after starting is defined as the starting friction. The starting friction increased with the loading time before starting. PVA hydrogel exhibited significantly lower starting friction less than 0.12 even after loading of 60 min as shown in Fig.1. Higher molecular weight of sodium hyaluronate reduced the starting friction. This is caused by viscous effect of hyaluronate solution to maintain the squeeze film formation. For HA of 0.58×10^6 and 1.00×10^6 , the immersion in HA solution for 14 days reduced the friction. Therefore, the lower starting friction less than 0.1 appears to be maintained for PVA hydrogel with high

water content. This fact suggests that the PVA has better frictional property as artificial cartilage.

On the contrary, polyurethane with higher stiffness and higher strength showed very high starting friction such as 2.2 after 60 min loading for all HA solutions. This high friction can induce the loosening of the compliant surface layer in usual daily activities after long standing. However, the immersion of the polyurethane specimen in HA solution for 14 days could remarkably reduce the starting friction to about 0.5 as coefficient of friction. HA of 1.00×10^6 exhibited the lowest value of 0.3. This fact indicates the possibility of polyurethane as artificial cartilage after surface modification.

Figure 1: Influence of loading time, molecular weight of sodium hyaluronate and immersion in HA solutions on starting friction for PVA hydrogel against stainless steel

SUMMARY

The variation of starting friction for PVA hydrogel and polyurethane as artificial cartilage was examined. It was indicated that the higher molecular weight HA solution is effective to reduce friction for PVA and the immersion in medium molecular weight HA solution is effective for polyurethane.

THREE-DIMENSIONAL SCANNING ACOUSTIC MICROSCOPY OF THE INTACT INTERVERTEBRAL DISC: VISUALISATION OF LAMELLAE, COLLAGEN BUNDLES AND LESIONS.

S. Johnson¹, M. Halliwell², M. Jones² and D. McNally¹

²Department of Medical Physics and Bioengineering. United Bristol Healthcare NHS Trust. Bristol. UK.

INTRODUCTION

The intervertebral disc plays a key role in the aetiology of low back pain. A disc consists of a fluid-like nucleus pulposus constrained laterally by the fibrous annulus fibrosus (AF). The AF has a complex structure that comprises concentrically organised lamellae composed of collagen bundles embedded within a proteoglycan matrix and arranged at specific orientations with respect to the spine; the direction of fibre orientation alternates between successive layers. The collagen fibres act to reinforce the disc and are critical to its mechanical function. Lesions cause disruption to the organised structure and are involved in the failure of the disc. Visualisation of disc structure has relied previously upon time consuming and destructive methods, such as histology, that do not enable structures to be observed within intact specimens; this precludes repetitive testing of the same specimen. The present study employs non-destructive scanning acoustic microscopy (SAM) to visualize the normal disc structure and examine the three dimensional morphology of pathological lesions within the AF.

METHODS

Eight porcine lumbar discs and adjacent vertebrae were dissected free from soft tissue and the posterior vertebral elements removed to enable access to the entire disc circumference. Discs were then mounted into a water bath contained within the SAM. The SAM consists of a 50MHz transducer (axial resolution 30 μ m; penetration depth approx. 2mm), 4-stepper motor driven stages controlled via a PC and a bath for coupling medium. The transducer operates in pulse-echo mode and images are displayed so that the amplitude of echoes reflected from tissue boundaries determines the brightness of the display. The time difference between the propagation of the initial pulse and the echo's return gives a measure of the depth of the reflecting surface.

A 3-D data set consisting of between 256 and 800 slices of a region of interest (ROI), of variable size, was acquired from one of three circumferential locations: the anterior AF, the antero-lateral AF and the postero-lateral AF. Typically, the scanned ROI included the AF and part of the adjacent vertebral body, in two of the discs the ROI was restricted to an area of approximately 2mm² to maximize structural detail from the AF. The 3-D data sets are viewed in the three orthogonal planes; X, Y and Z using a multi-planar slice display. A 3-D projection of the data was also generated to enable the complete ROI to be viewed.

RESULTS AND DISCUSSION

A typical 3-D data set viewed in the three orthogonal planes is shown in Figure 1. Viewed in the transverse and sagittal planes (Fig. 1 a, b), the AF is characterised by strong alternate light and dark banding; the former represent the boundary between adjacent lamellae. Lamellae could be followed between their insertions in adjacent vertebral bodies. Collagen bundles are clearly visible in images generated perpendicular to the disc surface, as if looking at the surface of a tangential cut through the AF; bundle orientation alternates between adjacent lamellae (Fig. 1 c). A 3-D projection view of the complete 3-D data set reveals both the lamella structure and the orientation of collagen bundles within each lamella (Figure 1d). Lesions, characterized by an hypoechoic region within the AF, were observed in 2 of the 8 specimens; all were located at the periphery and had a "Discuss" shaped 3-D morphology. The lesions were arranged circumferentially and may represent either small circumferential lesions or areas of delamination.

Figure 1: Visualisation of disc structure. (a) transverse, (b) sagittal and (c) tangential planes. (d) 3-D projection of data. (e) Projection showing lesions in the AF (closed arrow heads).

SUMMARY

The lamella and collagen bundle structure were readily visible using 3-D SAM. Discrete lesions with a characteristic "Discuss" morphology were observed within the peripheral AF. SAM enables non-destructive imaging of disc structure that may be used to improve understanding of the relationship between disc structure, function and mechanical degeneration.

EFFECT OF BODY POSTURE ON GEOMETRY OF THE ABDOMINAL AORTIC BIFURCATION

INTRODUCTION

Haemodynamic factors have been postulated to be responsible for the focal nature of atherosclerosis, and local patterns of blood flow are strongly dependent on vascular geometry. The existence of geometric risk factors for atherosclerosis has thus been proposed, as certain anatomical features might favour a flow environment that is pathogenic (Friedman et al 1983).

The aorto-iliac bifurcation is known to exhibit a high incidence of plaque formation. Attempts have therefore been made to characterise haemodynamic conditions quantitatively in the abdominal aorta and its bifurcation using computational fluid dynamics (Taylor et al 1998, Long et al 1997). However, flow simulations have usually been performed with geometries based on data acquired from subjects lying in the supine position during magnetic resonance (MR) scanning. Different body postures might alter the aortic bifurcation geometry, which could affect the simulated haemodynamics greatly. Moreover, people do not spend their whole lives in the supine position, so if the flow simulations are to represent *in vivo* arterial flows satisfactorily, it becomes necessary to understand how changes in body posture affect geometry and hence flow at the aortic bifurcation. To our knowledge, the effects of body posture on aortic bifurcation geometry have not previously been studied.

METHOD

Two subjects were scanned between the renal bifurcation and the ilio-femoral bifurcation with a 1.5T whole body MR scanner using 2D time-of-flight (TOF) technique. Each subject was scanned supine and prone. Models of the aorto-iliac bifurcation were reconstructed from a series of cross-sectional images using our own image segmentation and geometry reconstruction programme.

RESULTS AND DISCUSSION

Fig. 1 shows the 3D geometry of the bifurcation reconstructed from images acquired in the supine position. For each subject, bifurcation geometries in the two postures were analysed in terms of branching angles, curvatures, shape factors, 3D vessel centre lines and position of bifurcation (high or low). The non-planarity is measured by the average perpendicular distance from the centre lines to the reference plane which is formed by the last points on each vessel centre line in the bifurcation region. In the present study, the bifurcation region covers an area one diameter proximal to and distal from the bifurcation apex. Fig. 2 shows the centre line of the aorto-iliac bifurcation of the same subject acquired in the supine and prone positions with non-planarity values of 0.5155mm and 0.1081mm respectively. These changes in geometry may be important, as they might strongly affect the local haemodynamics.

Figure 1: A human aorto-iliac bifurcation reconstructed from MR images acquired in the supine position.

Figure 2: Centre line of a human aorto-iliac bifurcation in two different body postures. x, y, and z are the co-ordinates in mm.

SUMMARY

The importance of this study is that it demonstrates changes in the geometry of the abdominal-aortic bifurcation following alterations in posture. The effects of such alterations in geometry on local haemodynamics remain to be determined.

OVERWEIGHT AND OBESITY IN POSTURE: A BIOMECHANICAL EVALUATION OF SPINE ANGLES

Federica Sibella¹, Manuela Galli¹, Marcello Crivellini¹

¹Bioengineering Department, Politecnico di Milano, Milano, Italy
e-mail: sibella@biomed.polimi.it web site: www.gaitlab.biomed.polimi.it

INTRODUCTION

The loading condition of the spine in obese subjects results certainly excessive and sometimes it can lead to biomechanical modifications and pathological alterations of the musculo-skeletal system. A quantitative assessment of the spine angles in the sagittal plane during quiet standing in normal and overweight subjects provides useful biomechanical information about the effect of an anomalous body weight increasing on the spine.

The main aim of this study was to evaluate biomechanical aspects of the spine loading condition by calculating spine angles overweight and obese patients in comparison to normals.

METHODS

We analyzed a total number of 26 women (mean age 32.5 s.d. 5.91 years) divided into 4 subgroups in relation to BMI value: 1) underweight (6 subjects), mean BMI 19.81, s.d. 0.86 2) normal weight (10 subjects), mean BMI 22.33 s.d. 1.55 3) overweight (5 subjects), 26.21 s.d. 1.09 4) obese (5 subjects), mean BMI 38.94 s.d. 8.99 .

A motion measurement system (ELITE, bts[®], IT) provided the 3D coordinates of reflective passive markers and a force platform (AMTI, Newton, MA) provided the ground reaction forces and the trajectory of the Centre of Pressure. In particular, 11 markers were placed over the spinosus processes every two vertebrae from c7 to sacrum. Each subject was asked to stand on the force platform in orthostatic indifferent position with eyes open for three successive acquisition trials. Each trial was 30 secs long. This abstract is focused only on kinematic aspects. The curve that interpolates all the 11 points in the sagittal plane was found using an algorithm based on cubic splines. From this curve two significative angles parameters were extracted: angle of lordosis (θ_L) and angle of kyphosis (θ_C).

RESULTS AND DISCUSSION

A significative correlation between increasing BMI and a variation of the calculated parameters lordotic angle (θ_L) and cifotic angle (θ_C) was found: for increasing values of BMI a decreasing value of the two considered angles was to notice (see Figure 1 and 2). The decrease of the lordotic angle (θ_L), in relation to an increasing value of the BMI is a sign of an iper-lordotic posture in obese women This result confirms the conclusions of some previous studies that used radiographic images as a tool to investigate spine angles in obese subjects. The decrease of the kyphotic angle (θ_C), in relation to an increasing value of the BMI is a sign of an iper-kyphotic posture in obese women. This is probably due to a spine

overloading and it seems to be a way to compensate the iper-lordotic posture, in order to maintain a good balance during quiet standing.

Figure 1: angle of lordosis in relation to BMI value

Figure 2: angle of kyphosis in relation to BMI value

SUMMARY

As a conclusion, we can say that these results, obtained with a non-invasive optoelectronic device, confirm previous results, obtained with a more invasive tool (radiographic images). The simple biomechanical model that we used to define spine angles in the sagittal plane, can help to get information about the posture of any kind of subject and maybe try to explain different attitudes from a biomechanical point of view.

NUMERICAL SIMULATION OF INTERFACIAL STRESS FOR EXTENSIVE PREMOLAR CAVITY UNDER DIFFERENT OCCLUSAL FORCES

Heng-Liang Liu¹, Ming-Yih Lee¹, Yen-hsiang Chang² and Chun-Li Lin¹

¹Department of Mechanical Engineering, Chang Gung University, Tao-Yuan, Taiwan, germy@ms65.url.com.tw

²Operative Dentistry, Chang Gung Memorial Hospital, Tao-Yuan, Taiwan

INTRODUCTION

Traditionally, the extensive cavity restoration has to spent large amount of efforts and time-consuming by direct or indirect method. The CAD/CAM systems are adequate to fabricate all-ceramic restoration for extensive cavity. However, interfacial bonded strength between tooth tissue and restoration material is suspected after restored by CAD/CAM system. The objective of this study was to estimate the interfacial stresses for extensive premolar cavity with various designed restoration shape under different occlusal loading.

METHODS

An intact premolar was designed for extensive cavity shape, depth was from lingual cusp tip to high of contour and width was from fissure line to lingual cusp. Restoration was then performed using CEREC system (Sirona Dental Systems, Bensheim, Germany). The 3D finite element model (Fig. 1(a)) of restored premolar with sound material properties (enamel, dentin, pulp, and ceramic) was generated in ANSYS (Ansys Inc, Houston, USA, 1994) after embedded, sliced, image process, caught material contour procedures. Other four individual cavity finite element models were developed by modify element material properties in the zone of cavity areas. All designed shape of restorations have the same dimensions except width distance from fissure line to lingual wall (D). The various width distances are average divided from 2/3D to 1D. Premolars were individual subject to 200N with 45 degrees incline acted on tooth and restoration, respectively, near the interface between natural tooth and restoration. An in-house program was used to combine with ANSYS to calculate the interfacial stress for five different cavity designs with two occlusal forces.

The interfacial stresses (normal and shear) obtained for each design are listed in Table 1 (Fig. 1(b)). Higher normal stress on buccal and lingual wall inducing by bending moment increased restoration width in the restored premolars under the same occlusal loading condition. In addition, larger normal stress on interfacial bonded areas by occlusal force acting on natural tooth than on restorative material for longer moment arm under the same restoration shape design.

SUMMARY

Under limited data, occlusal contact adjustment might be an essential factor than shape design for extensive cavity in clinic.

CYCLIC STRAIN AND FLUID FLOW INDUCE DIFFERENT RESPONSES IN HUMAN BONE CELLS

Mullender, M¹, El Haj, A J², Yang, Y², Magnay, J², van Duin, M A¹, Klein-Nulend, J¹

INTRODUCTION

When bone is subjected to mechanical loads, osteocytes and osteoblasts have been shown to produce signaling molecules, which mediate bone remodeling (Burger, 1999). It is thought that osteocytes detect these mechanical loads by sensing fluid flow through the lacuno-canalicular network in bone. Osteoblasts, however, are located on the bone surface. They may also be directly stimulated by mechanical strain. The objective of this study was to examine if fluid flow or direct cell strain induces the production of signaling molecules or matrix proteins in bone cells. Therefore, we subjected primary human bone cells to either pulsating fluid flow (PFF) or cyclic strain (CS) *in vitro*. The production of nitric oxide (NO) and prostaglandin E₂ (PGE₂) was measured. Both are early mediators in mechanically induced bone formation. To evaluate the effect on matrix production, the amount of collagen type I was measured.

METHODS

Primary human bone cells were obtained from bone fragments of three patients (1.5; 14; 16 yrs.). The outgrowing bone cells were cultured in α -MEM with 10% FBS. Second-passage primary cultures were treated with pulsating fluid flow (PFF) or cyclic strain (CS). Cells were plated on polylysine coated glass slides and incubated for 24 h in DMEM with 2% FBS. The cells were then loaded for 1 h by PFF (0.6 \pm 0.3 Pa, 8.5 Pa/sec, 5 Hz) or CS by four-point bending (\sim 1000 μ strain, 1 Hz). Control cultures were kept accordingly, without loading. All cell cultures were post-incubated until 24 h after loading. The conditioned medium was assayed for NO, measured as nitrite (NO₂⁻), using the Griess reagent and for PGE₂ by enzyme-immunoassay. Cells were harvested for measurement of total protein and DNA. The quantity of collagen I was analyzed by Western Blot. Data were analyzed using the general linear model. A $p < 0.05$ was considered as significant.

RESULTS

The total amount of DNA did not differ between treatment and control groups. Treatment with PFF caused a significant increase in the production of NO during flow (Figure 1B). PFF stimulated PGE₂ production up to 12-fold after 24h post incubation. CS also stimulated the release of NO significantly (Figure 1A), but not PGE₂ (Figure 1C). PFF inhibited and CS stimulated the production of collagen type I (Figure 2).

DISCUSSION

Fluid flow through the lacuno-canalicular system is believed to be a key mechanism by which osteocytes sense mechanical loads. They are considered to convey this information to cells at the bone surface by signaling molecules. Our results showed that primary human bone cells responded to pulsating fluid

flow by an increased release of such molecules. However, the production of the matrix protein collagen I was inhibited by PFF. In contrast, CS stimulated the production of collagen I and did not stimulate PGE₂ release. The release of NO was upregulated by both PFF and CS.

We have shown previously that human bone cells respond to CS by an upregulation of c-fos expression, a transcription regulator of matrix production. Stretch activated channels and integrin mediated pathways are critical for this response but not PGE₂ (Peake, 2000). This might explain the increased collagen production and the lack of PGE₂ response after CS. The results suggest that bone cells can discriminate between strain directly applied through the substrate and strain induced by flow-derived shear stress. Furthermore, activation of these different mechanical pathways may either stimulate or inhibit the production of matrix proteins.

Figure 1: Both CS and PFF stimulated NO release (A, B). PGE₂ did not increase after CS (C). PGE₂ increased after PFF (D), but this was significant only after 24 h post incubation.

Figure 2: Collagen I expression is given as load over control ratio (no response gives a ratio of 1). CS stimulates collagen I production, whereas PFF inhibits collagen I production.

NON-NEWTONIAN EFFECT IN THE ARTERIAL BLOOD FLOW

Józef Wojnarowski¹ and Kryspin Mirola²

¹ Silesian Technical University, Gliwice, Poland

² Bielsko-Biala Technical University, Bielsko-Biala, Poland

INTRODUCTION

One of the most important questions of hemodynamics is the question about manner of flow rheology specification. In this present paper, Hagen - Poiseuille's model has been used in analysis of influences of human blood state parameters, such as hemocritic number and level of protein in plasma (more precisely fibrinogen and globulin level) on type of behaviour of velocity field in cross-section of blood vessel.

METHODS

Phenomenon of blood flow in a main vessel can be described by equation system of mass and momentum balances:

$$\frac{1}{r} \frac{\partial}{\partial r} r u_r + \frac{1}{r} \frac{\partial u_\theta}{\partial \theta} + \frac{\partial u_z}{\partial z} = 0, \quad (1)$$

$$\rho \left(\frac{\partial u_z}{\partial t} + u_r \frac{\partial u_z}{\partial r} + \frac{u_\theta}{r} \frac{\partial u_z}{\partial \theta} + u_z \frac{\partial u_z}{\partial z} \right) = \quad (2)$$

$$-\frac{\partial p}{\partial z} + \left(\frac{1}{r} \frac{\partial}{\partial r} r \tau_{rz} + \frac{1}{r} \frac{\partial \tau_{\theta r}}{\partial \theta} + \frac{\partial \tau_{zz}}{\partial z} \right)$$

In the case of flow through a vessel, a longitudinal dimension of a canal is essentially higher than a cross-section dimension, and therefore an axial component of transport is several times greater than radial and tangent. Therefore these transport components can be dropped.

A phenomenological model equation requires a definition of a stress-strain relationship. In this work Walburn-Schneck empirical model has been applied. By substituting of constitutive equation into (1) and (2), we have after integration

$$u_z = -\frac{1-c_3 H}{2-c_3 H} \left(2c_1 e^{\frac{c_2 H + c_4}{H^2} \frac{TPMA}{H^2}} \right)^{\frac{1}{c_3 H - 1}} \left(\frac{dp}{dz} \right)^{\frac{1}{1-c_3 H}} R^{\frac{2-c_3 H}{1-c_3 H}} \left(1 - \left(\frac{r}{R} \right)^{\frac{2-c_3 H}{1-c_3 H}} \right) \quad (3)$$

formulae of velocity distribution in arterial cross section and

$$\lambda = 2^{4-c_3 H} \frac{c_1}{\rho u^{1+c_3 H} D^{1-c_3 H}} e^{\frac{c_2 H + c_4}{H^2} \frac{TPMA}{H^2}} \left(\frac{4-3c_3 H}{1-c_3 H} \right)^{1-c_3 H}. \quad (4)$$

hydrodynamics friction coefficient.

RESULTS AND DISCUSSION

Obtained equation (3), (4) describes an arterial flow phenomena by velocity distribution and pressure drop with regards to real blood state parameters. Let's consider, as an example, the distribution of blood velocity in a vessel cross section. Figure 1 presents distribution of velocity in dimensionless, as a function of radial co-ordinate.

Figure 1: Dimensionless velocity distribution in a vessel cross section for Newtonian (N) and non-Newtonian (hematocrit 30, 45, 60 ml/100ml) fluid

SUMMARY

Performed detailed analysis shows the following regularities connected with hematological and flow parameters:

- strong influence of pseudo-plastic properties; due to decreasing shear velocity;
- decreasing of value of maximal velocity in relation to average velocity, what is confirmed by more flat profile of velocities together with increase of hematocrit number and proteins level measured by *TPMA* indicator;
- essential sensitivity of considered parameters on hematocrit number and simultaneously several times less sensitivity to changes of levels of fibrinogens and globulins.

Non-Newtonian effects and their consequences are more and more important in case when blood composition would be different from proper (regular) one for human body - what indicates that it occurs a particular correlation between pathological states of blood flow system.

PEAK POWER CHANGES RESPONSIBLE FOR GAIT SPEED INCREASES IN PERSONS WITH STROKE FOLLOWING A TRAINING PROGRAM

Krishnaji Parvataneni and Sandra Olney

Human Mobility Research Group, Queen's University, Kingston, Canada, K7L 3N6

INTRODUCTION

Gait speed is arguably the single best measure of motor performance, correlating highly with most measures of impairment, disability and health outcome (Bohannon, 1992, Berg et al., 1989). Muscle groups of the lower limb generate and absorb the power required to walk at a safe speed in typical patterns (Winter, 1987). In order of size of the power generators in normal individuals they are: A2, ankle plantarflexors at push-off; H3, hip flexors at pull-off; H1, hip extensors in early stance; K2, knee extensors in early stance. K3 is an important absorber at push-off. Knowledge of the power changes occurring with increased speeds would enable clinicians to target specific muscle groups for retraining. The purpose of this study was to determine the changes in power produced by lower limb muscle groups of persons with stroke who increased their speed of walking after a training program.

METHODS

We examined the peak powers from the hip, knee and ankle of 28 persons (age = 64.2yrs \pm 11.7) with chronic stroke (onset time = 4.8yrs \pm 7) before and after a training program of 10 weeks, all of whom had an increase in their gait speed. The gait data were collected using a Peak Motus two-dimensional motion analysis system (Peak Performance Technologies Inc., Englewood, Co.), with an AMTI force platform (Advanced Mechanical Technologies Inc., Newton, MA) and subjected to inverse link segment analysis (Winter, 1979). One trial each from the affected and unaffected side with similar speeds were selected for data analysis.

RESULTS AND DISCUSSION

The walking speed after training as measured from the gait analysis trials averaged 0.83m/s (\pm 0.33), which was significantly faster than the baseline speed, which averaged 0.69m/s (\pm 0.31). The descriptive statistics and comparisons

of peak powers at major points in the gait cycle from the affected and unaffected sides, before and after training are presented in Table 1. The results show an overall increase in average peak power generation at the hip, knee and ankle on the affected as well as the unaffected sides. The largest increase in peak power generation was observed in the ankle plantarflexors (A2) on the affected side (0.74 ± 1.16 W/kg) followed by the ankle plantarflexors (A2) on the unaffected side (0.46 ± 0.98 W/kg). The next largest increases were by the hip extensors (H1) in early stance on the affected side (0.25 ± 0.5 W/kg) and flexors (H3) at pull-off on the unaffected side (0.26 ± 0.32 W/kg).

To show the distribution of increases across subjects, we identified subjects with peak power increases of greater than 0.1W/kg. Of the 28 subjects, 21 subjects showed increases on the affected side in A2, 18 in H3, and 11 in H1. On the unaffected side, 20 subjects showed increases in A2, 19 in H3 and 13 in H1. Increase in peak power absorption by the knee extensors (K3) on the affected side was observed in 25 subjects and in 23 subjects on the unaffected side.

The importance of plantarflexor training on both sides is clear from these results, and one would expect gait training stressing push-off to be beneficial. Similarly, training of affected hip extensors (H1) and encouragement of the "push-from behind" on the affected side should be helpful. Hip flexor training on the unaffected side, and accentuation of pull-off is also indicated. Further research should be directed at assessing the effectiveness of training potentially compensatory muscle groups that were less used: affected side H2, and unaffected side H1.

RECRUITMENT OF ANKLE LIGAMENTS FIBRES DURING PASSIVE FLEXION

Rita Stagni¹, Alberto Leardini², Andrea Ensini²

¹ Dipartimento di Elettronica, Informatica e Sistemistica, Università degli Studi di Bologna, Italy, stagni@ior.it

² Movement Analysis Laboratory, Istituti Ortopedici Rizzoli, Bologna, Italy

INTRODUCTION

The knowledge of ligament fibre recruitment at the human joints is fundamental for the analysis of mobility, joint motion as controlled by articular surfaces and ligaments, and stability, joint resistance to relative movement of the bones when load is applied. Previous experimental and modelling studies have shown that ankle motion is guided by fibres within the CaFi and TiCa ligaments, which remain approximately isometric through passive flexion (Leardini et al, 1999). The purpose of this study was to identify more precisely the ligament fibres that guide this motion, to distinguish them from those that only limit motion.

METHODS

Three skeleto-ligamentous lower leg preparations including tibia, fibula, talus, calcaneus and intact ligaments were tested. Four spherical 0.8 mm diameter tantalum balls were stuck on the cortex of each of the four bones. Starting from maximum passive plantarflexion, the specimen was stopped in a series of different joint positions, increasing dorsiflexion until a little resistance from the joint was felt. Two roentgen tubes exposed simultaneously both the calibration cage and the specimen in each flexion position. The 3-D co-ordinates of the 16 tantalum balls were then reconstructed in each of the joint positions using standard RSA techniques (Selvik, 1989). The areas of origin and insertion of the main ankle ligaments, the tantalum balls and a series of anatomical landmarks were digitised by means of a 3D digitiser (FARO Technologies, Inc.). Calcaneofibular (CaFi), anterior talofibular (ATaFi), posterior talofibular (PTaFi), tibiocalcaneal (TiCa), deep anterior (DATiTa) and deep posterior (DPTiTa) tibiotalar were examined. The Singular Value Decomposition technique (Challis, 1995) was used to match RSA- and FARO- based ball positions. Eleven representative fibres were mapped in each of the ligaments. The instantaneous length of each fibre of each ligament was calculated in percentage of its maximum, hereinafter called Effective Length Fraction (ELF) of the fibre. ELF Variation (ELFV) from maximal plantarflexion to maximal dorsiflexion was also calculated.

RESULTS AND DISCUSSION

Figure 1 shows that the most anterior fibres of the CaFi ligament and the medio-anterior fascicle of fibres of the TiCa show the smallest variation with respect to their maximal elongation. The ELFV values in Table 1 confirm that the TiCa and CaFi ligaments are the ones, which remain most isometric, with a RMS value of the mean ELFV of 5.2% and 4.1% respectively.

Figure 1: ELF of each fibre of each ligament for a representative specimen. The most anterior (solid bold line), the middle (bold dashed line) and the most posterior (bold dotted line) fibres are depicted.

ELFV	Lateral Side			Medial Side		
	PTaFi	CaFi	AtaFi	DPTiTa	TiCa	DATiTa

RMS	8.2	4.1	8.1	29.8	5.2	25.8

Table 1: Mean value of ELFV over the three specimens for each of the 11 fibres of each of the 6 ligaments.

SUMMARY

Fibres within the CaFi and TiCa ligaments, which remain almost isometric along the passive Do/Pl range, have been identified. These are supposed to control and guide ankle motion in a preferred passive path, whereas all the other ligament fibres limit motion to resist external load. Fibre recruitment analysis in unloaded conditions provides the necessary geometrical basis for future studies of the mechanics of the ankle joint complex.

FINITE ELEMENT ANALYSIS OF GLENOID COMPONENT VERSION IN TOTAL SHOULDER ARTHROPLASTY

Andrew Hopkins¹, Ulrich Hansen¹ and Abdel Hassan²

¹ Biomechanics Section, Department of Mechanical Engineering, Imperial College, London, UK.

² Apley Research Fellow, St. Thomas Hospital, London, UK.

INTRODUCTION

Complications with Total Shoulder Arthroplasty are generally associated with failure of the component replacing the scapular articulation. One of the suggested mechanisms for the implant failure is the destruction of the cement mantle used to bond the prostheses to the bone. Cement degeneration is associated with the development of excessive tensile loads within the mantle.

A major complication of TSA surgical reconstruction is the difficulty associated with maintaining a suitably versed articular surface post-operatively. The version of the glenoid cavity relative to the scapular plane has been reported to vary, on average, by 7° from the central axis for patients suffering from rheumatoid arthritis (Couteau et al. 2001). The placement of the implant is generally evaluated using pre-operative CT scans, however variations such as geometric distortion and realignment of the trabecular structure of the glenoid due to rheumatoid arthritis may suggest to the surgeon an incorrect alignment/version of the component.

It is proposed that this variation of implant version from an anatomically ideal reconstruction might result in the generation of excessive tensile stresses within the cement mantle of the glenoid component. This in turn would cause destruction of this bonding interface and thus loosen the component. It has been suggested that this loosening will over time propagate into the 'rocking-horse' mechanism.

MATERIALS AND METHODS

A 3D Finite Element Analysis was performed upon four different scapulae, two of which represent a patient exhibiting rotator cuff deficiency and two models representing rheumatoid patients. Implant placement and version were discussed and simulated in the models in consultation with an orthopaedic surgeon. The suggested anatomically ideal version was modelled as were several of the probable off-set prosthesis inclinations.

Material properties were assigned to the models using interpolation between greyscale value, apparent density and Young's modulus (Rice et al. 1988, Schaffler & Burr 1988), and these values were modified for the cases of rheumatoid arthritis using simulated material properties (Dalstra et al. 1996). Anisotropy within the trabecular structure of the glenoid (Mansat et al. 1998) has been introduced to the models using a region based method.

A distributed pressure loading is applied to the contact surface upon the glenoid component using the theory of non-

conforming surfaces (Johnson 1985). The scapula bone was reduced to the superior lateral quarter as this was the principal area of interest.

Primary consideration is to be taken of the maximum principle stresses developed within the cement mantle. This is used to examine the percentage by volume of cement expected to survive a repetitive loading of 10 million cycles (Murphy et al. 2000).

RESULTS

Analysis of the different cases of version suggest that a variation in the sites of implant anchorage within the trabecular bone plays a significant factor in the distribution of stresses developed within the cement mantle. This effect was seen to be particularly pronounced within the rheumatoid simulations, where degenerated bone stock produced a more significant probability of cement mantle failure due to tensile stress peaks.

CONCLUSIONS

FEA can provide a useful resource of data regarding survivability of prostheses under conditions difficult to simulate within a laboratory experiment. The potential for misalignment or misplacement of an implant during surgery is a very real possibility, which could eventually be eliminated if techniques for optimisation of the anchorage sites for the prostheses are investigated sufficiently pre-operatively.

This study suggests that the interpretation of geometry and material property distribution, pre-operatively and during surgery, is critical to the long-term success of a procedure such as TSA.

ARCHITECTURE OF CONTRACTING HUMAN GASTROCNEMIUS MUSCLE: AN APPROACH FROM THREE-DIMENSIONAL ULTRASOUND IMAGING

Toshiyuki Kurihara, Yasuo Kawakami, Toshiaki Oda, Kentaro Chino, Tetsuo Fukunaga
Department of Life Sciences (Sports Sciences), University of Tokyo, Komaba, Japan, t-kuri@mti.biglobe.ne.jp

INTRODUCTION

Architectural parameters of skeletal muscles such as fascicle length, pennation angles, muscle thickness and tendon length are often studied. Recent in vivo approaches to the architecture of contracting human muscle have shown that muscle architecture changes by contraction even in isometric actions (Kawakami et al, 2000; Kawakami et al, 1998; Fukunaga et al, 1997). To understand the contraction-induced changes in muscle architecture, however, information on three-dimensional morphology of the whole muscle is necessary. The purpose of this study is to describe architectural changes in human gastrocnemius muscle upon contraction by using the 3D ultrasonography.

METHODS

The subject's right foot was firmly attached to an electric dynamometer. The ankle joint was fixed at 90 deg, and the knee joint was positioned at 0 deg. During the ultrasound data acquisition, the subject was asked to relax (rest condition, as reference), then to maintain isometric contractions at five force levels (20, 40, 60, 80, 100%MVC).

With the use of B-mode ultrasonography, cross-sectional images of muscles and tendinous tissues (tendons and aponeuroses) are visualized in a two-dimensional plane. In the present study, we employed this method to visualize them in a three-dimensional space. For this purpose, an electromagnetic position sensor was attached to the ultrasonic transducer to provide position and orientation information for each image acquired. Then all the serial ultrasonic images (recorded at 30 frames/s) were stored in a computer simultaneously with the positional information, from which fascicles and tendinous tissues were reconstructed three-dimensionally (Fig. 1).

RESULTS AND DISCUSSION

Preliminary results for 2 healthy male subjects showed that the length of muscle belly part of gastrocnemius was monotonically decreased as the force increased, but the length changes of aponeuroses as a function of force levels were nonlinear and different between the deep and superficial parts (Fig. 2). In addition, the reconstructed muscle showed three-dimensional deformation of both aponeuroses upon contraction. It was also shown that the muscle thickness was not constant over the force levels.

Work is in progress to improve the accuracy and validity of the present methodology and measured variables. In the further study, we will investigate the intramuscular variation of fascicle architecture.

EFFECT OF SKIN MOTION ARTEFACTS ON KNEE JOINT KINEMATICS

Rita Stagni¹, Silvia Fantozzi¹, Angelo Cappello¹, Francesco Brigliadori¹, Alberto Leardini²

¹ Dipartimento di Elettronica, Informatica e Sistemistica, Università degli Studi di Bologna, Italy, stagni@ior.it

² Movement Analysis Laboratory, Istituti Ortopedici Rizzoli, Bologna, Italy

INTRODUCTION

The reliability of clinical gait analysis is limited by the effect of Skin Motion Artefacts (SMA). Joint angles are calculated from trajectories of markers located on the skin of the subject under analysis. This procedure is based on the erroneous assumption that markers are rigidly connected with the underlying bony segment. How and to which extent SMA affect joint kinematics is a crucial issue. This has been investigated considering subjects wearing external fixators (Cappozzo et al., 1996) or other bone tracking devices (Manal et al., 2000), which limit SMA. The purpose of the present work was to investigate the effect of SMA in absence of skin sliding constraints and to evaluate the best location of skin markers (SM) for the reconstruction of knee kinematics.

MATERIALS AND METHODS

One patient operated of total knee replacement was acquired during stair climbing (SC) and sit-to-stand/stand-to-sit (STS) activities with fluoroscopy and stereophotogrammetry at the same time. Nineteen markers were uniformly attached laterally on the skin of the thigh, ten on the shank (Figure 1).

Figure 1: Skin markers distribution on the thigh and shank of the analysed subject.

The accurate 3D kinematics of the prosthesis components was reconstructed from the 2D single fluoroscopic view with an iterative procedure using CAD model based shape matching techniques (Banks et al., 1996). The position of the femoral component was calibrated in one reference position using four different clusters of SMs on the thigh: complete (CM: markers 1-19), proximal (PR: markers 1-8), central (CT: markers 5-12) and distal (DT: markers 9-19) subsets. The tibial component was calibrated in the same reference position with respect to the 10 SMs tibial cluster. The 3D prosthesis components kinematics was then reconstructed from the SM clusters (Challis, 1995).

Knee angles were calculated with Grood and Suntay convention (1983) from the 3D kinematics of prosthesis components obtained from fluoroscopy and SM. The Root

Mean Square Value (RMSV) of the difference between knee angles evaluated from SM and fluoroscopy in percentage of their corresponding range for STS and SC, was calculated for CM, PR, CT and DT clusters.

RESULTS AND DISCUSSION

Figure 2: RMSV of the difference between knee angles evaluated from SM and fluoroscopy in percentage of the range for STS and SC, evaluated for CM, PR, CT and DT clusters.

The FI/Ex angle was the least affected by SMA for both motor tasks with a maximum RMSV of the difference of 15% in SC considering the PR cluster. The Ab/Ad angle was the most affected by SMA: RMSV in the range 250% (DT) – 361% (PR) for STS, 134% (DT) – 185% (PR) for SC. These results suggest a better reconstruction of knee rotations can be obtained with the DT cluster, as observed for the In/Ex angle also, with a RMSV ranging between 50% (DT) and 67% (PR) for STS, and between 69% (DT) and 91% (PR) for SC.

SUMMARY

These experimental observations provide a quantification of SMA effects and a useful indication for the selection of the most appropriate cluster of markers for the reconstruction of knee kinematics during clinical gait analysis. Knee Ab/Ad angle was the most affected by SMA. The cluster positioned in the distal area of the femur performed the best in the reconstruction of knee kinematics.

A NEW METHOD FOR QUANTIFYING FIBRE BUNDLE ORIENTATION WITHIN INTACT INTERVERTEBRAL DISCS USING 3-D SCANNING ACOUSTIC MICROSCOPY.

Scott Johnson¹, Mike Jones², Mike Halliwell² and Donal McNally¹

¹Institute of Biomechanics, School of Mechanical, Materials, Manufacturing Engineering and Management. University of Nottingham, Nottingham. UK

²Department of Medical Physics and Bioengineering. United Bristol Healthcare NHS Trust, Bristol. UK.

INTRODUCTION

The collagen fibres of the intervertebral disc, particularly those in the annulus fibrosus (AF), act to reinforce the disc and are critical to its mechanical functioning. The fibres are grouped into bundles within lamellae and are tilted by approximately 60-65° with respect to the spinal axis; the direction of fibre tilt alternates between adjacent lamellae (Marchand and Ahmed, 1990). Changes in the orientation of collagen fibres enables the disc to accommodate structural distortions associated with axial compression, torsion and flexion. Previous methods used to investigate collagen orientation have employed destructive methods that preclude repetitive observations of structural changes within the same disc specimen. A new method of quantifying bundle orientation within intact discs through direct visualization of the collagen structure using scanning acoustic microscopy (SAM) has been developed. The findings of a preliminary study are described in this abstract.

METHODS

Four porcine lumbar discs and adjacent vertebrae were dissected free from soft tissue and the posterior vertebral elements removed. Each specimen was loaded into a manually operated screw-press capable of applying axial compression. The screw-press and disc were mounted into a water bath within the SAM. The SAM consists of a 50 MHz transducer (theoretical axial resolution 30µm), 4-stepper motor driven stages controlled via a PC and a bath for coupling medium. The transducer operates in pulse-echo mode and images are displayed so that the amplitude of echoes reflected from tissue boundaries determines the brightness of the display. The time difference between the propagation of the initial pulse and the echo's return gives a measure of the depth of the reflecting surface.

A 3-D image of the ventral surface of each disc specimen was acquired: i) before compression, ii) after application of first maximal compression and, iii) after application of a second maximal compression. Maximal compression was defined as the maximum amount of reasonable torque the author (SJ) could apply to the screw press without causing damage to the disc. The load applied to the disc was unknown, the aim of this preliminary study was to ascertain whether a change in disc structure and fibre bundle orientation could be detected.

Visualisation of the bundles structure between insertions in the cranial and caudal vertebrae is complicated by the circumferential and axial curvatures of the disc. To enable the orientation of the bundles to be viewed between their insertions, a method was devised to extract the bundle structure from individual lamellae.

The 3-D ultrasound data was viewed using a multi-planar slice display. Markers were manually placed within the substance of the two most superficial lamellae to map the contour of the lamellae. Structural detail between markers was resampled using linear interpolation and displayed as a separate image. Put simply, this method enables individual lamellae to be "peeled" from the 3-D volume and visualized. Analysis of the fibre orientation was performed using the Hough transform.

RESULTS AND DISCUSSION

Changes in the internal structure of the AF with compression were clearly evident in acoustic images (Figure 1a, b). The collagen bundle structure from individual lamellae was successfully extracted from the 3-D volumes and displayed as separate images (Figure 1c). Calculated fibre angles from the four disc specimens in an uncompressed state varied between 40-50° to the spinal axis; much lower than that reported in previous studies (60-65°; Marchand and Ahmed, 1990). This discrepancy may have arisen if the 3-D volumes have not been corrected to give anatomically accurate dimensions of the disc. After compression, fibres tended to become orientated more horizontally, as predicted by McNally and Arridge, (1995).

Figure 1: Sagittal views of a disc (a) uncompressed and (b) compressed. (c) Collagen bundle structure from a single lamella "peeled" from the 3-D volume.

SUMMARY

Analysis of fibre orientation was performed using a novel non-destructive technique involving 3-D SAM. Visualisation of collagen bundle structure within individual lamellae and the relative changes in bundle orientation following mechanical loading, can be observed using this technique. Determination of the precise orientation of the bundles with respect to the spinal axis requires further development. This technique provides information regarding the internal structure and mechanics of discs, and may be used to compliment information obtained through *in vitro* mechanical testing.

EXPERIMENTAL VALIDATION OF A COMPUTATIONAL MODEL OF THE PATELLOFEMORAL JOINT

John J. Elias¹, David R. Wilson^{2,3}, Robert Adamson², Norma J. MacIntyre³ and Andrew J. Cosgarea¹

¹Department of Orthopaedic Surgery, Johns Hopkins University, Baltimore, MD, elias@meric.info

²Orthopaedic Biomechanics Lab, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA

³Department of Mechanical Engineering and Human Mobility Research Centre, Queens University, Kingston, Ontario

INTRODUCTION

A computational model has been created to help orthopaedic surgeons predict how variations in patellofemoral anatomy and loading conditions influence the pressure applied to the cartilage during computationally simulated functional activities. This study was performed to determine how well this model predicts variations in the patellofemoral force and pressure distributions.

METHODS

Two cadaver knees were flexed from extension to near 90° in a rig that simulated a weight-bearing squat. The patellofemoral force distribution was measured continuously with a pressure sensor (Iscan, Tekscan), and movement of the tibia, femur and patella was tracked with a motion analysis system (PCReflex, Qualisys). Anatomical landmarks were digitized and a mapping procedure was used to determine the force and pressure distribution on the patellar surface through the flexion range (Wilson, 2002). Measurements were made for Q-angles of 0°, 5° and 10°.

Geometric models of each knee were constructed from CT images (Analyze, Mayo Foundation). The Q-angle was varied to simulate each experimental test. The tibia was flexed about the femur in 10° intervals. The patella was flexed, and aligned with the femur by aligning the posterior patella with a parallel surface within the trochlea. A static force analysis of the tibia determined the patella tendon force, which was used to quantify the quadriceps force (Huberti, 1984). For these input forces, the patellofemoral pressure distribution was quantified using the discrete element analysis technique (Elias, 2002). Variations in the total patellofemoral force, the ratio of the force applied to the lateral cartilage to the total force, and the position and magnitude of the medial and lateral pressure peaks were compared to the experimental results. The pressure peaks were normalized by the peak lateral pressure at the deepest flexion angle for a Q-angle of 5° to compare the experimental and computational results.

RESULTS AND DISCUSSION

For the 5° Q-angle, the model predicted force increases over the range of motion of 105% and 69% for knees 1 and 2, respectively, while these changes were measured to be 121% for knee 1 and 65% for knee 2. The model predicted the experimental finding that increasing the Q-angle from 0° to 10° increased the relative force on the lateral compartment (averaged over the flexion range) by 8% to 12%.

Fig. 1: Measured (top) and predicted (bottom) pressure distribution (flexion = 80°, knee 1).

The model predicted an increase in the peak pressure with flexion, as was found in the experiments. Increasing the Q-angle shifted the area of concentrated contact pressure laterally (Fig. 1) and increased the peak lateral pressure (Fig. 2). Predictions for knee 1 were more accurate than for knee 2.

Fig. 2: Variations in the computational (Comp) and experimental (Exp) peak lateral pressure with the flexion angle and Q-angle for knee 1 (top) and knee 2 (bottom).

SUMMARY

The computational model predicted how the patellofemoral force and pressure distributions vary with the flexion angle and Q-angle. This model will allow clinicians to predict how surgical procedures will influence patellofemoral biomechanics for computationally simulated activities.

FINITE ELEMENT MODELING AND ANALYSIS OF SINGLE CELL MICROMANIPULATION USING MAGNETIC BEADS

H. Karcher, M.R. Kaazempur-Mofrad and R.D. Kamm

Department of Mechanical Engineering and Division of Bioengineering and Environmental Health
Massachusetts Institute of Technology, Cambridge, MA

INTRODUCTION

The objective of this study is to provide insight in the mechanical reaction of the cell during magnetocytometry experiments (application of a controlled force to a single cell via magnetic microbeads). A computational finite element model is developed to analyze the forcing of one microbead on a cell monolayer and determine the patterns of induced mechanical stress/strain fields. Detailed distribution of displacement and stress fields can then be used to: (i) determine the mechanical properties of the cells, (ii) correlate the localized stress/strain patterns to biological responses of the cell, and finally (iii) offer a simple theoretical model to explain the experimental observations.

MODEL DESCRIPTION

Geometry and Material Properties. The model consists of two parts: the magnetic bead of diameter $4.5\mu\text{m}$ and the cell monolayer. The cell monolayer is itself composed of (i) a cylinder ($20\mu\text{m}$ high and $60\mu\text{m}$ wide) accounting for the cytoskeleton and (ii) an infinitely thin plate featuring the membrane and the actin cortex. The model allows for increasing the contact surface between the bead and the membrane. The magnetic bead is modeled as a homogeneous, isotropic elastic (Hook) model with Young's modulus of $E=10,000\text{ Pa}$ and Poisson's ratio of $\nu=0.30$ (McVittie, 2000). The cell membrane and actin cortex are assumed as incompressible homogeneous, isotropic viscoelastic (Maxwell) model with bending stiffness of $D=2\cdot 10^{-19}\text{ N.m}$ and shear viscosity of $\mu=10^{-3}\text{ dyn.s./cm}$ (Hwang, 1997; Evans, 1983). The cytoskeleton too was modeled as Maxwell model with shear modulus and viscosity of $G_C=100\text{ Pa}$ and $\mu_C=100\text{ Pa.s}$ (Yamada, 2000).

Boundary conditions. A zero-displacement is imposed at the bottom surface, i.e. the cell monolayer is fixed to a rigid substrate. No other constraint is imposed on the perimeter of the cell monolayer (free stress). The magnetic forcing on the bead is represented by a $0.5\mu\text{m}$ displacement imposed in 2s at the center of the bead.

Solution Techniques. A finite element model was developed using a commercially-available software ADINA (Watertown, MA). The mesh consisted of 2016 quadrilateral elements with 31,495 nodes. The thin membrane was modeled with a single layer of nodes and shell elements.

RESULTS AND DISCUSSION

A linear relationship between reaction and displacement at the center of the bead is observed with slope $28\text{pN}/\mu\text{m}$. It is however possible that a further displacement of the bead gives rise to non-linearity. The stress field appears localized at the vicinity of the bead (cutoff radius of $5\text{-}8\mu\text{m}$) and dominated by

shear stress rather than pressure. The displacement field (see Fig.1) exhibits a pulling/squeezing pattern characteristic of the bead rolling. More interesting is the existence of a zero-displacement zone right below the bead. Work is currently underway to impose a greater displacement to probe the degree of microbead's rolling/translation.

Fig. 1: Displacement field in the x-direction. Cross-sectional view. The displacement is imposed along the x-direction. Only a part of the bead (unfilled light blue line network) is displayed.

SUMMARY

A computational FEM model is developed for the magnetocytometry micromanipulation of the cell. The model provides a robust tool for analysis of detailed strain/stress fields induced in the cell monolayer. Correlation of the computational model and experimental findings promises to shed light on the mechanical properties of the cell and their variation under different mechanical/biological stimulations.

THE VARIABILITY OF MAXIMUM VERTICAL JUMPS

Sukhoon Yoon¹ and John H. Challis²

¹ Biomechanics/Sports Medicine Lab, The University of Tennessee, Knoxville, Tennessee, USA, syoon1@utk.edu

² Biomechanics Laboratory, Department of Kinesiology, The Pennsylvania State University, University Park, Pennsylvania, USA

INTRODUCTION

The kinematics and kinetics of maximum vertical jumps have been the subject matter of a large number of studies. However, little attention has been given the variability of the performance of maximum vertical jumps. The purpose of this study was to examine for a group of subjects the variability of a series of maximum vertical jumps. The study analyzed the kinematics and kinetics of the jumps, and computed intra-subject (within-subject) and inter-subject (between-subjects) variability.

METHODS

Ten healthy male subjects (age: 25.3 ± 3.1 years; height: 177.5 ± 5.8 cm; body mass: 73.4 ± 8.5 kg) each performed ten maximum countermovement vertical jumps. Force plate (Type 4080s, Bertec) and kinematic (Pro-Reflex System) data were collected from the initiation of movement until the instant of take-off. From these data resultant joint moments were computed. For each subject and the group data the coefficients of variation (CV; Winter, 1983) were computed for the joint angles, angular velocities, ground reaction forces, and resultant joint moments.

RESULTS

The mean jump height was 0.33 ± 0.072 m; the mean CV for the subject in jump height was $5.1 \pm 2.7\%$. The intra- and inter-subject joint angle and angular velocity profiles all showed low variability (Table 1), with the trend, seen throughout these results, that the intra-subject variability was lower than the inter-subject variability.

Table 1: The mean (\pm standard deviation) of the coefficients of variation for the intra-subject and inter-subject joint angle and angular velocity profiles for the vertical jumps.

Joint	Joint Angle		Joint Angular Velocity	
	Intra-Subject	Inter-Subject	Intra-Subject	Inter-Subject
Ankle	$2.3 \% \pm 0.7$	6.9%	$13.4 \% \pm 4.2$	20.2%
Knee	$4.1 \% \pm 1.4$	9.7%	$12.6 \% \pm 3.5$	23.2%
Hip	$4.3 \% \pm 1.0$	8.1%	$11.7 \% \pm 2.3$	20.7%

The horizontal ground reaction force profiles were produced with larger relative variability than the vertical forces (Table 2). The mean peak horizontal ground reaction force was 2.2 ± 0.3 N.kg⁻¹, which is much smaller than the mean of the peak vertical ground reaction force for all subjects that was 22.8 ± 2.6 N.kg⁻¹, where the ground reaction force data have been normalized with respect to each subject's body mass.

Table 2: The mean (\pm standard deviation) of the coefficients of variation for the intra-subject and inter-subject ground reaction force profiles for the vertical jumps.

Ground Reaction Force	Intra-Subject	Inter-Subject
Horizontal	$40.9 \% \pm 9.8$	84.0%
Vertical	$8.3 \% \pm 1.9$	19.0%

The resultant joint moment profiles all showed the lowest variability at the knee joint followed by ankle and hip joints (Table 3). This trend was consistent across all subjects, and for the inter-subject data. The variability of the support moment (sum of all extensor moments) was very similar to that of the ankle joint.

Table 3: The mean (\pm standard deviation) of the coefficients of variation for the intra-subject and inter-subject resultant joint moments for the vertical jumps.

Joint	Intra-Subject	Inter-Subject
Ankle	$14.8 \% \pm 2.3$	28.1%
Knee	$12.7 \% \pm 1.9$	25.7%
Hip	$20.6 \% \pm 4.3$	36.9%
Support	$15.0 \% \pm 2.1$	28.8%

DISCUSSION

Vertical jumping has received considerable attention in experimental and modeling studies. This study addressed the variability of maximum vertical jumps. The data from this study were contrasted to data on the variability of human gait and running (Winter, 1983, 1991). The jumping task had much lower variability, it is hypothesized that this lower variability was due the maximal nature of the task, and/or because jumping has a relatively invariant movement pattern.

This study has investigated the variability of the kinematics and kinetics of maximal vertical jumps. It has demonstrated that for this maximal task, the jumps are produced very consistently both intra- and inter-subject. It would be interesting to see if this trend exists for the other maximal tasks. The study provides guidance for design of studies of jumping, as the low variability of all measures vindicates those studies that select only one trial from a sequence of trials for detailed analysis

CALIBRATION OF KINEMATIC MODELS FOR MOTION CAPTURE

Iain W. Charlton, Paul Tate, Paul Smyth and Lasse Roren

Vicon Motion System Ltd, 14 Minns Business Park, West Way, Oxford, UK, OX2 0JB

www.vicon.com

INTRODUCTION

In the past, the measurement of human kinematics through marker based motion capture has relied on relationships between marker triads (technical – anatomical calibration, Williams *et al.*, 1996, Murray, 1999). Furthermore, knowledge of the constraints provided by the skeleton has only been utilized recently (global optimisation, Lu and O’Conner, 1999). Such constrained models are sensitive to estimates of the joint centres, segment lengths and marker locations. The use of statistical information in marker position and joint locations is also rarely used to contribute to the overall quality and confidence measure in estimated kinematic data.

We present a method for utilising generalised kinematic models of the skeleton and optimising the parameters using confidence measures in both the initial and the improved estimate based on the range of movement measured.

METHODS

A parameterised lower limb skeletal model was used, containing joint locations, joint types, segment lengths and marker locations on the various segments. Data was captured at 120Hz over 4 seconds from a single subject performing a relatively large range of motion with the legs.

Using standard algorithms, the model markers were fitted to measured marker data by minimising the Mahalanobis distance (statistical measure) in the error between model and measured marker co-ordinates for each time frame.

Calibration of the skeletal model was then performed by optimising the locations of markers, joint centres and segment lengths. This was done by minimising the Mahalanobis distance in marker error for a number of time frames simultaneously as a function of the skeleton model parameters. This was augmented by minimising the Mahalanobis distance in the difference between the original and predicted model parameters. A-priori estimates of the covariance in model marker locations and other model parameters were used in the calculation of Mahalanobis distances in both cases. A standard Levenberg – Marquardt algorithm was used to solve these equations.

Following each calibration step, a new kinematic fit was performed and the whole process repeated until a suitable convergence criterion in fit residual was met.

RESULTS AND DISCUSSION

The RMS fit residual for the initial model was 29.3mm, which rapidly reduced to 2mm after 3 iterations of the calibration procedure. Little improvement in the residual took place subsequently (Figure 1). Several discontinuities in the joint angles were also removed by the calibration process.

Figure 1: RMS residual in fit during the calibration process.

SUMMARY

A method is presented for optimising generalised skeletal models, which accounts for confidence in the model accuracy. Also, the nature of the kinematic models is divorced from the calibration process, allowing varying complexity and different types of model to be used.

Convergence of the calibration algorithm to an order of magnitude less than the fit residual is rapid. Furthermore, confidence in the optimised model parameters is available retrospectively, allowing quick assessment of the suitability of captured data for the calibration process.

BIOMECHANICAL DIFFERENCES OF FALL ARREST USING THE UPPER EXTREMITY DUE TO AGING

Kyu-Jung Kim, Ph.D.¹, James A. Ashton-Miller, Ph.D.²

¹Department of Mechanical Engineering, University of Wisconsin-Milwaukee, Milwaukee, WI, USA, kimk2@uwm.edu

²Department of Mechanical Engineering and Applied Mechanics, University of Michigan, Ann Arbor, MI, USA

INTRODUCTION

Falls impose significant threats to the health of older adults. Especially, fractures of the upper limb account for approximately one third of total osteoporotic fractures. A great majority of the upper limb fractures occur as a result of using the upper extremity to break a forward or backward fall and a subsequent direct impact of the fractured site. Earlier epidemiology and clinical studies failed to incorporate the aspects of the faller's activities during falling. It is unclear whether a specific age group of fallers who experience upper limb fractures has some characteristic body reactions during the fall incidence.

METHODS

Ten old males were volunteered to participate (Mean: age = 66.4 years). Ten healthy young males with matched height and weight were also volunteered as a control group (Mean: age = 24.1 years). A subject wearing a safety harness was standing on a narrow platform. Four different distances between the base of the platform and the wall-mounted force plate were maintained at 40 cm, 60 cm, 80 cm, and 100 cm, respectively. Two different types of falling mode were repeated three times at each distance. With hands down, a subject voluntarily initiated the forward lean at the comfortable speed and broke the fall by putting the hands on the force plates (self-initiated falls). With hands down, a subject was leaning forward at 10 degrees vertically into the lean control cable. The cable was released after a random time delay (0~5 sec) and the subject broke the fall by the same way above (cable-released falls). The 3-dimensional positions of the markers at each joint in the upper extremity were recorded at 300 Hz using an optoelectronic motion analysis system. The impact forces on the hand were simultaneously recorded. To test the effects of fall distance, age, or falling mode on the impact force and joint kinematics parameters, fully-factorial multiple analysis-of-variance (ANOVA) was conducted.

RESULTS AND DISCUSSION

The measured impact force demonstrated a characteristic bimodal pattern with two distinct impact (F_1) and braking (F_2) peaks (Chiu 1998, Kim 2001). The fall impact conditions were moderate compared to the reported fracture loading (Table 1). From the ANOVA, the falling distance showed statistically significant effects on all the impact force and timing parameters ($p < 0.05$) except for the peak impact time ($p = 0.846$). The age effect was demonstrated in the timing

parameters ($p < 0.04$). Similar results were obtained from the ANOVA for the joint kinematic parameters. The falling distance affected all the kinematic parameters ($p < 0.0005$). The age effect was noted in the wrist and elbow joint angles at touchdown ($p < 0.0005$). The old adults (OA) tended to extend their wrists less but extend their elbows more at touchdown than the young adults (YA) or have more outstretched arms

The falling mode (self-initiated vs. cable-released) had another major effects on all the parameters from the ANOVA ($p < 0.018$), except again for the peak impact time ($p = 0.189$). The OA showed more dramatic differences in their performance between the two different types of falling. Especially, at closer positions (40 or 60 cm), the OA had a 10 to 15 times higher peak impact force ($p < 0.05$ from post hoc t-tests) and a 3~4 times shorter peak braking time ($p < 0.05$) in cable-released falls. Subsequently, the joint kinematic parameters were significantly different between the two types of falling mode at those positions ($p < 0.02$).

SUMMARY

Though having similar physical capabilities of successfully arresting falls, the OA demonstrated more detrimental impact and kinematics conditions under the circumstance with limited available reaction time.

Table 1. Peak impact (F_1) and peak braking forces (F_2), and corresponding occurrence times after touchdown (T_1 and T_2 , respectively) for cable-released falls. (Mean \pm S.D.).

Distance	Group	F_1 [BW]	F_2 [BW]	T_1 [msec]	T_2 [msec]
40 cm	YA	0.25 \pm 0.13	0.23 \pm 0.07	34 \pm 10	153 \pm 29
	OA	0.43 \pm 0.19*	0.24 \pm 0.05	39 \pm 13	110 \pm 28
60 cm	YA	0.29 \pm 0.18	0.29 \pm 0.05	36 \pm 12	185 \pm 66
	OA	0.28 \pm 0.14†	0.26 \pm 0.04	46 \pm 17	170 \pm 49
80 cm	YA	0.32 \pm 0.19	0.35 \pm 0.06	47 \pm 24	191 \pm 78
	OA	0.20 \pm 0.17	0.31 \pm 0.04	43 \pm 27	204 \pm 76
100 cm	YA	0.42 \pm 0.28	0.42 \pm 0.05	39 \pm 17	143 \pm 46
	OA	0.31 \pm 0.23	0.37 \pm 0.04	46 \pm 30	168 \pm 34

THE FORCE-VELOCITY RELATION STUDIED WITH A PNEUMATIC LEG-EXTENSION DEVICE

F Borg, M Herrala

Jyväskylä University/Chydenius Institute, Kokkola, Finland

INTRODUCTION

The purpose of the present study was to find out whether a simple Hill-modell for the muscle could be useful for understanding the results obtained using an off-the-shelf pneumatic leg extension exercise machine (non-isokinetic).

MATHEMATICAL MODEL

We use one of the simplest versions of the Hill-modell as described e.g. by W Herzog (1995). Accordingly the force-velocity relationship may be written as

$$(1) \quad \frac{v}{v_0} = \frac{1 - \frac{F}{F_0}}{1 + c \frac{F}{F_0}} \quad \frac{F}{F_0} = \frac{1 - \frac{v}{v_0}}{1 + c \frac{v}{v_0}}$$

where F_0 is the isometric maximum force, and v_0 is the maximum contraction velocity. We have only one parameter c , the so called *shape parameter*. Generally, a higher value for c suggests a muscle with a higher proportion of fast twitch fibers. Using the scaled variables $u = v/v_0$ and $f = F/F_0$ the force-velocity relation describes a symmetric curve. From this one sees that the power $P = Fv$ attains its maximum at the midpoint of the curve for which

$$(2) \quad u = f = \frac{\sqrt{1+c} - 1}{c}$$

Nigg and v. d. Bogert (1995) quote a typical value around $c = 2.5$ for the shape parameter which corresponds to a maximum power output at velocity $v = 0.35 v_0$ and force $F = 0.35 F_0$.

METHODS

A pneumatic resistance machine (HUR Co, www.hur.fi) was used for recording MVC leg extensions employing varying resistance levels (2 to 8 bars). An inclinometer measures the angle of the lever (a measure of the joint angle) and a force transducer measures the torque exerted by the lower leg. Also isometric tests were performed in order to obtain the maximum isometric force. If we map the maximum torque versus maximum angular velocity for the tests we get points that generally lie quite close to a downsloping line as expected from the force-velocity relation. The shape parameter c for each subject was calculated by solving (2) for c by setting $f = TQp/TQ0$, where TQp is the torque measured at maximum power output and $TQ0$ is the isometric maximum. Since c is quite sensitive to the variations in the f we get a quite high variation in c between individuals. However, using a data set provided by Raimo Kuhanen (Kultu, Research Institute of Exercise Medicine) comprising 25 subjects, we were able to do some statistics.

RESULTS AND DISCUSSION

Measurements from 25 male (semipro hockey team) were analyzed (right leg). Computing the shape parameter as described above we obtained an average value of 3.04 ± 2.23 . The average of the scaled torque (which is the same as scaled force) $TQp/TQ0$ was 0.35 ± 0.06 which may be compared to the quoted value of 0.35; i.e., $c = 2.5$. The maximum velocity $VEL0$ measured at the lowest load is naturally an underestimate of the true maximum velocity. From the average velocity at maximum power, $VELp$, which was found to be 410 deg/s (7.16 rad/s), we can estimate the average of the maximum velocity v_0 as $VELp/0.35 = 1170$ deg/s (20.4 rad/s), which is about 0.66 m/s for a quadriceps muscle assuming a moment radius of 3.3 cm. Above we have neglected the muscle length factor. More accurate results could likely be obtained taking this into account, but as a first approximation (1) will do as the joint angle region for maximum power were quite similar for all subjects. An interesting observation is that if we fit a straight line (which works quite well)

$$(3) \quad TQ = a \cdot VEL + b$$

to the measured torques and velocities (a straight line approximation of the force-velocity curve) it is found that the a and b parameters are strongly correlated. This can be easily explained on the basis of (1) if we suppose that (3) is close to a tangent to the curve (1). Indeed, (1) would then predict a relationship

$$(4) \quad a = -\frac{1}{v} b + \frac{F}{v}$$

where v is the velocity and F the force at the tangent point. Indeed, when we calculated the averages of $1/VEL$ and TQ/VEL for the 3 bar resistance level tests we got 0.00238 s/deg and 0.255 N m s/deg respectively, to be compared with the regression line $a = -0.00238 b + 0.258$ for the a and b parameters of the test group (correlation coefficient being - .80).

SUMMARY

Our cursory study shows that the simple Hill-modell (1) can help explain some important features of the data obtained with the pneumatic leg extension machine and thus suggests future comparisons with more detailed models.

EFFECT OF A COMPRESSIVE FOLLOWER LOAD AND A TENSILE FORCE ON INTRADISCAL PRESSURE AND INTERSEGMENTAL ROTATION OF THE LUMBAR SPINE

Hans-Joachim Wilke¹, Antonius Rohlmann², Sylvia Neller¹, Georg Bergmann², Lutz Claes¹

¹Dept. of Orthopaedic Research and Biomechanics, University of Ulm, Ulm, Germany, hans-joachim.wilke@medizin.uni-ulm.de

²Biomechanics Laboratory, University Hospital Benjamin Franklin, Free University of Berlin, Germany, rohlmann@biomechanik.de

INTRODUCTION

Various loading conditions are used for investigations on the spine. This makes a comparison of different studies difficult. Pure moments in the three anatomical main planes have the great advantage that all spine levels are exposed to the same constant load.

Patwardhan et al. (1999) introduced a follower load which stabilizes the spine considerably. A follower load is a compressive load applied along a follower load path that approximates the tangent to a curve of the lumbar spine, thus subjecting the whole lumbar spine to nearly pure compression. Loading the spine in tension is difficult to realize in normal life since muscle forces will prevent this. However, passive traction may be possible in the operating theatre under anesthesia. The behavior of a disc under axial tension is not fully understood.

The aim of this study was to determine the influence of a follower load up to 280 N and an axial tensile load up to 240 N on intradiscal pressure and intersegmental motion of the lumbar spine.

MATERIAL AND METHODS

Ten fresh-frozen, human cadaveric lumbar spines were tested. All soft tissue was removed, leaving the capsules, ligaments, and other supporting structures intact. Biomechanical testing was performed in a spine loading apparatus (Wilke et al., 1994). The specimens were stepwise loaded and unloaded with a follower load of up to 280 N with steps of 20 to 30 N and then with an axial tensile force of up to 240 N with steps of 10 to 20 N. This loading procedure was performed twice. During the first loading only translation but no angular motion of the upper vertebra was allowed, while during the second loading unconstraint motion of the upper vertebra was possible.

The compressive follower load was applied to the specimens using a cable and dead weights. The cable was passed through the center above of the cranial L1 vertebral endplate and guided through eyelets fixed laterally on both sides in the middle of the a.p. diameter of each vertebral body. Thus the load path followed the curvature of the lumbar spine in the sagittal plane. Because the cable guides moved with the vertebrae, the load path approximated the tangent to the spinal curve also when the spine was deformed under loading (Rohlmann et al, 2001).

Intradiscal pressure was measured in each disc by flexible pressure transducers. They had a constant diameter of 1.2 mm. Intersegmental motion was measured simultaneously at each level using an ultrasound based 3D motion analysis system. This system was fixed to the frame of the spine tester and to each mobile segment of the specimen.

RESULTS

Intradiscal pressure increased nearly linearly at all levels with increasing follower load. For an axial tensile force up to about 100 N the pressure changes as function of the force were nearly the same as during compression. For higher tensile forces the pressure changes were only small. The different disc levels showed the same tendency, however, the maximum pressure was higher for the upper than the lower levels. Constraining angular motion of the L1 vertebra had only a minor influence on intradiscal pressure.

The deformation of the specimens due to a follower load was relatively small in the case where the L1 vertebra could rotate freely. It occurred mainly in the sagittal plane. For a follower load of 280 N the average total angle in that plane was about 5.5° and for the tensile force of 240 N it was around 4.5°. The lordotic curvature of the specimens decreased for both loading cases. A follower load caused nearly the same angular motion changes at all levels while a tensile force led to higher deformations in the lower than in the upper lumbar spine. The interspecimen differences were high, especially at the levels L3-L4 and L4-L5. When angular motion of the L1 vertebra was constrained, the deformation of the specimens was negligible.

DISCUSSION

The results of this study with a follower load are in agreement with those of previous studies (Rohlmann et al, 2001, Patwardhan et al, 1999). An axial tensile force of up to 100 N led to nearly the same relative intradiscal pressure changes as a reduction of 100 N follower load to the unloaded state. A further increase of the axial tensile force had only a slight effect on intradiscal pressure. For both, follower load and axial tensile load, the deformations of the specimens were similar. The specimens were straightened and their lordotic curvature decreases. In the case of follower load the cable guides on the lateral side of the vertebra were responsible for this straightening. A vertical compressive load without cable guides would have increased the curvature of the specimens. Constraining angular motion of the L1 vertebra during loading had only a minor effect on intradiscal pressure but a considerable one on the angular deformation of the specimen. These deformations were relatively small and had therefore obviously only a slight effect on intradiscal pressure.

PASSIVE STRETCHES PROTECT MUSCLE IN OLD AND YOUNG MICE FROM LENGTHENING CONTRACTION-INDUCED INJURY

Timothy J. Koh¹, Jennifer M. Petersen², Francis X. Pizzi², Susan V. Brooks¹

¹Institute of Gerontology, University of Michigan, tjkoh@uic.edu

²Department of Kinesiology, University of Toledo

INTRODUCTION

Conditioning with lengthening contractions protects skeletal muscles in young and old animals from subsequent lengthening contraction-induced injury, although muscles in old mice appear to adapt more slowly (McBride et al., 1995; Brooks et al., 2001). Lengthening contractions and associated damage are not required for inducing protection in young mice, as stretches of passive muscle and isometric contractions protect muscle from injury in these mice (Koh and Brooks, 2001). We tested the hypothesis that passive stretches and isometric contractions would also protect muscle in old mice from contraction-induced injury.

METHODS

Extensor digitorum longus (EDL) muscles from young (3 month old) and old (24 month old) mice were subjected *in situ* to lengthening contractions either with or without prior conditioning with passive stretches or isometric contractions (n=7-9 each group). Conditioning was performed using 75 repetitions at 0.25 Hz of either passive stretches of 20% strain relative to optimal muscle fiber length (L_f) or 75 isometric contractions at L_f with stimulation at 150Hz. Two weeks after conditioning, 3 sets of 75 lengthening contractions were performed using strain of 20% L_f initiated 100ms after 150Hz stimulation. Three days after lengthening contractions, maximum isometric force was measured *in situ* and muscles excised for histological analysis. Injury was assessed by the deficit in maximum isometric force (P_o) compared to that measured before lengthening contractions. Data were analyzed using two-way analysis of variance.

RESULTS AND DISCUSSION

Mouse mass was significantly greater for old versus young mice ($p < 0.05$), whereas EDL muscle mass, initial P_o , and specific P_o did not differ significantly, and were virtually identical (Table).

Table. Body mass, EDL muscle mass and P_o for young and old mice. Means and standard errors shown. *significantly different from young ($p < 0.05$).

	Young	Old
Body mass (g)	26.4 (0.6)	30.3 (0.6)*
EDL mass (mg)	10.3 (0.2)	10.6 (0.2)
P_o (mN)	397 (11)	396 (11)
Specific P_o (N/cm²)	23.4 (0.6)	22.8 (0.6)

Unconditioned muscle from both young and old mice showed large force deficits following the lengthening contraction protocol ($p < 0.05$; Figure). There was a significant effect of

conditioning on the force deficit ($p < 0.05$) but no significant effect of age. There was also no significant interaction effect. Post-hoc analysis using the Student-Neumann-Keuls test indicated that only conditioning with passive stretch significantly reduced the force deficit. These results demonstrate that conditioning with passive stretch protects skeletal muscle in both young and old animals from subsequent lengthening contraction-induced injury, with no difference in protection between young and old mice.

Figure. Force deficits 3 days after 225 lengthening contractions for unconditioned EDL muscles and muscles conditioned with passive stretches or isometric contractions. Data from young and old animals were grouped for this figure. Means and standard errors shown. *significantly different from unconditioned ($p < 0.05$).

SUMMARY

The major finding of this study was that a single bout of passive stretches protected EDL muscles in both young and old animals from subsequent lengthening contraction-induced force deficits. Additional assays of injury including percentage of overtly injured fibers and inflammatory cell involvement are ongoing. The results of this study may have implications for protecting muscle in old individuals from damage.

BLOOD FLOW STRUCTURE CONTRIBUTING TO THE RUPTURE OF CEREBRAL ANEURYSM

Taku Morino¹, Kiyoe Nomura, Takatsugu Yamauchi², Kazuo Tanishita³, Satoshi Tateshima⁴, Yuichi Murayama and Fernando Vinuela

¹Center for Life Science & Technology, Keio University, Yokohama, Japan, taku@2000.jukuin.keio.ac.jp

INTRODUCTION

The overall morbidity and mortality for aneurysmal subarachnoid hemorrhage is unacceptably high, even though most cerebral aneurysms do not rupture. The decision to perform preventive treatment for unruptured aneurysms must be based on a prediction of which aneurysms are likely to rupture. However, there are no reliable predictors for rupture now. Ujiie et al. reported that intra-aneurysmal flow was classified into two patterns according to aspect ratio (dome depth/neck width) and one was associated with rupture (1999). We measured detailed flow structure with PIV and LDV in realistic cerebral aneurysm models based on CT images in order to discuss the relationship between rupture and blood flow structure.

METHODS

We built three realistic rigid models of cerebral aneurysm by photoforming method. Model 1 is an unruptured middle cerebral bifurcation aneurysm, model 2 is a ruptured middle cerebral aneurysm, and model 3 is an unruptured basilar tip aneurysm. The flow waveform in the parent arteries was simulated to the physiological pulsatile flow in cerebral arteries. Maximum/mean/minimum Reynold's number was 680/520/410 for model 1 and 2, and 800/430/340 for model 3. Frequency parameter was 6.0 for model 1 and 2, and 5.0 for model 3. We used a laser Doppler velocimeter (LDV) and particle image velocimetry (PIV) for the velocity measurement and estimated wall shear stress.

RESULTS AND DISCUSSION

We found that intra-aneurysmal flow was classified into two patterns according to aspect ratio, which corresponds to Ujiie et al.'s study (1999). One consisted only of single circulating flow in model 1 (Figure 1-a) and 3, the other consisted of circulating flow and recirculating flow in the bleb in model 2 (Figure 1-b). Model 2 is ruptured aneurysm and the flow pattern as in Fig.1-b seems to be associated with rupture.

Figure 2 shows wall shear stress distribution in model 2. The values were extrapolated in order to match with that in human cerebral aneurysms. It had a peak at the bleb ($x^* = 0$). Rupture

of cerebral aneurysm occurs preferentially at bleb. Therefore, high wall shear stress might be related to the rupture.

SUMMARY

We measured detailed velocity profiles with PIV and LDV in realistic cerebral aneurysm models based on CT images and also estimated wall shear stress. Physiological pulsatile flow in cerebral arteries was completely simulated in the parent arteries. Intra-aneurysmal flow was classified into two patterns and one seemed associated with aneurysmal rupture. Wall shear stress had a peak at bleb. That implies that cerebral aneurysm ruptures at bleb.

INTRODUCTION

The effects of two anesthetic protocols on stretch-injured and healthy rabbit skeletal muscle were assessed. The torque-producing capabilities of the tibialis anterior and the extensor digitorum longus muscles were measured at ankle joint angles of 0°, 30°, 60° and 90°. Isometric torque measurements were made at various intervals before and after an eccentric stretch injury to the right leg. One anesthetic protocol utilized an intramuscular injection of ketamine, xylazine and acepromazine; the other anesthetic was inhaled isoflurane. Torque data were obtained under each anesthetic for both healthy and injured legs.

METHODS

The injury system comprises a geared electric motor, a loading frame, a torque sensor, an angular position sensor, a closed loop control system, and disposable electrodes. The nerve stimulator provides a 50 Hz. pulse rate, 0.5-ms pulse width and variable current output.

To stimulate the peroneal nerve, two electrodes were used to direct current through the desired tissues. A small incision distal to the ankle over the dorsum of the foot exposed the TA tendon. The encapsulating fascia was then cut away. Both TA tendons were exposed, the right for the purposes of injury, the left as a sham operation. Once the surgery was complete, the rabbit was situated in the test apparatus such that its right leg was aligned so that the knee joint was at 90° and the foot permitted to follow the physiologic rotation of the ankle joint. An angular displacement of 90 degrees was applied to the ankle joint of an anesthetized rabbit while its hind leg was stabilized, the tibialis anterior tendon shortened, and the peroneal nerve stimulated to consistently produce a stretch injury. All animals were injured at 1.4 cm of tendon pre-shortening and stimulated with 2.8 mA of current. Talocrural joint angles 0, 30, 60 and 90 degrees were obtained in random order for each leg.

All rabbits were tested immediately prior to injury and immediately post injury. They were again tested at 4, 12, 18 and 24 hours post injury, followed by further testing at 3, 5, and 7 days. Rabbits 1-5 were anesthetized with 1.5 cc intramuscular injection into the gluteus maximus for a total of 3 ccs of a 3:1:1 ketamine: acepromazine:xylazine; redoses were 1 cc of ketamine as needed. Rabbits 6-10 were anesthetized with 3-5% isoflurane per 1.5-2 L O₂.

RESULTS AND DISCUSSION

In the first set (rabbits 1-5), considerable time was required for the rabbits to recover from the intramuscular anesthetic, and the testing schedule on day 1 proved to be particularly stressful to the animals. Rabbit 4 died under initial injection. Rabbit 1 showed extreme sensitivity after Day 1 and could not be stimulated via surface stimulation. Under direct neural stimulation the muscle would not contract and the animal was sacrificed on Day 3 with an assumed neuropathy. Rabbit 2 showed similar sensitivity on Day 3 and no data were obtained on subsequent days. On Days 5 and 7, Rabbit 2 could tolerate stimulation although very low torque values were obtained. In each rabbit a steady decline in joint torque was observed for both the injured and sham control legs over the first 24hr with recovery in the following 3 days.

The rabbits anesthetized with isoflurane (Group 2; Rabbits 6-10) recovered from the anesthetic much more rapidly, and hence the testing schedule on day 1 was less stressful. The hypersensitivity demonstrated by the first group of animals was absent in the second group. Unlike the first group, Rabbits 6-10 showed no loss of joint torque in the sham control legs. The torque loss induced in the injured leg recovered in a similar fashion to the animals in Group 1.

SUMMARY

Ketamine has been linked to increased muscle acetylcholinesterase activity (Ingals et al, 1996). Veterinary evidence also links it to neuropathies in certain animals. (Schiffman and Lopez). The high doses required in our protocol appeared to have caused cumulative damage that was irreversible. Thus, it appears that at least for multiple time points of testing, inhalational isoflurane is preferable to intramuscular anesthetic regimens when assessing muscle and joint function.

INTRODUCTION

In the sport medicine, prosthesis and rehabilitation it is necessary to evaluate the dynamical loads on joint tissues during different motions. Usually, experimental simulators are used. However such experiments require a great deal of time and expense. In contrast the virtual simulators allows relatively quickly and accurate adjusting the model and evaluating dynamical load in the joint components during wide range of desirable motions. The goal of this work was to create the most realistic virtual mechanical model of the knee joint and to perform modeling allowed us to calculate a dynamical load on the main ligaments of the knee during so dangerous for Anterior Cruciate Ligament (ACL) motions, as jump landing and downhill skier backward fall.

METHODS

The mechanical simulator of the knee joint was created using ADAMS™ (Mechanical Dynamics, Inc., Ann Arbor, MI, USA) software. The application of the commercially available software allows us to create a universal tool for investigation loads in the knee joint. The knee model includes femur, fibula, tibia, meniscuses and surrounded soft tissues. Lateral and medial meniscuses are placed on the plateau of the tibia. Their movement is limited by corresponding ligaments. Each femoral condyle was modeled by two merged spheres, as described in (O'Connor J. et al., 1990) for the flat case. The anterior spheres are in contact with the patella implementing sphere-plane contact model, but the posterior spheres are in contact with spherical upper surfaces of the meniscuses. The contact forces are based on the Hertz's model of interaction, including stiffness, damping and friction. The lateral and medial meniscuses and condyles have surface of different curvatures. Therefore such model provides the tibio-femoral internal/external rotation in the joint (Ilyin I. et al, 2001).

The model includes cruciate, collateral and meniscus ligaments as well as patellar tendon. Each ligament or tendon was simulated by several nonlinear springs. The dependencies of force on deformation were obtained by spline approximation of real experimental data obtained in (Woo S. L-Y., D.J. Adams, 1990). All groups of muscles also were simulated by springs and dampers.

The simulator was evaluated in well-explored motion - curtsy, and then was applied for modeling of dynamical loads on cruciate ligaments during landing on heel after jump and during downhill skier backward fall.

RESULTS AND DISCUSSION

As the result of this work the virtual three-dimensional model of the human knee joint was developed, that allows exploring extremal loads in the joint.

The adequacy of this model to the real human knee was demonstrated by modeling the good explored motion - curtsy. The dependences of main ligament tension on the angle of knee flexion were obtained.

The model was applied to numerical modeling of dynamical loads in the knee joint during the landing on the heel after jump on the slippery and not slippery surfaces with different visco-elastic properties. This movement leads to anterior-posterior displacement of the thigh relatively to the shank at the moment of landing that results in tension of cruciate ligaments. It was shown that at the landing on the slippery surface, when the leg slips out under the man, the tensile force of ACL doubles tensile force of posterior cruciate ligament. Such landing on the relatively extended leg can lead to ACL rupture for older persons if the jump is 50 cm high. Then the ACL tension exceeds 1000 N.

The dynamical load on ACL during the downhill skier backward fall was analyzed. The following was revealed:

- During the backward fall the shank moves forward relatively to the thigh. The maximum load on ACL corresponds to maximum horizontal acceleration of the shank, which is achieved at the knee flexion angle equal to 90 degrees.
- Decrease of the angle between top of the ski boot and ground decreases the risk of ACL injury up to 20%.
- Increase of quadriceps contraction during the backward fall proportionally decreases the maximum load on ACL.
- Maximum load on ACL proportionally increases with increase of skier's weight.

Thus, there was developed a universal tool to explore different type of injury-dangerous motions of the knee joint.

EFFECTS OF JOINT ANGLE ON RECOVERY OF TORQUE FOLLOWING MUSCLE STRETCH INJURY

INTRODUCTION

Measurement of joint torque provides important information about recovery following muscle injury in animal models (Warren et al, 1999). The torque-joint angle profiles for normal and stretch-injured muscle were determined in 6 New Zealand White rabbits. Isometric torque-producing capabilities of the tibialis anterior (TA) and extensor digitorum longus (EDL) muscles were measured at talocrural joint angles of 0°, 30°, 60° and 90° (90° corresponds to full plantar flexion). Torque data were obtained under isoflurane anesthesia at several time points post-injury to determine the effects of joint angle and time post-injury on recovery following a controlled muscle stretch injury (Fig 1-3).

METHODS

The injury system consists of a geared electric motor, a loading frame, a torque sensor, an angular position sensor, a closed loop control system, and disposable electrodes. The nerve stimulator provides a 50 Hz. pulse rate, 0.5-ms pulse width and variable current output.

The animals were anesthetized with 3-5% isoflurane/1.5-2 L O₂. A current-driven surface neural stimulation system was designed and fabricated to produce TA muscle tetany. This non-invasive system provides reproducible and consistent stimulation of the TA without co-contraction of the antagonist hamstrings. Prior to muscle stimulation, the TA tendon was pre-shortened 1.4cm with a customized tendon-shortening device. An angular displacement of 90 degrees was then applied to the ankle joint while the peroneal nerve was simultaneously stimulated to produce a stretch injury at the TA myotendinous junction. Pilot testing demonstrated an order effect, thus the angle order (0, 30, 60, 90 deg) was kept the same through experiments on all 6 animals.

All rabbits were tested immediately prior to injury and immediately post injury. They were again tested at 4, 12, 18 and 24 hours post injury, followed by further evaluation at 3,5, and 7 days. Data are plotted as Mean +/- SEM (Figs 1-3).

RESULTS AND DISCUSSION

Torque deficits were most apparent at the intermediate angles (30° and 60°) compared with 0° and 90° (Figs 1 and 2). The magnitude of change in joint torque was largest in the first 24hr after injury (Figs 1 and 2). There was a noticeable torque deficit at all joint angles in the control leg immediately following injury (Fig 3).

Fig 1. Torque vs. Angle over Time post Injury (Injured leg)

Fig 2. Torque vs. Angle over Time post Injury (Injured Leg)

Fig 3. Torque vs. Angle over Time (Control Leg)

SUMMARY

There appears to be a continual decline in muscle performance in the first 24hr following stretch injury. However, a less severe deficit was also observed in the control leg immediately post injury that may reflect a host defense response, or perhaps an anesthetic effect. Loss in muscle performance following injury also appears to be effected by joint angle. Together, these findings may suggest early intervention to prevent the initial loss of muscle strength following stretch injury.

CONTRIBUTION OF MONO- AND BIARTICULAR MUSCLES TO EXTENDING KNEE JOINT MOMENTS IN RUNNERS AND CYCLISTS

Hans H.C.M. Savelberg and Sigrid Braspenning

Department of Human Movement Sciences, Nutrition and Toxicology Research Institute Maastricht, Maastricht University, The Netherlands. hans.savelberg@bw.unimaas.nl

INTRODUCTION

Generally differences in muscle properties, due to training, ageing or genetic predisposition, are studied by measuring maximal joint moments. For several reasons this approach gives limited information. Firstly, differences or adaptation in numbers of sarcomeres in series are neglected. To understand dynamic behaviour this knowledge is essential [Lieber and Fridén, 2000]. Secondly, this approach neglects that generally several muscles contribute to a joint moment. Moreover, control of the direction and magnitude of an external force requires tuning of the recruitment of mono- and biarticular [ant]agonists [Van Ingen Schenau *et al.*, 1992]. Consequently, adaptation of individual muscles to different movements are not uniquely represented by the maximal joint moment. In this study it is hypothesized that in all involved muscles functional differences or adaptations will exist for movements requiring different control of external force, *i.e.* cycling and running. It is expected that these adaptations are not independent. Also maximal joint moment will not be a sufficient measure to monitor this kind of differences.

METHODS

On a dynamometer ten runners [$>20\text{km/wk}$] and ten cyclists [$>100\text{km/wk}$] performed voluntary maximal, isometric knee extensions at twenty different combinations of knee [0 30 60 85 110degrees] and hip joint angles [0 40 70 100degrees]. The active knee joint moment was assessed. A model was used to determine RF length for each hip/knee joint combination [Hawkins and Hull, 1991]. This set up allowed to calculate changed contributions of both biarticular RF and monoarticular vasti to the knee joint moment [Herzog *et al.*, 1991].

RESULTS

No difference in maximal knee joint moment was found. However, the range of joint moments registered for the runners was smaller than for the cyclists, indicating that the runners had a flatter curve. Also the cyclists reached the maximal joint moment at more flexed knee joint angles. The latter was reflected in the knee joint angle at which the vasti contribute maximally: for runners this occurred at 74 degrees for the cyclists at 81 degrees [Figure 1]. Also the increase in joint moment contribution by the vasti in the studied knee joint range was larger for the cyclists than the runners. For the RF no significant differences between both groups were found. It seems that the range of joint angles studied coincided with the ascending part of the force-length curve of the RF for the runners and the top of the curve for the cyclists [Figure 2].

Figure 1: Change in contribution of vasti to knee extending moment as a function of knee joint angles for cyclist [triangles] and runners [circles]

Figure 2: Change in contribution of the RF to knee extending moment as a function of knee and hip joint angles for cyclists [lower surface] and runners [upper surface].

DISCUSSION

This study showed that differences in properties of mono- and biarticular knee joint extensors underlie similar maximal knee joint moment. For runners the optimal length of RF occurs to be larger than for cyclists, this might represent a larger number of sarcomeres in series [Herzog *et al.*, 1991]. The difference in optimal vasti length cannot unequivocally be addressed to the number of sarcomeres, alternatively it can be explained by a shift in maximal force ratios between the three heads of vasti. When knee and hip joint angle patterns for cyclists and runners are compared to the moment-angle diagrams, it occurs that cyclist use their vasti around optimal length, while runners operate on the lower part of the ascending limb. Both groups use their RF around optimal length. These different properties will lead to different ratios between both muscle groups in runners and cyclists. Since tuning between mono- and biarticular muscles affects direction of external force, it can be suggested that these different properties affect the co-ordination.

DISCOLIGAMENTOUS STRUCTURES OF THE LOWER CERVICAL SPINE GET INJURED IN *IN VITRO* LOW-SPEED SIDE COLLISIONS

INTRODUCTION

The role of ligamentous structures of the upper cervical spine in whiplash injury is still controversially discussed. Especially the alar ligaments are often deemed to be responsible for long lasting clinical symptoms. These ligaments protect the upper cervical spine against excessive lateral bending and axial rotation movements, which mainly occur in side collisions. The objective of the present in vitro-study therefore was to examine whether the alar ligaments or any other structures of the cervical spine are damaged in side collisions.

METHODS

An acceleration apparatus was designed, which allows acceleration of cadaveric cervical spine specimens in any desired direction. Its basic components are a pneumatic acceleration unit, a sled and a railtrack, which is 9m in length. On the sled the cervical spine specimens are fixed on a damped pivot table, which is allowed to tilt passively around an axis, which is aligned perpendicular to the direction of the acceleration. This damped pivoting movement accounts for the passive movements of the trunk during collision.

In order to guaranty adequate inertia, a dummy head was designed with a weight of 4.5kg. It can easily be mounted on the occiput of the cadaveric specimens. On the sled, before acceleration, this dummy head is suspended with a suspension cord, which is cut t_0 in order to allow the head to move completely unconstrained and to ensure physiological loading of the specimens.

Six human osteoligamentous cervical spine specimens (occiput to T1) were subjected to incremental 90°-side collision from the right without head contact beginning with 1g, followed by 2g, 3g, 4g, ... until structural failure occurred. For quantification of functional injuries, the three-dimensional flexibility of each single segment of the specimens was tested in a spine tester before and after each acceleration.

RESULTS

The sled acceleration pulses always had a duration of about 125ms. During the “1g”-collision, the maximum sled acceleration was in median 1.3g, during the “2g”-collision

2.4g and during the “3g”-collision 3.8g whereas the maximum resultant head acceleration was always nearly two-fold higher. Integration of the filtered accelerometer data resulted in a velocity change Δv of the sled of 4.3 km/h in the 1g-collision, 8.1 km/h in the 2g-collision and 12.5 km/h in the 3g-collision. In all six specimens structural failure always occurred in the lower cervical spine and always affected the left facet joint capsules and the intervertebral discs. In four specimens this damage occurred during the 2g-collision, in one during 3g's and in one during 4g's.

The flexibility of the specimens mainly increased in the lower cervical spine in lateral bending and to a minor extend in axial rotation. Inflexion and extension almost no destabilizing effect could be observed.

DISCUSSION

Low-speed side-collisions mainly seemed to stress discoligamentous structures of the lower cervical spine. The upper and middle cervical spine including the alar ligaments might have been less stressed since the bending moment arising from the weight of the head increases towards the lower segments.

Since the effect of muscle forces could not have been taken into account, the present in vitro study has to be deemed a “worst case scenario”. The measured critical sled acceleration of 2g to 4g until structural failure can therefore not directly be transferred to reality. However, clinically the lower cervical spine also seems to be more often affected by whiplash than the upper and middle cervical spine.

CONCLUSION

In vitro low-speed side collisions caused functional and structural injury to discoligamentous structures of the lower cervical spine but not to the alar ligaments.

INTRODUCTION

Vascular endothelial cells respond to fluid shear stress in a variety of ways (e.g. Davies, 1995). The close correlation between the early atherosclerotic lesions and branches of human arterial systems suggests that large gradients of the wall shear stress near arterial branches may play a role in the initiation and development of atherosclerosis. A number of studies have investigated the effects of fluid shear stress gradients on vascular endothelium (e.g. Tardy, *et al.* 1997). This study examines the effects of flows on endothelial cells, focusing on the local flow field near the wall where endothelial cells exist. Emphasis is given to cross-flows associated with shear stress gradients (or fluid accelerations) in the flow direction, and their effects on movement of molecules and biological cells in the fluid to endothelial cells on the boundary wall.

THEORETICAL CONSIDERATIONS

For simplicity, we limit our analysis to two-dimensional flows and use local polar coordinates for any smooth boundaries (shown in Figure 1). Shear stress at any point, e.g. point P, on the wall is

$$\tau_{R\theta} = \mu \left(\frac{1}{R} \frac{\partial V_R}{\partial \theta} + \frac{\partial V_\theta}{\partial R} - \frac{V_\theta}{R} \right)_{Wall}$$

With no slip boundary conditions, i.e. $V_R \equiv 0, V_\theta \equiv 0$, the wall shear stress gradient in the flow direction

$$G \equiv \frac{\partial \tau_{R\theta}}{R \partial \theta} = \frac{\mu}{R} \left(\frac{\partial^2 V_\theta}{\partial \theta \partial R} \right)_{Wall}$$

Continuity of fluid gives

$$\frac{\partial V_\theta}{\partial \theta} = - \left(R \frac{\partial V_R}{\partial R} + V_R \right)$$

With no slip conditions, we have

$$\left(\frac{\partial V_R}{\partial R} \right)_{Wall} \equiv 0 \quad \dots\dots\dots (A)$$

hence, the shear stress gradient

$$G = - \frac{\mu}{R} \left(R \frac{\partial^2 V_R}{\partial R^2} \right)_{Wall}$$

At given θ values, Taylor series of the V_R at point $R+\xi$ are

$$V_R(R+\xi) = V_R(R) + V'_R(R)\xi + \frac{1}{2}V''_R(R)\xi^2 + \dots$$

where ' represents the differentiation with respect to the R. Since $V_R = 0$ and $V'_R = 0$ at the wall (from equation A),

$$V_R(R+\xi) = \frac{1}{2}V''_R(R)\xi^2 = - \frac{G}{2\mu}\xi^2 \quad \dots\dots\dots (B)$$

Figure 1. Local polar coordinates for point P on the boundary.

RESULTS AND DISCUSSION

From equation B, we find that near the boundary wall, the cross-flow velocity V_R is proportional to $-G$. Figure 2 representing a schematic of the cross-flows, indicates that when shear stress gradients are positive (i.e. $G > 0$), there are fluid convections towards the boundary wall, and vice versa.

Figure 2. Schematics of cross-flows associated shear stress gradients G.

Depending on the flow geometries and conditions, the cross-flows, V_R may be comparable to or much smaller than the bulk flow, V_θ , but is still present provided there are changes in the wall shear stress (i.e. non-zero shear stress gradients). This is true for any smooth boundary walls, including parallel plate surfaces used in *in vitro* endothelial cell studies. The cross-flow convection, associated with shear stress gradients, affects the movement of molecules and cells in the fluid to endothelial cells at the boundary, as well as the dispersion of particles released by the endothelium into the fluid stream.

SUMMARY

This study addresses a related phenomenon of the effects of shear stress gradients on endothelial cells. We demonstrated that for any smooth boundaries, there are cross-flow fluid convections either towards or away from the boundary associated with local shear stress gradients. These convections influence the movement of biological cells and particles in the fluid to endothelial cells at the boundary, contributing to the interaction between endothelial cells and fluid shear stress gradients.

ON-ICE ACCELERATION AS A FUNCTION OF THE WINGATE ANAEROBIC TEST AND A BIOMECHANICAL ASSESSMENT OF SKATING TECHNIQUE IN ELITE ICE HOCKEY PLAYERS

Neil A. Purves, Moira N. McPherson, William J. Montelpare, Teresa Socha, Robert Thayer

Research Centre, School of Kinesiology, Lakehead University, Thunder Bay, Ontario, Canada
mmcphers@gale.lakeheadu.ca

INTRODUCTION

Success in ice hockey depends on an individual's ability to accelerate from a standing start or from a change in direction. Previous research to determine those factors which provided the greatest contribution to on-ice acceleration has been limited to 2D biomechanical analyses of skating technique, without regard for the influence of physiological measures. The purpose of this study was to predict on-ice acceleration in elite ice hockey players using peak anaerobic power and kinematic variables from a 3D analysis of the biomechanics of skating technique. A sub purpose of this study was to examine the variability of skating technique at the elite level.

METHODS

The study involved the analysis of 37 ice hockey players from the Florida Panthers and Los Angeles Kings participating in a 1999 Prospects Camp. The players completed a 30 second, maximal intensity Wingate anaerobic cycle ergometer test against a resistance of 0.095 kg.kg bodyweight⁻¹. Peak anaerobic power was calculated and recorded as the highest anaerobic power value produced during any of the five second intervals. One week following the Wingate anaerobic test, the players performed two maximal, on-ice accelerations over a distance of 20 meters, while being recorded at 60Hz by two, PanasonicTM CL-350 digital cameras mounted on Peak PerformanceTM pan/tilt heads. The Peak Performance 3D Video Analysis System and a 23 point spatial model were used to extract the raw coordinates for the fastest of the two trials for each player, as measured by a photoelectric timer. The system was then used to smooth the raw data and produce a 3D image. Center of mass and specific kinematic variables were measured at push-off and touchdown for the first five strides. Time, velocity and average acceleration were measured 1.52m, 3.03m, 4.54, and 6.06 from the first push-off. Descriptive statistics for all kinematic data were performed using SPSSTM. Exploratory principal components factor analyses (PCA) were performed using SASTM to a) filter the set of predictor variables by eliminating confounding kinematic variables from further analyses, and b) identify the underlying relationships between groups of kinematic variables which represent important characteristics of ice hockey skating. Performance measures for strides loading in series within variable sets identified by the PCA were transposed into a single composite score using a log-log transformation of the power function. Multiple regression analyses using a backward stepwise approach was used to determine the set of variables that best predict on-ice acceleration. The variability in skating technique was

examined using estimates of skewness and kurtosis for the variables identified by the PCA and predictive equation.

RESULTS AND DISCUSSION

The results of the PCA highlighted three latent variables that described key characteristics of skating. The loadings on each latent variable indicated that in order to optimize performance players should attempt to maximize their push-off during the first stride, prepare for propulsion with knees fully flexed at touchdown, and maintain an efficient body position throughout acceleration to maximize propulsion. Regression analysis revealed that the time to skate six meters is best predicted by player eight, stride length, propulsive time, peak anaerobic power, hip and knee angle at push-off on the first stride, hip abduction angle at push-off, and toe-to-centre of mass distance at touchdown on the third stride. The homogeneity of variance in the measures that predicted skating performance indicated that little variability exist in the skating technique used by ice hockey players at the elite level.

SUMMARY

Exploratory factor analyses were used to filter the set of kinematic data by eliminating confounding kinematic variables and to identify and quantify the relationship between kinematic measures that together described important characteristics of ice hockey technique. The use of the log-log transformation of the power function to transpose raw scores within a variable set into a single composite score captured the progressive nature of the skating stride without masking the unique contribution of each individual stride. The inclusion of peak anaerobic power in the regression model demonstrates the importance of combining physiological and biomechanical measures in an attempt to accurately describe or predict sport performance.

COMPARISON OF CLINICAL PERFORMANCE AND STABILOGRAM MEASURES IN PATIENTS WITH DEGENERATIVE LUMBAR SPINAL STENOSIS

Maura Iversen^{1,2,3}, Ashok Nimgade^{3,4}, Mark Lyle¹ and Jack Dennerlein⁴

¹Human Performance Laboratory, Department of Physical Therapy, Simmons College

²Brigham & Women's Hospital, ³Harvard Medical School, ⁴Harvard School of Public Health, Boston, MA

INTRODUCTION

Over two million US adults endure substantial activity limitation because of chronic low back pain each year (Lavsky-Shulan et al, 1985). Degenerative lumbar spinal stenosis (LSS) is a progressive syndrome characterized clinically by exacerbation of symptoms with lumbar extension and relief with flexion (Katz, 1994). Symptoms of degenerative LSS generally worsen with lumbar extension and improve with flexion. Clinically, these patients demonstrate a higher prevalence of balance disturbances with static and dynamic activities and decreased proprioception.

The Timed Up and Go (TUG) test (Podsiadlo et al, 1991) assesses functional independence and is useful because it describes realistic mobility activities including fall risk situations. The purpose of this study is to describe the relationship between stabilogram (Collins, 1995) measures of postural sway and motor control and performance measures commonly used in clinical settings. It is hypothesized that stabilogram measures and balance performance tests will present a consistent clinical profile in patients with symptomatic degenerative LSS. It is further hypothesized that patients with more severe disease will demonstrate greater dysfunction than patients with milder disease.

METHODS

A descriptive case series was used to compare clinical performance and outcomes measures with stabilogram assessments of balance. Four patients (3 female, 1 male) with clinically confirmed degenerative LSS were recruited from the Spine Center of a large tertiary care institution. Eligibility criteria included: (i) age 55 years and older; (ii) back, buttock and/or leg pain exacerbated by lumbar extension, and (iii) physician's judgment that the patient had clinically significant LSS and low back pain > 6 months. Subjects were excluded if: (i) they reported an increase in pain with lumbar flexion; (ii) had h/o low back surgery, or epidural steroid injection within the last 6 months; (iii) had medical problems that limited their function more than low back pain.

Patients were examined by a physical therapist and completed a demographic questionnaire, the Short Form -36

(Ware et al., 1993), and the Walking Capacity and Symptom Severity form (Stucki et al, 1996), developed specifically for older adults with LSS and related spinal disorders. The Cumulative Index Rating Scale was completed on each patient (Linn et al, 1968). A standard six-degree-of-freedom force plate measured the position of the center-of-pressure (COP) under the feet during 30 seconds of quiet standing with and with eyes closed over 10 trials. Stabilogram-diffusion analysis of the COP trajectories provided steady-state behavior and functional interaction of the neuromuscular mechanisms underlying the maintenance of erect posture (Collins et al, 1995). Patients also completed the Timed-Up and Go Test (Podsiadlo et al, 1991).

RESULTS AND DISCUSSION

The summary parameters from the three components, the physical exam, the health survey, and the force plate COP trajectories are presented in Table 1. These pilot data are all within range of expected values for LSS patients. The absolute stabilogram measures, specifically the larger critical time transition, indicated that LSS patients rely more on open loop control for balance. Correlation with the clinical parameters is not obvious; however, the one subject with a long time up and go parameter had longer critical times in the eyes open stage, suggesting the visual perception influences the person's postural control. Furthermore, the subject with the highest CIRS score had the lowest critical times suggesting this subject may not have impaired balance control.

This study, of course, is limited in the number of patients and it is therefore difficult to draw any major conclusions. However, the data do contain several trends pertaining to visual feedback in the stabilogram data and the clinical test parameters relating to risk of fall.

INTRODUCTION

One of the requirements following total knee arthroplasty, apart from the principle goal of pain reduction, is the return to normal function with stability of the joint during normal daily activity. The purpose of this study was to develop a technique for monitoring the functional effect of fixed and rotating bearing knee replacements *in-vivo*. A method was developed [Holt et al, 2000] to measure clinical knee rotations and is applied to four subject groups, with knee function classified as: normal, pre-operative osteo-arthritic, post-operative fixed and rotating bearing TKR (FTKR and RTKR respectively).

METHODS

A method has been developed [Holt et al, 2000] to calculate knee rotation and translation using marker clusters placed on the thigh and shank. Six degrees of freedom of the knee are calculated using the Joint Co-ordinate System [Grood and Suntay, 1983] with transformation matrices relating marker cluster and bony axes [Soderquist and Wedin, 1993]. Marker clusters rather than single marker placements minimise skin movement artefact and errors associated with standard optical motion analysis techniques [Capello et al, 1997].

The validated method [1] is applied to an on-going clinical trial to study knee function of normal subjects in comparison with pre-operative osteo-arthritic and three to twelve months post-operative TKR allowing a measure of return to normal knee function and a consideration of knee replacement design compatibility with initial functional specification. A major aim of the study is to investigate the external-internal tibial rotation range of motion (EIROM) as an indication of functional outcome and the patient group is thus further defined as having either FTKR or RTKR designs.

RESULTS AND DISCUSSION

Static jig tests and dynamic normal gait validation showed repeatability for rotation and translation measures. Comparison of subject categories introduced into the clinical trial shown in figure 1 indicates mean EIROM for different groups sizes. Preliminary results are given for the majority of FTKR subjects and the study is continuing to increase subject numbers for both FTKR and RTKR. With greatest recovery

after 12 months, both knee designs provide a return to normal EIROM with implications regarding TKR design.

Figure 1: Mean external-internal tibial range of motion for pre-op, FTKR and RTKR post-op and normal subjects (m = months post-op)

SUMMARY

A movement analysis technique using marker clusters is used to study the effect of fixed and rotating bearing knee replacement components on post-operative knee function *in vivo*. Preliminary results indicate a return to normal function for both sets of patients after a 12-month recovery period.

INFLUENCE OF A RIDER TO THE BACK OF A HORSE IN DIFFERENT GAITS

B. Frühwirth¹, C. Peham¹, M. Scheidl³

¹Clinic for Orthopedics, Veterinary University Vienna, Vienna/Austria

³FH Wieselburg, Wieselburg/Austria

INTRODUCTION

Back pain and diseases of the spine are known as significant problems in equine sports and veterinary medicine. Information about the strains and stresses that a horse encounters while being ridden might be an important link between symptomatic description and functional diagnosis, and thus might improve prevention, treatment and management of back pain. Up to now, the biomechanics of the equine back under conditions usually present today, especially while being ridden, have not yet been sufficiently investigated.

The aim of this study is to compare the pressure distribution and motion of the horses back with different loads (with and without rider), applied in different gaits.

MATERIALS AND METHODS

We measured 12 horses (age 7-25 years, 410-650 Kg, various breed, different training levels) without clinical signs of back pain (Licka et al. 1998).

All horses were analysed in three different gaits (walk, sitting trot, gallop) with rider, and in walk and trot without rider. For this investigation the regularly used saddles of each horse were taken. The fit of the saddles was checked by a veterinarian and the saddler of the Spanish Riding school of Vienna.

Measurements were carried out from the right side, with a system of six cameras (Motion Analysis Corporation). The pressure distribution under the saddle was recorded with the PLIANCE saddle mat (NOVEL Inc., Munich). At least five recordings of each combination were taken with the two simultaneously triggered measuring systems. From the pressure distribution we calculated the maximum overall force (MOF) in relation to the mass of rider and saddle, and the Centre of Pressure (COP) of the overall force. The range of back motion was determined at T5, L4, and S1.

RESULTS AND DISCUSSION

The MOF and the COP with and without rider is shown in table 1. Our results demonstrate, that force transmission in walk is more stable with rider (less variation of the COP) than without (only saddle). The rider's weight concentrates the load on a smaller area. In trot the situation is reversed. The COP varies more when ridden (table 1). The MOF is about six times higher when ridden in walk, and about seven times in trot. There was no significant difference in lateral motion of the back between ridden and unridden horse.

One of the most important problems in equestrian sports is to fit the saddle properly to a horses back. To achieve a proper fit it is extremely recommendable to know the accurate stress applied by saddle and rider. This investigation potentially enables us to estimate and predict the behaviour of the back under certain load and stress regimes. This again constitutes a fundamental building block for developing a biomechanical model of the equine back, and for designing and refining new saddle types.

THE EPIDEMIOLOGY AND BIOMECHANICS OF BICYCLE HANDLEBAR IMPACT INJURIES IN CHILDREN

Steven R. McFaul

Injury Section, Health Surveillance and Epidemiology Division, Centre for Healthy Human Development
Population and Public Health Branch, Health Canada, E-mail: steven_mcfaul@hc-sc.gc.ca

INTRODUCTION

Head and upper extremity injuries are frequent in bicyclists. Abdomino-thoracic injuries, although less common, are potentially serious. The handlebar of the bicycle has been implicated in serious and sometimes fatal injuries to the abdominal organs for over 30 years (Bergqvist et al, 1985). However, details as to the mechanism of such injuries and the mechanics of the impact have only recently been addressed (Winston et al, 1998).

The purpose of the present study is twofold: *i*) to describe the circumstances of abdomino-thoracic bicycle handlebar impact injuries in Canada's principal injury surveillance database (CHIRPP) and *ii*) to develop a simple mechanical model of various handlebar impact scenarios to determine the potential magnitude of the impact forces involved and any variables which may be important in prevention and control efforts.

METHODS

The Canadian Hospitals Injury Reporting and Prevention Program (CHIRPP) is an injury surveillance system supported by Health Canada that has been collecting Information on circumstances of injuries since 1990 in ten pediatric and 5 general hospitals across Canada. The entire database (1,098,334 records as of March 2001) was searched for records involving abdomino-thoracic injury (s) coupled with the handlebars as the direct cause of injury.

Epidemiological information from CHIRPP and other details were used to formulate the mechanical model which estimates the compressive force of the impact based on the pre-crash velocity of the bicycle, the impact angle, the mass of the child and the bicycle and the location of the centre of mass of the bicycle-rider system. The results of the model are compared to data on the compressive tolerances of the liver and spleen (Sturtz, 1995).

RESULTS AND DISCUSSION

A total of 650 cases (76.6% males), or about 1.5% of all bicyclist cases in the database, were identified. Almost half (47.9%) of all cases involved children aged 5-9 years, which proportion is larger than that for all bicyclist cases (38.1%, $p < 0.005$). Of the cases with enough detail regarding the mechanism, 39.8% involved a spearing impact (handlebar end) and 30.1% were frontal impacts across the horizontal aspect of the handlebar. The typical profile of handlebar impact injuries involves a child, between the ages of 6 and 11 years, a low velocity, single-party (non-motor vehicle) event, losing control of the bicycle due to a surface irregularity,

falling on or progressing into the handlebars and suffering an abdominal injury. The low velocity of such events optimizes the conditions for the child to interact with the bicycle in contrast to a catapult-type scenario, which occurs more often with older riders at higher speeds, often involving motor vehicles. At least one-fifth (19.1%) of the cases involved injuries to internal organs (16.7%) or to abdominal blood vessels or abdomino-thoracic muscle tissue (2.4%). Almost three-quarters of the cases involved only superficial injuries upon presentation, however in the literature (e.g. Spitz, 1999) there is often a diagnostic delay in up to 67%-86% of cases with internal injuries due to blunt trauma. It is possible that some of the injuries diagnosed as superficial in the emergency department were later found to be more serious.

Table 1 details the results of a simulation of the model. Clearly, the angle of impact is an important parameter in the resulting compressive force experienced by the child. The spleen appears particularly vulnerable, and in children the spleen and the liver are more exposed below the ribs compared to adults.

Table 1. The compressive impact force (N) as a function of the impact angle at different subject anthropometries for a spearing mechanism. An impact angle of 0 degrees indicates the handlebar perpendicular to the coronal plane. Subject is a male traveling at a pre-crash velocity of 2.23 m/s. Liver and spleen columns are compressive tolerances (N), Sturtz (1995).

Angle (deg.)	3 rd %ile 5 years	50 th %ile 10 years	97 th %ile 13 years	Liver	Spleen
5	6,981	8,474	14,272	2,649	785
15	2,351	2,854	4,806	2,649	785
25	1,440	1,748	2,943	2,649	785
45	860	1,045	1,759	2,649	785
90	608	739	1,244	2,649	785

SUMMARY

Handlebar impact injuries are rare but potentially very serious and considering the young age of the victims and the vulnerability of the child's abdomen, prevention efforts are important. The simple mechanical model reveals the potential for high impact forces relative to the organ tolerances.

ADAPTING BODY SEGMENT PARAMETERS FOR BIOMECHANICAL CALCULATIONS IN CHILDREN

Timothy K Woo¹ and David H. McFarland

Scientific Development Department, Biotonix inc., Montreal, Canada

¹e-mail: woot@biotonix.com web site: www.biotonix.com

INTRODUCTION

Using appropriate body segment parameters for the age, sex and perhaps ethnicity of the intended population is crucial for biomechanical modeling. There is a renewed interest in looking at the development of biomechanical characteristics of children at different life stages. Despite this, the most readily available and widely used data for various body segments parameters comes from the classic studies using elderly adult, Caucasian male cadavers. Clearly, such parameters are not applicable to young children, as the body segment proportions change during development. During adulthood, a person's head and neck represents 8.1% (Dempster 1955) of the total body weight where as a five year old child's head will represent 18.1% (Jensen 1986) of their total body weight.

To find the appropriate body segment data, we began a systematic review of the available literature and data sets to arrive at a consensus of appropriate biomechanical parameters for children. Our particular focus was to use these data sets to adapt the center of gravity calculations and moment of force calculations for children of different developmental ages for the Biotonix BioPrint system. This is a web-based musculo-skeletal assessment and corrective exercise system. The purpose of this paper is to demonstrate the potential problems of inappropriately applying adult to infant/child calculations of center of gravity and moment of force estimations.

PROCEDURE

A single-segment moment of force (Chaffin 1984) and a center of gravity estimation (Enoka 1994) were calculated twice, once using adult body segment parameters (Dempster 1955) and once using children's body segment parameters (Jensen 1986). These biomechanical formulas were applied to three female subjects (mean age 13.3) as well to simulated postures of children aged 4 to 15 in quiet standing with a 5° anterior head position. The simulated posture used anthropometric measures collected by Pheasant (1986). The differences in using adult parameters versus children's parameters were plotted in the graphs shown in the results.

RESULTS AND DISCUSSION

The following two figures show the differences in using adult versus children's body segment parameters in the center of mass calculation and moment of force calculation of the head and neck. Figure 1 shows the differences in calculated center of mass (mean 11.9 SD 2.4). The difference between children and adult center of gravity decreases as age increases. This trend is normal, as the children age, their body's will become more similar to those of adults. A noticeable decrease in the

difference in center of mass is observed beginning at age 10 and 11. This is due to the rapid growth that is associated with puberty.

Figure 1. The underestimated vertical difference in calculated center of mass using adult parameters in place of children's

Figure 2 shows the difference in moment of forces of the head and neck. Adult parameters underestimate the moment until the age of 13. At the age of 15 there is a large overestimation of the moment of force. This increase is partially due to the body segment parameters that are used in children. The linear changes in body segment parameters are not appropriate during adolescence when puberty occurs as major growth occurs during this period.

Figure 2. The underestimated difference in moments of force using different adult parameters in place of children's

SUMMARY

The results of this study show the importance of using appropriate body segment parameters in biomechanical modeling. Although the body segments may not be perfect, it is important to utilize the parameters that best suit the population to eliminate as many of the confounding factors as possible.

NUMERICAL SIMULATION OF FLUID-STRUCTURE INTERACTION OF THE INTRACRANIAL ARTERY

Ryo Torii¹, Marie Oshima², Toshio Kobayashi² and Kiyoshi Takagi³

¹School of Mechanical Engineering, The University of Tokyo

²Institute of Industrial Science, The University of Tokyo

³School of Medicine, Teikyo University

INTRODUCTION

Over 90% of subarachnoid hemorrhages are caused by rupture of cerebral aneurysms. Although the risk of rupture is known to be under 1%, aneurysms are usually operated if they are identified. On the other hand, the risk of postoperative sequelae is over 10% (The international study of unruptured intracranial aneurysms investigators, 1998). Thus it is important to predict risk factors of rupture of cerebral aneurysms in order to avoid unnecessary surgeries. Since it is reported that growth and rupture of aneurysms are associated with hemodynamic factors, the authors have been conducted a study to predict growth and rupture of cerebral aneurysms using numerical simulation. In this paper, numerical method for interaction between blood flow and arterial wall is developed. Results are compared with those of numerical simulations with rigid arterial wall. Especially, as WSS (wall shear stress) is an important factor for cerebrovascular disorders (Malek, A. M., et. al., 1999), effects of elastic arterial wall on WSS distribution are investigated.

COMPUTATIONAL METHODS

For fluid calculation with moving domains, ALE (arbitrary Lagrangian-Eulerian) FEM (Finite Element Method) is used to discretize both Navier-Stokes and the continuity equations. For structural calculation, FEM is used to discretize the equilibrium equation with the elastic constitutive law. Fluid and structural equations are iteratively solved by exchanging pressure and displacement at the boundaries.

COMPUTATIONAL MODEL

Three dimensional geometry of the ICA (internal carotid artery) is extracted from CT (Computed Tomographic) angiography (see Figure 1). The arterial wall is assumed to be elastic body with thickness of 0.3 mm. The elastic coefficient and Poisson's ratio are 1.0Mpa and 0.4 respectively. Womersley velocity profile is used for the inflow boundary condition. The outflow boundary conditions are assumed to be traction free, and the wall boundary conditions for fluid are non-slip, respectively. The inflow and outflow boundaries are fixed in structural calculation. The Reynolds number varies from 80 to 430. All calculations were performed on SGI Origin2000.

RESULTS AND DISCUSSIONS

The maximum deformation of elastic arterial wall is small (6.54×10^{-6} [m], about 0.164 % of diameter of ICA). But from comparison of instantaneous WSS distributions between

elastic and rigid wall calculations, WSS distributions are different as shown in Figure 2. The difference can be explained by following two effects of interaction between blood flow and arterial wall. Firstly, as indicated by the arrow in Figure 2 (a), the centerline of elastic artery moves in the outward direction of curvature and velocity gradient near inside arterial wall becomes higher than that in case of rigid wall. Thus the location and magnitude of the maximum WSS are changed. The maximum WSS is 297 dyn/cm² in elastic wall calculation while that is 160 dyn/cm² in rigid wall calculation. Secondly, irregularity of arterial wall is smoothed by fluid force and overall WSS distribution varies. These results indicate that effect of elastic arterial wall on blood flow simulation is considerable.

SUMMARY

Numerical simulations of the internal carotid artery were performed considering elasticity of arterial wall. As a result, it is shown that effect of elastic arterial wall on WSS distribution is significant even though wall deformation is small. Thus it indicates that elasticity of arterial wall is essential in numerical simulation of blood flow.

ANTERIOR INTERBODY FUSION WITH TRANSFACET SCREWS: A BIOMECHANICAL STUDY

S.L. Evans¹, C. A. Holt¹, L. Jones¹, D. Dillon², S. Ahuja² and P. Davies²

¹Division of Materials and Minerals, Cardiff School of Engineering, Cardiff University, P O Box 925, The Parade, Cardiff, CF24 0YF, UK. EAVNS SL6@CARDIFF.AC.UK

INTRODUCTION

Transfacet screws are widely used to provide additional stability in anterior spinal surgery. The aim of this study was to determine whether it is better to implant transfacet screws before or after implanting an anterior cage for interbody fusion. A 3D motion analysis technique based on methods previously used for measuring knee movement has been modified to measure relative movements of two vertebral bodies [Hunt et al, 2001], and this technique was used in the present study.

METHODS

L4/L5 calf spines segments were mounted on a base plate using 6.5mm cancellous screws and bone cement. A second smaller plate was attached to the superior surface of the upper vertebral body for attachment of the loading jig. Marker clusters were attached to both upper and lower vertebral bodies using Kirschner wires. Three anatomical landmarks on each vertebral body were identified using a marked pointer to establish the anatomical axis system. 2Nm moments were applied about each anatomical axis and the resulting movements were measured using a Qualisys motion analysis system. Rotations and translations about each anatomical axis were then calculated using the method previously described.

For one group of five specimens transfacet Magerl screws were implanted, followed by a Syncage implant (Stratec), and in a further five tests the anterior cage was implanted first.

RESULTS AND DISCUSSION

Implanting the cage first produced a significantly smaller range of motion, both in flexion/extension ($p=0.02$) and in axial rotation ($p=0.03$). In lateral bending the range of motion was reduced, but the difference was not statistically significant ($p=0.38$).

When the cage is implanted first, the vertebral bodies are distracted so that the posterior longitudinal ligament (PLL) is taut, and the facet joints are locked. The screws then provide some additional stability. If the screws are implanted first,

they tend to prevent tensioning of the PLL so that the range of motion is much greater.

Figure 1: Range of motion in flexion- extension (FE), lateral flexion (LF) and axial rotation (AR) as a percentage of the unimplanted range of motion (\pm standard deviation).

SUMMARY

Implanting the cage before the transfacet screws resulted in a much more stable construct, which should promote successful fusion. This difference is ascribed to the tensioning effect of inserting the cage on the posterior longitudinal ligament.

LUMBAR SPINE MOTION ANALYSIS VIA AUTOMATIC SEGMENTATION

Yalin Zheng¹, Robert Allen² and Mark S. Nixon¹

yz99r@ecs.soton.ac.uk

¹Department of Electronics and Computer Science, University of Southampton, Southampton, SO17 1BJ, UK.

²Institute of Sound & Vibration Research, University of Southampton, Southampton, SO17 1BJ, UK.

INTRODUCTION

Low back pain is a very common problem and the consequent cost is enormous. In spite of its prevalence, however, it is still difficult to obtain accurate diagnosis. Mechanical disorder is now often regarded as the main cause. Presently, a number of studies are directed at measurement of spine kinematics. Since the lumbar spine is a deep-rooted structure, this has been difficult until digital videofluoroscopic (DVF) imaging was developed [Breen et. al. 1989]. In this paper, DVF is used to acquire the motion sequence of the lumbar spine, to solve the problems with manual location of the vertebrae within the sequence, a spatio-temporal Hough transform (STHT) [Zheng et. al. 2001] has been developed to automatically locate vertebrae in DVF images and results of tests are very promising.

METHODS

During DVF image acquisition, the subject lies on a table which can be moved at a controlled rate. A major advantage of DVF is that it can capture a whole motion sequence with a radiation dose that is lower than a single X-ray plate of the lumbar spine. This reduction, however, incurs deteriorated image quality and causes problems with edge detection. Phase congruency [Kovesi 1999], which detects edges by phase information, is used here for improved edge detection. Phase congruency has significant advantage over most of the gradient-based methods as it can cope with uneven contrast and brightness within the image. Fig. 1 (b) shows convincing results in L5 edge (L_n is the n th vertebra of the lumbar spine).

Figure 1: DVF image, edge map and extraction results.

The Hough transform (HT) is a powerful tool in computer vision for extracting objects in images by evidence gathering in a parameter space [Leavers 1993]. Here an STHT has been developed to locate five lumbar vertebrae in each frame of a selected sequence while the subject moves from a neutral position into flexion, then back through neutral to extension, and finally to neutral position. The new STHT differs from the traditional HT in that it considers not only the parameter space,

but also the spatio-temporal information, that is, the relationships between vertebrae within a single frame as well as throughout the whole sequence. However, the huge search space involved leads to increased computational cost. To solve this problem, a genetic algorithm [Goldberg 1998] is employed to find the optimal values of a “fitness function” which is the combination of the two terms discussed above. Aided by the spatio-temporal information, the STHT can provide us with more robust results. Fig. 1 shows a DVF image, its edge map and vertebral extraction results.

RESULTS

The extraction results from the STHT enable us to conduct further kinematic study of the lumbar spine. Fig. 2 shows the motion pattern in the x direction of the centers of five lumbar vertebrae moving from full flexion to extension, and reveals a sinusoidal feature. In data acquisition the interface between the moving lower and the static upper sections of the table was at the level of L3. This is to maximise the focus on the whole lumbar spine. It explains why L3 moves less than the other four segments.

Figure 2: Motion pattern of the lumbar spine.

CONCLUSION

Our method shows potential for automatic extraction of the vertebrae in moving DVF images of the lumbar spine. We are currently applying this to a large database of spine motion from which the kinematics at the segmental level will be produced. Further validation studies using a calibration model are also being undertaken.

INTRODUCTION

The paper aims to investigate the relationship between cerebrovascular geometry and hemodynamics in order to predict rupture and creation of cerebral aneurysms. The authors have been developing a numerical simulation system, which consists of medical image-based geometric modeling, grid generation, finite element fluid simulation, and scientific visualization (Oshima, 2001). A database system is designed so as to organize and analyze medical imaging, physiological, and numerical data. Using 15 cases of the middle cerebral artery (MCA) calculations from the database system, the multivariate analysis are performed to estimate a maximum wall shear stress. The results are compared and show good agreement with those of numerical analysis. It is found that diameter of the MCA, ratio of diameter of branching to that of the MCA, and bifurcation angle between the MCA and branching arteries are important geometric factors in determining maximum wall shear stresses.

MEDICAL IMAGE-BASED SIMULATION SYSTEM

Due to over-tessellated polygonal surfaces extracted from CT images, smoothing operation is carried out combining polygon reduction technique (Garland, 1997) and smoothing technique (Taubin, 1995). After construction of geometric model, computational grids are generated for the finite element analysis of incompressible Newtonian blood flow. The inflow boundary conditions are prescribed using velocity data at the entrance of the MCA measured by the transcranial Doppler ultrasound technique. Overall procedure for the numerical system is summarized in Figure 1.

Figure 1: Flowchart of overall Simulation System

MULTIVARIATE ANALYSIS USING DATABASE

The present database system can deal with text data as well as graphic data such as visualization pictures and movies. For the multivariate analysis, 6 parameters are chosen to represent the vascular geometry as follows: 1) diameter of the MCA(D_p),

2) the ratio of the diameter of branching artery to that of the MCA(D_1/D_p and D_2/D_p), and 3) angle between branching artery and MCA(α_1, α_2) and between two branching arteries (α_3).

RESULTS AND DISCUSSION

The multivariate analysis is conducted for 15 cases to examine effects of vascular geometry on the maximum wall shear stress. Comparison of the simulation and the estimation results are described in Figure 2. The analysis shows that the parameters, D_p , D_1/D_p , and α_1 affect the magnitude of maximum wall shear stress. As a results, the magnitude of maximum wall shear stress decreases associated with increase in D_p , D_1/D_p , and α_1 .

Figure 2 : Maximum wall shear stress of numerical results and estimated values by multivariate analysis.

SUMMARY

The medical image-based simulation and database system is developed to evaluate effects of cerebrovascular geometry on hemodynamics. A total of 15 cases for the MCA are analyzed. The multivariate analysis is conducted to estimate the maximum wall shear stresses using 6 geometric parameters and results in good agreement with the simulation results. It is shown that the wall shear stress are affected by 3 parameters (diameter of MCA, and ratio of diameter and angles of branching to that of the MCA). The magnitude of maxim wall shear stress decreases as those of 3 parameters increases.

A DUAL MASS SPRING – DASHPOT MODEL OF THE EXCHANGE OF FORCES BETWEEN THE BACKPACK, HIPS AND SHOULDERS DURING WALKING

INTRODUCTION

A model describing the exchange of forces between the backpack, hips and shoulders during walking is proposed (Figure 1). The intent of the model is to provide backpack designers with a simple tool that can give them the information needed to design backpacks that better distribute the forces between the hips and shoulders. The model is described by the following equation:

$$F_{BP} = k_{hip}x + c_{hip}\dot{x} + k_{shoulder}x + c_{shoulder}\dot{x}$$

x , and \dot{x} represent vertical instantaneous displacement, and velocity (respectively) of the backpack's center of mass (COM), F_{BP} together with the $mass_{BP} \cdot gravity$ are all the external forces acting to accelerate the backpack's COM. k represents the stiffness of the springs at the hips and shoulders, and c represents damping at the hips and shoulders.

Figure 1 Dual Mass Spring-Dashpot Model of Backpack.

The model is designed to predict the vertical force acting on the hips and shoulders based on the vertical force acting on the backpack COM, the stiffness and damping at the shoulders and the stiffness and damping at the hips. Stiffness and damping for the shoulders and hips are separate terms in the model, consequently there is no assumption that the stiffness or damping at the shoulders is equal to the stiffness or damping at the hips. However, the model does capture the fact that differences in stiffness and damping at the shoulders will affect stiffness and damping at the hips.

METHODS

One male volunteer 22 years old walked on a treadmill at 1.34 m/s with 3 backpack weights 134, 267 and, 401 N (30, 60, and 90 pounds). Hip-belt tension and backpack COM location were constant for all backpack-walking conditions. The backpack had a lightweight polymeric frame with force transducers between the hip-belt and frame. The pack was designed to only make contact with the upper back and shoulders and the hips. Force data was sampled from the force transducers at 1000 Hz. Kinematic data of the motion of the backpack COM were collected at 100 Hz. Thirty seconds of data were collected from the subject, yielding on average approximately 25 strides of

data. The instantaneous vertical force acting on the BP COM was calculated from its mass and instantaneous vertical acceleration. Vertical force on the shoulders (and upper back) was calculated as the difference between the vertical force on the BP COM and the vertical force on the hips.

The values of stiffness and damping terms were based on the force acting on the BP COM. Values of stiffness and damping ranging from 0 to 20 were substituted in the model and used to predict the forces acting at the hips and shoulder. The predicted shoulder and hip forces were then compared (using linear regression) to the forces at the shoulders and hips that were calculated from the kinematic and transducers data respectively. The values of stiffness and damping that yielded the highest r^2 were retained for the subsequent analysis. In order to determine the robustness of the values of stiffness and damping terms across backpack mass conditions, the model was used to predict hip and shoulder forces while the subject carried the 60 and 90 pound backpack. In all cases, the strength of the prediction of the model was determined using 2 linear regressions (for hip and shoulder separately), with predicted force as the dependent variable and the force calculated from the transducers or kinematics as the independent variable.

RESULTS

$k_{hip} = 2$; $k_{shoulder} = 2$; $c_{hip} = 4$; and $c_{shoulder} = 12$ yielded the highest r^2 values (0.82 for hip; 0.93 for shoulder) for predicting *both* the hip and shoulder force. It should be noted that other values of stiffness and damping resulted in higher r^2 values for the shoulder, however this resulted in lower r^2 values for the hip. These stiffness and damping values were used to predict hip and shoulder force for the same subject walking with a 60 and a 90-pound backpack. The r^2 values for the 60-pound pack were 0.74 (hip) and 0.81 (shoulder); the r^2 values for the 90-pound pack were 0.86 (hip) and 0.87 (shoulder).

DISCUSSION

The increase in damping at the shoulders may result from the shoulders bearing a much greater proportion of the backpack mass during walking (LaFiandra et al. in press). More research is required to substantiate this hypothesis. The lower r -squared values obtained for the 60-pound backpack suggests it may be necessary to re-tune the model for different backpack masses. We also conducted a between subject test of the model's robustness, the results of which are forthcoming.

INTRODUCTION

The plantar aponeurosis (PA) originates from the medial tubercle of the calcaneus and inserts on the phalanges through complex network of fibrous tissues. It is known to be a major contributor to arch support via the “windlass mechanism” and has the potential to transfer Achilles tendon forces to the forefoot (Hicks, 1954). Recently, Hamel et al. (2001) investigated the influence of plantar fasciotomy on forefoot loading and Carlson et al. (2000) examined PA strain in relation to toe extension and Achilles force. However, the load transfer mechanism between the Achilles tendon and the forefoot under lifelike conditions remains poorly understood. The objectives of this study were to measure PA force during cadaver simulations of walking and to determine its magnitude relative to Achilles tension.

METHODS

Seven cadaver feet (age: 66 ± 20 y; BM: 57.2 ± 10.0 kg) were tested in a Dynamic Gait Simulator (DGS; Sharkey and Hamel, 1998). The DGS prescribes knee kinematics and applies forces to the tendons of extrinsic foot muscles to reproduce foot motion and the ground reaction forces occurring during the stance phase of walking. The PA was exposed by dissecting a strip of superficial plantar tissue (~2 cm) anterior to the calcaneal origin. A fiberoptic cable was passed through the PA perpendicular to its longitudinal axis to measure PA force (Komi et al., 1996). Tendon forces applied by the DGS, ground reaction forces, and raw fiberoptic output from the PA during walking simulations were recorded simultaneously.

Following experimental measurements, the transducer was calibrated *in situ* by applying known forces to the PA using a materials testing device (MTS Sys. Corp.). The specimen was placed in a fixture with the calcaneus and forefoot potted and midfoot structures except the PA dissected. The fixture aligned the longitudinal axis of the PA with the loading axis of the MTS. The calibration loading rate approximated loading rates experienced in the walking simulations, and cable migration was monitored to reduce the potential for error (Erdemir et al., *in press*).

RESULTS AND DISCUSSION

PA tension increased gradually until push-off (Figure 1). Peak forces (0.6-1.5 BW) were found to be lower than the model predictions of Giddings et al. (2000). The fiberoptic technique

may be subject to errors due to twisting of the PA, but the PA forces measured were well below published PA failure loads (Kitaoka et al., 1994). A linear fit using data from all specimens revealed PA force to be a function of Achilles tension (PA force = $0.47 \times \text{AT force} + 0.041 \text{ BW}$, $R^2 = 0.58$).

The PA is loaded substantially during stance phase as a combined result of toe extension and contraction of the extrinsic plantarflexors and was shown to be a vital structure for load transmission during normal gait. Surgeries involving partial or full fasciotomy may alter this load transfer mechanism and disturb dynamic function of the foot.

Figure 1. Plantar aponeurosis, Achilles and vertical ground reaction forces, normalized by body weight (mean \pm SD).

INTRODUCTION

The tarsometatarsal joints (TMT) of the midfoot are complex articulations involving the three cuneiforms, the cuboid, and the metatarsal bones. Since the medial TMT joints are located along the medial longitudinal arch, the torsional stiffnesses of these joints play important roles in arch deformation, force transfer, and energy storage during gait (Lakin, 2001).

Stokes et al. (1976), used metatarsal geometry, force data, and quasi-static calculations to estimate the axial loads, shear loads, and bending moments routinely imposed on the TMT joints. Recently, Jacob (2001) improved on Stokes's calculations by incorporating more precise metatarsal geometry and forefoot loading criteria. Knowledge of TMT joint stiffness, as defined by torque versus angular displacement curves, could provide a basis from which to judge the accuracy of these computational estimates. Yet, there is little, if any, empirical data concerning the structural properties of the TMT joints. The objective of this *in vitro* study was to determine the torsional stiffness of the 1st TMT joint under physiologic moments.

METHODS

Six cadaver feet were dissected to yield intact midfoot sections composed of the mid-tarsal (navicular, cuboid, and cuneiform) and metatarsal bones. Care was taken to preserve the joint capsule and ligamentous structures at the 1st TMT. The tarsus of each sample was potted in PMMA to a level just proximal to the TMT joint line, and the 1st metatarsal head was fitted with a linkage for distal load application. The preparation was then mounted in an unconstrained testing apparatus, which applied force to the metatarsal head in a direction perpendicular to the long axis of the bone.

Each specimen was cyclically loaded in sequential fashion to pre-determined peak torque levels: 2.5, 5.0, 7.5, and 10 N-m. For each peak torque, ten conditioning cycles were executed, followed by six test cycles. Joint loading was conducted at 0.05 Hz; force and displacement data were sampled at 100 Hz. Data were averaged over the six test cycles and across all specimens, and then curve fit to obtain mean torque-angle curves for each peak torque level.

RESULTS AND DISCUSSION

The 1st TMT joint displayed nonlinear behavior, indicated by the dependence of joint stiffness on flexion angle ($T=K(\theta)*\theta$). A least squares curve fit defined 1st TMT joint stiffness as $K(\theta) = 3.23*10^{-4} \theta^3 + 3.85*10^{-4} \theta^2 + 1.04*10^{-3} \theta + 0.0693$ (Fig.1). The torque versus angular displacement curves displayed a transition point at approximately 4 degrees of dorsiflexion, which corresponded to a joint torque of 0.4 Nm.

Below this threshold, joint stiffness was essentially constant at 0.1 Nm/deg. Beyond the 4 degree threshold, joint stiffness changed markedly as a function of dorsiflexion as characterized by the cubic polynomial, $K(\theta)$. For example, at a higher angular displacement of 9 degrees, joint stiffness increased to 0.34 Nm/deg.

Previous quasi-static models of the 1st TMT generalize the contributions of soft tissue by combining different muscle actions into one force vector, and neglecting the contributions of supporting structures such as the plantar fascia, which may lead to an overestimation of joint torque (Jacob 2001). The joints tested in this study dramatically increased in stiffness beyond a threshold displacement of approximately 4 degrees dorsiflexion, which is also the normal limit of motion defined by Wanivenhaus (1989). Taken together, these data suggest that the joint torques experienced at the 1st TMT during normal dynamic conditions may be substantially lower than values predicted by previous computational analyses.

Figure 1. Mean torque-angle curve with standard deviations for 6 first TMT joints. The dashed line, $T=K(\theta)*(\theta)$ represents the non-linear polynomial that defines joint stiffness.

INTRODUCTION

Dynamic plantar pressure measurements offer a unique opportunity to assess foot functioning during stance phase in running. However a biomechanical or clinical interpretation has to take within-subject, or between-trial variability into account. Only Cornwall and McPoil (2000) studied within-subject variability for LMFI (Lateral-Medial Force Index) and LMAI (Lateral-Medial Area Index) obtained during 3 trials of barefoot walking. Intraclass Correlation Coefficient (ICC) values were .386 and .374 respectively.

The purpose of this study was first to investigate the between-trial variability for a large number of variables deduced from plantar pressure measurements. Second, difference was studied between left foot and right foot pressure data.

METHOD

Plantar pressure data were collected from 80 healthy undergraduate physical education students without lower extremity abnormalities. A footscan pressure plate (RsScan nv., 2m x 0.4m, 16384 sensors, 480 Hz, dynamic calibration with AMTI) was mounted in the middle of a 16.5m long wooden running track. The subjects were asked to run barefoot at a speed of 3.3m/s (+/- 0.17m/s). Prior to the measurements, all subjects performed habituation trials. Three valid left and three valid right stance phases were measured. After testing one observer placed 8 regions (medial heel, lateral heel, metatarsal heads I to V and hallux) on the footprints for all trials. Temporal data (i.e. time to peak pressure, instants on which the regions make contact and instants on which the regions end footcontact) peak pressure data and relative and absolute impulses were calculated for all 8 regions. Eight medio-lateral ratio's were calculated at four instants of the footcontact, namely initial contact (IC), midstance (Mst) – i.e. contact of one of the metatarsal heads –, foot flat (FF) – i.e. contact of all metatarsal heads – and heel off (HO). Excursion ranges of these ratio's were calculated over three intervals (IC-Mst, Mst-FF and FF-HO) and also medio-lateral displacements of center of pressure. Between-trial variability was investigated by using ICC (SPSS 10.0). Differences between left foot

trials and right foot trials was studied by using a paired sample T-test.

RESULTS AND DISCUSSION

The ICC values are summarized for 5 categories of plantar pressure variables in table 1. ICC values for total contact time are .843 for the left foot and .789 for the right foot, and therefore temporal variables are absolute reported.

In general, peak pressure variables and impulses, show rather high ICC values (mostly above 0.7). The temporal variables show very different ICC values with between-trial variability becoming lower during forefoot contact. This is also true for the medio-lateral ratio's. Also the impulses showed high ICC values for the regions in the forefoot, but lower ones for the heel regions. On the other hand, peak pressure variables showed an overall low between-trial variability. Medio-lateral COP displacements showed low ICC values. Two factors may play a role here. First, these variables are calculated on time instants and over time intervals and therefore timing dependent (with rather large variability). Second, in each footprint the observer had to define a foot axis (metatarsal II – middle of the heel) as a reference for COP location. A minor shift of this axis in the three trials may induce between trial variability. Most variables deduced from plantar pressure measurements during barefoot running display good ICC (26% > 0.7) to satisfactory ICC (68% > 0.5) with mid-forefoot contact period in favour. Higher variability is assumed present due to the transient nature of initial heel contact. In the second part of the study, differences between left foot contacts and right foot contacts were found, especially in the calculated values of the medio-lateral ratio's. Also peak pressure variables showed differences between left and right foot.

In conclusion, for interpreting purposes it is important both (1) to measure a sufficient number of trials, and (2) to analyse left and right foot trials separately.

REACTION TIMES DURING A SIMULATED BASEBALL-FIELDING TASK ARE INFLUENCED BY BASEBALL VELOCITY, LEVEL OF ATTENTION, AND AGE

INTRODUCTION

Nearly 90% of catastrophic injuries in youth baseball occur by direct contact of a baseball or a baseball bat to the head, neck, or chest of the youth (Rutherford et al., 1984). The potential for injury is increased if the time required for a batted ball to reach a given field location is less than the reaction time of the player. This project investigates the reaction times of young baseball players performing a simulated fielding task and characterizes how ball velocity and level of attention influence reaction time for various age groups of boys and girls.

METHODS

Fifty boys and 50 girls (ages 8-16 years) who participate in competitive/recreational baseball programs were recruited. Each youth stood in a standard fielding position and were asked to simulate a baseball catch when a baseball was projected towards them. A pitching machine, located 45 feet away and directed toward the youth, was employed to project the baseballs. A safety net, located 10 feet in front of the youth (i.e., between the youth and the pitching machine), was used to protect the youth from the incoming baseball. Forty trials were performed. Trials were randomly blocked by level of baseball velocity: 60 mph and 75 mph. Within each block, trials were randomly divided between two levels of attention: full attention and split attention. Examples of split attention tasks include counting backwards, naming familiar objects, or spelling difficult words. Split attention tasks varied between trials and were gauged to the age of the youth. The data collection included motion capture of the baseball and of three reflective markers placed on the youth's baseball glove. The instant of ball projection was quantified with an accelerometer and synchronized with the motion capture data. Reaction time was calculated as the time from the instant of ball projection until initial motion of the baseball glove. Statistical analysis involved a 2x2 (ball velocity by level of attention) repeated measures ANOVA using age as a covariate and sex as a between-subject factor.

RESULTS AND DISCUSSION

When the ball was projected at 75 mph, reaction times were significantly faster than when the ball was projected at 60 mph ($p < 0.01$). Reaction times were significantly faster when the youth were at full attention compared to split attention ($p < 0.01$). The older age groups had significantly faster reaction times compared to the younger age groups ($p < 0.01$). Reaction times did not differ significantly between boys and girls ($p > 0.05$). A significant sex by level of attention interaction was identified ($p < 0.01$). All other interactions were not significant (all $p > 0.05$).

Surprisingly, the faster ball velocity produced faster reaction times. It is currently unknown if ball velocities greater than 75 mph would elicit faster reaction times. Another unexpected finding was the sex by level of attention interaction. For the full attention trials, boys and girls did not differ in reaction time. For the split attention trials, girls reacted 20 msec slower than during the full attention trials, whereas boys showed no change in reaction time between the full attention and the split attention trials. Although this suggests that girls had a more difficult time performing multiple tasks, the delay in reaction time during the split attention trials was expected.

STEADINESS IN YOUNG AND ELDERLY BEFORE AND AFTER A 5-WEEK PERIOD OF STRENGTH TRAINING

Jesper Sandfeld¹, Bente R. Jensen²

¹National Institute of Occupational Health, Denmark (Jes@ami.dk)

²Institute of Exercise and Sports Sciences, University of Copenhagen

INTRODUCTION

At present, not only the young but also the elderly part of the work force uses computer and computer mouse to solve the daily tasks at work. These instruments require extensive fine motor control skills, which seem to be reduced with age (Grimby & Saltin, 1983, Enoka et al. 1999, Laursen et al. 2001). Loss of fine motor control skills as e.g. impaired steadiness may affect the ability to perform everyday working tasks. The aim was to study hand-steadiness in young and elderly and to evaluate the effect of training.

METHODS

25 subjects participated in the study. 12 young (27 ± 2.6 yrs. (SD), 6 females, 6 males.) and 13 elderly (67 ± 3.8 yrs. (SD), 6 females, 7 males).

Figure 1. The experimental set-up

The subjects performed wrist extension/flexion tasks. Wrist movements measured with electro-goniometer were displayed on a computer screen. The task for the subjects was to follow a pre-defined trace displayed on a computer screen (duration = 20 s), which required the subject to perform a wrist extension (concentric contraction) from a vertical to a horizontal position for 7 s (constant angular velocity of $12.8^\circ/\text{s}$), maintain the horizontal wrist position for 6 s (isometric) and finally to lower the hand (eccentric) back to vertical position (7 s).

The task was performed 12 times. Three times with each of 4 loads: 0 (hand weight), 4, 12.5 and 25% of isometric maximum voluntary contraction (MVC). The loads are average loads, calculated on the basis that the moment arm changes during the movement described. Test order was randomised. Hand-steadiness was measured as standard deviation of the acceleration.

Training consisted of 5 weeks of heavy strength training of arm and shoulder muscles. Three sessions each week with 3 sets of 4-8 repetitions for each muscle group were obligatory. Steadiness and wrist extensor muscle strength (isometric and dynamic (isokinetic in Biodex System 3)) were measured before and after the 5 weeks of training.

RESULTS AND DISCUSSION

Before training, steadiness during concentric wrist extension was significantly reduced in the elderly group compared to the young at the loads 0, 4 and 12.5 %MVC ($p \leq 0.05$). Changes in fine motor control during ageing are considered to be due to neurological and morphological changes. After training the isometric MVC in the wrist extensor muscles in the young group increased 12.4% ($p \leq 0.05$), but only a tendency to an increase in dynamic strength was found (10%, $p = 0.1$). In the elderly group the isometric MVC increased 12.0% and dynamic strength increased 14.0% ($p \leq 0.05$). A 5-week training period mainly influences neurological factors. Thus, changes in steadiness due to training are assumed primarily to be an effect of changes in the neurological parameters. After training an improvement in steadiness was found in the young group at the load of 4%MVC ($p \leq 0.05$). For the elderly group steadiness improved for loads corresponding to 0, 4, 12.5%MVC ($p \leq 0.05$) (Fig 2). Steadiness measured during isometric and eccentric contraction mirror to a large extent the results from the concentric contraction, indicating a general improvement of hand-steadiness.

Figure 2: Steadiness during concentric wrist extension before and after heavy strength training.

CONCLUSION

After training the hand-steadiness of the elderly group during concentric wrist extension reached the pre-training levels of the young group. This indicates that changes in steadiness due to age to a large extent are a result of neurological changes, which can be reversed by a short period of strength training.

INTRODUCTION

Many manual wheelchair users (MWCUs) have upper extremity impairment (UEI) due to paralysis or motor control deficits. In spite of their UEI, these individuals are functionally independent. Maximal isometric strength has been reported to have an inverse relationship to physical strain during certain functional tasks. (Dallemeijer, 1996) Additionally, level of spinal lesion was directly related to dynamic propulsion characteristics, however, without specific classification of UEI. (Dallemeijer, 1996,1994) The purpose of this study was to compare biomechanical characteristics of dynamic (MzD) and static (MzS) propulsive moments in functionally independent MWCUs with and without UEI. It was hypothesized that 1) MWCUs with UEI would demonstrate smaller MzD and MzS compared with those without UEI and 2) relationship exists between UEI and specific functional tasks.

METHODS

Subjects included 38 MWCUs (12 with UEI, 26 without UEI, mean age = 38.1±8.4 years, WC use = 11.3±8.4 years). Following informed consent and medical screening, propulsion mechanics were measured during a maximal exercise test to exhaustion (defined as volitional inability to sustain the target velocity of 3km/hr). A wheelchair ergometer instrumented with a PY-6 six-component force/torque transducer (Bertec Corp, Worthington, OH) in the wheel hub was used to measure handrim forces and moments. Orientation of the x-y-z transducer coordinates was tangential (forward+), radial (up+) and medial-lateral (into the wheel+), respectively. MzD was defined as the propulsive moment occurring at the peak power output (POpeak). Handrim data was collected at 360 Hz and averaged over three cycles. For the MzS, subjects placed their hands at top-dead -center of their wheel and gave three maximal forward propulsion efforts with the wheelchair held stationary. Force from this maximal propulsive motion was collected at 30Hz using a uniaxial (200 lb max) force transducer (Transducer Technologies, Temecula, CA) attached to the rear aspect of the wheel. For MzS, peak force from each of the three trials was averaged and mathematically converted to moments based on the radius of the wheel. All subjects performed a 13 item functional test developed to assess level of independence in MWCUs. The Wheelchair Users Functional Assessment (WUFA©) includes home and community mobility skills. (Feliciano,1994)

Pearson product moment correlations determined relationships between MzD, MzS and the 13 functional tasks ($r^2 \geq 0.3$).

ANOVA was used to determine if differences existed between the groups in MzD, MzS and tasks correlated to these measures ($p \leq 0.05$). ANCOVA determined differences in MzD between groups with POpeak covaried.

RESULTS

Total WUFA scores (UEI = 83.5, without UEI = 84.0) and MzS (UEI = 24.2Nm, without UEI = 31.8 Nm) were not different between the groups. Four tasks (wheelchair propulsion of street crossing, ascending a ramp, and ascending a curb, and rising from the floor to wheelchair) correlated to the propulsive measures and POpeak (Table1). POpeak ($p < 0.01$) and MzD ($p = 0.025$) were significantly lower for the UEI group. However, when POpeak was covaried, MzD was not different between those with UEI and those without UEI.

Table 1: Pearson Product Moment Correlation of Biomechanical Measures vs Functional tasks

	Street crossing	Ramp	Curb	Floor-WC
MzD	0.47	0.54	0.48	0.35
MzS	0.56	0.44	0.44	0.46
POpeak	0.61	0.54	0.69	0.50

DISCUSSION/CONCLUSION

Although static and dynamic measures were lower in the MWCUs with UEI, there was no difference in their level of functional independence. Correlations found were similar to findings in previous studies. MWCUs with UEI were able to propel at the same proportion of their maximum effort as those without UEI. These findings may provide insight into how MWCUs with UEI remain functionally independent.

INTRODUCTION

Articular cartilage repair is one of the key fields in tissue and cell engineering. However, very few studies deal with the mechanical environment required to enhance this process (Smith C. 2001, Wu J. Z. 2001). The goal of this study is to investigate the biomechanics of an osteochondral implant once in place. More specifically, the combined influence on the implant performance of the articular surface alignment mismatch (V1), the implant material properties (V2), and the implant/host integration (V3) has been studied under static loading conditions.

METHODS

The investigations were carried out with a 3D Finite Element model of a "ball in a socket" which represented the human medial knee compartment (femoral condyle on the tibial glenoid). The effect of the meniscus was taken into account by removing 40% of the load. The focal defect was assumed cylindrical ($r = 8$ mm), limited to the femoral cartilage and located at the vertical of the contact point. The cartilage, subchondral plate and trabecular bone were represented. Geometrical features and material properties, which were assumed isotropic homogeneous and linear elastic, corresponded to average values found in the literature. The implant was composed of two layers : the fabric (3.5 mm thick) and the cover (1 mm thick). It matched the defect in terms of radius. Finally, a standing up equivalent static load (176.58 N) was applied vertically onto the femur (Figure 1).

Figure 1 : Section of the system with implant

V1 took the values 0 mm and -0.5 mm. The variations of V2 corresponded to $E_{\text{implant fabric}}$ of 30% and 75% $E_{\text{cartilage}}$ (E defined as the Young Modulus). V3 equalled total (T) and zero (N^*) integration at the implant/host radial interface. The combination of these 3 variables resulted in 8 different configurations including the ones used as references : with (D_{ref}) and without (N_{ref}) damage. The numerical simulations were performed with the code PAM SAFE (ESI Group).

RESULTS AND DISCUSSION

The result coherence and consistency were checked, and the model was judged suitable for qualitative purpose.

The model simulated the primary mode of failure related to a chondral focal defect. Indeed, the simulations showed a large deformation of the femoral cartilage at the edge delimited by the focal defect. This resulted in maintaining a large contact area with a moderate increase of the normal/vertical stresses compared to the healthy tissue configuration (N_{ref}). However, the tensile radial strains (X) in the cartilage corner rose up by +425% (Figure 2).

Figure 2 : Radial strains in cartilage and implant fabric

When $E_{\text{implant fabric}}$ equalled to 30% of $E_{\text{cartilage}}$ and V3 took N^* , the increase of the tensile radial strains was reduced to +250%. Moreover, maximum radial (X) and normal (Y) strains within the fabric were found to be significantly higher than in the healthy tissue. In addition to the above results, it was found that, with the -0.5 mm positioning mismatch below the articular surface, the implant behaved as void filler with no mechanical contributions. Finally, the implant material properties appeared to be very influential on the mechanical response.

CONCLUSION

The implant works against the primary failure mode by taking part of the total load, and by limiting directly the radial deformation when it interacts with the wall of the focal defect. With V1 equals to -0.5 mm, almost no load is transferred by the implant and therefore it behaves as a void filler. V2 was found very influential. Indeed, V2 drives the stiffness of the implant and consequently controls the load sharing. Due to the numerous modelling assumptions, the results have to be considered from a qualitative point of view only. Further steps will consist of refining the model and carrying out a sensitivity study.

MICROSTRUCTURAL ASSESSMENT OF TRABECULAR BONE FAILURE BEHAVIOR

Ara Nazarian^{1,2}, Martin Stauber² and Ralph Müller^{1,2}

¹Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA

²Institute for Biomedical Engineering, Swiss Federal Institute of Technology, Zürich, Switzerland

INTRODUCTION

Osteoporosis occurs most frequently in post-menopausal women and the elderly. It is defined as a systemic skeletal disease characterized by low bone mass and micro-architectural deterioration of bone tissue, with a concomitant increase in bone fragility and fracture risk^{1,2}. Until recently the structural analysis of these fractures has been limited to two-dimensional sections. More recently, an image-guided technique, utilizing micro-compression in combination with micro-computed tomography (micro-CT), has been developed, which allows direct three-dimensional visualization and quantification of fracture progression on the microscopic level³. The goal of this project was first, to design a new micro-mechanical testing system, composed of the micro-compression device (MCD) and the material testing and data acquisition system (MTDAQ), and second, to validate the testing system to perform step-wise testing of trabecular bone specimens using image-guided failure analysis (IGFA).

METHODS

IGFA is based on time-lapsed compression and imaging of bone specimens. The testing protocol consists of applying sequential compression steps of 0%, 2%, 4%, 8%, 12%, 16% and 20% global nominal strain, while simultaneously measuring nominal stress. The specimen is imaged after each strain step to observe microstructural deformation. The MCD is designed to house the test specimens and act as a transportable link between the mechanical testing and micro-CT imaging. Previously, the MCD was loaded axially via a standard Instron-type mechanical testing system. The axial strain was applied through a pushpin on the MCD cap and locked manually. This combination introduced errors in the form of strain application fluctuation, due to reduced sensitivity of the testing machine at small strains, and the application of unknown manual torque in the strain locking process. In order to alleviate these problems, the MCD is instead interfaced with the MTDAQ. This system is designed to introduce axial strain to the specimen using a custom micro-stepping compression actuator. Also, an onboard LVDT measures the applied strain of the specimen. To establish accuracy and reproducibility of this new device, a total of 61 specimens were cored along the principal trabecular axis and cut into cylinders of \varnothing 8 mm x 12 mm for human vertebral specimens (n=31), and \varnothing 8 mm x 16 mm for whale vertebral bone (n=20) and ERG aluminum foam (n=10) specimens. The specimens were then divided into two groups with similar

mass and densities and one group was tested from 0-20% strain based on conventional continuous mechanical testing, while the other was tested from 0-20% strain using IGFA.

RESULTS

Mechanical properties obtained from the continuous and step-wise methods were not significantly different for aluminum foam, whale and human trabecular bone specimens. Both testing methods yielded very similar stress-strain graphs with almost identical elastic and plastic regions. In aluminum specimens a general trend of buckling was observed within the structure due to imposed strain, where the individual structural elements throughout the entire specimen tended to bend and buckle. However, failure was observed differently in whale and human trabecular bone specimens. In these cases, a transaxial subregion of the specimen would fold dramatically with the associated individual trabeculae experiencing high levels of deformations such as bending and buckling, whereas the remaining regions and elements were kept relatively intact. It was observed that although the mineral phase of the bone failed in a brittle manner, it showed a very ductile post failure behavior indicating that the collagen network is able to keep the trabeculae together over a large range of strains.

DISCUSSION

A novel MTDAQ was successfully designed and validated for step-wise IGFA and time-lapsed micro-CT imaging. One of the limitations of the system was the load frame compliance, which can be partially accounted for if incorporated in the strain measurements of the specimens. Another limitation was the method of displacement measurement, which measures the displacement of the end-effector. In order to measure the specimen's mid-axis strain, a novel strain measurement technique is currently under investigation. In summary, step-wise micro-compression yielded the same mechanical properties as classical continuous tests for porous materials, and IGFA provided insight in the pre and post failure behavior of these structures.

INTRODUCTION

Microcracks in bone are assumed to increase the risk of bone fractures and to stimulate bone remodeling. Several methods of histochemical staining have been reported to detect the microcracks in fresh and undecalcified sections of bone. However, in order to clarify the process of the insidious micro bone fractures, it may be important to know the biomechanical changes of bone properties surrounding the microdamages. In this paper, the detection of microcracks in bone without staining and the measurement of mechanical properties around the microcracks were attempted using the scanning acoustic microscope (SAM).

MATERIALS AND METHODS

The femurs of old females (65 years old and 86 years old) and of young beagle dog (8 months old) were harvested and trimmed into some parts with a bone saw. The specimen was embedded in Specific20 (Struers), an acrylic resin consolidated in lower temperature, with impregnation by a vacuum pump and the surface of specimen was polished with diamond papers.

H-SAM200 (Hitachi Construction Machinery Co.) was used as the SAM machine and a 200MHz of ultrasound was used in the observation. Four kinds of measurement were performed: acoustic impedance obtained from C-mode imaging, ultrasound velocity from XZ-mode imaging, elastic modulus and density calculated from the intensity of reflected wave by comparison with that of aluminum.

RESULTS AND DISCUSSION

Figure 1 shows the C-mode image sample. As shown in this figure, microcracks were detected easily by SAM though it was difficult to find the cracks by optical microscope with no staining.

Figure 2 shows the distribution of bone density around the microcrack shown in Fig. 1. It was clarified that micro scale distribution of material properties of bone could be measured using SAM and the density and the elastic modulus of bone were decreased around microcracks.

Figure 1: C-mode image at trochanter major of old female. Red rectangular indicates the measured area for mechanical properties.

In the measurement of young beagle dogs, microcracks were also detected and low density material was found at a microcrack. It would be estimated as the callus by its mechanical properties, and this indicates the development of the callus in the repair process of microcrack same as in that of macro scale bone fracture.

CONCLUSION

By SAM measurement, microcracks in bone were detected easily without staining and it was clarified that the mechanical properties around microcracks decrease and the occurrence of callus in repair process of microcrack are predicted. SAM could be utilized for identification of microcracks as well as for evaluation of its microscale biomechanical properties.

Figure 2: Distribution of density around the microcrack shown in Fig. 1. The density decreases around the crack.

KINEMATICS OF THE HEART

Pernilla Selskog¹, Einar Heiberg^{1,2}, Tino Ebbers², Lars Wigström^{1,2} and Matts Karlsson¹

Linköpings universitet, Linköping, Sweden

INTRODUCTION

The heart muscle (myocardium) has anisotropic, non-linear and time-dependent mechanical properties and is a complex three-dimensional structure. During the cardiac cycle, the myocardium undergoes large elastic deformations as a consequence of the active muscle contraction along the muscle fibers and their relaxation, respectively. A four-dimensional (4D) description (three spatial dimensions + time) of the mechanical properties of the myocardium may be of interest in the assessment of myocardial function. Time-resolved 3D phase contrast MRI makes it possible to quantify all three-velocity components, which is necessary to accurately describe the velocities in the heart. We present a method for estimation of myocardial kinematics using 3D time-resolved phase contrast MRI.

METHODS AND RESULTS

The 3D cine phase contrast MRI pulse sequence provides velocity vector information in a 3D spatial grid throughout the cardiac cycle (Wigström et al 1996). Unwanted magnetic gradient fields produced according to the Maxwell equations and phase shifts due to Eddy currents in the coils of the MRI scanner are compensated for. Saturation pulses in the S/I direction are used to reduce the signal from the blood. The data set consists of 32 time frames, each containing a 256x256x32 grid with vectors and gray scale data describing the velocities and anatomy, respectively.

Clinically relevant kinematic parameters, such as strain and strain rate, can be calculated from the velocity data. In order to describe the myocardial properties throughout the heart cycle we need to track discrete sites on the myocardium. This can be achieved by defining a parametric finite element mesh for the myocardium. The velocity information may then be used to track the motion of nodes in the mesh. The borders of the myocardium, necessary to define the mesh, can be found by selecting the traces which return to their starting point, as discussed by Ebbers et al (Ebbers 2001) and shown in Figure 1

Figure 1: Segmentation using particle trace (magnitude and myocardial probability). Left: Early diastole, Right: Mid-diastole

The deformation of the mesh will describe the deformation of the myocardium and the trajectory data can thereby be used for

strain calculations.

Kinematic parameters, such as strain and strain rate, are represented by tensors, which for three dimensions will have nine components. A visualization method enabling interpretation is therefore needed.

Tensors may be visualized as an ellipsoid in each data point. The three axis of the ellipsoid represent the eigenvectors (principal directions) of the tensor and the length of the axis represent the three eigenvalues (principal values), respectively. This visualizes both magnitude and direction of, for example, the deformation rate of the myocardium (Selskog et al 2001). The results of the tensor visualization method are shown in Figure 2, here displaying strain rate in a region of interest on a surface in the left ventricular myocardium (left). The orientation of the ellipsoids represents the main direction of instantaneous deformation at this time in the cardiac cycle (middle and right). The ellipsoids are colored according to the largest eigenvalue (sorted by magnitude) and the surface color represents the sum of the squares of the eigenvalues.

Figure 2: Tensor visualization using ellipsoids.

DISCUSSION

A method is suggested that allows a 4D description of the mechanical properties of the myocardium. The borders of the myocardium are successfully defined in the velocity data, enabling calculation of kinematic parameters, such as strain. The visualization method displays the full tensors, revealing the main direction of deformation or deformation rate. Complete strain and strain rate tensors represent a step towards quantification of myocardial motion and increased understanding of the complex mechanical properties of the heart. Using phase contrast velocity measurements also provides the possibility of adding blood flow information for a more complete description of cardiac dynamics.

MEASUREMENT OF ERYTHROCYTES DEFORMABILITY WITH COUNTER-ROTATING PARALLEL DISK SYSTEM

INTRODUCTION

Erythrocytes deform to pass through capillary in micro-circulation. Deformability of erythrocytes is an important parameter to maintain blood circulation. To measure erythrocytes deformation, several methodology have been designed in the previous studies. Measurement of erythrocytes deformability is available to detect their sublethal damage and to design micro-capsule like artificial erythrocytes. In this study, erythrocytes deformability was quantitatively evaluated with shear stress responsiveness in the counter-rotating parallel disk system.

METHODS

A parallel-disk-type rheoscope system has been designed and manufactured. In the system, Couette-type shear field is induced in the fluid between two counter-rotating disks, which are made of transparent silica glass (5 mm thickness, 80 mm diameter). The distance was maintained 0.1 mm between two disks supported with ball bearings (100 mm diameter). The rotating speed (<0.4 rad/s) was regulated with a stepping motor, which is controlled by a computer. The shear rate (<200 1/s), which is calculated from the velocity difference (<20 mm/s) between two disks and from the dimension between two disks, is constant regardless of the distance from the disk. An erythrocyte can be observed under shear without translational movement, when it is suspended at the stationary plane in the middle part of the shear field. Deformation of erythrocytes was viewed at a distance of 27 mm from the rotational axis through an optical-phase-contrast microscope with an objective lens of 20 magnifications, which has a long focal length of 6.9 mm. The picture was recorded with a charge coupled device camera at a shutter speed of 0.001 s, with a video tape recorder, and with a computer. Human erythrocytes were suspended in a dextran water solution (hematocrit of 0.5%, viscosity between 0.02 Pa s and 0.06 Pa s) and were sheared between two counter rotating disks at 25 degrees C.

Erythrocytes deform from biconcave to ellipsoid in Couette-type of shear field. Erythrocytes deformation was quantified with an elongation index (E), which was calculated from the length of major axis (L) and that of the minor axis (W) by $E=(L-W)/(L+W)$. E becomes zero in a sphere ($L=W$), and approaches to unity as the deformation advances ($L \gg W$). The elongation index (E) was plotted as a function of shear stress (S), and the fitting exponential curve was calculated by $E=C(1-\exp(-S/R))$, Where C is the critical elongation and R is the shear stress responsiveness.

RESULTS AND DISCUSSION

The dextran concentration in medium does not affect on shear stress responsiveness. Erythrocytes deformation is not governed by shear rate, but by shear stress in these shear condition. Couette-type flow has an advantage to quantify the shear, because uniform shear rate is applied to the whole space. The counter rotating rheoscope is a device to observe sheared cells, which are suspended at the stationary plane in the middle part of Couette-type flow without contact between cells and surfaces. Increase of stiffness of the disks minimizes secondary flow.

Figure 1: Relation between medium viscosity and shear stress responsiveness.

SUMMARY

The designed experimental system has enough geometrical accuracy to evaluate shear stress responsiveness. The present study shows that erythrocyte deformation is not governed by shear rate, but by shear stress.

INFLUENCE OF VISCOELASTIC HEEL INSERTS ON PEAK IMPACT LOADING AND PEAK ANKLE DORSI-FLEXION

Sharon Dixon and Victoria Stiles

School of Sport and Health Sciences, University of Exeter, Exeter, United Kingdom. s.j.dixon@exeter.ac.uk.

INTRODUCTION

Viscoelastic heel inserts have been reported as a successful intervention for the treatment of Achilles tendon pain (MacLellan and Vyvyan, 1981). However, the mechanism by which these inserts reduce Achilles tendon pain is not clear. One suggested explanation is that they reduce peak impact loading as the heel strikes the ground. Although viscoelastic heel inserts have been shown to reduce peak impact deceleration when placed in dress shoes (Light et al. 1980), a study on the effect of full-length inserts in running shoes reported no influence on peak impact loading (Nigg et al., 1988). An alternative suggested mechanism by which heel inserts are a successful treatment is that they result in a raised heel during midstance, causing a reduction in peak ankle dorsi-flexion, and thus a reduction in Achilles tendon strain. The potential of heel inserts to reduce peak ankle dorsi-flexion has previously been demonstrated in a barefoot study in which the heel was raised using high density ethyl-vinyl acetate inserts attached to the rear of the foot (Dixon and Kerwin, 1999). However, the influence of viscoelastic inserts placed in the rear of running shoes is not fully understood. The purpose of the present study was to investigate the influence of viscoelastic heel inserts during running. It was hypothesised that the placement of viscoelastic heel inserts in running shoes would reduce peak impact loading and would also result in a reduction in peak ankle dorsi-flexion.

METHODS

Seven distance runners volunteered to participate in the study. Each runner performed eight shod running trials at 3.83 m.s⁻¹ ($\pm 5\%$) under each of three conditions: no insert, insert1 (7.5mm maximum thickness), insert2 (15mm maximum thickness). Both inserts were constructed from the same viscoelastic material and were tapered along a length of 80 mm. For each running trial, force plate data were collected for a right-footed ground contact (AMTI, 600Hz). Sagittal plane kinematic data were collected simultaneously using a Peak optical system (Peak Technologies, 120Hz). Ankle joint angles were determined using markers placed at the knee, ankle and toe, with an increase in angle defined to indicate an increase in ankle joint dorsi-flexion.

Group mean values were calculated for peak magnitude and rate of loading of impact force, time of occurrence of peak impact force and peak ankle dorsi-flexion angle for each of the running conditions. Significant differences between the baseline (shoe only) condition and the insert conditions were tested using an ANOVA with repeated measures ($p < 0.05$).

RESULTS AND DISCUSSION

Mean group values and standard deviations for all variables are illustrated in Table 1. Although there appears to be a tendency for impact loading to be reduced by the use of increased viscoelastic material at the heel, none of the observed reductions were significant. Peak ankle dorsi-flexion was found to be reduced with the use of an increased thickness of heel insert, with insert2 causing a significant reduction compared with the no insert condition ($p < 0.05$).

Table 1. Peak impact force and time of occurrence, peak rate of loading and peak ankle dorsi-flexion for each of the running conditions. Mean values (standard deviation). (* $p < 0.05$).

	no insert	insert1	insert2
Peak impact force (Bodyweights)	2.20 (0.60)	2.04 (0.46)	2.01 (0.46)
Time of Peak impact force (ms)	33.5 (4.2)	34.0 (5.7)	34.4 (5.8)
Peak rate of loading (Bodyweights.s ⁻¹)	126.3 (41.2)	117.6 (46.0)	113.0 (43.7)
Peak ankle dorsi-flexion (degrees)	95.1 (2.8)	93.9 (1.0)	92.0* (2.5)

The hypothesis that viscoelastic heel inserts reduce peak impact loading when placed in running shoes is not supported by the results of the present study. This agrees with the findings of Nigg et al. (1988) for full-length inserts, and is likely to be the result of running shoes already providing sufficient heel cushioning. The hypothesis that viscoelastic heel inserts reduce peak ankle dorsi-flexion during running is supported in the present study, but only for the thicker of the two inserts. It is therefore suggested that for optimum treatment of Achilles tendon pain an insert of maximum thickness greater than 7.5mm may be preferred to a thinner insert.

SUMMARY

The results of the present study highlight the role of increased heel lift when using a viscoelastic heel insert intervention in running shoes.

EXPERIMENTAL INVESTIGATION OF THE ROLE OF THROMBUS ON THE PRESSURE-STRAIN RELATIONSHIP IN HUMAN ABDOMINAL AORTIC ANEURYSM

Madhavan L. Raghavan¹, Jarin Kratzberg¹ and Erasmo Simão da Silva²

¹Department of Biomedical Engineering, University of Iowa, Iowa City, IA

²Department of Surgery, University of São Paulo School of Medicine, São Paulo, SP, Brazil

INTRODUCTION

An abdominal aortic aneurysm (AAA) – a focal dilation of the human abdominal aorta – typically contains substantial amounts of thrombus lining the inner wall. It has been hypothesized that thrombus may act like a cushion to reduce the pressure-induced stress in the AAA wall, thus lowering its risk of rupture (Wang, 2001). To investigate this hypothesis, we experimentally measured and compared the strain in human AAA with and without thrombus using autopsy specimens.

METHODS

Experimentation: Four AAA specimens were harvested from cadavers during autopsies performed at the Service for Confirmation of Deaths, São Paulo University School of Medicine. The specimens varied in size (4 – 8 cm) and amounts of thrombus. Each specimen was hung from a frame using 3 hooks at marked locations. A ruler was also hung beside the AAA. A tripod-fixed digital camera was placed such that it faces the anterior portion of the AAA at its elevation. A balloon connected to a pressure gauge was inserted from the proximal end. Using the balloon, the AAA was inflated to 0, 80, 100, and 120 mmHg. Simultaneously, the AAA was photographed using the digital camera at each of the four pressures. This procedure was repeated by placing the digital camera at the left, posterior and right views also. Next, the AAA was removed from the frame and all the thrombus inside the AAA was scrapped out intraluminally. The AAA was then hung back in the frame taking care to ensure that it is hung from the same three hooks at exactly the same points. This ensured that the anterior, left, posterior, and right views of the thrombus-free AAA are not different from the earlier position with thrombus. The specimen was once again gradually inflated and photographs similarly taken for all four pressures from all four views.

Data Analysis: The outline of the AAA on the individual images for all the specimens and the ruler were digitized using Scion Image (ver 4, Scion Corp, Frederick, MD). A custom-written Visual Basic algorithm was used to import the digitized outlines into Microsoft excel, convert distances to cm using ruler measurements, calculate the area inside the AAA for all four views at the four pressures, determine the % change in area from 0 through 80, 100, and 120 mmHg for each view and the overall average for all views combined.

RESULTS AND DISCUSSION

Of the four AAA, AAA# 1&2 were large (dia >7cm) and had substantial amounts of thrombus. AAA# 3&4 were relatively small (dia < 5 cm) with moderate amounts of thrombus. The view-averaged % change in area for AAA# 1, 3 & 4 was significantly higher without thrombus than with it. AAA #2, exhibited low % change in area, but it was slightly greater with thrombus than without it. Figure 1 graphically illustrates the results.

Figure 1: Percent change in area - pressure relationship for the four AAA studied with and without thrombus. The area strain is an average of individual % change in area from the four views.

SUMMARY

We have experimentally investigated the role of thrombus on the AAA wall strain. It appears from the results that thrombus is indeed reducing the strain on the AAA wall, lending support to the hypothesis that thrombus reduces wall stress and therefore rupture risk. AAA #2 alone showed a reverse result, but appeared to exhibit relatively low strain in the pressure range studied. It is unclear whether digitization/experimental error magnified by its low strain may have caused this or if this is indicative of a genuine phenomenon. Study of a larger population coupled with detailed analysis of the type and configuration of thrombus is ongoing to investigate further.

INTRODUCTION

Trabecular bone remodeling is caused by cellular activities on trabecular surface driven by a local mechanical stimulus. To understand and predict trabecular structural changes due to remodeling, it is important to clarify *in vivo* mechanical stimulus at microstructural level. In this study, local stress nonuniformity as a mechanical stimulus for trabecular surface remodeling was evaluated using digital image-based finite element model of rat vertebral body.

METHODS

A digital image-based model for a center part of rat L1 vertebral body was constructed from X-ray micro CT data, as shown in Fig. 1. A bone element was $12.8 \mu\text{m}$ on each side, and assumed to be a homogeneous and isotropic material with Young's modulus 20 GPa and Poisson's ratio 0.3. As a daily loading condition, compressive displacement was applied to the upper plane of the image-based model to apply the total loads 10 N. Finite element analysis was conducted to calculate local nonuniformity of Mises equivalent stress $\Gamma = \ln(\sigma_c/\sigma_d)$ (Adachi et al., 1997) over the trabecular surface in central hexahedron cancellous region, as indicated by dotted lines in Fig. 1. Here, σ_c denotes the stress at the point \mathbf{x}_c on trabecular surface, and σ_d denotes the neighbor stress around the point \mathbf{x}_c :

$$\sigma_d = \int_S w(l) \sigma_r dS / \int_S w(l) dS. \quad (1)$$

In Eq.(1), σ_r denotes the stress at the point \mathbf{x}_r on the trabecular surface S , l denotes the distance between the points \mathbf{x}_c and \mathbf{x}_r , and $w(l)$ is a weight function decreasing to the distance l . σ_d was evaluated within a sensing distance $l_L = 200 \mu\text{m}$ in this study.

Figure 1: Image-based model of rat vertebral body.

Figure 2: Mechanical stimulus Γ in cancellous region obtained by image-based finite element method.

RESULTS AND DISCUSSION

Mechanical stimulus Γ on trabecular surface was distributed depending on trabecular microstructure, as shown in Fig. 2(a), although the vertebral body was under simple external loading. This result indicates digital image-based finite element method is useful in quantifying mechanical stimulus at trabecular level for three-dimensionally complicated structure in the actual bone. Considering a role of osteocyte as a mechanosensor, mechanical stimulus Γ in the case of integrating over the volume dV in Eq. (1) was also obtained. Frequency of the mechanical stimulus, defined by normalized trabecular surface area S/S_{total} to the mechanical stimulus Γ , showed that mechanical stimulus Γ for volume integration was shifted to formation side ($\Gamma > 0$) compared to that for surface integration, as shown in Fig. 2(b). This result suggests that osteocytes existing in bone matrix would play an important role in maintaining an amount of bone volume.

CONCLUSION

Mechanical stimulus for trabecular surface remodeling was evaluated using digital image-based finite element model of rat vertebral body considering *in vivo* three-dimensionally complicated trabecular structure. The proposed simulation method would be useful in understanding mechanosensory system in trabecular surface remodeling.

THE HEALING RESPONSE OF ACL AND MCL INJURIES IS INITIALLY SIMILAR BUT DIVERGES WITH TIME

Lo IKY, Marchuk LL, Leatherbarrow KE, Sutherland C, Barclay L, Hart DA, Frank CB

McCaig Centre For Joint Injury And Arthritis Research, University Of Calgary, Calgary, AB, Canada, email: cfrank@ucalgary.ca

INTRODUCTION

Medial collateral ligaments (MCLs) heal with the formation of scar tissue. In contrast, for reasons which remain unclear, anterior cruciate ligament (ACL) injuries are said to have a poor or absent healing (scarring) response (reviewed in Lo et al, 1999). However, recent studies have suggested that in some cases, particularly in partial ACL injuries, the ACL can exhibit some signs of a healing response although this has not been well characterized (Hefti et al., 1991). The purpose of this study was to evaluate a subset of extracellular matrix molecules during MCL and ACL healing in the ovine model.

METHODS

13 skeletally mature, female suffix-cross sheep were utilized for the study. 4 animals were used as normal control animals. In 9 animals, the right leg was used as the experimental limb and the left leg as an additional contralateral control. The MCL was transected at the joint line and the posterolateral band (PL) of the ACL was then transected and allowed to retract. The anteromedial (AM) band and posterior cruciate ligament were left undisturbed. The animals were allowed to recover with unrestricted activities. The midsubstance of the MCL and PL-ACL scar was harvested at 0, 6 and 12 weeks following injury. Tissue was analyzed by reverse transcriptase polymerase chain reaction (RT-PCR) and immunohistochemistry. RT-PCR was performed as previously described (Boykiw et al., 1998) for biglycan, decorin, type I collagen and type III collagen using sheep-specific primer sets. Results were normalized to the housekeeping gene GAPDH. Indirect immunofluorescence microscopy was performed using 7 µm paraffin sections and antibodies to decorin (P Scott) and biglycan (P. Roughley) using standard immunohistochemical techniques. All comparative sections were incubated simultaneously and visualized and photographed on an Axiostop 2 plus fluorescence microscope (Zeiss, Germany) under standardized exposure times. One-way ANOVA with post-hoc t-tests and Bonferroni correction were used to determine differences between groups.

RESULTS

At 6 weeks, changes in mRNA levels were strikingly similar in the MCL and PL-ACL scar tissue. mRNA levels for biglycan, type I collagen and type III collagen were increased in both the PL-ACL and MCL scar tissue of injured legs versus uninjured contralateral or normal controls ($p < 0.008$). In addition, decorin mRNA levels were significantly decreased in the MCL ($p = 0.01$) and ACL ($p = 0.001$) at 6 weeks. At 12 weeks, both MCL and PL-ACL scar tissue continued to demonstrate similar changes with increased mRNA levels for type I and III collagen ($p < 0.001$). In addition, the MCL scar tissue biglycan mRNA levels were increased ($p < 0.02$) and decorin mRNA levels were decreased ($p < 0.04$). In contrast, in 12 week PL-ACL scar tissue, biglycan mRNA and decorin mRNA levels were not significantly different from controls.

To confirm differences seen at the mRNA level, immunofluorescence microscopy was performed for decorin and biglycan. In the MCL, immunofluorescent staining for decorin was decreased at 6 and 12 weeks while biglycan was increased at 6 and 12 weeks when compared to normal controls. However, in the PL-ACL, immunofluorescent detection of decorin decreased in 6 week scars but appeared to increase at 12 weeks. Immunofluorescent detection of biglycan was increased in both 6 week and 12 week PL-ACL scars when compared to normal but appeared to decrease at 12 weeks when compared to 6 weeks scars.

DISCUSSION

Following injury, many authors have suggested that the ACL does not heal or fails to show any evidence of a healing response. Our results suggest that following partial ACL injury, new tissue can form in the gap containing cells, which undergo similar extracellular matrix molecule changes to those in healing MCLs at 6 weeks. By 12 weeks however, the scarring response appears distinctly different. While the MCL of the sheep continues to demonstrate increased biglycan and decreased decorin levels, the PL-ACL demonstrated decreased biglycan and increased decorin levels when compared to 6 week PL-ACL scars. These proteoglycans have been previously identified as being altered in the rabbit MCL healing model (Boykiw et al., 1998), suggesting some similarities between the healing responses of different species.

Interestingly, increased biglycan levels have been associated with other models of chronic scarring including hypertrophic scar formation in skin or kidney fibrosis (Scott et al., 1996; Yamamoto et al., 1994). Thus, the decreased levels of biglycan when compared to MCL scars or 6 week PL-ACL scars may indicate that the scarring response may be inadequate or prematurely halted in PL-ACLs. In addition, decorin appeared to increase at 12 weeks in the ACL scar. With its known action of inhibiting collagen fibrillogenesis, increasing decorin levels may prevent or inhibit collagen fibril formation and thus scarring (Vogel et al., 1984). Although these changes may be secondary effects, they may also be potential factors in the eventual failure of functional healing of the ACL.

INTRODUCTION

Platelet transfusion is the only effective therapy for bleeding associated with thrombocytopenia. However, platelet suspension has several serious problems such as the insufficiency or the transmitting of virus. To break these problems, substitutes for platelets have been desired. Even though many substitutes have proposed, any products couldn't be employed in clinical, because there is no methodology for assessing the haemostatic functions of such substitutes. In present study, we assessed the ability of platelet substitute $r\text{GPIIb}\alpha$ -AMS, which interacts with ristocetin induced platelet aggregation, and then, at the first step to evaluate the ability, we observed the adhesive motion under flow condition.

METHODS

We used rectangular channel consisted of two glass plates and upper and lower chambers to fix them. Two glass plates, the thickness of 200 μm , were placed with an interval of 200 μm . The interval was applied as the rectangular channel. One glass plate was coated with vWF (100 $\mu\text{g}/\text{ml}$), and the another with BSA (1%). $r\text{GPIIb}\alpha$ -AMS was labeled with fluorescein isothiocyanate (FITC), and excited with argon-ion laser (ILT4590, Ion Laser Technology). Steady flow was introduced by gravity at an upper chamber. Because of transparency, we used red cell ghosts suspension prepared with hypotonic lysis method. The motion of flowing near the wall was obtained by using a High Speed Camera (SPEED CAM+, Weinberger) with an Image Intensifier (XX1420AA, Delft Electronic Products). The Image was processed with NIH Image (U.S. National Institute of Health) and abstracted the single particle images. Then we identified the same particle and measured the concentration profile and the drift velocity.

RESULTS AND DISCUSSION

The concentration profiles of $r\text{GPIIb}\alpha$ -AMS at high shear rate showed the near-wall excess (NWE). The highest concentration was 5 times as high as that at the center, whereas it was 2.4 times at low shear rate (Figure 1). Many previous works demonstrated the NWE of platelet-sized particles, and NWE was thought to accelerate the interaction between platelets and injured vessel wall. So it seems that $r\text{GPIIb}\alpha$ -AMS has a property to arrest bleeding haemorheologically. $r\text{GPIIb}\alpha$ -AMS adhered to vWF

surface, although no interaction observed with BSA surface. In the time-series, $r\text{GPIIb}\alpha$ -AMS flowing near the vWF surface moved more randomly, since several particles adhered the wall (Figure 2). This behavior seems to contribute to the thrombus formation.

EFFECT OF HAMSTRINGS MUSCLE ACTION ON STABILITY OF THE ACL-DEFICIENT KNEE

Takashi Yanagawa¹, Kevin Shelburne¹, Frank Serpas², and Marcus Pandy²

INTRODUCTION

Knee-extension exercise is a common component of rehabilitation regimens aimed at maintaining quadriceps muscle strength following injury to the ACL. Unfortunately, this exercise may cause large anterior tibial translations (ATT) when the ACL is absent. Excessive ATT may lead to damage to the meniscus and other passive structures inside the knee. Several studies have shown that hamstrings co-contraction can reduce ATT in the ACL-deficient (ACLD) knee. Hagood et al. (1990) reported hamstring co-activation at all speeds during maximal isokinetic knee extension exercise. Relatively little is known, however, about the *amount* of hamstrings activation needed to keep ATT within normal limits during knee extension exercise. Also, no results are available for the effects of hamstrings muscle action on stability of the ACLD knee during isokinetic knee extension. The purpose of this study was to quantify the effect of hamstrings muscle action on stability of the ACLD knee during isokinetic extension exercise at various speeds. The limit of knee-joint stability was defined as the peak ATT calculated for maximum isometric contractions of the quadriceps in the ACL-intact knee in the absence of hamstrings co-contraction.

METHODS

Modeling and forward-dynamics simulation were used to study the interactions between knee-extension speed, hamstrings co-contraction, and ATT. Isokinetic knee extension was simulated using a sagittal-plane model of the knee and lower leg. The geometry of the model bones was adapted from cadaver data. Tibiofemoral and patellofemoral articulation were each modeled as single-point contact. Eleven elastic elements described the geometric and mechanical properties of the knee ligaments and posterior capsule. The model was actuated by eleven musculotendinous units. The path of each muscle was represented by a straight line, except when it contacted and wrapped around the bones and other muscles (Shelburne and Pandy, 1997). The lower leg was distally constrained by its connection to the massless arm of a simulation isokinetic exercise machine. It was assumed for the duration of each simulated exercise that the quadriceps were fully activated and that the other muscles (including hamstrings) were fully deactivated. However, the passive forces developed by the muscles were taken into account. Details of the simulations are described by Serpas et al. (in press).

RESULTS AND DISCUSSION

ATT was inversely related to extension speed in the ACLD knee. There was also an inverse relationship between ATT and

hamstrings co-contraction level at all extension speeds. Some amount of hamstrings activation was needed at all speeds to stabilize the model ACLD knee. Although peak ATT decreased as extension speed increased, the decrease was insufficient to prevent excessive ATT (knee instability), even at the highest extension speeds (360 deg/sec). However, relatively low levels of hamstrings activation were needed to stabilize the ACLD knee at speeds above 300 deg/sec. For example, the hamstrings must be activated at least 35% of maximum for the model ACLD knee to remain stable during isometric extension; in contrast, when the model knee was extended at a rate of 360 deg/sec, only 10% of maximum hamstrings activation was needed (Fig. 1). If a rehabilitation program is to include isokinetic exercise as an adjunct to thigh muscle strengthening, it will be important to ensure that the ACLD patient is capable of co-contracting his/her hamstrings during this exercise; otherwise, excessive ATT over time may cause damage to the menisci and other passive structures, resulting in further degeneration of the joint.

Figure 1: Hamstrings contraction required for knee stability at all isokinetic speeds.

SUMMARY

If ACL-deficient patients can be trained or artificially stimulated to co-contraction their hamstrings muscles during isokinetic knee extension, then this exercise is appropriate for maintaining strength of the thigh muscles without compromising anterior stability of the knee. The results of this study also suggest that hamstrings co-contraction is more effective than low-resistance extension exercise as a therapy for conservative treatment of the ACLD knee.

MODELING OF MANUAL WHEELCHAIR PROPULSION USING OPTIMIZATION

LY Guo^{1&2}, KD Zhao¹, FC Su², K-N An¹

¹Orthopedic Biomechanics Laboratory, Mayo Clinic, Rochester, MN 55905

²Institute of Biomedical Engineering, National Cheng Kung University, Tainan, 701 TAIWAN

INTRODUCTION

Collection of biomechanical data is essential for understanding handrim wheelchair propulsion. Biomechanical models can add to our understanding by clarifying how upper extremity segments and muscles interact to execute the motor task. Therefore, we have developed a two-dimensional model of the upper arm, forearm, and wheelchair wheel to study different aspects of the man-machine environment, including the mechanical constraints and effectiveness of force application while propelling a wheelchair. The goal of this study is to develop and validate the model as well as present predictions of handrim kinetics during wheelchair propulsion.

METHODS

A planar model was developed at incremental changes in wheel angle throughout the propulsion cycle. Anthropometric and strength data were collected from subjects as inputs to the model and model predictions of handrim force and progression moment were compared to those collected from the subjects during quasi-static wheelchair propulsion.

Analytic Modeling

The analytical model is comprised of three segments (the upper arm, lower arm and hand, and hand to wheel hub) (Fig. 1). At each hand position, the unknown forces on the handrim (F_h) are obtained by maximizing the progression moment about the wheel axle (M_o),

subject to the following equality and inequality constraints:

$$\begin{aligned} M_s &= P_s \times F_h \\ M_e &= P_e \times F_h \\ M_o &= P_r \times F_h \\ -M_{se} &\leq M_s \leq M_{sf} \\ -M_{ee} &\leq M_e \leq M_{ef} \end{aligned}$$

Figure 1: Analytical model of wheelchair propulsion mechanics

where M_s and the M_e are the flexion/extension moments at the shoulder and elbow joints, respectively, due to the force F_h . P_s , P_e , and P_r are the position vectors of the shoulder, elbow, and wheel axle relative to the point of force application on the handrim. M_{se} , M_{sf} and M_{ee} , M_{ef} are the maximum shoulder and elbow joint strengths in extension and flexion.

Experimental Measurement

Five healthy male subjects (30 to 40 years old) participated in this study. Lengths of the upper arm and forearm as well as the

shoulder position relative to the wheel axle, were obtained.

Isometric shoulder and elbow flexion and extension strengths throughout the ranges of motion were measured using a KinCom125 AP[®], and fitted to second order polynomials as function of joint angle. An instrumented wheelchair developed in our laboratory was used to measure applied handrim forces and moments on the handrim at wheel angles (θ) of 120, 105, 90, 75 and 60 degrees during static wheelchair propulsion.

RESULTS AND DISCUSSION

The model predicted a progression moment that is larger at the initial and terminal propulsion positions (i.e. wheel angles of 120 and 60 degrees respectively) and is smaller in mid-propulsion. The experimental results supported this finding (Table 1). This phenomenon may result from a mechanical disadvantage of the upper arm musculature at mid-propulsion. At mid-propulsion, the reaction force on the hand is nearly perpendicular to the moment arms of the force about the shoulder and elbow. Thus, even small forces result in large moments at the two joints. Differences in force direction are quite small between model and experiment at all propulsion positions. Differences in force magnitude and progression moment between model and experiment were smaller in the initial and mid propulsion hand positions than in the terminal propulsion (Figure 2).

Figure 2: The difference in force magnitude and force direction between model and experiment at wheel angles of 120°(A) 90° (B) 60° (C)

SUMMARY

A planar model has been successfully developed and validated which could be useful in examining the mechanics of wheelchair propulsion and in wheelchair design and fitting. In the future, the model will be further refined to include muscle dynamics and to be three-dimensional.

COMPUTATIONAL MODELLING OF BLOOD FLOW AND ARTERY WALL INTERACTION

Debbie Grossman, Chris Bailey, Koulis A. Pericleous and Avril K. Slone

Centre for Numerical Modelling and Process Analysis University of Greenwich, Old Royal Naval College
10 Park Row, Greenwich, LONDON SE10 9LS United Kingdom
E-mail D.Grossman@gre.ac.uk

INTRODUCTION

The study of diseases of the Circulatory System is an increasingly active research area. Since annually this accounts for approximately 40% of all the deaths in the United Kingdom. Traditionally, studies have been carried out on either blood flow phenomena or arterial wall behaviour, with a variety of models being used for both. Newtonian and non-Newtonian models for blood flow see C.A. Taylor *et al*, and shell theory amongst others, for the arterial wall.

Clinical research has shown that there is two-way interaction between the artery wall and blood flow, which must be considered if the arterial wall behaviour is to be modelled accurately. Some attempts are now being made to couple the two distinct models of the two phenomena. However this usually involves the linking of two very different commercial codes e.g. S.Z. Zhao *et al* used CFX and ABAQUS, which provides a number of additional complications. Here we will present details on a research effort that is developing novel, closely integrated solution procedures for both blood flow and artery wall deformation. At this stage of the work 3D results will be demonstrated where the blood is non-Newtonian and the artery wall elastic.

METHODOLOGY

Due to the multiphysics nature of the problem there are three distinct parts to the solution: (1) Blood flow, (2) Artery wall behaviour and (3) Interaction between the two.

(1) BLOOD FLOW

For the blood flow a conventional computational fluid dynamics method is used with a choice of models for bloods non-Newtonian properties namely the Power-law and Casson's Equation.

(2) ARTERY WALL BEHAVIOUR

Here initially the wall was modelled as a single layered elastic wall. This is expanded to 2 layers based on the fact that the intima (inner layer) of the aorta is a single layer of cells so has little impact on the wall behaviour, G.A. Holzapfel *et al*. Various studies have determined that the arterial wall behaviour is non-linear and viscoelastic it is our intention to incorporate these properties into the model in future.

(3) INTERACTION

The approach presented here is based on that presented by A. Slone *et al* who employed a dynamic mesh approach to dynamic fluid structure interaction for an aircraft wing in fluid flow. In the case of transient runs, the finite volume analysis is performed at the end of each fluid time step, the mesh is deformed and the fluid flow is calculated for the next time step using the deformed mesh.

RESULTS

At this stage of the work simple 3D geometric results will be demonstrated where the blood is non-Newtonian and the artery wall a two layered elastic material. In this case the effects of the blood on the artery wall are considered, where the fluid pressure is applied to the artery wall.

It is hoped to include a realistic pressure pulse and corresponding arterial wall movement based on actual data taken in vivo from a dog.

SUMMARY

A single software framework PHYSICA is being used to provide solutions for both the blood flow (using CFD techniques) and the corresponding artery wall deformation (using FV method) with results from each feeding directly back into the next time step. It is our intention to demonstrate the one-way fluid-structure interaction between non-Newtonian blood flow and a compliant linear elastic artery wall within a 3 dimensional model.

IN-SITU CHONDROCYTE DEFORMATION IN EARLY STAGE OSTEOARTHRITIC (OA) ARTICULAR CARTILAGE

Andrea Clark¹, Walter Herzog¹, John Matyas², Leona Barclay² and Tim Leonard¹
University of Calgary, Calgary, Alberta, Canada

¹ Human Performance Laboratory, Faculty of Kinesiology walter@kin.ucalgary.ca

²The McCaig Centre for Joint Injury and Arthritis Research

INTRODUCTION

Chondrocytes and their nuclei deform throughout the depth of articular cartilage in proportion to the magnitude of applied compression (3). Furthermore, deformation alters the biosynthetic activity of normal chondrocytes in vitro (5). Little is known about how compression influences the magnitude and local variation of chondrocyte deformation in situ, and if these parameters change with disease. Our aim was to evaluate variations in chondrocyte deformation throughout intact specimens of early stage OA cartilage subjected to uniform static compression.

METHODS

Six cats were euthanised 16 weeks post-unilateral anterior cruciate ligament transection (ACL-T), a model of OA (4). A cylindrical, metal indenter was used to apply a surface pressure of 9MPa to the centre of the articular cartilage of the experimental femoral groove and patella. After load relaxation, the cartilage was fixed in RHT fixative (1) and full-thickness osteochondral blocks were harvested from identical anatomical sites in experimental and contralateral specimens. Sections stained with toluidine blue were examined under the light microscope.

RESULTS

Morphologically, the contralateral knees were grossly normal with the experimental knees showing typical initial signs of degeneration. Histologically, the experimental patellar cartilage had increased in thickness and showed decreased matrix staining in the superficial layer compared to contralateral and healthy patellae. Furthermore, chondrocytes from the superficial and middle layers of experimental patellae were more rounded (Fig 1a), arranged in clusters, and had an increased volume density. These changes were not observed in the experimental femoral grooves.

Static compression decreased the aspect ratio of chondrocytes throughout the depth of both tissues (Fig 1). Comparison with results obtained from healthy articular cartilage (1) showed that this decrease was similar for OA and healthy femoral cartilage, however differed in the superficial and middle layers of patellar cartilage. The change in aspect ratio of superficial and middle layer patellar chondrocytes being smaller in magnitude in OA compared to healthy tissue (Fig 1a).

DISCUSSION

The results of this study demonstrate architectural and compositional adaptation in patellar articular cartilage 16 weeks post ACL-T. Furthermore, in the indented superficial and middle layers of patellar cartilage, chondrocytes in OA tissue flattened less than chondrocytes in healthy tissue. In contrast these differences were not observed in the femoral groove cartilage.

The contrast in pathology between patellar and femoral groove articular cartilages demonstrated here was also evident (though

Figure 1: Graphs of transformed chondrocyte aspect ratio (CAR) ($y=\{3 \times \ln[\text{CAR}]\}+10$) as a function of cartilage depth for (a) patellar and (b) femoral groove tissues. Each graph compares healthy ($n=4$) and OA ($n=1$) tissue in the unindented control and indented state. Values of CAR have been averaged (\pm SD) within 5 or 10% bins throughout the cartilage depth so that $n>10$ cells for each bin. Representative ellipses placed at their corresponding values of transformed aspect ratio are shown pictorially on the right.

different in nature) >57 months post ACL-T in the cat (1). Together, these results demonstrate the site specific nature of cartilage adaptation with the progression of OA, even across articulating cartilage surfaces of the patellofemoral joint. We speculate that this is caused by the differing nature of the load experienced by the surfaces and the variations in the cartilage properties across the joint in healthy tissue. Furthermore, the site specific architectural and compositional adaptation of cartilage with OA influences the deformation, and presumably, the metabolic response of chondrocytes in situ.

INTRODUCTION

Recently, a method of measuring the actual area of fingertip motion using the motion analysis system was developed (Chiu & Su, 1996). This scientific and objective method complemented the traditional evaluations of assessing an injured finger. However, it was not suitable for measuring the motor function of the thumb. The major movement of the finger is in the flexion/extension plane associated with little rotation and lateral movement. Thus, the area of fingertip motion is concentrated to a two-dimensional plane. However, the motion of the thumb is completely different from that of the other digits with broadly ranging movements in a three-dimensional space. Assessing the volume covered by the moving track of thumb tip in three-dimensional space would be more precise, but more complicated than the current methods for another digits. The maximal working space of the thumb-tip is defined as the maximal motion range of the thumb-tip movement in the 3-D. This working space is formed by the largest range of motion of each joint of the thumb. It also means that it is impossible for the movements of thumb-tip to exceed this maximal working space. The objective of this study was to develop a quantitative evaluation method of measuring maximal working space and to establish a kinematics model of the thumb.

METHODS

Fifteen adults without previous and present injuries of the thumb and three patients were recruited in this experiment. Six normal subjects were involved in the first part of the study to assess the reliability of the measurement of the thumb tip motion by the motion analysis system. Nine normal subjects and three patients were studied to assess the value of maximal working space and kinematics of the thumb. Since the length of the thumb influences the volume of working space, the length of each thumb studied was measured before the motion analysis investigation. The maximal motion space was evaluated by the ExperVisionTM motion analysis system (Motion Analysis Corp, CA, USA). Eleven retro-reflective markers, 4 mm in diameter, were placed on the dorsal side of the thumb. The subjects were asked to adopt two extreme motion patterns (A and B) of the thumb to form the maximal working space when filmed by the video camera (Fig. 1). Through registering, reconstructing the markers and transforming the coordinate systems, a computer software system was developed for numerical integration to compute the maximal working volume and the kinematics of the thumb.

RESULTS AND DISCUSSION

The reliability of the repeated measurements of the maximal motion area of the thumb-tip movement was calculated as 0.89. The two motion paths formed by the two designed movements are shown in Fig. 2a. The maximal working space of the thumb-tip motion is shown in Fig. 2b. The linear relationship between the maximal volume and the thumb length was also

determined: $Motion\ area\ (cm^2) = 0.677 \times (finger\ length)^2$. The angular variations of each joint of the thumb were also calculated and are illustrated in Fig. 3.

Figure 1: The two designed movements (A and B) of the thumb to form the maximal working space of the thumb-tip motion

Figure 2: The two motion paths (left) and maximal working space of the thumb-tip motion in the 3D (right)

Figure 3: The goniometry through entire movement of MP joint of the thumb of one subject

SUMMARY

A quantitative evaluation method for assessing the motion impairment of the thumb has been developed. In this study, both an evaluation method of the maximal working space of the thumb tip, as well as kinematic model of the thumb, were developed.

INCREASED DESMIN IN RAT DORSIFLEXORS AFTER A SINGLE BOUT OF ECCENTRIC EXERCISE

Ilona A. Barash¹, David Peters¹, Gordon J. Lutz¹, Jan Fridén² and Richard L. Lieber¹
rlieber@ucsd.edu; Departments of Orthopaedics and Bioengineering
¹University of California, San Diego School of Medicine, La Jolla, CA 92037
²Department of Hand Surgery, Göteborg University, Göteborg, Sweden

INTRODUCTION

Eccentric contraction (EC) causes skeletal muscle injury and decreased force output (Proske and Morgan, 2001). Even a single bout of EC is known to prevent subsequent injury (Morgan and Allen, 1999), but the mechanism of this protection is unknown. One of the earliest changes detected in muscle after EC is a loss of desmin immunohistochemical staining within minutes after the contractions begin (Lieber et al, 1996). This study demonstrates two points: it demonstrates “protection” from EC-induced muscle injury in a rat model and shows that one long term effect of EC is to increase the relative amount of desmin in the muscle.

METHODS

All procedures were approved by the University of California and V.A. Medical Center Committees on the Use of Animal Subjects in Research. Thirty EC's, at two minute intervals, were induced by stimulating the peroneal nerve of male Sprague-Dawley rats at 100Hz while the foot was actively plantarflexed using a dual-mode servo motor (Cambridge Tech, Model 6650), similar to that previously reported for the rabbit model (Lieber et al, 1994). Ankle angle was rotated 38° corresponding to a fiber length change of 12% in the tibialis anterior (TA) muscle. Joint torque and tissue were analyzed 6, 12, 24, 48, 72, and 168 hours after the EC bout. One group of animals (the “protected” group) was exposed to two bouts of ECs separated by 72 hours, with torque measured 48 hours after the second EC bout. Muscles were snap frozen and a 25µm thick cross-section was taken from the central belly of the TA and immediately extracted on ice in SDS-PAGE sample buffer. Western blots were run, in triplicate, from each time point using antibodies to desmin (DER-11, Novocastra; 1:100) and actin (A4700, Sigma; 1:100,000), along with desmin and actin standards on each gel. Data are presented as mean±SEM and were analyzed by one way ANOVA with Fisher's PLSD *post hoc* test when appropriate.

Figure 1: Dorsiflexion torque measured 48 hours after EC, normalized to pre-EC torque. The protected group underwent two bouts of ECs separated by 72 hours. The unprotected group generated 77.3±3.7% of pre-EC torque while the protected group generated 99.8±6.2% of pre-EC torque.

RESULTS

Isometric dorsiflexion torque measured 48 hours after a single bout of EC was only 77% of torque measured prior to EC ($p<0.01$, asterisk Fig. 1). Maximum isometric torque measured 48 hours after the second bout of EC, however, was not decreased, *i.e.*, the muscle was protected from EC-induced injury (Fig. 1). These data demonstrate functional protection of the muscle from injury after a single EC bout. Structurally, we measured a three-fold increase in the ratio of desmin to actin from control levels of 0.00435 ± 0.000661 to 0.0125 ± 0.00125 168 hours after EC ($p<0.0001$, Fig. 2).

Figure 2: Desmin/actin ratio measured from Western blots at various time points after a single EC bout (asterisks, $p<0.05$).

DISCUSSION

These data reveal that one bout of ECs in this model protect against subsequent injury induced by ECs. Maximum isometric dorsiflexion torque was significantly decreased 48 hours after a bout of 30 ECs compared to original torque values, but this decrease did not occur if the muscles were preconditioned by a bout of eccentric contractions 72 hours earlier. The second result is that the relative amount of desmin in muscle cells increases after a single bout of eccentric contractions. It is unknown whether this desmin is incorporated into the cytoskeleton and whether increased desmin is directly responsible for the protective effect observed. Future studies are required to localize the newly synthesized desmin and to determine its structural role (if any) in muscle cell force transmission (Sam et al. 2000).

EVALUATION OF ALTERNATIVE MATERIAL FOR THE PREVENTION OF PRESSURE SORES

Rajshree Mootanah¹ Vijai Ranawat² and John Dowell³

³John Dowell, Orthopaedic Consultant, Broomfield Hospital, Chelmsford, Essex, jkdowell@lineone.net

INTRODUCTION

Pressure sores are potentially serious complications caused by capillary closure due to extended periods of immobilisation. Capillary blood flow pressure ranges between 22 and 32 mm Hg (Landis, 1930) and when externally applied loads create localised pressure above this level, blood flow is likely to be obstructed and circulation is reduced, resulting in pressure sores. Excessive and prolonged pressure excludes blood from the skin and subcutaneous layers and may cause thromboses, ulcer and necrosis. A variety of products are used in hospitals to reduce pressure sores, but most are very costly and harbour bacteria and therefore could transmit infections when re-used.

In hospitals, the incidence of pressure ulcers seems to range from 2.7% (Gerson, 1975) to 29.5% (Clarke and Kadhon, 1988). The yearly UK costs of pressure sore treatments have been estimated to be £755 million (West and Priestley, 1994). The aim of this study is to investigate the potential use of more cost effective disposable products, without compromising on efficacy.

METHODS

Currently marketed (jelly pad) and novel (bubble wrap) pressure relief products were used in this study to compare pressures generated when a subject sat on the different products. The X-sensor pressure mapping system, which consists of a thin mat containing grids of miniature force sensors, was placed between the subject and the pressure relief products, one at a time, to electronically record information on pressure distributions. The pressure relief system was placed on a support surface similar to theatre bed.

Pressure data were recorded every second for 10 seconds while the subject was sitting on each of the pressure relief products. Each test was repeated five times and the average pressure data was computed. Pressure information for each product was compared.

RESULTS AND DISCUSSION

Average and peak pressure values recorded for the different pressure relief products are shown in figure 1. These results show that bubblewrap seems to be a better pressure relief product than jelly pad. Two to four layers of bubblewrap give seem to be the optimum number. It was observed, in general, that when the bubblewraps were placed in opposite directions, the values of peak and average pressures were lower than when they were placed in the same direction.

Figure 1: Peak and average pressure values for different pressure relief products; bw stands for bubblewrap

The pressure mapping system only records values of normal pressures and does not give any indication of values of shear force

es generated. The extent of sideways motion of the bubblewrap indicates low possibility of shear build-up. However, further investigations need to be carried out to evaluate shear forces resulting from the different products.

SUMMARY

Based on the above investigations, we believe that bubblewrap is a better product for the prevention of pressure sores. Bubblewrap results in lower peak and average pressure values than jelly pad. Moreover, bubblewrap is cheap, disposable and is less likely to transmit infections.

EFFECTS OF MATRIX PROPERTIES ON INTRACELLULAR SIGNALING

Jeng-Yu Lai¹, Jeffrey R. Basford², Mark R. Pittelkow¹, Mark E. Zobitz³

Departments of Dermatology¹, Physical Medicine & Rehabilitation², and Orthopedics³, Mayo Clinic, Rochester, MN, USA

INTRODUCTION

Cell responses to external electrical, hormonal, and mechanical stimuli result in signal transduction processes that alter gene expression. Mechanical stimuli, in particular, are known to affect cell differentiation. However, our knowledge is fragmented. While the cytoskeletal system is important in intracellular signal transduction and proteoglycans appear to interact with the cytoskeleton, no studies have correlated matrix properties and intracellular signal transduction. At least part of the signal transduction pathway that mediates responses to mechanical forces is coupled to activation of extracellular signal-regulated kinases (ERK) and c-Jun N-terminal kinase (JNK) which, in turn, regulate downstream transcription factors and nuclear events linked to specific cell responses (Xia *et al.*, 1995). This project investigated the changes in the extent of activated ERK as a function of matrix property.

METHODS

Gels of various ratios of polyacrylamide (A) and BIS (B) were produced (Table 1, Pelham *et al.*, 1997). The gels were tested with a dynamic mechanical analyzer (TA Instruments, New Castle, DE) to determine the Young's modulus (E) over a frequency range of 1-200 Hz. Numerical modeling was performed using JMP software (SAS Institute, Cary, NC).

Table 1. Gels for Modeling

	1	2	3	4	5	6
Acrylamide (%)	40	40	40	20	10	20
BIS (%)	1.38	0.69	0.34	0.69	0.34	0.34

The gels that were intended to support cell growth contained growth medium, in lieu of water. Normal human epithelial keratinocytes were isolated from neonatal foreskin and were seeded on the gel surfaces at a density of 2×10^5 per plate. Cell cultures were lysed with 100 microliters of MAPK solution (Auclair *et al.*, 1999). Extracts were heated at 100° C for 5 min, loaded onto a 12% polyacrylamide gel for PAGE, and transferred to a membrane. The membrane was blotted against activated ERK 1/2 and total ERK.

The images were scanned and measured by the Scion Image software (Scion Corp., Fredrick, MD). Expression of total ERK served as control.

RESULTS AND DISCUSSION

The Young's modulus of the gels were found to be consistent, except gel 1 (Figure 1). The averages at 80 Hz were used for modeling. The model was determined to be $E = -13.57 + 1.72A + 34.73B$, $R^2 = 0.97$.

The expression of activated ERK is shown in Figure 2, Series 1. Since there is no apparent correlation between the Young's modulus and the expression, we suspected that the matrices were much stiffer than physiological state. Therefore, less stiff matrices were produced and the result was shown in

Figure 2, Series 2. Unexpectedly, the expression of activated ERK did not completely correlate with the Young's modulus. However, correlation could be observed when the constituents of the gels were compared (Table 2).

Table 2. Ratios of Gels and ERK Expression

A (%)	20	20	20	30	10	10
B (%)	0.69	0.34	0.17	0.34	0.34	0.17
ERK	1.43	1.10	0.47	1.00	0.63	1.06
E*	44.79	32.64	26.73	101.44	15.44	9.53

*Calculated Young's modulus (kPa) based on the model.

Figure 1. Young's Modulus.

Figure 2. ERK Expressions.

Based on the results, we concluded that the Young's modulus alone is not a good predictor for cellular responses. That is, the mechanical property of a matrix, determined by both stiffness and flexibility, will affect cellular physiology. Additionally, the ratio between acrylamide and BIS can affect the pore size, which could influence cellular physiology. Integrin expression and activity on the cell surface may also play an important role. Knowledge obtained from these studies may lead to new therapeutic modalities for diabetic and other chronic wounds.

ERRORS INTRODUCED BY THE GROUND REACTION FORCES APPROACH ON JOINT MOMENT CALCULATION DURING GAIT.

Danik Lafond, Mathieu Charbonneau, Karl F. Zabjek and François Prince

Laboratoire du mouvement, Centre de réadaptation Marie-Enfant, Hôpital Ste-Justine.

Department of Kinesiology, University of Montreal, P.O. Box 6128, Downtown Station Montreal, Quebec, CANADA, H3C 3J7

INTRODUCTION

When attempting to calculate the joint moment, it is generally accepted that the inverse dynamics solution, initially described by Bresler and Frankel (1950), is the most accurate approach. Although the inverse dynamics solution (M_{ID}) has known intrinsic errors, few authors point out that the ground reaction force vector approach (M_{GRF}) may introduce more important bias in the estimation of joint moments. To our knowledge, no extensive comparison of joint moments profile has been done using both the M_{ID} and M_{GRF} approaches. The purpose of this study is to compare the two approaches and to document the potential misinterpretation of gait pattern introduced by the use of the M_{GRF} approach.

METHODS

Three OPTOTRAK® position sensors (Northern Digital, Waterloo, Ontario, Canada) and two force platforms (AMTI, Watertown, MA, USA) were used to collect kinematic and kinetic data simultaneously during each gait trial. Using the same kinematics and force platform data, joint moments in the sagittal plane at the ankle, knee and hip were calculated under M_{ID} and M_{GRF} approaches in eighteen elderly subjects. The M_{GRF} were then determined by the dot product of the ground reaction force amplitude and its orthogonal distance from the axis of rotation at each joint. Trigonometric solutions were used to calculate the lever arm between ground reaction force vector and the joint axis of rotation. To estimate the error on joint moment associated with the use of M_{GRF} , the standard error (S_e) at the ankle, knee and hip joints was calculated. The S_e allows the importance of the error in magnitude associated with the use of the M_{GRF} approach while the inverse dynamic solution served as the “gold standard”. To estimate the bias on the temporal sequence of joint moment, the time delay between the corresponding curve's peaks and crossing zero of M_{ID} and M_{GRF} was used. The timing lag was calculated in percentage of stance phase.

RESULTS AND DISCUSSION

A typical joint moment time-series curve for each joint is presented at Figure 1. It is noted that the M_{GRF} and the M_{ID} time-series are quite similar at the ankle joint. Therefore, at the hip, the differences in magnitude become larger and it is clearly seen that hip extensor moment from M_{GRF} calculation is delayed compared with the M_{ID} leading to opposite polarity of joint moment during the late stance phase.

The magnitude of the S_e was 1.6 N·m, 3.4 N·m and 11.4 N·m respectively at the ankle, knee and hip joints. Discrepancies were found to be as high as 40 N·m at the hip. The results also

indicate that hip and knee moments estimated by M_{GRF} are delayed when compared to M_{ID} . The M_{GRF} approach increases the hip extensor moment duration up to 39% of stance phase (mean of 8.2%). This result is shown in a proportion of 80% (66/84) of trials and 89% (16/18) of subjects. These temporal errors lead to an opposite polarity of joint moment during the late stance phase. Therefore, a hip extensor moment could be identified instead of a true hip flexor moment. As noted by Wells (1981), the largest error is seen at push-off, where the accelerations of the segments are greatest.

Figure 1. Graphical representation of joint moments obtained by M_{GRF} and M_{ID} .

These biases may lead to wrong conclusions in pathological gait analysis. As a clinical tool, joint moment profile should be as precise as possible to make appropriate decisions and intervention. The results showed magnitude and temporal errors that may lead to wrong identification of muscle activity, particularly around push-off. Therefore, it is concluded that M_{GRF} is not a good estimation of joint moment profile, even in a clinical setting.

PELVIC FLOOR MUSCLE STRAINS DURING VAGINAL BIRTH

Kuo-cheng Lien, Brian Mooney, John O.L. DeLancey¹ and James A. Ashton-Miller

Biomechanics Research Laboratory, Departments of Mechanical Engineering, and ¹Obstetrics and Gynecology, University of Michigan, Michigan, USA. klien@umich.edu

INTRODUCTION

One in nine American women suffer from the debilitating conditions of incontinence and pelvic organ prolapse. The greatest risk factor for developing these conditions is the vaginal delivery of a child (Foldsprang, 1992). The pathomechanics of the injury are not well understood, although excess tissue strain may be implicated. There are, however, no estimates of the magnitude or location of the maximal tissue strains during human birth. This is partly due to the three-dimensional anatomic complexity of the pelvic floor structures and their hidden location. The goal of this research was to estimate the magnitude of the average strains in each of the pelvic floor muscles during the second stage of labor.

METHODS

A healthy 34 year-old nulliparous woman gave written informed consent to have her pelvis imaged using a 1.5 T magnetic resonance (MR) scanner. The outlines of each of the pelvic pelvic bones, muscles and organs were traced on 30 consecutive 5-mm axial sections, digitized, and imported into an engineering graphics program (IDEASTM). The serial sections were lofted to yield a 3-D model of the female pelvis and pelvic floor. Using descriptions of origins and insertions in the anatomic literature, the origins and insertions of the levator ani muscles were identified on the pelvis. 24 parallel-fibered muscle bands, 1 - 5mm thick and 5 - 10mm wide, were used to represent the left and right pelvic floor muscles: iliococcygeus, pubococcygeus, puborectal and puboperineus. As a first-order approximation, the 3rd, 50th, and 97th fetal head diameters (at 42 week gestation) were represented by spheres of equivalent diameter. We modeled the incremental descent of the model fetal head relative to the ischial tuberosities, as it passes around the pubic bone following the Curve of Carus. As the descent progressed, the different bands of the pelvic floor muscles were successively engaged by the head and then stretched. The strain in each band was calculated for each stage of descent (Figure 1).

RESULTS AND DISCUSSION

The results for the 50th centile head show that the ilioococcygeal muscle bands were engaged by 0.55 cm head descent, the pubococcygeal muscles by 2.5 cm descent, and the puborectal and puboperineus muscles by 4.4 cm descent (Fig.1). The puboperineus muscle was the last muscle to be engaged, yet was strained more than any other muscle band: its maximum strain reached 300%. A single passive stretch exceeding 50% strain in a striated muscle from a non-gravida causes pliometric injury (Brooks et al., 1995). It is therefore a biological wonder that pelvic floor muscle can tolerate much

Figure 1: The relationship between fetal head descent (abscissae, in cm; icons from simulation at top) and the resulting muscle strain (ordinate, in percent) for selected muscles. The labels at right identify the puboperineus (PP), iliococcygeus (IC), pubococcygeus (PC), and puborectal (PR) muscle bands. The largest strains are induced in the puboperineus (PP) muscle, the last muscle to be engaged by the fetal head. Bands within each muscle are numbered by a numerical suffix in a dorsal-to-ventral direction. The shaded area represents usual non-injurious operating region of passive striated muscle in response to a single stretch.

larger apparent strains without injury. Hormonal mechanisms are likely involved. Preliminary findings from our MR study suggest, however, that a significant proportion of nulliparous women were injured during vaginal delivery. Muscle defects, visible on MR scans six months postpartum, appear in the regions of greatest muscle strain predicted by the present simulation (Mooney, et al., 2002).

SUMMARY

These are the first estimates of pelvic floor muscle strains during human birth. The maximum apparent muscle strain, 300%, was found in puboperineus, late in the second stage of labor.

A NOVEL ALGORITHM FOR ESTIMATING HEAD IMPACT MAGNITUDE AND LOCATION

Joseph J. Crisco¹, Richard M. Greenwald², Jeffrey Chu²

¹Dept. of Orthopaedics, Brown Medical School/Rhode Island Hospital and Div. of Engineering, Brown University, Providence, RI
²Simbex, Lebanon, NH. E-mail: joseph_crisco@brown.edu

INTRODUCTION

Concussions are a major injury in sports. While head accelerations are the likely injury mechanism, the correlation between head acceleration and concussion injury has not been established. Current systems for measuring head accelerations are costly or not applicable for wide spread use in sports. This paper presents an algorithm for estimating peak head acceleration and impact location using an array of low-cost single-axis accelerometers.

METHODS

Algorithm: It is assumed that the intersection of a horizontal plane with the head is a circular cross-section (HCS), described by a radial coordinate system with the origin at the center, 0° posterior, and 90° to the right. A given number (n) of single-axis accelerometers are located about and normal to the HCS with the axis towards the center. The HCS is assumed to behave as a rigid body accelerated by a single impact in the plane of the HCS. Given these assumptions, it can be shown that the acceleration components normal to the HCS vary as the cosine of the location on the HCS. Thus, from the n peak accelerations and the location of each accelerometer, the algorithm determines the magnitude and location of the impact using a least-squares curve fit of a cosine function with two variables: amplitude and phase shift. The amplitude is then the peak impact acceleration to the HCS and the phase shift is the impact location on the HCS. In application, these values are the linear head acceleration and the hit location.

Numerical Simulation: A parametric study was performed by examining the effect of n , and the effect of random noise on the location and the acceleration magnitudes of each accelerometer. A wide range of parameter sets were studied, but for the results reported here, the specific parameters were set at $n = 3$, located at 120°, 0° and 120° about the HCS. The standard deviations in the noise were set at 5° degrees and 5% for accelerometer location and peak, respectively. The simulation was repeated 10 times with impacts located at increments of 5° around the HCS.

Experimental Testing: Testing was performed using a twin-wire drop system (ASTM F1446) with a tri-axial accelerometer mounted at the center of gravity (CG) of a standard ISO headform. A specially designed array of single-axis accelerometers ($n = 3$) was fitted to the headform in the horizontal plane, which defined the HCS. Three drops (2.2 m/s) were performed at each of several locations around the HCS. The algorithm was used to predict the peak impact acceleration and impact location. These values were compared to the CG acceleration of the headform and the known impact locations.

RESULTS AND DISCUSSION

In the numerical simulation, errors were most sensitive to accelerometer location compared to errors in peak acceleration. For the given set of parameters studied here, the maximum standard deviation of the error in the predicted peak acceleration was 9%, and the maximum standard deviation of the hit location error was approximately 6°.

Figure 1: The error in the estimated peak acceleration and location of an impact to a headform from experimental drops.

Experimentally, the estimated peak impact acceleration averaged 5.4% lower than headform CG acceleration with an average 3.2% error in impact location (Figure 1). Limitations of the current algorithm include 2D impacts only on the transverse plane, and estimation of only linear acceleration. Using this algorithm, a system with several low-cost single axis accelerometers placed orthogonal to the surface of the head can provide estimates of head acceleration within 10% of measured accelerations, allowing widespread data collection of head impacts in sport.

SUMMARY

A new algorithm for measuring head acceleration from impacts was developed, studied with numerical simulation, and validated by experimental testing. This algorithm provides a cost-effective approach for studying head impacts and concussion injuries which was heretofore not possible.

STRUCTURAL COMPETENCE OF OSTEOPENIC THORACOLUMBAR VERTEBRAE FOLLOWING ANTERIOR-WEDGE FRACTURE

Ron N Alkalay, Dietrich von Stechow

Orthopedic Biomechanics laboratory, Beth Israel Deaconess Medical Center, Boston, MA.

INTRODUCTION

Age related vertebral compression fractures cause significant physical and psychological impairments. Although data exists on the ability of osteopenic vertebrae to carry compressive loads and the use of imaging methods to predict vertebral fracture, little is known on the effect of low rate fracture on the structural integrity and consequent mechanical load carrying ability of such vertebra under complex loads, both immediately post-fracture and after a recovery period.

METHODS

Nineteen thoracic and lumbar vertebrae from three spines, aged 65-78 years, were radiographed to estimate the body posterior and anterior height and their Bone Mineral Density measured using DXA (Hologic 2000+, Hologic, MA). A custom testing jig was employed to test the vertebrae to failure using a hydraulic test system (1331, Instron, Canton, MA) under combined compression-flexion at a rate of 5mm/min. Failure was defined as 50% reduction in the vertebra anterior height or a reduction of 10% in maximum load. A 6DOF load cell (MC5, AMTI, MA) was employed to measure the resulted forces and moments and displacement to failure measured via the material testing system with the data acquired using LabView (National Instruments, TX) at the rate of 10Hz. The failed vertebrae were allowed to recover for 30 min, the vertebral body heights re-measured and the vertebrae re-tested. Matched pair analysis was used to test for difference in maximal failure load and stiffness, estimated from the linear portion of the load-displacement curves, between the two tests for each of the measured parameters (JMP, SAS, NC).

RESULTS AND DISCUSSION

Vertebral BMD yielded a mean and standard deviation of $(0.5 \pm 0.1 \text{ g/cm}^2)$ for L1 indicating the donor spines to be osteoporotic. The vertebral body failed by a continuous reduction in its anterior height with the vertebral body anterior and posterior heights showing a mean reduction of 19.2% and 7.2%. At the end of the 30 minutes recovery period, the vertebral body regained 5.3% and 2.1% of its height respectively. Compared to the intact vertebrae, the post-recovery vertebrae showed a highly significant reduction in its ability to resist applied compression-flexion loading, Table 1. For example, the ultimate compressive load and flexion moment were reduced by an average of 28% with the compressive stiffness reduced by 40%, Table 1. Clearly, when comparing the estimated stiffness for the in-plane forces and moments the recovered vertebra underwent significantly higher deformations per applied load (Table 1). However,

apart from lateral bending, the remaining load responses did not differ significantly (Table 1).

Table 1 Mechanical parameters measured for the intact and the recovered vertebrae

This study investigated the effect of flexion-compression fracture on the structural competence of failed and recovered osteopenic thoracolumbar vertebrae. Compared to the intact vertebrae, the failed vertebrae exhibited a significant reduction in structural load carrying ability and increased deformation, particularly in the plane of loading (Table 1). However, the mean reduction in axial compression, flexion and anterior-posterior strength were 23-28% of the intact vertebrae, whilst out of plane response, although showing a high reduction, were highly variable. Furthermore, the fractured vertebrae presented a marked rebound of the vertebral body heights. This data suggests osteopenic vertebrae having recovered for a period of time, to retain a substantial load carrying ability. In assessing the elderly patient without neurological compromise, this residual structural competence ought to be considered in deciding on the appropriate treatment modality.

SUMMARY

The residual structural competence of failed osteopenic thoracolumbar vertebrae having undergone recovery, in response to complex loads, was investigated. The recovered vertebrae, although showing decreased competence and higher deformation under the applied loads, did retain a significant portion of their initial competence when compared to the intact vertebrae.

MOTOR ADAPTATIONS TO CHANGES IN LIMB MECHANICAL PROPERTIES DURING VOLUNTARY GAIT MODIFICATIONS

Stephen D. Prentice and Adrienne T. Hol

Gait and Posture Lab, Department of Kinesiology, University of Waterloo, Waterloo, Ontario, Canada

sprentic@healthy.uwaterloo.ca

INTRODUCTION

The ability to safely walk through a cluttered environment involves the formation of precise limb trajectories to eliminate the risk of trips and falls. The central nervous system must have a fine awareness for specific limb dynamics in order to seamlessly superimpose these discrete voluntary movements upon the ongoing locomotor actions. The success of this integration depends greatly on how well the neural and mechanical systems interact. The role of limb dynamics in the formation of locomotor strategies is not fully understood and it is not clear as to how well the locomotor control system can adapt to changes in limb mechanics. The purpose of this study was to examine how the locomotor control system can adapt its movement strategies following a change in the inertia of the leg segment of both lower limbs.

METHODS

Eight participants were instructed to perform two walking tasks: level unobstructed walking and walking over a 30cm obstacle, under three limb weighting conditions (NW: non-weighted, W: weighted, WR: weight removed). A total of 90 trials (15 trials for each walking/weighting condition) were completed in the following order: level walking–NW, obstructed walking–NW, level walking–W, obstructed walking–W, obstructed walking–WR and level walking–WR. During obstructed trials, the obstacle was positioned midway between the left and right foot contacts of a step halfway along the walkway and the starting position was fixed such that the right foot always led over the obstacle. For the block of weighted trials, a custom weight (4.5kg) was attached bilaterally on the centre of mass of each leg segment.

Kinematic data for the limbs and trunk were obtained using an OPTOTRAK 3D motion measurement system ($f_s = 60\text{Hz}$ & low-pass filtered at 6Hz). Linear envelop EMG was recorded ($f_s = 240\text{Hz}$) bilaterally from: rectus femoris, biceps femoris, tibialis anterior and soleus. Kinematic data and force plate data were used to determine joint moments and powers using inverse dynamics. Initial analyses have focused on performance during the obstacle condition.

RESULTS AND DISCUSSION

Kinematic, kinetic and EMG data of the initial trials of the weighted trials over the obstacle were compared to the average profiles of the non-weighted conditions. Overall, the joint kinematics were very similar following the addition of the mass with the largest changes being observed as an increased knee extension during swing (Fig. 1). During early swing, there is a marked decrease in the knee flexor power generation (Fig. 1) which is predominate in NW obstacle conditions (McFadyen & Winter, 1991; Prentice & Patla,

Figure 1: Knee & hip kinematics and kinetics. Profiles are from one subject during the obstacle condition. Grey = $mn \pm 95\%CI$ of NW($n=15$), thick = 1st trial W, dotted = 10th trial W.

1995). This reduced knee action was accompanied by a prolonged hip pull off power. Fluctuations in the moment and power profiles of the hip and knee indicate the poor initial estimation of limb mechanics which becomes more refined in the later exposures to the obstacle to resemble that reported previously under weighted conditions (Reid & Prentice, 2001). These modifications in joint kinetics indicate that even during the initial exposure to the obstacles with added weight, individuals were able to produce an altered yet immature movement strategy.

SUMMARY

Individuals were able to rapidly adapt to the new mechanical limb properties. There was a brief period in which the nervous system explored the nature of the change in limb dynamics to further refine the appropriate response. The resulting strategy was not simply a magnitude adjustment of the actions used in the non-weighted conditions but involved a different muscle activation pattern and thus a different locus of energy generation that was gradually developed during the initial exposures to the obstacle.

PREDICTIONS OF INFANT BRAIN INJURES IN MINOR FALLS AND INFLICTED EVENTS

Michael T. Prange and Susan S. Margulies

Department of Bioengineering, University of Pennsylvania, Philadelphia PA margulies@seas.upenn.edu

INTRODUCTION The majority of serious traumatic brain injury in infants and toddlers is due to child abuse and abused children with brain injury have a worse outcome than those with accidental brain injury (Billmire and Myers 1985, Ewing-Cobbs et al., 1998). The suspicion of abuse often arises when the event history appears not to correspond to the injury in the child. Because the mechanisms of head injuries due to shaking, shaking with impact, and falls are not yet established, the differentiation between accidental and inflicted head injury is problematic. This study develops axonal injury predictions in the infant using a finite element model.

METHODS A 3-D finite element model of a 1 month old infant head, infant material properties, axonal tissue injury thresholds, and typical loading conditions were combined to predict the incidence of axonal injury during abusive and accidental events. The brain geometry was extracted from resonance (MR) images obtained from the radiology database at the Children's Hospital of Philadelphia, with IRB approval. The brain tissue was modeled as a nonlinear, homogenous, isotropic, viscoelastic, incompressible material, with parameters fit to experimental data obtained from mixed gray/white matter brain specimens from newborn piglets (Prange, 2002). Scenarios simulated were limited to inertial loading events with no contact or contact with a widely distributed load to the skull with no anticipated skull fracture. Simulated events included a 1.5m fall onto 10cm thick mattress foam, a shake without impact, an inflicted impact onto the mattress foam. Because these events were assumed to produce little or no significant skull deformation, the loads were approximated as purely inertial, and the skull was represented as a rigid material.

After convergence analysis, simulations were performed (ABAQUS/Explicit, HKS Inc.) using loads we obtained with a custom-designed instrumented infant dummy experiencing these events. Tissue deformations were computed by the finite element model and subsequently transformed to regional axonal injury predictions, using injury thresholds we determined from purely inertial porcine studies. Because of the lack of high-rate data for the infant skull, suture, and bridging vein properties, and little experimental data regarding in vivo motion at the skull/brain boundary, no predictions of subdural hemorrhage or skull fracture can be made and injury predictions in this study were limited to only axonal damage.

RESULTS Detailed comparisons were performed between predicted regional stress/strains and actual injuries in these regions for the same controlled movements in the newborn piglet (N=6). The output parameters investigated, peak maximum principal strain (pkE1), peak maximum shear strain (pkSSTRAIN), and peak maximum shear stress (pkSSTRESS), all correlated well with occurrence of axonal injury. Injury threshold values were determined to be 0.336,

0.282, 0.299kPa, for pkE1, pkSSTRAIN, and pkSSTRESS, respectively.

Simulations of the loads measured from 1.5m falls onto mattress foam were mostly translational, and produced peak strain and stress levels below axonal injury thresholds for infants. Shakes and moderate inflicted impact scenarios produced higher strains and stresses than the fall simulation, but less than 1% of the brain volume was expected to experience axonal injury. The severe inflicted impact event was associated with the largest load, and resulted in the largest strain and stress levels and extent of injury, with axonal injury predicted in 11-30% of the brain, depending on the output parameter used in the evaluation. Regions injured were primarily in the subcortical and deep white matter regions.

DISCUSSION The rigid skull approximation may underestimate the extent of injury with impact. However, this study supports the theory that shaking alone is not expected to produce significant primary axonal injury in the infant, but that axonal injury may occur with inflicted impacts onto soft materials.

HYPERELASTIC REPRESENTATION OF HIP JOINT CAPSULE: A FINITE ELEMENT VALIDATION

Kristofer J. Stewart, Douglas R. Pedersen, Richard A. Brand, and Thomas D. Brown
Orthopaedic Biomechanics Lab, 2181 Westlawn Building,
University of Iowa, Iowa City, IA 52242
E-mail: kristofer-stewart@uiowa.edu Web: poppy.obrl.uiowa.edu

INTRODUCTION

Contemporary computational models (Scifert, 1999), which are used extensively to study total hip impingement and dislocation, allow for the practical incorporation of the effects of joint capsule on both motion and the loads transmitted to other parts of the joint. However, these models to date have not included mechanical representation of the hip capsule. Since capsule insufficiency is clinically regarded as predisposing to dislocation, incorporating capsule representation is an important aspect of making these models yet more credible.

METHODS

In a series of ten cadaver specimens, quantitative mechanical properties of the hip capsule were obtained experimentally for the entire intact structure, and subsequently for eight individual sectors of the hip capsule (Stewart, 2001). Material properties (i.e., structural tangent stiffness, failure load, ultimate strength, tangent modulus) were calculated using the load-displacement and geometric data collected for each of the sectors. The load-displacement curves provide the basis for adding hyperelastic representation to an existing finite element (FE) model. Of the various hyperelastic material models available in the ABAQUS 6.2 finite element library, the Yeoh model (a variation of the reduced-polynomial strain energy function) satisfactorily fits the experimental data. Eight sectors, meshed with continuum elements having Yeoh hyperelastic material characteristics, are incorporated into a whole-joint FE model at proper anatomical insertion points.

Figure 1: Two samples of Yeoh model fit to physical data.

A size-scalable FE mesh, developed using 1-mm serial section data from the Visual Human database, provides detailed anatomic zoning of the hemi-pelvis and femur (Fig 2A). This model replicates the whole-capsule cadaveric hip tensile tests by distracting the femur away from the acetabulum in the direction of the femoral neck axis.

Figure 2: (A) Rigid Bzier surface mesh used for whole-capsule joint distraction validation exercises, (B) and the resulting comparison of experimental and computational load-displacement curves.

RESULTS AND DISCUSSION

Initial validation exercises of the FE model reveal a load-deformation behavior similar to that obtained from the physical experiments (Fig 2B).

This “soft tissue” finite element model can now be used to parametrically investigate and quantify the effects of hip joint capsule on joint kinetics and dislocation mechanics. Specific parametric series of interest include generalized capsulo-ligamentous laxity and stiffness deficit (or absence) of individual capsule structures.

ARE ESTIMATES OF QUADRICEPS STRENGTH VALID? IMPLICATIONS FOR CLINICAL DECISION MAKING

Kurt Manal, Glenn Williams, Peter Barrance and Thomas S. Buchanan

Center for Biomedical Engineering Research. University of Delaware, Newark, DE. USA. manal@udel.edu

INTRODUCTION

Weakness of the quadriceps muscle group is common following anterior cruciate ligament (ACL) injury and reconstruction (Heimstra et al., 2000). Quadriceps strength is assessed indirectly by measuring the patient's maximum knee extension moment. Patient positioning and concomitant contraction of the hamstrings can reduce the magnitude of the extension moment, and therefore the perceived strength of the quadriceps. It is important to understand how these factors affect the magnitude of the extensor moment, because the results of such testing are used in surgical decision making, rehabilitation progression and "return to sport" (Williams et al., 2001). The purpose of this study was to examine how subject positioning and co-contraction of the hamstrings can reduce the knee extension moment. We hypothesized that these factors can lead to an underestimation in quadriceps strength of approximately the same value used clinically to define quadriceps weakness (i.e., 10%-20%).

METHODS

(1) A biomechanical model of the leg (Delp et al., 1990) was used to estimate how small changes ($\pm 10^\circ$) in knee and hip angle from a prescribed testing position alter the moment generating potential of the quadriceps. The extension moment in each position was expressed relative to the moment with the model in 70° & 90° of knee and hip flexion. Muscle activations for the hamstrings and quadriceps were set at 0.0 & 1.0 respectively (i.e., to simulate a case of zero co-contraction).

(2) EMGs from 6 ACL deficient subjects were recorded during isometric, maximal knee extension and flexion with the knee and hip in 70° & 90° of flexion. EMGs for the medial (MH) and lateral hamstrings (LH) were processed as described in Lloyd & Buchanan (1998). Muscle activity for the MH & LH during the knee extension trials was expressed relative to the activity recorded during maximal knee flexion. This was done for the involved and uninvolved legs of each subject.

RESULTS AND DISCUSSION

Percent change in knee extension moment due to varying knee and hip angle $\pm 10^\circ$ is displayed in Figure 1. Note that these data were calculated using the biomechanical model of the leg. Joint configurations for which the extensor moment changed by more than $\pm 5\%$ are shaded in red. The extensor moment was underestimated by 11% with the knee and hip extended 10° from the prescribed test position. In contrast, the moment was 8% greater with the knee and hip in $+10^\circ$ of flexion.

The magnitude of the flexor activity during maximal knee extension is displayed in Figure 2. An assumption when making side-to-side strength comparisons is that the

antagonistic activity of the hamstrings is the same for both legs. In general, this was not the case for the subjects tested in this study (i.e., the data in Fig. 2 do not fall on the diagonal line). For example, MH activity of the involved leg for subject "*" was 22% of the peak value recorded during maximal flexion, while muscle activity for the MH of the uninvolved leg was only 9%. Also note that muscle activity for the flexors during knee extension was generally greater than 10% of the muscle's peak value during flexion. This is significant because the moment arms for MH & LH are close to their maximum values with the leg in the position tested. Using the EMG data for subject "*" and the biomechanical model of the leg, we estimated that the

Figure 1. % change as a function of position from test angle. NB: (+) values represent a decrease in the moment.

Figure 2. % Max MH & LH muscle activity during knee extension (n=6). "*" = data for same subject.

would be 18% weaker for the involved leg due to the greater hamstrings activity. Moreover, positioning the involved leg in greater knee and hip extension would further undermine the perceived quadriceps strength. The magnitude of this "error" is significant because it lies in the same range used clinically to define quadriceps weakness (i.e., side-to-side differences of 10%-20%). This finding was consistent with our hypothesis.

SUMMARY

Preliminary results for a group of ACL deficient subjects demonstrate that noteworthy activity of the hamstrings is present during quadriceps strength testing. The clinical relevance of this work is that modified testing procedures may be needed to better evaluate quadriceps strength.

THE TENSILE PROPERTIES OF THE HEALING GOAT MCL AFTER A COMBINED MCL/ACL INJURY

Steven D. Abramowitch, Masayoshi Yagi, Eiichi Tsuda, Savio L-Y. Woo

Musculoskeletal Research Center, Department of Orthopaedic Surgery, University of Pittsburgh
Pittsburgh, PA. 412-648-2000. Fax: 412-648-2001. decenzod@msx.upmc.edu

INTRODUCTION

The optimal animal model for the study of a combined injury to the medial collateral ligament (MCL) and anterior cruciate ligament (ACL) has yet to be established. With the high incidence (<50%) of ACL graft failure and joint deterioration in the rabbit and canine models, an animal model is needed in which long-term ACL reconstructions are successful (Yamaji 1996, Woo 1990). The large knee joint and robust activity level of the goat is attractive for studies of ligament healing (Ng 1995). Thus, the objective of this study was to determine the structural properties of the healing goat femur-MCL-tibia complex (FMTC) and the mechanical properties of the healing goat MCL at 6 weeks after a combined MCL/ACL injury.

METHODS

Eight skeletally mature female Saanen goats (weight 37.3 ± 4.3 kg) were used in this study. The ACL of the right knee was transected and reconstructed with a bone-patellar tendon-bone autograft. Subsequently, a mop-end tear was created in the MCL (Weiss 1991). The contralateral knee served as a sham-operated control. The goats were allowed free cage activity after surgery. At 6 weeks, the animals were euthanized and the hind legs were harvested for biomechanical testing. Specimens (8 healing and 6 sham-operated) were dissected leaving an FMTC. The cross-sectional area of the MCL was measured using a laser micrometer (Lee 1990). Each FMTC was positioned in custom designed clamps and fixed to an InstronTM testing machine (model 4502) in a 37°C saline bath. The FMTC was loaded to failure at 10 mm/min. Strain was measured by tracking two reflective markers on the midsubstance using a Motion AnalysisTM system (VP320). Structural properties of the FMTC (stiffness, ultimate load) and mechanical properties of the MCL substance (tangent modulus between 3%-7% strain) were calculated from the resulting load-elongation and stress-strain curves, respectively (Scheffler 2001). Statistical analysis was performed using an unpaired t-test. Significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

The ACL graft was intact after 6 weeks. Grossly, each healing MCL was darker and less shiny than the MCLs in the sham-operated controls. Further, no joint surface deterioration or

osteophyte formation was observed. The cross-sectional area of the healing MCL was 2.7 times larger than that of the sham-operated MCL ($p < 0.05$; Table 1). In terms of the structural properties of the FMTC, the stiffness and ultimate load at failure of the healing FMTC was less than 50% and 27% of that for the sham-operated FMTC, respectively ($p < 0.05$; Table 1). In terms of the mechanical properties of the MCL substance, the tangent modulus of the healing MCL was less than 13% of that for the sham-operated MCL ($p < 0.05$).

Figure 1: Typical load-elongation and stress-strain curves.

This study determined the tensile properties of the healing goat MCL at 6 weeks after a combined MCL/ACL injury treated with ACL reconstruction. The parameter values of sham-operated controls are similar to those found previously (Scheffler 2001). Further, the parameter values of the healed MCL range from 29% to 52% lower than those reported for an isolated MCL injury using the goat model. This result may be attributed to severity of injury to the knee. Overall, the goat model is suitable for studying the combined MCL/ACL injury as the results are consistent with those observed using other animal models, yet none of the complications were observed.

DISSOCIATION BETWEEN DYNAMIC STRESS AND INTRAMUSCULAR PRESSURE IN ISOLATED RABBIT TIBIALIS ANTERIOR MUSCLE

Jennifer Davis¹, Kenton K. Kaufman², Richard L. Lieber¹, Email: rlieber@ucsd.edu

¹ University of California and Veterans Administration Medical Centers, San Diego, CA. & ² Mayo Clinic, Rochester, MN.

INTRODUCTION Reports in the literature suggest that intramuscular pressure (IMP) may serve as a reliable index of muscle force measured. Recently, it was shown that IMP predicts relative active and passive isometric muscle stress in animal models (Davis et al., 2001). However, since movement is dynamic, the purpose of this study was to quantify the relationship between IMP and dynamic muscle stress during both concentric and eccentric contractions.

METHODS The experimental model was the tibialis anterior (TA) of the New Zealand White rabbit (mass=2.5 ±0.5 kg, n = 10). The knee was fixed in a custom jig, TA exposed, and distal tendon attached to a servomotor (Model 300B, Aurora Scientific Inc.). A cuff electrode was placed around the peroneal nerve for muscle activation (Pulsar 6Bp Stimulator FHC Inc.). A 360 μm fiber optic pressure sensor (Luna Innovations Inc.) was inserted in line with the long axis of the fibers. The force-velocity relationship was generated during activation of the muscle at 60 Hz for 650 ms with a 2-minute rest interval between each contraction. Fiber length (L_f) was calculated from muscle length using a 0.67 fiber length-to-muscle length ratio. For concentric and eccentric contractions, muscle length was initially set to $L_0+5\%L_f$ or $L_0-5\%L_f$ respectively. The experiment ended with 2 contractions that combined both shortening (and lengthening) in opposite order. Tension records were converted to stress using the muscle's calculated physiological cross sectional area (PCSA).

RESULTS AND DISCUSSION The TA muscle force-velocity curve had the classic shape of a rectangular hyperbola, which was characterized by a V_{max} of 5.5 L_f/s and a P_0 of 230±18.6kPa (Fig. 1A). This compared favorably with Close's (1972) classic values for mammalian muscle. The shape of the IMP-velocity curve mimicked the shape of the force-velocity curve for concentric contractions but with much higher variability (Fig. 1B). The corresponding points on the IMP-velocity demonstrated a maximum IMP (I_0) of 24±6.3 mmHg and at V_{max} IMP decreased to 5.9±13.3 mmHg. For the eccentric portion of the IMP-velocity curve, a precipitous drop in pressure relative to I_0 was observed (Fig. 1B). Combined contractions demonstrated a profound history effect. The stresses at various points during the protocol were

that began with shortening (Fig. 2B), muscle stresses were significantly different as revealed by one-way ANOVA ($p<0.0006$). Values for IMP at each of these points displayed reproducible but unexpected relative levels. For example, I_{01} was greater than I_0 in spite of the fact that P_{01} was lower than P_0 . Further, while P_E was greater than P_{01} due to eccentric contraction, I_E was lower than I_{01} (Fig. 2C). A similar dissociation was observed for the protocol that began with lengthening. In summary the combined protocol demonstrated both a history effect and an order effect between combinations. The reason for these effects is not clear but may relate to transducer movement, tissue fluid flow or muscle volume changes.

INTRODUCTION

Dislocation after total hip arthroplasty is a common complication frequently caused solely by improper acetabular cup orientation. Current practices for establishing cup orientation vary substantially and systems using computerized imaging and intraoperative display have been developed to provide consistent results (McCollum, DiGioia). However, most facilities do not have access to emerging technologies and the cost is substantially increased because each procedure requires CT or MRI data. The purpose of this study was to investigate a new method for positioning the acetabular cup based on bony acetabular landmarks that are readily identified intraoperatively after reaming.

METHODS

Three landmarks that would be unaffected by osteophyte formation were selected: 1) the most lateral point of the ischial sulcus, which is also the lowest point of the sulcus when felt with a blunt-tipped probe; 2) the saddlepoint at the confluence between the iliopubic eminence and the superior pubic ramus, which is also effectively five millimeters from the acetabular rim along the ridge of the pubic ramus; 3) the most superior point of the acetabulum, which intra-operatively is used to establish the overhang of the acetabular cup: when viewed radiographically, the most superior point is also the most lateral. Note that the points on the sulcus and ramus are inferior to the rim of the acetabulum and establish the level of the cup inside the reamed cavity.

The use of landmarks for component orientation can be judged to be successful if neither dislocations nor other mechanical problems occur in practice. Given that an acceptable post-operative range of motion should essentially recreate pre-operative functionality and not constrain restored activity, post-operative cup orientation may be expected to approximate native acetabular orientation. In clinical practice, however, cup abduction is estimated in pre-operative planning so that the native acetabulum is equal to or is less than the cup abduction. Therefore, the hypotheses of the study were that the landmarks 1) would provide a low dislocation rate clinically and 2) would recreate native cup anteversion but have less abduction.

To establish the clinical validity of the landmark method of cup placement, the technique was used in 329 total hip arthroplasties from 1996 to 2000 and the patients were followed until July 2001, with an average follow-up of 2.5 years. A special device was constructed to quantify *in vitro* acetabular orientation. The device used a sequence of body-based rotations of a gimbal to physically display the amount of

rotation on carefully scribed scales accurate to 0.5 degrees. To establish the relationship of the acetabulum itself to the resulting three-dimensional cup orientation, the orientation of the acetabuli in 14 acetabuli in seven pelvises from cadavers was measured. Then, after reaming, cups were placed in the pelvises using the landmark method and the cup orientation was measured again.

RESULTS AND DISCUSSION

In the clinical study, two dislocations occurred after arthroplasty. One occurred at 4 months while the patient was using a recumbent bicycle in physical therapy and the second dislocation occurred in the recovery room. Both cases were reduced with conscious sedation and treated with hip abduction orthotics for 12 weeks. There were no subsequent dislocations, giving a favorable dislocation rate of 0.61%.(DiGioia)

In the laboratory study of seven pelvises, the anteversion of the cups after implantation was similar to the value of the native acetabulum. The post-operative anteversion and abduction were respectively 0.7 degrees more and 7.1 degrees less than the pre-operative measures. (Table 1) Statistical analysis with corrected, paired t-tests showed no significant differences between pre- and post-operative cases.

Proper orientation of the acetabular cup in total hip arthroplasty based on the patient's bony anatomic landmarks can significantly reduce the dislocation rate. The landmark method of cup placement reproduces native anteversion and provides good superior coverage of the femoral head. In conclusion, surgeons can effectively use landmarks to orient acetabular cups without additional equipment.

Table 1: Pre- and Post-operative Orientation

	Mean [°]	S.D.
Preoperative Abduction	44.3	5.7
Postoperative Abduction	37.2	10.
Preoperative Anteversion	31.1	5.5
Postoperative Anteversion	31.8	11.

EVALUATION OF PATELLA TENDON AS A GRAFT MATERIAL FOR ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION IN AN OVINE MODEL

Christopher A. Barnsdale, Hirotaka Azuma, Shigenobu Fukushima, Gail M. Thornton, Cyril B. Frank, Nigel G. Shrive

INTRODUCTION

One option for anterior cruciate ligament (ACL) reconstruction in humans uses an autologous central third of the patella tendon (PT) graft. To be successful, such PT grafts must structurally replace the features of the ACL. The same logic is true for grafts in animal models of ACL injury. Our goal is to create a sheep model of ACL injury and PT replacement, if the PT can, in fact, replace the key functions of the normal ACL. To that end, the ovine ACL and its two component parts (anteromedial (AM) and posterolateral (PL) bands) must be related mechanically and compared with a PT graft to determine both their structural and material behavior. This is the first step in determining potential efficacy of an appropriately sized PT graft to replace part or all of the normal ACL. Our hypothesis was that the PT and ACL bands would have similar material properties.

METHODS

PTs and ACLs from fifteen skeletally mature Suffolk-Cross sheep were tested uniaxially to failure: PT (n=5), ACL-AM (n=5) and ACL-PL (n=5). Bone-PT-bone complexes were mounted uniaxially in an MTS system with the patella mounted at 45° relative to the long axis of the tibia. The PT was sized to a 4mm central portion, aligned with the actuator, and its length and area measured using digital calipers and custom area calipers, respectively. The complex was elongated to failure at 50mm/min measuring load vs. time. Whole bone-ACL-whole bone complexes were mounted at 60° flexion (tibial/femoral long axes) (*Figure 1*) and one ACL bundle was then cut. The ACL was aligned with the actuator and its length and area measured. The ACL was elongated to failure at 50mm/min. Cross-sectional area, failure load and failure stress of PT and ACL were compared using Student's

t-tests and power was calculated.

Figure 1 – MTS Sheep Table for Uniaxial ACL Testing

RESULTS AND DISCUSSION

The cross-sectional area of the ACL-AM, ACL-PL and PT were similar. In this preliminary study, failure load comparison between the PT and ACL-PL revealed a significant difference. The failure load comparison between the PT and ACL-AM was significant ($p=0.03$) but had low power ($P=0.5$). Likewise, comparison of failure stresses of the PT to both the ACL-PL and ACL-AM were significantly different but also had low power ($p=0.04$ and $P=0.5$). The failure load and stress of sheep central third PT grafts were statistically significantly less than the ACL-AM and ACL-PL (*Figure 2*). However, due to the preliminary nature of this study, only the comparison between the failure load of the PT and ACL-PL was statistically powerful. Power analysis indicated that the sample size must be doubled ($P=0.8$). Contrary to our hypothesis, these preliminary results suggest that PT failure stress was less than the ACL-AM and ACL-PL; thus, such grafts would have to be larger than the original ACL to achieve the same structural strength.

Figure 2 – Mean Failure Stresses of Sheep Tissues

SUMMARY

The failure properties of sheep central third PT grafts were compared to both AM and PL bundles of the ACL. The failure load and stress of the PT grafts were significantly less than the ACL-PL and ACL-AM. The sample size of the current study (n=5) must be doubled to confirm that these statistically significant results are also statistically powerful. The data from this preliminary study reveals both structural and material inferiority of the PT, which suggests that the PT may not be an appropriate graft material for the ovine ACL-AM, ACL-PL or whole ACL.

BIOMECHANICS OF SINGLE-LEVEL CERVICAL FUSION TECHNIQUES: COMPARISON OF GRAFT-PLATE FUSION WITH AN INTERBODY CAGE DEVICE

Denis J. DiAngelo¹, Amanda M. Thomas¹, and Kevin T. Foley²

¹School of Biomedical Engineering, The University of Tennessee Health Science Center, Memphis, TN, ddiangelo@utmem.edu

²Department of Neurosurgery, The University of Tennessee Health Science Center, Memphis, TN

INTRODUCTION

Anterior cervical graft fusion alone or supplemented with an anterior cervical plating system may be used to treat the diseased cervical spine. An anterior cervical plate is intended to restore the mechanical integrity of the operated spine and decrease graft complications. An alternative method to single-level graft fusion is to use an interbody device. The objective of this study was to compare the biomechanical stability of a graft-plated construct with an interbody cage device.

METHODS

Six human cadaveric cervical spines (3 male and 3 female, average age 79.3 ± 5 years) were biomechanically tested in four conditions: 1) harvested (H), 2) single-level discectomy with graft alone (GR) (Cornerstone SR, Regeneration Technologies, Inc. Alachua, FL), 3) graft with anterior cervical plate (GAP) (Atlantis plating system; Medtronic Sofamor Danek, Memphis, TN), and 4) one centrally located interbody fusion device (CAGE) (BAK/C, Sulzer Spine-Tech, Minneapolis, MN). The spines were mounted in a programmable tester and loaded in flexion and extension, right and left lateral bending, and right and left axial rotation. Measurements included vertebral motions, overall spine rotation, and applied load and moment. Global (C2-T1) rotational stiffness was calculated and normalized to the H condition to control intrinsic differences in the specimens. The relative rotations at the superior (S), operated (O), and inferior (I) motion segment units (MSU) were normalized with respect to the overall rotation of those three (S+O+I) MSUs and compared. A one-way ANOVA ($p < 0.05$) was used to statistically analyze the normalized motion and stiffness data.

RESULTS AND DISCUSSION

The moment values of the altered spine conditions normalized to the harvested condition are listed in Table 1. In flexion, lateral bending, and axial rotation, the normalized moments increased; in extension, they decreased. There were no significant differences between the instrumented conditions, although the GAP condition typically had the greatest value. The normalized motion data are given in Table 2. For flexion, extension, and lateral bending, the motion normalized to the harvested condition at the operated level decreased. There were no significant differences in the normalized motion patterns between the graft-plated spines and the spines having an interbody cage. The distribution of the motion at the operated and adjacent segments for flexion and extension loading is shown in Figure 1. For both instrumented conditions, there was a trend in decreased motion at the operated site that was compensated by the adjacent segments.

DYNAMICS OF CEREBRAL BLOOD FLOW REGULATION USING A LUMPED PARAMETER MODEL

Mette Olufsen¹, Ali Nadim², and Lewis Lipsitz³

¹Department of Mathematics, North Carolina State University, Raleigh, North Carolina

²Keck Graduate Institute, Claremont Graduate University, Claremont, California

³Hebrew Rehabilitation Center for Aged, Beth Israel Deaconess Medical Center, and Harvard Medical School, Boston, Massachusetts

INTRODUCTION

Cerebral blood flow dynamics is analyzed to study changes in key parameters (systemic and cerebrovascular resistances) during posture change from sitting to standing. The model sheds light on vascular adaptation to hypotensive stress, and can help to determine some of the changes in cerebral autoregulation that occur during hypertension.

METHODS

Existing data for 10 healthy young and 10 hypertensive subjects from Doppler measurements of cerebral blood velocity in the middle cerebral artery (MCA) and Finapres pressure in the finger are analyzed. Measurements show that as the subject stands up pressure falls and the blood flow pulse widens (Lipsitz 2000). The MCA blood flow is modeled using a three-element windkessel model represented by a circuit with two resistors (R_S , R_P) and a capacitor (C_S), (Olufsen 2002). The model input is the finger pressure p_F and the output is the flow q_{MCA} in the MCA. From this circuit we have derived an equation for impedance ($Z = P/Q$) of the MCA.

$$\frac{P_F}{Q_{MCA}} = \frac{R_P + R_S + i\omega C_S R_S R_P}{1 + i\omega C_S R_P} \equiv Z_w(\omega)$$

Let Z_m be the impedance obtained from the measurements. Then, the parameters for the model can be determined by fitting the impedance of the model to the impedance of the data. The zero- and large-frequency limits of the model yield relations that only involve the resistances:

$$\lim_{\omega \rightarrow \infty} Z_w(\omega) = R_S, \quad \lim_{\omega \rightarrow 0} Z_w(\omega) = R_S + R_P$$

The compliance C_S can be computed from analyzing the modulus of the impedance $|Z|$ as a function of frequency. We have estimated the model parameters in two ways; getting a parameter for each of the three intervals (sitting, transition, and standing) and getting parameters on a beat-to-beat basis.

RESULTS AND DISCUSSION

Using the measured pressure as input we were able to compute the flow in the MCA, compare it with the measured flow, and extract the dynamic changes of the model parameters during posture change (see Figure 1). The results show that during posture change, the mean flow and pressure and their ratio (the total resistance) fall (for ~10 s) and then increase (for ~10 s) to a new steady state (in fact the total resistance increases slightly before it falls). The peripheral resistance increases significantly in the beginning before it falls as the total resistance. As expected the heart rate goes up for about 10-15 s, and then it

falls to the new steady state. These results can be explained as follows: Immediately after standing the arterial pressure falls because of blood pooling in the legs and splanchnic circulation. The reduction in arterial pressure may unload the baroreceptors in the carotid arteries, aortic arch, and cardiopulmonary circulation, causing reflex cardio-acceleration and systemic vasoconstriction. When cerebral autoregulation becomes engaged approximately 10 s after the initial fall in pressure, cerebrovascular resistance decreases as expected, to restore blood flow back to baseline. The initial increase in cerebrovascular resistance may explain the widening of the cerebral blood flow pulse velocity, observed in the young subjects. In fact, our model confirms this hypothesis. If we modify the cerebrovascular resistance to prevent its increase (as seen in the hypertensive subjects) due to the initial response by the baroreceptors, the blood flow pulse does not widen.

Figure 1: Traces show (top to bottom) pressure [mmHg], flow [cm^3/s], mean pressure, mean flow, total resistance, systemic and cerebrovascular resistance [$\text{mmHg s}/\text{cm}^3$] and heart rate [beats/s] as a function of time.

FORCE DEPENDENCE OF THE P-SELECTIN/PSGL-1 BOND DISSOCIATION

Bryan Marshall¹, Rodger P. McEver², and Cheng Zhu¹

¹Schools of Mechanical Engineering and Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA 30332, USA, cheng.zhu@me.gatech.edu, ²Warren Medical Research Institute and Departments of Medicine and Biochemistry and Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104, USA.

INTRODUCTION

The interaction between P-selectin and its ligand P-selectin glycoprotein ligand 1 (PSGL-1) mediates leukocyte tethering and rolling on the endothelium of the blood vessel wall. The binding of these two molecules plays a critical role in the inflammatory response. Because it occurs in a mechanically stressful environment, this transient interaction depends not only on the kinetic rates but also their dependence on force.

An atomic force microscope (AFM) was utilized to study the force dependence of the disassociation kinetics of the P-selectin/PSGL-1 bond. Previously we employed two separate methods: 1. a constant force was applied to the bond and the lifetime distribution was recorded as a function of force, 2. the bond was loaded to failure at a constant rate and the rupture force distribution was recorded as a function of loading rate. The kinetic parameters estimated from the two methods were very different. Here we report a new method used to determine the source of the discrepancies.

METHODS

P-selectin was purified from human platelets and reconstituted in a supported lipid bilayer by using the method of vesicle fusion on a coverslip precoated with a polymer. Monomeric soluble (s)PSGL-1 was secreted by CHO cell transfectants and coupled to a Thermomicroscopes cantilever tip using the capture antibody PL2.

Experiments were done by repeatedly moving the PSGL-1 in and out of contact with the P-selectin bilayer. Lifetime experiments consisted of four phases: Approach, Contact, Retraction, and Holding. The force applied to a bond was controlled by the distance the cantilever was retracted from the surface of the P-selectin bilayer, the further the distance, the larger the force. Loading rate experiments consisted of only three phases: Approach, Contact, and Retraction. Bonds were loaded at constant rate until rupture occurred.

RESULTS AND DISCUSSION

In the lifetime method, the mean lifetime was interpreted as the inverse of the off-rate. The mean lifetime of the P-selectin/PSGL-1 bond displayed a biphasic dependence on force, which initially increased with force and then decreased. This indicated the presence of a catch bond with long lifetime at low force, which transitioned into a slip bond at 11 pN.

In the loading rate method, the peak force from the rupture force histogram was plotted against the log of the loading rate. Data so analyzed exhibited two line segments, which was interpreted as the presence of a slip bond with two energy barriers, suggesting fast disassociation with much shorter bond lifetimes than those actually measured in the lifetime assay.

To reconcile the differences between these two methods, a new method was used to simultaneously analyze the two sets of data. Regardless the method used to obtain them, data were analyzed by plotting the cumulative probability of bond disassociation against the time to bond rupture, starting from the instant when the bond is first loaded (Figure 1).

Figure 1: Three sets of data from the lifetime method (loading rate ~ 100 pN/s) are compared with one data set from the loading rate method (loading rate ~ 300 pN/s).

All four data sets display the same behavior while the bond is being loaded. Once a constant force is applied to the bond, the behavior deviates. The constant force appears to stabilize the bond, necessitating a second set of kinetic parameters to model its behavior. It is during this deviation that the catch bond becomes visible. Without probing the bond at a constant force, the loading rate method was unable to detect the catch bond. This suggests that the off-rate of the P-selectin/PSGL-1 bond cannot be described as a function of force but a functional of the force history.

VISCOELASTIC CHARACTERIZATION OF COLLAGEN GEL CONSTRUCTS

Laxminarayanan Krishnan¹, Jeffrey A. Weiss¹, Michael D. Wessman¹, James B. Hoying², Rosalina Das¹

¹Dept of Bioengineering, University of Utah, 50 S Central Campus Drive, Rm 2480, Salt Lake City, UT 84112. (jeff.weiss@utah.edu)

INTRODUCTION

Extracellular matrix (ECM) tissue constructs are simplified systems for in vitro study of conditions such as injury, healing and tumorigenesis. Quantification of changes in material properties of ECM constructs can elucidate fundamental biological processes that occur during wound healing and assist in developing design strategies for functional tissue-engineered constructs. Our interest stems from ongoing studies of angiogenesis in vitro (Hoying et al., 1996), with application to optimization of musculoskeletal soft tissue healing. As a prerequisite to this work, the present objectives were to design and characterize a system for in vitro viscoelastic characterization of collagen gels, and to use the system to characterize the effects of strain rate, equilibrium strain level and test day on material properties of the gels.

MATERIALS AND METHODS

Collagen I gels were polymerized at 37°C in custom chambers between fixed and moveable anchor posts, yielding an aspect ratio of 4:1. Gels were polymerized through holes in the posts, providing a firm anchor for uniaxial tensile testing (Fig 1).

Fig 1: Acrylite chambers with polymerized gel. (a) Actuating post, (b) reservoir, (c) fixed post (c) attached to base of chamber.

Fig 2: Photograph of test device. Inset: interface with load cell.

The system used a piezoelectric stage (PiezoJena, Hopedale, MA) to apply sinusoidal strains (Fig 2). The stage (A) was driven by signals from a function generator and an LVDT (Schaevitz, Hampton, VA) tracked displacement. Chambers were mounted to the stage and the mobile anchor interfaced (B) with a load cell (Transducer Tech, Temecula, CA, acc ±0.00012N). Sinusoidal oscillations (1% mag.) were applied about equilibrium strain levels of 2, 4 and 6%. Linear viscoelasticity theory was used to calculate dynamic stiffness (M , Pascals) and phase shift (ϕ , radians) as a function of equilibrium strain level and frequency:

$$M = \frac{A_{\sigma}}{A_{\epsilon}}; \quad \phi = \phi_{\sigma} - \phi_{\epsilon}.$$

Here ($A_{\epsilon}, \phi_{\epsilon}$) and ($A_{\sigma}, \phi_{\sigma}$) are the amplitude and phase of the strain-time and stress-time data, respectively. Two sets of gels (N=11 in each group) were tested on 1st and 7th day of culture.

Fig 3: Dynamic stiffness and phase shift at Day 1 (left col) & Day 7 (rt. col).

RESULTS

Dynamic stiffness increased with frequency and strain level ($p < 0.001$, Fig 3). For a given strain level there was no significant change in dynamic stiffness ($p = 0.346, 0.155, 0.249$) and phase shift with day of testing. The phase shift decreased up to 1 Hz and then increased. Equilibrium stresses showed an increase with increasing strain level ($p < 0.001$) without significant effect of test day ($p = 0.832$).

DISCUSSION

Stiffening of the gels was not seen – this might be expected by an increase in stabilization of collagen fibers (Hayashi, 1974). A linear increase in dynamic stiffness and decrease in phase angle up to 1 Hz is consistent with studies on cell-populated matrices (Wakatsuki, 2000). The change in phase shift with frequency cannot be explained by quasilinear viscoelastic theory. Over the range of frequency tested, the damping goes down up to 1 Hz and then increases again at higher frequencies, indicating that the most viscous behavior is at low and high frequencies. With this new device and data on native gels material properties, the influence of vessel fragments and growth during angiogenesis can now be examined.

ACCURACY OF NON DIFFERENTIAL GPS FOR DETERMINATION OF SPEED OVER GROUND

Witte T.H. Wilson A.M.

Structure and Motion Lab, The Royal Veterinary College, North Mymms, Hatfield, Herts AL9 7TA England

INTRODUCTION

In studies of human and animal locomotion many measures are expressed relative to speed. Speed is easily determined during treadmill exercise but when making measurements during over-ground locomotion average speed is often determined by chronometry over a pre-measured track (Schutz & Herren, 2000). Differential GPS and/or double-frequency receivers have been shown to provide accurate speed measurements, but such units are heavy (4kg) and expensive (Terrier *et al*, 2000). Recent developments in GPS technology for car navigation and incorporation into mobile phones mean that it is now possible to buy an OEM module GPS that weighs as little as 7g with the potential to program as a data logger (Steiner *et al*, 2000). Such a unit has immense potential for logging and subsequent downloading of speed data during field exercise. The accuracy of such systems is unclear with most manufacturers reporting velocity accuracies of 0.1 to 0.2ms⁻¹. Speed is calculated through a combination of position differentiation and measurement of Doppler shift of the carrier wave, meaning that speed accuracy is not just a function of the accuracy and drift in position data. Unfortunately, no detailed information is available about how such calculations are made. This study was designed to evaluate the accuracy of GPS speed measurement under varying conditions.

METHODS

A bicycle speedometer was modified to transmit a pulse once per wheel revolution via a radiotelemetry link. The bicycle was ridden around the 6th lane of a 400m running track at speeds of 10, 15 and 20 kmh⁻¹. The GPS receiver (RoyalTek REB-2100) was fixed to the helmet of the rider and speed over ground, position dilution of precision (PDOP) and satellites used were logged once per second.

A second experiment was undertaken at 15kmh⁻¹ with an aluminium shield fixed so as to block satellite reception on one side of the antenna. This meant that the effect of changing the satellites used for the position fix could be examined as the cyclist went round the track

Data were logged in LabView and instantaneous speed calculated from the telemetered pulses. Comparison of actual speed and GPS speed was undertaken and the effect of satellite

number, speed, PDOP and whether on a bend or straight examined on a total of 185 samples.

RESULTS AND DISCUSSION

The mean speed measured by the GPS was 0.063ms⁻¹ lower than the speed determined from the cycle wheel. The mean random error (i.e. mean unsigned difference between GPS and cycle speed) was 0.16ms⁻¹ and 50% of the values were within 0.12ms⁻¹. The error was not a function of speed (0.079ms⁻¹ at 10kmh⁻¹, .222ms⁻¹ at 15kmh⁻¹, 0.183ms⁻¹ at 20kmh⁻¹).

PDOP varied between 2.5 and 50 during the study. PDOP is inversely proportional to the volume of the pyramid formed by lines running from the receiver to 4 satellites observed and has a multiplicative effect on the position error value. No effect on random error was however observed until PDOP reached a value of 9. Number of satellites used (range 3-6) also had no effect on accuracy of speed determination. There was no difference in the mean speed difference or the random error as a function of straight or bend – we had expected an under estimate of velocity because the GPS would “cut” the corner. Changing satellite also appeared to have little or no effect on velocity – no jump was observed in either the positional or speed data.

SUMMARY

GPS can be used to determine speed over ground with 50% of readings within 0.12ms⁻¹ of the true value. The accuracy of speed determination was preserved even when the positional data was degraded due to poor satellite number or geometry. Some smoothing of the speed data is evident.

INTRODUCTION

Despite the frequency of reported knee pain, especially patellofemoral (PF), there is still a lack of specificity in diagnosing the pathology causing this pain, due primarily to limited clinical and research tools for the direct and non-invasive measurement of *in vivo* musculoskeletal dynamics. This leads to confusion when designing treatment plans and to difficulty in assessing the efficacy of any intervention. Broad categories such as chondromalacia, anterior knee pain, or maltracking are often too quickly accepted as a diagnosis without the underlying etiology being researched. With the advent of new imaging technologies allowing the non-invasive study of *in vivo* musculoskeletal kinematics during volitional tasks, we have an opportunity to revisit these broad classifications in order to develop more specific diagnosis that can be correlated with specific impairments. Our previous work has shown both cine phase contrast magnetic resonance imaging (cine-PC MRI) and fast-PC MRI to be accurate and precise in acquiring such 3D measures. With this knowledge, we have begun to study the kinematics of compromised joints, specifically PF maltracking.

METHODS

The study included a total of five unimpaired subjects (29.0±7.9 years, 1.7±0.3m, 60.8±11.8kg; 8 knees) who had no history of knee pathology or pain and one subject (28 years, 1.75m, 75kg) clinically defined as having patellofemoral pain syndrome (PPS) with suspected maltracking. For the PPS subject, data were collected on her more severely impaired knee. All subjects were placed in a supine position within a 1.5 GE CX imager and were asked to flex and extend their knee, from full extension to ~40° of flexion, at 35 cycles/minute. Images were taken in the sagittal plane at the approximate centerline of the femur and patella using a fast-PC protocol (2nex, TR=9msec, 2 views/acquisition, imaging time=2:48). The fast-PC protocol was not available during the imaging session with the PPS subject. Therefore, the impaired knee was scanned using a cine-PC protocol (2nex, TR=21 msec, imaging time=5:33). In order to establish anatomically based reference frames, fastcard anatomical images were taken in 3 axial planes during the movement, as well. Using Fourier integration algorithms developed previously (Zhu, et al. 1996), regions on the patella, femur, and tibia were selected (at t=0) and tracked in 3D space throughout the motion cycle. Data were translated into 3D xyz body-fixed orientation angles (flexion, tilt, and twist) describing the patellar and tibial orientation relative to the femur.

RESULTS

The unimpaired data was similar to that previously acquired (Sheehan, Zajac, Drace, 1999). Specifically, the unimpaired subjects showed very little change in patellar tilt angle [RPTA = (max PTA) - (min PTA at or near full extension) = -4.7±3.3°], as the knee extended (Fig 1). The impaired knee demonstrated a rapid lateral change at the end of the extension cycle (RPTA=-28.2°). Also, this subject noted that the required ~5.5 minutes of movement for the cine-PC exam began to aggravate her knee joint slightly.

Figure 1: Patellar Tilt Angle (PTA). The filled boxes represent the average unimpaired PTA (±1SD-grey area). Not all subjects had the same knee range of motion, due to variations limb lengths. Thus, the dark gray boxes represent the regions where less than one half of the subjects are represented in the average. Open boxes represent the PTA from the impaired subject.

DISCUSSION

These preliminary results are highly encouraging in terms of our ability to use PC MRI to quantify the underlying kinematics pathologies linked to PF pain. The rapid change in the patellar tilt angle may be indicative of high stresses being placed on the cartilage of the PPS subject when the patella contacts the femur. Enrollment of additional impaired and unimpaired subjects into this study is currently underway so that statistically significant differences between these populations can be identified. Based on our previous precision study and the comments of our impaired subject, we would highly recommend the use of fast-PC over cine-PC MRI in future studies due to its slightly higher precision and shorter imaging times.

INTRODUCTION

Variations in optic flow have been shown to alter postural adjustments during treadmill walking (Warren, et al., 2001; Bardy, et al., 1999). Kram's group has examined the effects of gravity-assist on body kinematics during treadmill walking (Griffin, et al., 1999; Donelan and Kram, 1997; Kram, et al., 1997). However, little is known about the interaction between visual flow cues and body unloading during locomotion. Miller, et al. (2001) have shown that scene motion and gravity-assist together increase the variability of torso orientation during treadmill walking. The purpose of this study was to determine if the combination of visual scene motion and partial gravity-assist (i.e., body unloading) alters gait temporal parameters and foot placement during treadmill locomotion.

METHODS

Five subjects (3 male; 2 female; age 30 ± 4.4 yrs; weight 70.3 ± 8.6 kg; height 170.8 ± 8.3 cm) participated in this study. A pneumatic device, called the "Pogo", provided gravity-assist. Subjects were strapped into the Pogo's harness system, which is designed to allow for six degrees of freedom. While in the Pogo, subjects walked on a motorized treadmill at 4 km/hr (2.5 mi/hr). A virtual office scene was back-projected on a screen placed 1.5 meters in front of the subject. During a 60-second trial, the scene remained stationary for the first 30 seconds (sec), then rotated in either pitch, roll or yaw for the remaining 30 sec. The Pogo was set to three gravity-assist levels: 1/3 body-weight (BW); 2/3 BW; 1 BW (i.e., no assist). Three trials were recorded for each scene rotation and gravity-assist combination (27 total). Kinematic (Motion Analysis Corp, Santa Rosa, CA) and footswitch (Motion Lab Systems, Baton Rouge, LA) data were recorded from 15 sec before the start of scene motion to 15 sec after the start of scene motion (i.e., T_0+15 sec to T_0+45 sec).

Using footswitch data, temporal variables and duty factor were determined. The step direction (the angle of the line segment starting at the foot's xy-position at toe-off to the subsequent heel contact) and stride length were calculated with kinematic data. The variances of the step direction, step length and temporal parameters were computed over all analyzed gait cycles within both the static scene and scene motion periods of each trial. A paired t-test was used to determine significant increases in the variance of the parameters during scene motion as opposed to that during steady state ($p < 0.05$).

RESULTS AND DISCUSSION

Variability of step direction (Figure 1) increased during scene motion ($p=0.003$), as did the duty factors for both feet (left: $p=0.002$; right: $p=0.006$). Stride length did not significantly increase, nor did the gait temporal parameters, except for left-foot step time ($p=0.029$) and right-foot stance time ($p=0.022$).

Figure 1: Plot showing step direction in the xy-plane (in degrees) for a representative trial in which the subject experienced 1/3 BW and the visual scene rotated in roll. Each symbol represents one gait cycle.

SUMMARY

The combination of visual scene motion and gravity-assist significantly increased the variability of foot placement and duty factor during treadmill walking. Stride length variability was not affected. Given that the combination of gravity-assist and visual scene motion affect walking kinematics, varying treadmill harness tension and visual scenes within a variable practice program may be implemented as an in-flight training tool or countermeasure to minimize the effects of space flight on balance and coordination.

DIMINISHED STEPPING RESPONSES LEAD TO FALLS IN BOTH YOUNG AND OLDER ADULTS

INTRODUCTION

Falls are a significant source of morbidity and mortality in older adults (Sattin, 1992). In order to reduce the incidence of falls by older adults, it is important to determine exactly why these falls occur. In particular, are there age-differences in the responses to a perturbation that place older adults at a higher risk of falling than the young? To date, there has been no direct comparison of the responses leading to actual falls by young and older adults. This study investigated whether age-differences exist in the mechanism of falling versus recovery upon an unexpected and novel slipping perturbation.

METHODS

An unexpected and novel forward slip was induced, using bilateral low-friction platforms, during a sit-to-stand task in 60 young and 41 older (≥ 65 yrs.) healthy, safety-harnessed adults. After 4 normal sit-to-stand trials, a 24cm slip was induced just after seat-off. Kinematics of 26 markers were recorded (Peak Performance, CO). Outcomes were classified into recoveries, assists, or falls, based on the extent of hip descent and the force on the safety harness. Falls were further classified by whether or not a step was initiated before the “fall.” Fisher’s exact test identified differences in outcome occurrence. One- or two-way ANOVAs investigated effects of age group and/or slip outcome on selected kinematic variables. Variables were the horizontal position and velocity (Xcom, VXcom) of the body center of mass (COM) relative to the more posterior heel, the vertical height and velocity (Zhip, VZhip) of the bilateral hip midpoint, and step length. Events of interest were slip onset, mid-slip, the start of hip descent, step initiation (init.), and step touchdown (TD). Step timing was determined from recorded ground reaction forces (AMTI, MA).

RESULTS AND DISCUSSION

A greater proportion of older than young adults fell (76% vs. 30%; $p < .001$). Stepping occurred in all but one recovery, but “no-step” falls comprised 20% and 34% of falls by young and older adults, respectively, with no difference in the proportion

of no-step falls between age groups ($p = .26$). The state of the body at slip onset, the slip duration, and the COM backward velocity at mid-slip all differed between age groups, yet none of these variables differed between recoveries and falls.

Instead, falling was related to the kinematics of hip descent and of the first step (Table 1). Fallers underwent a greater change in Zhip and VZhip between first step initiation and touchdown and placed their stepping foot less posterior to the COM. The hips of older adult fallers, both step and no-step, also began to descend from a lower height. Increased hip descent, indicative of a “collapse” of the support (non-stepping) limb, together with a less posterior stepping foot placement, arguably reflect a diminished stepping response in those who fell. The no-step fallers then represent those individuals in whom the stepping response was diminished to the point of near-absence. It is most likely that these diminished stepping responses reflect a poor selection or scaling by the central nervous system (CNS) of the response to an unexpected and unfamiliar perturbation.

Increased falling in older adults might thus be attributable to more frequent mis-selection or mis-scaling of a recovery response by the CNS. The fact that older fallers began to descend from a lower hip height might also indicate that decreased lower extremity strength contributed to increased falling by older adults. Finally, regardless of slip outcome, older adults placed their stepping foot less posterior to the COM than the young. In fact, older adults were more likely than young to employ a second backward step for recovery (89% vs. 34%; $p < .01$). These results suggest a multi-factorial source of the decreased ability of older adults to recover and that training of recovery responses might reduce falling.

PRESSURE DISTRIBUTION MEASUREMENT FOR DESIGN OF WAIST BELTS IN PERSONAL LOAD CARRIAGE SYSTEMS

L. Hadcock, J.M. Stevenson, J.T. Bryant
Ergonomics Research Group, Queen's University, Kingston, ON
9ljh2@qmlink.queensu.ca

INTRODUCTION

In previous research studies, two types of backpacks have been modeled, a shoulder-based model and a shoulder plus waist belt model. In the shoulder-based model, a strap sensor in the lower shoulder strap allowed the lumbar and shoulder reaction forces to be resolved (MacNeil, 1996). This model was validated with 20 subjects and accurately predicted shoulder ($r=0.92$, for four of five packs) and lumbar discomfort ($r=0.93$) (Stevenson, 1995). The second model added a waist belt and other straps such as load lifters and sternum straps. To resolve the forces, a standardized torso was mounted on a force platform with a second load cell at the L3 level to separate shoulder and waist components. This model was considered less successful because of the indeterminacy of friction and an inadequate understanding of the waist belt forces (Rigby, 1999). Therefore, the purpose of this study was to design a standardized method of comparing waist belt features and designs, independent of the rest of the pack, to define and validate the mathematical model of the backpack.

METHODS

A standardized lower torso model with known mathematical properties was constructed. The lower torso was designed to be unisex with the waist circumference matching that of a 50th percentile man. The waist-to-hip ratio was 0.8, an acceptable value for both genders. It was covered with Bocklite, a skin analog, which represented a person with 3% body fat. Tekscan sensors were affixed to the Bocklite surface to record pressures applied by the waist belt. The torso was mounted on a jig that was placed

Figure 1. Standardized Torso Model

The geometric shape of the torso allowed for the measured Tekscan pressures to be converted to vector normals and subsequently resolved and summed as single forces and moments acting on the torso. These calculated values were compared to those measured by a six-degree of freedom load cell beneath the torso model and a load application device.

Loads were applied with the calibrated application device and the results of the Tekscan and load cell measurements were compared. A simplified shoulder was attached to a second load cell at L3 above the torso as a method to mount the pack with minimal contact on the upper torso. Different waist belt designs could be easily isolated and compared while being loaded realistically with the specific pack design.

RESULTS AND DISCUSSION

Resolved force data from the calibrated force plate and a load application device showed good agreement. The Tekscan results were consistently lower than both of the other instruments, by up to 45%. The vector resolution of measured Tekscan forces in the X, Y, and Z directions were proportionally accurate, relative to the direction of the applied force, indicating that the sensel location coordinates and their calculated normal vectors were not the major source of error. Simple summation of the individual sensel measurements provided force measurements greater than the applied forces. This indicated the need for the use of a mathematical model for resolving the forces on a curved surface. A coefficient of friction was measured using an inclined plane with the same properties as the torso model. Results were only marginally more accurate when this coefficient of friction was included in the calculations.

SUMMARY

Preliminary results indicate that the standardized torso model is a useful design tool that can realistically model and compare waist belt forces. The measurement of contact pressures with Tekscan sensors requires better calibration to be considered a valid design tool.

EFFECTS OF DIABETES ON THE STRENGTH OF THE PLANTAR SKIN-FAT INTERFACE

Yan Chen, Brian Davis, Antonio Valdevit

Department of Biomedical Engineering, Cleveland Clinic Foundation, Cleveland, USA

cheny@bme.ri.ccf.org

INTRODUCTION

Foot ulceration is one of the most common complications of diabetes mellitus. Research has suggested that the plantar skin-fat interface may be the site for initial ulcer formation since peak first principal stresses at this location dramatically increase with changes in material properties and boundary conditions (Thompson, 1997). The goal of this study was to compare the skin-fat interface strength in diabetic and non-diabetic feet.

METHODS

For 21 diabetic (68 ± 2.4 years) and 17 non-diabetic (74.6 ± 3.8 years) foot specimens, the plantar skin surface was cut into a 9×2 array from the first metatarsal head (row 1) to the anterior heel (row 9) and divided down the medial/lateral axis. Each strip of skin was 1 cm wide and 2 mm deep. The skin was clamped to a load cell and tension was applied at a rate of 1 mm/sec as the skin was peeled off the underlying fat tissue. During testing the foot specimen was held in a supine position in a custom designed jig that was placed on top of a transitional unit that could move in both x and y directions to keep the peeling force vertical to the peeling site. This unit was then mounted on a universal MTS machine. The mean peeling force over the entire removal process was calculated and normalized to the width of the skin strip (i.e. $F=N/cm$).

RESULTS

The strength of the skin-fat interface was significantly different

	Diabetic group (n=21)		Non-diabetic group(n=17)	
	Medial	Lateral	Medial	Lateral
Row 1	32.2±6.7	38.2±10.6	31.9±13.6	30.8±9.6
Row 2	33.2±9.2	36.1±12.7	29.0±9.4	30.4±7.9
Row 3	30.7±8.7	31.2±11.4	26.0±8.5	25.1±9.3
Row 4	28.1±8.0	28.7±9.1	24.7±8.6	24.4±10.5
Row 5	26.1±7.5	26.4±7.1	22.5±7.7	24.4±10.5
Row 6	28.3±9.5	29.6±7.8	22.7±7.9	24.4±9.5
Row 7	32.7±10.0	31.9±9.0	24.5±8.7	26.5±9.8
Row 8	34.4±9.9	34.2±10.7	29.3±8.9	27.7±10.2
Row 9	46.7±16.5	42.5±15.3	35.9±14.4	34.7±13.9

Table 1. The mean and standard deviation for the mean skin-fat strength (N/cm) at different regions across the plantar surface of the foot.

($p < 0.05$) with the diabetic strips requiring greater skin removal force (Table 1). There was no significant difference between medial and lateral strips within both groups. The skin-fat strength decreased with age in the non-diabetic group ($p < 0.00$, Fig 1), but this trend did not exist in the diabetic group.

Fig 1. Skin-fat interface strength vs age in the non-diabetic group.

DISCUSSION

This experiment demonstrated that the strength of the skin-fat interface in the diabetic group was higher than in the non-diabetic group. Due to tissue property changes and bone deformity, diabetic patients usually experience elevated vertical stress at the foot-ground interface. The strength of the skin-fat interface might be an adaptive response to this elevated vertical stress. The trend with age in the non-diabetic group might also be explained by this assumption. In general, people become less active with age, which implies less stress under the foot, and thus lower skin-fat interface strength. In the diabetic group, as age increases, the stress concentration might be greater because of changes taking place in the foot due to diabetes, thus the decreasing trend with age did not exist in the diabetic group.

TESTING DURATION REQUIRED TO ACCURATELY PREDICT LIGAMENT VISCOELASTICITY

Eugene Manley¹, Paolo Provenzano¹, Dennis Heisey², Roderic Lakes³ and Ray Vanderby, Jr.¹

¹Departments of Biomedical Engineering and Orthopedic Surgery, ²Department of Surgery, and ³Departments of Biomedical Engineering and Engineering Physics, University of Wisconsin, Madison, WI, USA, vanderby@surgery.wisc.edu

INTRODUCTION

Extensive viscoelastic testing has been performed on ligaments and tendons, but only (King, et al. 2000) has studied the viscoelastic effects over extended continuous time durations. Our goal is to test ligaments under creep and stress relaxation with the intent of determining how much time needs to be allocated to effectively obtain viscoelastic behavior of ligaments. The goal is to reduce the testing time needed for specimens so that more specimens can be prepared and analyzed in a shorter time frame.

METHODS

Male Sprague-Daley rats (300±50g) were used in all experiments. Specimen harvesting and testing were adopted from the methods of Provenzano, et al. (2001) as was some of the data. The animals were divided into two groups, creep (n=9) or stress relaxation (n=14). The stress relaxation (SR) samples consisted of two phases, eight subjected to 1000s of testing and six subjected to 10,000s of testing. The data from the first three decades (1-1000s) of all samples were pooled together, and then data based on the six long term duration (10,000s) were analyzed separately. All of the samples were subjected to a ramp-up to creep and relaxation.

Data analysis was done on the specimens to determine an adequate time frame for testing ligaments in both creep and relaxation to accurately predict ligament behavior. Both the Standard Regression approach (columns 1-2 in the Tables) and the Random Coefficients (columns 3-6 in the Tables) approach were applied.

RESULTS AND DISCUSSION

Table 1. Creep Standard Regression and Random Coefficients

Time (s)	mean ¹	SD ²	E[M] ³	SD(I) ⁴	SD(E[M]) ⁵	CV ⁶
<10	0.089	0.056	0.088	0.052	0.018	20%
<100	0.091	0.039	0.091	0.039	0.013	14%
<1000	0.079	0.030	0.079	0.030	0.010	13%

Table 1 shows the data for the standard approach of averaging regression coefficients versus the random coefficient approach for creep. Testing for 1000seconds only produces a 1% increase in accuracy of the measurement of ligament behavior as shown by the CV. The extra degree of precision will not affect results to any significant degree.

Table 2. S.R. Standard Regression and Random Coefficients

Time (s)	mean ¹	SD ²	E[M] ³	SD(I) ⁴	SD(E[M]) ⁵	CV ⁶
>10	-0.029	0.019	-0.029	0.019	0.0051	18%
>100	-0.033	0.019	-0.033	0.019	0.0050	15%
>1000	-0.032	0.017	-0.032	0.017	0.0044	14%
>10000	-0.033	0.018	-0.033	0.017	0.0047	14%

Table 2 shows the stress relaxation standard regression rates versus the random coefficients. Testing for 1000 seconds is again shown to only increase the accuracy of the data by 1% from the first two decades. Testing for a fourth decade offers no increase at all in data accuracy.

Random coefficients accounts for the variability in individual samples by separating out the material property (creep and relaxation) from the testing variability. The log linear model of the form: strain=a+b*log_e(time) for creep, and log_e(stress)=a+b*log_e(time) for stress relaxation. It is clearly shown that testing for durations longer than 100seconds does not offer any significant increase in the accuracy of the measurements of creep and relaxation. Though not shown, the data separated for just the four decades showed that there are large variations in linearity through the fourth decade. Due to variability of testing these materials, most information is obtained at the beginning of testing that cannot be used later.

¹Average of Standard Regression coefficients for each sample

²Standard deviation of Standard Regression coefficients

³Random Coefficients estimate of material property (creep or relax.)

⁴Estimated std. dev. of individual increments of creep or relaxation

⁵Standard error of the estimated creep or relaxation, E[M]

⁶Percent coefficient of variation: 100*SD(E[M])/E[M]

SUMMARY

Our statistics show you can reliably predict material behavior by doing short duration tests for a large number of samples.

VERTICAL JUMPING PERFORMANCE IN 8-12-YEAR-OLD RHYTHMIC GYMNASTS

Helena Gapeyeva¹, Tatjana Kums², Mati Pääsuke¹, Jaan Ereline¹

University of Tartu, Tartu, Estonia

¹Laboratory of Kinesiology and Biomechanics, Institute of Exercise Biology, spbiol@ut.ee

²Institute of Sports Pedagogy

INTRODUCTION

The vertical jumps can be used as a model to study explosive force-generating capacity of the lower extremities. A squat jump consists of a concentric muscle action of the leg extensor muscles while counter-movement jump consists of an eccentric-concentric muscle action. It has been shown to have a potentating effect of stretch-shortening cycle to vertical jumping performance in young adult subjects (Bosco et al, 1982), however, the age-related differences of this potentating effect are poorly understood. The aim of the study was to compare the vertical jumping performance in 8-10- and 11-12-year-old female rhythmic gymnasts.

METHODS

The vertical jumping performance in young female rhythmic gymnasts recorded before the competition (I group, n=7, and II group, n=9; Table 1).

Table 1: Anthropometrical characteristics of gymnasts

Characteristics	I group	II group
Age (years)	8.7±0.3	11.7±0.2 ***
Height (cm)	137.0±2.8	149.0±2.3 **
Body mass (kg)	31.0±1.5	37.2±0.1.0 **
BMI (kg·m ⁻²)	16.5±0.6	16.8±0.2
Training period (years)	2.4±0.5	3.1±0.7

Gymnasts performed the squatting jumps (SJ), counter-movement jumps (CMJ) and counter-movement jumps with the help of arms (CMJA), and a 30 s hopping test (HT) on a force platform PD-3A (VISTI, Russia) with the dimensions of 0.75x0.75 m and natural frequency of 150 Hz. Three maximal SJ, CMJ and CMJA recorded on-line and the trial with the best height of jump (H) was analysed in each case. The vertical velocity of take-off (Vv), height of jump (H) and peak vertical ground reaction force (VGRF) recorded.

RESULTS AND DISCUSSION

The Vv was significantly higher in CMJA as compared to SJ and CMJ (Table 2) for both groups ($p<0.01$). Gymnasts of II group had greater Vv in all kinds of jumps in comparison with I group. The older gymnasts had greater values of height of jump in all types of jumps. There were no differences in Vv and H of jump in SJ as compared to CMJ for both groups ($p>0.05$). The VGRF of SJ was significantly lower ($p<0.05$) in

comparison with CMJ and CMJA for II group, and difference of VGRF was not significant for I group. Younger gymnasts had the lower mean power of jumps (11.8 ± 0.6 and 15.6 ± 1.2 W in I and II group, respectively) and bigger decrease of power during the HT ($p<0.05$) as compared to II group (42.0 ± 3.9 and $36.2\pm3.6\%$, respectively).

Table 2: Vertical jumping performance characteristics of 8-10- (I group) and 11-12-years-old rhythmic gymnasts

Parameters	Type of jump	I group	II group
Vv (m·s ⁻¹)	SJ	1.81±0.05	2.13±0.06 **
	CMJ	1.80±0.06	2.16±0.06 **
	CMJA	2.18±0.04	2.42±2.17 **
H (cm)	SJ	18.4±1.0	23.3±1.3 *
	CMJ	19.6±1.1	23.9±1.4 *
	CMJA	24.1±0.9	30.0±1.7 *
VGRF (N)	SJ	488.3±50.1	494.4±24.3
	CMJ	511.4±57.6	527.6±42.6
	CMJA	550.1±65.0	594.0±39.2

Significance of difference in characteristics between groups: * $p<0.05$; ** $p<0.01$; *** $p<0.001$

SUMMARY

The significant increase in vertical jumping height during puberty is well documented (Häkkinen et al, 1989). Younger gymnasts cannot use positive effect of stretch-shortening cycle to vertical jumping performance in counter-movement jumps (Bobbert et al, 1996). It has been suggested that the expression of muscle strength is dependent on myelination of the motor nerves, which is not completed until sexual maturity (Brooks and Fahey, 1985).

KINEMATIC COMPARISON OF TREADMILL GAIT WITH BODY WEIGHT SUSPENSION BETWEEN UNIMPAIRED SUBJECTS AND SUBJECTS WITH PARKINSON'S DISEASE.

A. Joseph Threlkeld¹, Lance D. Cooper¹, Pamela M. Sprenkle², John M. Berton²

Biodynamics Laboratory, Creighton University, Omaha, Nebraska, USA, jthrel@creighton.edu

¹Department of Physical Therapy, ²Department of Neurology

INTRODUCTION

Treadmill training combined with body weight suspension (BWS) is used to improve gait in subjects with neurologic conditions including Parkinson's Disease (PD). (Dobkin 1999; Miyai et al 2000) A key impairment of persons with PD is diminished angular excursion of the lower extremity (LE) joints. (Morris et al. 2001) To normalize proprioceptive input in PD gait patterns, BWS must induce kinematic patterns similar to those induced in unimpaired persons. Our purpose was to compare the kinematic responses of unimpaired and PD subjects to selected BWS levels at a single treadmill speed.

METHODS

Subjects were 7 unimpaired volunteers (Norm group; 2F, 5M, 25±3 yrs) and 7 volunteers with PD (PD group; 1F, 6M; 68±9 yrs; Hoehn & Yahr Stage 2 to 3). All subjects walked on a level treadmill at 80cm/sec at both 30% and 50% BWS suspension levels (Vigor Equipment Neuro II). The suspension level presentation order was randomized. A 4-camera 60Hz reflective marker motion capture system (MotionAnalysis Hi-Res) was used to collect 3D kinematic data. 8 to 12 strides from each subject under each condition were time normalized to percent of cycle, ensemble averaged (MotionAnalysis Orthotrak) and data from the right and left sides collapsed. Temporospacial data and sagittal plane kinematics of the LE joints were compared at critical points between conditions using two-way repeated measures ANOVA at a significance level of $p \leq .01$.

RESULTS AND DISCUSSION

The PD group took smaller steps ($p=.013$) but at a higher cadence ($p=.032$) than Norm but BWS level did not affect these factors. Average ankle dorsiflexion during singlelimb stance was unaffected by BWS ($p=.017$) but was greater in the PD group ($p=.002$). Maximum plantarflexion during swing increased with more BWS ($p=.008$) but was unaffected by group ($p=.05$). Maximum knee flexion during single limb stance decreased with more BWS ($p=.002$) but was unaffected

by group ($p=.35$). Maximum knee flexion during swing was reduced with more BWS ($p=.004$) but was unaffected by group ($p=.34$). Hip flexion at footstrike was reduced by BWS ($p=.004$) but unaffected by group ($p=.34$). Maximum hip extension during stance was unaffected by BWS ($p=.74$) or group ($p=.56$).

ANKLE KINEMATICS

SUMMARY

There were baseline gait differences between groups but LE kinematic changes produced by BWS were comparable in both Norm and PD subjects.

APOPTOSIS IN LIGAMENT AFTER A SUB-FAILURE STRETCH

Paolo P. Provenzano¹, Peter Muir², Zhengling Hao², and Ray Vanderby Jr.¹

¹Orthopedic Research Laboratories, Dept. of Biomedical Engineering and Orthopedic Surgery, and ²Comparative Orthopedic Laboratory, Dept. of Veterinary Medicine, University of Wisconsin, Madison, WI, USA, email: vanderby@surgery.wisc.edu

INTRODUCTION

The aim of this study was to use immunohistochemistry (IHC) to examine the cellular response to a sub-failure ligament stretch. MMP-1 and -13 are collagenases which are important factors regulating remodeling of the extracellular matrix (ECM) of ligament and have been shown play a role in ligament healing (Hellio Le Graverand *et al.*, 2000). Apoptosis (programmed cell death) is an organized physiologic process that is critical for normal development and homeostasis, while necrosis is not planned and is often associated with a traumatic event resulting in loss of cell membrane integrity. Apoptosis has been associated with rotator cuff tendon pathology (Yuan *et al.*, 2001) and with increasing loads in vein grafts (Moore *et al.*, 2001). Cellular necrosis precedes structural damage in sub-failure stretched medial collateral ligament (MCL; Provenzano *et al.*, 2002). We therefore, hypothesize that a sub-failure ligament stretch will cause apoptosis and MMP-1 and -13 activation.

METHODS

Four MCLs were removed from Sprague-Dawley rats (Right leg receiving a sub-failure stretch; Left leg contralateral control). The femur-MCL-tibia (FMT) complex was harvested and kept hydrated. The FMT complex was loaded into a custom designed load frame/sterile tissue culture bath containing standard media (DMEM w/10% FBS, nonessential a.a., L-glut., pen. and strep.). In the load frame/bath the MCL was preloaded to 0.1N, preconditioned (10 cycles at 1% strain), and stretched in displacement control (10%/sec) to 4% strain (a strain which is in the linear region (~40 failure strain), and has been shown to result in cellular damage in the rat MCL (Provenzano *et al.* 2002)). Control ligament were handled in the same manner as stretched MCLs (minus stretch) with the same time from tissue harvest to incubation. After mechanical testing, MCLs were incubated for 4 hours (standard media). Tissues were fixed in Zamboni's fixative and longitudinal frozen sections (10 μ m) were made. Fibroblast apoptosis was detected using the TUNEL assay. Peroxidase-labeled antidigoxigenin with DAB/cobalt/nickel staining was used to localize TUNEL-positive (+) cells. Mayer's hematoxylin was used as a counter stain. MMP staining was performed with mouse monoclonal anti-MMP-1 and -13 antibodies, 1:50 dilution, and incubated for 1hr at room temperature. Negative controls were included in both assays. The interior portions of the ligament were examined and compared in order to reduce any edge effects from harvest and handling.

RESULTS AND DISCUSSION

IHC demonstrated fibroblasts in the sub-failure stretched MCLs to be MMP-1 and -13 negative which does not support our hypothesis (not shown). Fibroblasts receiving a sub-failure stretch were TUNEL+, indicating that apoptosis was taking place, while control tissues showed almost no cells undergoing apoptosis. These results support our hypothesis (Fig. 1). This suggests that upregulation of ligament fibroblast apoptosis is an early response to sub-failure injury.

FIG. 1: Control MCLs (A & C) show normal cells (blue) while Stretched MCLs (B & D) display apoptotic (TUNEL+) cells (brown) 4 hours after a sub-failure stretch. Arrows emphasize apoptotic fibroblasts.

SUMMARY

Results of this study indicate that after MCLs undergo apoptosis but not detectable MMP-1 and -13 expression 4 hours after sub-failure stretch.

FACTORS RELATED TO BALL VELOCITY DURING AN INSTEP SOCCER KICK

John K. DeWitt¹ and Richard N. Hinrichs²

Exercise and Sport Research Institute, Arizona State University, Tempe, AZ, USA

¹Graduate Student, john_dewitt@hotmail.com, ²Associate Professor

INTRODUCTION

Kicking is a complex interceptive action requiring the coordination of multiple segments with the intent of obtaining maximal endpoint (i.e., foot) velocity at the time of contact with the ball. While contact is made with the foot, many segments, including the lower leg, thigh, pelvis and upper body must be coordinated throughout the motion. The peak and impact velocities of each segmental endpoint affect the velocity of the foot at impact. The purpose of this investigation was to identify those factors that are related to faster ball velocities.

METHODS

Sixteen experienced male soccer players were videotaped while kicking a stationary soccer ball as hard as possible with their right foot into a regulation goal (similar to a penalty kick). All testing was completed inside a gymnasium. The two trials for each subject that resulted in the greatest ball velocity were selected for further analysis. Video data were digitized and converted to 3D coordinates via the DLT algorithm. Data were smoothed and 3D velocities were computed. The two trials for each subject were combined into a mean trial, resulting in sixteen means values for each variable examined.

A deterministic model was developed relating the peak and impact velocities of the left hip, right hip, right knee, and foot center of mass (CM) to ball velocity. The pyramid-like model was developed to better illustrate the relation of each factor to the desired result (See Figure 1).

Resultant and component velocities were correlated to 3D resultant ball velocity. Factors found to be significantly related to ball velocity were examined until the end of the model was reached, or until no significant correlation was found. A factor was considered for further analysis if the magnitude or any component of velocity was significantly correlated with ball velocity.

RESULTS

The mean ball velocity for the group was 26.32 ± 2.47 m/s. The foot CM magnitude and downward velocity at impact and the coefficient of restitution (e) between the ball and the foot were found to be significantly correlated with ball velocity. Mechanical factors that were significantly correlated with ball velocity included:

- Impact (Imp) left hip vertical (V) velocity
- Decrease in the magnitude (mag) and lateral (L) velocity of the left hip from peak to Imp

- Mag and forward (F) right knee Imp velocity with respect to (wrt) the right hip
- Peak right knee mag and F velocity wrt the right hip
- Increase in right knee V velocity wrt the right hip from peak to Imp
- Peak thigh segmental angular velocity
- Mag, V, and L Imp velocity of the foot CM wrt the knee
- Mag, V and L peak velocity of the foot CM wrt the knee
- Peak lower leg segmental angular velocity

Figure 1: The deterministic model of a soccer kick. Bold lines indicate factors significantly correlated with ball velocity.

DISCUSSION

Velocity variables related to the entire body, the right knee and the right foot CM were significantly correlated with ball velocity, suggesting that approach velocity and torques created at the swing hip and swing knee are important when attempting to generate high foot velocity (and thus, high ball velocity). The significant relationship between ball velocity and e suggest that the quality of contact is important.

The lack of relationship between right hip variables and ball velocity suggests that the rotational velocity of the pelvis is not a contributor to ball velocity. It is possible that the role of the pelvis might be to allow the upper and lower leg musculature more time to produce forces that affect the velocity of the foot CM rather than to generate momentum itself.

The finding that greater downward velocities of the foot CM at impact were correlated with ball velocity indicates that athletes actually kick down onto the ball. This could occur to allow interception of the ball with the foot at the time that the foot CM is at its maximum velocity. The downward velocity of the foot CM at impact could trap the ball against the ground as the foot contacts the ball. This could increase the impulse applied to the ball, resulting in greater release velocities.

MUSCLE FATIGUE AND SPINAL INSTABILITY: AN ELECTROMYOGRAPHIC STUDY

Sheri P. Silfies and Andrew R. Karduna
Rehabilitation Sciences, MCP Hahnemann University, Philadelphia, PA, USA
email: silfies@drexel.edu

INTRODUCTION

The use of surface electromyographic (EMG) techniques has played a major role in our understanding of the functional activity of trunk muscles in both healthy and low back pain (LBP) subjects. Numerous studies have used EMG to identify the relationship between LBP and trunk muscle fatigue or altered motor control (Roy SH, et al., 1989; McGill SM, 1991). Specifically, shifts in EMG spectral parameters have been found to be associated with localized muscle fatigue and these parameters have been used to identify muscle impairments associated with LBP (Peach JP, McGill SM, 1998). The purpose of this study was to further investigate these effects in patients with clinical lumbar instability.

MATERIALS AND METHODS

Subjects-Thirty-six subjects were studied with IRB approval. Three groups of subjects were matched on the basis of age, gender and body mass index. Twelve LBP subjects were diagnosed with clinical lumbar instability (CLI) and twelve with mechanical LBP (MLBP) deemed unrelated to instability. An additional twelve healthy subjects had no history of low back pain that limited function or required medical intervention.

EMG-Pre-amplified surface electrodes were applied bilaterally over two extensor muscles: lumbar multifidus (LM) and the lumbar erector spinae group (LES). Data were collected at 1248 Hz, amplified and bandpass filtered (10-750 Hz).

Protocol-To assess extensor muscle fatigue, subjects performed a 30-second sustained isometric contraction in a standing neutral position. The target force was set at 80% of their maximum voluntary isometric (MVIC) extensor force production. Two fatigue trials were completed 5-minutes apart.

Data Analysis-A fast Fourier transformation (FFT) was used to perform a spectral analysis over each second of data. The median frequency (MF) was calculated for each interval. The initial median frequency (IMF) and MF slope over time were computed from linear regression analyses. Data were averaged over the two trials for analysis. Separate ANOVAs were completed for the IMF and MF slope for each muscle.

RESULTS

No significant differences were found for the IMF parameter. Results for the MF slope parameter are presented in Figure 1. Significant group differences in MF slope were found for the left LM ($p=0.011$) and the left LES ($p=0.007$). The right LM ($p=0.052$) and right LES ($p=0.092$) approached significance. *Post hoc* analysis revealed the differences existed between the CLI and control groups.

Figure 1. Mean (\pm SD) of MF slope values for groups clustered by muscle (i.e. RLM- right lumbar multifidus).

DISCUSSION

Based upon these data the CLI group demonstrated significantly less localized muscle fatigue than the control group. This may be secondary to alterations in neuromuscular control, muscular inhibition secondary to pain or altered muscle physiology in the CLI group. Results of this study are inconsistent with previous research indicating subjects with non-specific MLBP fatigue more than healthy controls (Roy SH, et al., 1989; Peach JP, McGill SM, 1998). Our LBP groups are characteristically different from those previously reported in the literature in that they were painful at the time of the study and had radiographic evidence of structural changes. However, it is unlikely that our results differ due to lower MVIC effort levels from subjects with current LBP, since there were no significant group differences in extensor force production. These results indicate that LBP patients with evidence of CLI may have impairments not in muscle fatigability, but in the neuromuscular control system. Identifying the appropriate impairments in this LBP subgroup has direct relevance to clinical evaluation, rehabilitation and injury prevention.

H-REFLEXES IN HUMAN FOREARM MUSCLES ARE ATTENUATED DURING RHYTHMIC ARM MOVEMENT

Alain Frigon, David F. Collins and E. Paul Zehr

Neurophysiology Laboratory, Faculty of Physical Education & Recreation and Centre for Neuroscience,
(afrigon@ualberta.ca), University of Alberta, Edmonton, Alberta, CANADA.

INTRODUCTION

Transmission along the group I afferent pathway to motoneurons of homonymous leg muscles in humans is extensively gated according to the task performed (for review see Brooke et al. 1997). This is demonstrated experimentally as an attenuation of the magnitude of electrically-evoked Hoffmann (H-) reflexes in the soleus muscle during tasks such as walking and cycling, compared to static control values. Soleus H-reflexes are also modulated according to the phase of such rhythmic tasks. Thus, the afferent pathway to leg motoneurons is gated both between and within tasks. Whether a similar control is exerted over group I pathways to upper limb motoneurons is unclear. There is evidence that the control of cutaneous reflex pathways is similar for the upper and lower limb (Zehr and Kido, 2001). The present experiments test the hypothesis that during rhythmic arm movements, transmission through group I reflex pathways to wrist flexor motoneurons is attenuated compared to stationary controls and is modulated according to the movement phase.

METHODS

Nine subjects participated with informed consent. Muscle activity (EMG) was recorded using surface electrodes placed bilaterally over flexor carpi radialis (FCR) and other muscles controlling the wrist, elbow, and shoulder. H-reflexes were evoked in the wrist flexors by electrical stimulation (1 ms pulse width) delivered through surface electrodes placed over the median nerve ~2 cm proximal to the elbow. Seated subjects performed rhythmic arm cycling movements on a custom-made hydraulic ergometer situated at shoulder height in front of them. The position of the stimulated (right) limb is described relative to the clock face with 12 o'clock at the top and the movement proceeding in a clockwise direction. Reflexes were sampled at 12, 3, 6 and 9 o'clock of the movement cycle. Static control reflexes were collected at each position while subjects were stationary and maintained a tonic contraction of the wrist flexors. For each condition, 75 reflexes were collected over a range of stimulation intensities from below motor threshold to that which evoked a maximal motor (M wave) response (M_{max}) and M/H recruitment curves were constructed. Mean values of ~10 reflexes were calculated at three places (ascending, descending limbs and H_{max}) on each recruitment curve. Repeated measures analysis of variance tests were used to identify significant differences between data taken from the selected regions of the M/H curves. The data presented in this abstract are taken from the ascending limb.

RESULTS AND DISCUSSION

Figure 1 shows attenuation of H-reflex amplitude across the range of stimulus intensities studied for stimulation at the 3 o'clock position. For the group, there was a 39% decrease ($p=0.007$) in mean reflex amplitude during cycling compared to control. The attenuation was significant at each of the four phases of the movement studied, but the amount of attenuation did not depend on the phase of the movement cycle ($p=0.18$). For all comparisons there were no significant differences in M wave amplitude. These results demonstrate a task-dependent gating of the pathway from group I afferents to alpha motoneurons of the upper limb similar to that shown for the

lower limb. However, unlike in the lower limb, reflex amplitudes were not modulated according to movement phase.

Figure 1: M/H recruitment curve for data recorded at the 3 o'clock position. The inset shows averaged data taken from single sweeps on the ascending limb of the curve.

SUMMARY

Rhythmic arm movement suppresses forearm H-reflexes therefore a similar task-dependent control strategy exists for regulating transmission through group I pathways in the arms and legs. However, the lack of phase-dependent modulation implies subtle differences between the neural control of reflex pathways from muscle afferents in the arms and legs.

AN *IN VIVO* EXPERIMENT-BASED GROWTH MODEL FOR INTIMAL HYPERPLASIA IN RAT VEIN GRAFT

Dalin Tang¹, Chun Yang² and Shu Q. Liu³

¹Mathematical Sciences Department, Worcester Polytechnic Institute, Worcester MA USA 01609, dtang@wpi.edu

²Mathematics Department, Beijing Normal University, Beijing, China

³Biomedical Engineering Dept., Northwestern University, Evanston, IL USA 60208

INTRODUCTION. Vein grafts are commonly used to replace malfunctioned arteries. However, vein graft failure often occurs due to intimal hyperplasia. Blood flow and fluid shear stress have been shown to affect the formation and growth of vein graft neointima. While extensive studies have been carried out, the mechanisms of intimal hyperplasia remain un-resolved. Recent studies have shown that vortex blood flow and reduced shear stress are associated with neointima formation and an elimination of vortex flow by using an engineering approach prevents these pathological changes (Liu, 1998). In this paper, a computational growth model based on Liu's experimental data is introduced and solved to simulate the formation and growth of vein graft stenosis and to better understand the factors involved in the process.

METHOD. The geometry, blood flow rate, and mechanical parameters of vein grafts and host arteries, presented in previous reports, are used here (Tang et al, 2001; Liu, 1998). A nonlinear axisymmetric thick-wall model with fluid-wall interactions is introduced to simulate wall deformation, wall stress/strain distributions, and viscous flow in a vein graft to quantify wall tensile stress and flow conditions which may affect the restenosis process. The flow is assumed to be laminar, Newtonian, viscous and incompressible. The Navier-Stokes equations are used as the governing equations. Both host artery and vein graft are assumed to be elastic, homogeneous, isotropic and nearly incompressible. An incremental linear elasticity approach is used to implement the nonlinear elastic properties of the materials. A numerical method using generalized finite differences with staggered grids and upwind techniques for the fluid model, a finite element method for the wall model, and an incremental boundary iteration method for the fluid-wall interaction is introduced to solve the full FSI model. A growth function which related the growth rate of intimal hyperplasia to fluid shear stress is introduced to adjust the inner wall thickness. The wall and fluid models are solved iteratively, with wall thickness adjusted periodically according to shear stress distributions. Numerical results are compared with experiments and the growth function is adjusted so that numerical results become consistent with experimental measurements.

RESULTS AND DISCUSSION. The geometry of the vein graft and the mesh used in our computations are given in Fig. 1. The growth function is chosen so that no growth would take place if shear stress is greater than 10 dyn/cm², and would increase linearly as shear stress decreases from 10 dyn/cm² to 0 (direction ignored). Fig. 2 shows the circumferential stress distribution in the artery and the graft. Fig. 3 gives the vector

plot of flow velocity in the graft region, showing the presence of eddy flow, in conjunction with reduced fluid shear stress, and focal neointima. Fig. 4. plots shear stress along the inner artery wall, showing a nonengineered graft is associated with a near zero shear stress, which creates favorable conditions for hyperplasia. Fig. 5 gives the tube shape with neointima growth at days 0, 6, 12, 30 which are consistent with experimental observations (Liu, 1998).

CONCLUSION. Shear stress plays an important role in neointima formation in experimental in vein graft. Engineering techniques can be used to modulate the distribution of fluid shear stress, prevent focal neointima formation and reduce the risk of graft failure.

CAN INVERSE DYNAMICS BE COMPUTED WITH A RIGID BODY MODEL

H. Böhm, H. Ruder

Institute of Astronomy and Astrophysics,
Department of Theoretical Astrophysics & Computational Physics,
Eberhard Karls University, Tübingen, Germany

INTRODUCTION

Inverse dynamics computation of resultant muscle torques in dynamical movements often lead to improper peaks in the joint torques which can not be generated from the human body in short times (van den Bogert 1996). One reason for these peaks can be found in deficiencies during the measurements. The more important problem is that the inverse computation is done with input data measured on complex real biosystems. These biosystems are incompatible with the rigid body model used for computation. For example the markers fixed on one segment of the human body do not fulfill the rigid body assumptions, because the distances between the markers are not constant during the movement. One solution to obtain a better result in the resultant joint torques can be found in (Chao et al. 1973). The authors forward simulated the movement and optimized the resultant joint torques till the marker movement was reproduced. The disadvantage of this method by Chao et al. is the high computationally cost.

The aim of this study is to demonstrate an effective method to generate joint coordinates compatible with the rigid body model used for inverse computation.

METHODS

The rigid body model in three dimensions used in this study consists of 14 segments connected by revolute joints. Segment mass, inertia and joint positions are taken from regression formulas (NASA 1978). In a standing trial the marker positions on the human body are recorded and the marker positions are assigned to the local coordinate system of the respective segment of the rigid body model. Spring damper elements are attached between the marker points defined in the local body coordinate system and the global marker positions. During the movement the spring damper elements are pulling the model through space along the unfiltered marker trajectories. This requires a forward dynamical computation of the movement for which the equations of motion are formulated with a recursive Newton Euler method (Shabana 2001). With this procedure the rigid body constraints are maintained throughout the movement. The changes due to wobbling of the markers do not directly result in changes in the joint angles, they are compensated by the spring damper elements. The joint angles of the rigid body generated during the movement are therefore in agreement with the mass and inertia properties of the model. To compare this method with those commonly used in inverse dynamics (van den Bogert 1996) the joint angles are calculated from the 15 Hz low pass filtered marker coordinates (Spoor 1980). The joint angles obtained from

the two methods and the unfiltered ground reaction force data are taken to inverse dynamically calculating the resultant joint torques. Calculated is a running trial with a running speed of three m/s. To test whether the obtained resultant joint torques from the two methods are in agreement with the model, the running movement is forward dynamically simulated using the calculated joint torques.

RESULTS AND DISCUSSION

Compared to the common method, the resultant joint torques calculated using the spring damper elements show smooth joint torque curves at touch down. Due to the smoothness of the data the resultant joint torques can be successfully used for the forward simulation of the movement. It was not able to simulate the movement with the joint torques obtained with the common method.

The joint torques calculated with the spring damper method are similar to those described by (Chao et al. 1973), but the spring damper method is computationally more efficient because the movement is only simulated once. Whether this approach leads to realistic joint torques of the real biosystem could not be answered and is a question of the model used to describe the human body. For a rigid body model it is a very efficient and robust method to compute inverse dynamics in highly dynamic movements.

ASSESSMENT OF SINCERITY OF EFFORT DURING ISOMETRIC STRENGTH TESTING

John H. Challis¹ and H.J. Sommer III²

¹Biomechanics Laboratory, Department of Kinesiology, The Pennsylvania State University, University Park, Pennsylvania, USA
Email: jhc10@psu.edu

²Department of Mechanical and Nuclear Engineering, The Pennsylvania State University, University Park, Pennsylvania, USA

INTRODUCTION

Assessment of muscle strength is often an important part of clinical assessment, for example post anterior cruciate reconstruction surgery. The assessment of muscle weakness, by comparing one limbs strength with the other, or with a norm is used in legal cases concerned with personal injury. Isometric strength curves are estimated by having subjects perform exertions at a range of joint angles. Irrespective of the use made of muscle strength tests it would be useful to be able to assess the sincerity of effort of the participant.

Previous attempts to assess sincerity of effort under isometric conditions have focussed on factors such as the gradient of the rise of the time-moment curve, and the variability of the plateau (e.g. Gilbert and Knowlton, 1983; Saunders and Bohannon, 1991). These approaches have not been able to reliably distinguish between maximum and sub-maximal efforts. The purpose of this study was to examine two new methods for assessing the sincerity of effort during isometric strength testing.

METHODS

Sixteen subjects (eight female) gave informed consent to participate in this study (age - 24.4 years \pm 5.3, mass - 74.9 kg \pm 12.3, height - 1.711 m \pm 0.110). After appropriate warm-up the subjects performed a series of static knee extensions using a Biodex dynamometer (model III), with the knee at 90 and the hip at 105 degrees of flexion. The subjects were secured to the dynamometer to eliminate any effects of extraneous movements on the results. The dynamometer position was manipulated so the axis of rotation of the knee joint was aligned with the axis of rotation of the dynamometer. Each subject was asked to perform three maximum isometric knee extensions, and three faked maximum efforts. Each trial lasted five seconds with two minutes rest between all trials.

The output from the tests were time-moment curves, these were assessed using two procedures,

Procedure A - the plateaus of the curves were identified and analyzed using a random walk analysis (Peng et al., 1994).

Procedure B - the time-moment curves were assessed using the approximate entropy (*ApEn*) algorithm described by Pincus (1991). *ApEn* is a measure of the regularity of a data set. It takes sequences of *m* data points and determines the logarithmic likelihood that this sequence is similar to other sequences of data points. If the data set is regular then *ApEn* has a small value; conversely *ApEn* increases in value with increasing irregularity of the data set. A parameter *r* is used to determine the closeness of data sequences, which effectively

filters out sequences which are not close. For the comparisons made in this study *m* was set to 2, and *r* was set at the measurement precision of the Biodex dynamometer.

Each sampled data set was normalized with respect to its peak moment. The reason for this normalization was to remove any bias, due to the signals absolute magnitude, in identifying the maximum from the faked maximum trials.

RESULTS

Peak moments recorded for the faked maximums had a mean value of 59% of the maximum efforts peak moments. The scaling exponent from the random walk analysis was higher in the maximum condition than in the faked maximum for 69% of trials. This analysis indicated the data sets were representative of brown noise. The *ApEn* in 88% of trials indicated the maximum trials were more irregular than the faked maximum trials. If both criteria are used then 94% of the maximum trials could be identified.

DISCUSSION

Assessing the time-moment curves using both a random walk analysis and computation of the signals approximate entropy was successful in identifying maximum from sub-maximum isometric strength test efforts. It was possible that the subjects did not all produce maximum efforts during the testing. In this case these results indicate the analysis can distinguish efforts of different intensities, not just between sub-maximum and maximum efforts. This approach warrants further examination for other joints, an older populations, and subjects recovering from surgery.

EFFECT OF POLYETHYLENE THICKNESS ON STRESSES OF AN ANKLE JOINT IMPLANT

Karol Galik¹, Mark C Miller^{1,2} and Patrick J Smolinski¹

¹Mechanical Department, University of Pittsburgh, PA, karolgalik@yahoo.com; ²Duquesne University, Pittsburgh, PA

INTRODUCTION

Wear of the polyethylene components in total joint replacements can lead to osteolysis and aseptic loosening of the implants. The amount of wear is associated with the magnitude of contact stresses at the articulating surfaces. Previous studies showed a significant decrease of contact pressure for polyethylene thicknesses greater than 4 mm for nearly conformal surfaces (Bartel, 1985) and for thicknesses greater than 8 mm for non-conforming surfaces (Bartel, 1986). However, these studies were based on calculations of contact pressure for which no upper limit was defined by the yield strength of the material. The present study analyzed stresses in polyethylene based on the von Mises failure criteria with specific application to ankle arthroplasty with nearly conformal cylindrical articulating surfaces.

METHODS

Three models were used in the study. First, an analytical solution assuming plain strain conditions was derived for a rigid cylinder contacting compliant polyethylene of finite thickness. Secondly, a full 3-D FEM model of the ankle implant including the tibia and fibula was created and the mesh in the contacting areas was refined using submodeling techniques (Fig. 1). Finally, because a 2-D analysis may approximate the geometry of conformal concentric cylinders, a 2-D FEM model was created. In all models, a load of five times body weight (3,337 N) was applied. The polyethylene was modeled as elastic, with $\nu=0.46$ and $E=567$ Mpa, for the analytical solution and as elasto-plastic (DeHeer, 1992) for the other two models. All materials were isotropic. The talar component was modeled as rigid.

RESULTS AND DISCUSSION

No significant contact pressure decrease was found with thickness greater than 5 mm for the 3-D FEM analysis. The analytical solution showed the same trend with smaller magnitudes. However, the von Mises stress (Fig 2b) showed the opposite trend, in that these stresses increased with increasing thickness. Investigation of all components of stresses revealed that the difference between the components increased even though all three components decreased in value. The equation for von Mises stress (see below) is a function of these differences rather than of the absolute values.

$$\sigma_m = \{0.5[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2]\}^{0.5}$$

From Figure 2 it is also evident that contact pressure could be estimated using simple analytical solutions. The 2-D model predicted the same contact pressure as the 3-D model.

However, von Mises stress strongly depended on the overall shape of the model. There was also a difference in the von Mises stress between the 3-D and 2-D model, which can be attributed to the fact that the plain strain conditions were violated as the polyethylene thickness increased.

SUMMARY

Results showed that with increased thickness, under plain strain conditions, the contact pressure decreased while von Mises stress increased. Contact pressure was less sensitive to the changes in the shape outside of the sagittal plane than was the von Mises stress. The 2-D FEM model was a good approximation of a full 3-D model if plain strain conditions were satisfied.

DYNAMIC GEARING AT THE LIMB JOINTS OF JUMPING DOGS

Colin Gregersen and David Carrier¹

Department of Biology, University of Utah, Salt Lake City, Utah, U.S.A.

¹carrier@biology.utah.edu

INTRODUCTION

If an animal were to rely on actively shortening muscles, jumping performance could be enhanced if the gear ratios of the muscles increased throughout the jump (Carrier *et al.*, 1994; Carrier *et al.*, 1998). Because the force produced by muscle fibers declines in a hyperbolic fashion as shortening velocity increases, there exists an optimal shortening velocity at which power production is maximized. However, the gear ratio of a muscle that shortens at a constant rate must change if the muscle is to contribute to acceleration of the animal. Specifically, the ratio of the ground force to muscle moment arms of an extensor muscle would have to increase as the joint extends.

To determine if this type of gearing occurs in jumping dogs we 1) calculated the gear ratios of the extensor muscles at the limb joints, 2) measured the changes in length of an extensor muscle of a joint that exhibited an increasing gear ratio pattern, and 3) calculated the relative contribution of the joints with an increasing gear ratio to the total external work produced during jumping.

METHODS

The ground reaction force moment arm was computed during jumping in three dogs utilizing a sagittal plane analytic model. The model assumed that the limbs remained in the sagittal plane during jumping and that the mass and inertia contributions of the limb segments were zero. By convention, a positive joint moment indicated that the ground reaction force acted to flex the joint. The gear ratio calculations utilized the same convention. Sonomicrometry was used to measure length changes in the vastus lateralis muscle.

RESULTS

Four of the six joints examined (wrist, elbow, ankle and hip) exhibited a decrease in extensor gear ratio during jumping. In contrast, the gear ratios at the shoulder and knee joints started out negative and increased linearly throughout the jump (Fig. 1). The gear ratio became positive midway through support at both joints.

During jumping, the average shortening of the vastus lateralis muscle ranged from 17 to 29.5% of standing length (Fig. 1). The shortening velocity for the muscle was generally constant throughout the jump as illustrated in Figure 1, and ranged from 2.7 to 3.9 muscle lengths per second.

The knee extensors produced very little negative work, but produced a significant amount of positive work. The knee extensors produced 34% of the positive external work of the hind limb, and 26.6% of the total positive external work.

Figure 1. Sample recording of the length changes and electromyography from the vastus lateralis muscle plotted relative to recordings of knee angle, gear ratio, and ground forces.

SUMMARY

The shoulder and knee joints exhibit a pattern of increasing gear ratio that could facilitate maximum power production of their extensor muscles. Consistent with the dynamic gearing hypothesis, the pattern of shortening of the vastus lateralis muscle indicates that the knee extensor muscles shorten at a velocity near that which produces peak muscle power. Additionally, the extensor muscles of the knee produce 26.6% of the total positive work of a jump. These results suggest that dynamic gearing at the knee joint is an important factor in the mechanics of jumping dogs.

THE DEVELOPMENT OF A KEYBOARD FORCE PLATFORM

Theodore Becker¹ Peter Johnson² and Jack Tigh Dennerlein¹

¹Harvard Occupational Biomechanics, Harvard School of Public Health, Boston, MA, USA

²Department of Environmental Health, University of Washington, Seattle, WA, USA

INTRODUCTION

As a person uses a computer there are many forces that act on their body. Many factors, such as the types of keyboard, mouse, computer workplace design being used, and the anthropometrics of the person will contribute to the type and magnitudes of the forces acting on the fingertips. Understanding the relationships between these factors and the applied forces can guide manufacturers and researchers to design more ergonomically friendly computer keyboards, as well as the associations between computer keyboard use and musculoskeletal disorders. In order to better understand the forces experienced during typing we developed a force sensing system that allows us to test the magnitude and location of force on a keyboard, during use without significantly altering the height or position of the keyboard. The design will be used at people's own workstations and therefore must be minimally invasive. We are using this system as part of a larger study to determine the musculoskeletal exposure a person encounters during typical computer use activities.

MATERIALS & METHODS

The keyboard force sensing system (Figure 1) is comprised of a rectangular aluminum plate 3.18 mm thick and accepts most commercially available standard and alternative keyboards. Four, 5 lb. Entran load cells, model ELFS-B3-5L, are mounted to the underside of the aluminum plate in a trapezoidal arrangement to decrease the level of vibration. The load cells are mounted in shallow cuts into the surface of the plate. The wires from the load cells are mounted in grooves and lead to the rear of the plate and then to the keyboard amplifier and then onto the data collection computer through a National Instruments A/D board at 200 Hz. The force data was digitally low pass filtered with a cut-off frequency of 20 Hz.

Figure: The keyboard force platform design.

The keyboard platform was tested for load and position accuracy, both statically and dynamically. For the static tests three weights (1.0N, 3.0N and 6.0N) were placed on the platform in a grid with 41 points located 6 cm apart. For the

dynamic tests five points on the platform were tapped five times each with a 0.25N weight dropped from a height of 3cm. This was done with no weight on the platform and then with a 1.0N weight over each load cell to mimic the weight of a keyboard resting on the platform. The centroid for the tapping experiments was calculated using the mean force during the tap.

RESULTS AND SUMMARY

As the weight on the point being tested is increased the platform becomes more accurate for both the static and dynamic experiments (Tables 1 and 2). The location algorithm contains the total force in the denominator. As a result, a small signal to noise ratio will increase the noise in the location prediction. For the dynamic tapping, the noise may be due the platform not resting on the table evenly and a rocking between supports may occur. With the weight of standard keyboard spread over the entire platform the platform becomes more stable. The precision of the key was increased with the 1.0N weight over each load cell. The area of a single keyswitch is approximately 2.25 cm². The standard deviations of the forces are more than acceptable for measuring forces on the keyboard. One limitation to this force platform is that it is only able to measure single keystrokes. For example if a person were to hold down two keys at the same time the resultant force would be measured somewhere between the two keys.

Table 1 Static Force

Wt.	Distance Err (cm)	
	Mean	Stdev.
1.0N	0.445	0.278
3.0N	0.178	0.112
6.0N	0.148	0.074

Table 2 Dynamic Tapping

Wt.	Distance Err (cm)	
	Mean	Stdev.
0.0N	3.936	0.703
4.0N*	0.651	0.376

*1N over each sensor.

In summary, the keyboard force platform is a useful tool for measuring the dynamic forces on a keyboard during typing. A single key strike on a keyboard requires approximately 1.5 N of force (Rempel, 1994), combined with the weight of the keyboard creates enough stabilizing force to make the force platform's accuracy and precision errors acceptable for use in research.

DEPENDENCE OF VISCOELASTIC PROPERTIES ON COLLAGEN ECM MICROSTRUCTURE

INTRODUCTION

One of the most critical aspects of functional tissue engineering is the ability to mimic the structural-mechanical properties of extracellular matrix (ECM) scaffolds that naturally serve to organize cells and regulate their behavior. Unfortunately, the tremendous diversity of ECM components and their complex organization *in vivo* make it difficult to decipher the contribution of individual molecules to its structural-mechanical behavior. Numerous mechanical studies have established that tissue explants and collagen-based scaffolds are viscoelastic and exhibit time-dependent mechanical properties. For example, model tissue, consisting of type I collagen and fibroblasts, exhibited nonlinear stress-strain responses after strain cycling (Wagenseil et al., 2001). However, the relationship between viscoelastic properties and 3D microstructure has not been defined. Previously we have shown that adjustment of collagen polymerization conditions, including collagen concentration and pH, provides a convenient means of producing collagen ECMs with distinct 3D micro-structures (Roeder et al., 2002). Using this model system, the dependence of viscoelastic properties on the 3D microstructure of collagen fibrils was determined.

METHODS

Native type I collagen prepared from calf skin (Sigma Chemical Co., St. Louis, MO) was dissolved in 0.01 M hydrochloric acid to achieve desired concentrations. To prepare 3D collagen ECMs that varied in fibril density, solutions of collagen were neutralized to achieve final collagen concentrations of 0.5 to 3 mg/ml while maintaining the same total phosphate content, ionic strength (0.14 M), and pH (7.4). To produce collagen ECMs that varied in fibril diameter and length, collagen solutions were neutralized with 10X PBS buffers with altered ratios of Na_2HPO_4 and KH_2PO_4 to produce pH conditions ranging from 6 to 9. Neutralized collagen solutions were then polymerized in "dog-bone" shaped molds in a humidified environment at 37°C. Viscoelastic properties of the 3D collagen matrices were measured using a modified Minimat 2000 miniature materials tester (Rheometric Scientific, Inc., Piscataway, NJ). Specimens were maintained in an aqueous environment representing physiological temperature, composition, and pH during mechanical testing. The viscoelastic behavior of the 3D collagen ECMs was characterized by determining (1) the time dependent decrease in stress upon application of fixed strain (stress relaxation), (2) the effect of cyclic loading and unloading (preconditioning), and (3) the time dependent decrease in strain with a fixed stress (creep).

RESULTS AND DISCUSSION

Previously, we have demonstrated that the 3D microstructure of a collagen matrix is an important determinant of its quasistatic mechanical behavior, including linear modulus and failure stress (Roeder et al., 2002). Results of this study establish the relationship between the viscoelastic properties of a 3D collagen ECM and its microstructure. For example, Figure 1 shows the effect of preconditioning (cyclic loading and unloading) on 3D collagen matrices polymerized at pH 7.4 and pH 6.0. Collagen fibrils formed under acidic conditions were shorter and thicker while those formed under basic conditions were longer and thinner (Roeder et al., 2002). In both cases, the first cycle had the greatest hysteresis loop with less hysteresis at successive cycles. The maximum stress decreased between successive cycles, and was an order of magnitude lower at the first cycle for pH 6.0 (0.6 kPa) versus pH 7.4 (4 kPa). Between the first and fifth cycles, the maximum stress was reduced by 47% and 35% for the pH 7.4 and pH 6.0 collagen matrices, respectively. In summary, the results of this study provide fundamental information that will ultimately contribute to the establishment and prioritization of design criteria for engineering ECM-like scaffolds to be used clinically to guide tissue repair and replacement.

THE BIOMECHANICS OF DART THROWING: CHANGES DURING PRACTICE.

Jennifer J. Jeansonne, Li Li and Richard A. Magill

Department of Kinesiology, Louisiana State University, Baton Rouge, Louisiana USA. jjeans@lsu.edu

INTRODUCTION

Coordination changes can best be evaluated in the manner described by Bernstein (1967). As the learner determines the most efficient or effective way to perform a skill, changes in the person's movement coordination pattern occur. How this coordination changes from one point in time to the next provides critical information about how the learner adapts a movement to produce skilled activity. More specifically, coordination describes how the joints are positioned at a specific moment of time, and how those positions change across several moments of time. This adaptation of specific components of the limbs throughout the learning of a complex motor skill is referred to as coordination changes. As the beginner performs a new task, he/she typically tries to reduce the number of degrees of freedom that must be controlled by constraining the body or multiple body segments. This "freezing" of degrees of freedom at the initial stages of learning is eventually followed by an "unfreezing" of degrees of freedom toward the later stages of learning. During the progression of skill learning, the degrees of freedom are released gradually, allowing the learner to use more degrees of freedom in adaptable ways as the skill level increases. Unfortunately, the research literature contains limited biomechanical information describing the coordination changes that occur when people learn a new motor skill. This study provides a description of those changes throughout the course of learning to throw a dart to a stationary target.

METHODS

Novice dart throwers were instructed to stand in a comfortable position at a specified location and told to throw the dart to a circular target that would appear on a cardboard screen in front of them at approximately eye level. The dart was removed after each throw so that subjects would start each practice trial with an uncluttered target. Each subject

performed 150 throws per day for four days. Subjects were told only the goal of the task; no instructions were given about how to throw the dart. At the beginning of each trial the target circle would appear on the screen. After each throw of the dart, the X, Y coordinates of its location on the target were recorded. Kinematics was recorded on every 15 throws. Reflective markers were placed on the hand (FIN), wrist (MED, LAT), elbow (LAT), shoulders, head, chest (STERN, CLAV), back (C7, T10), waist (LASI, RASI, LPSI, RPSI) and dart. Kinematic data were collected using the VICON eight-camera motion system.

RESULTS AND DISCUSSION

Analysis of the position, velocity and acceleration of the wrist, elbow, shoulder and thorax provided evidence of the changes in coordination that occurred as novices learned this task. Early in practice the observed pattern was to increase the angles at the shoulder and elbow, followed by a large change in the chest angle (figure 1). This residual movement by the chest, which occurred after release, indicated that the subject was using the upper body to move the arm to throw the dart. This indicates a freezing of degrees of freedom at the chest, shoulder, and elbow early in practice. The pattern later in practice was to stabilize the elbow at $\sim 120^\circ$ prior to release and follow through with the forearm to an elbow angle of $\sim 30^\circ$. The magnitude of change in elbow angle was much smaller later in practice compared to day 1. This observation suggests that the subject released the degrees of freedom at the shoulder and chest throughout practice. Additional support for the freeing of degrees of freedom was observed in the changes in velocity of the elbow and wrist. Early in practice there was an increase in elbow velocity and a decrease in wrist velocity, while later in practice there was a decrease in elbow velocity and an increase in wrist velocity. These changes suggest that with practice, the subjects began to use their wrist and elbow independently from their shoulder and upper body.

SUMMARY

Novice dart throwers practiced throwing a dart at a stationary target for 600 trials. Kinematic analysis showed that early in practice, subjects constrained their chest, shoulder, and elbow to act as a single unit throughout the throw. But, with increasing amounts of practice they began to use the wrist more and decrease the movements at the chest and shoulder. The results of this experiment provide evidence that to control multiple degrees of freedom when performing a complex skill, novices will "freeze" certain degrees of freedom to enable them to achieve the goal of the skill. As novices acquire more experience, they begin to release these degrees of freedom to increase their skill performance capabilities.

THE EFFECT OF BONE QUALITY ON INTRA-MEDULLARY FIXATION OF THE PROXIMAL HUMERUS USING A RETRO-GRADE NAIL

P Manning , M B Rajesh, L Neumann, M Parry , W A Wallace.
The Institute of Biomechanics, The University of Nottingham, UK
Angus.Wallace@rcsed.ac.uk

INTRODUCTION

The integrity of the rotator cuff is maintained in retrograde nailing of the humerus offering a potential benefit over conventional ante-grade nailing, where there is a significant incidence of post-op poor shoulder function. The proximal locking of retrograde nails has proved troublesome. The new Halder humeral nail allows cancellous bone fixation using a trio wire. It is not known whether bone quality affects the function of this trio wire.

METHODS

Ten fresh frozen adult humeri were obtained at post-mortem and stored according to the "SAE" protocol for the preservation of human surrogates for biomechanical testing. All specimens underwent standard morphometrical measurements. Each specimen was assessed for bone quality using a Lunar- Expert DXA scanner. Each specimen was instrumented with the correct size retrograde nail under image intensifier control by the same specialist shoulder surgeon. A standardised osteotomy recreated a proximal humeral fracture.

Each specimen was tested for failure of the trio wire in rotation using a certified universal-testing applying pure torque, through the axis of the nail, within the bone. The testing protocol allowed for assessments of torque hold at 10, 20 and 30° rotation. In the event of torque maintenance at 30°, the specimen was rotated further to failure. Failure of torque hold was defined as a 10% drop in measured pure torque.

**Proximal
humeral
fracture**

RESULTS AND DISCUSSION

For two specimens technical problems resulted in them being unsuitable for testing. Eight were tested to full failure at the proximal end. The mean failure of torque hold for the nail was $1.25\text{Nm} \pm 0.14$, median 1.2Nm. The mean rotation observed at failure was $29.2^\circ \pm 17.43$, median 34.3° . In sub-failure testing to 10° rotation a mean recoil of only 54% was observed, with significant deformation of the trio wire, similarly at 20°, 50.5% and at 30°, 38%.

There was no significant correlation at the 5% ($p < 0.05$) level between the observed bone mineral density of either the humeral head, neck, tuberosity or total proximal bone mineral density and the observed torque hold at failure.

Distally, no failures of the fixation were observed. Reproducibility of the tests was proven with strong correlation observed between failure torque at 10, 20 and 30°s.

SUMMARY

It would appear that proximal humeral bone quality is not important in determining the suitability for a retrograde nail with a trio wire. The nail would appear to function equally well in poor quality bone or good bone, possibly due to the radial force imparted by the trio wire to the cortex. This implies that the nail can be used in patients with marked osteoporosis.

The mean failure of torque hold is low when the nail is compared to other fixation devices. There is significant deformation of the trio wire on rotation even when there is no failure of torque hold. However the nail does offer significant advantages over ante-grade nails in preserving the rotator cuff. It would seem important that if the nail is used, patients should have their arm immobilised for rotation until bony union is underway.

Nail in Situ**

A BIOMECHANICAL ANALYSIS OF INTERNAL FIXATION OF TRANSVERSE ACETABULAR FRACTURES

Alyssa L. DeMarco¹, Kent N. Bachus², Daniel S. Horwitz³

¹MacInnis Engineering Associates, Richmond, British Columbia, Canada

²Orthopaedic Bioengineering Research Laboratory, University of Utah, Salt Lake City, Utah, USA

³Department of Orthopedics, University of Utah School of Medicine, Salt Lake City, Utah, USA

INTRODUCTION

The surgical stabilization of transverse acetabular fractures remains controversial in terms of approach and method of fixation. The three most frequently used methods of internal fixation are i) dual posterior column plating (2PP), ii) single posterior column plating with placement of a posterior to anterior “homerun screw” down the anterior column (PP&HS), and iii) single posterior column plating with single anterior column plating (PP&AP). Plating of both columns (PP&AP) is generally reserved for widely displaced, unstable fractures, while the other two techniques are more often used when the anterior column is minimally displaced. The purpose of this study was to evaluate the biomechanical stability of these three fixation modalities when applied to a reproducible transverse acetabular fracture model in human cadaveric pelvis. The hypothesis tested was that the PP&AP and the PP&HS methods of fixation would be similar in stability and significantly more stable than the 2PP method.

METHODS

Transverse acetabular fractures were simulated by a single orthopedic surgeon (DSH) with the use of a hand held thin blade oscillating saw (System II Sag Saw, Stryker, Kalamazoo, MI, USA) and a custom cutting jig which allowed the simulated fracture to consistently be made 2 cm below the superior lateral rim of the acetabulum at a 45° angle superior to the horizontal position. Seven joints from nine pelvis were tested. The fractures were reduced and instrumented three times (in random order), each time with a different construct. All screw plate constructs utilized 3.5mm pelvic reconstruction plates and the homerun screw was a fully threaded 4.5mm cortical screw. Each joint was loaded through simulated abductor muscle contraction (Bay et al, 1997) to a joint reaction force of approximately body weight. During loading, motion was measured along the plane of the osteotomy using a high-resolution differential variable reluctance transducer (DVRT, Microstrain, Burlington, VT, USA). Motion was compared between methods using an ANOVA with a Fisher's PLSD post hoc test ($\alpha < 0.05$). The variance of each method was compared using an F-ratio test.

RESULTS AND DISCUSSION

Means and standard deviations of the measured displacements during simulated partial weight bearing for the 2PP, the PP&HS, and the PP&AP were 0.641 ± 0.656 mm, 0.452 ± 0.445 mm, and 0.145 ± 0.089 mm, respectively (Figure 1) and were not significantly different. From the Fisher's PLSD test, the displacements measured for the three fixation methods

were not found to be statistically different: 2PP versus PP&HS ($p = 0.454$), 2PP versus PP&AP ($p = 0.06$), PP&AP versus PP&HS ($p = 0.229$). The variances between 2PP versus PP&AP ($p = 0.001$) and PP&AP versus PP&HS ($p = 0.001$) were found to be significantly different. The variances between the 2PP and the PP&HS ($p = 0.368$) were not found to be significantly different.

Figure 1: Means and standard deviations of the displacement during loading of the hip joint for each fixation modality.

SUMMARY

When treating transverse acetabular fractures there are three methods commonly used 2PP, PP&HS, and PP&AP. The results from this study suggest that, under ideal surgical conditions, the degree of stabilization achieved using the PP&AP method is predictable and relatively unaffected by differences between specimens whereas the other two methods are not. The stability achieved through the 2PP and the PP&HS methods was found similar in its unpredictability.

THEORETICAL CONSIDERATIONS FOR THE INFLUENCE OF ARM SWING ON VERTICAL JUMP TAKE-OFF VELOCITY

Nebojsa Wraskic and James J. Dowling

Department of Kinesiology, McMaster University, Hamilton, Ontario, Canada

INTRODUCTION

There are many instances when body segments can be manipulated in order to make movements more efficient or to improve performance. One such situation involves the use of arms during vertical jumping. Hochmuth (1984) showed that when a vertical jump is performed with an arm swing, a greater take-off velocity is achieved by prolonging the time in which the legs can produce force. Furthermore, the deceleration of the arms prior to take-off causes a reaction force which further accelerates the rest of the body by adding to the force being produced by the muscular contractions of the leg muscles. For the sake of simplicity, Hochmuth's simulation assumed that the force curves for the legs and arms were constant. The purpose of this simulation was to introduce a more physiological based model to examine the role of arm swing during vertical jumping.

METHODS

The current simulation used the same assumptions as those of Hochmuth's and are as follows: 1) the acceleration path of the arms and hands = 0.785 m; 2) the acceleration path of the residual body = 0.5 m; 3) the velocities of the residual body and that of the arms and hands must be the same at the instant of take-off. The equations for the force-velocity curves that were used for the residual body or, in other words, for the legs were taken from Alexander (1995) and are as follows:

$F_m = F_{m,iso} [1.8 - 0.8(v_{max} - v)/(v_{max} + 23v)]$ for $v < 0$ and $F_m = F_{m,iso} (v_{max} + v)/(v_{max} - 3v)$ for $0 < v < v_{max}$, where F_m = muscular force; $F_{m,iso}$ = isometric muscular force; v = shortening velocity; v_{max} = max shortening velocity (10 m/s). The timing of the arm swing was manipulated by selecting a range of start times of the deceleration phase relative to the time of take-off (Δt) from 0 to -0.3 seconds. The vertical velocity at the instant of take-off was the dependent variable.

Figure 1: Schematic of model showing movement paths for the residual body (0.5 m) and arms and hands (0.785 m).

RESULTS AND DISCUSSION

The results indicated that there was an optimal time at which the arms should begin to decelerate in order for the body to achieve its maximum take-off velocity. Figure 2 shows that

the maximum take-off velocity occurs when the arms start to decelerate 0.084 seconds before take-off occurs.

Figure 2: Depicts range of take-off velocities after manipulating time of arm deceleration prior to take-off.

Figure 3: Depicts velocities of arms and hands and that of the residual body for the optimal take-off velocity.

SUMMARY

Compared to Hochmuth's simulation, the take-off velocities from this physiological model are much lower and the time the arms and hands should start to decelerate in order to achieve the maximum take-off velocity is of greater importance.

THE IMPACT OF ANTERIOR CERVICAL FUSION UPON CERVICAL SPINE RANGE OF MOTION AND OVERALL NECK FLEXIBILITY

John H. Thinnes¹, Sorin Sigler¹, Alan S. Hilibrand², Scott Daffner², Alexander R. Vaccaro², Todd J. Alberts²

¹Biomechanics Laboratory, Drexel University, Philadelphia, PA, USA jthinnes@drexel.edu

²Rothman Institute of Orthopedic Surgery, Philadelphia PA, USA

INTRODUCTION

Anterior decompression and stabilization (fusion) of the cervical spine is a common surgical treatment for spondylotic radiculopathy and myelopathy (Ref). This surgery involves fusion of two or more vertebrae. There is a clinical concern that this surgery compromises the functional ability of the patient by reducing his/her neck's range of motion (ROM) and flexibility. Therefore, this study was conducted to quantify, *in vivo*, the effects of Anterior Cervical Fusion (ACF) on the overall ROM and flexibility. It is our hypotheses that 1) following surgical stabilization involving two or three vertebrae a majority of the range of motion lost at the stabilized levels is accommodated in the upper cervical spine with little impact upon the overall ROM and flexibility. However, 2) surgical stabilization involving four or more vertebrae causes a significant reduction in overall ROM and flexibility, which may affect the functional ability of the patient.

METHODS

In order to accomplish the goals of this study and test the validity of its hypotheses, the ROM and flexibility of the cervical spine was measured, *in vivo*, in four groups of subjects. The first group consisted of ten healthy, asymptomatic adults. Data obtained from this group served as the reference to which the patient groups were compared. The second, third and fourth groups consisted of patients who underwent surgical stabilization of two, three or five vertebrae correspondingly. All patients were tested pre and post surgically.

The passive ROM and flexibility of the cervical spine was measured using a specially designed device – the Neck Flexibility Tester (NFT). This device, shown schematically in Figure 1, was developed and validated in the past (Ref). The device consists of a linkage attached across the subject's neck (between torso and head) which measures the motion of the head produced in response to moments applied manually by an operator. Both the motion and the applied loads are

recorded continuously on a computer. The testing procedure consists of a passive ROM measurement followed by flexibility

Figure 1: Neck Flexibility Tester

measurements in which the neck is loaded in various directions and the motion and applied load are recorded. A complete series of test consisted of ROM and flexibility measured in axial rotation, lateral bending and flexion.

RESULTS AND DISCUSSION

ROM values in degrees and flexibility values in degrees per Newton meter are summarized in table 1. The first number in any field is the average of the group and the second, in parenthesis, is the standard deviation. All three patient groups preoperatively and postoperatively exhibit less ROM than the asymptomatic controls. Also, all patients displayed less flexibility in lateral bending and flexion than the normal control. Surgery caused a decrease in ROM in axial rotation in all patients and an increase in ROM in lateral bending. In flexion, groups 2 and 3 showed an increase and group 4 displayed a decrease. Surgery had little effect on the neck in lateral bending and flexion. In axial rotation the largest effect of surgery was observed in patients in group 4.

SUMMARY

Fusing two or three vertebrae has little effect on the overall ROM and flexibility of the neck. Some limitation was observed in patients with five fused vertebrae.

THE GEOMETRY OF GALLOPING

Michael T. Butcher, John E. A. Bertram and James R. Usherwood

Department of Nutrition, Food and Exercise Science, Florida State University, Tallahassee, Florida USA

e-mail: jbertram@garnet.acns.fsu.edu

INTRODUCTION

Many quadrupeds use galloping gaits for high-speed locomotion. Galloping gaits have traditionally been described in terms of footfall timing patterns and limb phase relationships (Hildebrand, 1977). To date however, no compelling mechanistic explanation of galloping has been reported. Recently, it was suggested that galloping involves a combination of pendular and spring-based mechanisms akin to the bipedal skip (Minetti, 1998). Though interesting, this explanation fails to account for the observed pattern of limb phase relationships. An alternative mechanical strategy is described as the basis of the gallop, one that functions through minimizing collisional energy loss. We use this model to describe the basic mechanics behind galloping and compare it to horse locomotion.

METHODS

Under almost all circumstances, a limb coming in contact with a surface will involve a mechanical collision; that component of the animal's velocity aligned with the contact limb will be lost. Collisional energy losses can be reduced if a smaller proportion of the velocity vector is oriented parallel to the limb. The remaining velocity (perpendicular to the limb) will be redirected. It is possible to recover substantial velocity even when only inelastic collisions are considered.

The model (geometric deflection) describes the path of the CoM as it is cyclically redirected from the last flight phase to the following. Although the motion appears to involve bouncing, there need not be any springs involved (Ruina and Bertram, in prep.). This motion is much the same as a stone skipping on a pond, in this case there is an obvious bouncing motion but there is no storage and recovery of strain energy.

To test the validity of the model, experimental ground reaction force data of horses galloping at a canter (slow gallop) from Merkens et al. (1993) were compared to the footfall and limb collision orientation pattern predicted by a three-limbed geometric deflection model. A three-limbed model is appropriate for analysis here because the canter is considered a "three-beat gait" where the leading hind limb and the trailing forelimb contact the ground nearly simultaneously and thus apply force to the surface in unison.

RESULTS AND DISCUSSION

The simple geometric deflection model is in accord with experimentally determined ground reaction force orientation, and also footfall sequence of cantering horses. Neural-based

models can describe observed footfall patterns but they lack a mechanical justification. Spring-based models account for energy oscillations, but do not explain limb phase relationships. Both of these are explained by minimizing collisional losses. The model is simple, but differs substantially in its perspective. This approach may explain the limb coordination strategy in the gallop and how it provides for high-speed locomotion beyond the spring-based limitations of the bouncing trot gait.

Figure 1: The canter gait of a horse with orientation of mean ground reaction force vectors (above) compared to collision geometry predicted by the geometric deflection model (below). Mean orientation matches well with the collision geometry predicted from the model. Vectors are drawn to scale based on mean vertical and horizontal force magnitudes over the limb's stance duration.

SUMMARY

The mechanics behind galloping remain elusive. A model that focuses on collisional losses at foot contact suggests that the gallop may simply involve the 'geometric deflection' of available velocity. The model is shown to predict the footfall pattern and reaction force orientation of a canter.

TRAINING-INDUCED CHANGES IN KNEE STABILIZATION STRATEGIES AFTER ACL RUPTURE

Terese L. Chmielewski and Lynn Snyder-Mackler

Department of Physical Therapy, University of Delaware, Newark, Delaware, USA

<http://www.udel.edu/PT>

INTRODUCTION

Patients with anterior cruciate ligament (ACL) rupture selected by a screening mechanism (potential copers) use strategies to dynamically stabilize their injured knee that are superior to those used by patients who experience knee instability (non-copers) (Fitzgerald, 2000a; Chmielewski, 2001). Potential copers who receive training with perturbation of support surfaces are more likely to return to sports without knee instability, suggesting improved knee stabilization strategies post-training (Fitzgerald 2000b). Perturbations applied during gait provide a method to challenge the knee stability of patients with ACL rupture; therefore, the purpose of this study was to compare the knee kinematics of potential copers and uninjured subjects during unperturbed and perturbed gait, before and after a training program, to gain insight into training-induced changes in dynamic knee stabilization strategies after ACL rupture.

METHODS

Subjects with an ACL rupture, classified as potential copers by a screening examination, were enrolled in this study. Age- and sex-matched control subjects were also recruited. All subjects participated in a 10-session training program including perturbation of support surfaces (Fitzgerald, 2000b). Gait analysis was performed before and after the training program. Six trials of free-speed walking (unperturbed trials) were collected, followed by 6 trials each in which a custom-built platform translated horizontally in an anterior or lateral direction (5.8 cm at 40 cm/s) at heel contact (perturbed trials).

In each condition, the sagittal plane knee angle at initial contact (KAIC), peak knee flexion angle during weight acceptance (PKFA), peak knee extension angle at mid-stance (PKEA) and duration of weight acceptance (DWA; time from initial contact to peak knee flexion) were analyzed.

RESULTS AND DISCUSSION

Complete pre- and post-training data have been collected on 5 potential copers and 3 control subjects. A total of 10 subjects will be recruited in each group for this study.

Preliminary pre-training results show less knee flexion at initial contact, a reduced peak knee angle during weight acceptance, greater knee flexion at mid-stance and a longer duration of weight acceptance in potential copers compared to uninjured subjects across all conditions. After training, the knee angle at initial contact and the duration of weight acceptance were more similar between groups across all conditions. Potential copers' post-training peak knee angle was increased in the unperturbed condition and lateral perturbed condition (Table 1). Although the potential copers' post-training peak knee angle did not change in the anterior perturbed condition, uninjured subjects had less knee flexion, minimizing differences between groups. The post-training knee angle at mid-stance remained more flexed in potential copers compared to uninjured subjects in all conditions.

Comparing the different conditions, potential copers' peak knee angle was the lowest, and the duration of weight acceptance the longest, in the pre-training anterior perturbation condition. This may indicate a strategy to prolong hamstring activity to counter the effects of quadriceps activity, producing co-contraction to stabilize the knee.

SUMMARY

The preliminary results of this study show that: 1) Prior to perturbation training, potential copers have different knee kinematics compared to uninjured controls, 2) Training appears to allow potential copers to use knee kinematics similar to uninjured subjects during weight acceptance, but does not alter the knee angle at mid-stance, and 3) Anterior perturbations appear to be the most destabilizing to untrained potential copers.

WHOLE BODY BIOMECHANICS OF RESPONSES TO SLIPS

Rakié Cham¹ (chamr@msx.upmc.edu), Brian Moyer¹ and Mark S. Redfern^{1,2}

¹Department of Bioengineering and ²Department of Otolaryngology
University of Pittsburgh, Pittsburgh, PA, USA

INTRODUCTION

Accidental injuries and deaths are often the result of slips/falls. Previous slip/fall studies, critical to the understanding of the relationship between gait and falls, have focused on the dominant role of the leading (sliding) leg (Redfern et al., 2001). However, the trailing foot may be of importance as well. Thus, the goal of this paper is to describe whole body biomechanics following a slip, including bilateral postural adjustments of the upper/lower extremities, head and trunk, as well as corrective moments generated at the joints.

METHODS

Five healthy male subjects, aged 35 years or less, were screened for neurological, vestibular and orthopedic abnormalities prior to their recruitment in the study. Subjects were equipped with a safety harness and LEDs, and instructed to walk naturally across a vinyl tile walkway instrumented with two Bertec force plates (FP). Ground reaction forces and whole body motion (2 Optotrak-3020 motion measurement systems) were recorded bilaterally at 60 Hz. Subjects were informed that the first few trials would be dry to ensure natural gait. Then, a soap solution was applied to the left FP without the subject's knowledge. Data processing included the derivation of foot kinematics (linear/angular position, velocity and acceleration), whole body joint angles and joint moments. The foot and body kinematics are reported here.

RESULTS , DISCUSSION AND CONCLUSIONS

The flexion reactions at the leading leg previously reported by Cham & Redfern (2001) during a slip were confirmed here (Fig 1). Those responses are apparent approximately 200 ms after heel contact (HC) with the slippery surface (Fig 3). In addition, the swing phase of the trailing leg during a slip was interrupted (Fig 1). The subject rotated the swing foot down such that the toe contacted first while the leading foot was sliding (Figs 2 and 3). This interruption of the trailing leg's swing phase began at 300 to 400 ms after HC with the slippery surface. Thus, the results reported here suggest that the trailing leg indeed plays a role in the biomechanics of slips.

Other results showed evidence of neck flexion, shoulder/elbow flexion as well differences in the moments generated at the right/left leg joints during slips. In conclusion, this study is a step forward towards the goal of identifying the role of body segments during slip-initiated recovery reactions.

Figure 1: Posture on (a) dry, (b) slippery floors. $\Delta t \sim 67$ ms.

Figure 2: Foot-floor angle on dry/slippy floors. The trailing foot assists in recovery responses as it reversed its rotational motion to land toe first (arrow), attempting to stop slipping.

TRAP MAY CONTRIBUTE TO ALTERED MECHANICAL PROPERTIES IN LIGAMENT AFTER CHEMICAL SYMPATHECTOMY

Kelley W. Dwyer¹, Paolo P. Provenzano¹, Peter Muir², Ray Vanderby, Jr.¹.

¹Orthopedic Research Laboratories, Dept. of Biomedical Engineering and Orthopedic Surgery, and ²Comparative Orthopedic Laboratory, Dept. of Veterinary Medicine, University of Wisconsin, Madison, WI, USA (vanderby@surgery.wisc.edu)

INTRODUCTION

The extracellular matrix (ECM) of ligaments undergoes continual remodeling (ECM degradation, biosynthesis, and matrix assembly). The peripheral nervous system (PNS) plays an effector role in ligament homeostasis and healing (Schaffer, 1998; McDougall, 1997). Previously, we have shown that chemical sympathectomy (inhibition of the sympathetic nervous system) through treatment with guanethidine leads to a reduction in mechanical strength of the rat MCL (Provenzano, 2002). The purpose of this study was to 1. further quantify the mechanical changes caused by sympathectomy and 2. determine agents that are responsible for ligament degradation in guanethidine treated rats.

METHODS

Eight Wistar rats were infused with guanethidine (40mg/kg/day) via subcutaneously implanted osmotic pumps (Alza Corp.). Eight additional control rats were infused with 0.9% saline in a similar manner. Following 10 days of infusion, the rats were euthanized. For mechanical testing the femur-MCL-tibia complex was carefully harvested and cross-sectional area measured. Tissues were inserted into our custom testing system, preloaded to 0.1N, preconditioned (10 cycles at 1% strain), and pulled to failure in displacement control (10%/s). Strain was optically measured on the ligament and synchronized with force measurements. Values compared were ultimate stress, strain at failure, and elastic modulus. An unpaired t-test was used to analyze the data. Differences were considered significant at $p < 0.05$. For histology, contralateral ligaments were harvested *in toto* (4 treated, 4 controls), fixed in Zamboni's fixative, flash frozen at -70°C , sectioned (6 μm), and mounted on slides. Slides were incubated in reaction solution, consisting of equal parts tris-maleate buffer and hexazonium parasaniline buffer with 50mM sodium-potassium tartrate, for two hours. Following incubation, slides were washed, dehydrated, coverslipped, and investigated for the presence of tartrate resistant acid phosphatase (TRAP), a collagenolytic enzyme (Oddie, 2000).

RESULTS AND DISCUSSION

All guanethidine treated animals developed ptosis (indicative

of sympathectomy) by the second day of treatment, which persisted throughout the treatment period. Significant differences between ultimate stress, strain at failure, and elastic modulus were seen between guanethidine treated rats and controls (Table 1). Additionally, histological techniques demonstrated the presence of TRAP in guanethidine treated rats (Figure 1), but not in controls. To our knowledge, no

other studies show TRAP in ligament tissue.

Figure 1: Active TRAP (red) in guanethidine treated rat MCL. Active TRAP was not seen in controls.

SUMMARY

Inhibition of the sympathetic PNS through guanethidine treatment leads to a reduction in ligament strength and changes to strain at failure and modulus. Guanethidine treatment also leads to the presence of active TRAP in many areas of the ligament. The presence of active TRAP suggests a role for this enzyme in ligament degradation following the inhibition of the PNS.

¹UCB-UCSF Joint Bioengineering Graduate Group, University of California at Berkeley, Berkeley, CA, USA.

²University of California at Berkeley, Bioengineering Department, Berkeley, CA, USA, lp Pruitt@newton.me.berkeley.edu

³University of California at San Francisco, Radiology Dept., Magnetic Resonance Science Center, San Francisco, CA, USA.

INTRODUCTION

The goal of this study was to investigate correlations between the local biochemical composition, mechanical properties, and structural parameters of trabecular bone. Nanoindentation was used to measure mechanical properties, Fourier Transform Infrared (FTIR) spectroscopy to characterize bone mineral composition, and microcomputed tomography (μ -CT) to evaluate trabecular bone structure.

METHODS

Femoral head specimens were obtained from 3 patients undergoing surgery for bone disorders and stored in formalin. Cylindrical cores were drilled from the superior, inferior, and side poles of each head, dehydrated, and embedded in polymethyl methacrylate (PMMA) for slicing. Cores then underwent μ -CT scans to obtain structural properties using 3-D imaging at a resolution of 26 μ m. Properties measured included: bone volume fraction (BV/TV), trabecular thickness (Tb.Th.), trabecular number (Tb.N.), trabecular separation (Tb.Sp.), and trabecular connectivity (Conn.D.).

Five embedded cores were sliced transversely into 1 mm thick cross-sections. Every other cross-section was then subjected to nanoindentation, while the complementary surfaces on adjacent slices were subjected to FTIR spectroscopy. The remaining 8 cores were each sliced longitudinally into half-cylinders, with one side being sliced into 2-4 mm sections for FTIR analysis. Nanoindentation was performed on the complementary unsectioned surface.

The characterization of mechanical properties was performed using the Hysitron TriboIndenter (Hysitron Inc., Minneapolis, MN). Samples were stained with alizarin red to allow for visualization of trabecular bone tissue. At least 25 specific indentation points were then chosen using the optics attached to the indenter. A trapezoidal loading curve was applied to each site with a loading rate of 40 μ N/s, a 10 second hold at 400 μ N, and an unloading rate of 40 μ N/s. Using the Oliver and Pharr method (Oliver and Pharr, 1992), the reduced modulus (E_r) and hardness (H) at each point were determined.

FTIR analysis was performed using a Nicolet Avatar 360 (Madison, WI) spectrometer with an ATR accessory. Spectra were collected for 64 scans with a 4 cm^{-1} resolution for each sample. After baseline correction, normalization to scale, and

subtraction of the pure PMMA spectrum, spectra were analyzed from 675-4000 cm^{-1} . Mineral:matrix ratios were then determined from the ratio of phosphate absorption (900-1200 cm^{-1}) to collagen amide I absorption (1585-1725 cm^{-1}), while carbonate:mineral ratios were calculated from the ratio of carbonate absorption (840-890 cm^{-1}) to the phosphate band. The 1020/1030 ratio was also determined to serve as an indicator of crystallinity, with lower values corresponding to higher crystallinity.

RESULTS AND DISCUSSION

Representative data from 3 slices of a single core are summarized in Table 1. As seen in the table, mechanical and biochemical properties tend to vary over a small range, while some structural parameters display a greater variability. From the data obtained, no obvious structure-property relationship appears evident within the individual slices of a single femoral bone sample or as a function of depth in the core. Data was then averaged for each core, and for each entire bone specimen. No trends were apparent in local mechanical and biochemical properties between cores or specimens. Instead, the results suggest that trabecular bone bulk mechanical property variation may be more dependent upon structural parameters than biochemical and mechanical properties.

Table 1: Representative structural, mechanical, and biochemical properties of three slices from a single core.

Property	Slice 4	Slice 10	Slice 14

INCREASING AGE SLOWS RECOVERY OF FUNCTION FOLLOWING ACHILLES TENDON INJURY IN THE RAT

Lori Vogelpohl, Donald D. Anderson, Joseph E. Hale, Stefanie D. Stangier, and Carlos A. Guanche
Biomechanics Laboratory, Minneapolis Sports Medicine Center
Minneapolis, MN, e-mail: ander284@umn.edu

INTRODUCTION

The application of exogenous insulin-like growth factor-I (IGF-I) has been shown to improve healing in muscle (Menetrey et al, 2000), stimulate bone remodeling (Chihara and Sugimoto, 1997) and speed recovery after tendon injury (Kurtz et al, 1999) in young healthy animals. These findings may have broader implications in the treatment of populations with impaired healing capacity. Increasing age negatively influences the rate at which wounds heal (Eaglestein, 1989) and impairs tendon metabolism, in particular (Almekinders and Deol, 1999). Reduced bioavailability of IGF-I with aging previously reported (Adams and Moore, 1995) might well explain altered healing rates in the aged population. By supplementing the native IGF-I supply we aim to accelerate healing following muscle / tendon injury in the aged.

As a first step towards this end, we performed experiments in rats to establish whether or not age influences the rate of functional recovery from surgically induced tendon injury.

METHODS

Eighteen Sprague-Dawley rats, six in each of three different age groups (4, 11, and 19 months old), were studied. These ages were chosen to represent young, middle, and old age, based on growth and survival curves provided by the animal vendor. During a one week period of acclimatization, rats were trained for functional evaluation of their locomotion.

At surgery, rats were anesthetized using pentobarbital and subjected to sharp transection of their left Achilles tendon using techniques previously described (Kurtz et al, 1999). Following surgery, animals were returned to their cages and allowed food and activity ad libitum.

Rats were evaluated to characterize locomotor function in terms of the Achilles Functional Index (AFI), derived from rat pawprints (Kurtz et al, 1999). Deficits in Achilles tendon function following transection produce alterations in the rat's gait, reflected by decreased AFI values compared to baseline. Rats were walked pre-operatively to establish a baseline, and they were then walked on post-operative days 1, 2, 3, and subsequent odd-numbered days until post-operative day 15.

Linear regressions of AFI values vs. the number of days after injury were performed for averages within each of the three age groups, allowing comparison of the rate at which Achilles function was recovered between ages.

RESULTS AND DISCUSSION

Two of the oldest aged rats died of post-operative complications associated with anesthesia; one the day of surgery, and the other two days after surgery. The mean AFI values obtained for the three age groups are shown below in Figure 1. Linear regressions of the AFI ($R^2 = 0.89$) showed a nearly two-fold difference in the rate of functional recovery between the youngest age group and the two older age groups as measured by the slope of the linear fit.

One limitation of this study is the relatively small sample size, although in previous study, groups of six animals provided sufficient power to detect a 25% difference in the AFI at an 85% confidence level. Future testing will involve a larger sample size (replacing animals lost to complications) and further statistical analysis.

STABLE FORWARD DYNAMIC SIMULATION of BIPEDAL GAIT USING SPACE-TIME ANALYSIS

K.P. Granata¹, D.Brogan² and P.N. Sheth²

Motion Analysis and Motor Performance Laboratory, University of Virginia, Charlottesville, VA.

¹Depts Orthopaedic Surgery and Biomedical Engineering, ²Dept Computer Science ³Dept Mechanical and Aerospace Engineering

INTRODUCTION

Bipedal walking is a highly sophisticated form of legged locomotion requires limit-cycle stability despite the fact that a significant part of the walking cycle violates in static equilibrium. Forward-dynamic simulations of compass-like bipedal gait are useful for the study of walking stability but have been limited to numeric solutions methods (Goswami 1996). Consequently, forward-dynamic walking models are often limited by assumptions regarding controlling activation and/or initial state configurations. The goal of this study was to document a method for determining optimal movement trajectory based upon the constraint that the repetitive gait pattern must be dynamically stable.

METHODS

A 2-D knee-less walker was simulated with a revolute hip joint at the HAT mass (McGeer 1993). Non-linear second-order equations of motion are well established (Goswami 1996) and demonstrate the movement trajectory is determined by the ground slope γ , the mass ratio m_{Leg}/M_{HAT} and mass distribution. Foot-strike was assumed plastic and the transition stage at foot-strike instantaneous, i.e. no double-support period. The state vector following foot-strike is related to the pre-impact state by algebraic relations describing conservation of momentum (Hurmuzlu 1992).

The governing equations were implemented using an ordinary-differential equation solver (MathWorks, Natick MA) to integrating forward in time. Differential equations were assumed homogeneous, i.e. passive walker. Limit-cycle stability was determined from numerical eigenvalue analyses of perturbed trajectories (Garcia 1998). Initial conditions generating stable solutions can only be determined through linear-approximation or by trial-and-error estimation.

The model was also implemented using space-time methods (Witkin 1988) to restrict the solution to dynamically stable trajectories. Movement trajectories were represented through piece-wise linear segmentation; using $n=35$ time increments to represent 0.6 sec the gait cycle. The entire movement trajectory was established with an angle vector θ_i at every time increment $t=1..n$ and associated torque vector τ_i . Forward-integration is not required as the differential equations are represented as piece-wise linear functions of the angle trajectory (see Witkin 1988). Using optimization techniques the entire movement trajectory θ_i was determined by minimizing $\Sigma \tau_i^2 / (\text{step length})$. Movement trajectory end-points were constrained to satisfy the algebraic transition behavior, i.e. conservation of momentum. Most importantly

Figure 1. Movement trajectories of the walker at 2 down-hill slopes from the forward-integration and space-time methods. Up-hill walking is also illustrated for the space-time analyses.

the movement trajectory was constrained such that system dynamics must satisfy limit-cycle stability, i.e. the solution method will produce only trajectory with stable gait behavior

RESULTS AND DISCUSSION

Phase-plane representation of movement trajectories are illustrated for ground slopes $=2^\circ, 4^\circ$ (FIGURE 1). Similar movement behaviors were achieved from the two simulation methods with longer step lengths from the space-time method because the optimization criterion was penalized by short step lengths. Actuator torques determined by the space-time method converged to zero for all time increments during down-hill walking; identical to the forward-integration results wherein homogeneous solution was prescribed, i.e. a passive walker (McGeer 1993). Although stable solution to uphill walking does not exist for homogeneous forward-integration methods the constrained search technique readily identified the movement trajectory and activation torques necessary to establish stable uphill walking.

SUMMARY

Methods of constrained search can be used to identify movement trajectories based upon the premise that the bipedal walking behavior must be dynamically stable. Pathologic disturbance to normal walking behavior will result in a compensatory movement trajectory only if the modified behavior is stable. This simulation method may permit determination of stable pathologic walking behavior

THE EFFECTS OF HYDRATION TIME ON LIGAMENT VISCOELASTICITY

INTRODUCTION

Ligaments are soft connective tissues that display viscoelastic behavior. Researchers have studied the effects of hydration on ligament and tendon using various solutions (Chimich, et. al. 1992; Hannafin and Arnockzy 1994; Thornton et. al 2001), but have not studied the role of hydration in individual ligaments subjected to repeated viscoelastic testing and recovery in a single solution. It has been shown that cyclic loading of ligaments causes a reduction in water content and that ligaments with greater water contents relax faster than those with less water (Chimich, 1992). Ligaments that are cycled may lose water due to a ringing out effect. This led us to hypothesize that if a ligament is tested and allowed to recover in physiologic saline for ten times the testing time, that when the ligament is retested it will creep at a faster. Studies have shown that 10 times the testing time is adequate for recovery of tissue gage length (Provenzano, 2001; Turner, 1973).

METHODS

The methodology was adopted from Provenzano et. al (2001). There were two exceptions. The male Sprague-Dawley rats used were 310±40g. The rats were divided into two groups: Group 1 (n=9 ligaments) consisted of MCLs subjected to 1000s creep after harvest, then allowed ten times (10,000s) recovery time in phosphate buffered saline (1x), and retested at the same load. Care was taken to ensure the tests were started at the same preload (0.1N). Group 2 (n=8 pairs of ligaments) consisted of one leg subjected to creep for 1000s after dissection, while the contralateral leg was hydrated in physiologic PBS for 10 times the testing time, then subjected to creep for 1000s.

The data analysis was done by fitting data with a power law formulation (At^n), where n is the rate of creep. The power law formulation has been shown to describe this type of data well (Provenzano et. al 2001). The data was analyzed with a 2-tailed paired t-test. The null hypothesis is that hydration will not affect viscoelastic behavior.

RESULTS AND DISCUSSION

For Group 1 there was a significant difference in rates of creep between samples that were tested immediately after harvest (time zero) and retested after hydration for 10000 sec (0.0203 ± 0.0012) and (0.0142 ± 0.0006), respectively. The p value was 0.043, which accents the difference between testing states and rejects our hypothesis (Fig. 1). This shows that

hydration affects the rate of creep when a single ligament is subjected to repeated testing. This decrease in creep rate may be due to a decrease in the space between the collagen fibers and exudation of water from the ligament. Group 2 (data not shown) showed no significant difference between contralateral legs for the rate of creep (0.0248 ± 0.006) and (0.0251 ± 0.0058), respectively. This may be explained by the fact that since the contralateral legs were never initially subjected to creep there was never any water loss. In addition, duplicating exact testing configuration in contralateral ligaments is difficult, adding to noise in the data.

Figure 1: Changes in the rate of creep associated with hydration. There is a significant difference between specimens tested after harvesting and tissues retested after recovery in physiologic solution. * Indicates significant diff.

SUMMARY

These studies show that repeated creep testing of ligaments results in a decrease in the rate of creep with hydration time. This result was not demonstrated in contralateral legs, but may be due to different load histories before hydration. Also this could be a result of differences with the mounting of the specimen or signifies that it is not hydration alone that affects ligament behavior.

METABOLIC COST OF LATERAL LEG SWING IN HUMAN WALKING

David Shipman¹, J. Maxwell Donelan², Rodger Kram³, and Arthur D. Kuo⁴

INTRODUCTION

We have previously demonstrated that walking with narrow steps requires more metabolic energy than normal walking (Donelan, et al., 2001). One possible reason is that, with narrow walking, people must move their swing leg laterally to avoid colliding with their stance leg. We tested this hypothesis by inducing subjects to walk with increasing amounts of lateral leg swing and measured the associated metabolic cost.

METHODS

Ten healthy adults (6 male, 4 female) participated in the study after providing informed consent. We asked the subjects to follow lines marked on a treadmill belt to enforce their previously determined preferred step width (mean 10.7 cm, s.d. 2.3 cm), and used a metronome to enforce their previously determined preferred step frequency. Subjects walked at 1.25 m/s.

We constructed a device to enforce minimum foot separation at mid-swing during walking (see Fig. 1). The device consists of modified commercial ankle brace. We attached blades medially to enforce a minimum distance between the walker's feet when the swing leg passes the stance leg during walking.

Subjects performed trials with three different blade sizes, along with a baseline trial in which the blades were placed on the lateral surfaces of the ankle braces. The blade sizes used were one-half of the subject's preferred step width, and 1 cm wider and narrower.

We determined metabolic cost by analyzing the gas content of expired breaths. We calculated metabolic power (Watts) for each trial and subtracted the metabolic power for standing from all walking values. Finally, we computed the added metabolic cost as a percent of the baseline trial. We measured net ground reaction forces and moments along 3 geometric axes

Figure 1: Device for enforcing minimum swing width

Figure 2: Metabolic costs associated with lateral leg swing

as subjects walked on a force treadmill (Kram, et al., 1998). We then calculated actual step widths from these values.

RESULTS AND DISCUSSION

Despite prior familiarization training, subjects sometimes had difficulty following the target step width lines, typically using a somewhat wider step width than specified. We calculated the actual step widths used and then computed the associated swing width. This swing width is the amount of lateral diversion the swing foot experiences in swinging around the stance foot. We had selected the medium blade width so as to require the same swing width as is experienced when walking without blades at zero step width. Figure 2 shows the added metabolic cost associated with increasing swing width. Under the assumption that power is proportional to amplitude squared, we have plotted a quadratic best fit line proportional to swing width squared (factor 0.15%/cm²). For our subjects, zero step width walking is associated with a mean swing width of 10.7 cm, corresponding to an added metabolic cost of 17%.

SUMMARY

Consistent with our hypothesis, we found that metabolic cost increased substantially with increases in lateral limb swing such as are required during walking at narrow step widths.

INTRODUCTION

Global shoulder girdle (SG) movements are defined as elevation, depression, protraction and retraction (Lehmkuhl & Smith, 1983). These movements involve four bones and three joints: the scapula, clavicle, sternum, the first rib, and the acromio-clavicular, sterno-clavicular and scapulo-thoracic joints (Kapandji, 1997). The SG is an important part of the shoulder complex and arm movements depend on adequate ROM and muscle function in this area. Since several disorders involve the SG area, there is a need to develop objective and rigorous methods to assess the global SG active movements. The purpose of this study was to determine the concurrent validity of active range of motion (AROM) of the SG elevation, protraction and retraction as measured with a goniometer and a tape measure. These simple clinical measurements were compared to those computed from infrared markers placed over specific bony landmarks on healthy subjects.

METHODS

A sample of convenience of thirty healthy subjects, 15 females and 15 males, with a mean age of 45.3 (± 11.5) years, participated in the study. Each subject was assessed by two physiotherapists having 5 and 15 years of clinical experience. AROM of the SG was measured in a sitting position, arms hanging aside the body, using the two clinical methods: goniometry and tape measure. The same movements were then evaluated with a three-dimensional (3D) movement analysis system (Optotrak 3020). Markers were placed on the subjects' head, shoulders, manubrium, scapula, cervical and thoracic spines. The location of some markers was readjusted at the end of the movements to reduce any potential error associated with overlying skin movement during scapular motion (van der Helm & Pronk, 1995). For each SG movement, the Pearson correlation coefficient (r) was calculated to evaluate the concurrent validity between goniometer and the 3D angular data as well as that between tape measure and 3D linear data obtained using the Optotrak analysis system.

RESULTS AND DISCUSSION

AROM was much greater in elevation than in the other movements (Table 1). For each movement, the differences between sides were less than 3° or 0.3 cm. Elevation was the most valid movement, with the tape measure ($r = 0.74-0.84$, $p < 0.01$) and the goniometer ($r = 0.74-0.80$, $p < 0.01$). With this latter method, measurements performed on the dominant side of the subjects by the examiner with less experience had poorer

concurrent validity ($r = 0.63$, $p < 0.01$). Concurrent validity was lower but still acceptable for retraction measured with the goniometer, especially on the dominant side ($r = 0.55-0.60$, $p < 0.01$). It was poor for retraction on both sides with the tape measure, ($r = 0.34-0.43$, $p < 0.05$) and for protraction, with both measurement methods ($r = 0.10-0.43$, $p < 0.05$). The goniometer used in clinical setting allowed the measurement of movement in one plane of motion. With SG protraction and retraction, a certain amount of elevation was observed for many subjects. This combined motion, which has also been reported by Conway (1961), made it difficult to maintain the goniometer in the plane of motion especially during protraction measurements. Consequently, examiners reported problems keeping the body of the goniometer aligned with the sternal notch and the arms, parallel to the sternum and the clavicle. During retraction and protraction, parallax errors may also have occurred due to the location of the body of the goniometer in the transverse plane, under the subject's chin. In protraction, occasional forward motion of the subject's head probably added to these reading problems. Moreover, examiners also mentioned difficulties in localizing the medial angle of the scapula at the end of these movements with the tape measure. It is believed that these factors might have decreased the concurrent validity of the protraction and retraction movements.

SUMMARY

The results of this study demonstrated the validity of the goniometer and tape measures for SG elevation. Concurrent validity was acceptable for retraction with the goniometer, especially on the dominant side. It was poor to fair when assessed with the tape measure. Future research is needed to improve the clinical assessment of AROM in protraction and retraction.

MEASURING CENTER OF MASS DISPLACEMENT DURING GAIT: WHOLE-BODY KINEMATIC MODEL VS. GROUND REACTION FORCE CALCULATION

INTRODUCTION

Center of Mass (CM) displacement measurement in gait analysis has mainly been limited to either an assumption of a fixed position with the pelvis or as displacements derived from ground reaction forces (GRF) according to

$$\iint \frac{\vec{F}_{CM} - m\vec{g}}{m} dt^2 = \iint \vec{a}_{CM} dt^2$$

and applying integration constants based on assumptions of similar initial and final positions and constant velocity. A typical gait lab has 2 force platforms to measure GRF, making it difficult to collect GRF under both feet from one stride cycle. Numerical adjustments to estimate two phases of double-support time can be made (Whittle, 1997). Measuring CM displacement using GRF from 2 force platforms has disadvantages: 1) Subjects must walk over the platforms in the required fashion, 2) Displacement, not position, of the CM is measured, 3) No information of joint movement is gained, 4) Results are sensitive to small deviations in mass estimates and integration constants.

In modern 3-D gait analysis, a readily-available whole-body model is feasible and routinely available. CM displacement derived from a kinematic model would enable analysis of specific movements on the CM displacement as well as estimate the position of the CM anatomically.

METHODS

Model: 3-D gait analysis using 34 retro-reflective markers was performed (Vicon® 512) at 50 Hz. A 15-segment model (head, trunk, 3-segment arms, pelvis, and 3-segment legs) is used in which the CM is defined as the centroid of the system. The model is a standard install with a common motion analysis system (Plug In Gait, Vicon Motion Systems®, Oxford, England) but has not yet been validated as a whole-body model. The lower body model is well documented (Kadaba et al, 1990).

Subjects and procedure: 14 children (ages 5-12, mean 10.7 years) with no physical disability and 28 children with myelomeningocele (MMC, ages 6-17, mean 10.4 years, with varying muscle paresis) were tested in 3-D gait analysis at a self-selected speed. CM trajectory was determined as the centroid of the 15-segment model and was distinguished into vertical and lateral displacements.

GRF in 3 directions was measured simultaneously at 1000 Hz using 2 force platforms (Kistler®). Mass was measured first from a digital scale, then for comparison as the average vertical GRF in the stride cycle. When the required platform support was observed, a double second-order numerical integration was performed twice (using Matlab® software) using appropriate integration constants.

Peak displacements from the two methods were compared in both lateral and vertical directions for a subgroup of 14 MMC and 8 normal stride cycles. In 7 trials, a correlation coefficient between the methods was calculated. A sensitivity analysis of mass estimation will be performed on both methods as well as a thorough correlation comparison.

RESULTS AND DISCUSSION

Figure 1: CM displacements from the 2 methods in one MMC subject in one stride.

Comparison of the two methods of calculating the CoM displacement showed that the GRF integration yielded higher peak displacements: 4.0% lateral and 21.4% vertical than the centroid method. The general agreement between the methods was much better in the lateral direction than in the vertical: the correlation in a sub-group of 7 trials showed $r^2=0.98$ lateral and $r^2=0.77$ vertical. Small changes in mass estimation resulted in large changes in both the vertical CM trajectory and in the peak displacement: up to 10% better agreement was observed when mass was calculated from the GRF during walking, though the masses varied by less than 1%. Due to the GRF method's sensitivity to mass estimation and integration constants, we are wary of its accuracy. While the kinematic model is sensitive to errors in segment parameters and is not applicable in all situations, it shows value in providing at least relative estimations of CM position and displacement and has the major advantage of simultaneous joint motion collection.

MUSCLE FORCE NOT WORK DEFINES MUSCLE CONTRIBUTIONS TO FORWARD PROGRESSION

INTRODUCTION

The uniarticular, and not the biarticular, ankle plantar flexors were previously shown to contribute significantly to trunk forward progression from mid stance into pre-swing (late stance) (Neptune et al., 2001). However, other muscles (specific muscles not identified in that study) also contributed to forward progression both in early stance into single-leg support (beginning of stance) and in late stance. We hypothesized that these other muscles contribute to trunk forward progression by redistributing segmental energy by decelerating the leg and accelerating the trunk through active concentric, isometric and eccentric force generation. That is, it is force generation per se that is critical to segmental energy redistribution, irrespective of whether that muscle performs positive work, no work at all, or even negative work.

METHODS

To assess this hypothesis, a forward dynamical simulation that emulated observed walking kinematics and kinetics of young adult subjects was analyzed to quantify the muscle induced-energetics of the trunk and leg segments. Those muscles contributing to trunk progression (i.e., forward acceleration of the trunk) were identified. The musculoskeletal model and simulation were developed using SIMM/Dynamics Pipeline (MusculoGraphics, Inc.) and consisted of the trunk, right and left legs. Each leg consisted of the thigh, shank, foot and fifteen individual Hill-type musculotendon actuators. The trunk was allowed to translate and rotate in the sagittal plane, while the hip, knee and ankle joints were frictionless revolute. The model's dynamical equations-of-motion were derived using SD/FAST (PTC, Inc.). The contact between the foot and the ground was modeled with discrete visco-elastic elements located on the bottom of the foot. The individual muscle excitation patterns were modeled as block patterns and an optimization framework systematically varied the muscle controls to replicate the experimental data.

RESULTS AND DISCUSSION

The uniarticular knee extensors (vasti, VAS) contributed to trunk progression in the beginning of stance by redistributing segmental energy between the legs and trunk (Fig. 1A). VAS decelerated the leg segments (Fig. 1A, dashed line is negative), causing them to lose energy, and accelerated the trunk forward (as well as upward) through its contribution to the hip intersegmental force (Fig. 1B), causing the trunk to gain energy (Fig. 1A, dotted line is positive). VAS provided this mechanism for the redistribution of energy from the leg to the trunk even though its activity was eccentric, isometric and then concentric (Fig. 1A, solid line is initially negative, momentarily zero, then positive). The concentric uniarticular hip extensors acted co-functional with VAS in early stance by

also decelerating the leg and accelerating the trunk. The eccentric rectus femoris (RF) in late stance also redistributed segmental energy to accelerate the trunk forward by acting to accelerate the knee and hip into extension, made possible through dynamic coupling of the body segments. Other muscular contributions to trunk progression, besides from the previously identified plantar flexors, were negligible (e.g., RF in beginning of stance, biarticular hamstrings, hip flexors).

Figure 1: A) Musculotendon mechanical power output by VAS (*Net Power*) and the distribution of this power to the ipsilateral (*Ipsi leg*) and contralateral (*Cntr leg*) leg segments and trunk (*Trunk*) over the gait cycle. Solid horizontal bars indicate muscle excitation timing. B) Contribution by VAS in Early Stance (10% gait cycle) to the intersegmental joint forces and the trunk and leg segmental energetics. The summed hip intersegmental force from both hips accelerates the trunk segment's center-of-mass upwards and forward, causing the trunk to gain energy ("+"). The intersegmental joint forces by VAS decelerate forward motion of the thigh and shank causing them to lose energy ("-").

SUMMARY

The redistribution of segmental energy by the uniarticular hip and knee extensors in the beginning of stance and by RF in late stance contribute significantly to trunk forward progression to complement the late-stance contributions of the ankle plantar flexors. We conclude that muscle force generation is the determining factor in how individual muscles contribute to forward progression, rather than muscle work, since concentric, isometric and eccentric muscle action can all act to accelerate the trunk forward.

INTRODUCTION

Muscle vibrations have been associated with force oscillations due to the unfused contraction of motor units (MUs – Vaz et al., 1996). If so, then recruitment of larger MUs should increase the magnitude of these vibrations, whereas increasing firing rates should increase tetanic fusion and decrease the magnitude of muscle vibrations. It is well known that muscles of the hand (small muscles) recruit Mus up to 50% of the maximal voluntary contraction (MVC), and increase force by increasing the firing rates of MUs from 50 to 100% MVC (Milner-Brown et al., 1973; Kukulka and Clamann, 1981; Basmajian and De Luca, 1985). Therefore, an increase in the magnitude of the mechanomyographic (MMG) signal should be observed with recruitment, while a decrease should be observed with increasing MU firing rates. The purpose of this study was to test the hypothesis that the amplitude and frequency content of the MMG signal are related to the muscle's recruitment strategies.

METHODS

MMG signals were obtained from the first dorsal interosseus of 12 male and 3 female subjects (age 19 to 50 years) during different levels of voluntary isometric contraction (10% to 70% MVC, with a 5 minute interval between trials) using a miniature accelerometer (Entran, EGA-10D) attached to the skin with double-sided adhesive tape. Abduction of the index finger was performed against a load cell (Alfa Instruments, 5Kgf) attached to an aluminium plate designed for the experiment and mounted on a concrete table. The different levels of voluntary effort were displayed on an oscilloscope to provide the subjects with visual feedback. MMG signals were extracted for segments of 4 seconds from the middle of the trials to ensure that transient signals at the beginning and end of the contraction were excluded. Root mean square (RMS) values were obtained from the raw MMG signals. Signals were band-pass filtered with cut-off frequencies of 4 and of 262 Hz. Median frequency (MDF) was calculated from the power frequency spectrum which was obtained through an FFT algorithm.

RESULTS AND DISCUSSION

RMS values increased with increasing voluntary effort up to 50% MVC and remained about constant from 50% MVC to 70% MVC (Figure 1). Our results do not agree with the results of Stokes and Cooper (1992), who showed an increase in RMS with increasing voluntary effort for the adductor pollicis muscle, but are similar to the results of Madeleine et al. (2001) for the first dorsal interosseus muscle. It appears that the reported increase in MU recruitment for this muscle is responsible for the observed increase in MMG amplitude, whereas the leveling off from 50 to 70% MVC might be related with increases in MU firing rates. MDF of the MMG signal tended to decrease with increasing voluntary effort

(Figure 2). The frequency content of the MMG signal has been related to both MU firing rates and the contractile properties of the active MUs (Orizio, 1993). Increases in the firing rates of MUs, therefore, should produce an increase in the MDF of the MMG signal with increasing voluntary effort. Our results do not agree with this relation between the MDF and MU firing rates. It appears that the frequency contents of the MMG signal are related with changes in the mechanical behavior of MUs, but not with MU firing rates.

Figure 1. RMS values (mean + SD) of the MMG signal as a function of voluntary effort.

Figure 2. MDF values (mean + SD) of the MMG signal as a function of voluntary effort.

VISUO-LOCOMOTOR CONTROL DURING ANTICIPATORY LOCOMOTOR ADJUSTMENTS

Lori Ann Vallis^{1,2}, Bradford J. McFadyen^{1,2} and Martin Gérin-Lajoie^{1,2}

¹Center for Interdisciplinary Research in Rehabilitation and Social Integration (CIRRS), Québec, Canada

²Faculty of Medicine, Laval University, Québec, Canada G1K 7P4

INTRODUCTION

Successful navigation of cluttered environments is critical for maintaining independence and an acceptable standard of living. The appearance of gait as an 'automatic' motor skill misrepresents the levels of control that are required, specifically transmitting and interpreting available sensory information as well as planning and executing successful locomotion. The purpose of this study was to investigate body segment coordination strategies used for walking around a vertical obstacle placed in the travel path.

METHODS

Five healthy subjects (3 female and 2 male; age 26.6 ± 3.2 years, height 174.11 ± 11.12 cm, weight 77.84 ± 8.00 kg) volunteered for the study. Experimental protocol was approved by the ethics committee of the Québec Rehabilitation Institute and informed consent was given by all participants. Exclusion criteria included any self-reported neurological, musculoskeletal or visual impairment. Data shown is part of a larger study and only kinematic data will be discussed in this abstract.

Fourteen infrared markers, three on the feet, pelvis, trunk, and head, and one on each wrist, were tracked using the Optotrak motion analysis system (60 Hz; Northern Digital Inc, Canada). Certain anatomical points were also probed in relation to these markers to allow the calculation of principle axes and the creation of virtual marker movement (e.g., heels). Eye movement (not reported here) was captured with the ISCAN system (120 Hz) mounted on a baseball cap.

Participants walked at their natural self-selected pace along a 9-m path. Five unobstructed (control) trials were collected first. Then subjects were required to avoid a cylindrical obstacle (height 2-m, circumference 73.85-cm). No instructions were initially given as to left or right deviations. However, once five trials of walking in one direction were collected, participants were asked to walk in the other direction to ensure an equal number of trials in each direction.

In this preliminary study, data analyzed were step length, step width, yaw (transverse plan) angles of the head and trunk, roll (frontal plane) angle of the trunk, and medio-lateral centre of mass displacement. The onset of changes in the variables was measured as the point in time when data started to deviate from the average control profile, providing the deviation continued beyond one standard deviation of the average control data. Onset times were calculated as the time before the COM crossed the obstacle in the direction of progression.

RESULTS AND DISCUSSION

Preliminary analyses indicate that there was no use of trunk roll and no significant differences between onset of M-L center of mass deviation (1.84 s), head yaw (1.91 s) and trunk yaw (1.89 s) prior to crossing the obstacle in the direction of progression. However, sequencing of body segment reorientation was variable and the head segment did not systematically anticipate change in direction of locomotion before the rest of the body as reported in steering literature (Hollands *et al.*, 2001; Patla *et al.*, 1999). This may be due, in part, to the fact that reorientation of the head to establish a new frame of reference is not required as the goal of the current task is to continue walking in the forward direction after crossing the obstacle.

Translation of the COM in a new direction of travel can be achieved both through alternate placement of the contralateral foot prior to the turn step and use of a hip strategy, illustrated by trunk roll (Hollands *et al.*, 2001; Patla *et al.*, 1999). Kinematic data from the current study indicate no modifications in trunk roll, the COM trajectory is altered through contralateral foot placement (100% of trials).

SUMMARY

Anticipatory adjustments of body segment orientation are initiated by the central nervous system to ensure safe obstacle avoidance. These locomotor adjustments require a different control strategy for deviation of the COM trajectory than observed in steering tasks. Analyses of eye movement amplitude and timing are currently underway.

INTRODUCTION

Overuse injuries are common among competitive runners with stress fractures (SF) being one of the most serious overuse injuries. SF are among the top 5 cited running-related injuries and females are twice as likely to experience a SF as their male counterparts. The etiology of SF is multifactorial in nature but is related, in part, to some combination of bone structure, peak forces, loading rates, as well as lower extremity running mechanics. Therefore, the purpose of this investigation was to examine differences in ground reaction force (GRF), tibial acceleration, bone structure, and kinematic variables between competitive female distance runners who had sustained a previous lower extremity SF and uninjured control subjects. It was hypothesized that peak tibial acceleration, vertical GRF loading rates, and lower extremity stiffness would be greater in the injured runners and area moment of inertia of the tibia and knee flexion excursion would be lower. In addition, those variables which were different would contribute significantly to the prediction of which runners had sustained a SF.

METHODS

Subjects consisted of 8 females with a history of at least one lower extremity SF and 8 females with no SF history who served as a control group (CON). All subjects were between ages 18-35 and ran between 30-80 miles per week. These subjects are part of a larger ongoing study investigating factors associated with SF in women runners. GRF and tibial acceleration data were recorded from 5 running trials. Three radiographs of the distal lower extremity were used to calculate the tibial area moment of inertia (Milgrom et al., 1989). Variables of interest included peak positive tibial acceleration (PPA), peak vertical GRF (VGRF), instantaneous loading rate (ILR), stiffness (STF), knee flexion excursion (KFlex) and tibial area moment of inertia in the anterior/posterior plane (I_{AP}). Independent t-tests were used to assess differences between groups. A backward, stepwise statistical regression analysis was used to determine the factors that best predicted which subjects had previously suffered a SF.

RESULTS AND DISCUSSION

Of the 8 total SF, 5 were tibial, 2 were fibular and 1 was metatarsal. Results indicated that both PPA and ILR were

significantly ($p < 0.05$) greater in the SF group (Table 1). Although not significant ($p > 0.05$), a trend towards greater stiffness and reduced knee flexion excursion in the SF group was also observed (Table 1). Williams et al. (2001) also reported a significantly higher load rate and great stiffness in a group of runners with high arch feet and a greater incidence of stress injuries. However, Crossley et al. (1999) reported no significant differences in GRF variables between SF and control subjects.

Other investigations have reported that bone geometry was significantly different between SF and control groups (Crossley, 1999; Milgrom, 1989). However, in the present investigation, the SF group exhibited similar tibial I_{AP} values as compared with the control group (Table 1). A small subject population may account for discrepancies between previous studies and the results of this investigation.

The results indicate that PPA and ILR explained 46% of the variance ($p = 0.01$) in predicting subjects who had previously suffered a SF. ($y = 3.50 + -0.12PPA + -0.01ILR$). None of the remaining variables entered into the regression equation. However, it is possible that these results may change as more subjects are analyzed during this ongoing study.

SUMMARY

These data suggest that 1) subjects who had previously suffered a lower extremity SF demonstrated greater GRF loading rates, shock, and stiffness and reduced knee flexion excursion as compared with noninjured controls and 2) kinetic measures can be used to predict which subjects had previously sustained a SF.

BONE RESORPTION IN SHOULDER SURFACE REPLACEMENT ARTHROPLASTY

Ulrich Hansen and Andrew Hopkins

Biomechanics Section, Department of Mechanical Engineering, Imperial College, London, UK.
u.Hansen@ic.ac.uk

INTRODUCTION

Surface replacement prostheses have several important advantages over stemmed implants. During the surface replacement procedure only the cartilage and a thin layer of underlying bone is removed. Therefore, should the implant ever become loose there will be plenty of bone stock for a more traditional stemmed arthroplasty. Over the last decade the importance of incorporating the natural anatomy in the design of shoulder prostheses has become apparent. As the geometry of the humeral bone is largely maintained the surface replacement is easily placed in the correct anatomical position.

Despite these advantages the surface replacement prosthesis is not the choice of most surgeons. This probably stems from associations to the generally recognised failure of surface replacements in hip arthroplasty. These failures have been attributed to; avascular necrosis, bone resorption under the spherical cap due to stress shielding or accelerated wear. The present work tries to evaluate if bone resorption is an issue in surface replacement arthroplasty of the shoulder.

METHODS

A 3D finite element mesh of the bone and implant was created (Figure 1). Material properties were assigned to the model using interpolation between greyscale value, apparent density and Young's modulus (Rice et al. 1988, Schaffler & Burr 1988). Distributed pressure representing the joint load as well as muscle forces representing the deltoid and the

Figure 1: Finite element mesh of implant and humeral bone. Orange section is humeral bone reshaped to fit the implant which simulates the surface cutter action during surgery. rotator cuff muscles were applied while the distal end of the humerus was rigidly fixed. Bone remodelling is predicted on

the basis of the difference between local strain energy density pre and post implantation (Huiskes et al., 1987).

RESULTS

Figure 2 shows the predicted strain energy density in a cross section through the humeral head of two simulations. The figure compares the strain energy density from a simulation of the natural shoulder with the results of a simulation including and implant. In the figure relating to the natural shoulder the area corresponding to the implant have been removed to facilitate comparison between the two simulations. Figure 2 shows reduced strain energy density levels under the cup and increased levels under the peg indicating a potential for bone resorption and bone failure under the cup and peg, respectively.

Figure 2: Strain energy density predictions. Natural shoulder (left) and shoulder with implant (right).

SUMMARY AND DISCUSSION

The strain energy densities are reduced below the lazy zone of the bone remodelling signal, hence, bone resorption would be expected. However, the design and loading of this cementless implant will encourage relatively large interface micromotions at the distal end of the cup. If this interface micromotion is large enough to cause the deposition of a soft interlayer at the distal interface this is likely to cause higher energy density levels under the cup and hence less or no resorption under the cup. Therefore, the simulations are being extended to include interface micromotion and interface failure.

CAN INERTIAL FORCES ALONE CAUSE LIMB FOLDING DURING PROTRACTION?

Danielle F. Preedy¹ and Jeremy F. Burn

Comparative Morphology Center, University of Bristol, Southwell Street, Bristol. BS2 8EJ. UNITED KINGDOM.

dani.preedy@bristol.ac.uk¹

INTRODUCTION

Repositioning of the limb during the swing phase is an inherent requirement in a limb-based system for locomotion. Animals that have evolved to be cursorial, such as the ungulates, have musculo-skeletal adaptations that have reduced the mass of the distal limb segments. This study uses a link-segment model of the forelimb to investigate the hypothesis that folding of the forelimb during the first part of swing is a consequence of inertial forces alone, without digital and carpal flexor muscle activity.

METHODS

Figure 1: Model output sequence for protraction at 2 m/s

A three-segment link segment model, representing the radius, metacarpus and digit, was constructed from published morphometric data using a dynamic simulation package (Working Model 2D, Knowledge Revolution, USA). Constraints over the flexor side of the ‘carpal’ and ‘metacarpophalangeal’ joints prevented hyperextension. The center of mass of the proximal segment was given time dependent velocities from experimental data collected from horses. Limb protraction during locomotion at velocities of 1.8 to 12 m/s, was simulated using the model and compared to experimental data. The ‘carpal’ joint angle was used as a quantitative measure of limb folding and ANOVA were used to compare the output from the model with experimental data.

RESULTS AND DISCUSSION

Folding of the limb around the carpus due to inertial forces was dependent on subject velocity both in the simulation and in the experimental data ($p < 0.001$). At high velocities the

model consistently overestimated the amount of folding seen in vivo.

Figure 2: Scatter graph of carpal joint angle against subject velocity to compare the amount of folding of the limb in the experimental data and the simulation as velocity increased during an incremental exercise test. ○ minimum carpal angle achieved in the experimental data, ■ minimum ‘carpal’ angle achieved in the model □, ‘carpal’ angle in the model at the time when experimental joint angle was at its minimum.

At speeds above 4 m/s the limb did not completely unfold during the second half of the swing phase. The overfolding demonstrated by the model suggests that significant extensor muscular effort may be required during the second part of swing and during limb placement at the beginning of stance. These data suggest that carpal folding during protraction may occur entirely due to the inertia of the distal segments alone, which would act to reduce the mechanical cost of limb protraction. The model will be developed further to include the effect of carpal ligaments and connective tissue.

SUMMARY

The data presented suggest that work by the extensor muscles is important, particularly during reversal of the limb prior to impact. The results from this study support the hypothesis that the folding of the distal limb during swing is a passive event that is dependent on the motion of the proximal segments and inertial forces alone. Passive folding during protraction may be an energy saving mechanism that reduces the metabolic cost of repositioning the limb.

SURFACTANT ATTENUATION OF GAS EMBOLISM-INDUCED THROMBIN PRODUCTION

David M. Eckmann^{1,3} and Scott L. Diamond^{2,3}

Departments of Anesthesia¹ and Chemical Engineering² and
Institute for Medicine and Engineering³, University of Pennsylvania, Philadelphia, Pennsylvania
deckmann@mail.med.upenn.edu

INTRODUCTION

There are many causes of cerebrovascular gas embolization including cardiopulmonary bypass and decompression illness. Neurologic injury can develop from thromboinflammatory responses including microthrombi formation provoked by intravascular gas bubbles. We hypothesized that addition of a surface active compound targeted to air-liquid interfaces would reduce the activation of thrombin formation precipitated by blood exposure to bubbles. We tested this hypothesis in an *in vitro* controlled-shear environment using fluorometric assays of thrombin production in gas embolized human blood.

METHODS

With Institutional Review Board approval, whole blood was drawn from four healthy volunteers ($n = 4$) on each of three occasions. Citrated blood was equal-volume diluted into calcium-free HEPES buffered saline. The Factor IIa (thrombin) specific fluorogenic substrate Boc-VPR was added in 50 μ M concentration. Blood samples were assigned to four groups: sparging (controlled gas embolization) in the presence of surfactant; sparging in the absence of surfactant; surfactant added but no sparging; and no surfactant, no sparging. Samples were recalcified with CaCl_2 . Surfactant (Dow Corning Antifoam 1510US), if called for, was added at 1.5 Volume %. Samples were allowed to sit for one minute or were sparged for one minute with air microbubbles. Samples were placed onto silanized coverslips and sheared at 100 (low) and 500 (high) sec^{-1} for 5, 10, and 20 minutes at 37 °C with a cone-plate viscometer and then placed into excess stop buffer (50 mM EDTA). Samples were evaluated by fluorimetry with excitation and emission wavelengths set to 352 and 470 nm, respectively (Figure 1). Baseline fluorimetry measurements of EDTA, surfactant and fluorogenic substrate were also acquired for offset of the experimental data. Mean values and standard deviations of the fluorescence intensity data were calculated for each treatment group and compared using analysis of variation. Differences between groups were considered significant for $p < 0.05$ using the Bonferroni correction.

RESULTS AND DISCUSSION

Increasing the shear rate increased total thrombin production at each time point. Increasing the duration of shear exposure increased thrombin production at each level of imposed shear. Surfactant addition without sparging had no effect on thrombin

production compared to baseline. Thrombin production further increased over time as a result of both level and duration of shearing following sample sparging. Thrombin production was elevated more than 3.6 fold after 20 minutes of high shear ($p < 0.005$ compared to baseline) with sparging (Figure 2). Thrombin production was also increased with sparging in the presence of surfactant (2.45 fold, $p < 0.005$ compared to baseline), but there was 44% less thrombin formed than if sparging proceeded without surfactant treatment ($p < 0.01$).

Figure 1: Fluorescence spectrum of thrombin-specific fluorogenic substrate. **Figure 2:** Relative fluorescence intensity after 20 minutes of shearing at 500 sec^{-1} . Sample preparation was A) no sparging, no surfactant, B) no sparging with surfactant, C) sparging without surfactant, and D) sparging with surfactant. * $p < 0.005$ compared to A, # $p < 0.005$ compared to C.

SUMMARY

These findings demonstrate that sparging (gas embolization) of whole blood increases thrombin production. The degree of increase of activation of clotting is both shear-rate- and time-dependent. The addition of the surfactant prior to sparging and shearing significantly reduces thrombin production. This experiment suggests surfactants may have a clinical application to attenuate blood activation caused by gas embolization.

TIBIOFEMORAL KINEMATICS AND CONTACT PATTERNS ARE ALTERED DUE TO WEAKNESS OF THE SEMITENDINOSUS AND GRACILIS MUSCLES

Michael R. Torry¹, Takashi Yanagawa¹, Kevin Shelburne¹, J.R. Steadman², W.I. Sterett²
Steadman♦Hawkins Sports Medicine Foundation¹ and Clinic², Vail, Colorado, mike.torry@shsmf.org

INTRODUCTION

Hamstring function is vital to normal knee kinematics (Kwak et al., 2000). About 21% of all ACL reconstructions use the combined semitendinosus and gracilis tendons (STG) as the graft of choice for correction of ACL deficiency (Campbell, 1998). Long-term graft harvest site morbidity of this surgical technique is controversial. Some investigators contend that the tendons regenerate (Simonian et al., 1997), others report the regeneration is incomplete (Yasuda et al., 1995). Some have reported no significant strength changes due to the harvest (Simonian et al., 1997), while others have reported a 5-20% flexor torque decrease (Yasuda et al., 1995). The only consensus is that the early rehabilitation period is characterized by a general decrease in flexor-extensor strength. We sought to understand the functional consequences of the STG ACL reconstruction on the kinematics and articular contact patterns of the knee during isometric exercises. Since it is unclear *if* or *to what extent* the strength of the STG muscles are affected by graft harvest, we simulated various levels of strength deficit of the STG muscles using a mathematical model of the knee. We hypothesized that a weakened STG muscle complex would alter knee joint kinematics and articular contact points from the baseline (full-strength STG) condition.

METHODS

The musculoskeletal knee model has been described in detail (Pandy and Sasaki, 1998; Pandy et al., 1998). The model includes the patella, tibia, and femur; 13 non-linear springs representing the major tibiofemoral ligaments; 13 muscle-tendon units spanning the tibiofemoral joint; and a model of articular cartilage (Fig. 1). Maximum isometric contractions of the hamstrings were simulated at knee flexion angles from 0° - 90° in 15° increments. Muscle weakness relative to this baseline condition was simulated by decreasing the gracilis and semitendinosus muscle activation to 90%, 75%, and 50% of baseline. Changes in tibiofemoral contact point locations, tibial rotation angle, and anterior tibial translation as a function of STG activation level are reported.

Figure 1. 3-D model.

RESULTS AND DISCUSSION

The tibia tended to rotate externally relative to the femur as the knee flexed (Fig. 2). The difference in rotation between

the baseline and reduced strength conditions was more pronounced at greater flexion angles. The tibia also moved posteriorly as flexion increased. At each flexion angle, this posterior motion was reduced when the STG muscles were weaker. The combined result of the translation and rotation of the tibia caused the medial tibiofemoral contact point to move posteriorly, while the lateral contact point moved anteromedially with increasing flexion. When the STG muscles were weakened, the medial contact point was more posterior. The STG muscles assist in internal rotation of the tibia, so weakness in these muscles reduced the internal rotation moment on the tibia.

Figure 2. Internal rotation of the tibia relative to the femur in the baseline and reduced activation conditions.

SUMMARY

Reducing the STG muscle strength has little effect on tibial kinematics at small flexion angles because these muscles primarily pull the tibia proximal relative to femur at these angles. As flexion increased, the effects of reduced muscle strength were more pronounced. The aberrant kinematics seen at larger flexion angles may adversely affect STG graft patients who use more knee flexion range of motion in their daily lives.

COMPARISON OF QUANTITATIVE MEASURES OF TREMOR AS PREDICTORS OF SURGICAL OUTCOME

Duane Morrow¹, Joseph Matsumoto², Ann Rabatin¹ and Kenton Kaufman¹

¹Motion Analysis Laboratory, Division of Orthopedic Research and ²Department of Neurology
Mayo Clinic, Rochester, MN 55905 USA

INTRODUCTION

The lasting effect of stereotactic neurosurgery in abating cerebellar tremor has not been definitively decided. It has been suggested that surgery is more effective in patients with minimal ataxia in the tremulous limb, but this is difficult to establish clinically (Alusi, 1999). While other studies have studied the frequency of tremor to classify pathologies (Spyers-Ashby, 1999), we contend that the severity or magnitude of the tremor is also necessary to predict potential surgical efficacy. The purpose of this study is to use pre- and post-surgical evaluations of three different methods used to objectively quantify tremor to assess their potential to predict surgical outcomes.

METHODS

Nine patients with clinically definite multiple sclerosis (MS) were studied. Each patient was evaluated pre- and at 3-months post-surgery using the Box and Blocks test (BB), the Clinical Tremor Rating Scale (CTRS), and Quantitative Movement Analysis (QMA). The BB test is a timed dexterity test in which the subject attempts to manipulate small blocks from one side to another of a divided box (range 0-25, worst to best). CTRS quantifies tremor amplitude as scored visually by a neurologist (range 0-26, best to worst). Developed in our laboratory, QMA quantifies tremor severity using electromagnetic sensors recording hand positions during simulated activities of daily living. QMA scores are derived from the power spectral density of hand velocity (range, 0-6, best to worst). Along with these quantified measures, a neurologist's general assessment of the surgical outcome as Excellent, Good, or Poor was recorded.

RESULTS AND DISCUSSION

Results are summarized in Figure 1 below. The pre-surgical baseline scores are plotted against their respective post-surgical improvement reflected by the change in scores.

Results of the BB test (Fig. 1A) demonstrate the severity of the tremor (few subjects could manipulate any block prior to surgery). Patients deemed to have Excellent outcomes generally showed the largest improvement in BB scores, but clearly no predictive ability exists in this test. A trend in improvement versus baseline impairment begins to be seen in the CTRS results (Fig. 1B). However, the Good and Excellent outcomes are mixed, and not clearly separated. Outcomes groups become more clearly delineated in the results of the QMA analysis. As Figure 1C) indicates, baseline values of greater than 4.25 lead to a greater reduction in tremor post surgery. It should be noted that the Poor outcome which had a baseline QMA > 4 was the result of an incomplete surgery which is included for completeness.

SUMMARY

While all three tests are useful in guiding clinical decision-making, only QMA seems to be able to predict surgical efficacy. While further studies need to be performed to confirm these findings, there appears to be a threshold in tremor severity, as measured by QMA, above which the attempt at surgical reduction of tremor is warranted.

EXPERIMENTAL QUANTIFICATION OF MUSCLE CONTRIBUTIONS TO WHOLE LIMB STIFFNESS AND STABILITY

Eric J. Perreault and Thomas G. Sandercock

Department of Physiology, Northwestern University Medical School, Chicago, IL, USA

e-perreault@northwestern.edu

INTRODUCTION

In many motor tasks, muscles act to control the limb endpoint. Successful task completion requires strength to counter external forces and stability to maintain limb posture. These simultaneous requirements can be at odds with each other. McIntyre et al. (1996) demonstrated that reaction forces directed towards the joints (e.g. ground reaction forces pointing towards the hip) interact with limb geometry to reduce limb stability. Net stability is due to these external force effects combined with the stability provided by muscles resisting these forces. The dual constraints of force and stability in 3D space may thus have important implications for the claim that vertebrate motor systems are highly redundant. There are many more muscles than degrees of freedom, and determining how muscles are selected for a particular motor task remains one of the fundamental challenges to understanding normal motor behavior (Bernstein 1967).

This study seeks to quantify the contributions of cat hindlimb muscles to the 3-dimensional force generation and stability properties of the entire limb. Our hypothesis is that anti-gravity extensors must be co-activated in with flexors to counter the destabilizing effects of ground reaction forces. The need for endpoint stabilization may explain the widespread extensor-flexor co-activation at the onset of the locomotor stance phase.

METHODS

Experiments were performed on the left hindlimb of deeply anaesthetized cats. Limb stability was quantified by endpoint stiffness: the relation between imposed limb displacements and the opposing endpoint forces (Perreault, et al. 2001). The “endpoint” was defined as the middle of the foot at the end of the metatarsals. Stiffness was estimated using a 6 DOF robot (Staubli, Inc.) and load cell (JR3), allowing characterization limb mechanics in all 6 DOF relevant to normal function. Results for only the translational DOF are presented here. Preliminary data was collected for 3 experimental conditions: passive, electrical stimulation of the triceps surae (TS) on its own, and in conjunction with the hamstrings (HAM).

RESULTS AND DISCUSSION

Figure 1 shows results for one cat. (A) shows stiffness ellipsoids and endpoint forces for all three experimental conditions. These ellipsoids depict the 3D endpoint stiffness. The long axis shows the direction in which the limb is most resistant to external perturbations of posture. For all conditions the maximal stiffness was oriented along the tibia. Stiffness magnitude increased as additional muscles were stimulated. The stiffness of the HAM could not be measured in isolation,

as HAM stimulation produced strong knee abduction, precluding comparison with the passive and TS trials. Nevertheless, limb posture was constant during HAM+TS stimulation, allowing HAM stiffness to be estimated by subtraction. HAM stiffness was unstable, as depicted in (B). This shows the endpoint force response to unit displacements in different directions (black arrows) and the ground reaction force orientation due to hamstrings activation (blue arrow). Note that the hamstrings assists endpoint displacements oriented towards the contralateral hip. These preliminary results support our hypothesis that muscles generating downward forces (leg extensors) decrease limb stability.

Figure 1: (A) Two views of the 3D stiffness ellipsoids and endpoint forces measured during each experimental condition. (B) Endpoint instability caused by activation of hamstrings.

EMBOLISM BUBBLE ADHESION FORCE IN EXCISED PERFUSED MICROVESSELS

David M. Eckmann¹ and Akira Suzuki²

¹Department of Anesthesia and Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania

²Department of Anesthesia, Hamamatsu University, Hamamatsu, Japan
deckmann@mail.med.upenn.edu

INTRODUCTION

Cerebroarterial gas embolism occurs frequently in cardiac surgery and decompression sickness. Embolism bubbles lodge in 50-200 μm diameter vessels (Branger & Eckmann, 1999), and there is no readily available clinical therapy. Determining the mechanism of binding interactions between the bubble surface and the vessel wall causing bubble adhesion is critical to the development of a specific therapy to promote dewetting (Eckmann et al, 2001), bubble dislodgement (Cavanagh & Eckmann, 1999) and accelerate reperfusion through embolized vessels (Branger & Eckmann, 2002). We measured the force required to displace bubbles lodged in excised, perfused microvessels and characterized the net adhesion force per unit surface area of bubble contacting the vessel wall.

METHODS

With Institutional Animal Care and Use Committee approval, 2nd order mesenteric arterioles were removed from adult Wistar rats. Vessels were mounted between micropipettes in a perfusion chamber (Living Systems, Burlington, VT) placed on an inverted microscope (Nikon Axiovert) connected to a CCD camera. Vessels were bathed in Ringers solution and perfused with either Ringers solution ($n = 6$) or Ringers solution containing 5% bovine serum albumin (BSA) ($n = 6$). The bath fluid and perfusate were kept at 37 °C and equilibrated with 5% CO_2 , 21% O_2 and balance N_2 . Preservation of endothelial- and smooth muscle- mediated vascular responses was confirmed by topical application of phenylephrine and acetylcholine. Flow through the vessel was stopped and an air microbubble (3-4 nl) was injected using a Drummond Nanoject instrument via a 10 μm diameter micropipette placed through the vessel wall (Figures 1 & 2). The bubble was allowed to reside intravascularly for 1, 10 or 20 minutes at which time the pressure on the perfusate inflow side was raised until the bubble dislodged. The differential pressure across the bubble, ΔP , was recorded at the moment of bubble movement. Bubble length, L , and vessel internal diameter, D , were determined from videomicrometry. The bubble adhesion force per unit surface area, κ , was calculated to be $\kappa = \Delta P D / 4L$.

RESULTS AND DISCUSSION

Table 1 shows results for κ , the adhesion force per unit area, at different durations of embolization. κ remained uniform over time in the absence of BSA but it increased with time in the

presence of BSA. At any particular time point, κ was greater in the presence of the protein than without it. This was statistically significant ($p < 0.05$, Students t-test) at 10 and 20 minutes.

Figure 2: Microscopy image of excised, embolized microvessel.

SUMMARY

The magnitude of and temporal development of the adhesion force of microbubbles to the vessel wall is highly dependent on the presence of a protein in the perfusate. This suggests an adhesive interaction between the endothelium and proteins that have adsorbed to the gas-liquid interface.

SHOCK ABSORBING POTENTIAL OF THE UNGULATE DIGITAL CUSHION

Justine Robilliard and Jeremy F. Burn¹

Department of Anatomy, University of Bristol, Southwell Street, Bristol, BS2 8EJ

¹Corresponding author: J.F.Burn@bris.ac.uk

INTRODUCTION

Metatarsal and heel pads in plantigrade and digitigrade animals play an important role in isolating the limbs from potentially damaging impact forces during locomotion. In ungulates, the digital cushion within the hoof capsule is thought to be an analogous structure but there is no scientific evidence to support this hypothesis. For the digital cushion to function as a shock absorber it must have a significant mechanical interaction with surrounding structures. Shock isolation could be provided either by visco-elastic properties of the digital cushion or by surrounding visco-elastic structures if the digital cushion were to act as a force transmitter. The aim of this study was to determine the degree to which the equine digital cushion interacts mechanically with surrounding structures and to determine its material properties.

METHODS

Cyclic loading was applied to the distal sections of five cadaveric equine limbs using a servo-hydraulic materials testing machine. The magnitude and rate of the applied load were chosen to produce limb kinematics that were equivalent to published *in-vivo* data for horses at 8m/s canter. Pressure within the digital cushion was recorded using a 2mm diameter pressure measuring needle inserted via the heels into the geometric centre of the lateral lobe of digital cushion. Force, displacement, and intra digital cushion pressure were recorded simultaneously at 200samples/sec. using a PC-based data logger.

Cylindrical specimens of digital cushion 1cm diameter and 1.5cm in length were cut from the medial and lateral lobes of five digital cushions. The specimens were loaded in axial compression using the same materials test machine both with, and without constraint on the lateral expansion of the specimens. The load applied to the specimens was derived from the pressure recorded during previous loading of the cadaveric limbs.

RESULTS AND DISCUSSION

Intra digital cushion pressure increased significantly as the limb was loaded (figure 1). The increase was non-linear and showed hysteresis between loading and unloading. The pressure rise was functionally significant and implies that the digital cushion may be involved in shock prevention.

The unconstrained isolated specimens compressed to a fraction of their original length with negligible applied stress after which stress increased with negligible decrease in the length of the specimen. This suggested the material was behaving as a liquid within its physiological strain range.

Figure 1:

The constrained samples showed a small decrease in volume for applied pressures of up to five times greater than the those recorded in the loaded cadaveric limbs. There was no apparent hysteresis between loading and unloading the constrained specimens. This indicates that the digital cushion acts hydrodynamically to transmit pressure to surrounding structures. It would further suggest that the visco-elastic behaviour observed in pressure measurements from the cadaveric limb was due to the properties of surrounding material and not the digital cushion. Further work is required to determine whether expansion of the hoof wall would account for these observations.

SUMMARY

The study investigated the potential for the ungulate digital cushion to act as a shock absorber during locomotion. Significant positive pressures were measured within the equine digital cushion during *in-vitro* limb loading. Materials testing of digital cushion specimens indicates that pressure is transmitted to surrounding structures which may act to prevent shock transients during locomotion from being propagated proximally through the limb.

REGIONAL DIFFERENCES IN CELLULAR DENSITIES IN HUMAN AND OVINE MITRAL VALVES

Kristina T. Jensen, Karyn S. Kunzelman, Kelley W. Dwyer, David W. Quick, Richard P. Cochran

Cardiothoracic Surgery and Biomedical Engineering Department, University of Wisconsin, Madison, Wisconsin, USA
karynk@surgery.wisc.edu

INTRODUCTION

Our prior work has demonstrated that procollagen and heat shock protein expression is altered in mitral valves subject to mitral regurgitation (MR) (Quick, 2001). However, little research has been done to examine the cellular distribution within the mitral valve that is responsible for this protein expression. A better understanding of the cellular distribution will lend further insight into how mitral valve remodeling occurs and how to prevent detrimental remodeling. The goal of this study was to determine if there are regional differences in cellular densities within human and ovine mitral valves.

METHODS

Mitral valves were excised from explanted human hearts from transplant recipients (n=7) and non-diseased hearts (n=2), and from sheep in a study comparing normal hearts to hearts that were surgically altered to mimic heart diseases (n=28). The anterior leaflets were trimmed of excess muscle and chordae tendineae, sectioned, mounted on microscope slides, and stained for nuclei with a standard hematoxylin protocol.

A digital image analysis system (Quick, 1999) was utilized to examine the histologic sections. At three locations along the valve (annulus, middle, and free edge), the number of nuclei and the area were determined for a two-millimeter long segment (Figure 1). From this information, the cellular density (number of nuclei per unit area) was determined for each location. Paired t-tests were done to statistically compare different locations. A significance level of $p < 0.05$ was used.

Figure 1: Three 2-mm long segments were analyzed for nuclear presents in each specimen.

RESULTS AND DISCUSSION

In the human valves, the cellular density at the free edge was significantly larger than in the middle section ($p < 0.002$) and annulus ($p < 0.001$). In the sheep valves, cellular density at the free edge was significantly larger than the middle section ($p < 0.001$) and annulus ($p < 0.001$), and the cellular density at the middle was significantly larger than the annulus ($p < 0.001$) (Figure 2).

The fibrosa, consisting of mainly collagen, is dominant at the annulus and tapers toward the free edge of the valve where the spongiosa layer (mainly GAGs) is dominant. The majority of the anterior leaflet is under tension. In contrast, the free edge of the valve, where the anterior leaflet coapts with the posterior leaflet, is mainly under compression. As a result of coaptation, which allows stress sharing between the leaflets, this region of the valve is under lower stress (Quick, 1999).

Figure 2: Cellular densities for human and ovine anterior leaflet of the mitral valves at the annulus, middle, and free edge. * $p < 0.001$ compared to annulus, ** $p < 0.002$ compared to middle, *** $p < 0.001$ compared to middle.

SUMMARY

The mitral valve is a very complex apparatus. The mechanisms for valve remodeling in response to stress have not been determined. Prior research has shown that protein concentrations change with altered stress (MR) (Kunzelman, 1998; Quick, 2001). This study suggests that regional differences in cellularity may be another possible mechanism for valve adaptation.

LOGISTIC TIME CONSTANT OF ISOVOLUMIC RELAXATION PRESSURE-TIME CURVE IN THE LEFT VENTRICLE

Junichi Araki¹, Hiromi Matsubara², Hiroyuki Suga³ and Fumihiko Kajiya¹

¹Department of Cardiovascular Physiology, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan

²Department of Cardiovascular Medicine, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan

³National Cardiovascular Center Research Institute, Suita, Osaka, Japan

INTRODUCTION

Weiss et al originally determined the time constant by fitting a monoexponential model to left ventricular (LV) pressure decrease during isovolumic relaxation after the time of peak negative value of the first derivative of LV pressure (dP/dt). The time constant derived from the monoexponential model has been widely used as an index of LV relaxation rate or lusitropism in both experimental and clinical studies, although this model has several well-recognized problems. In the present study, we proposed a logistic model and derived a "logistic" time constant (T_L) as a better alternative to the conventional "monoexponential" time constant (T_E).

METHODS

A total of 189 beats (147 isovolumic and 42 ejecting beats) were investigated in seven canine excised cross-circulated heart preparations. The conventional monoexponential model was given by

$$P(t) = P_0 \exp(-t/T_E) + P_{\text{asymptote}}$$

where $P(t)$ is an observed LV isovolumic relaxation pressure-time curve, P_0 is an amplitude constant, $P_{\text{asymptote}}$ is a nonzero asymptote, t is time after peak negative dP/dt , and T_E is the time constant of exponent that has conventionally been used as the time constant monoexponential function. Our proposed logistic model was given by

$$P(t) = P_A / (1 + \exp(t/T_L)) + P_B$$

where P_A is an amplitude constant, P_B is a nonzero asymptote, t is time, and T_L is the time constant of the exponent. We designated T_L as a logistic time constant to distinguish it from the T_E . We compared the goodness of fit of the logistic curve to the same $P(t)$ curve.

RESULTS AND DISCUSSION

We found that the logistic model fitted much more precisely all the observed LV isovolumic relaxation pressure-time curves than the monoexponential model ($P < 0.05$). The logistic model also fitted well both the time curve of the first derivative of the observed $P(t)$ (dP/dt) and the dP/dt - $P(t)$ phase-plane curve. Like T_E , T_L indicated that volume loading depressed LV lusitropism and that increasing heart rate and ejection fraction augmented it. T_L was independent of the choice of cutoff point defining the end of isovolumic relaxation; T_E was dependent on that choice (Figure 1).

Figure 1: Representative plots of observed dP/dt vs instantaneous LV $P(t)$ (phase-plane diagram). Observed data points from the time of peak negative dP/dt to the time when $P(t)$ reached the three different relaxation pressure levels. B and D are close-ups of rectangular areas in A and C.

CONCLUSIONS

We conclude that the logistic model provides a better curve fit to the LV pressure decrease during isovolumic relaxation in both isovolumic and ejecting contractions. T_L can more reliably characterize the rate of LV relaxation or lusitropism than T_E . We therefore propose T_L as a better alternative to T_E for evaluating LV lusitropism.

NUTRIENT DIFFUSION AND FLOW-INDUCED NUTRIENT TRANSPORT IN 3-D CELL-SCAFFOLD COMPOSITES

Edward A. Botchwey^{1,2}, Cato T. Laurencin², Elliot M. Levine³, and Solomon R. Pollack¹

¹Department of Bioengineering, University of Pennsylvania, Philadelphia PA, email: botchwey@seas.upenn.edu

²Center for Advanced Biomaterials and Tissue Engineering, Department of Chemical Engineering, Drexel University

³The Wistar Institute

INTRODUCTION

Studies in our laboratory have shown that the passive diffusion of nutrients within 3-D scaffolds used for *in vitro* tissue engineering of bone may be insufficient to maintain cell viability beyond 300microns. Therefore, we designed new microcarrier scaffolds for bone tissue engineering in a rotating bioreactor(Botchwey, et al. 2001). The purpose of this study was 1) to characterize the efficiency of passive nutrient diffusion to bone cells within our 3-D scaffolds under static culture conditions and 2) to quantify internal fluid perfusion and flow-induced nutrient transport to cells within the scaffolds during bioreactor rotation.

METHODS

We have developed a one-dimensional model to evaluate glucose diffusion within our cylindrical 3-D microcarrier scaffolds. In the absence of flow, diffusion within the scaffold is given by:

$$D\sigma \frac{\partial^2}{\partial x^2} C(x) = Q(x), (1) \text{ where } Q(x) = \frac{N\hat{R}}{nL}, (2)$$

$Q(x)$ is the rate of glucose consumption as a function of pore length x and all other terms are defined in Table 1 along with their sources. The boundary conditions are given by:

$$C_0 = C(0) \text{ and } \frac{\partial}{\partial x} C\left(\frac{L}{2}\right) = 0, (3)$$

C_0 represents media glucose concentration at the exterior boundary of the scaffold. Symmetry of glucose concentration within the pores results in the 0 value of the derivative. The solution to the boundary value problem is given by:

$$C(x) = C_0 - \frac{N\hat{R}}{2Dn\sigma L}(Lx - x^2), (4)$$

Fluid flow rate through the pores during bioreactor rotation was calculated using Darcy's law, given by:

$$U = -\left(\frac{K}{\eta}\right)\frac{\Delta P}{L}, (5) \quad K = \frac{\varepsilon \delta^2}{96\eta\tau^2}, (6)$$

where K is Darcy's permeability for the scaffold. Assuming uniform cell density within the pores, the decrease in nutrient concentration per incremental length, Δx , is given by:

$$Q(\Delta x) = \frac{N\hat{R}\Delta x}{\sigma U}, (7)$$

Parametric analysis of fluid perfusion through the scaffold was performed as a function of pore size, pore volume, and pore channel tortuosity.

RESULTS AND DISCUSSION

Based on the geometry and pore architecture of 3-D scaffolds used for tissue engineering of bone by our laboratory and

Table 1. Physical Data and Nomenclature

$D = 6.6\text{e-}10$	Diffusivity of glucose (m^2/s) [3]
$\hat{R} = 1.6\text{e-}14$	Single osteoblast rate of glucose consumption (g/s) [4]
$L = .0025$	Length of the cylindrical scaffold (m) [1]
$N = 10000$	Total number of cells within the scaffold [1]
$\eta = 0.799\text{e-}3$	Dynamic Viscosity (kg m-1 s-1) [2]
$\Delta P/L = 7.9\text{e}4$	Pressure gradient across the scaffold (N m) [2]
n	Total number of cylindrical pores [1]
σ	Cross-sectional area of an individual pore [2]
ε	Fluid volume fraction of the Scaffold [2]
δ	Median pore diameter of the Scaffold[2]
τ	Tortuosity (pore path length per unit scaffold thickness) [2]

others(Ishaug-Riley, et al. 1998; Botchwey, et al. 2001; Botchwey, et al. 2002), our results showed that passive glucose diffusion was insufficient to maintain minimum glucose concentration beyond a depth of 300 μm within the pores of the scaffold. This result is consistent with experimental observations of osseous tissue ingrowth within 3-D scaffolds proposed for bone tissue engineering. Values of internal fluid perfusion within 3-D microcarrier scaffolds were calculated based on scaffold properties (Table 1) and motion analysis previously reported(Botchwey, et al. 2001). Internal flow rate increased linearly with pore volume from a maximum of approximately 0.01m/s to 0.001 m/s. Variation in pore diameter in the range required for tissue ingrowth, namely 100 to 300 μm , produced a range of internal fluid flow rates from 0.002 to 0.011 m/s respectively. In the range of tortuosity ($\tau = 1\text{-}3$) describing most porous materials, internal flow rates ranged from 0.008m/s to 0.002 m/s. Flow-induced glucose transport with uniform consumption by N cells (as above) within pores indicates that a minimum internal flow rate of $3.1\text{x}10^{-4}$ m/s is required to maintain minimum concentration within the pores of the scaffold. Our studies of tissue ingrowth within these microcarrier scaffolds in the rotating bioreactor have shown no depth limitations to tissue ingrowth. In our ongoing studies, we are examining the effect of flow induced nutrient transport on glucose metabolism in culture. These studies will also examine the effects of both 3-D culture and media flow on gene expression and mineralized matrix synthesis *in vitro*.

SUMMARY

This model provides an excellent vehicle for the study of *in vitro* bone tissue synthesis under physiologically relevant 3-D flow conditions.

THE EFFECT OF PLATE DESIGN, ENDPLATE PREPARATION AND BONE MINERAL DENSITY ON IMMEDIATE STABILIZATION IN AN ANTERIOR CERVICAL PLATE FIXATION MODEL

Marcel Dvorak¹, Tobias Pitzen², Qingan Zhu¹, Jeff Gordon¹, Charles Fisher¹, Thomas Oxland¹

¹Department of Orthopaedics, University of British Columbia, Vancouver, British Columbia, Canada, toxland@interchange.ubc.ca

²Department of Neurosurgery, University of Saarland, Homburg, Germany

INTRODUCTION

There are two conceptual anterior plate designs in the cervical spine: a 'rigid' screw-plate design and a 'dynamic' design that allows sliding between the screw and plate. The effect of these different plate designs on spinal flexibility has not been analyzed in a cadaveric model (Brodke 2001), particularly with reference to the effects of variables such as endplate preparation and vertebral bone density. The objective of this study was to evaluate spinal stabilization provided by the two different plate designs. Endplate preparation for bone graft fusion and load shared by the plate were also considered in the present study.

METHODS

Nine cadaveric cervical spines were dissected into twenty-four functional spinal units. Bone mineral density of vertebral bodies was measured using DEXA. All specimens were randomly divided into four groups according to the combination of anterior plates (CSLP plate by Synthes and ABC plate by Aesculap) and endplate preparation (with and without endplate). Each specimen was injured by dissection of all posterior elements followed by anterior plate fixation with bone graft. A strain gauge was glued onto the plates and calibrated under an isolated pure bending moment. Flexibility testing was conducted in flexion-extension, lateral bending and axial rotation on each specimen for the intact and anterior plate condition by the application of a pure moment at 1°/sec to a maximum of 1.5Nm. Ranges of motion (ROM) and neutral zones (NZ) were calculated to compare the cervical spine fixations. A general linear model with multi-ANOVA was used to analyze effect of plates and endplate preparation, and load sharing between the two plates.

RESULTS AND DISCUSSION

There was no significant effect of plate design on flexibility except in extension, where the ABC plate reduced ROM compared to CSLP ($p=0.03$, Figure 1). There was no significant difference in the NZ or ROM between the two endplate preparation techniques in any direction. ABC shared 13% of bending moment, which is less than 39% shared by CSLP plate in flexion-extension. ROM correlated significantly with BMD in flexion and axial rotation, and NZ in flexion-extension and axial rotation (Figure 2).

Figure 1: Effect of plates and endplate preparation on ranges of motion.

Figure 2. Correlation between bone mineral density and the range of motion in flexion.

SUMMARY

The two different designs of anterior plates in the cervical spine provided similar stabilization to the spine with the sole exception being the enhanced stabilization from the ABC plate in extension. Possibly, this was an effect of the increased load sharing role of the interbody bone graft, which was a clear difference between the two designs. The bone mineral density was clearly an important factor in the degree of stabilization achieved, regardless of the method of fixation.

SOCKET COMFORT AND PERCEIVED FUNCTIONAL ABILITY IN UNILATERAL TRANSTIBIAL AMPUTEE PATIENTS USING PLASTER-CAST AND CAD/CAM MANUFACTURED SOCKETS

M. Alvarez¹, J.L. Ronsky², R. Aggarwala³, J. Harder⁴, R.F. Zernicke¹

Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada

¹Human Performance Laboratory, Faculty of Kinesiology, mjalvare@ucalgary.ca, ²Department of Mechanical & Manufacturing Engineering, ³Department of Mathematics & Statistics, ⁴Department of Surgery, Alberta Children's Hospital, Calgary, Alberta

INTRODUCTION

Quality of life for a transtibial amputee is partially dictated by the way a prosthesis limb allows them to perform normal daily routines and sustain self-sufficiency. Problems with fit and ultimately comfort have impeded acceptable daily functioning and accentuated physical disability (Burgess, 1981; Sanders, 1986). Legro and colleagues (1999) found that lower limb amputees rated the ability to walk and proper fit as the most important function and characteristic of a prosthesis. The objective of this research study was to assess quality of life and functional levels of Canadian unilateral transtibial amputees and evaluate whether they were a function of socket manufacturing techniques. These objectives were met through a questionnaire developed at the University of Calgary.

METHODS

This research study is a descriptive study involving a cross-sectional survey of the adult unilateral transtibial amputee population. Nonprobability sampling was used to recruit subjects. Purposive sampling from 10 sites across 6 provinces was the primary method of subject recruitment. Subjects were assigned to one of three groups based on method of socket manufacturing: (1) Always used plaster-cast method; (2) Always used CAD/CAM method; and (3) Switched from plaster-cast to CAD/CAM method. The inclusion criteria specified that participants had to: (1) be at least 18 years of age; (2) have a unilateral transtibial amputation one or more years earlier; (3) have no other major physical limitations; and (4) provide informed consent. Each subject completed two quality of life questionnaires during two separate telephone interviews, the SF-36 and the Selected Aspects of Quality of Life for Canadian Unilateral Transtibial Amputees developed at the University of Calgary.

RESULTS

Of the 102 patients who completed both questionnaires, 35 were assessed in the Always Plaster-cast group, 7 in the Always CAD/CAM group, and 11 in the Plaster to CAD/CAM group. The mean age of the total sample was 57.40 (+/- 14.44). Seventy-nine percent of the total sample was male.

One-way ANOVA revealed there were no significant differences between groups in their satisfaction with comfort while walking ($p=0.56$), comfort while running ($p=0.62$), and appearance of their gait ($p=0.37$). All subjects in the Always CAD/CAM group reported that they did not run with their prosthesis. Sixty-four percent of the total sample responded similarly.

Participants who only used a CAD/CAM socket reported significantly lower scores compared to those who only used a plaster-cast socket in terms of their perceived ability to walk inside their home, walk outside on uneven ground, walk on

slippery surfaces, use an escalator, stepping up a sidewalk curb, and go up a few steps without a handrail ($p<0.05$). Amputees who switched from plaster-cast sockets to CAD/CAM sockets reported significantly higher scores than those who only used a CAD/CAM socket in the areas of walking inside their home, walking in crowded rooms and narrow spaces, walking outdoors on uneven ground and slippery surfaces, stepping up a sidewalk curb, going up and down steps without a handrail, and walking as quickly as they needed to ($p<0.05$). There was no significant difference between the three groups in the areas of walking outside on even ground, going down a few steps without a handrail, and stepping down a sidewalk curb. No significant difference was found between the Always Plaster-cast group and the Plaster to CAD/CAM group (Figure 1).

Figure 1. Subscale scores of perceived functional ability for three groups of transtibial amputees ($\alpha<0.05$). Walking items: 1=inside home, 2=crowded room, 3=narrow spaces, 4=outside, even ground, 5=outside, uneven ground, 14=walk as quickly as needed. Balance items: 6=slippery surfaces, 7=up steps with rail, 8=down steps with rail, 9=escalator, 10=step up curb, 11=step down curb, 12=up steps, no rail, 13=down steps, no rail.

Stepwise linear regression analysis revealed that walking capacities could significantly predict success with activities related to balance such as climbing stairs ($r^2=0.59$).

CONCLUSIONS

Preliminary results showed that amputees who had always used a CAD/CAM socket seemed to have lower perceived locomotor functional abilities than persons who currently use or have used plaster-cast sockets. Since five out of the seven persons in this group were greater than 65 years of age, this may have been related to age.

INFLUENCE OF SEGMENT RIGIDITIES ON GROUND REACTION FORCES DURING LANDING

Rhonda L. Boros and John H. Challis

Biomechanics Laboratory, Department of Kinesiology, The Pennsylvania State University, University Park, Pennsylvania, USA

E-mail: rlb248@psu.edu

INTRODUCTION

Vertical ground reaction forces (VGRF) realized during landing from a drop range in magnitude from 2 to 14 times bodyweight, depending on the height dropped and point of initial contact (e.g. on toes or heels). Dissipation of energy has typically been attributed to shoe and heel pad material properties and joint kinematics/kinetics. Landing impact, locomotion, and jumping studies have traditionally utilized a rigid-body model in determining joint kinetics and material deformation properties of the heel pad, substantially increasing the potential for error in estimates of joint loading (Gruber et al., 1998).

The influence of soft tissue motion on VGRFs during landing however is still being explored, and only recently have wobbling mass models appeared in the impact biomechanics literature. Few however account for accurate distribution of the segmented soft tissue (e.g. greater skeletal mass than soft tissue mass in the thigh). The initial point of impact during many footfalls is the heel pad, yet to date studies have tended to ignore these properties therefore eliminating force dissipation effects below the ankle. The purpose of this study was to design a wobbling mass model to predict VGRF profiles obtained experimentally during landing from a drop, and to use this model to explore rigid and soft tissue contributions to the VGRF.

METHODS

A wobbling mass model was formulated in Working Model 2D (version 5.0, Knowledge Revolution, San Mateo, CA) in an effort to predict VGRF trace profiles obtained experimentally from a single subject landing from a 0.4m drop. The heel pad, foot, shank, thigh, torso and 6 wobbling masses were modeled as various mass-spring-damper systems.

A single female subject, (height-1.59m, mass-65.2kg), performed five flat-footed landings from a hanging position, landing with both feet simultaneously on a force platform (720 Hz). Knee, hip and arm motion was not constrained once the subject released from the bar, and the subject was instructed to maintain a relatively upright posture (e.g. head up watching the wall). Anthropometric measures were obtained and segmented soft tissue and skeletal masses for head/trunk/arms, thigh, and shank/foot were determined (Clarys and Marfell-Jones, 1986), and a visceral mass estimate of 9 kg (Minetti and Belli, 1994) served as inputs into a wobbling mass landing model. Time-frequency analyses of experimental and model predicted VGRF traces were performed in MATLAB 5.3.

RESULTS

The experimental mean peak VGRF was 6.7 ± 0.2 body weights (BW), with peak forces occurring 0.0183 ± 0.0081 s after initial impact. Power spectral density analysis of the VGRFs revealed 95% of the signal power occurred below a frequency of 23.5 ± 3.5 Hz. Analysis of the first 40 ms only revealed signal power several orders of magnitude greater (mean and 95% frequencies of 39.7 and 229.4 Hz).

Wobbling mass simulations replicated mean peak VGRF within one standard deviation (6.5 BW). Power spectral density analysis of the simulated VGRF revealed a peak frequency of 8.1 Hz, with 95% of the signal power lying below a frequency of 13.2 Hz. Analysis of the first 40 ms of the simulated signal revealed a mean frequency of 83.4 Hz and substantial signal power up to 314.4 Hz. The rigid feet (57.1 and 289.2 Hz) and torso (24.3 and 170.4 Hz) elements had mean and 95% frequency components nearest to the experimental data (39.7 ± 17.6 and 229.4 ± 56.1 Hz) for the first 40 ms of landing impact. The motion of these model components is therefore considered to substantially contribute to the high frequency “impact” portion of the VGRF curve. Frequency components for the wobbling masses for the first 40 ms of impact were similar, ranging from 59.9 to 131.9 Hz (mean) and 294.0 to 333.6 Hz (95%), however were out of phase with the rigid model components.

DISCUSSION

The data indicate 37.5% of modeled total mass was associated with soft tissue components. Combining all of the mass into “rigid” segments resulted in a 4.4% increase in peak VGRF and a slight shift in the time frequency plot. Considering that the mean frequency content for the rigid and wobbling mass segments were similar, and peak VGRF was greater without the wobbling masses, it can be argued that in vivo the relative motion of the rigid and wobbling masses is opposite in phase and therefore the combined rigid/soft tissue motion is conducive to force attenuation, not just for VGRF but also joint loads.

THE EFFECT OF A NOVEL CAGE DESIGN ON STABILIZATION IN THE LUMBAR SPINE

Michael Johnson¹, Qingan Zhu¹, Andy Sennett², Marcel Dvorak¹, Charles Fisher¹, Thomas Oxland¹

¹Department of Orthopaedics, University of British Columbia, Vancouver, British Columbia, Canada, toxland@interchange.ubc.ca

²Cortek Inc. Boston, Massachusetts, USA

INTRODUCTION

Spinal interbody cages provide good stabilization to the lumbar spine, but their ineffectiveness in extension has been noted (Lund 1998, Oxland 2000). To address this point, a novel interbody cage has been developed with a dovetail feature to “lock” adjacent vertebral bodies, particularly in distraction. The objective of this study was to determine if the design modification of a dovetail results in improved immediate three-dimensional spinal stabilization, compared to an identical cage without the dovetail.

METHODS

Eight cadaveric specimens (L4-L5) were used. Each specimen was subjected to a flexibility test in flexion-extension, lateral bending and axial rotation with pure moments ($\pm 5.0\text{Nm}$). The test was performed for the intact specimen and after anterior Dovetail and non-Dovetail interbody cage insertion (Cortek, Boston, MA) (Figure 1). The positions of the vertebral bodies were monitored using an optoelectronic camera system (Optotrak 3020, Northern Digital, ON). Neutral zone (NZ) and range of motion (ROM) were calculated. Paired Student's t-test was used to determine the effect of cage design on the spinal stabilization.

Figure 1: Anterior view of the dovetail implant in a specimen. Note the “dovetail” feature against the vertebra within the grey circle.

RESULTS AND DISCUSSION

The ROMs decreased significantly following Dovetail or non-Dovetail cage fixation in all directions, as well as NZ in lateral bending. The ROM ratios to intact with Dovetail and non-Dovetail fixation were 0.73 and 0.80 in flexion, 0.72 and 0.73

in extension, 0.46 and 0.54 in lateral bending, and 0.71 and 0.80 in axial rotation, respectively, with the only significant difference being in lateral bending ($p=0.038$) (Figure 2). The NZ ratios to intact with Dovetail fixation were close to those with non-Dovetail fixation.

Figure 2: Ranges of motion of L4-L5 segment with Dovetail and Non-Dovetail cage.

SUMMARY

Recent questions regarding spinal stabilization with various interbody cage designs, especially in extension, have been raised from biomechanical testing. It was notable that the Dovetail design feature did not reduce motion in extension more than the non-Dovetail cage. Of interest was that the degree of stabilization in extension for both cages was better than the intact spine, which has not been observed previously [Lund 1998, Oxland 2000]. Of note was that Dovetail cage provided more stabilization to the spine in lateral bending.

HUMAN PERFORMANCE-BASED PEDIATRIC WHEELCHAIR PRESCRIPTION

Jeremy Carrle and Dave Hawkins¹

Human Performance Laboratory, University of California, Davis, CA, USA

¹email: dahawkins@ucdavis.edu

INTRODUCTION

Mobility impaired children need appropriately designed and configured wheelchairs. Configuration guidelines exist for adults but little work has been done to establish appropriate guidelines for children (Brubaker, 1986). It was hypothesized that the propelling capabilities of pediatric wheelchair users could be predicted and improved using biomechanical analysis and testing. Wheelchair wheels were tested to determine the forces required to initiate movement of a pediatric wheelchair. A static mathematical model and experimental testing techniques were utilized to identify the required joint torques in the initial pre-movement phase of the push. A model that evaluates the force produced in various seating positions is being developed based on results from these analyses and validated with human subjects.

METHODS

The forces required to initiate movement of a pediatric wheelchair were experimentally measured and validated for 6 wheels on 3 surfaces (described previously Carrle and Hawkins, 2001)

A static model of a pediatric wheelchair and child was developed to assess a child's ability to self-propel and to determine the optimal wheelchair configuration for that child. The model uses child-chair specific data (body segment lengths, wheel type, ground material, age, weight, and maximum voluntary contraction (MVC) joint torques) to predict the force required to initiate movement, to determine the maximum force that the child can produce on the handrim, and to identify the effect variations in model parameters (force direction, hand position, torso angle, and the distance from the hip to the wheel hub) have on the child's ability to produce this force. Relative information regarding seat position is extracted based on the average force produced over a range of hand positions and torso angles. The validity of the model is being tested using pediatric subjects (5 wheelchair users and 5 able-bodied), ages 3-7. Forces on the handrim of a simulated-stationary wheelchair and joint positions are recorded for each trial using a force plate and a video-based motion analysis system respectively.

The final aspect of the project involves the development of guidelines and/or software to assist in pediatric wheelchair prescription. Guidelines will be evaluated with the help of pediatric wheelchair specialists.

RESULTS AND DISCUSSION

Model predictions of optimal seating configuration are consistent with common practice of wheelchair dealers and are being compared to experimental results. The maximum force that can be applied at the handrim is highly dependent on the direction of the force and the hand position on the handrim. Regardless of seat and torso position, some hand positions and force directions make it difficult to impart a force tangential to the handrim without putting a large moment on the shoulder. The model predicts that seat positions that are lower and farther behind the traditional seat position tend to increase the child's ability to produce handrim force. Physical therapists that perform wheelchair evaluations agree that forward configurations are better in situations with small children. The elbow and shoulder limit force production in most positions, except when the shoulder and elbow are directly in line with the force vector.

Preliminary results from testing three children in 6 to 10 seat positions indicate that the maximum joint torques attainable, during a simulated-static wheelchair test, can be predicted with the MVC strength tests. The average torques measured during the simulated-static wheelchair test were 97% of max values (standard deviation of 36%).

Model results (propelling force at the handrim) were on average 41N different than the model values. The differences are largely due to the disproportionately greater error in the forward-wheel configuration. Efforts are being undertaken to understand this difference and improve the model.

SUMMARY

A new approach is being developed to facilitate pediatric wheelchair prescription by determining a child's ability to self-propel and by identifying an appropriate style of wheelchair and seating configuration based on the child's anatomy and joint strength.

INVESTIGATION OF CEMENTLESS CUP MICROMOTION AND STABILITY AFTER TOTAL HIP ARTHROPLASTY

Luke Aram¹, Andy Lehman², Paul Lewis³, Todd Render³, Jorge Ochoa³, Farid Amirouch¹, and Mark Gonzalez²

University of Illinois at Chicago, Dept of Mechanical Engineering¹ and Orthopaedic Surgery², Chicago, IL, USA amirouch@uic.edu
DePuy Orthopaedics, Warsaw, Indiana, USA

INTRODUCTION

The objective of this study is to investigate the initial stability of cementless cup hip prosthesis as a function of the patients bone density and body weight in a cadaver model. The main focus is to address the combined axial and torsional loading of the artificial hip in relation to the joint stability and the patient's bone density.

Initial implant fixation is essential to the success of a total joint. Basic functions like climbing stairs and standing from a chair can eccentrically load the hip prosthesis and produce a torque on the acetabular cup (Dennis, Komistek, et. al. 2001). This torque results in a shear force across the bone prosthesis interface that produces hip micromotion (HMM). Micromotion greater than 50 to 100 microns is known prevent bone ingrowth into a porous cup (Jasty, Bragdon, et.al. 1997). The obvious and most common solution to this is to use an adjunctive screw to affix the cup to the acetabulum. However, screw holes are direct pathways for polyethylene wear particles to enter the bone-cup interface. These particles are phagocytosed by macrophages that in turn release an array of cellular mediators that are capable of inducing cell proliferation, promoting osteoclast formation, and resorption of adjacent bone.

METHODS

Seven fresh-frozen cadaver pelvises were cleaned of all soft tissues. The femoral necks were then chosen for DEXA scans. Next, uncemented cups were placed into each of the acetabula with 2mm of underreaming in relation to the cup. Pinnacle cups were then chosen. The acetabulum was then potted in a metal box, eliminating viscoelastic deformation of the pelvis relative to the sensors.

A custom jig was designed that applies both torque and axial force to the prosthesis similar to that produced inside the body. A lever arm was set to 2-cm, simulating an impingement on the rim of the cup 2-cm from the center. One hundred cycles of loading at 200-N and 4-N/m was applied to each pelvis. The loading was incremented by 100-N and 2 N-m until the interface failed. Six LVDT displacement sensors were arranged around the cup in order to measure HMM in five degrees (3 displacements and 2 rotational). The LVDT sensors measure linear motion with 1-micron repeatability. Each sensor was calibrated with a 25-micron gap gauge.

Figure 1: A photograph of the experimental setup used to both load the hip and record micromotion.

RESULTS AND DISCUSSION

The amount of torque necessary to create micromotion of 50 and 100 microns was then recorded. Also between 150 and 250 microns, we noticed a failure of the interface. At this point, plastic deformation was evident. Permanent deformation was noticeable, as the prosthesis did not return to its original position. Also, a constant loading cycle produced an increasing deformation until the interface failed. The force and torque at failure was also recorded.

SUMMARY

Most surgeons agree that if the bone quality is good enough, a press-fit prosthesis without adjunctive screw is the optimal approach. However, most surgeons cannot make a bone quality assessment until the prosthesis is already in place. Therefore, uncemented prosthesis with adjunctive screw holes still remains popular.

The purpose of this project is to correlate resistance to shear of the interference fit with the bone density of the acetabulum. This data is useful when addressing shell / bone interface and the need of future fixation such as adjunctive screws.

AN ANALYTICAL DESCRIPTION OF KINEMATIC CROSTALK

Scott Landry and Kevin Deluzio

The Dynamics of Human Motion Laboratory, School of Biomedical Engineering, Dalhousie University, Halifax, Canada

Communicating author, landrys@is2.dal.ca

INTRODUCTION

Kinematic crosstalk is a form of error associated with the measurement of joint angles and it occurs when the chosen joint coordinate system is not aligned with the true rotation axes of a joint. In the knee for example, misalignment of the flexion axis or joint coordinate axes results in significant ab/adduction and int/external rotation angle error. Kadaba et al (1990) and Piazza et al (2000) have made reference to this error and stated that the error was related to the amount of axis misalignment and the degree of flexion. Kinematic crosstalk has also been revealed through correlation between the measured joint angles. Deluzio (2001) proposed using principal component analysis (pca) with a mechanical model to eliminate crosstalk and identify the true joint axes of rotation. No study, however, has been able to determine an analytical description of this crosstalk-induced error.

The purpose of this study was to use simulation to: i) create a numerical model capable of introducing crosstalk, ii) find an analytical equation to describe the resulting measurement error caused by crosstalk and iii) investigate the use of pca in eliminating the effects of crosstalk.

METHODS

A numerical model was created to simulate kinematic crosstalk through misalignment of a fixed coordinate system (MatLAB). A joint coordinate system was established for both a fixed and moving body, with the moving body undergoing rotation from -180° to 180° about a true flexion axis. Due to the order dependence of calculating Cardan angles, misalignment of the flexion axis has the greatest effect on crosstalk. To misalign the flexion axis anywhere in space, two ordered rotations were performed (Figure 1). Each rotation was chosen in increments from $\pm 15^\circ$ in 5° steps and once positioned, the misaligned joint coordinate system was used to calculate the three crosstalk Cardan angles for the known motion.

Figure 1: Misaligning flexion axis to a desired orientation using ordered rotations of δ_1 and δ_2 about the K and L axes, respectively.

A principal component analysis of the three crosstalk angles (Deluzio, 2001) was performed to determine if the orientation of the true flexion axis could be found using the first eigenvector, thereby eliminating the effects of crosstalk.

RESULTS

Misalignment of the fixed body joint coordinate system with respect to the true flexion axis of the model resulted in kinematic crosstalk. The introduced angle measurement errors were observed to be sinusoidal in nature and dependent on the degree of axis misalignment and flexion angle. The analytical functions describing the crosstalk errors for ab/adduction and int/external rotation were found to be:

$$\text{error}_{\text{ab/adduction}} = \delta_1 \times \sin(\theta) - \delta_2 \times \cos(\theta)$$

$$\text{error}_{\text{int/external rotation}} = -\delta_2 \times \sin(\theta) - \delta_1 \times \cos(\theta)$$

where: δ_1 - misalignment of axis in transverse plane ($^\circ$)

δ_2 - misalignment of axis in frontal plane ($^\circ$)

θ - flexion angle ($^\circ$)

errors - difference between true and crosstalk angles

The application of pca to the crosstalk angle measurements was able to identify the single degree of freedom motion. Also, for small symmetrical flexion/extension angles (i.e. $\sin \theta \approx \theta$) pca was able to determine the orientation of the true flexion axis with respect to the misaligned axis.

DISCUSSION

While the dependence of crosstalk error on flexion angle and axis misalignment has previously been stated (Kadaba et al, 1990 and Piazza et al, 2000), this study represents the first time that an analytical model has been described to explain this error. The analytical solution describes the error in ab/adduction and int/external rotation in terms of the flexion angle and the amount of axis misalignment in both planes. The technique of pca also proved to be effective, with the analytical model explaining some of the limitations of using pca to correct for crosstalk error.

This analytical description for crosstalk-induced angle measurement error completely specifies the effects of this error and offers the potential for the development of techniques to correct for it.

IN VIVO INTRACARDIAC HEMODYNAMICS: DOES FLOW INFLUENCE MORPHOLOGY?

Jay R. Hove, Reinhard W. Köster, Arian S. Forouhar, Gabriel Acevedo-Bolton, Scott E. Fraser and Morteza Gharib

Correspondence should be addressed to jhove@caltech.edu

INTRODUCTION

In vitro studies on cultured cardiac endothelial cells have shown that fluid-mechanical forces induce changes in cellular morphology through cytoskeletal rearrangement as well as changes in the gene expression profile. To link these *in vitro* data to the intact heart, a quantitative *in vivo* analysis of intracardiac flow forces is necessary. In this presentation we will describe real-time *in vivo* imaging of intracardiac blood flow within the beating hearts of living zebrafish embryos and describe the development of hearts where the natural hemodynamic milieu has been experimentally altered.

METHODS

Two embryonic stages of the zebrafish (*Danio rerio*) were chosen for their distinct heart morphologies: 4.5 days post fertilization (dpf) and 37 hours post fertilization (hpf). Pigment-blocked zebrafish embryos were lightly anesthetized and immobilized in ultra-low gelling agarose.

Gross cardiac dynamics were defined using high-speed transmitted light microscopy with valve dynamics visualized through high-speed laser-scanning microscopy on transgenic embryos expressing GFP. Blood flow patterns were identified by fluorescent labeling of blood serum (Bodipy-Ceramide) and observing the trajectories of dark, streaking erythrocytes. Fluid forces were more precisely quantified using real-time cine imaging of the flow at 440 frames·sec⁻¹ and digital particle image velocimetry (DPIV) to calculate the velocity vector fields and circulation patterns generated by moving red blood cells.

To test the possible influences of flow through the heart on its development, we implanted 50 µm glass beads into the inflow/outflow tracts of 57 hpf embryos and examined the resulting cardiac development.

RESULTS AND DISCUSSION

In the valved 4.5 dpf embryos we discovered a highly dynamic flow environment with high-speed (0.5 cm·s⁻¹) jets and swirling vortices (Fig. 1). Ejection fractions were calculated at nearly 60%, surprisingly close to that of the adult human left ventricle. Viscous flow at these speeds, within such small structures yields enormous wall shear stresses (>75 dyne·cm⁻²). Valveless 37 hpf hearts showed jets with velocities

approaching 1.5 mm·s⁻¹ yielding wall shears of 2.5 dyne·cm⁻². Blockage of the inflow tract (in front of the sinus venosus) or outflow tract (ventriculo-bulbal constriction) showed severe regurgitation of blood inside the heart with shear forces reduced 8-10 fold over controls. Among the more striking effects of the procedure was retarded cardiac looping and malformation of the third chamber (bulbus arteriosus).

Figure 1: High-velocity circulation and blood jet Generated in the 4.5 dpf embryonic zebrafish heart during ventricular systole. Contour colors are indicative of vortical strength and direction of rotation.

SUMMARY

We conclude that the physiology and development of the embryonic heart is linked by hemodynamics. We have shown that intracardiac wall shear stress reaches significant levels above cellular sensitivity even at primitive heart stages early in embryogenesis. Interference with intracardiac hemodynamics through physical blockage results in severe cardiac malformations. Our findings underscore the importance of examining the interplay between genetics and epigenetic factors in analyzing pathogenesis of embryonic vascular defects and cardiovascular disease.

APPLICATION OF A NONLINEAR MODEL TO DESCRIBE LIGAMENT BEHAVIOR

Paolo P. Provenzano¹, Roderic S. Lakes², David T. Corr¹, Ray Vanderby Jr.¹

¹Orthopedic Research Laboratories, Dept. of Biomedical Engineering and Orthopedic Surgery, ²Dept. of Biomedical Engineering and Engineering Physics, University of Wisconsin, Madison, WI, USA, vanderby@surgery.wisc.edu

INTRODUCTION

Recent experiments in rat medial collateral ligament (MCL) revealed that the rate of stress relaxation is strain dependent (Provenzano *et al.* 2001). This nonlinear behavior requires a more general description than the separable quasi-linear viscoelasticity (QLV) theory commonly used in tissue biomechanics since QLV will predict the same relaxation rate regardless of strain magnitude. The purpose of this study was to determine whether the nonlinear Modified Superposition formulation (often called nonlinear superposition) could adequately model the strain dependent stress-relaxation behavior of ligaments.

ANALYSIS

The single integral formulation of the Modified Superposition method (Findley *et al.* 1976) allows the relaxation function to depend on strain level:

$$\sigma(\epsilon, t) = \int_0^t E(t - \tau, \epsilon(\tau)) \frac{d\epsilon(\tau)}{d\tau} d\tau. \quad (1)$$

The form of the relaxation function will be chosen as a strain-dependent power law: $E(\epsilon, t) = A(\epsilon) t^{B(\epsilon)}$. The function $A(\epsilon)$ represents the initial modulus (E_0), obtained from a stress-strain or isochronal curve describing the nonlinear elastic behavior. The function $B(\epsilon)$ describes the strain dependent rate of relaxation and can take the form $B(\epsilon) = g(\epsilon)n_0$, where n_0 is some initial relaxation rate and $g(\epsilon)$ accounts for strain dependent nonlinearity in rate. Considering the strain history to be controlled by a Heaviside step Eq 1. becomes : $\sigma(\epsilon, t) = E_0 \epsilon t^{g(\epsilon)n_0}$. In addition, a more complex strain history function will be examined. A sinusoidal strain history of the form: $\epsilon(t) = 0.5\epsilon_0[1 - \cos(\alpha\pi t)]$ (ϵ_0 = strain amplitude and $\alpha = 2X$ frequency). The resulting form of Eq. 1 is:

$$\sigma(\epsilon, t) = \frac{\pi\alpha\epsilon_0}{2} \int_0^t A(\epsilon)(t - \tau)^{B(\epsilon)} \sin(\alpha\pi\tau) d\tau. \quad (2)$$

The model will be fit to experimental data from Provenzano *et al.*, 2001. To the authors' knowledge no tests exist revealing strain dependent relaxation behavior during cyclic testing. Hence, Equation 2 demonstrates model behavior only.

RESULTS AND DISCUSSION

Modified superposition theory fits the data well for all strain levels (Fig. 1). Application of the model resulted in σ_0 values of 1.45, 5.72, 10.10, and 15.25 MPa for 0.82, 1.74, 2.38, and

3.74% strain, respectively, capturing elastic nonlinearity. The rate term, $B(\epsilon)$, decreases as strain increases (-0.14, -0.054, -0.026, and -0.012 for 0.82, 1.74, 2.38, and 3.74% strain, respectively) capturing nonlinearity in the rate of relaxation.

Fig. 1: Application of Modified Superposition (lines) to experimental stress relaxation (points) for testing at various strain levels in a single rat ligament. $R^2 = 0.91, 0.91, 0.96$, and 0.95 for $\epsilon = 0.82\%, 1.74\%, 2.38\%$ and 3.74% , respectively.

For Eq. 2 the function $A(\epsilon)$ was determined from a typical σ - ϵ curve and $B(\epsilon)$ was obtained by fitting rate data over a range of strains (~ 0.25 - 5.0%). The peak stresses at a constant frequency factor display strain-dependent behavior, although to a lesser extent than seen with constant strain (Fig. 1). When examining model behavior over one order of magnitude of frequency ($\alpha = 0.1$ to 1.0), initial stress increased. Relaxation rate, increases with increasing frequency. Hence, the model predicts that relaxation rate is both strain and frequency dependent.

SUMMARY

Modified superposition theory describes nonlinear stress relaxation behavior well and allows a single modulus to account for differences in relaxation rate with strain.

MECHANICAL PROPERTIES OF CARTILAGE SPECIMEN IN RATS – SMALL SCALE INDENTER TESTING APPLIED TO TYPICAL LAB ANIMALS

Uwe G. Kersting¹, Anja Niehoff², Michael M. Morlock³, Horst Michna⁴, Gert-Peter Brueggemann²

¹ Department of Sport and Exercise Science, University of Auckland

² Department of Biomechanics, German Sport University Cologne

³ Biomechanics Section, Technical University of Hamburg-Harburg

⁴ Department Morphology and Tumor Research, German Sport University Cologne

INTRODUCTION

Indenter testing has been demonstrated as a valid method to characterise material properties of cartilage specimen (Sakamoto et al., 1996). Rather large species have been investigated in most cases which require an extensive expenditure on animal keeping. In this study a down-scaled testing procedure is proposed and applied to Sprague-Dawley rats as typical lab animals.

The aim of this study was to develop and apply a miniature testing apparatus to investigate full thickness cartilage specimen by a small indenter. The procedure described was applied to a sample of animals experiencing running exercise of different amounts for four, eight and 12 weeks.

METHODS

Animals were decapitated and the legs were detached at the hip joint. The knee joint was dissected carefully in custom made preparation pool with grip screws under TBS. The left leg was frozen at -80°C immediately after dissection and stored until mechanical testing. A relaxation test was performed using a solid spherical (0.5 mm diameter) indenter in a TBS bath on a material test machine (Z2.5/TN1S, Zwick; Fig. 1 and 2A). By use of a microscope with angular scale, specimens were orientated in a way that the indenter approached the cartilage surface perpendicularly. A ramp load of 300 ± 5 mN (F_{\max}) was applied and the achieved deformation held constant for 250 s. Stiffness, short and long term relaxation were quantified by calculation of the rise time (t_r), and times where the load had decreased to $\frac{1}{2}$ ($t_{1/2}$) or $1/e$ ($t_{1/e}$) of the F_{\max} and the final load (F_{end}) after 250 s (Fig. 2B).

Figure 1: A: Adjustable specimen positioning desk B: Indenter orientation (TBS solution removed for illustrative reasons)

Ninety female Sprague-Dawley rats (starting age three weeks) were fed and watered ad libitum. The sample was split into

nine groups of ten animals each, which were killed after four, eight or 12 weeks of training. Three groups served as sedentary controls (C1 – C3). Six groups were kept in custom

Dimensions of apparatus and data analysis

Figure 2: A: Sketch of the cartilage dimensions, h = cartilage thickness, a : radius of contact area, r : radius of indenter B: Example of a force reading. Parameters described in text.

made devices containing an ordinary cage connected to a running wheel; three groups had unlimited access to the wheel (.1) while the other three could only train for half of their time (.2; T11 – T32). Running distance was counted by a magnetic switch at each wheel, monitored by a computer system.

RESULTS AND DISCUSSION

The dimensions of the apparatus correspond to recommendations from analytical studies (Sakamoto et al., 1996). Fig. 3 demonstrates that age and different training regimes produce systematic changes in mechanical properties of the rat knee joint.

Figure 3: $t_{1/2}$ for nine training groups

SUMMARY

A miniature cartilage testing apparatus was introduced which matches technical requirements given by analytical studies. Systematic differences were demonstrated with respect to training regime. The approach provides a great potential for controlled studies on cartilage adaptation.

INTRODUCTION

Muscle excursion is important in regulating sarcomere number. Evidences in support of this idea have been shown in animal studies, where rabbits submitted to surgical procedure increased muscle excursion in 40% and in series sarcomere number in 22% (Koh and Herzog, 1998). In humans, increased excursion due to training may produce similar adaptation. Ballet dancers, for example, show increased ankle plantar flexion (Hamilton et al., 1992; Fração et al., 1999) compared to normal population, causing an increase in dorsiflexor (DF) muscle excursion. Volleyball players show an ankle joint range of motion similar to normal population, and work in a more DF position. Muscle adaptation due to these different types of joint demands might be responsible for modifying the torque-velocity relation. The purpose of this study was to compare the torque-velocity (T-V) relation of DF muscles and the electromyographic (EMG) activity of tibialis anterior muscle (TA) of classical ballet dancers and volleyball players.

METHODS

Twenty five female subjects (ballet dancers n=10; volleyball players n=15) participated in the study. DF muscles peak torque (T_{max}) was evaluated during maximal concentric voluntary contractions in different angular velocities (60, 120, 180, 240, 300, 360, 420°/s) using a Cybex Norm isokinetic dynamometer. EMG signals were obtained from the TA muscle by means of surface electrodes in a bipolar configuration. Root mean square (RMS) values were calculated from the raw EMG signals. T_{max} and RMS values were normalized for each subject. A two-way analysis of variance for repeated measures was used to evaluate possible statistical difference for each measured parameter (torque, RMS, velocity, group), as well as to test for interaction. The level of significance adopted was 0.05 for all tests.

RESULTS AND DISCUSSION

The torque behavior as a function of angular velocity was similar between the two groups ($p=0,1766$). An inverse hyperbolic relationship, similar to the classical relation described by Hill (1938), was observed for the two groups. However, the ballet dancers normalized torque was higher compared to the volleyball players for all angular velocities ($p=0,0001$; Figure 1). The normalized EMG RMS values were similar between the two groups among the different angular velocities ($p=0,4467$; Figure 2), showing that muscle activation was not responsible for the observed differences in torque production. Intrinsic adaptation of the ballet dancers DF muscles (i.e. increase in serial sarcomere number due to increased muscle excursion) seems to be responsible for the observed torque results. These ideas are similar to the ones proposed by Lieber (1992) where larger fibers should produce higher forces at higher shorting velocities. Another possibility would be that ballet dancers have a higher percentage of fast

twitch fibers in this muscle when compared to volleyball players. Although biopsy was not obtained to clarify this point, a higher percentage of fast twitch fibers in the ballet dancers does not seem reasonable as volleyball players show higher power demands in their activities than the ballet dancers.

Figure 1. Normalized DF torque-velocity relation (mean \pm standard deviation).

Figure 2. Normalized RMS values of TA in the different angular velocities (mean \pm standard deviation).

INTRODUCTION

Altered kinematics of the distal radioulnar joint (DRUJ) and/or bone impingement are considered causes of long-term complications associated with malunited distal radius fractures. However, a recent CT image-based *in vivo* study of patients with malunited distal radius fractures found that malunion did not alter forearm kinematics and that limitations of pronosupination were not caused by bony impingement (Moore et al., *in press*). In this study, data from the previous study was reanalyzed to explore focal changes in the articulation at the DRUJ (location and area of bone contact) and potential soft tissue constraints ('length' of the dorsal and palmar radioulnar ligaments).

METHODS

The bony surfaces and kinematics of both radii were obtained from the CT image volumes of nine volunteers with unilateral distal radius fractures (3M, 6F, age 55 ± 15.4 yrs.) scanned in neutral and multiple positions of supination and pronation (Moore et al., *in press*). The dorsal angulation and radial shortening of the injured wrists averaged 20.9 ± 5.8 degrees and 4 ± 3 mm, respectively. Focal changes in the articulation of the distal radius and ulna were assessed by comparing the area and location of bony contact. Contact area was estimated using a distance field representation thresholded to distances less than 5 mm. The location of the centroid of the contact area was described in a coordinate system with the origin at the ulna-carpal surface and positive in a proximal direction. Potential soft tissue constraints were assessed by calculating the 'length' of the dorsal and palmar radioulnar ligaments, defined as the shortest paths between insertion points constrained to avoid bone penetration. Paired Student's t tests were used to compare the uninjured and malunited DRUJs. P values ≤ 0.05 were considered to be statistically significant. The data reported here are for the neutral positions.

RESULTS

Ulna contact area was smaller and was located more proximally in the malunited forearms than in the uninjured contralateral forearms (Figure 1, Table 1). The length of the dorsal radioulnar ligament paths was on average 27% longer in the malunited forearms; the palmar ligament path lengths did not differ. In seven of the nine malunited forearms, the dorsal radioulnar ligament curved around the head of the ulna as it passed from the ulna to the radius. The average deflection of the dorsal radioulnar ligament in the malunited forearms

was 0.65 mm. No dorsal deflection was found for uninjured forearms.

Figure 1. a) Contact areas on both ulnas from a single volunteer. The shading and contours (1 mm apart) show distance to the radius. Note proximal shift and decreased size for malunited (right). b) Ligament paths for two forearms, same volunteer. Note ligament deflection for malunited (right).

Table 1. Contact area (5 mm threshold), location of the centroid of the contact area, and dorsal and palmar ligament lengths in neutral pronosupination.

	Uninjured	Malunited	P < 0.02
Contact Area (mm ²)	208.1 \pm 46.8	170.4 \pm 43.0	Yes
Centroid location (mm)	3.7 \pm 0.8	5.3 \pm 0.4	Yes
Dorsal lig. length (mm)	12.1 \pm 1.9	15.4 \pm 2.1	Yes
Palmar lig. length (mm)	14.8 \pm 1.2	15.0 \pm 2.8	No

DISCUSSION

Although Moore et al. found no significant differences in the pronosupination kinematics of the malunited and uninjured wrists evaluated, this study found significant differences in the size and location of the joint contact area, and in the soft tissue constraints of the DRUJ. The significant change in the dorsal radioulnar ligament length, but not in palmar ligament length, is consistent with the original malunion (all tilted dorsally). The proximal shift in the location of the centroid of the contact area is consistent with the radial shortening. The changes reported here present a possible etiology for the development of degenerative joint disease, and the change in ligament length may be one mechanism for the limitation of pronosupination.

INTRODUCTION

Atherosclerosis is associated with the accumulation of abnormal materials such as lipid, hematoma, and calcifications in artery walls. Structure-property relations of diseased artery constituents are essential for accurate modeling of disease progression and treatments. A study of formalin-fixed plaques using nanoindentation and Fourier Transform Infrared spectroscopy (FTIR) suggested that the stiffness of tissue samples increased as their mineral content increased (Ebenstein, 2002). In this study, the same approach is extended to the analysis of frozen and fresh tissue samples.

METHODS

Five carotid bifurcation endarterectomy specimens were used in this study. Three of the samples were fixed in formalin prior to mechanical analysis, one was frozen at -20°C , and one was tested fresh. All were tested after equilibrating in physiological saline at 25°C . Plaque samples were dissected into regions of relatively uniform composition. The regions were then potted in dental cement for mechanical testing.

Mechanical testing was performed using the Hysitron TriboIndenter (Minneapolis, MN). A trapezoidal loading curve was applied to 5-10 sites in each region, with peak loads ranging from 40 to 600 μN . Reduced modulus values (E_r) were calculated from the unloading curves following the method of Oliver and Pharr (Oliver and Pharr, 1992). After mechanical analysis, all samples were fixed in formalin and transferred to water for FTIR analysis.

FTIR was performed using the Nicolet Avatar 360 (Madison, WI) equipped with the ATR accessory. Spectra at 1-4 sites in

each tissue region were collected for 32 or 64 scans at 4 cm^{-1} resolution. After standard corrections and water subtraction, Mineral:Matrix ratios were calculated by dividing the area under the phosphate peak ($1200\text{-}900\text{ cm}^{-1}$) by the area under the collagen amide I peak ($1720\text{-}1585\text{ cm}^{-1}$).

RESULTS AND DISCUSSION

Reduced modulus and Mineral:Matrix ratios for tissue regions from three formalin-fixed plaques, one frozen plaque, and one fresh plaque are summarized in Table 1. Under all treatment conditions, increases in E_r between tissue categories was associated with increases in the Mineral: Matrix ratio, with hematoma being the softest and having the lowest mineral content, and calcification being the stiffest and having the highest mineral content. Further, the reduced modulus of formalin-fixed fibrous tissue is 4-fold higher than the values for fresh and frozen tissue, as expected due to the cross-linking effects of formalin.

SUMMARY

Using nanoindentation and FTIR, trends in tissue stiffness can be correlated to changes in tissue composition. In particular, increased reduced modulus values are associated with increased calcification content in the tissue. Further, differences in stiffness between fresh and formalin-fixed fibrous tissue are detectable using nanoindentation.

MATERIAL CLASSIFICATION OF BIAxIAL SOFT TISSUE RESPONSE

D. Claire Gloeckner^{1*}, Michael B. Chancellor² and Michael S. Sacks¹

¹Departments of Bioengineering and ²Urology, University of Pittsburgh, Pittsburgh, Pennsylvania, U.S.
dcgst11@pitt.edu

INTRODUCTION

A disadvantage in the use of phenomenological models is the requirement of choosing the model before the material classification is made. Hence, the procedure becomes an arbitrary operation; if the data does not fit the model, then the assumption of material classification is incorrect and another model chosen. Other methods used to determine material classification require complex strain-based protocols that may not be physiologic (Sacks 2000). Herein we describe a generalized method for material classification.

To demonstrate this method, we examined the differences in rat urinary bladder wall mechanics in normal and spinal cord injury in a rat model. Mechanically, the absence of neural control leads to changes in the function of the bladder (German, Bedwani et al. 1994; Kruse, Bennett et al. 1994). We have observed the phenomenon of quasi-isotropy in both normal and spinal cord injured bladder, complicating modeling. Incorporation of mechanical data into a predictive model is required for organ-level simulations that can aid in designing pharmaceutical and surgical interventions.

METHODS

Normal (n=12) and ten days post spinal cord injury (n=8) rat urinary bladder wall was obtained and biaxially cycled to obtain five protocols. Details of the testing and results can be found in (Gloeckner, Sacks et al. 2002). Each axial stress was fit separately to the following interpolation function with an r^2 of >0.99.

$$S_{ii} = \frac{\epsilon}{2} \exp(Q) \frac{dQ}{dE_{ii}} \text{ where}$$

$$Q = a_1 E_{11}^2 + a_2 E_{22}^2 + 2a_3 E_{11} E_{22} + a_4 E_{11}^2 E_{22} + a_5 E_{22}^2 E_{11} + a_6 E_{11}^2 E_{22}^2 + a_7 E_{11}^4 + a_8 E_{22}^4$$

All parameters and experimental strains were used to generate a square mesh of stress values in both material directions.

Figure 1: Stress contours overlaid with complete strain data of representative normal rat bladder wall.

RESULTS AND DISCUSSION

A representative normal sample is shown in fig 1. This normal specimen is clearly anisotropic with greater stretch in the x_1 axis. In contrast, the spinal cord injured example shown is close to isotropic (fig 2). Based on this information we then chose two appropriate models. As predicted, the isotropic model was insufficient for the normal data, but adequate for the spinal cord injured data (table).

The application of this method successfully allowed physiologic stress-based testing protocols to guide the form of the constitutive model without a priori assumptions.

$$4\text{-parameter: } S_{ii} = \frac{\epsilon}{2} \exp(Q) \frac{dQ}{dE_{ii}} \text{ where } Q = a_1 E_{11}^2 + a_2 E_{22}^2 + 2a_3 E_{11} E_{22}$$

$$\text{Isotropic: } W = c_1 [\exp(c_2 (I_1 - 3)) - 1]$$

Table 1: Mean parameters and r^2 values for two models.

	4-parameter					Isotropic		
	C	A ₁	A ₂	A ₃	R ₂	C ₁	C ₂	R ₂
Normal	1.75	28.0	39.9	27.1	0.86	6.65	5.03	0.58
SCI	0.85	42.4	45.4	-6.7	0.94	0.92	4.66	0.84

DYNAMIC TESTING OF RAT ACHILLES TENDONS

Stefanie D. Stangier, Joseph E. Hale and Donald D. Anderson
Biomechanics Laboratory, Minneapolis Sports Medicine Center
Minneapolis, MN, e-mail: stan0320@tc.umn.edu

INTRODUCTION

The viscoelastic nature of tendons and similar soft tissues has long presented a challenge to researchers, as many variables affect the mechanical properties measured. In the past, often only failure properties were studied (e.g. Kurtz, 1999). However, in real life, a tendon rarely sees conditions that are anywhere near failure (Fung, 1993).

The dynamic, sub-failure properties are of more interest. In light of the many possible tests conducted, it could then be argued that the best choice for the frequency of loading for a tendon specimen is close to a typical physiological value. In order to separate the elastic from the viscous effects, it has been proposed to test materials at frequencies much higher than these physiological values (Cooke, 1996). The aim of this pilot study was to determine whether the results of dynamic material testing of rat Achilles tendons are dependent on the testing frequency. The observations serve to streamline the dynamic testing procedure for use in future research.

METHODS

Two groups of rat Achilles tendons from various sources were subjected to a cyclic uniaxial testing protocol using the EnduraTEC ELeCTroForce™ (ELF) 3200 testing system. The recovery period for all specimens between tests was ten (10) minutes. For the first group of tendons, the test frequencies were 0.5, 1.0, 2.0, 5.0, 10 and 100 Hz respectively. The 0.5 Hz test served as preconditioning cycle. The sequence of the remaining five frequencies was random. The second group of tendons was subjected to preconditioning at 0.5 Hz for 10 cycles, followed by the actual testing at 0.5, 1.0, 2.0, 5.0, 10 and 50 Hz. Again, the sequence of the tests was randomized.

The tendons were held by a low temperature tissue grip at the muscle end, while the calcaneus was potted in bone cement at a 45° incline. The bracket holding the potted end permitted two degrees of freedom. A tensile pre-load of 2 N was applied. Tests were performed at room temperature, with specimens covered by moist gauze between tests. Following dynamic testing, the tendons were pulled to failure at 0.167 mm/s.

RESULTS AND DISCUSSION

The Dynamic Material Characterization (DMC) software that works with the WinTest system from EnduraTEC is based on the Voigt model of viscoelasticity: a spring in parallel with a damping element. The storage, loss and dynamic stiffness were computed from the force, displacement and phase angle.

Figure 1: Normalized dynamic stiffness in relation to the frequency of loading. The line represents mean values, while the symbols depict the results across all specimens..

Figure 1 (above) shows the dynamic stiffness for all tendons along with the mean and the standard deviations at each frequency tested. Values were normalized with respect to values at 0.5 Hz for each specimen, since the changes in stiffness were of more interest than the absolute values. The dynamic stiffness at 0.5 Hz was $157.4 (\pm 67.9)$ N/mm [mean \pm standard deviation]. Failure loads averaged 77.8 ± 11.8 N across the specimens tested, with the majority of failures occurring at the Achilles / calcaneal junction.

The dynamic stiffness reported is the complex composite of the storage stiffness and the loss stiffness. The storage stiffness is that associated with the purely elastic response of the tendon, while the loss stiffness accounts for the viscous portion. These values can alternatively be converted to the moduli more commonly used in the viscoelasticity literature.

EFFECT OF OSTEOPOROSIS IN A DISC-DEGENERATED LUMBAR SPINE

Ravikumar Varadarajan¹, Dr.F.M.L. Amirouche¹, Dr.Franklin C Wagner², Dr.Kern Guppy²

¹ Biomechanics Research Laboratory, University of Illinois at Chicago, rvarad1@uic.edu

² Department of Neurosurgery, University of Illinois at Chicago

INTRODUCTION

Disc Degeneration leads to various spinal disorders like Spondylosis, Stenosis and Osteophyte formation and Osteoporosis leads to endplate fracture. Biomechanical investigation of Disc Degeneration and Osteoporosis has been studied separately by many researchers(1,2). But there is not enough data on the combined effect of Osteoporosis and Disc Degeneration. This study focuses on effect of Osteoporosis in a Disc Degenerated Lumbar Spine.

METHODS

Five 3D Finite Element models of L4-L5 FSU:

1. Intact
2. Grade(I) Degenerated
3. Grade(I) Degenerated with Osteoporosis
4. Grade(II) Degenerated and
5. Grade(II) Degenerated with Osteoporosis

were used in this study. FE Model of intact was developed using ANSYS-v5.7. Geometric data of the Vertebrae, Facet joint and Intervertebral Disc were based on recent studies(3,4). Cortical bone, Cancellous bone, Annulus Ground Substance and Posterior Elements were modeled as 3D Isoparametric 8 node elements. The Intervertebral Disc was modeled similar to recent studies(5). Facet Contact was modeled as 3D point-to-point contact elements. All Ligaments were modeled as Tension only spar element and all material properties are based on (5,6). The Model is validated with recent literature(5).

Grade(I) Disc degeneration(Dehydrated Nucleus) was simulated by using stiffer solid elements for the Nucleus with Young's Modulus twice that of Annulus ground substance. Grade(II) degeneration was simulated by doubling the young's modulus of annulus ground substance and reducing the annulus fiber volume by 25%(5).

Osteoporosis of the vertebrae was simulated by reducing the young's modulus of Cancellous bone by 50%.

Axial Compression load of 405N was applied as uniform Pressure on the superior surface of L4 Vertebra. All Nodal points in the inferior surface of L5 vertebra were fixed in all directions.

RESULTS AND DISCUSSION

As the Degeneration level increases stiffness of the FSU increases but Osteoporosis reduces the stiffness. Intervertebral Disc bulge and stress in Annulus ground substance decreased with increase in degeneration level. There was no considerable change in Disc Bulge in the Degenerated Model with Osteoporosis.

Stresses in Pedicle decreased in normal degenerated model but increased in osteoporotic degenerated model

Disc degeneration reduced the contribution of cancellous bone. This reduction was larger in normal than in osteoporotic bone. Cortical bone stress increased with increase in degeneration level. This increase was larger in osteoporotic(20%) bone than in normal bone.

Endplate stresses increased as the degeneration level increases. Osteoporosis further increases the endplate stresses.

THE BIOMECHANICS OF THE SHOULDER DURING WHEELCHAIR PROPULSION UP RAMPS

Michelle B. Sabick¹ and Kai-Nan An²

¹Steadman ♦ Hawkins Sports Medicine Foundation, Vail, CO, USA, Michelle.Sabick@shsmf.org

²Biomechanics Laboratory, Department of Orthopedics, Mayo Foundation, Rochester, MN, USA

INTRODUCTION

The incidence of shoulder pain among manual wheelchair users is as high as 51% (Nichols *et al.*, 1979). Because wheelchair users rely on their upper extremities for mobility, shoulder injuries have detrimental effects on independence and quality of life. The joint forces generated during wheelchair propulsion are thought to cause chronic shoulder overuse injuries (Nichols *et al.*, 1979). One demanding and often painful task is negotiating a wheelchair up a ramp (Subbarao *et al.*, 1995). In tests where subjects used a variety of mobility aids to ascend ramps varying in grade from 1:20 to 1:8 (rise:run), manual wheelchair users had the most failures (Sanford *et al.*, 1997). Even though manual wheelchair users had difficulty, the authors suggested that the standards for ramp grade not be changed from their current values (a 1:12 maximum grade over a 9.1 m length and a 1:8 maximum grade for a 16.2 cm rise) (Sanford *et al.*, 1997). However, it is not clear whether consistently propelling a wheelchair up such ramps may cause damage to the shoulder over time. The aim of the current study was to quantify the effect of ramp grade on shoulder joint mechanics in light of the potential for injury.

METHODS

Sixteen paraplegic subjects propelled their wheelchairs up a 3.7 m adjustable grade ramp. Thirteen reflective markers were placed on each subject (Figure 1). The 3-D coordinates of the markers were collected at 60 Hz using a commercial six-camera motion capture system. Kinematics of the trunk, shoulder, elbow, and wrist were computed from the locations of the reflective markers using Euler angles. The subject's wheelchair wheels were replaced with instrumented wheels to

Figure 1. Marker placement for kinematic data collection.

record the force and moment applied to the wheelchair handrim at 100 Hz. The resultant forces and moments at the wrist, elbow, and shoulder were calculated using inverse dynamics. Each subject propelled his wheelchair up four ramp grades (level, 20:1, 12:1, 8:1) five times each in random order. Data were normalized in time to facilitate comparisons. Repeated measures ANOVA were performed to determine differences. In the case of a significant ANOVA, post-hoc Bonferroni/Dunn pairwise comparisons were performed.

RESULTS AND DISCUSSION

Peak shoulder joint moments in all three planes increased significantly for all the ramps compared to level ground. The largest shoulder moment was a flexion moment (Figure 2), which ranged from 14.3 ± 6.2 Nm on level ground to 46.7 ± 18.5 Nm on the 8:1 ramp ($p < .0001$) and peaked during the propulsion phase. Shoulder forces during propulsion were directed in the anterior, medial, and inferior directions. All of these values increased significantly from the level baseline condition to the ramps ($p < .0001$).

Figure 2. Mean (\pm SD) shoulder flexion moment as a function of ramp grade (* $p < 0.003$).

Peak shoulder flexion moment increased 225% from level ground to the 8:1 ramp. Peak anterior and inferior components of shoulder joint force increased 130% and 744%. The large increase in inferiorly directed force suggests that the shoulder is at greatest risk of compression injuries during wheelchair propulsion up ramps. Compression of the subacromial structures can occur if the humerus migrates superiorly and decreases the amount of subacromial space (Kulig *et al.*, 1998).

SUMMARY

Increasing ramp grade leads to dramatic increases in shoulder forces and torques. The shoulder compression force showed the greatest increase with ramp grade. Even relatively “easy” slopes significantly increase shoulder joint kinetics. The compressive forces generated during propulsion up ramps may lead to the common problem of subacromial impingement.

INVESTIGATION OF STRESSES AND MICROMOTION BETWEEN THE LINER AND THE ACETABULAR CUP IN TOTAL HIP REPLACEMENT IMPLANTS

Francisco Romero¹, Farid Amirouche¹, Mark Gonzalez², Paul Lewis³, Todd Render³, Jorge Ochoa³

¹University of Illinois at Chicago. Biomechanics Research Laboratory. fromer1@uic.edu

²University of Illinois at Chicago. Medical Campus. ³DePuy Orthopedics, Warsaw, Indiana, USA

INTRODUCTION

The proposed research focuses on the liner and acetabular cup of a THR implant when subject to dynamic loading conditions. The objective of this paper is to address both the normal loading with the femur head in the socket joint and the effect of eccentricity and femur head dislocation. The latter reflects the induced torques responsible for liner instabilities and joint unbalance or misalignment.

METHODS

A three-dimensional 3595 element FE model (Figure 1a-, 1b-) of the femur head, liner and acetabular cup was developed using ANSYS/LS-DYNA with 8 nodes hexahedron elements (Solid 164), positioned with 45° inclination and 25° anteversion.

Figure 1: FE models for a) Gait loading, b) dislocation

A rigid material type was chosen for the titanium components and a Plasticity bilinear material for the UHMWPE component. A linear contact between implant components was modeled using a surface-to-surface contact (STS) with an experimental friction coefficient between titanium and UHMWPE of $\mu=0.038$. The acetabular cup was fully constrained; the femur head was constrained in the rotational degrees of freedom while the UHMWPE liner was fully unconstrained. Two dynamic loading cases were considered using LS-DYNA. In the first loading case the femur head is perfectly aligned in the liner socket and gait forces obtained from an in vivo instrumented prosthesis were applied. Muscles force data as depicted by Bergmann et al. were converted to the coordinate system shown in Figure 1.a-. The final applied loads are shown in table 1. In the second loading case an eccentricity was applied to the femur head ($ecx=10\text{mm}$, $exy=4\text{mm}$ in shown CS).

Table 1: Hip joint forces during gait.

Time (sec)	0.0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
Fx (N)	16.94	225.4	419.6	901.1	735.4	647.7	581	450.5	168.4	101.8	64.15
Fy (N)	62.03	-225.4	-482.3	-1623	-1700	-1607	-1494	-1082	-372.7	-123.6	-26.04
Fz (N)	-44.32	0	-55.84	-414	-423.6	-281	-125	-173.2	-67.37	-42.37	-57.8

A maximum peak force of 2132 N was applied at an angle of 23.4° lateral and 5.7° posterior over the dislocated femoral head as shown in Figure 1.b. The maximum stresses (Mpa) and relative micromotions (mm) between the acetabular cup and liner were measured in both loading case conditions.

RESULTS AND DISCUSSION

The maximum displacement data for each loading case is represented by vectors as shown in Figure 2a-, 2b-. The maximum values are found to be 172 μm ($t=0.77\text{sec}$) for gait loading case and 680 μm ($t=0.02\text{ sec}$) during the dislocation loading case.

Figure 2: Max. displacement a) Gait loading, b) dislocation

The maximum stress achieved in both cases remains under UHMWPE Yield Stress limit with maximum values of 6.6 MPa in the first loading case and 21.9 MPa during impact in the dislocation analysis. Due to the range of values obtained, instabilities caused by micromotions and UHMWPE degradation are found to be minimal.

SUMMARY

An explicit dynamic study using Finite Elements that represents a more realistic testing procedure of THR components behavior is being developed. The latter will be validated against an experiment being developed by L. Aran et al.

TOOLS FOR COMPUTER-AIDED SURGERY: DISPLACEMENT AND VELOCITY WORKSPACES OF THE HUMAN KNEE

John E. Fuller¹, Michael C. Murphy² and Gregory A. Brown³

¹Schlumberger Reservoir Completions, Rosharon, TX, U.S.A.

²Dept. Of Mechanical Engineering, Louisiana State University, Baton Rouge, LA, U.S.A.

³Regions Hospital, St. Paul, MN, U.S.A.

INTRODUCTION

Quantitative comparisons of the kinematic outcomes of different joint reconstructions or total knee replacements would be an invaluable aid to surgeons in the design of successful treatment strategies. Workspace concepts developed in the field of robotics were applied to the study of the kinematics of the knee (Fuller, 2001). Fixed orientation displacement workspaces (FODW) are a map of all possible translations of the joint in a specified orientation and correspond clinically to the laxity of the joint. Each point on the surface of the FODW represents a constraint configuration, consisting of active ligament bands and surface contacts. At any point in a FODW, there are three sets of instantaneous helical axes (IHAs), corresponding to motions that do not change the constraints, motions that relax the constraints, and motions that violations of the constraints.

METHODS

Ligament lengths, ligament insertion sites, and articulating surface geometries were obtained from a matched pair of human cadaver knees through the use of computed tomography (CT) in the presence of titanium markers at ligament insertions and for reference coordinate systems. The specimens were scanned with the knee capsules undisturbed and reference markers implanted in the tibia and femur. The left knee was disarticulated and the insertions of the four major ligaments into the tibia and femur were marked and the specimen was rescanned. The resulting sets of images were correlated through the reference markers, yielding articulating surface and ligament geometries for the intact, left human knee specimen. Triangular facets were fitted to the surface data while ligaments were modeled as single filaments connecting insertion site centers. The fixed orientation displacement workspace was computed based on rigid body approximations for the articulating surfaces and inextensible link representations for each of the major ligaments

A constraint configuration was determined by studying the FODW of a model of the human knee near full extension (Fuller, 2001). Ligaments were modeled as single filament elements, inserting as spherical joints into the bone surfaces. Capable of supporting only tensile loads, ligament wrenches simplified to zero pitch wrenches, or pure force wrenches. Similarly, contact forces were modeled as point forces, considering the articulating surfaces as virtually frictionless. The resulting constraints contributed by surface contacts were also zero pitch wrenches. A basis for the velocity workspace boundary, consisting of the set of all twists reciprocal to the constraint wrenches, was computed using well-known techniques of linear algebra. A basis for the velocity workspace interior, defined by all twists not contrary to any

constraint wrench, was computed using techniques of convex analysis.

RESULTS AND DISCUSSION

Figure 1(a) shows a FODW for the knee near full extension. The outer surface of the FODW is defined by the actions of different ligament bands and the surface contacts. The primary constraints are labeled on the surface of the workspace. The two twist (IHA) basis for the reciprocal velocity workspace is shown in Figure 1(b) for one point in the FODW with all four ligaments active. All four constraint wrench axes intersect the IHA corresponding to the flexion-extension axis.

SUMMARY

Workspaces have the potential to provide a quantitative tool for assessing the kinematic outcomes of surgery and providing insight into joint function.

ABILITIES OF YOUNG AND OLD ADULTS TO ADJUST MEDIO-LATERAL STEP LOCATION DURING A FORWARD FALL

Darryl G. Thelen¹, Cécile Smeesters³, James A. Ashton-Miller^{2,3}, Shana Bailey¹, Rhadika Rapasinghe¹ and Neil B. Alexander⁴

³Mechanical Engineering Department, ⁴University of Michigan, Ann Arbor, MI, USA

INTRODUCTION

Old adults with a history of falls have greater difficulty with lateral stability than non-fallers (Lord et al., 1999) and hip fractures are frequently associated with falls to the side (Hayes et al., 1993). Thus, the ability to maintain and/or recover medio-lateral (ML) balance may be important in avoiding falls and fall injuries. Because the center-of-mass (COM) is typically outside the narrow base of single-support (Lyon and Day, 1997), stepping responses to recover balance require coordinated control and positioning of the ML step location relative to the trajectory of the COM. The objective of this study was to compare the ability of young and old adults to adjust their ML step location during induced forward falls. Due to age-related slowing in reaction time and rapid strength development (Thelen et al., 1996), we hypothesized that old adults would demonstrate a reduced ability to adjust their ML step location. We further hypothesized that inadequate ML adjustment of the COM would underlie this decreased ability.

METHODS

Twenty-two young (18-30yrs) and 24 old (65-85yrs) healthy adults participated. Forward falls were induced by releasing subjects from forward leans of 8° and 16°. Prior to each trial, subjects were instructed to recover balance by taking a single step with the right foot into one of three 16cm wide zones located directly in front of them (Figure 1). Two attempts were made for each zone and trials were presented in a random order. A successful trial involved stepping completely into the zone and not taking any additional steps. Success rates equaled the number of successful trials divided by the total number of trials. The time history of the COM trajectory was computed by double numerical integration of the foot-floor reactions (Lyon and Day, 1997). A rm-ANOVA was used to determine the effect of age on the toe-off (TO) time and ML motion of the COM prior to TO.

Figure 1: Mean step locations and COM trajectories of young males when they successfully stepped into the each of the three zones for 8° (a) and 16° (b) leans. Medio-lateral (ML), antero-posterior (AP).

RESULTS

Young adults demonstrated greater success rates than old adults in stepping into the specified zones (Table 1). The medial zone proved to be the most difficult for all subjects to step to. TO times were similar for the young and old adults, except for slower ($p<0.05$) TO for old adults when stepping to central and lateral targets at the 16° lean (Figure 2). Old adults generated less ($p<0.05$) medial motion of the COM prior to TO when stepping to medial and central targets (Figure 2).

Table 1: Success rates (%) achieved by young (Y) and old (O) adults in stepping into specified target zones.

Lean	Medial		Central		Lateral	
	Y	O	Y	O	Y	O
8°	75	29	98	82	88	73
16°	38	0	82	47	75	23

Figure 2: TO times and medial motion of COM prior to TO for young (solid bars) and old adults (white bars). * $p<0.05$.

DISCUSSION & CONCLUSIONS

Healthy old adults demonstrated greater difficulty in adjusting their ML step location during a forward fall than young adults. Interestingly, old adults often initiated the step as quickly as the young, particularly when stepping medially or straight ahead. However, the medial postural adjustment of the COM prior to TO was often reduced in old adults. Because the COM motion after TO is largely ballistic (Lyon and Day, 1997), the COM position and velocity at TO determine the COM location at landing. Consequently, inadequate control of the COM prior to TO, rather than a delayed stepping response, is the likely cause of the lower rates of success among old adults.

ANKLE ARTICULAR CARTILAGE THICKNESS IS ACCURATELY MEASURED WITH MULTI-DETECTOR COMPUTED TOMOGRAPHY (MDCT)

INTRODUCTION

Accurate measurements of *in vivo* ankle cartilage thickness are often needed for experimental analysis or clinical assessment. Conventionally, MRI has been the modality of choice for imaging cartilage, despite the well-recognized sequence-dependence of the tissue layer appearance. However, anecdotal observations from several clinical cases sensitized us to the extremely crisp cartilage rendition provided by multi-detector computed tomography (MDCT), done in concert with contrast media and air-injection.

MDCT has significant advantages over single or double slice helical CT or conventional CT. Up to four interweaving helices, generating four slices at a time and using collimators with better resolution, provide several substantial improvements. Data collection is faster, reducing patient movement artifact. Data have far improved temporal and spatial resolution and the isotropic images allow multiple image reconstructions in any arbitrary plane. Our Radiology Department has coupled MDCT with Vitrea[®] 3-D interpolation software, which by enabling sub-voxel computations further sharpens rendition. The visual appearance of cartilage on MDCT is so distinct as to suggest a potential for better-than-MRI geometric fidelity.

We designed an experiment to use MRI and MDCT to measure ankle cartilage at multiple articular surface locations in a series of cadaver foot/ankle specimens. The MRI and MDCT results were compared to location-matched direct physical thickness measurements.

METHODS

Four cadaver lower legs were transected perpendicular to the axis of the leg at approximately 5 cm superior to the medial malleolus. Care was taken to avoid capsule compromise so as to ensure subsequent contrast medium and air containment. Each foot/ankle specimen was mounted in neutral position in a custom fixture (entirely made of acetabular plastic for MRI compatibility) that served as a drill guide and (later) as a joint distracter. With the articular surfaces apposed, a grid of 1.5 mm diameter marker track holes was drilled through the joint from the tibial side. These holes penetrated the tibial subchondral plate, the tibial cartilage, the talar cartilage, and the talar subchondral plate, respectively. After drilling, the adjustable fixture distracted the joint approximately 3 mm to allow space for contrast medium and air infusion.

Ankles were MR-scanned using the 3-D SPGR sequence to best delineate cartilage. Total scan time for this sequence is approximately 20 minutes. For the MDCT scan, the specimens were first injected with 0.5 – 1.0 ml of Hypaque-60[®] contrast medium, followed by a bolus of 7-12 ml of air to enhance medium penetration. The MDCT scans were then performed using 1 mm collimation and 0.5 mm reconstruction. Scan times were less than one minute. MRI and MDCT images were ported to a workstation, and, using Vitrea[®], the images were searched to locate each of the marker tracts. Once located, the cartilage surface and bone interface adjacent to the tracts were cursor-delineated and used to calculate cartilage thickness at that tract location.

After MRI and MDCT scanning, the ankles were removed from the fixture and disarticulated to expose the articular surfaces. A cylindrical trephine was passed concentrically over the marker holes, removing annular cores of cartilage with their underlying bone. These plugs were then sectioned in half, longitudinally, and placed on the stage of an optical microscope. Using a superimposed optical comparator grid under 40x magnification, the cartilage thicknesses were measured adjacent to the tract holes. A single blinded observer performed all measurements.

RESULTS AND DISCUSSION

Using the described procedure, we obtained multiple, location-matched ankle cartilage thickness measurements via MRI, MDCT and direct physical measurement (the “gold standard”). Cartilage thicknesses at 58 talar and tibial articular sites on four ankles are summarized in Table 1. MDCT results were nearly indistinguishable ($p > 0.5$) from the gold standard physical measurements, whereas MRI significantly ($p < 0.005$) overestimated cartilage thickness. These results support air-injection contrast-enhanced MDCT as a technique for precise assessment of ankle articular cartilage thickness.

PROLONGED COMPRESSION OF INTERVERTEBRAL DISCS ACTIVATES MMP-2

Adam H. Hsieh and Jeffrey C. Lotz

Orthopaedic Bioengineering Laboratory, Department of Orthopaedic Surgery

University of California, San Francisco, California, USA

e-mail: ahsieh@itsa.ucsf.edu

web: carpal.ucsf.edu

INTRODUCTION

There is mounting evidence that mechanical loading plays a significant role in the initiation and progression of intervertebral disc degeneration. *In vivo* studies of load-induced disc degeneration in mice [Lotz et al, 1998, Lotz & Chin, 2000] have demonstrated that static compression results in disruption of the lamellar structure in the annulus fibrosus and in induction of fibrocartilaginous matrix in the nucleus pulposus. Since catabolic events may be important in these observed disc remodeling events, the objective of this study was to assess *in vivo* changes in active and latent (pro-) forms of matrix metalloproteinase (MMP)-2 in compressed discs.

METHODS

A degenerative phenotype was induced in coccygeal discs of 12-week old male Swiss-Webster mice (approved by the Committee on Animal Research, UCSF). Briefly, pairs of perpendicularly aligned stainless steel pins were inserted percutaneously through the diameters of the 9th and 10th caudal vertebrae. Pre-calibrated elastic bands were placed over these pins to apply 1.3 MPa compression. A third pair of pins was inserted through the 8th caudal vertebral body but with no elastics; the disc between the 8th and 9th vertebrae served as a sham control. Normal discs were obtained from mice having neither pins nor loads applied. Static compression was applied to discs for 1 day, 4 days, or 7 days, and mice were sacrificed immediately after the respective treatment periods. The tail discs of interest were surgically excised, snap-frozen, and pulverized at liquid nitrogen temperatures. Samples were extracted in a 50 mM Tris-HCl buffer and centrifuged at speed. Supernatants were then used in the Biotrak MMP-2 activity assay system (Amersham Biosciences, UK) following the manufacturer's protocol. Levels of both active (without aminophenyl mercuric acetate – APMA) and total (pro- and active; with APMA) MMP-2 were quantified using a plate reader (405 nm). Absolute concentrations of MMP-2 were normalized with respect to wet weight of the disc tissue measured immediately post-surgery. To improve normality, percentage data were transformed using a modified arcsine function. Transformed data of the different experimental groups were then compared using ANOVA ($\alpha = 0.05$) with Fisher's PLSD post-hoc analyses ($\alpha = 0.05$). All data are presented as mean \pm SEM.

RESULTS

No significant differences in total MMP-2 activity per unit wet weight were found between loaded and sham-treated discs for any loading duration ($p > 0.05$; data not shown). Figure 1

illustrates the time-course response of activated MMP-2. Compared with corresponding shams, there was no change in percent active MMP-2 in discs after 1 day static compression ($n = 3$). After 4 days of loading, however, discs exhibited a significant increase to nearly 50% ($n = 2$; $p < 0.005$). Elevation of active MMP-2 was sustained in discs through 7 days of loading ($n = 3$; $p < 0.05$). Sham-treated discs at all time points possessed percent active MMP-2 which were not significantly different from normal discs ($n = 3$).

Figure 1 – Effect of static compressive loads on levels of active MMP-2 expressed as a percentage of total MMP-2.

DISCUSSION

Static compression of coccygeal discs in mice led to changes in the intradiscal distribution between active and pro- forms of the enzyme MMP-2. Specifically, while total levels of MMP-2 remained essentially constant, there was a two-fold increase in MMP-2 activation by 4 days of compression. That the elevated levels were maintained after 7 days of loading may be indicative of a shift in the basal level of MMP-2 activity in the tissue, perhaps as a remodeling response to the new stress state of the disc. Since total levels of MMP-2 were unchanged, these data also suggest that prolonged loading did not significantly alter MMP-2 synthesis on either a transcriptional or translational level. Further studies, however, are required to explore the implications of these current observations more fully. Although MMPs have long been suggested to have an important role in normal and pathological conditions in the intervertebral disc [Goupille et al, 1998], the manner in which they are involved remain unclear. This study lends insight into some of the processes that lead to degenerative changes in the extracellular matrix of the disc.

FORCE CHARACTERISTICS FROM DROP LANDINGS ARE ASYMMETRICAL BETWEEN LEGS IN 7-11 YEAR OLD CHILDREN

Jeremy J. Bauer, Wilson C. Hayes and Christine M. Snow
Bone Research Laboratory, Oregon State University, Corvallis, Oregon, U.S.A.
email:bauerje@onid.orst.edu

INTRODUCTION

When developing exercise prescriptions for increasing bone mass, it is necessary to quantify the variables associated with osteogenesis. Given individual variations in bone responses to exercise, it is implied that there are also individual variations in the forces to which the skeleton is exposed, even in studies that use standardized loading protocols. In a recent study in which bone mass increased from drop landings, we did not observe a significant correlation between increases in bone mass at the hip and ground reaction forces (GRF's) even though GRF's ranged from 5-12 body weights (BW) (Bauer et al., 2001). One explanation for this finding is that the changes in bone were measured only at the left hip whereas the forces were measured from a two-footed landing onto a single force plate and thus, the possibility exists that the composite value does not reflect the true ground reaction forces at the left foot. If there is asymmetry in ground reaction forces between legs, then the most appropriate approach to use in the design of future studies would be to measure hip bone mass and forces on the same leg. In order to explore the symmetry question, we conducted a study to determine the degree of symmetry in ground reaction force magnitude and loading rate in children performing drop landings from 61cm. We hypothesize that, since asymmetries in GRF's have been reported in adults (Schot et al. 1994), we will observe similar findings in children.

METHODS

Fourteen children, 9.0 ± 1.2 years (6 boys, 8 girls) performed 15 drop landings onto two force plates from a height of 61cm. Vertical GRF's were collected on each leg at a sampling rate of 1000Hz. Average loading rate was defined as the slope of a line from 20% to 80% of the rising side of each force peak. A left/right difference score was determined for each variable within each subject by subtracting the left foot value from the right foot value then calculating the mean. The absolute value of the mean difference score for each subject and variable was then pooled for group description. One sample t-tests were used to compare the mean difference scores compared to zero for each variable. Statistical significance was set at $p < 0.01$.

Group mean GRF's at peak1 were 2.3 ± 0.3 (BW) and 2.3 ± 0.7 BW for the left and right foot, respectively, and, at peak2 were 4.8 ± 0.9 BW and 5.0 ± 1.0 BW for left and right foot, respectively. While these group means are very similar, they

do not reflect individual asymmetries (Figure 1). Loading rate at peak1 was 278 ± 55 BW/s and 283 ± 79 BW/s for the left and right foot, respectively and at peak2 was 349 ± 105 BW/s and 387 ± 122 BW/s for left and right foot, respectively.

Figure 1: Ground reaction force traces on the left (broken line) and right (solid line) foot from one subject.

RESULTS AND DISCUSSION

The mean difference in GRF's at peak1 and peak2 was 0.4 ± 0.3 BW and 0.8 ± 0.6 BW respectively. The mean difference in loading rate at peak1 and peak2 was 47 ± 36 BW/s and 81 ± 68 BW/s respectively. GRF's and loading rates at both peaks were significantly different from zero ($p < 0.01$).

SUMMARY

The presence of asymmetries in force variables confirms that, in children, ground reaction forces and loading rates from drop landings are different between legs, supporting the need to measure forces on the same side that bone mass is assessed.

FORCE GENERATION AND STABILITY CONSIDERATIONS FOR ISOMETRIC PUSHING

B. C. Bennett, H. Kang, and K. P. Granata

Motion Analysis and Motor Performance Laboratory, University of Virginia, Charlottesville, VA

Email: bcb3a@virginia.edu

INTRODUCTION

Approximately 20% of all back injuries in the U.S. are attributed to pushing and pulling. This occurs despite the fact these tasks are thought to avoid the large compressive loads of lifting and carrying. Push studies have found co-contraction of trunk muscles. This co-contraction may be required to stabilize the spine. Unfortunately this co-contraction also increases spinal compression. This study investigates the effect of handle height and level of effort upon the moments, forces, and stability requirements on the low back during a static pushing task. A simple inverted pendulum model was used to compare spinal stability for push tasks with stability for lift tasks.

METHODS

Eleven subjects pushed on a stationary handle at three bar heights (shoulder, mid, and waist), with three levels of exertion (max, 30% and 15% of body weight). Subjects pushed with feet parallel to the push bar. Forces in three dimensions were recorded. Torso position was measured by electromagnetic sensors on T10, S1, and the sternum. The measured postures and forces were used to compute the moments at L5/S1.

The trunk was modeled as a simple inverted spring pendulum (see Figure 1). For static conditions stability requires the second derivative of the potential energy to be equal to zero:

$$\frac{d^2V}{d\Theta^2} = K - L_{cg} m_t g (\cos(\Theta)) - FL_t \cos(\Phi) = 0.$$

The stiffness gradient (q) can be defined as the ratio of the

external moment at S1 to the effective stiffness: $q = \frac{M_{ext}}{K}$.

Large q values have been associated with low stability, because the stiffness of a muscle is dependent upon its level of force production.

RESULTS

Maximum horizontal force production was larger for lower

Figure 1: Free body diagram of the trunk while pushing.

bar heights ($p < 0.001$). Moments were largest at the highest

bar height ($p < 0.0001$) and max effort ($p < 0.001$). Overall

external trunk moments were in extension and were small, agreeing with published data. In addition subjects leaned forward into the bar creating a large axial (parallel to the trunk) force component without significant trunk moment.

The stiffness gradients for the push trials and for equivalent lifting trials are shown in Figure 2. There was a main effect for bar height ($p < 0.001$) and an interaction between effort and push vs lift ($p < 0.04$). Post hoc analyses revealed a larger q (less stable) for shoulder height pushes vs. waist height pushes ($p < 0.02$) and for 15% lifts vs. max lifts ($p < 0.02$).

Figure 2. The stiffness gradient is larger than for pushing than for comparable lift tasks for most conditions.

SUMMARY

The stiffness gradients indicate that the back is less stable during pushing than in lifting for all but the cases with least effort. Research on lifting (Granta & Marras, 2000) has found that trunk muscles co-contract to increase stability, suggesting this would occur in pushing. A pilot study (N=2) replicated the above tests with EMG signals recorded for the rectus abdominals, external and internal obliques, and the erector spinae muscles. These tests revealed large degrees of co-contraction of the trunk flexor and extensors for all conditions.

Taken as a whole these results reveal pushing to be a complex task where the stability of the spine is must be considered when designing or modeling pushing tasks.

THE PROXIMAL FIBERS OF THE INTEROSSEOUS MEMBRANE CONTRIBUTES TO STABILITY IN THE RADIAL DOMINANT SINGLE BONE FOREARM

Barry P Pereira, Anam Kueh Kour and Robert W H Pho
Dearpartment of Orthopaedic Surgery, National University of Singapore, Singapore, Singapore

INTRODUCTION

The aim of this study was to investigate the allowable extent of resecting a segment of the ulna and the interosseous membrane (IOM) proximally, without compromising the stability at the proximal radio-ulnar joint (PRUJ). This work hopes to determine the portion of the IOM that contributes to stability in distraction and varus-valgus loading about the elbow, in the case of a radial dominant single bone forearm, where the distal ulna is resected.

METHODS

Forty-eight freshly-frozen upper limbs (50-70 y-o, 17 males, 7 females), disarticulated at the shoulder joint, were used in this study. They were stripped of muscles and skin leaving intact the bones, joints and ligamentous capsules. The specimens were divided into 3 test groups. In Group I (n=16), the forearm was loaded in a longitudinal forward direction (FD) to the length of the radius. In Group II (n=16), the forearm was loaded in a medial direction transverse to the length of the radius. The failure criterion was when the forearm displaced by 45-degrees medially. This was taken as the criterion for failure in varus loading. In Group III (n=16), the forearm was loaded in a lateral direction transverse to the length of the radius. The specimens were loaded until the forearm displaced by 45-degrees laterally. This was taken as the criterion for failure in valgus loading. In all, the specimens were loaded with a continuously increasing load (5-kg-sec) with loading applied at the radius. For each loading group, four conditions (A,B, C, D) were tested assessing the contribution of the central band (CB) and the proximal reverse fibers (rf). For each condition, 4 specimens were used. Beginning with a break of the ulna at the level 20-cm from the radial head (control), segments of ulna was subsequently resected proximal together with the IOM, dividing it at the ulna attachment, in 3 sequences (Fig. 1).

RESULTS AND DISCUSSION

The mean length of the ulna for all forearms was 25.97-cm (SD, 1.59). A summary of the mean and standard deviation of load to failure for the 3 loading groups are tabulated in Table 1.

Figure 1: Four conditions (A, B, C, D) of ulna resection. **CB** =central band, and **rf** = proximal reverse fibers

In forward distraction, excision of the ulna and releasing the proximal reverse fibres (Condition D) results in a significant drop in the load to failure. In varus and valgus loading, releasing the central band (Conditions B, C) and the subsequently the proximal reverse fibers (D), resulted in significant drops in the loads to failure.

SUMMARY

The study reveals that the proximal reverse fibers plays an important secondary stabilising role in resisting further failure when the ulna is disrupted. The study provide limits to the extent of the ulna and the IOM that should be preserved if some stability in forearm distraction or varus-valgus loading is to be experienced in a radial dominant single bone forearm.

EFFECTS OF CUSTOM ORTHOTICS ON LOWER EXTREMITY KINEMATICS, KINETICS, AND MUSCLE ACTIVITY

Anne Mündermann¹, Benno M. Nigg, and R. Neil Humble
Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada
¹ahau@kin.ucalgary.ca

INTRODUCTION

Foot orthotics have been proposed as an effective treatment of running injuries. Their biomechanical efficacy is commonly evaluated in terms of reduction in maximum foot eversion during the stance phase of running. However, most studies found very small and non-significant differences between custom orthotic and no-orthotic conditions [1]. In a recent study, increased knee joint moments have been associated with Patellofemoral Pain Syndrome (PFPS) [2], which is the most common running injury [3]. Therefore, the main goal of foot orthotics may not solely be to reduce maximum eversion angle but also to decrease knee joint moments and to optimize muscle activity. Thus, the purpose of this study was to determine the effects of custom orthotics on lower extremity kinematics, kinetics and on muscle activity.

METHODS

21 recreational runners participated in this study (12 female, 9 male; weekly mileage: 15-40 km). All subjects were pronators and were free of injuries for at least 6 months prior to the study. Subjects were examined and casted by a podiatrist. Custom-orthotics with the goal to reduce pronation were fabricated for each subject. The control insert and the custom orthotics were placed in running sandals thereby allowing for skin marker placement directly on the heel. Kinematic and kinetic data were collected for 100 running trials (4.0 ± 0.2 m/s) per subject per condition (total: 4200 trials) during nine experimental sessions on a 30-meter runway. EMG signals were recorded from seven lower extremity muscles and root mean squares were calculated for five equal time intervals. Differences in EMG between the two conditions were detected using MANOVA ($\alpha = .05$).

RESULTS AND DISCUSSION

Foot eversion angle, knee abduction moments, external knee rotation moments and muscle activity were affected by the custom orthotics (Figure 1). When wearing the custom orthotics, foot eversion and foot inversion increased by $1.1 \pm 0.3^\circ$ and $2.2 \pm 0.7^\circ$, respectively. Knee joint moments, reaching their maximum between 50 and 60 % of ground contact, increased when wearing custom orthotics (6.3 ± 1.4 Nm; 2.9 ± 1.1 Nm). Significant differences in muscle activity were found at times when the effects of custom orthotics on foot eversion, knee abduction and external knee rotation moments were greatest. The results of this study showed that custom orthotics can be used to alter lower extremity kinematics, kinetics, and muscle activity. However, the changes produced with the tested orthotics were opposite to

the change initially attempted. Further research should assess the effect of these changes on lower extremity integrity.

Figure 1: Mean differences (SE) in EMG, foot eversion, knee abduction and external knee rotation moments during ground contact for running in custom orthotics compared to a control condition (TD: touch-down; TO: take-off; n=8).

SUBJECT-SPECIFIC FINITE ELEMENT MODELING OF THE HUMAN MEDIAL COLLATERAL LIGAMENT

John C. Gardiner and Jeffrey A. Weiss

Musculoskeletal Research Laboratories, Bioengineering Department, University of Utah, Salt Lake City, UT jeff.weiss@utah.edu

INTRODUCTION

Despite many studies of ligament function, questions remain about the precise mechanical role of some ligaments as well as the cause, effect, and optimal treatment for various injuries. This is in part due to experimental limits. The objectives of this study were to develop, analyze, and validate subject-specific finite element (FE) models of the femur, medial collateral ligament (MCL), and tibia. MCL strain distribution during valgus loading was measured experimentally and predicted using FE models. It was hypothesized that subject-specific FE models could predict experimental MCL strain.

MATERIALS AND METHODS

Eight male knees (50 ± 7 years) underwent an experimental and computational protocol. All skin, muscle, and periarticular soft tissue was removed until only bones, menisci, and major ligaments remained and a CT dataset was obtained for each knee. 10 varus-valgus cycles were applied at flexion angles of 0, 30, and 60° to limits of 10 N-m. Joint kinematics were measured with an instrumented spatial linkage. A 3x5 marker grid allowed fiber direction MCL strain to be quantified with a 3D video system (Gardiner 2001a). After joint testing, the MCL was dissected for measurement of stress-free lengths between markers. These data were combined with in situ values to determine total fiber strain. Tensile test specimens harvested parallel and transverse to the fiber direction were used to determine subject-specific MCL material behavior (Quapp 1998).

FE models were created for each knee (Fig 1). Geometry of the femur, MCL, and tibia was obtained from CT data. The MCL was modeled as transversely isotropic hyperelastic (Weiss 1996). The femur and tibia were defined as rigid allowing experimental kinematics to prescribe motions of the model. In situ strains measured during passive flexion were applied to the FE models as an initial condition (Gardiner 2001b). Regression analyses evaluated the ability of subject-specific FE models to predict experimental MCL strain.

RESULTS AND DISCUSSION

Excellent agreement was found between experimental measurements and FE predictions of regional MCL fiber strain (Fig 2). FE strain predictions significantly correlated with experimental values at all flexion angles (Fig 3) ($p < 0.001$ at all angles; $R^2 = 0.83, 0.72$, and 0.66 at 0, 30, and 60°

Fig 1: Polygonal surfaces and FE meshes for a single knee.

Fig 2: MCL fiber direction strain with 10 N-m valgus torque at flexion angles of 0, 30, and 60° for experimental measurements (left) and subject-specific FE models (right) for one knee. Discrete exp. values have been interpolated onto a FE mesh to generate a continuous depiction of results.

respectively). There was a slightly decreasing correlation between models and experiments with increasing flexion. Slope and intercept of regression lines did not indicate a constant trend toward under or overprediction by FE models.

The main goal of this work was to assess the ability of FE models to predict MCL strain during valgus loading. Models with subject-specific geometry, material properties, in situ strain, and kinematics yielded good predictions of experimental strains. Numerical techniques such as the current FE models are vital to characterize complex deformations occurring in soft tissue structures such as ligaments and to quantify resultant stress and strain fields on microstructural and tissue levels. This will facilitate future studies of ligament injury, healing, and patient-specific clinical treatment.

CONSISTENCY OF PUTTER TRAJECTORY AND GOLF PUTTING ACCURACY

Jeff McCarty and Shirley Rietdyk

Biomechanics Laboratory, Purdue University, West Lafayette, Indiana, USA

Direct Questions to: srietdyk@sls.purdue.edu

INTRODUCTION

Accuracy in putting is vital to success in golf because 40-50% of the game is played on the putting green. Empirical studies of putting have used accuracy tests to examine the effects of such variables as the type of stance (Gott and McGown, 1988), point of visual fixation (Aksamit and Husak, 1983; Gott and McGown, 1988; Steinberg, Frehlich, and Tennant, 1995), type of putter (Gwyn and Patch, 1993), and impulse of the putting stroke (Delay, et al., 1997). However, the effects of putter trajectory on accuracy have not been examined.

METHODS

Male golfers (n=21) with USGA handicaps participated. Two groups were examined: low handicap (LH, <14) and high handicap (HH, >14). Total body center of mass (COM) was calculated for a 15-segment model, including the putter. Putter and segment motion was detected with 19 IREDs (Optotrak, NDI). Center of pressure (COP) was calculated from an AMTI force plate.

Two putting distances were observed: 2m and 4m. Radial distance from the target was calculated for 25 putts at each distance.

RESULTS AND DISCUSSION

Participants in both groups were similar in accuracy from 2m (LH mean $22.0 \pm 15.2\text{cm}$, HH mean $25.0 \pm 17.4\text{cm}$) ($p=.17$). Participants in the LH group were significantly more accurate from 4m when compared to HH players (LH mean $26.6 \pm 14.9\text{cm}$, HH mean $34.3 \pm 19.1\text{cm}$) ($p=.001$). This validates our use of handicap as a means of grouping even though other strokes are used in the determination of handicap.

Preliminary data analysis shows that highly skilled golfers (LH) have greater consistency in their putting strokes (see fig. 1). The more accurate putter must coordinate joint and segment angles to produce a consistent putter trajectory. Future research will examine the joint and segment angles.

Instructional literature in golf putting advises players not to move during the stroke. Both low and high handicap players demonstrated movement, but COP data shows that LH players have less weight shift during putts. In combination with the accuracy results above, this supports the instructional literature. Reduced movement appears to influence accuracy in golf putting.

Low Handicap (0)

High Handicap (18)

Figure 1: Putter head trajectory for 4m putts.

SUMMARY

Low handicap players are more accurate putters at greater distances. The increased accuracy may be due to greater consistency of putter trajectory and decreased weight shift during the movement.

MAXIMUM ANTERO-POSTERIOR EXCURSION OF THE CENTER OF PRESSURE DURING SIT TO STAND AND STANDING SWAY MOVEMENTS

Robyn M. Burgess and John H. Challis

Biomechanics Laboratory, Department of Kinesiology, The Pennsylvania State University, University Park, PA, USA

Email: rmb255@psu.edu, jhc10@psu.edu

INTRODUCTION

The ability to be able to perform the sit to stand (STS) is a significant determinant of independence. For certain populations, performing the STS is problematic, with for example strength being a limiting factor for some elderly subjects (Hughes et al., 1996). Measurements of postural stability in the elderly indicate that they have a greater response to perturbations to their posture; that is their stability is more affected than it is for young subjects (Nakamura et al., 2001). At the end of the STS subjects often have to stand still, that is effectively following the perturbation caused by the STS. The purpose of this study was to examine the influence of the STS on postural stability.

METHODS

Five healthy college-age subjects (3 male, 2 female) participated in this study. Subjects were asked to position themselves on a force platform (Bertec, Inc.) with the feet in a comfortable stance. Markers were placed on the FP at the toe, heel, medial, and lateral sides of the foot, and subjects were asked to reposition the feet within those marks for each trial. Trial conditions were as follows: quiet standing for 60s, standing on two feet swaying backwards and forwards as far as possible for 30s, and perform STS from a stool height of 0.45m at normal, slower than normal, and faster than normal speeds. In the STS trials once upright stance was achieved subjects had to stand still for 10 seconds. For all tasks the feet remained flat on the ground. Each condition was attempted three times by the subject. Motion analysis data were recorded for the STS to determine when upright stance occurred. All data were sampled at a rate of 240 Hz.

Antero-posterior excursions of the center of pressure were computed for sway (SW) and STS trials in the antero-posterior direction. These values are reported as a percentage of subject foot length. Anterior excursions of the center of pressure are designated positive, and posterior excursions negative.

RESULTS

Movement times reflected the instructions given to the subjects: slow STS $2.54s \pm 0.46$; normal STS $2.19s \pm 0.44$; fast STS $1.37s \pm 0.33$. The maximum amount of voluntary sway was $+4.72\% \pm 0.18$ and $-4.05\% \pm 0.56$. In contrast the maximum excursion of the center of pressure in the slow STS was $+9.45\% \pm 0.69$ and $-24.10\% \pm 0.40$, and $+11.12\% \pm 0.89$ and $-20.10\% \pm 2.06$ for the fast STS. Figure 1 displays these excursions relative to foot position. A time-frequency analysis of the center of pressure data once upright stance was

achieved, revealed that it took longer for the amplitude and frequency of the data to attain quiet standing levels the faster the STS was performed. For example this time was twice as great for the normal speed STS trials compared with the slow speed STS trials.

Figure 1: Maximum antero-posterior excursion of the center of pressure during standing sway trials and sit to stand movements.

DISCUSSION

These data on young healthy subjects indicate that the antero-posterior translation of the center of pressure is greater during the STS than during the maximum voluntary sway of the subjects. This indicates one of the challenges of the STS, as subjects have to be comfortable with relatively large excursions of the center of pressure. Time-frequency analysis of the center of pressure data show the time evolving properties of the center of pressure. With increasing speed of motion the time-frequency profile of the center of pressure takes longer after an upright position is obtained to return to the levels associated with quiet standing, providing evidence that the STS provides an additional challenge to the postural control system.

This study provides evidence about the challenge of the STS on postural stability after the movement. Future studies will examine these phenomena in the elderly.

LIGAMENT FORCES IN THE ANTERIOR CRUCIATE DEFICIENT KNEE DURING GAIT

Kevin B. Shelburne¹, Marcus G. Pandy², Frank C. Anderson³, and Michael R. Torry¹

¹Steadman•Hawkins Sports Medicine Foundation, Vail, Colorado, U.S.A., Kevin.Shelburne@shsmf.org

³Department of Mechanical Engineering, Stanford University, U.S.A.

INTRODUCTION

The functional gait adaptations of anterior cruciate ligament deficient (ACLD) individuals have been well documented. It is generally believed that these adaptations function to reduce loading in the collateral ligaments, although direct evidence of *in vivo* ligament forces in walking is currently not available (Berchuck et al., 1990; Devita et al., 1997; Andriacchi and Birac, 1993). In this study, we tested the hypothesis that ACL insufficiency does not directly increase the forces transmitted to the collateral ligaments of the knee during gait. A theoretical approach was used to determine ligament forces in the ACLD knee during walking. Muscle forces derived from a dynamic optimization solution for normal gait (Anderson and Pandy, 2001) were used as input to a three-dimensional model of the knee (Pandy et al., 1998) to calculate ligament forces. The calculations were analyzed to describe and explain the interactions between muscle forces, anterior tibial translation, and the forces induced in the ligaments of the ACLD knee.

METHODS

The right leg was modeled using four rigid bodies: thigh, shank, hindfoot, and metatarsals. All joints were represented as described by Anderson and Pandy (2001), except the knee, which was modeled as a six degree-of-freedom joint. The geometry of the distal femur, proximal tibia, and patella was based on cadaver data reported for an average-size knee. The contacting surfaces of the femur and tibia were modeled as deformable, while those of the femur and patella were assumed to be rigid. Thirteen elastic elements were used to describe the geometric and mechanical properties of the knee ligaments and posterior capsule (Pandy et al., 1998). The model leg was actuated by thirteen musculotendinous units.

A combination of forward and inverse dynamics was used to determine the relative translations of the bones and the forces induced in the knee ligaments during walking. Joint motion, ground-reaction forces, and the corresponding muscle forces obtained from a dynamic optimization solution for gait (Anderson and Pandy, 2001) were input to the leg model. The dynamical equations of the motion for the three-dimensional knee model were then used to determine the forces induced in the knee ligaments at each instant of the gait cycle. Two simulations were performed: one with the ACL intact; the other with the ACL removed. The calculations did not include the effect of gait adaptations in the absence of the ACL.

RESULTS AND DISCUSSION

The ACL was loaded throughout the stance phase of gait in

the intact knee model; peak force in the model ACL was about 344 N just after opposite-toe-off (Fig. 1). In the ACLD model, peak MCL force increased to about one half of that calculated for the ACL in the intact joint. Anterior tibial translation increased throughout the stance phase in the ACLD knee with a maximum difference of 9mm. An increase in anterior tibial translation in the ACLD knee decreases the angle of the patellar tendon relative to the tibia, and this in turn reduces the anterior pull of the patellar tendon on the tibia. Thus, there is no substantial increase in the forces transmitted to the secondary ligaments, since the anterior shear force applied to the tibia drops when the ACL is absent. Peak anterior shear force applied by the patellar tendon was 297 N in the intact model and just 117 N when the ACL was removed.

Figure 1: Ligament forces during the stance phase of gait for the intact knee (top) and ACL-deficient knee (bottom).

SUMMARY

The model results indicate that there is only a modest increase in ligament forces during ACLD gait. The collateral ligaments are naturally protected by the increase in anterior tibial translation that occurs when the ACL is absent, since this reduces the anterior pull of the patellar tendon on the tibia.

INVESTIGATION OF GOLF CLUB INERTIAL PROPERTIES VIA BIOMECHANICAL MODELING

Darrin R. Richards and Gary T. Yamaguchi

Department of Bioengineering, Arizona State University, Tempe, AZ 85287-9709, USA

INTRODUCTION

It is very important for golfers to swing all clubs similarly (*i.e.* to have all clubs come square at impact given the same muscular actions). This is because a golfer cannot perform multiple swings, and adjust to the inertial characteristics of a particular club. The industry standard is to match golf clubs via “swingweights”, which is a static measurement of weight distribution. However, the golf swing is a very dynamic activity involving large inertial and centrifugal forces. In addition, the advent of increasingly light and longer graphite shafts have made the swingweight scale ineffective.

It has been proposed that the static method of quantifying the mass distribution in a golf club should be replaced by a technique which accounts for the dynamic properties of golf clubs. Cochran and Stobbs (1969) suggested that a better way to balance clubs would be to balance the moments of inertia. In this study, a 3D model was developed to quantitatively investigate the feasibility of doing this.

Figure 1: Marker positions (L), and ICR pathway of club (R).

METHODS

Kinematic data was collected from expert golfers using the MacReflex system (Qualisys, East Windsor, CT). Four cameras sampled marker positions at 120 Hz to submillimeter resolution. Nine markers were affixed to the subjects' body segments and clubs (Figure 1L). Kinematic changes to the body segmental angles, or to the club, caused by introducing slight weighting differences to the clubs were not detectable by our experimental measurement system. However, the instantaneous center of rotation data (Figure 1R) proved to be useful for defining the best measure of club moment of inertia.

A 6 degree-of-freedom, 3D, forward dynamic model driven by joint moments was derived and programmed using Kane's method (Yamaguchi, 2001). The model predicted kinematic variables as functions of time based on joint moment inputs, and was useful because it could quantify small kinematic changes that were too minute to measure experimentally. Baseline joint moments derived from an inverse dynamic analysis of a Nike Tour pro's swing were used as initial

inputs, and modified until the model reproduced essentially the same swing in forward dynamic mode as the tour pro. The model delivered a peak clubhead velocity of 52 m/s at 290 ms, and a peak club angular velocity of 39.8 rad/s.

To measure the effect of small changes to the mass distribution of the golf club, the masses, lengths, centers of mass, etc., were altered slightly by changing inertial parameters in the modeled golf club. Three situations were investigated: (i) a 5 cm shorter, 4.1 g heavier “unbalanced” club; (ii) a “swingweighted” version of the unbalanced club; and (iii) a “dynamically balanced” club. The dynamic balancing was accomplished by matching the moments of inertia of the original club and the dynamically balanced club about a point 33.9 cm from the butt end of the club. This point is related to the “average” ICR of the club during the latter portion of the swing, and was determined through trial and error.

RESULTS AND DISCUSSION

Table 1 summarizes the results obtained by the dynamic simulations. The path of the clubhead remained quite stable in all simulations. However, the angle of the clubface at impact and the time at impact changed dramatically. Clubface angle determines the amount of sideways curvature and adversely affects ball flight and distance. As shown, the unbalanced club produced a 3.65° slice, and the swingweight technique overcorrected the clubface angle to produce a 2.38° hook. Balancing the moment of inertias of the two clubs greatly improved the result.

Table 1: Summary of results during simulated golf swings.

Modified Variables	Unbalanced Club	Swingweight Balanced	Dynamically Balanced
Δ Velocity	-1.56 m/s	-2.39 m/s	-2.05 m/s
Hook/slice	3.65° slice	2.38° hook	0.06° slice
Push/pull	0.30° push	0.23° pull	0.00°
Toe-up/Toe-down	0.22° toe-down	0.26° toe-down	0.21° toe-down
Δ Elevation Angle	-3.46°	-2.07°	0.20°

RUNNING ON ARTIFICIAL HIP JOINTS - IS IT WISE ? A HIP SIMULATOR STUDY

John G. Bowsher¹, Jim Nevelos², Jenny Pickard², Julia C. Shelton¹

¹ IRC in Biomedical Materials, Queen Mary, University of London, London, UK, mail@johnbowsher.com

² Corin Medical, Cirencester, UK

INTRODUCTION

The question whether today's artificial joints are suitable for patients who undergo high-impact sports is yet to be fully understood. Although a small number of hip arthroplasty patients have shown continued clinical success while running marathons, performing down hill skiing (1), martial arts etc, the relationship between patient activities and implant failure have not been fully estimated. As hip joints are being implanted in younger and more active patients, coupled with the introduction of much lower wearing 2nd generation hip implants, it is therefore timely that laboratory investigations account for such high activity conditions. Also, it is very possible that alternative bearing combinations and novel coatings may offer further improved wear performances for active patients compared to today's prostheses.

A previous laboratory study has reported that simulated jogging did not generate excessive wear of lightly-crosslinked UHMWPE/CoCrMo implants (2), with the results showing only a 40% increase in jogging wear compared to normal walking. In terms of wear debris production, this result implies that for most patients, short periods of impact sports will not greatly reduce the survival of crosslinked polyethylene implants. Additional wear studies have also shown that the introduction of small areas of femoral damage during simulated jogging tests did not generate excessive polyethylene wear, Table 1, and may explain why many active patients have experienced good clinical success.

For metal-on-metal implants, the influence of high patient activities has yet to be investigated; thus the aim of this study was to quantify the influence of patient activity level on metal wear debris generation.

EXPERIMENTAL METHODS

A wear study was undertaken using two 40 mm diameter resurfacing bearings (cast CoCrMo alloy to BS7252-4), supplied by Corin Medical, UK. All wear tests were performed using an 8-station hip joint simulator (MTS Systems, USA), which applies a $\pm 23^\circ$ biaxial rocking motion. All test specimens were positioned physiologically, and were run in 25% bovine calf serum (17 mg/ml protein content) as a lubricant. Normal and simulated jogging tests were undertaken at 1 Hz and 1.75 Hz respectively, with maximum forces of 2450 N and 4500 N. Volumetric wear was measured gravimetrically, and was corrected using unloaded controls.

RESULTS AND DISCUSSION

The walking and jogging wear results for the metal-metal joints are shown in Table 1. This study offers continuing experimental evidence that higher patient activities, such as fast jogging, do not lead to excessive wear of 2nd generation hip implants. During simulated jogging, the maximum levels of frictional torque were generated at the point of contact after joint separation, typically 0.5 to 1.2 Nm, and 0.2 Nm without separation. These results are very encouraging for demanding and younger patients, as it would seem that a much higher level of patient activity can be withstood by modern implants than previously thought. Although it's strongly advised that hip arthroplasty patient avoid activities which may lead to large collisions and falls, the results from this study suggest that activities like jogging are well within the normal performance of most implants. In light of this result, further wear studies are currently underway, investigating alternative patient activities and implant bearing materials.

ADAPTATIONS IN LOWER EXTREMITY JOINT KINETICS TO INERTIAL ASYMMETRIES DURING WALKING

Philip E. Martin¹, Jeremy D. Smith¹, and Todd D. Royer²

¹Exercise and Sport Research Institute, Arizona State University, Tempe, Arizona (email: philip.martin@asu.edu)

²Department of Exercise and Sport Sciences, University of Delaware, Newark, Delaware

INTRODUCTION

Modeling the lower limb as a forced driven harmonic oscillator (FDHO; Holt et al., 1990; Kugler & Turvey, 1986), walking stride time can be predicted as a function of lower limb mass distribution properties. When leg inertial properties are increased symmetrically, stride time increases in a manner consistent with FDHO predictions (Holt et al., 1990). Asymmetrical inertial manipulation disrupts temporal and kinematic symmetry such that the weighted limb reflects a longer swing time and shorter stance time (Royer & Martin, 1999). Further, actual stride time is intermediate to FDHO predicted stride times for the unloaded and loaded legs. Adaptations at the muscle and joint kinetic level underlying these temporal changes have received limited attention. The purpose of this study was to investigate these adaptations by examining net joint moment profiles about the ankle, knee, and hip under asymmetrical lower extremity inertial conditions.

METHODS

Twelve healthy young adults, free of notable gait and structural asymmetries, served as subjects. Sagittal plane video (60 Hz) and ground reaction force (480 Hz) data were collected as subjects walked at $1.57 \text{ m}\cdot\text{s}^{-1}$. Subjects completed trials under a symmetrical, unloaded condition (Sym-NL) and asymmetrical inertia conditions (0.5, 1.0, or 2.0 kg masses added to one foot only). Net joint moments at the ankle, knee, and hip were computed from inverse dynamics. Segment inertial properties were predicted using methods of deLeva (1996). Moments were normalized temporally (100% stride) and to body weight and leg length to yield dimensionless expressions (Hof, 1996).

RESULTS AND DISCUSSION

Adaptations in the net ankle, knee, and hip moments (Figure 1) to asymmetrical loading occurred in both the unloaded (Asym-0 kg) and loaded (Asym-2 kg) legs when compared to the fully unloaded condition (Sym-NL), and increased systematically with increasing inertial asymmetry. Temporal shifts in the moments consistent with a shorter stance time and longer swing time were especially notable in the loaded limb (Asym-2 kg) during the second half of stance. Adaptations in joint moment amplitude were also apparent, particularly at the knee and hip. In the first half of stance, knee extensor function was greater and hip extensor function lower in the loaded leg. In later stance, the loaded limb reflected lower knee flexion and higher hip flexion actions. Swing phase asymmetry was

most apparent at the end of swing with the loaded leg reflecting higher knee flexor and hip extensor moments.

Figure 1. Average ankle, knee, and hip moments for Sym-NL and the most extreme asymmetrical inertia condition (Loaded leg: Asym-2 kg; unloaded leg: Asym-0 kg).

SUMMARY

The neuromuscular system, as reflected by net joint moments, adapts asymmetrically to imposed inertial asymmetries. This adaptation presumably is an attempt to retain as much symmetry temporally and kinematically as possible, even though both temporal and kinematic asymmetries emerge with increasing inertial imbalance.

THE TESTING AND VALIDATION OF A FAST RESPONSE INCLINOMETER

Peter W. Johnson¹, Chris Townsend² and Steve Arms²

¹ Department of Environmental Health, University of Washington, Seattle, WA, petej@u.washington.edu

² Microstrain, Inc., Burlington, VT

INTRODUCTION

The development of an ambulatory postural measurement tool with dynamic response may have widespread application in the field of biomechanics. Inclinometers have been primarily used for ambulatory posture measurement; however, these devices have a very slow response and typically cannot accurately measure dynamic movements. Therefore, the goal of this preliminary study was to test and characterize the performance of a prototype device, called a Flexion Angle Sensor with Gyro (FAS-G), for accurately measuring both static and dynamic movements.

METHODS

The prototype device (FAS-G; Microstrain, Inc; Burlington Vermont) was built and consisted of two accelerometers (inclinometers) and one piezo-ceramic gyro packaged in a 1.7 cm x 4.1 cm x 2.7cm plastic housing. The gyro has excellent rate response but poor signal stability over time (drift), whereas the inclinometers have great stability but poor rate response. By combining the output of the inclinometers with the gyro, the intention was to utilize the combined response of both sensors, that is, switching between the fast acting gyro signal during dynamic movements and the stable inclinometer signal during slow movements.

To test the device, the FAS-G was connected in series to an potentiometer (Model 157; Vishay Spectrol; Malvern, PA) and three tests were performed: 1) a static angle measurement tests where the FAS-G was placed in 0° , $\pm 30^\circ$, $\pm 60^\circ$ and $\pm 70^\circ$ of pitch and rotated at a slow rate between 0° and 360° of roll; 2) a dynamic swing test where the FAS-G was connected to a pendulum and subjected to swinging movements of up to $400^\circ/\text{s}$; and 3) a highly dynamic impulse test where the FAS-G was abruptly stopped in the middle of a pendulum swing. During the tests, the signals from the FAS-G, and potentiometer were collected and stored at 1000Hz using a portable computer instrumented with a data acquisition card (Model AI-16E-4; National Instruments; Austin, TX). The output between the FAS-G, inclinometers (accelerometer outputs from the FAS-G) and potentiometer (gold standard) were compared.

RESULTS AND DISCUSSION

Static Tests. Angle-angle plots comparing the outputs from the FAS-G and potentiometer demonstrated that the FAS-G accurately measured angles over 360° of roll with an average absolute error of 2.8° , 4.8° , 4.5° and 7.4° at 0° , $\pm 30^\circ$, $\pm 60^\circ$, $\pm 70^\circ$ of pitch respectively.

Dynamic and Impulse Tests. Figures 1 and 2 show typical results from the pendulum and impulse tests.

Figure 1: Comparison of outputs between the potentiometer, FAS-G and inclinometer during a typical pendulum test. The left graph is the full test and the right graph is the first 3 seconds. The FAS-G virtually tracked the dynamic swinging

movements as measured by the potentiometer (gold standard) whereas the conventional inclinometer both lagged and underestimated the magnitude of the movements. The absolute average error over the test was 0.6° for the FAS-G and 6.9° for the inclinometer.

Figure 2: Comparison of outputs between the potentiometer, FAS-G and inclinometer during a typical, highly dynamic, impulse test. The pendulum was rapidly stopped at roughly 3.3 seconds. The left graph is the full test and the right graph is the last second. The FAS-G tracked the movement during the highly dynamic impulse quite well, whereas the inclinometer both lagged and took a greater amount of time to settle after the abrupt stop.

SUMMARY

Preliminary tests indicated that the FAS-G performed well for both static and dynamic angle measurement. Movements with velocities up to $400^\circ/\text{s}$ were accurately measured. In addition, the impulse tests indicated that very abrupt movement changes may be accurately measured. As a result, the highly dynamic response of the FAS-G should allow the measurement of limb positions during both slow and fast movements. Unlike conventional inclinometers, the dynamic response of the FAS-G will allow the calculation of limb velocities and accelerations. Future testing will include the study of the FAS-G for measuring more rapid and random movements in order to determine the upper limits of dynamic measurement.

MECHANICS OF APE SWINGING (PASSIVE DYNAMIC BRACHIATION)

Mario Gomes (mwgl@cornell.edu) and Andy Ruina

The Human Power, Biomechanics, and Robotics Laboratory, Cornell University, Ithaca, NY, USA

INTRODUCTION

Long armed apes are able to move very rapidly through the treetops in a remarkably smooth manner. Are there some simple mechanical ideas which help explain how they achieve this type of locomotion with such apparent ease? In this work we examine the dynamics of several simplified rigid body models with a focus on energy conservation. Is it possible for the apes in our models to “brachiate” with *zero* energetic cost? To answer this, we would need to find periodic motions in the models which conserve energy.

Long armed apes have two distinct brachiating “gaits”: 1) a continuous contact gait where one hand is always in contact with the overhead support and 2) a faster ricochetal gait with a period of free flight between handholds. Both of these motions are very smooth and at times resemble the motion of a simple pendulum (Fleagle, J). Further, the hands don't make jarring impacts when grabbing a new support. Given these observations and the obvious necessity for energy efficiency, we hypothesized that perfectly efficient passive-dynamic motions could be found in these models. To test this hypothesis we examined a series of two dimensional, passive rigid body models for energy conserving, periodic motions.

METHODS

All of the models we examined consist of linked rigid bodies. We “cheat” slightly by assuming that there is a non-passive hand that can grab onto and release from a handhold, with which it is coincident at appropriate times. The grabbing and releasing of the hand does not produce or absorb any mechanical work so we simplify things by neglecting the energy required to grasp and release the handhold. There are no other actuators or springs. Thus the only way for energy to leave the system is in a collision with an impact of the hand with the handhold. The key to our models is finding motions where the hand collides with a new support at a relative velocity of zero, thus dissipating no energy when the hand contacts the support.

The first model examined is a single rigid body with inertia and massless arms, an extension of the point mass model of Bertram et al. Next, we examined a model consisting of arms with inertia and a point-mass body, i.e. two rigid bodies connected at a massive hinge joint. Lastly, we examined a three-link model with two arm links and a torso-leg link, i.e. three linked rigid bodies. For each model we considered both continuous contact and ricochetal brachiation. Numerical integration of the nonlinear equations of motion was the main tool of our study.

RESULTS AND DISCUSSION

For each of the models, not only were we able to find a collisionless periodic motion, but we found that a whole family of solutions exists for each set of model parameters.

In the third model, for example, the arms swing passively from handhold to handhold making smooth contact at the grab. Meanwhile, the body swings underneath in a manner reminiscent of actual gibbon brachiation as shown in figure 1.

Figure 1: A collisionless ricochetal motion for the three-link model

SUMMARY

Perfectly energy efficient brachiation is possible with a rigid body model. If it is possible for the “apes” in these models to brachiate without using any energy, then actual apes might exploit this to their benefit when coordinating their quick and smooth movements in the treetops. These results support the idea that energy efficiency may be a large factor in determining the coordination strategy used by brachiating apes and that passive-dynamic mechanisms are used to achieve this efficiency.

CERVICAL SPINE KINEMATICS FOLLOWING SEQUENTIAL SECTIONING: NOVEL IMPLICATIONS FOR EXTENSION TYPE INJURIES

Klane K. White¹, Catherine M. Robertson¹, Andrew T. Mahar², Peter O. Newton², Mark A. Gomez¹

¹ Department of Orthopedics, University of California San Diego, San Diego, CA

² Department of Orthopedics, Children's Hospital – San Diego, San Diego, CA

INTRODUCTION

Current clinical understanding of cervical spine kinematics in the intact and injured spine is based on well-referenced publications^{1,2}. Previously, Gomez et al. reported the use of a specially designed rig which induced an applied moment with a coupled vertical shear load.³ They found significantly greater angular changes than those referenced,^{1,2} as well as translation up to 5 mm in an intact motion segment. That study was limited to an examination of applied flexion moments with sequential cutting of soft tissue structures from posterior to anterior. The purpose of the present study is to examine the kinematics of individual motion segments in extension with sequential cutting of soft tissue structures from anterior to posterior.

METHODS

Cervical spines were harvested from seven fresh frozen human cadavers (ages 31-45) and sectioned into C2-C3, C4-C5 and C6-C7 motion segments. A loading rig fixed the lower vertebra to a sliding plate. The upper vertebra was fixed to a pulley system via 3.5 mm smooth pins: one through the center of the vertebral body and the other through the posterior arch. (Figure 1)

Figure 1: Loading rig for cervical testing.

A constant moment of 2 Nm with a coupled vertical shear load of 155 N ($\approx 25\%$ body weight) was applied to each motion segment. The linear translation of the sliding plate and the angular rotation of the pulleys were measured at two minutes with linear and rotatory variable differential transformers. Data were collected for intact segments, followed by serial transection of: (1) the anterior longitudinal ligament (ALL), (2) the anulus fibrosus (ALL+disc) and (3) the facet joint capsular ligaments (ALL+disc+facets). Linear and angular displacement values were measured after each transection. Repeated measures ANOVA ($p < 0.05$) and *post hoc* difference contrast tests for multiple comparisons were used to compare differences after serial sectioning and among the three motion segment levels.

RESULTS AND DISCUSSION

There was an significant ($p < 0.001$) increase in linear translation with sequential soft tissue transection. A significant sequential increase in angular rotation was also noted ($p < 0.001$). There was no significant difference among motion segments in either linear translation ($p = .25$) or angular rotation ($p = .20$).

Figure 2: Data for translation and rotation.

On average, the findings of increased linear translation agree with previous data^{1,2} with means less than 2.7 mm in all groups. The angular changes seen in this study were greater than those previously described^{1,2}. The maximum angular change in this study was 17.8° for an intact specimen (range $5.7 - 17.8$). Current recommendations for suspected cervical spine instability are angular deformity $> 11^\circ$ relative to adjacent motion segments on static lateral radiographs, or $> 20^\circ$ of sagittal plane rotation on dynamic radiographs.⁴ Many of the intact segments surpassed these parameters.

SUMMARY

This study of cervical spine motion segment kinematics found greater cervical spine motion than reported previously^{1,2}. The current test rig may better simulate physiologic cervical spine kinematics by applying a constant moment with a coupled vertical shear load. These data indicate that current recommendations for diagnosing cervical spine instability may be conservative, warranting further investigation.

HAMSTRINGS ACTION ALONE CANNOT LIMIT ANTERIOR TIBIAL TRANSLATION IN ACL-DEFICIENT GAIT

Kevin B. Shelburne¹ and Marcus G. Pandy²

¹Steadman•Hawkins Sports Medicine Foundation, Vail, Colorado, U.S.A., Kevin.Shelburne@shsmf.org

²Department of Biomedical Engineering, University of Texas at Austin, U.S.A.

INTRODUCTION

Numerous studies have suggested that increased activation of the hamstrings muscles may compensate for the loss of anterior tibial restraint in the ACL deficient (ACLD) knee (Solomonow, et al., 1987; Liu and Maitland, 2000). Virtually no data are available, however, for the amount of hamstrings force needed to keep the ACLD knee stable in any activity. In this study, we used a three-dimensional model of the lower limb to calculate anterior tibial translation (ATT) in ACLD walking. The model was also used to calculate the amount of hamstrings force needed to limit ATT and keep the ACLD knee stable during the gait cycle. The margin of stability was defined as the amount of ATT calculated for maximum isometric contractions of the quadriceps in the ACL-intact knee (Pandy and Shelburne, 1997). We hypothesized that hamstrings muscle action alone is sufficient to stabilize the knee throughout the stance phase of ACLD gait.

METHODS

A theoretical approach was used to find the relative positions of the bones and the forces induced in the ligaments during ACLD gait. The right leg was modeled using four rigid bodies: thigh, shank, hindfoot, and metatarsals. All joints were represented as described by Anderson and Pandy (2001a), except the knee, which was modeled as a six degree-of-freedom joint. The geometry of the distal femur, proximal tibia, and patella was based on cadaver data reported for an average-size knee. Thirteen elastic elements were used to describe the geometric and mechanical properties of the knee ligaments and capsule (Pandy et al., 1997). The model leg was actuated by thirteen musculotendinous units.

Joint motion, ground-reaction forces, and the corresponding muscle forces obtained from a dynamic optimization solution for normal gait (Anderson and Pandy, 2001a) were input to the leg model. The dynamical equations of the motion for the three-dimensional knee model were then used to determine the relative positions of the bones at each instant during the stance phase of ACLD gait. Three simulations were performed: (1) hamstrings force was calculated for normal walking with the knee intact; (2) the model ACL was removed before calculating the amount of hamstrings force needed to limit ATT to the level predicted for the intact model; and (3) the ACL was removed before calculating the amount of hamstrings force needed to limit ATT to the level predicted for maximum isometric contractions of the quadriceps.

RESULTS AND DISCUSSION

The model calculations showed that hamstrings muscle action

cannot limit ATT to the level calculated for the intact knee during normal gait (Fig. 1). Although less hamstrings force was needed to keep the knee stable in ACLD gait, this amount is still far greater than that developed in normal walking with the knee intact (Anderson and Pandy, 2001b). The inability of the hamstrings to limit ATT in ACLD gait is explained by the dependence of the geometry of these muscles on the flexion angle of the knee. When knee flexion angle is less than 15 degrees, as it is for much of the stance phase of walking, the angle between the line of action of the hamstrings and the long axis of the tibia remains small. In this case, hamstrings cannot exert a large enough posterior pull on the tibia to limit ATT in the stance phase of ACLD gait (Pandy and Shelburne, 1997).

Figure 1: Percent of peak isometric hamstrings force needed to limit ATT to the level calculated for the intact knee (black line) and to keep the ACLD knee stable (gray line). Also shown is the amount of hamstrings force predicted for normal gait (thin black line) (Anderson and Pandy, 2001b).

SUMMARY

Hamstrings co-contraction force needed to stabilize the knee in ACLD gait is far greater than that evident in normal walking. The ineffectiveness of hamstrings muscle action in ACLD gait is explained by the geometry of these muscles at the knee and by the fact that knee flexion angle remains relatively small in the stance phase of walking.

INTRODUCTION

Cell locomotion is implicated in many biological processes such as embryogenesis, inflammatory response, wound healing. The mechanism of cell locomotion is commonly divided into three steps : formation of a lamellipodial protrusion, adhesion of the lamellipodium to the substratum and translocation forward of the cell body. The first step has been extensively studied in term of the molecular basis of force generation but little is known about the mechanical properties of moving cells, especially the properties of the lamellipodium which plays a crucial role in cell locomotion. By using the Atomic Force Microscopy (AFM), we presently analysed the elastic modulus of the lamellipodium of fish epidermal keratocyte, a fast moving cell (velocity ~ 15 $\mu\text{m}/\text{min}$) characterised by high persistence and stability of shape during movement. The use of AFM allows us to locate cellular areas with different elastic properties and correlate them with the topography of the keratocyte.

METHODS

Keratocyte Culture: Black Tetra keratocytes were cultured in DMEM (Hepes modification; Sigma Immunochemicals) supplemented with 20 % FBS and antibiotics. Fish scales were extracted with tweezers, placed on dry coverslips and allowed to adhere for 30-60s to prevent floating. Culture medium was then added and the scales were kept at 30°C overnight to allow for migration of keratocytes onto the coverslip. Colonies of migrated cells were treated with 0.2 % trypsin and 0.02 % EDTA in PBS for ~30-60s and cells were allowed to recover 1-3 h in fresh medium before AFM experiments.

Atomic Force Microscope (AFM): A commercial AFM (Bioscope, Digital Instruments) combined with an inverted microscope was employed for this study. This combination allowed positioning of the AFM tip on the sample to micrometer precision. Soft silicon nitride cantilevers (force constant of 10 $\mu\text{m}/\text{N}$) were employed.

Data acquisition and analysis: The elastic modulus E can be calculated from the force curves, that correspond to the deflection of the AFM cantilever which is continuously monitored as it approaches the sample. As the cell moves at almost constant speed, the force curves are continuously recorded at a fixed point which is localised on the course of the cell and more precisely on the course of one cellular lobe. This method allows to obtain an analysis of E and of the cellular true height H along a line which is perpendicular to the leading edge of the cell and which crosses the lamellipodium. To calculate E and H from the force curves, we employed the Hertzian model for a purely elastic indentation in a flat and soft sample by a stiff cone (Radmacher, Fritz et al., 1996).

RESULTS AND DISCUSSION

Figure 1: Variations of the elastic modulus E and the true cellular height H of a migrating keratocyte along a scan line perpendicular to the leading edge of the cell.

These preliminary longitudinal assessments of the mechanical response of the migrating keratocyte show that the motile state of the cells is not disturbed by the AFM measurements. Concerning the profile of the elastic properties, it appears that the lamellipodium is more rigid at the leading edge than at the rear: E decreases from ≈ 75 kPa on the leading edge down to ≈ 5 kPa on the rear edge (Fig. 1). Moreover, the variations of E do not appear to depend on the lamellipodium thickness H , i.e., in the first part of the curve, the true height is approximately constant (≈ 75 nm) while the elastic modulus decreased from about 50%. These results confirm that the variations in elastic modulus are not caused by the influence of the underlying substrate. On the other hand, these mechanical properties, which are believed to reflect the underlying actin network properties (Hofmann, Rotsch et al., 1997), are consistent with the reduction of actin filament density from the front to the rear edge of keratocyte lamellipodia and with the dynamic network contraction model of keratocyte locomotion (Svitkina, Verkhovsky et al., 1997).

INTRODUCTION

When the coronary presents a partial occlusion, the myocard, depending on the degree of the occlusion severity, is no more sufficiently perfused. One of the solution consists of introducing a stent at the stenosis location. When multiple stenoses occur for example one in the coronary and one in its collateral, the cardiologists introduced two stents. However, in order to minimize the perturbations induce by the stent cell at the bifurcation, the cardiologists break the cell by inflating the balloon. This technique, cardiologist dependant, is aleatory. In addition, to the authors knowledge, no hydrodynamic studies in the literature analyze the stents influence on the flow patterns in a bifurcated artery. Therefore the goal of this numerical work is to provide informations of the perturbations induced by the presence of two stents in a bifurcated coronary with or without cell at the bifurcation position.

METHODS

The geometrical models are constituted of a 90° intersection of two cylinders. The first stent is located at the bifurcation and the second one in the collateral coronary. Several configurations have been investigated: 1) without stent in order to provide a reference flow features, 2) with two stents, 3) the stent cell located at the bifurcation is broken. The others cases represents a aleatory broken cell (4 and 5 case).

The shape of the stents is provided by a real deformed Palmaz stent issued from Abaqus code. The Navier Stokes equations are numerically solved using a volume finite package named Fluent. The viscosity is the blood viscosity $\nu=3.6 \times 10^{-6} \text{ m}^2/\text{s}$. The density, ρ is equal to 1050 kg/m^3 . The mesh, including the two stents, is constituted of 125335 tetrahedral elements.

RESULTS AND DISCUSSION

The figures 1 and 2 show the velocity vectors for respectively the $Z=0$ plane and the $Y=2.96 \text{ mm}$ plane. a) represents the case 2 and b) a broken cell case.

Figure 1 : velocity vectors in $Z=0$ plane

Figure 2 : velocity vectors in $Y=2.96 \text{ mm}$ plane

We observe (case 2, fig. 1a) two lateral jets and the occurrence of stasis areas downstream from the cells. In opposition the case 4 (fig. 1b) presents a large central jet. Therefore, the flow features depend on the cell overture. Figures 2a and b highlight the secondary structures differences. The well known counter rotative vortex are present for case 4 (fig. 2b) when for the case 2 (fig 2a), the motion induced by the jets through the cells modifies the classical counter rotatives vortex. The radial pressure gradient dominates the centrifugal force and stops the vortex formation.

SUMMARY

When two stents are introduced at bifurcation, the cell overture of one of them is so cardiologists dependent and the flow features so cell overture dependent that it would be reasonable to consider a specific stent design for a bifurcation implantation.

MODIFICATION IN THE POSTURAL CONTROL DURING LONG-TERM STANDING

Luís A. Imbiriba¹, Cíntia R. Cruz¹, Míriam R. M. Mainenti¹, José Magalhães¹, Marco A. C. Garcia¹
Líliam F. Oliveira¹ and Jurandir Nadal²

¹Laboratory of Biomechanics, EEFD, Federal University of Rio de Janeiro, aurelio@eefd.ufrj.br

²Biomedical Engineering Program, COPPE, Federal University of Rio de Janeiro, jn@peb.ufrj.br

INTRODUCTION

Stabilometry is an useful tool for studying postural balance control and also for clinical purposes. Although the test protocol is not well defined yet, it is recommended short term tests to minimize any effect due to fatigue (Le Clair et al, 1996 and Carpenter et al, 2001). Nevertheless there is no conclusive evidence of the fatigue process related to the test duration. The objective of this study is to identify modifications in some stabilometric parameters in long-term tests to help clarify this question.

METHODS

24 healthy volunteers, divided in two groups of 12 subjects (6 males e 6 females), were submitted to stabilometric tests. All subjects gave their consent. Subjects stood on a force platform, barefoot, with feet together. The session lasted for a total time of 31 minutes, with the register of seven trials of one minute in each 5 minutes. Between registers, group 1 (G1) sat on a chair, keeping the feet at the same place and group 2 (G2) continued standing on the platform.

In each trial, the subject had to choose a value at the Borg's scale that qualifies his sensation of tired and discomfort.

The analyzed stabilometric parameters were mean velocity, mean power frequency, mean position and the standard deviation of the center of pressure (COP) in lateral and anterior-posterior directions, as well as the elliptic area (Oliveira et al, 1996). It was used a 12 bits A/D converter with a sampling rate of 50 Hz and a filter anti-aliasing at 5 Hz. Two-way ANOVA for repeated measurements and Tukey's HSD post-hoc analysis were employed to compare groups (G1 and G2) and trials (seven levels).

RESULTS AND DISCUSSION

Figure 1 shows the results for Borg's scale between the groups. There was a statistic difference from the trial 5 (approximately 20 minutes) to the end of the test, where the group 2 related higher values on the scale ($p=0.000001$). The stabilometric parameter witch followed this tendency was the standard deviation of COP in the lateral direction (Figure 2) where the statistic difference between groups also appeared at the trial 5 ($p=0.002$).

Standard deviation and mean velocity in the anterior-posterior direction and the elliptical area were statistically different between groups from trial 4 (15 minutes) to 7 (30 minutes), except for trial 5, interestingly at the same trial the Borg's scale value differed statistically. Mean position, mean velocity and mean frequency of the lateral displacements were not different between groups at any moment of the test

duration. Mean frequency at the anterior posterior direction show a tendency to reduce during the test for both groups, although not significant ($p=0.162$).

This results shows that for the analysis of stabilometric parameters used, there is no evidence for short term test recommendation. Borg's scale, although not used here for its primarily purpose, could be a helpful tool in detecting fatigue sensation in stabilometric tests. Future studies will use electromiography to help identifying muscular fatigue process.

AUTOMATED SUBJECT-SPECIFIC SCALING OF SKELETONS TO MOTION-CAPTURED MARKERS

Victor Ng-Thow-Hing¹ and Jianbo Peng²

¹Fundamental Research Laboratories, Honda R&D Americas, Inc. vnghowhing@hrra.com

²Media Research Lab, New York University

INTRODUCTION

Simulations using generic musculo-skeletal models enable qualitative insights to be made about human motor tasks (Zajac, 1993). However, simulations using subject-specific skeletons can aid in making more quantitative comparisons of a simulated model with its real human counterpart. We have developed a flexible optimization framework for the automated scaling of subject-specific human skeletons from motion-captured data. The resulting skeleton can then be used for the simulation and analysis of musculo-skeletal function. The computation of joint centers from different gait models has yielded inconsistent results (Tabakin and Vaughan, 2000). Therefore, we avoid reconstruction of joint centers based solely from a single, static pose and we scale bones using direct information from marker positions rather than distances between derived joint centers (Musculographics, 2001). The purpose of this study is to compare the performance of two different optimization strategies for subject-specific skeleton fitting.

METHODS

The framework is based on a least squares minimization of the distance between recorded marker positions and virtual markers placed on a generic, scaleable human model. A constrained nonlinear optimization is used to simultaneously adjust joint and bone scaling parameters, producing a scaled skeleton with joint angles that fits the marker data.

The parameters, \mathbf{x} , of the optimization are partitioned into joint degrees of freedom, \mathbf{x}^J , and bone scale factors, \mathbf{x}^B . The optimization's objective function is a weighted sum of squared differences between the marker locations and their transformed counterparts on the generic model:

$$f(\mathbf{x}) = \sum_{s \in S} \sum_{m \in M_s} w_i \|T_s(\mathbf{x}^J)D_s(\mathbf{x}^B)v_m - m\|^2,$$

where S is the set of all segments in the skeleton and M_s is the set of markers associated with a segment s . The virtual marker, v_m , is the corresponding marker located on the generic human skeleton and is transformed by a matrix $T_s(\mathbf{x}^J)$, specifying the position and orientation of a bone segment s , and a nonuniform scaling matrix, $D_s(\mathbf{x}^B)$. Scale factors are constrained to be within anthropometric limits. The weights, w_i can be modulated to produce a stronger fit to selected markers and control rates of convergence to a solution.

Two different optimization strategies were implemented. The first method simultaneously optimizes all parameters \mathbf{x} of the

skeleton. The second method solves a series of smaller optimizations where each optimization solves a subset of \mathbf{x} corresponding to the joint and scaling parameters of a local region of the skeleton's segments. For each frame of a motion-captured walking sequence, the optimization procedure was applied to fit the skeleton to the marker configuration of the subject's pose. The bone's scale factors over the entire motion sequence were averaged and fixed for a second optimization pass over the motion sequence that adjusts only \mathbf{x}^J . This prevents the bones from changing shape during the motion sequence because of inter-frame marker noise.

RESULTS AND DISCUSSION

Figure 1 displays a fitted skeleton from a walking motion

Figure 1: Image from a motion-capture session is compared with the corresponding fitted skeleton.

sequence from which joint angle trajectories can be obtained. Although the second optimization method was four times faster, the first method produced a 20% average reduction in the fitting error over all frames of the motion sequence. We suggest the second method can be used to quickly find a good initial guess to accelerate convergence of the first method.

SUMMARY

A framework for automated fitting of a generic human skeleton to subject-specific anthropometric markers has been described. We are planning sensitivity analyses to investigate the robustness of the algorithm to noise and errors in marker placement.

SPINAL CANAL OCCLUSION IN FLEXION-COMPRESSION : THE EFFECT OF INJURY MECHANISM IN AN UPPER THORACIC SPINE EXPERIMENTAL MODEL

Thomas Oxland¹, Qingan Zhu¹, Randy Ching², Chris Lane¹, Charles Fisher¹, Marcel Dvorak¹

¹Department of Orthopaedics, University of British Columbia, Vancouver, British Columbia, Canada, toxland@interchange.ubc.ca

²Department of Orthopaedics, University of Washington, Seattle, Washington, USA

INTRODUCTION

Spinal canal occlusion (SCO) has been measured during burst fractures in the thoracolumbar and cervical spine [Chang 1994, Panjabi 1995, Ching 1997, Carter 2000] and dynamic SCO was significantly higher than post-injury SCO. However, there is virtually no information on SCO along the spinal canal, and specifically no reports of SCO for different injury mechanisms of the spine. Therefore, the objectives of the present study were to contrast the dynamic SCO for different flexion-compression spinal injuries, specifically comparing dynamic and post-injury SCO and determining how these occlusion levels varied along the spinal canal.

METHODS

Nine cadaveric spine specimens (T1-T4) were used. A custom designed spinal canal occlusion transducer was used to measure the cross-sectional area of the spinal canal, based on the changing electrical resistance of saline water under a constant current between eight discrete segments along the canal [Raynak 1998]. A known compressive displacement was applied to the upper vertebra at 500mm/sec, at 10cm anterior to the balance point of the specimen. In six specimens, the anterior translation of T1 was constrained while it was allowed to translate freely in three specimens. For the constrained test, the initial displacement was 5mm, and was followed by displacements of 10mm, 15mm, 20mm, and finally 25mm. These displacements were 10, 20, 30, 40, and 50mm for the unconstrained cases. The maximum SCO during compression was defined as the dynamic SCO. The SCO immediately after the applied compression was defined as the post-injury SCO. The dynamic and post-injury SCO for the constrained and unconstrained cases were compared with a Mann-Whitney U-test.

RESULTS AND DISCUSSION

For the constrained specimens, the general fracture pattern was a fracture-dislocation at T2-T3, while the fracture pattern of the unconstrained specimens was distractive injury at T4. The dynamic SCO for the constrained cases was significantly greater than for the unconstrained at equivalent axial displacements ($p=0.023$; Figure 1). For the constrained cases, the occlusion along the spinal canal with progressive compression demonstrated that the maximum dynamic SCO occurred in the T2 region with a 2cm extent (Figure 2). The dynamic SCO was greater than the post-injury SCO, decreasing significantly from 10mm compression compared to the intact spinal canal area.

Figure 1: Effect of translational constraint on the dynamic spinal canal area with incremental compression. Note that an area of 140mm² represents 100% occlusion.

Figure 2: Dynamic spinal canal area from T1 to T4 with the progressive compression for the constrained cases.

SUMMARY

There was a clear effect of spinal column injury mechanism on the SCO. Constrained conditions led to a fracture-dislocation, which caused substantial SCO, extending at least over 2cm for the most severe injuries. Peak dynamic occlusion was higher than the post-injury occlusion which was consistent with the literature. These early findings will be extended to other injury-types in the spine and may have implications for experimental models of spinal cord injury.

JOINT KINEMATICS OF POSTURAL SWAY RESPONSE TO SINUSOIDAL GALVANIC VESTIBULAR STIMULATION

L. Daniel Latt¹ and Mark S. Redfern^{1,2}

Human Movement and Balance Laboratory, University of Pittsburgh, Pittsburgh, PA

Departments of Bioengineering¹ and Otolaryngology²

INTRODUCTION

The postural control system is responsible for integrating visual, somatosensory, and vestibular sensations and producing an appropriate response to maintain balance. One approach to studying this system is to perturb the system and measure its response. This response may involve rotations at multiple joints. It has been well characterized for the response to a platform perturbation (Horak, 1986), which stimulates both somatosensory and vestibular sensations. The response to a purely vestibular stimulus, such as, galvanic vestibular stimulation (GVS, an electrical current applied to the skin behind the ears, which elicits sway in standing subjects, Coats, 1972) has not been fully characterized. The goal of this project was to determine the differences in joint kinematics in the response to sinusoidal GVS that result from changing the stimulus frequency. It was hypothesized that lower frequency stimuli, would elicit a simple response about the ankles, whereas higher frequency stimuli would elicit a more complex (multi-joint) response.

METHODS

Binural-bipolar GVS was applied to the skin overlying the mastoid processes of 10 subjects while they stood with their eyes closed. The position in the frontal plane of each of the segments of the body (head, thorax, pelvis, thigh, and shank) was monitored with a magnetic position tracking system. The stimulus conditions included 4 frequencies (0.1, 0.25, 0.45, and 1.1 Hz) at various amplitudes from 0.05 to 1.0 mA. Five trials were conducted at each frequency; the order of presentation was randomized. A minimum of 10 cycles or 30 seconds of each stimulus was presented in each of the trials. The response power was calculated as the sum of the Fourier coefficients at or near (± 0.025 Hz) the stimulus frequency.

RESULTS AND DISCUSSION

As the frequency of the stimulus was increased, the response power at all joints decreased (Figure 1). Additionally, the relative distribution of power across the joints changed such that power at the ankle decreased, while power at the hip, back and neck increased. Thus, the predominant mode of the response changed from simple rotation about the ankle to compound rotation at the hips, back, and neck. This shifting of

modes with stimulus condition has been described in the response to sagittal plane platform perturbations (Horak, 1986). One potential reason for the change in response mode is that while movement about the ankles is very effective in translating the center of pressure, the large inertia of the body prevents such changes from occurring rapidly. Thus sway about the ankles cannot play as large a role when rapid movements are required.

Figure 1: Response power mean and standard error by joint and stimulus frequency.

SUMMARY

The postural sway response to GVS in the frontal plane occurs at the hips, back, neck and ankles. The relative contribution of each of these joints to the response depends upon the frequency of the stimulus. A low frequency stimulus elicits a response that is primarily about the ankles, whereas the response to higher frequency stimuli involves the hips, back, and neck more than the ankles.

ARE THE ARTICULAR CONTACT STRESSES IN THE KNEE JOINT DURING DEEP FLEXION CRITICAL?

Ashvin Thambyah, James Goh, Shamal Das De

Department of Orthopaedic Surgery, National University of Singapore, SINGAPORE.

INTRODUCTION

Accurate and functionally relevant intra articular contact stresses in the natural knee joint is difficult to measure in particular those that result from walking and squatting. Given the evidence that osteoarthritis and cartilage damage can occur in the knee as a result of frequent, abnormal and high contact stresses (Swann and Seedham 1993, Dekel and Weissman 1978), the relevance in measuring the functional stresses (Jurman 1977) becomes especially significant for populations (such as Asian) where cultural and social habits commonly include high weight-bearing daily activities of deep flexion such as squatting and kneeling. The role of the entire meniscus, cartilage and soft tissue to neutralise high stresses become increasingly diminished in larger flexion angles where the tibiofemoral contact is largely reduced (Hefzy et al 1998). In this study, contact stresses are measured for the natural knee in various degrees of flexion simulating walking and squatting. It is the aim of this study that by determining the contact stresses in the natural joint, insight would be provided on the associated risks on the weight-bearing structures when an individual performs functional activities such as walking and squatting.

METHODOLOGY

The following description summarises the methods used in obtaining the input parameters for the simulation in the experimental model. Motion analysis of a healthy 60-year-old male was performed for level walking and squatting. From this, kinematic and kinetic data was obtained. X-rays of the subject were also taken in standing and squatting to obtain estimates of bone morphometry and soft tissue insertion positions. Loading conditions and the respective knee joint orientation in various phases of walking and squatting were derived and applied to quasi-static biomechanical testing on 5 cadaver knees in which pressure transducers were inserted in the articulation to measure contact stresses in these various phases.

Five Loading conditions were prescribed:

Heel Strike (HS) - 5.5° flexion up to 2.25 x body weight (BW)
Single Limb Stance (SLS) - 15.5° flexion up to 3.5 BW
Toe-off (TO) - 4.5° flexion up to 1.85 BW
Deep Flexion 1 (DF1) - 90° flexion up to 4 BW
Deep Flexion 2 (DF2) - 120° flexion up to 5 BW

During testing, the contact stress in each specimen was measured in real time using sensors that were inserted into the

joint and between the articulating surfaces of the tibia and femur. The pressure (contact stress) measurement system consisted of a thin (0.1mm) plastic pressure sensor (K-Scan sensor and software from Tekscan Inc, Boston, USA) interfaced with a desktop PC, running software that displayed in real time and recorded the force and pressure values from the sensor. Data was streamed into an output file for statistical analysis and graphical organisation. P-values were calculated to test for significance (<0.05) in differences between means.

RESULTS

During the loading conditions that simulated the selected points of interest in stance phase of gait (HS, TO, SLS) average contact stresses in the cadaver knee joints were 14.1 MPa (± 2.5) with little variation. However, these stresses were significantly ($p < 0.05$) larger in the deep flexion and squatting loading conditions (DF1, DF2) where it increases by over 80% to 26.6 MPa (± 7.1).

DISCUSSION

The stresses observed in the cadaver knees in deep flexion come very close to crossing the limit of 25 MPa for cartilage where fissures and lacerations have been shown to occur (Haut 1989). The reduced contact area when the knee was flexed at 90° and 120° was most likely the cause for the increase in the pressure reading.

CONCLUSION

Weight-bearing deep flexion results in critically high contact stresses in the natural knee which may in turn predispose one who does it often enough to a higher risk of primary osteoarthritis of the knee, given the premise that unduly high and frequent contact stresses in the joint is one of the causes of the disease.

COMPENSATORY CORRECTIVE RESPONSES INDUCED BY CUTANEOUS NERVE STIMULATION IN THE HAND AND FOOT DURING WALKING

Carlos Haridas and E. Paul Zehr

Neurophysiology Laboratory, Faculty of Physical Education & Recreation and Centre for Neuroscience
University of Alberta, Edmonton, Alberta, CANADA (charidas@ualberta.ca)

INTRODUCTION

Previous studies indicate that electrical stimulation of a cutaneous nerve innervating the dorsum of the foot (superficial peroneal; SP) elicits a stumble corrective response in the lower extremity muscles of the stimulated leg during swing (Van Wezel et al., 1997; Zehr et al., 1997). It has also been shown that reflexes are evoked in the foot with electrical stimulation of a cutaneous nerve in the hand (superficial radial (SR); innervates the dorso-lateral surface) during a static task (Zehr et al., 2001). The purpose of this study was to investigate reflexly evoked kinematics at the ankle with electrical stimulation of the foot and hand during walking.

METHODS

Sixteen subjects were recruited with informed written consent to walk on a treadmill. Cutaneous reflexes were evoked with trains (5×1.0 ms pulses @ 300 Hz) of electrical stimulation delivered at non-noxious intensities pseudorandomly to the right SP and SR nerves. Kinematic data was recorded from both ankles, and was analyzed in a 120-200 ms window post-stimulus. Electromyographic (EMG) data was recorded from the lower and upper extremity muscles bilaterally. Step cycle information was collected using insole force-sensing resistors. Each step cycle was divided into 16 portions. Changes in angle with stimuli occurring in the same portion of the walking cycle were averaged together, and reflexly induced changes in ankle angle were determined by examining the kinematic data from which the control kinematic data was subtracted.

RESULTS AND DISCUSSION

Significant ($p < 0.05$) reflexly induced changes in joint angle were observed at both ankles during the stance-to-swing transition with either SP or SR stimulation. The mean response during the stance-swing transition for the right ankle was an increase in plantarflexion (PF) during SP stimulation, which reversed to an increase in dorsiflexion (DF) during SR stimulation (Figure 1, left side). SP and SR stimulation also resulted in an increase in DF in the left ankle during its stance-swing phase.

The SP-induced PF in the right ankle at the swing-stance transition may reflect a stumbling corrective response, which could allow for the foot to drag itself over an obstacle while entering the swing phase. Increased DF in the left ankle during the swing-stance transition could retard forward progression of the leg, allowing for a longer duration of stance, which could assist in maintaining balance while the opposite foot is being perturbed.

For SR stimulation, while the right leg is at the stance-swing transition, there was increased DF (Figure 1, right side), which

Figure 1: Mean values (\pm SEM) for right ankle (stimulated side) angle changes with SP and SR stimulation (*, difference from zero at $p < 0.05$). ▲ indicates site of stimulation.

may serve to retard forward motion. At this point in the step cycle, the right wrist is in front of the body, so this response may prevent forward progression into the obstacle. Increased DF in the left ankle with SR stimulation was also observed while it was in the stance-swing transition.

SUMMARY

A reversal in ankle angle direction was seen in the right ankle at the stance-swing transition point in the step cycle between SP (PF) and SR (DF) stimulation. No difference was seen in the left ankle during its stance-swing transition point with different nerve stimulation. The results suggest nerve-specific responses, which also differ according to where the ankle is in the step cycle (Komiya et al., 2001; Van Wezel et al., 1997). This study suggests that nerve-specific responses also extend to non-stimulated limbs. Finally, the findings also suggest a behavioural relevance for the kinematic responses

MATERIAL PROPERTIES OF THE HUMAN CALCANEAL FAT PAD: VALIDATION EXPERIMENTS

Janice E. Miller-Young¹ and Neil A. Duncan²
University of Calgary, Calgary, Alberta, Canada
¹Human Performance Lab
²Dept of Civil Engineering

INTRODUCTION

Finite element (FE) models of the foot have been used to analyse calcaneal stress distributions (Giddings et al., 2000) and the influence of shoe design on pressure and stress in the plantar soft tissues (Lemmon et al, 1997; Thompson et al., 1999). However, the predictions of an FE model are critically dependent on realistic geometry and material properties. Although a material model of the heel fat pad has been developed from isolated fat pad samples, the ability of this model to predict behaviour of the intact fat pad using the FE formulation must be assessed. The purpose of this study was to obtain heel pad compression data that could be used to evaluate the quality of the heel pad material model.

METHODS

Five cadaveric feet were obtained from 3 males and 2 females (ages 63 – 72). Sagittal plane X-rays were obtained. Each foot was fixed into a stainless steel clamp with three bolts that screwed into the calcaneus, and the heel fat pad was exposed by removing the skin from the plantar surface of the heel.

Heel indentation tests were performed in an MTS machine (MTS Systems Corporation, Eden Prairie, Minnesota, USA). The foot clamp was bolted to the MTS table (with the exposed heel pad facing up) and a 2 cm diameter indenter was attached to the load cell and actuator above. Based on the range of impact velocities that occur in locomotion and the capabilities of the MTS machine, indentation tests were performed at rates of 175 and 350 mm/s, 3 trials each. Each test was performed to approximately 50% of the thickness of the fat pad (estimated from X-rays).

At the end of the “intact” experiments, the heel fat pad was dissected from the foot and refrozen so that it was hard enough to permit a cylindrical plug to be cut. An 8 mm biopsy punch was used to cut cylindrical samples from the center of the fat pad with the long axis of the cylinder corresponding to the direction perpendicular to the skin surface. Unconfined compression tests were performed on the individual cylindrical plugs at 175 and 350 mm/s, and stress relaxation tests held for 1 minute, all at approximately 50% deformation. The results of these tests can be used to determine material parameters of a hyperelastic, viscoelastic constitutive equation for the heel fat pad (Miller-Young and Duncan, 2001).

RESULTS AND DISCUSSION

On average, the forces measured during the intact heel pad indentation tests were 1.9 times higher than those measured during the cylindrical plug compression tests for the same foot (figure 1). The standard deviations were too small to show on the curves for the cylindrical plugs (max 4.4 and 6.7 kPa for 175 and 350 mm/s tests, respectively). It is speculated that the difference between plug and intact fat pad results is due to the differences in boundary conditions between the two tests.

Figure 1: Variable-rate compression results (mean and SD) for cylindrical plug material tests and intact fat pad indentation tests for one foot (age = 63).

A material model will be derived from the material tests of the cylindrical plug and evaluated using a 2D FE model of the indentation experiment on the corresponding foot. The geometry of the calcaneus will be obtained from the X-rays of each foot, and several meshes will be developed in order to test the mesh density required to obtain a converged solution.

A FAST CIRCLE FINDING TECHNIQUE FOR DIGITAL RSA

P. Thistlethwaite¹, J.L. Ronsky¹, H.S. Gill²

¹Department of Mechanical and Manufacturing Engineering, University of Calgary

²University of Oxford, Nuffield Department of Orthopaedic Surgery/OOEC

INTRODUCTION

A fundamental component of the RSA technique is identification of radio-opaque markers. In a digital RSA system this identification process can be automated by employing a circle finding technique to an edge detected image. Usually, for this task, some variation of the Hough circle transform (Duda, R.D., Hart, P.E. 1972) is used. This process can be very computationally expensive and represents the bulk of time an automated digital RSA process will require to compute 3D positions (95% - Vrooman, H.A. 1998). Similar results to the Hough transform can be achieved with a convolution-based method while drastically decreasing the computation time. This study investigated the performance of this convolution-based circle finding method.

METHODS

To evaluate the performance of the convolution-based technique it was compared to the discrete Hough circle transform quantitatively for computational time and qualitatively for response. Ten 361x361 pixel, 8-bit grayscale test images acquired from RSA study radiographs were edge detected and used as starting points for both techniques (Figure 1). One of these test images was placed on backgrounds ranging from 316 to 1061 pixels square (15 images) and these were also used as a basis for comparison. The images contain circles of three different radii: 20, 16 and 4 pixels. These correspond to background and foreground calibration markers, and reference markers respectively.

Figure 1: Example original and edge image. The line and arrow show the plane and viewing direction for the example response projections shown in Figure 2.

RESULTS AND DISCUSSION

In both methods a calculation must be performed to search for each circle radius independently. The total circle finding computational time is the sum of times for each radius. A clear computational advantage is provided with the convolution method in all test situations (Table 1). The computational time for the Hough transform varies linearly with the number of edge pixels in the image while the convolution method is invariant to this change (Table 1 – Part 1). Increasing image size increases the computational time for both methods but also increases the computational advantage of the convolution method (Table 1 – Part 2). The response of the two methods is very similar (Figure 2) although the background response appears slightly higher in the convolution method. The peak response of the convolution method is more tightly grouped which should allow it to be easily thresholded.

Figure 2: Representative 2D projections of response for the Hough transform (top) and convolution method (bottom)

SUMMARY

The convolution-based circle finding method can provide similar response to the Hough transform method while providing drastically reduced computation times.

A MODEL FOR EMULATION OF WRIST JOINT IMPEDANCE

Amanda M. Laslo and Theodore E. Milner*

School of Kinesiology, Simon Fraser University, Burnaby, B.C., V5A 1S6, Canada

*Corresponding author tmilner@sfu.ca tel: 604 291 3398, fax: 604 291 3040

INTRODUCTION

Models of mechanical impedance have been previously used as control schemes for electromechanical emulators (Abul-Haj and Hogan, 1987). In this study, we have developed a model of mechanical impedance based on the torque measured during imposed, bidirectional rotations of the wrist. The objective was to improve the ability of an artificial joint to emulate the impedance of an intact human joint. Unlike other linear models of mechanical impedance (Kearney and Hunter, 1982), the present model reveals that damping (B) is independent of torque, and that torque due to damping is small compared to torque due to stiffness (K). In addition, there is an initial high-slope region of the torque vs. displacement curve for which the parameters are different than the remaining cycles.

METHODS

Wrist torque was measured during imposed, bidirectional rotations of the wrist joint. A torque motor was used to generate an extensor moment, τ , which the subject matched by applying an equal and opposite flexor torque that was maintained throughout each of the trials. The investigator displaced the wrist using a sinusoidal motion while torque, T , position, θ , and velocity, $\dot{\theta}$, were measured and recorded. Four different trial conditions were tested at activation levels corresponding to flexor torques of 0, 1, 2, and 3 Nm. The displacement frequencies and amplitudes used were 2.4 Hz and 1.2 Hz, and 20 degrees and 10 degrees, respectively.

Torque vs. position graphs were plotted for each trial to investigate the shape of the hysteresis. At torques greater than 0 Nm, a drift in the central position of the hysteresis loop over time was detected and taken into account by including a correction term, ct , in the model:

$$T - I\ddot{\theta} = (K_0 - K_1\tau)(\theta - \theta_0) + B_0\dot{\theta} + ct + T_0$$

where I is the moment of inertia, t is time, and K_0 , K_1 , B_0 , c and T_0 are constant parameters.

The data were separated into an initial high-slope region and the remaining cycles. Multiple linear regression analyses were conducted to determine parameters for each region.

RESULTS AND DISCUSSION

Regression analysis of the initial high-slope region of displacement showed that two parameters, K_0 and K_1 , were sufficient for an accurate model of mechanical impedance.

Wrist Torque vs. Position at 0 Nm

Figure 1: Data for one trial at 0 Nm. One cycle consists of wrist rotation in one direction through the displacement range.

Including the K_1 parameter increased the R^2 value from 0.58 to 0.95, indicating a large effect of torque on stiffness. Including B_0 in the regression had a minimal effect on the overall fit of the model, increasing the R^2 value by only 0.008. Furthermore, since the B_0 parameter was slightly negative it was eliminated from the model.

Regression performed on the remaining displacement cycles revealed that damping had a greater influence on the accuracy of the model than for the initial high-slope region. Including the B_0 parameter improved the R^2 value from 0.93 (with K_0 and K_1) to 0.96. However, damping was found to be independent of torque, as the addition of the B_1 parameter had no effect on the fit of the model ($R^2=0.96$).

The K_0 parameter was greater in the high-slope region (51% difference), whereas the K_1 parameter was lower (6% difference), than during the remaining displacement cycles.

SUMMARY

The results of this study show that in the initial portion of a displacement, the wrist behaves like a pure spring with torque dependent stiffness, whereas once the muscles have been stretched beyond the high stiffness region, it behaves like a torque dependent spring of lower stiffness with a small amount of damping.

ARE SPINAL FACET LOADS INFLUENCED BY THE FIXATION METHOD?

Qingan Zhu¹, Youngbae Park², Jeff Gordon¹, Simon Sjøvold¹, Michael Johnson¹, Charles Fisher¹, Marcel Dvorak¹, Thomas Oxland¹

¹Department of Orthopaedics, University of British Columbia, Vancouver, British Columbia, Canada, toxland@interchange.ubc.ca

²Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Taejeon, South Korea

INTRODUCTION

It is well-established that spinal fixation reduces intervertebral motions, and that there is variation in the rigidity of different methods such as pedicle screw fixation or interbody cage stabilization. It has been hypothesized (Oxland 2000) that some of these changes, particularly with interbody cages, are due to modification of the contact in the articular facets. A non-invasive method for determining facet loads has been used in vivo and in vitro in the canine lumbar spine (Buttermann 1991,1992). The technique models the inferior articular process as a cantilevered plate and determines the facet load and its location using extraarticular strains on one facet (Luo 1996). In the present study, a modification of this noninvasive technique was used to evaluate the facet load in a cadaveric lumbar spine model to determine the effect of different spinal fixation techniques, specifically interbody cage and pedicle screw fixation.

METHODS

Eight cadaveric specimens (L4-L5) were used. Eight uniaxial strain gauges (Tokyo Sokki Kenkyujo, Tokyo, Japan) were bonded to the posterior aspect of the left and right inferior facet of L4. Flexibility testing in flexion-extension, lateral bending and axial rotation with pure moments ($\pm 5.0\text{Nm}$) was performed for each specimen in the intact state, after pedicle screw fixation (USS, Synthes Spine), and after interbody cage insertion (Dovetail, Cortek, Boston, MA). The L4-L5 level was transected following the flexibility test and the L4 vertebra was secured for calibration of the facets. In the calibration, known forces were applied to the facet surface and the corresponding strains recorded. The relationship between the eight strains (ϵ), the facet forces (F_L , F_R), and the force location ((x_L, y_L) , (x_R, y_R)) was assumed to be of the form:

$$\epsilon = \mathbf{f}_L(x_L, y_L) F_L + \mathbf{f}_R(x_R, y_R) F_R$$

A least squares method was used to determine the facet forces during the flexibility testing, based on the recorded strains. A repeated measures ANOVA was used to compare the peak facet loads and thereby determine the effect of the different fixation techniques on facet loads.

RESULTS AND DISCUSSION

The loading pattern between the left and right facets was generally symmetric in all directions for the intact specimen (Figure 1). Interbody cage insertion had little effect in flexion loading, but increased facet compression significantly in extension. Pedicle screw fixation slightly increased facet

compression in flexion ($p=0.001$) and decreased facet compression in extension ($p=0.035$). The facet load changed

little in lateral bending after both fixation types. In axial rotation, the interbody cage increased the compression on one facet, while pedicle screw fixation reduced the facet loads.

Figure 1: Left and right facet loads in flexion, extension, left and right lateral bending and left and right axial rotation.

SUMMARY

A noninvasive technique using extra-articular strains was used to measure in vitro facet loads in the cadaveric lumbar spine. The fixation methods of interbody cage stabilization and pedicle screw fixation each affected the facet loads significantly in different directions. The clinical significance of these findings is unknown.

STRUCTURAL TESTING FOR SYMMETRY OF THE HIPS BY VIBRATION TECHNIQUE

Kevin Kwong¹, Xiaolin Huang¹ and Jack Cheng²

¹Department of Rehabilitation Sciences, The Hong Kong Polytechnic University, Hong Kong SAR, China

²Department of Orthopaedics and Traumatology, The Chinese University of Hong Kong, Hong Kong SAR, China

INTRODUCTION

A vibration technique, which provides a practical structural testing for bony symmetry of the hips, has been developed. The results of this study offer a baseline for further acoustical investigations in orthopaedics for conditions such as developmental dysplasia of the hip, degenerative osteoarthritis and loosening of hip arthroplasty, which associate with asymmetrical structure of the bone and joints.

METHODS

From an excitation system, a signal generator delivered a pink noise, which was then fed to a power amplifier, to drive an electrodynamic exciter. A vibratory force (< 1 N, RMS) was applied at the sacrum through a plastic probe, and a hand-held exciter was used instead for tests on pre-school children and neonates. The transduction system comprised of a pair of identical microphones installed separately in the tubes of two stethoscopes, forming the stethoscope-microphone assemblies, which were placed over the greater trochanters and secured by a 2.5 cm wide rubber band wrapped round the pelvis. The data acquisition system was a dual-channel signal analyser, which acquired the acoustic signals and processed the relative acoustic response by digital filters in 1/3 octave frequency bands. The coherence assessed the degree of linear relationship between the sound signals and the discrepancy evaluated the degree of structural asymmetry between bilateral hips, according to the following equation, where, Output (L) and Output (R) were acoustic signals picked up respectively from the left and right hips.

$$Discrepancy = Abs \left(20 \log \left[\frac{Output(L)}{Output(R)} \right] \right) dB$$

It was hypothesized that there would be equal acoustic transmission through symmetrical bony structure of normal subjects. Any asymmetry in the bone and joints would result in a difference in the acoustic response measured at both hips. The discrepancy was therefore an objective measure of structural asymmetry of the hips. Three groups of normal subjects: 27 adults, 20 pre-school children and 24 neonates were tested.

RESULTS AND DISCUSSION

For the adult group, the coherence was above 0.9 and the discrepancy between the two hips was < 3 dB in the frequency range of 160 to 400 Hz. For the pre-school children, the coherence was slightly lower and the discrepancy was less

stable. This was due to the difficulty in keeping a stable position for the pre-school children during the testing. The lowest discrepancy was found to be < 2dB in the frequency range of 200 to 315 Hz. For the normal neonates, the lowest discrepancy was found to be < 1.25 dB in a wider frequency range of 160 to 315 Hz, where coherence > 0.96. However, these results cannot help identify the specific cause of the discrepancy. Discrepancy due to natural differences between both sides of the body is highly possible.

Figure 1. Coherence

Figure 2. Discrepancy

SUMMARY

The optimal frequency range for test of structural symmetry of adult hips is 160 to 400 Hz, where the discrepancy is below 3 dB. The neonates show a smaller discrepancy (< 1.25 dB) in a wider frequency range (100 to 400 Hz). The results for pre-school children were less satisfactory by referring to the lower coherence and greater discrepancy when compared with the other two groups. Results of this study could be considered as baseline discrepancy for normal hips. Discrepancy bigger than the figures quoted about could be suggestive of structural asymmetry of the hips.

²Graduate School of Medicine, Tohoku University, Sendai, Japan

INTRODUCTION

Thoracic aortic aneurysm is a crucial disease because its diameter will grow until rupture, usually accompanied with fatal consequences. At present, the aneurysm is replaced with aortic prostheses when its diameter exceeds 5.5 cm to avoid rupture. However, some aneurysms rupture at a diameter smaller than 5.5 cm. This empirical knowledge is not a sufficient criterion. A reliable predictor would be necessary in assessing potential for aneurysm rupture. Although uniaxial tensile test has been performed on abdominal aortic aneurysm to obtain ultimate strength (Raghavan et al., 1996), rupture properties should be evaluated by pressure-imposed test from a physiological standpoint.

In this study, we measure rupture properties of thoracic aortic aneurysms using pressure-imposed test. An experimental setup is newly designed to rupture rectangular specimens excised from aneurysms.

METHODS

Ten square specimens were obtained from human thoracic aortic aneurysms (68 ± 9 years, mean \pm SD) during aneurysmectomy. All procedures were carried out in accordance with permission for experimental use of the Tohoku University. Experimental setup of pressure-imposed test is schematically shown in Figure 1. The square specimen (20 mm x 20 mm) was fixed between two metal plates with a hole of 15 mm in diameter. Air pressure was applied into a rubber balloon to inflate the specimen at a rate of 10 mmHg/s until rupture occurred. Deformation process was observed through two CCD cameras and a high-speed camera. Breaking stress and strain were estimated from the specimen geometry considering incompressibility. The high-speed camera was used for detailed observation of ruptured site (data not shown).

RESULTS AND DISCUSSION

Four specimens did not rupture even at a maximum pressure of around 5000 mmHg while six specimens finally ruptured. One would expect rupture to occur longitudinally in normal aorta, whereas any tendency in the direction of aneurysm rupture was not observed. Breaking stress and strain for ruptured specimens are summarized in Table 1. Data for unruptured specimens are expressed as maximum stress and strain at the maximum pressure and also shown in the table. Groenink et al. (1999) investigated breaking stress of normal human thoracic aorta using pressure-diameter test in relation to age and showed that mean breaking stress was 0.80 MPa at 60 years.

Our data were slightly higher than their results. It is interesting that strains are quite different between ruptured and unruptured groups at the similar stress. Further study is needed to elucidate a patient-specific histology to examine the relationship between rupture properties and wall structure.

SUMMARY

We have measured rupture properties of human aneurysms using pressure-imposed test. Breaking stress of aneurysms was 0.97 ± 0.39 MPa (mean \pm SD), showing slightly higher value than that for normal aorta. This may be a rationale for further studies concerning a reliable criterion for elective repair.

LOWER LIMB KINEMATICS OF ICE HOCKEY FORWARD SKATING

Ryan Chang¹, Rene Turcotte¹, Richard Lefebvre², David Montgomery¹, David Pearsall¹

¹Department of Kinesiology and Physical Education, McGill University, Montréal, Québec, Canada

²Bauer Nike Hockey, St. Jérôme, Quebec, Canada

INTRODUCTION

The sparsely existing quantitative kinematic research in ice hockey is likely, in part, a result of the obstacles in gathering such data. The stride traverse is long while the movements are highly three-dimensional. This study attempts to quantify kinematics of the lower limb during forward ice hockey treadmill skating.

METHODS

Joint kinematic data at the hip, knee and ankle were acquired through electrogoniometry at a sampling rate of 1KHz. The five (n=5) subjects were varsity level ice hockey players, each having been well trained on the skating treadmill.

Forward skating was analyzed at 3 randomly ordered velocities: 3.33 m/s, 5.00 m/s and 6.67 m/s. Foot strike was identified to the activation of the vastus medialis muscle. Twenty strides were used for the calculation of the average at each velocity. Data were smoothed by a 4th order Butterworth filter at a cut-off frequency of 10 Hz and normalized to the subjects standing position.

RESULTS AND DISCUSSION

Typical movement patterns of the hip, knee and ankle for one subject are presented (Figures1-3).

Figure 1: Local flexion/extension data at the hip for three forward skating velocities.

The data reveals a push-off phase consisting of extension at the hip and knee and plantarflexion at the ankle. This particular subject shows a trend of increasing range of motion at the knee with increased velocity. However, the same trend is not observed in the ankle data. Greatest range of motion is seen in the fastest velocity at the hip also.

Figure 2: Flexion/extension data for the knee during three forward skating velocities.

Figure 3: Plantar/dorsiflexion of the ankle during the forward skating stride for three different velocities.

As seen in this set of data, preliminary analysis reveals a longer push-off phase with a shorter swing time when strides are normalized. Further interpretation and analysis is in progress.

SUMMARY

The study demonstrates the feasibility of using goniometry to quantify lower limb kinematic patterns while skating in ice hockey. Adopting this approach, issues of skating techniques and the mechanics of other skating skills (e.g. starts, stops, backwards, pivots, cross-overs) can be examined. Information thus collected can be applied to directly to coaching, injury rehabilitation and equipment design.

FORWARD ICE HOCKEY SKATING: COMPARISON OF EMG ACTIVATION PATTERNS AT THREE VELOCITIES

R. Goudreault, D. Pearsall, R. Turcotte, D. Montgomery, R. Lefebvre
McGill University, Montréal, Québec, Canada

INTRODUCTION

Ice hockey is a sport that requires a combination of numerous skills including skating, puck handling, shooting, and checking skills. Though a popular sport, to date research on the biomechanical evaluation of the ice hockey skills have been limited to a few studies regarding the stick and forward mechanics of skating (Marino 1977). Given the limited specific ice hockey research, our best understanding of forward skating mechanics may be drawn from research focused on speed skating. Interpretation of speed skating mechanics can be useful for identifying the general movement patterns similar to ice hockey; however, fundamental differences in equipment, skill, repertoire, and play context preclude suggesting a direct transfer of speed skating to ice hockey skating (Marino, 1977). The purpose of this study is to compare the EMG activity of the lower limb in forward skating at three different speeds using the skate treadmill.

METHODS

Seven varsity hockey players from McGill University (age = 22.1 ± 1.2 years, height = 1.8 ± 0.1 m, weight = 82.1 ± 8.5 kg) participated. Testing was done using a skate treadmill. Skin was shaved of hair, abraded and cleaned at the area of the electrode placement on the right leg. Disposable bipolar differential electrodes (Meditrace) were placed 1 cm apart on the vastus medialis (VM), adductor magnus (Add), biceps femoris (BF), gluteus maximus, tibialis anterior (TA), peroneus longus (PL), and lateral gastrocnemius (GL).

The EMG signals were measured using a portable data logger, the Multi Signal System ME3000P8 muscle tester unit (Biomation Inc, Ottawa, Canada). Subjects skated at 12 km/hr, 18 km/hr, and 24 km/hr, with a two-minute rest between trials. Twenty strides measures per subject of muscle activity were parsed, rectified, and then processed using a 4th order Butterworth filter. The individual strides were segmented and normalized to 100% stride, equivalent to stride time duration (blade contact to blade contact). The EMG magnitudes were normalized to 100% of the maximum value obtained during dynamic contraction for each subject when skating at 24 km/hr (MDC_{24}). An ensemble average was calculated following intrasubject calculations of 20 strides per subject.

RESULTS AND DISCUSSION

Significant differences can be seen in the amplitude of muscle activation for most muscles, as well as a few temporal differences. There were often significant increases in the peak amplitude at 24 km/hr when compared to 12km/hr.

Figure 1: m. vastus medialis: EMG patterns of forward skating at three velocities: 12, 18 and 24 km/hr

Generally, as expected, it can be seen that as speed increased so does the level of activation. In most cases EMG activity at 24km/hr was significantly higher than the speed of 12km/hr. The medium speed of 18 km/hr showed few significant differences from the slow and fast speeds. This may be accounted for by the level of standard deviation found in EMG, which at 18km/hr could range close to the values found at 12 and 24 km/hr.

Skating locomotion is similar to walking in that both skills have similar single and double support phases. Likewise, increase in speed in walking produces similar augmentation in EMG amplitudes. For instance, Winter (1983) presented EMG patterns of five muscles at three speeds of walking on a treadmill. His results show that the pattern shapes remain essentially the same with the exception of the amplitude, which increases with speed. This interaction is identical to the effect found in the current forward ice skating study.

There were few significant differences in temporal values. The 1st peak during the glide phase, the VM and TA were significantly ($p < 0.05$) later at speed 24 km/hr. At the end of deactivation after the 2nd peak at push-off, the Add and GL were significantly later at speed 24km/hr. The peak of the Add and GL at the push-off was significantly higher than both speeds of 12 and 18 km/hr. The lack of differences in temporal effects could be accounted by the fact that as speed increased, the stride rate increased, not the stride length. The skater was taking more steps, and essentially the muscle coordination pattern remained constant.

In conclusion, this study has shown that an increase in velocity results in an increase in the amount of muscle activation, but the muscle coordination patterns remain the same.

GAIT ADAPTATIONS TO TRANSVERSE SLOPES

M. Nicolaou, D. Pearsall

Department of Kinesiology & Physical Education, Montréal, Québec, Canada

INTRODUCTION

Humans encounter the challenge of slopes or grades of various orientations and combinations on a daily basis. Gait adaptations to graded slopes such as inclines and declines have been studied [1,2,3]. However, little research has been conducted on the effects of banked, crowned or side (transverse) sloped terrains on walking, particularly with respect to identifying the functional adaptive asymmetries produced [4,5]. Thus, the purpose of the study was to identify the lower limb kinematic adaptations in normal gait to accommodate to static transverse slopes (0%, 5% and 10%).

METHODS

Five male subjects were recruited (age: 24 ± 3.2 years; height: 175 ± 12.6 cm, mass: 72.8 ± 0.1 kg). An electromagnetic tracking device, the Ultratrak® (Polhemus Inc., Burlington, VT, USA) was used to collect the kinematic data at 60Hz while the subjects performed the walking trials at a self-selected pace. Filmbox® software (Kaydara, Montreal, CAN) was used to control the Ultratrak® data recording. The wooden platform was elevated to the 5% and 10% slope conditions by additional wooden supports. Angular kinematic profiles of the ankle, knee and hip were calculated.

RESULTS AND DISCUSSION

Significant ($p < 0.05$) joint angle changes occurred in both the uphill (UH) and downhill (DH) lower limbs. Specifically, the UH ankle (Fig 1a) was more dorsiflexed throughout the gait cycle at both the 5% and 10% slope in comparison to level, where as, the DH ankle exhibited increased plantarflexion. With respect to the knee (Fig 1b), the UH side was more flexed than at level. The DH knee was significantly more extended on both 5% and 10% slope. The sagittal plane hip kinematics were primarily affected in the DH limb (Fig 1c). Extension was greater at both the 5% and 10% slope conditions. The UH limb was relatively unperturbed in flexion/extension.

SUMMARY

Gait adaptations occur in both the UH and DH lower limbs on transverse slopes. Asymmetric changes in limb kinematics in part compensated for the unlevel surface. The adjustments appear to functionally shorten the UH limb for clearance of the walkway and to lengthen the DH limb to ensure stable ground contact.

Figure 1. Mean (\pm SD) ankle (a), knee (b) and hip (c) kinematics during level (0%) walking in comparison to the uphill and downhill (5% and 10%) grades

DESIGN METHOD OF POROUS SCAFFOLD MICROSTRUCTURE USING COMPUTATIONAL SIMULATION FOR BONE REGENERATION

Taiji Adachi^{1,2}, Yuji Kawano¹, Yoshihiro Tomita^{1,2}, and Scott J. Hollister³

¹Solid Mechanics Laboratory, Department of Mechanical Engineering, Kobe University, Kobe, Japan, adachi@mech.kobe-u.ac.jp

INTRODUCTION

In bone regeneration using a biodegradable scaffold, geometry of porous scaffold microstructure is a key factor to control properties of regenerated bone as well as regeneration process (Hollister, *et al.* 1999). In this study, a framework of a new design method for porous scaffold microstructure is proposed using computational simulation for bone regeneration.

METHODS

By solving degradation of scaffold and formation of new bone in the same time frame, bone regeneration process was simulated (Adachi *et al.* 2001). Degradation of the scaffold was expressed as decrease in its stiffness, Young's modulus E_s , that is assumed to decrease proportionally to the molecular weight whose rate is related to the local water contents governed by the diffusion equation. New bone is assumed to form on the surfaces of old bone and scaffold, in which a rate equation of the trabecular surface remodeling (Adachi *et al.* 1997) was modified to express the new bone formation. Pixel/voxel finite element method was applied to simulate the bone regeneration process in bone-scaffold system.

Two-dimensional porous scaffold (Fig.1) was used in this case study, where the pore radius r was considered as a design valuable. Assuming periodicity of micro-structure, a unit cell (Fig.2(b)) was analyzed under uniaxial compressive loading. The unit cell was discretized into 25 x 50 pixel elements with size of 20 μm . Material properties were set as $E_s = 10 \text{ GPa}$, $\nu_s = 0.3$ for scaffold and $E_b = 20 \text{ GPa}$, $\nu_b = 0.3$ for bone.

RESULTS AND DISCUSSION

Bone regeneration process for the case of $r = 300 \mu\text{m}$ is shown in Fig.2(a), where functional transition from scaffold to bone as a load-bearing component was represented. For the cases of $r = 100$ to $400 \mu\text{m}$, changes in total strain energy of bone-scaffold system are plotted in Fig.2(b), showing that the mechanical function in regeneration process depends on initial pore radius r . From the mechanical viewpoint, stiffness as a bone-scaffold system is required to keep at the desired value during and after the process.

To evaluate mechanical function in the regeneration process, change in strain energy of a bone-scaffold system was calculated. Thus, the design problem was formulated to find an optimal initial pore radius of the scaffold microstructure that minimizes the objective function.

$$\Phi(r) = \int_0^T |U(t) - U_b| dt, \quad (1)$$

where U_b is for an ideal bone and T is the completion time of bone regeneration. From regeneration simulation for $50 \mu\text{m} < r < 400 \mu\text{m}$, the optimum radius was found depending on the desired strain energy U_b , that is stiffness of the desired bone.

For further application to design three-dimensional scaffold microstructure, characteristics of scaffold degradation and new bone formation have to be clarified experimentally which give us more appropriate rate equations in the bone regeneration process. Extension to a three-dimensional scaffold design with complex microstructures is necessary to apply to *in vivo* study.

POSTURAL ESTIMATES FROM DIGITAL IMAGES: INTER- AND INTRA-TESTER RELIABILITY

Timothy K. Woo and David J. Pearsall,

Department of Kinesiology & Physical Education, McGill University, Montréal, Québec, Canada

INTRODUCTION

The present investigation was designed to assess the ability of examiners to reliably place reflective anatomical markers over well-established skeletal landmarks: specifically, intra- and inter-tester (within and between) examiner consistency.

METHODS

Three examiners evaluated 12 subjects (6 male, 6 female; age=22.7±4.6 and 25.8±10.2, respectively). Prior to the assessment, examiners were trained on designated marker placement for approximately one hour, one week prior to testing. Examiners evaluated each of the experimental subjects on two separate days. Evaluations involved the palpation of anatomical landmarks and the placement of 32 reflective markers. Four digital images (Epson, 1024x768 pixels) were recorded against a calibrated backdrop, and then processed (Biotonix software) to provide 30 biomechanical measures of body segments in three planes: anterior, posterior and lateral. Comparison within and between testers was done by using inter-class correlation coefficients as outlined in Portney and Watkins (2000).

RESULTS AND DISCUSSION

A high degree of intra-rater reliability was found when comparing the measures for the two different measurement days (Table 1). With the exception of three measures, the measures demonstrated repeatability in marker placements (ICC=0.76 to 0.96). High inter-examiner reliability also was observed (ICC=0.61 to 0.97) for 27 of 29 parameters. Low consistency was associated with marker placements overlying pelvic and upper leg locations (and the measures generated from these marker placements). In particular, the markers placed over the superior border of the upper leg (greater trochanter) gave rise to the lowest inter-rater correlation values (i.e. 0.33, 0.45). Moderate correlations were associated with markers placed over the ankles, back of the knees and posterior pelvis.

SUMMARY

High inter- and intra-examiner reliability was found in the ability of examiners to place markers over anatomical markers that define optimal posture. Some locations appear to be more difficult than others to reliably place markers, and additional attention to training is warranted.

Table 1 Intra and inter-tester ICCs of the postural measures.

NECK MUSCLE STRAINS IN WHIPLASH INJURY

Anita N. Vasavada¹, John R. Brault², and Gunter P. Siegmund^{2,3}

¹Department of Biological Systems Engineering, Washington State University, Pullman, WA, USA; vasavada@wsu.edu

²MacInnis Engineering Associates, Richmond, BC, Canada

³School of Human Kinetics, University of British Columbia, Vancouver, BC, Canada

INTRODUCTION

Considerable uncertainty exists regarding the role of neck muscles in whiplash injury. Neck muscle forces affect head and neck kinematics, and neck muscles may contribute to the injury of other neck tissues or may themselves be injured due to imposed lengthening. Thus, it is important to know neck muscle strains, forces and torques in order to understand mechanisms of whiplash injury. The purpose of this study was to examine strains in neck muscles by using a biomechanical model of the neck musculature together with the experimental kinematics of subjects exposed to low-speed rear-end impacts.

METHODS

A model of the head and neck musculoskeletal system of a 50th percentile male was used for this analysis (Vasavada et al., 1998). The model was implemented in Software for Interactive Musculoskeletal Modeling (Musculographics, Inc., Santa Rosa, CA) and incorporated 19 muscle pairs and muscle force-generating parameters. The sternocleidomastoid (SCM) muscle was represented by three segments: sterno-mastoid (sm), cleido-mastoid (cm), and cleido-occipital (co); whereas splenius capitis (SPL) and semispinalis capitis (SEMI) were each represented by one segment. Kinematic data from 11 male subjects (height ± 3 cm of 50th percentile) exposed to rear-end collisions at a speed change of 8 km/h were used in this study (Siegmund et al., 1997). The head and neck dimensions of the biomechanical model were within one standard deviation of the subject data. The translation and rotation of the head relative to the torso were imposed on the biomechanical model and the time histories of musculotendon length and strain were calculated.

RESULTS AND DISCUSSION

The initial motion of the head relative to the torso was retraction (posterior translation) and extension, followed by protraction (anterior translation) and flexion during forward rebound off the head restraint. The model predicted that the sterno-mastoid and cleido-mastoid segments of SCM lengthened less than 2%, but that the cleido-occipital segment experienced up to 4% strain during retraction (Figure 1). The small length changes for the sterno-mastoid and cleido-mastoid segments are consistent with their less effective line of action to resist head retraction, despite being active during this interval (Brault et al., 2000). SPL and SEMI initially shortened as much as 25%. In the final protracted posture, SEMI remained shorter than its initial length, whereas SPL was 10%

longer than its initial length. After the initial shortening, the total lengthening in SPL was 35% of initial length. The large strains in SPL in the protraction phase indicate that injury to this muscle may be a mechanism of whiplash injury. Further, if tendon stiffness is relatively high, strains in muscle fibers will be considerably greater than the computed musculotendon strains.

Figure 1: Musculotendon strain in three segments of SCM, SPL and SEMI. Average muscle onset occurred at 84 ms and peak retraction at 150 ms post impact.

SUMMARY

Based on this analysis, the induced kinematics that occur during whiplash loading are potentially injurious to the neck muscles and ligaments. We found that SCM underwent 2-4% lengthening during the retraction phase of whiplash, while SPL lengthened 35% in the final protraction phase. These results were consistent with a higher frequency of posterior than anterior neck pain in whiplash patients (Ryan et al. 1993). Future studies should address two issues: (1) loads and strains in shorter neck muscles and ligaments due to the induced intervertebral kinematics in protracted and retracted postures; and (2) the ability of SCM to resist head retraction.

DYNAMIC BEHAVIOR OF ACTIN FILAMENTS IN CULTURED ENDOTHELIAL CELLS DURING EXPOSURE TO SHEAR STRESS

Toshiro Ohashi, Kei Tsuyuki, Tsugumasa Yamamoto, and Masaaki Sato

Biomechanics Laboratory, Graduate School of Mechanical Engineering, Tohoku University, Sendai, Miyagi, Japan

INTRODUCTION

We have been interested in the mechanism of mechanical responses of endothelial cells, especially the roles of actin filaments (Kataoka et al., 1998; Sato et al., 2000). It has been pointed out that actin filaments may be moved around, form stress fibers and finally locate at the desired positions during endothelial exposure to flow (Davies, 1995). In this process integrins are expected to play important roles to decide the positions of actin filaments and/or stress fibers (Urbich et al., 2000). Dynamic process of actin filament behavior is not observed in ordinary method, because cell must be fixed and the actin is stained. However, we can utilize recent advances techniques using GFP (green fluorescent protein) combined with actin to observe the dynamic behavior in living cells.

We would like to report the detailed moving process of actin filaments in endothelial cells during exposure to shear stress and discuss the mechanisms.

METHODS

A plasmid encoding GFP fused to the amino terminus of actin (the vector was cordially provided by Dr. G. Marriott, Max-Planck-Institute for Biochemistry, Germany) was transfected into cultured bovine aortic endothelial cells (BAECs) using a liposomal method. Cells were plated on a specially ordered 35 mm glass-base dish (Asahi Techno Glass). An I/O unit was set in the dish to compose a flow chamber with flow section of 0.5 mm in height. All experiments were performed with confluent monolayers of cell. Cells expressing GFP-actin were observed in flow condition. Fluid shear stress of 2 Pa was applied using the parallel plate flow chamber. Distribution and dynamic behavior of actin filaments in a cell were observed under a confocal laser scanning microscope and the images were recorded on a computer through a high resolution digital CCD camera.

RESULTS AND DISCUSSION

A typical example of time course of changes in structure of actin filaments is shown in Figure 1. It was already confirmed by separate experiments that localization of GFP-actin coincided with the F-actin filaments stained by rhodamine-phalloidin in ordinary method. Before exposure to shear stress, actin filaments were observed as star-like configurations around upstream side (lower side of a cell in Figure 1). After exposure to shear stress, the star-like structure disappeared, development of actin filaments was observed around upstream side, and the cell elongated slightly at 60 min. Actin filaments then developed around downstream side of within 120 min. At around 180 min, the more elongated cell was observed. The shape index value of the cell reduced from

0.76 (0 min) to 0.59 (180 min). Since the focal adhesion proteins, integrins, should play important roles in re-organization of actin filaments, we need to simultaneously observe the dynamic movements. At present, we also need more examples to conclude general moving process of actin filaments in shear stress condition.

SUMMARY

We observed the dynamic process of actin filament movement in endothelial cells expressing GFP-actin during exposure to flow. Actin structure was changed at upstream side within 60 min and at downstream side within 120 min. A cell started to elongate at around 60 min.

MEDIAL-LATERAL COP VELOCITY DURING STANDING RELATES TO ASYMMETRY AND FUNCTIONAL BALANCE IN INDIVIDUALS WITH STROKE

Daniel S. Marigold^{1,3}, Janice J. Eng^{2,3}, Kelly S. Chu^{2,3}, and C. Maria Kim^{2,3}

Rehab Research Lab³, GF Strong Rehab Centre, Vancouver, British Columbia, Canada, www.rehab.ubc.ca/jeng

INTRODUCTION

Impairments such as muscle weakness, pain, spasticity, visual disturbance, contractures, and sensory dysfunction contribute to poor balance and a high rate of falls in individuals with stroke (Kanis et al., 2001). Although force plate measures are commonly used to assess standing postural control in older adults, the reliability and validity of these measures are not well established for individuals with stroke. The purpose of this study was to 1) determine the test-retest reliability of standing postural sway measures, 2) establish the relationship between postural sway and weight-bearing asymmetry, and 3) determine the relationship between postural sway and clinical balance scores in individuals following stroke.

METHODS

Twenty-eight individuals with chronic stroke (age of 62.0 ± 8.6 years, height of 166.9 ± 11.3 cm, duration of injury of 4.1 ± 2.7 years, Berg Balance score of 44.8 ± 5.5 points, 12 left cerebrovascular accident [CVA], and 16 right CVA) participated in this study. Participants performed two quiet standing conditions, eyes open and eyes closed, on two separate test days. Force plate data (Bertec) was collected for 30 seconds and variables calculated included RMS centre of pressure (COP) displacement (disp.) and velocity in both the medial-lateral (M/L) and anterior-posterior (A/P) directions. The vertical force asymmetry between the paretic and non-paretic limb was also calculated (Robinson et al., 1987), where a higher asymmetry index represented greater weight-bearing on the non-paretic limb relative to the paretic limb. The 14-item Berg Balance score was used to provide a clinical measure of functional balance. Intraclass Correlation Coefficients (ICCs) assessed the reliability between the two test sessions. Pearson Correlations quantified the relationship a) between standing asymmetry and postural sway and b) between the Berg Balance score and postural sway.

RESULTS AND DISCUSSION

High test-retest reliability was found for the A/P COP displacement and velocity and M/L COP velocity (ICCs = 0.73-0.90). M/L COP displacement with eyes open and closed demonstrated moderate reliability (ICCs = 0.63-0.66). Further analyses used the means of the two test sessions (Table 1).

Table 1: Postural sway measures (mean \pm SD), N=28.

Sway Measure	Eyes Open	Eyes Closed
M/L COP (cm)	0.178 ± 0.052	0.241 ± 0.088
M/L COP Velocity (cm/s)	0.887 ± 0.308	1.399 ± 0.566
A/P COP (cm)	0.360 ± 0.093	0.503 ± 0.160
A/P COP Velocity (cm/s)	1.737 ± 0.609	2.985 ± 1.240

Interestingly, it appears that an increase in weight-bearing asymmetry results in less M/L sway velocity in the eyes open condition (Table 2). It is possible that individuals who load their non-paretic limb more may choose a strategy, which relies on lateral ligamentous support from the hip and knee to “lock” the limb and reduce sway.

Table 2: Correlations between COP measures, asymmetry and the Berg Balance score.

COP measure	M/L disp.	M/L velocity	A/P disp.	A/P velocity
Eyes open				
Asymmetry	-0.29	-0.49**	-0.004	-0.20
Berg	-0.16	-0.59**	-0.21	-0.42*
Eyes closed				
Asymmetry	-0.16	-0.23	0.09	-0.08
Berg	-0.17	-0.43*	0.04	-0.09

* Significant at $p < 0.05$ ** Significant at $p < 0.01$

With the eyes closed, the relationships between asymmetry and sway measures were not significant, suggesting that visual input plays a key role in controlling sway in individuals with stroke. Lastly, a decrease in postural sway velocity (particularly in the M/L direction) was related to greater functional balance (i.e. Berg Balance score). This observation concurs with previous reports (Niam et al., 1999; Stevenson & Garland, 1996).

SUMMARY

This study demonstrates that COP velocity is a reliable measure to assess postural sway in individuals with chronic stroke. Clinicians should be aware that the extent of weight-bearing asymmetry will influence postural sway and very low sway values could indicate minimal loading on the paretic limb. Further research on the mechanical influence of asymmetry on postural sway is recommended.

FAILURE LOAD FOR SINGLE SCREW VERSUS SINGLE SCREW PLUS STAPLE CONSTRUCTS IN THE PEDIATRIC THORACIC SPINE: DIFFERENCES BETWEEN “PLOWING” AND “LEVERING”

Andrew Mahar, Richard Oka, David Brown, Peter Newton
Department of Orthopedics, Children’s Hospital, San Diego, CA

INTRODUCTION

Anterior spinal instrumentation systems for correction of scoliosis require comparison between vertebral body screws. Prior tests have applied tensile loads parallel to the screw axis (pullout). However, pullout tests do not represent the only clinical failure mode. Intraoperatively, loads are applied at the screw/bone interface in a direction orthogonal to the screw axis. While the failure is commonly described as “plowing” (translation of the screw through the bone); failures may also be described as “levering” (pitching of the screw within the bone). This difference in mechanical loading is not well described in the literature. To improve the fixation of the screw/bone interface, screws may be augmented with staple. There is little biomechanical data describing the differences in “levering” or “plowing” failure modes. The purpose of this study was to examine differences between a single screw versus a single screw plus staple when tested to failure by both “plowing” and “levering”.

METHODS

Commercially available polyurethane foam (Pacific Research Laboratories, Vashon Island, WA) of 7-lb./ft³ density was selected to simulate the cortico-cancellous bone of the vertebral body. The foam was cut to the anatomic dimensions of pediatric thoracic vertebral bodies (H = 2.5cm, W = 3.0cm, L = 3.0cm). The 5.0 Moss-Miami anterior instrumentation system from Depuy Acromed was used for each test. The inclusion of the staple was randomized across specimens. All screws (6.0mm diameter) were inserted transversely across the “anterior vertebral body”. The anterior portion of the foam block was unsupported during mechanical testing to simulate a vertebral body after adjacent discectomies. Each body was inserted to a rigid fixation device inside a MTS 858 servohydraulic testing machine. A 5.0mm stainless steel rod was then placed in the screw head and bent to 90 degrees to allow insertion to the piston actuator (Figure 1). For “plowing”, the screw was rigidly fixed to the rod with inner and outer nuts, maintaining the screw rod interface at 90 degrees. For levering, the rods were fixed to the screw via the inner and outer nuts, but not tightened, to allow rotation of the rod and changes to the screw-rod orientation. Each mode of failure was tested parallel to the longitudinal axis of the spine. Displacement (mm) and force (N) were sampled at 100Hz for the duration of each displacement control test. Screws were driven to 10mm of displacement and failure was recorded as the maximum force recorded during the test. The average failure load for “levering” and “plowing” were analyzed with a two-way ANOVA ($p<0.05$) to determine differences in failure mechanics. The presence of the staple was also a dependent variable.

Figure 1: Schematic describing directions for plowing and levering during failure testing (without inner/outer nuts).

RESULTS AND DISCUSSION

Table 1: Screw/Bone Interface Failure Loads (N)

	Mean	Std. Deviation
Levering		
With Staple (n=8)	123.10	8.11
Without Staple (n=8)	104.19	9.12
Plowing		
With Staple (n=8)	211.39	44.50
Without Staple (n=8)	170.69	46.57

(interaction term = 0.5)

The increased failure force for the “plowing” conditions was statistically greater ($p<0.0000$) than the failure force for “levering”. For the “levering” condition, the presence of the staple significantly increased the failure force ($p<0.0011$). For the “plowing” condition, the presence of the staple increased the failure force, but this was not statistically significant ($p<0.3$).

CONCLUSION

“Plowing” and “levering” represent two distinct scenarios for bone-screw interface loading/failure. Anterior scoliosis correction may involve both “plowing” and “levering” during different phases of compression between screws. These data suggest a greater influence of the staple in the “levering” mode of loading. The differences in load magnitude under these scenarios may provide insight into fixation failures and vertebral body fractures intraoperatively.

TRANSIENT FOOT GROUND REACTION FORCES AND PROSTHETIC PYLON ATTENUATION DURING GAIT

Glenn K. Klute^{1,2}, Jocelyn S. Berge³, Joseph M. Czerniecki^{1,4}

¹Dept. of Veterans Affairs, Puget Sound Health Care System, Seattle, WA (gklute@u.washington.edu)

Depts. of Electrical Engineering², Bioengineering³, and Rehabilitation Medicine⁴, University of Washington, Seattle, WA

INTRODUCTION

It is widely believed that transient forces generated at initial contact during locomotion are responsible for degenerative joint disease, residual limb blisters and ulceration, muscle tears, stress fractures, and chronic low back pain (Whittle, 1999). For the lower extremity amputee with only residual capacity to attenuate transient forces, prosthesis manufacturers have designed and marketed shock-absorbing pylons. Our interest is to (1) measure these transient forces in a unilateral transtibial amputee sample population and (2) determine if a shock-absorbing prosthetic pylon can attenuate these forces.

METHODS

Unilateral transtibial amputees ($n=5$) were fit with a prosthesis able to accommodate both a rigid pylon and a shock-absorbing pylon (Total Torsion, Blatchford, UK). After a three-week acclimation period, subjects walked at their self-selected speed (3-5 repeated trials) across a force plate ($f_s=600\text{Hz}$, $f_c=100\text{Hz}$; Kistler, SWE). The subjects were then fit with the other pylon (random order) and the acclimation and test protocols were repeated. All provided informed consent. Transient forces, by their very nature, decay during the sample period and hence do not contribute significantly to the magnitude of Fourier series coefficients. Our approach used a stationary wavelet discrete transform with a least asymmetric wavelet (width 8) to preserve both time and frequency content. The least asymmetric wavelet was selected to minimize sidelobes outside the nominal pass-band (Percival and Walden, 2000). The multi-resolution analysis included pass-bands from 9 to 18 Hz (pb1), from 18 to 38 Hz (pb2), from 38 to 75 Hz (pb3), and from 75 to 100 Hz (pb4). Peak vertical foot ground reaction force magnitudes within each pass-band were averaged for each pylon condition. A repeated measures analysis of variance was performed with an *a priori* alpha of $p<0.05$.

RESULTS AND DISCUSSION

The multi-resolution wavelet analysis of the vertical foot ground reaction force for a unilateral transtibial amputee walking with a rigid and a shock-absorbing pylon revealed surprisingly large transient forces that decay within the first 100 msec after initial contact (Figure 1). The mean peak vertical foot ground reaction forces generally decrease in magnitude with increasing pass-band frequencies (Figure 2). All but the 19 to 38 Hz pass-band (pb2) showed reduced magnitude transients for the shock-absorbing pylon when compared to the rigid pylon but none were statistically significant [pb1: $F(1,4)=2.22$, $p=0.21$; pb2: $F(1,4)=0.25$, $p=0.64$; pb3: $F(1,4)=5.69$, $p=0.08$; pb4: $F(1,4)=5.67$, $p=0.08$].

Figure 1: Typical foot ground reaction force observations and multi-resolution wavelet analysis pass-bands (pb2 and pb3 only) for an amputee with a rigid and a shock-absorbing pylon.

Figure 2: The peak vertical foot ground reaction force (Fz) at observed in each pass-band ($n=5$, mean \pm s.d.).

SUMMARY

Antonsson and Mann (1985) report negligible foot ground reaction force magnitudes above 15 Hz (fast Fourier transform). Our wavelet-based approach demonstrates substantial transients exist at much higher frequencies (up to 100 Hz) in the first 100 msec following initial contact. Shock-absorbing pylons appeared to have smaller transients than rigid pylons in 3 of 4 pass-bands (9-18, 38-75, and 75-100 Hz) but were not statistically different. It remains to be determined if this lack of difference is clinically relevant.

INTRODUCTION

The use of seat cushion orthosis is required for various plegic patients and the elderly to prevent pressure sore. To design of an air seat cushion for prevention of decubitus ulcer, interface pressure characteristics between the buttock and cushion are important. The main design factors could be the distribution of interface pressure, the minimization of mean and peak interface pressure values, and the reduction of interface shear force and pressure gradient. Thus, a suitable design of the cushion satisfying all requirements is a difficult problem. To develop an air seat cushion orthosis, an appropriate and effective numerical tool is required. The purpose of the study was to develop an air seat cushion orthosis having optimized air cells representing evenly distributed and lower interface pressure between the buttock and cushion surface. For the purpose, advanced finite elements (FE) of cushion and human buttock models were utilized.

METHODS

Since the interface pressure, as well as deformation behavior of air cell in the cushion were concerns, an air cell was modeled using the airbag model in PAM-SAFE (ESI, France). Figure 1 was the base FE model of air cell. The material of air cell was the chloroprene rubber that is mostly used in the air cushion

orthosis. Since the inflating behavior of air cell in the service range, the material behavior is assumed to be linear. The material properties were obtained from experiments using the chloroprene rubber specimens. The inflating behavior of air cell model was checked by experiments. The completed base FE seat cushion model showed in Figure 2.

The human buttock model was constructed using dimensional data from CT scanning of a plegic patient. The material properties of hard and soft tissues were obtained from previously developed the H-model (IPS International, Korea). The analysis is composed of two procedures. Firstly, the inflating simulation of the seat cushion up to the service air cell pressure was performed. Then, the human model was seated on the orthosis model to obtain the interface pressure characteristics. Figure 3 was the simulation configuration using the orthosis and human model.

To obtain appropriate, or near optimum design of the orthosis, a design procedure was applied using a sensitivity analysis. The design factors were the height of air cell, the number of rib of air cell on the transverse plane, and the density of air cell

in the orthosis. For all cases, the sensitivity analyses were performed to obtain a near optimal design of the orthosis.

RESULTS AND DISCUSSION

Figure 4 shows the comparisons of air cell behavior form the experiment and simulation. The expansion curves of air cell shows a reasonable agreement. Figure 5 shows the interface pressure distributions from the test (left) and simulation (right). For the sensitivity analyses, an optimum height of air cell minimizing interface shear force and maximum pressure was 60 mm (Figure 6 and Table 1). An optimum number of rib of the air cell was 8 based on the strain distribution (Figure 7). The density of air cell was selected as a medium density. After optimizing, the interface pressure characteristics were significantly improved compared to those of the base orthosis model (Figure 8).

THE EFFECT OF BRACING ON PATELLAR ALIGNMENT AND PATELLOFEMORAL JOINT CONTACT AREA IN PERSONS WITH PATELLOFEMORAL PAIN

Li-der Chan¹, Samuel R. Ward¹, Yu-jen Chen¹, Michael S. Terk², Christopher M. Powers^{1,2}

¹Musculoskeletal Biomechanics Research Laboratory, University of Southern Calif., Los Angeles, CA. lidercha@usc.edu

²LAC/USC Imaging Science Center, Dept. of Radiology, Keck School of Medicine, University of Southern Calif., Los Angeles, CA.

INTRODUCTION

Bracing is commonly used in the management of patellofemoral pain (PFP), however, the mechanism by which braces influence symptoms has not been clearly elucidated. One thought is that bracing changes patellar alignment thereby altering the magnitude and/or location of the patellofemoral joint contact area. To date, this hypothesis has not been tested. The purpose of this study was to examine the influence of two braces on patellar alignment as well as the magnitude and location of patellofemoral joint contact area.

METHODS

Eleven subjects with a diagnosis of PFP participated (mean age 31.2 ± 6.7 , height 164.2 ± 5.2 cm, weight 56.4 ± 5.4 kg). Subjects were included if they reported pain reduction with at least one of the braces evaluated. Axial MR images of the patellofemoral joint were obtained at 0, 20, 40, and 60° of knee flexion against a resistance of 25% body weight (Ward, 2001). Imaging was performed under three conditions: 1) dynamic patellar orthosis (Breg Inc.), 2) elastic sleeve brace (Don Joy Inc.), and, 3) no brace. Using previously described methods, measurements of patellofemoral joint contact area (medial facet, lateral facet and total area) were made (Ward, 2001). In addition, medial/lateral patellar displacement and patellar tilt were quantified at each knee flexion angle (Powers, 1998). Separate two-way ANOVA's with repeated measures (brace condition x knee angle) were performed for each dependent variable.

RESULTS AND DISCUSSION

When collapsed across all knee flexion angles, no significant differences in patellar alignment were noted between the elastic sleeve brace and non-braced conditions, however, the dynamic orthosis resulted in a small but significant decrease in lateral displacement compared to the non-braced condition ($62 \pm 0.2\%$ vs. $60 \pm 0.2\%$ of the patella lateral to midline; $p=0.041$). Both the dynamic orthosis and elastic sleeve braces increased total contact area compared to the non-brace condition (non-braced: 250.3 ± 13.3 mm², dynamic orthosis: 293.8 ± 18.3 mm², elastic sleeve brace: 303.5 ± 20.0 mm², $p=0.004$) (Figure 1). Both braces significantly increased lateral facet contact area compared to the non-brace condition (non-braced: 197.8 ± 9.8 mm², dynamic orthosis: 232.1 ± 11.9 mm², elastic sleeve brace: 227.5 ± 12.8 mm², $p=0.007$), however, only the elastic sleeve brace provided significantly greater medial facet contact area when compared to the non-braced condition (non-braced: 52.5 ± 6.7 mm², elastic sleeve brace: 76.1 ± 9.8 mm², $p=0.005$).

Figure 1: Changes in medial facet contact area (MFCA), lateral facet contact area (LFCA), total contact area (TCA). * $p=0.004$, ** $p=0.007$, *** $p=0.005$. (Data collapsed across all knee flexion angles)

SUMMARY

Both the dynamic orthosis and elastic sleeve brace significantly increased total contact area over the non-braced condition by 17.4 % and 21.3 % respectively. The increase in total contact area observed with the elastic sleeve brace was achieved through significant increases in medial and lateral facet contact area, while the increase in total contact area with the dynamic orthosis was achieved through a significant increase in lateral facet contact area. Changes in contact area following bracing likely occurred as result of direct compression as changes in patella alignment were minimal. Alterations in the magnitude and location of contact area may have implications with respect to pain and stress relief in the PFP population.

METHOD TO MEASURE SUSTAINABLE LOADS IN SUTURED URETHRAL TISSUE

William Baker, Kris Okumu, Michael Drews, R. Bruce Martin

Department of Urology and Orthopaedic Research Labs, University of California, Davis Sacramento, California
Corresponding Author: William.Baker@med.va.gov

INTRODUCTION

Vesicourethral anastomosis stricture affects 20% of men following radical prostatectomy. A review of literature shows that many factors contribute to stricture formation but the pathophysiology has not been well studied. Little attention has been paid to the mechanical properties of suture materials and the stresses that they have to bridge to produce a sound anastomosis. After removal of the prostate gland, a 3 – 6 cm gap between the bladder and urethra must be closed. Dynamic forces cause traction in opposite directions. Properties of suture material have been documented in literature but there is little agreement with regard to the best suture material for specific purposes. We have developed a method to measure the force at tissue failure in sutured bovine urethra for monofilament and braided suture of differing gauge.

METHODS

Eight, entire bovine urethra from freshly slaughtered bulls, including the bladder neck, were cleaned of investing tissue. The cylinders of tissue were trisected longitudinally into rectangles and secured in a U-shaped clamp designed in our lab. The tissue was sutured 6 mm from the open end and a 12 cm loop formed by tying the free ends of suture. The tissue holder was attached to the moveable stage of an Instron Tensiometer Model 1122 (Instron Instruments, Canton MA) and the suture looped around a hook secured to the fixed, lower stage. The sutured tissue was distracted at 20 mm/min and a load-displacement curve recorded on a PC using ASYST software (ASYST Technologies, Santa Clara, CA). Yield load was recorded as well as maximum load at tissue failure. Yield load was defined as:

$$\Delta F / F_{predicted} > 5\%$$

where

$$\Delta F = F_{predicted} - F_{actual}$$

To measure the maximum load sustainable by suture material itself, 12 cm loops of suture were distracted at 20 mm/min until failure.

RESULTS AND DISCUSSION

Yield load and maximum load in sutured tissue were directly proportional to suture gauge and were higher with monofilament compared to braided suture. Yield load in tissue with 0 gauge monofilament suture was 111% greater than with 4.0 gauge suture. Yield load in tissue with 0 gauge braided suture was 79.6% greater than with 4.0 gauge suture. The maximum load in tissue with 0 gauge monofilament suture was 71% greater than with 4.0 gauge suture. The maximum load in tissue with 0 gauge braided suture was 34% greater

with 4.0 gauge suture. The loops of suture material failed at maximum loads higher than loads sustained by sutured tissue. Since suture failed at loads much higher than that of tissue failure, these results show that in this model, the mechanical properties of tissue are of primary importance. Thus, from a purely mechanical perspective, monofilament suture of large gauge is superior for suturing urethral tissue. Nevertheless, other factors must be considered in selecting appropriate suture. Monofilament suture offers excellent glide characteristics and causes minimal tissue trauma. This decreased tissue trauma may explain the higher sustainable loads in sutured tissue. However, monofilament suture, especially of larger gauge, is difficult to manipulate. Braided suture is easier to handle and has superior knot tying strength compared to monofilament suture. In vivo, however, braided suture loses tensile strength faster than monofilament suture and provides better media for bacterial colonization.

EMG CHANGES IN PARASPINAL MUSCLE OF SCOLIOSIS PATIENTS AFTER SPINAL FUSION

W W. Lu¹, Yong Hu¹, K D K Luk¹, Qiu Guixing², J C Y Leong¹

¹Department of Orthopaedic Surgery, The University of Hong Kong, China

²Dept of Orthopaedic Surgery, The Peking Union Medical College Hospital, Beijing China

INTRODUCTION

Adolescent idiopathic scoliosis is the most common spinal deformity, and surgical correction followed by spinal fusion is the basic method of treatment with a Cobb angle of greater than 40°. However, previous studies have noted incidences of developing pseudarthrosis, low back pain, spinal stiffness and instability following spinal fusion. The function of the paraspinal muscles after spinal fusion is still unknown. The purpose of this study was to compare spinal muscle function in normal subjects and scoliotics pre- and post-fusion, with particular attention on the effects of long term follow up.

MATERIALS AND METHODS

Fifteen healthy subjects (mean age 19 years) and 19 patients (mean age 18 years) with adolescent idiopathic scoliosis were evaluated. All the patients had right-side thoracic curves with a mean Cobb angle of 56°(8 degrees). They received posterior spinal fusion from T2-T5 to T12 and were followed up for a minimum of 2 years after surgery.

EMG signals were collected from healthy subjects and patients before surgery and two years after surgery. Six pairs of surface electrodes were placed along the paraspinal muscles over the left and right side of upper (T3-4), lower thoracic (T10-11) and lumbar (L2-3) regions respectively. In spinal fusion cases, the thoracic electrodes were placed inside the fusion range and the lumbar electrodes were placed on the non-fused region. Each surface EMG electrode (bipolar Ag-AgCl Disc electrodes, (=2cm) was applied to the cleaned skin. EMG signals were differentially amplified 1000 times and filtered using a band-width of 10 to 1000 Hz. The raw EMG signals were digitized at a sampling rate of 1000 Hz using a BTS EMG system (BTS Inc, Milan, Italy).

Two trial EMG signals were recorded in a relaxed upright standing posture. Then three tasks (forward, right, and left lateral bending) were carried out. Each subject performed two trials for each task. After removing DC components, the root mean square value (RMS) and the median frequency (MF) of each interval was calculated. ANOVA was used to compare functional changes between the groups and tasks.

RESULTS

The ANOVA analysis showed significant differences between control, pre- and post-operative groups, both in RMS and MF ($p < 0.01$ in both cases). During upright standing, pre-operative

scoliosis patients showed higher RMS activities in the thoracic region than the normal control group. After spinal fusion, the RMS in the thoracic region decreased but was still higher than that of the control group. In contrast, the RMS over the lumbar region of post-operative patients significantly increased in comparison to pre-operative patients ($p < 0.01$). In lateral

bending, normal subjects showed a higher RMS on the bending side so that the RMS is greater on the left side during left lateral bending, and vice versa. However, both pre- and post-operative scoliosis patients, did not show such contraction patterns.

Observing the changes in EMG spectra following spinal fusion, the MF showed increase in the thoracic region, but decrease in the lumbar region. In comparison to normal subjects, the pre-operative scoliosis patients showed lower MF in thoracic region and higher MF in the lumbar region, especially in upright standing. After spinal fusion, this trend in MF was diminished.

DISCUSSION & SUMMARY

Previous long-term follow-up studies have reported adjacent disc degeneration syndrome after spine fusion. However, the causes of these complications after spinal fusion have not been clearly investigated. Changes in the biomechanical properties of the trunk following fusion are likely to cause change in the paraspinal muscle functions. Muscle disuse and localized atrophy may be found in some regions. In this study, EMG activities were compared between normal subjects and scoliotics before and after spinal fusion. Significant differences were found. The paraspinal muscles in the thoracic and lumbar regions showed significant differences in fused spines. The thoracic paraspinal muscles were found to be less active after spinal fusion, probably due to atrophy. Paraspinal muscles in the lumbar region showed a higher EMG activity, suggesting increased muscle activity.

INTRODUCTION:

It is estimated that arthritis affects 355 millions of patients all over the world, causing pain, deformity, stiffness, and incapacity. When the joints are destroyed, artificial joint replacement of the hip, knee, shoulder, and elbow has provided excellent result in most cases. In the case of the finger joints, results are unsatisfactory. The initial design of various hinge prosthesis led to loosening, breakage, and erosion through the bone. A series of two components prosthesis did not lead to better results. Ceramics have favorable characteristics as a biomaterials and has been used in joint replacement. The purpose of this study was to evaluate the wear and fatigue properties of a novel ceramic finger joint(CFJ).

MATERIALS AND METHODS

Seven sets of CFJ were tested, three were zirconia (100% ZrO₂) and four sets were alumina (Al₂O₃+ ZrO₂). Both the male and female parts were made of the same material. The test was carried out using a finger wear simulator with 3 stations (self designed). The whole test lasted 5 millions cycles, which represent a clinical follow-up of five years. The male and female parts were fixed to a polyurethane holder in the wear simulator. The experiment was conducted in 50 percent bovine serum (SIGMA Lot 29H8401) with 50 percent distilled water as lubricant under room temperature of 23 °C. The lubricant was replaced from the station every one million cycles, and the cleaned CFJ was weighted at each stop-weigh measurement. The test was restarted with fresh bovine serum solution.

The axial compression of 20N was applied during the testing and the range of motion was 60° (flexion-extension) with frequency of 2 Hz. The amounts of worn particles from the CFJ to lubricant were measured by inductively coupled plasma atomic emission spectrometry (ICP) (ZEISS, Plasmaquant 110). 5ml lubricant was acquired with 1ml 10% Nitric-acid added, and before testing, additional 25 ml distilled water was added. A gravimetric or weigh loss method was chosen for wear assessment. The weigh loss of the CFJ was measured using a balance (Denver Instrument M-220) with accuracy of 0.1mg.

SEM and EDX (Cambridge SEM 440, made in Britain) were used for observing the surface morphology and composition of the CFJ after 5 million cycles.

RESULTS

The size of particles is about 1-10 μm for the alumina CFJ and the particles were melted and contacted tightly together observed by SEM. The mainly composition is Al₂O₃ (>90%)

with other element (Ca, Si, Zr) defined by EDX. After five million cycles, the bearing surface was slightly worn, but no cracks were observed. The average weigh loss was 1.9mg per million cycles and wear rate was 3.9μm per million cycles. The particle size of Zirconia CFJ was about 1μm and the composition was ZrO₂ only. Cracks were found on the surface of the CFJ before wear testing. After four million cycles, the length and depth of cracks were significant increased and the tests were stopped. The average weigh loss was 0.332 mg per million cycles and the wear rate was 0.46 μm per million cycles (Table 1).

DISCUSSION

Many biomaterials have been used for finger prostheses, metal to metal, titanium, silicone, metal to plastic. However, most of these implants developed fractures within few years. Ceramics have many favorable biomaterial characteristics, such as strong corrosion resistance, good chemical, dimensional stability, and very good mechanical strength. Although ceramics are brittle, an optimal techniques by combining zirconia and alumina may enhance the brittleness

KNEE LOADING IN A MENISCECTOMY POPULATION: A RISK FACTOR FOR OSTEOARTHRITIS?

INTRODUCTION

Mechanical factors are believed to contribute to the development of knee osteoarthritis (OA). The incidence and severity of knee OA has been associated with knee adduction moments during stance phase of gait (Sharma et al., 1998). As the loading of the medial and lateral tibiofemoral joint is largely determined by the adduction moment, it is considered a possible factor in the development of knee OA. Gait adaptations following knee trauma may alter loading of the knee joint, and contribute a possible mechanism for the increased risk of knee OA following meniscectomy (Sommerlath et al., 1991). The purpose of this study is to compare gait patterns in young, pre-osteoarthritic adults who recently underwent partial meniscectomy, to a control group with no history of knee injury or disease.

METHODS

Preliminary data from 45 meniscectomy patients (~6 weeks post-surgery) and 20 controls has currently been analysed from a larger cohort of 180 people. Subjects were aged 20 to 45 years and screened for existing knee OA, previous or current knee joint pain, stiffness, laxity, disease, injury (excepting meniscus tear in patient group), or any other pathology that may affect gait. Three-dimensional gait analysis was performed using a 50 Hz, six-camera VICON motion analysis system, with AMTI force platforms. Joint kinematics and kinetics were calculated using a custom seven-segment lower limb model. External knee moments were normalised to individual's height and mass, and analysed over stance. Data was statistically tested using two-way repeated measures ANOVA, Bonferroni corrected for multiple comparisons, and with the p value for significance set at <0.05 .

RESULTS AND DISCUSSION

The meniscectomy group display larger knee adduction moments over stance ($p<.05$), compared to the control group (see Figure 1.). These findings suggest that a post-

Figure 1: Knee adduction moments during stance

meniscectomy population load the medial compartment of the tibiofemoral joint with more force during stance phase of gait, and may therefore be predisposed to degenerative joint changes within that compartment.

Based on the average knee adduction moment, 'high' and 'low' loading categories were determined as greater than and less than one standard deviation away from the mean of the control scores, respectively. Subjects were categorised as high, normal or low loaders (see Table 1).

Table 1: Percentage of subjects in different loading categories

Loading Category	Control	Meniscectomy
Low	21%	5%
Normal	68%	42%
High	11%	53%

A greater proportion of the meniscectomy group was classified as a high loader. This increased proportion of high loaders in the patient group may relate to the greater proportion of meniscectomy patients developing knee OA in the long term.

Knee flexion moments did not differ between groups, although the meniscectomy group showed significantly reduced flexion (92%) and extension (82%) moments on the meniscus leg ($p<0.01$). A similar unloading pattern was noted between the meniscectomy and contralateral legs for the adduction moments within the patient group. Overall, the meniscectomy group experience greater adduction moments at the knee joint yet appear to have an altered gait strategy to unload the involved knee. This may be a residual gait pattern from that adopted due to the pain associated with the initial injury.

SUMMARY

The knee adduction moment loads the medial tibiofemoral joint. If experienced at magnitudes beyond that of the coping threshold of the joint, this loading may give rise degenerative changes and the development of knee OA. This study has identified larger than normal knee adduction moments in a pre-osteoarthritic meniscectomy population, a large proportion of which will develop knee OA. Further studies prospectively investigating the development of knee OA within different loading groups will elucidate this question of cause and effect.

BIOMECHANICAL ANALYSIS OF SIDE-STEP CUTTING: ARE FEMALES AT GREATER RISK FOR ACL INJURY?

Susan M Sigward and Christopher M Powers

Musculoskeletal Biomechanics Research Laboratory, University of Southern California, Los Angeles, CA

INTRODUCTION

Non-contact anterior cruciate ligament (ACL) injury rates are 3-8 times greater for female athletes than their male counterparts (Griffin 2000). A large number of non-contact ACL injuries occur during the deceleration phase of a cutting maneuver (i.e. following foot strike) when a rotation torque is applied to the slightly flexed knee (Delfico 1998, Kirkendall 2000). This mechanism of injury concurs with in-vitro studies that have demonstrated that the combination of knee rotation and varus/valgus moments place the highest strain on the ACL when applied between 0 and 30 degrees of flexion (Markolf 1995, Dürselen 1995). Evaluation of gender performance differences, as measured by kinematic and kinetic variables, during common athletic maneuvers may provide insight into loading patterns that put the female athlete "at risk" for and ACL injury. Previous studies comparing males and females performing athletic maneuvers have focused primarily on kinematic and EMG data and have not addressed moments or torque experienced at the hip or knee. The objectives of this study are to: 1) quantify gender differences in hip and knee kinematics and moments during a side-step cutting maneuver 2) identify performance patterns that put females at increased risk for ACL injury.

METHODS

Twelve subjects (6 male and 6 female; ages 21-32) with no history of ACL injury or current lower extremity pathology participated in the study. Subjects performed four trials of a side-step cutting maneuver. Each participant ran at a speed of 6-7.0 m/s, planted their right foot on the force plate and changed direction to the left at a 35-60 degree angle. Anthropometric data, 3-D knee kinematics (VICON Motion System, 120 Hz), and ground reaction forces (AMTI force plate, 600 Hz) were used to calculate moments in all three planes at the hip and knee (inverse dynamics equations). Peak angles and moments (external) were identified during the early deceleration phase (20% of the cut cycle). Gender differences were evaluated with paired t-tests ($p < 0.05$).

RESULTS

During the first 20% of the cut, females demonstrated greater hip adduction angles and moments compared to males (Figure 1). In addition, females demonstrated greater knee valgus angles and experienced larger knee varus moments (Figure 2). Both groups demonstrated similar knee flexion angles, knee internal rotation moments, and knee internal rotation motion.

DISCUSSION

These data suggest that males and females demonstrate different kinematic and kinetic profiles at the hip and knee

Figure 1

Hip Frontal Plane ROM and Moments

Figure 2

Knee Frontal Plane ROM and Moments

during side step cutting. Differences were found in the early deceleration phase, at time at which the knee is in a less flexed, more vulnerable position. The female athletes demonstrated a profile in which increased hip adduction translated into increased valgus at the knee. Knee valgus and internal rotation combined with a larger varus moment knee could place greater tension on the ACL (Markolf). These gender differences may place females at greater risk for injury.

THE COMBINED EFFECTS OF DISUSE AND GONADECTOMY ON BONE MECHANICS IN MALE AND FEMALE RATS

INTRODUCTION

Both decreased steroidal hormones and activity levels may lower bone mass in the elderly increasing their risk of fracture. Reduced estrogen in female rats accelerates the decline in bone mass in the proximal tibia and the vertebrae and decreases bone strength (Wronski et al, 1989, Peng et al, 1994). Increased activity of both osteoblasts and osteoclasts throughout the skeleton are responsible for the lower bone mass. On the other hand, rat models of hind limb unweighting resulted in decreased trabecular bone volume and tibia bone mineral density (BMD) through decreased bone formation. Decreases in the number of osteoblasts with no effect on bone resorption were reported from unloaded rat models (Halloran et al., 1986, Dehority et al, 1999). The purpose of this study was to investigate the interaction of these two mechanisms of bone loss in the cortical tibial diaphysis of mature male and female rats.

METHODS

Male and female rats (6-7 mo) were randomly assigned to four groups: control (C), ovariectomized/orchiectomized (OVX/ORC), hind-limb unweighted (HLU), ovariectomized/orchiectomized and hind-limb unweighted (OVX/ORC-HLU). Eight OVX female rats were injected with estradiol benzoate on days 7, 14, and 21 days post-surgery (OVX-E2). After bilateral removal of ovaries and testes using aseptic surgical technique and following a two week recovery period, the OVX/ORC-HLU groups were then tail suspended. The tail suspension method was used to unload the hind limbs of rats in both the HLU and OVX/ORC-HLU groups. The animals were suspended at an angle that allowed free movement in their cages on their forelimbs. A five-day adaptation period preceded the 2-week unloading period. After sacrifice the tibiae were harvested for density and mechanical measurements. Bone mineral content (BMC) (g) and bone mineral density (BMD) (g/cm²) were measured using dual energy x-ray absorptiometry (Hologic QDR-1000). Torsional testing was used to assess the structural properties of the tibial diaphysis. The tibiae were internally rotated under rotational control to failure at a rate of 1 deg/sec. (Instron 8500R, Instron Corp., Canton, MA). The following parameters, maximal torsion, rotation to failure, stiffness and energy absorbed to failure were compared between groups. Cortical wall thickness was measured on 9 points of 4 cross-sections of the tibia diaphysis. A two-way Anova was used to determine interactions of HLU and OVX/ORC. Tukey post hoc tests were performed (p < 0.05). Bone strength variables were evaluated using an ANOVA with co-variates of cortical wall thickness and body weight.

RESULTS AND DISCUSSION

The body weight at sacrifice of the OVX group was significantly higher than all groups in the female rats. The

bone mineral density (BMD) was lower in the OVX group compared to control (C) animals and (OVX+E2) animals (Table1), consistent with previous results of ovariectomized rats (Wronski et al, 1989). HLU and OVX-HLU resulted in BMD values lower than OVX values (Table 1). The combined effect of HLU and OVX did not result in any further decrease in BMD compared to HLU alone. The decrease in BMD did not translate into decreased mechanical variables or a decrease in cortical wall thickness (Table 2). The periosteal circumference of these animals was maintained that preserved the mechanical tolerance of the tibial diaphysis. The decrease in BMD that occurred in the tibia may have been at the trabecular sites of the proximal tibia. Similar trends in BMD and torsional strength were found in male rats, however these were not significant.

Table 1: Bone Mineral Density (g/cm²) values.

Group	Male	Female
Control	0.180 (0.009)	0.160 (0.005)
OVX+E2		0.157 (0.005)
ORX/OVX	0.175 (0.0045)	0.153 (0.010)
HLU-F	0.173 (0.0089)	0.140 (0.005)*#
OVX+HLU	0.173 (0.005)	0.138 (0.003)*

- Different from OVX group. # Different from control

Table 2: Maximum Torque (kN*degree) values.

Group	Torque (kN*deg)	
	Male	Female
Control	0.379 (0.051)	0.225 (0.036)
OVX+E2		0.277 (0.057)
OVX/ORX	0.393 (0.069)	0.220 (0.034)
HLU-F	0.353 (0.134)	0.238 (0.056)
OVX+HLU	0.312 (0.122)	0.219 (0.023)

SUMMARY

The duration of the unloading may have been too brief to manifest cortical bone changes in aged rats. Older bone is less affected by mechanical loading and may be less responsive to an absence of loading.

IS PERMANENT ARTERIAL FILTRATION POSSIBLE? IN VIVO ASSESMENT OF A FILTRATION DEVICE FOR EMBOLIC STROKE PREVENTION

Ygael Grad¹, Boaz Nishri¹, David Tanne², Shmuel Einav³, Bruch B Lieber⁴, Ofer Yodfat¹

¹ MindGuard Medical Devices Ltd., Alon Hatavor 1 Caesarea Industrial Park, Israel 38900, ygael@mindguard.net

³ Dept. of Biomedical Eng. Tel Aviv University, Ramat Aviv Tel Aviv, Israel 69978

⁴ Center for Neurovascular Surgery and Stroke Research, University of Miami, FL. 33124

PURPOSE

A new permanent arterial filtering device (*the Diverter*) was designed for implantation at the carotid bifurcation (CCA to ECA, thus filtering the ICA ostium, Fig. 1). The filter prevents thrombi originating proximal to it from reaching the intracranial circulation and inducing an embolic stroke. Our aim in this study was to test the patency of the permanent arterial filter in the ilio-femoral bifurcations of swine.

Fig. 1, *The Diverter* implanted from the CCA to the ECA in the carotid bifurcation. The filtered ICA ostium (top left) prevents emboli from reaching the brain (bottom left)

MATERIALS AND METHODS

A total of 29 Diverters, composed of multiple fine wire meshes, were implanted in ilio-femoral bifurcations of 45kg female swine. The bifurcations carrying the implants were harvested at intervals of 2,4,9 and 18 weeks post device implantation for evaluation. The patency ratio of the filtered ostium, defined as ratio of the patent over total area of the ostium, was calculated using microscopy and computerized image processing morphometry.

RESULTS

Angiography and ultrasound Duplex scanning prior to animal sacrifice found the Diverter open to flow without occlusion or discernable stenosis up to 18 weeks post implantation in all devices except for 3 mechanical failures. On average, the

Diverter mesh covered a lumen of 23mm² at the bifurcation while the average cross sectional area of the filtered artery one diameter distal to the bifurcation was 11mm². The non-filtering part of the Diverters were fully covered by a neointima 4 weeks post implantation. Morphometry and microscopy showed that the majority of the filtered area (90% on average) of the 26 specimens remained patent, as shown in **Table 1**. A small number of the filtering wires, mainly at the rim of the filtering mesh area, were covered by fibrin containing deposition in some of the diverters.

Table 1, Filtered area patency results

Harvesting week	Implanted specimens	Implantation mechanical failure	Harvested specimens	Patency ratio [%]
2	4	1	3	93
4	6	1	5	92
9	5	1	4	72
18	14	0	14	93
-	(Total=29)	(3)	(26)	-

CONCLUSIONS

Implantation of a permanent arterial filtration device is feasible. In the swine model, all implanted devices (n=26) remains patent with no deleterious encroachment of tissue on the filtering portion of the diverter up to 18 weeks. Our preliminary findings suggest that a novel therapy by the Diverter is feasible for patients at high risk of embolic stroke from proximal sources.

MOTOR LEARNING PROTOCOL OF THE HIP WALKING STRATEGY IN INDIVIDUALS WITH DIABETIC PERIPHERAL NEUROPATHY

Karen L. Perell PhD, RKT¹ and Janice Roper PhD, RN²

VA Greater Los Angeles Healthcare System

¹ Director, Physical Medicine & Rehabilitation Gait Laboratory, ² Director, Nursing Research and Education

INTRODUCTION

Mueller et al. (1994) used gait training to reduce high foot pressures in patients with diabetic peripheral neuropathy, but have failed to study the "learning" by classical motor learning theories. While all subjects reduced their forefoot plantar pressures, no follow-up retention tests were utilized or feedback necessary to elicit the desired motor pattern discussed. Sanderson & Cavanagh (1990) suggest that proprioception plays an integral role in the use of feedback to develop error-detection mechanisms by integrating visual feedback and kinesthetic variables. In the diabetic peripheral neuropathy population, proprioception and kinesthesia may be compromised. To date, no studies have demonstrated whether individuals with diabetic peripheral neuropathy can "learn" a motor task (e.g. demonstrate follow-up retention of a changed motor pattern over days or weeks). The purpose of this study is to compare plantar pressures following a short-term gait training program in subjects with type II diabetes and peripheral neuropathy immediately, 1 week and 1 month post.

METHODS

Twenty subjects (age 50-80 years old) with a history of type II diabetes and peripheral neuropathy are randomized into a feedback group and a no-feedback group. All subjects receive instruction regarding using a "hip" strategy (pull their leg forward from the hip) rather than an "ankle" strategy (push off from the ankle) gait and asked to practice following the training until the follow-up testing. The feedback group receives summary feedback at the end of each trial regarding performance, while the no-feedback group receives no feedback. Baseline gait analysis (5 trials) prior to any instruction, training (15 trials), and immediate retention (5 trials) testing are done on the same day. Additional retention testing (5 trials) is done at 1 week and 1 month. EMED Pedar (Novel Electronics, St. Paul MN) insoles are worn within the subject's shoes. Peak plantar pressures across the metatarsal heads are compared across time points and groups.

RESULTS AND DISCUSSION

Preliminary data from the feedback group demonstrate significant reduction in plantar pressures under the 2nd/3rd metatarsal heads remained at the 1 week retention (Figure 1). The reduction demonstrated under the 4th/5th metatarsal heads immediately following training was not maintained statistically at the 1 week retention test (Figure 2).

Similar to Mueller et al (1994), we observed that individuals with diabetic peripheral neuropathy can change their walking pattern from an "ankle" strategy to a "hip" strategy with little training with consequential reduction in forefoot plantar pressure. We demonstrate that this change can be maintained over the course of at least 1 week, specifically in areas of greatest pressure (2nd/3rd metatarsal heads).

Figure 2: Mean \pm standard deviation of baseline, immediate retention, and 1 week retention peak plantar pressures under the 2nd/3rd metatarsal heads for the preliminary data of the feedback group.

Figure 3: Mean \pm standard deviation of baseline, immediate retention, and 1 week retention peak plantar pressures under the 4th/5th metatarsal heads for the preliminary data of the feedback group.

SUMMARY:

Individuals with diabetic peripheral neuropathy are at high risk for foot ulceration due to walking patterns, which facilitate increased plantar pressures. Foot ulceration often leads to lower limb amputation with high financial and quality of life costs for the individual and the healthcare system (Ollendorf et al. 1998). Consequently, gait training strategies to create long-lasting changes in gait patterns which reduce plantar pressures may have important effects on ulceration and amputation rates. While this study cannot assess ulceration rates within its design, ultimately, it will provide the first step in understanding the effect that altered motor patterns have on plantar pressures and ulceration rates. The key component, however, is that subjects with diabetic peripheral neuropathy can improve and retain motor patterns which facilitate reduced plantar pressures.

***In vivo* MEASUREMENT OF MUSCLE FIBER BEHAVIOR IN THE TRICEPS SURAE MUSCLE DURING TENSIONAL SUMMATION**

Toshiaki Oda, Kentaro Chino, Toshiyuki Kurihara, Yasuo Kawakami and Tetsuo Fukunaga
Department of Life sciences (Sports Sciences), University of Tokyo, Japan, cc16712@mail.ecc.u-tokyo.ac.jp

INTRODUCTION

Tensional summation induced by increment of neuro-stimulation number results from fusion of twitch in skeletal muscle. Little is known about the muscle behavior during tensional summation *in vivo*. In the present study, we directly measured the fascicle length to investigate the muscle behavior in tensional summation.

METHODS

Five healthy male volunteers, aged 24 –30, participated as subjects. The subject was seated with knee joint and ankle joint at 180 deg and 90 deg, respectively. The twitch and the tensional summation were evoked by percutaneous supramaximal electrical stimulation of the tibial nerve at 1-3 times (frequency was 30Hz). The ultrasound apparatus (SSD-5500, Aloka, Japan) having a 7.5 MHz linear-array probe was used and the sequence of longitudinal ultrasonic images (78Hz) of medial gastrocnemius (MG) and soleus (Sol) at the level of 30 % of the lower leg length were recorded and synchronized with the torque (TRQ) data. Fascicle length from the image was measured using image analysis software (NIH Image, National Institute of Health, USA). Contractile velocity was calculated to differentiate the fascicle length change by time.

RESULTS AND DISCUSSION

It was shown that fascicles of MG and Sol dynamically changed their length (Fig. 1) and hence contractile velocity, even during twitch contraction. The peak TRQ became larger when stimulus number increased. The increment of peak TRQ were significantly correlated to the amount of the maximal fascicle shortening (Figure 2 A). The length change of MG was larger than that of SOL. In addition, MG showed higher mean contractile velocity in the shortening phase compared with Sol (Figure 2B). Interestingly, the mean velocity of both muscles became faster at higher contraction levels, even at the same stimulation frequency.

This study clearly indicated that MG and Sol *in vivo*, although having a common tendon, behave differently during twitch contractions. This difference might have been caused by differences in fiber types and series elasticity.

Figure 1: An example of time course of fascicle length. The

graph shows mean value of all subjects for a single twitch. Time zero corresponded to the instance of electrical stimulation.

GLOBAL OPTIMIZATION FOR RECOVERING THE POSITION AND ORIENTATION OF FREE-FORM OBJECTS IN MEDICAL IMAGING REGISTRATION USING A NEW SMOOTHING APPROACH

Mohamed Mahfouz^{1,2}, William Hoff², Robert Underwood², Richard Komistek¹, Douglas Dennis¹
¹Rocky Mountain Musculoskeletal Research Laboratory, Denver, Colorado, mmahfouz@rmmrl.org
²Colorado School of Mines, Golden Colorado

INTRODUCTION

Intensity-based three-dimensional to two-dimensional (3D-2D) image registration requires finding the projective transformation (i.e., a composition of rigid displacement and perspective projection), which maps a 3D object onto a 2D image of this object (Penney, 1998). The objective of this study was to develop a 3D-2D registration that can be used to determine the kinematics of total joint arthroplasty (TJA) implants, and non-implanted (normal) joints using 2D video fluoroscopy images (Mahfouz, 2002).

METHODS

An objective function is used that directly compares the input 2D image to a predicted image, generated by rendering the 3D object in a hypothesized pose. By adjusting the hypothesized pose until the objective function reaches a minimum, we can determine the pose of the object. However, the objective function usually contains large numbers of local minima due to the noise in X-ray images and hence, it will be generally too expensive to solve registration problems directly on the objective function. We present a novel method for determining the rigid body transformation that uses a new coarse-to-fine approach. Our method transforms the problem from the objective function space to image space. We apply a spatial averaging filter to smooth the X-ray image, which removes the shallow local minima. The method performs unconstrained optimization using variable metric (quasi-Newton) methods, which are gradient-based algorithms that require fewer function evaluations. By selecting different smoothing filters, images with different degrees of smoothness can be derived.

The intent is to first solve the global optimization problem on very smooth images, and then use this solution to gradually solve the problem on less smooth images and ultimately the original, unsmoothed image (Figure 1).

Coarse-to-Fine Strategy

Figure 1. Coarse-to Fine Strategy

RESULTS AND DISCUSSION

Experimental results for 3D surface to 2D projection matching are presented for real data (Table 1). The combination of spatial averaging smoothing of the image with variable metric optimization technique results in a method that solves the 3D-

2D for arbitrary anatomical and implant shapes accurately and quickly (Figure 2).

Figure 2. Smoothed Image Space (left), Non Smoothed Image Space (right).

SUMMARY

This study has described a new method for measuring the kinematics of TKA knees from single plane fluoroscopy images. This method is robust with respect to image noise, occlusions, and low object-to-background contrast. We use a direct image-to-image similarity measure, taking advantage of the speed of modern computer graphics workstations to quickly render simulated (predicted) images. As a result, we do not require an accurate segmentation of the implant silhouette in the image (which can be prone to errors). We avoided the large number of local minima by smoothing the image space and applied unconstrained optimization using quasi-Newton methods that require fewer iterations. The results from this study has revealed significant advantages over previously described methodology. (Banks, 1996)

CFD ANALYSIS OF FLOW THROUGH MECHANICAL HEART VALVES

Idit Avrahami, Moshe Rosenfeld,

Department of Biomedical Engineering, Faculty of Engineering, Tel-Aviv University, Tel-Aviv, Israel. idita@eng.tau.ac.il

INTRODUCTION

Newly developed artificial heart pumps commonly use mechanical heart valves (MHV) such as tilting disk or bileaflet valves. The fluid dynamics associated with MHV plays a critical role in determining the longevity of these devices. The present study simulates numerically the flow across MHV in the mitral position, in order to establish the time dependent global flow field for several typical cases. The analyses used models of tilting disk and bileaflet valves in a straight channel and in realistic left-ventricle (LV) geometry.

The objectives were to study the effect of unsteadiness, the significant of the third dimension, the effect of model geometry and the motion of the valve on the flow field as well as to investigate the possibility of cavitation.

METHOD

Numerical analyzes were performed to investigate the flow through 2-D and 3-D models of tilting disk and bileaflet valves placed in a straight channel and in simplified models of the natural left ventricle (LV). A commercial CFD package (FIDAP, Fluent Inc, Evanston) was used. Cases with constant and pulsatile inflow conditions and cases with fixed and moving valves were analyzed. Four different fluid-structure interaction (FSI) methods were developed and used to couple the motion of the valve with the calculated flow field in the moving valve cases: (a) strong FSI coupling (every time step), (b) interaction at the end of several time-steps, (c) interaction at the end of each pulse and (d) interaction after several cycles.

RESULTS AND DISCUSSION

The valves, even in their fully open position, posed a significant obstruction to the flow. The jets generated between the valve tips and the walls, created a vortical flow consisting of large vortices next to the valve and a row of vortices along each wall. Major difference was found between the constant and the pulsatile inflow conditions. However, the simulations with fixed valve and physiological incoming flow consistently results in safe estimations of several critical quantities such as the axial force or the maximal shear stress on the valve or the transvalvular pressure drop.

In the 2D channel model with moving valve case, all algorithms converged to the same valve motion and flow behavior. The algorithm with cycle-wise interaction (algorithm c) had the best overall convergence rate. Algorithm (b) needed 12,240 time steps (=6 pulses) for full convergence while algorithm (c) required only 6,800 time-step calculations (=10 pulses) for full convergence. No advantages were found for the

algorithm (d) with interaction after several cycles. Typical results are shown in Figure 1.

Because of the relatively high Reynolds number ($Re=3000$), the flow in the more complex models of MHV in realistic left ventricle (LV) geometry did not converge into a simple pulsating flow, and the motion of the valve did not repeat itself every cardiac cycle, although the variations were in a limited range. It was also shown that vortices created in the instance of valve closure decreased the pressure significantly and thus might increase the possibility of cavitation.

Figure 1: vorticity contours of the flow across models of (a) 3D fixed tilting disk valve in a tube and (b) 2D moving bileaflet valve in LV.

SUMMARY

The flow field across the MHV was strongly influenced by the valve type and the inflow conditions. The model geometry, the third dimension and the motion of the valve hardly affected the global features of the flow in the fully open phases. Cycle-wise FSI algorithms had clear advantage over strong FSI algorithms because of the periodic nature of the flow.

A COMPARISON OF BI-LATERAL DEFICIT IN ELITE ENDURANCE AND ELITE POWER ATHLETES DURING DROP JUMPS

Matthew Pain and Masayuki Koitabashi

Department of PE, SS, & RM, Loughborough University, Loughborough, Leics, LE11 3TU, UK
m.t.g.pain@lboro.ac.uk

INTRODUCTION

Bilateral deficit can be described as the inability to produce a maximal voluntary force in both limbs simultaneously (Taniguchi, 1998, Challis 1998). The most often cited reason for bilateral deficit is a lesser activation of fast twitch motor units (Kawakami et al. 1998).

Drop jumps are a stretch-shorten cycle activity characterized by high muscular forces and velocities. Drop jumps can produce greater jump heights than conventional jumps, however after a certain threshold landing velocity there is a decrease in jump height. Consideration of this factor needs to be kept in mind when comparing drop jumps of different heights as the mechanism for performance modulation is not fully known.

Drop jump ability is greatest amongst power athletes, who are considered to have a greater percentage of fast twitch motor units (Viitasalo et al., 1998). It is hypothesized that although elite power athletes will have greater jumping ability than elite endurance athletes, the power athletes will exhibit a greater degree of bilateral deficit in drop jumps due to a higher level of fast twitch motor units.

METHODS

Five elite endurance athletes and five elite power athletes, performed a series of 1 legged and 2 legged drop jumps from three heights; 15cm, 30cm and 60cm (two legged only). These heights were chosen to compare 1 legged and 2 legged performances in terms of: equal energy and impulse absorbed per leg during the eccentric phase, and equal drop height.

Jumps were performed without arm swing and with instruction to minimize the free leg usage in 1 legged jumps. Force and 3-D movement data were recorded at 800 Hz using a Kistler force plate synchronized with a CODA mpx30. Motion data were reduced to a planar motion for subsequent analysis. EMG data were recorded for 4 athletes, 7 muscles per leg, for further analysis.

Bilateral deficit was calculated using dominant and non-dominant leg jump heights.

$BD = 100 - 100(\text{bilateral height} / (\text{left height} + \text{right height}))$

RESULTS AND DISCUSSION

As expected the power athletes performed significantly better ($p < 0.05$). They jumped 35 to 50% higher than the endurance athletes. They had significantly shorter contact times, higher ground reaction forces, less range of joint motion and higher concentric power. They also exhibited a much larger degree of bilateral deficit in all combinations of drop height (Table 1).

Table 1. Bilateral deficit for all combinations of drop height
b = 2 legged, md = dominant leg, mn = non-dominant leg

Jump height combinations	% deficit Power	% deficit Endurance
60b vs. 30md + 30mn	4.9	0.8
30b vs. 15md + 15mn	14.9	2.4
60b vs. 15md + 15mn	11.6	0.8
30b vs. 30md + 30mn	8.4	-5.2
15b vs. 15md + 15mn	13.8	8.1

Although the results support the hypothesis it is important to note that the 30cm single leg drop jumps appear to be above the performance enhancing height. It may be the 15cm drop height was too great for the endurance athletes as well. Selection of drop height is critical to allow fair comparisons in drop jumps.

Preliminary examination of EMG data show a similar deficit pattern in iEMG but also show different activation patterns between power and endurance athletes when going from 2 legged to 1 legged jumps. This change in pattern could also be a contributing factor to bilateral deficit.

SUMMARY

Power athletes, with a higher proportion of fast twitch motor units, exhibit much higher degrees of bi-lateral deficit in drop jumps, than endurance athletes. This could indicate that bi-lateral deficit is caused by inhibition of these motor units.

EVALUATION OF A MAGNETIC TRACKING DEVICE FOR ESTIMATING CUMULATIVE LOW BACK COMPRESSION

Agnew, M.J.¹, Andrews, D.M.¹, Callaghan, J.P.², and Potvin, J.R.¹

¹ Faculty of Human Kinetics, University of Windsor, Windsor, Ontario, Canada, dandrews@uwindsor.ca

² Department of Human Biology & Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada

INTRODUCTION

Recent investigations regarding the measurement of cumulative loading in the low back have used video based data as a means of measuring cumulative load. Although the technique employed by Callaghan et al. (2001) proved to reduce the amount of data required to estimate cumulative load with little relative error, the recording and digitization of video data still requires a significant amount of time dedicated to data analysis. Through the use of a magnetic tracking device, positional data can be collected instantaneously without the time consuming task of digitization. The purpose of this study was to evaluate the use of a magnetic collection device as a means of measuring cumulative compression at the L5/S1 joint of the spine.

METHODS

Five male subjects performed a total of 27 sagittal plane lift/lower trials of varying conditions (3 lifting tasks x 3 load masses x 3 repetitions). The three lifting tasks were as follows: lift and place from the floor to a shelf at shoulder height (135 cm), lift and place from the floor to a tabletop at knuckle height (76 cm), and lift and place from the floor over a 88 cm barrier to a table top (76 cm). The three load masses chosen for this study were 2.5, 7, and 15 kg. Two-dimensional kinematic data were collected using reflective joint markers and a magnetic tracking device (FastrakTM, Polhemus Technologies). Reflective markers were placed at the hand, ankle, and from two fins attached at the C7/T1 and L5/S1 joints. FastrakTM sensors were placed at the hand, ankle and on the skin at the site of the C7/T1 and L5/S1 joint centers. In order to synchronize the two collection devices, a signal light was placed in the field of view to indicate the start/stop of the collection period. Video data were digitized using motion capture software (Ariel Technologies) at a sample rate of 30 Hz. Data acquired from both collection methods were input into a regression-based biomechanical model (Potvin, 1997). This model calculated lumbosacral compression through the NIOSH (1991) inputs of H and V, as well as trunk angle, subject mass (kg), and gender. Cumulative estimates of L5/S1 compression were estimated for both collection methods through rectangular integration of the compression/time histories (Figure 1).

RESULTS AND DISCUSSION

The cumulative compression estimates generated from both measurement methods proved to be significantly different ($p < 0.05$). The magnetic tracking device tended to overestimate

the amount of cumulative compression present in general, with a relative, mean difference of 3.5% when collapsed across all subjects, tasks and loads. Although this relative difference exists, the estimates of the two measurement devices are highly correlated ($r = 0.97$). Further analysis of the relative error present between collection methods revealed that the lowest error occurred in the shoulder height and tabletop lift conditions (1.8% and 1.2%, respectively) and that the highest amount of relative error existed in the "bin-reach" task (7.2%). Due to the long reach required for this task and given the accuracy range of the tracking device it may be that the relative error in this condition is due to an incorrect estimation of the 2-D location of the hand by the tracking device.

Figure 1: Time history displaying differences between the Video (thin line) and FastrakTM methods (thick line).

SUMMARY

The results of this study indicate that a magnetic tracking device can be used as a means of collecting cumulative compression experienced in the low back during the execution of a materials handling task. The use of such a device significantly reduces the amount of data processing required to measure cumulative compression in the low back. As such, this measurement protocol could prove to be useful in further investigations of cumulative loading in the low back in a laboratory setting.

OPTIMIZATION OF A NEW BLOOD FILTRATION DEVICE FOR EMBOLIC STROKE PREVENTION

Ygael Grad¹, Boaz Nishri¹, David Tanne², Shmuel Einav³, Bruch B Lieber⁴, Ofer Yodfat¹

INTRODUCTION

Implantable devices that permanently filter arterial blood flow have not been previously reported to the best of our knowledge. Filtration of blood can prevent emboli originating proximal to the filter from entering the cerebral circulation and could significantly reduce the burden of embolic stroke. Hemodynamic related shear stresses, however, resulting from the introduction of an arterial filter, may induce platelet activation, aggregation, and provoke the coagulation cascade. Our aim was to study the hemodynamic parameters governing blood filtration in-vitro, and then test a new hemodynamically optimized arterial filtering device (the *Diverter*) in-vivo.

METHODS

Continuous Digital Particle Image Velocimetry (CDPIV) was employed to map the flow field and interrogate flow disturbances induced by various filtering meshes in a compliant transparent model (Fig. 1, Fig. 2) of the carotid bifurcation under physiological flow conditions. The local flow field around of one filtering filament was studied as well. Shear stresses (Fig. 3) and residence times were calculated and the Activation parameter (AP) was assessed by time integration of shear stress multiplied by the residence time. An in vivo swine model was applied to assess the validity of the in-vitro results, by testing the patency of 30 harvested filtering devices implanted in arterial bifurcations.

RESULTS

A structure based on thin filaments was found to be hemodynamically superior, inducing very low local Reynolds numbers. The blood activation parameter (in terms of shear stress and residence time) for such structure was found to be about 2 orders of magnitude lower than the threshold known to activate the hemostatic system. The global flow field generated in the *Diverter*'s wake depends on mesh geometry, and was designed to minimize flow disturbances. A filtering device designed based on the above parameters, and implanted in arterial bifurcations of a swine model, remained patent upon sacrifice up to 18 weeks post implantation.

CONCLUSIONS

Permanent arterial filters can be optimized based on hemodynamic considerations derived in-vitro by CDPIV. A

thin filament based design was found to minimize hemodynamic disturbances and the AP. An arterial filter designed based on the in vitro findings remained patent in a swine model and did not invoke occlusive thrombi. These findings serve as the basis for a novel vascular interventional approach for treatment of embolic disease.

gwss@bioeng.ucsd.edu

INTRODUCTION

Most cells have internal membrane structures with regions of high membrane curvatures, which may be subject to large deformation and shape changes during cell activities such as migration, endo- or exocytosis, or cell division. One of the remarkable features in this respect are local plasmalemmal membrane regions with high curvature, such as caveolae (plasmalemmal vesicles) and clathrin coated pits. Vesicles are between 50 to 100 nm in diameter with a membrane thickness of about 5 nm. Vesicles are enriched with membrane proteins, cholesterol and membrane signalling molecules to a level not found in the outer membrane domain of the plasmalemmal membrane [1]. However, little is known about the mechanics of highly bend membrane structures, such as caveolae. We examine here the membrane structure of caveolae with high curvature subject to membrane tension.

METHODS

The vesicles are assumed to consist of a flat outer membrane and a curved inner membrane with constant curvature in the unstressed state [2]. The membrane properties are uniform and support bending stress and in plane membrane shear stress. The membrane area is assumed to be constant. A strain energy functional for the membrane was formulated, including the effects of bending and in-plane shear strain energy [3]. A variational principle was used to derive a set of Euler equations that were solved numerically in form of simultaneous, nonlinear differential equations [2].

RESULTS AND DISCUSSION

Attachment of a flat outer membrane to the curved inner membrane yields a stable membrane structure with a neck typical for caveolae seen on electron micrographs [4]. The membrane tension required to unfold the vesicles is relative insensitive with respect to the exact shape of the vesicle, unless it becomes fully unfolded and approaches a relative flat membrane. Upon stretch of the outer membrane, the caveolae dramatically change shape. The vesicle neck disappears abruptly leading to membrane shapes that consist of curved indentations. While the resting shape of vesicles is predominantly affected by membrane bending energy, the membrane shear elasticity makes a significant contribution as the vesicle is subject to stretch and unfolding. Membrane shear elasticity (for a range of values recorded in the red cell membrane) serves to modify the detailed membrane shapes of vesicles but does not interfere with the fundamental structure of vesicle shapes. The shear elasticity has a significant effect on the equilibrium shape of the vesicle, particularly in the vicinity of its neck region where curvature changes sharply

[5]. An increasing membrane tension is required to unfold vesicles with smaller initial radius, in agreement with experimental evidence [6].

SUMMARY

The current model for caveolae assuming two domains, an inner membrane domain with high curvature and an outer domain with flat shape without attachment to cytoskeletal fibers, yields mechanically stable and realistic shapes seen on endothelial cells. The unbending of curved membrane structures may make an important contribution to the cortical tension encountered in many cells [6].

COORDINATION OF CAT GASTROCNEMIUS AND SOLEUS DURING LOCOMOTION BASED ON DIRECT MEASUREMENT OF IN VIVO MUSCLE FORCES AND EMGS.

Motoshi Kaya, Tim Leonard, and Walter Herzog

Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada
motoshi@kin.ucalgary.ca

INTRODUCTION

Previous studies on cat locomotion suggested that the medial gastrocnemius (MG) forces and activities increased with increasing speeds and intensities of walking, while the soleus (SOL) forces and activities remained nearly constant for a wide range of walking speeds (1, 2, 3). Therefore, MG forces and activities increase as external demands increase. For SOL, several mechanisms have been proposed to account for the lack of increase in force with increasing demands: 1) SOL was said to be fully activated at low demands, therefore SOL forces were thought to primarily depend on the contractile conditions (1, 2) Increases in SOL activity were thought to be offset by speed-dependent inhibitory effects from cutaneous and rubrospinal inputs (2), and 3) SOL activity was said to be inhibited by increasing MG forces through force-dependent inhibitory pathways (4). None of these mechanisms has been tested rigorously for in vivo movement tasks. The purpose of this study was to determine the coordination of SOL and MG during a variety of walking conditions and to test these proposed mechanisms.

METHODS

Six adult male cats were trained to walk on slopes of 30 deg downhill, level, 30, 45, and 60 deg uphill, and at different speeds on a motor-driven treadmill (0.4-1.2 m/s), running, and landing on the ground. The kinematics of the cat hind-limb were assessed by high-speed video analysis. Forces in SOL and MG were measured using buckle-type force transducers (1). EMG activities were measured using indwelling, bipolar fine wire electrodes (3). Muscle lengths were estimated using kinematics and muscle moment arm measurements.

RESULTS AND DISCUSSION

SOL peak forces and root mean square (RMS) values of SOL EMGs for all experimental conditions were not related (Fig.1a), while MG forces and EMGs showed a strong linear relationship. During uphill walking, SOL EMG was similar and SOL forces were smaller than the corresponding values for level or downhill walking. The lack of increase in EMG activity would have been interpreted by (1) as a saturation of activation. However, activation preceding landing movements was substantially greater than that for all walking conditions (Fig.1a, encircled values) indicating that SOL was not fully activated during the walking conditions. Hodgson (2) argued that SOL is inhibited in a speed-dependent way, however, walking at different speeds gave similar SOL EMG values. In order to test whether SOL forces were primarily dependent on the contractile conditions, we determined the speed of SOL

contraction at the instant of peak force. Speeds of muscle shortening were greatest for uphill and lowest (negative, eccentric contraction) for downhill walking (Fig.1b). In accordance with the force-velocity relationship (and the similar activation levels across conditions), SOL forces were greatest for the smallest shortening speeds and were smallest for the greatest shortening speeds (Fig.1b). Finally, we found a negative relationship between peak MG and SOL forces, suggesting that MG may inhibit SOL forces, as proposed by (4) for decerebrate cats. However, there was no negative relationship between MG and SOL activation. Therefore, the negative relationship between peak MG and SOL forces could not be explained by reciprocal inhibition (4), but was likely associated with the SOL contractile conditions.

SUMMARY

Our results did not support any of the mechanisms previously proposed for SOL force control. It seems that SOL is not fully activated at slow speeds of walking, as proposed by (1), and that SOL is not inhibited in a speed-dependent manner, as suggested by (2). Finally, reciprocal inhibition from MG to SOL, as proposed by (4) also does not appear to hold in the freely walking cat. Rather, it appears that SOL is activated in a fairly constant (but not maximal) manner during locomotion, and that changes in SOL force can be explained to a great degree by changing contractile conditions. The constant SOL activation might be governed through the spinal pattern generator known to operate in cats.

ANKLE KINEMATICS USING ONE AND TWO SEGMENT FOOT MODELS

Bryan Heiderscheit¹, David Tiberio², Sarah Houger¹, Shane Jackson¹, Brian Malone¹ and Tim Vander Wilt¹

¹Human Performance Laboratory, Des Moines University, Des Moines, IA, USA, bryan.heiderscheit@dmu.edu

²Department of Physical Therapy, University of Connecticut, Storrs, CT, USA

INTRODUCTION

The accurate measurement of three-dimensional foot and ankle motion remains a difficult problem. Most often, the foot is considered a rigid segment (Kadaba et al., 1990; Areblad et al., 1990). Measurements of foot motion based on calcaneal markers ignore the motion occurring in the distal foot segments, while methods using a combination of calcaneal and forefoot marker placement may not accurately measure motion of the subtalar joint (Reischl SF et al., 2000). Additional investigations have employed multi-segment models of the foot to improve the understanding of foot kinematics during locomotion (Arampatzis et al., 2002; Leardini et al., 1999). The purpose of this study was to compare calculated foot and ankle angles when the foot is treated as a single rigid segment as opposed to two (forefoot and rearfoot).

METHODS

Twenty non-impaired subjects (aged 23-30) provided consent to participate in the investigation. Three-dimensional kinematic data were recorded (60Hz) bilaterally using a seven-camera (Falcon Hi-Res) Motion Analysis system (Motion Analysis Corporation, Santa Rosa, CA) during 15 trials of barefoot walking. Reflective marker triads were securely placed on the posterior surface of the leg and calcaneus, with a third attached to the dorsal surface of the first cuneiform. Each triad defined a separate rigid body (i.e. leg, rearfoot and forefoot). In addition, markers attached to the head of the 5th metatarsal and lateral malleolus were used in conjunction with the most distal calcaneal marker to evaluate the entire foot as a rigid segment.

Three-dimensional segment and joint angles were calculated using a joint coordinate system approach in reference to a static standing trial. Ankle angles were calculated using the leg and rigid foot configuration (one segment), as well as the leg and the rearfoot (two segment). Resulting ankle motions from the two approaches were compared within each subject using cross correlations and RMS values, with 95% confidence intervals (CI) reported.

RESULTS AND DISCUSSION

Table 1: One and two segment model comparison (95% CI).

Motion	RMS (°)	r
Flexion/extension	(3.1, 3.6)	(0.93, 0.98)
Inversion/eversion	(3.9, 4.7)	(0.47, 0.82)
Abduction/adduction	(3.6, 4.4)	(0.39, 0.78)

The two models demonstrated the greatest pattern similarity with least magnitude difference during flexion/extension.

Figure 1: Ankle a) inversion (IN) & eversion (EV) and b) dorsiflexion (DF) & plantarflexion (PF) calculated from the one and two segment approach.

The one segment foot model resulted in greater total range of motion during all motions analyzed. Specifically, distinct differences in calculated ankle angles were observed at the beginning and end of the stance phase (Figure 1). At heel-strike the one segment model demonstrated an inverted position twice that of the two segment model, with greater inversion observed until mid-stance. During walking and running analysis, much emphasis is placed on the foot and ankle motion during the loading portion of stance. Whether a one or two segment model is used during the analysis will influence the interpretation.

SUMMARY

The ankle angles calculated using one and two segment foot models produced distinct differences in each plane of motion. The one segment model resulted in increased total range of motion, with most differences present during the initial 40% and final 20% of stance.

A STOCHASTIC MODEL OF FATIGUE DAMAGE DEVELOPMENT IN BONE CEMENT

S. L. Evans

School of Engineering, Cardiff University, PO Box 925, The Parade, Cardiff CF24 0YF, UK

INTRODUCTION

PMMA bone cement is widely used in hip and knee replacement with excellent clinical results. However, in the long term, failure of the cement may result in loosening and may provide a path for wear particles or fluid pressure from the joint capsule to reach the bone and cause resorption. An better understanding of cement fatigue could lead to improvements in long term clinical results.

Although bone cement fatigue has been widely studied, at present it is not possible to model or predict failure *in vivo*. The failure process involves several stages, including crack initiation from voids or other defects, accumulation of damage through the growth of microcracks, the concentration of damage in a dominant crack, the propagation of this crack in the long crack regime and finally fast fracture. Each stage may occupy a different proportion of the total life, depending on factors such as geometry, stress level, defect distribution and the loading spectrum, and tests on specimens may not accurately weight the relative importance of each stage.

This paper presents a computational simulation which is intended to allow these factors to be evaluated, and to provide a framework for further development, including more detailed representation of damage development and a finite element representation of the *in vivo* geometry and stress distribution. The model is stochastic, incorporating random variations in defect distribution, allowing some evaluation of the effects of variation between specimens.

METHODS

Following Taylor et al. [2001], the model was based on a direct fracture mechanics representation of individual defects, rather than a damage accumulation approach. This allows the various mechanisms of damage accumulation to be modelled. An array of randomly distributed was generated and their growth was simulated on a cycle- by- cycle basis using a Paris Law model. Variable amplitude loads represented different activities and overloads. Initially it was assumed that spherical voids are present with normally distributed diameters, and that cracks initiate from these voids on first loading, as found by Lennon et al [2001]. The transition between the early stage where the crack is much smaller than the void, and the development of a circular crack much larger than the void, was modelled by interpolation based on previous boundary element models [Evans, 2001]. A three point bend configuration was modelled, using an analytical solution for the stresses in the specimen. An uncoupled analysis was used with each crack assumed to grow without affecting the stresses or other cracks. Possible endpoints include fast fracture, growth of a crack to the exterior surface and the approach of one crack to another.

RESULTS

Figure 1. Typical results for 100 runs.

Fig. 1 shows an S-N curve for 100 simulations at various loads. The results exhibit typical S-N behaviour, but the endpoint changed from fast fracture (closed circles) to cracks reaching the surface (open circles).

DISCUSSION AND CONCLUSIONS

Initial results predict the observed fatigue behaviour reasonably well at high stresses, but at low loads the cracks become excessively large before failure. In the high cycle fatigue regime, it would be necessary to represent the dominant cracks in a coupled model, and a simulation based on accumulation of many small microcracks may be inappropriate. Laboratory tests under high, constant amplitude loads may not lead to the same type of failure as the gradual accumulation of damage under lower, variable amplitude loads in a thin cement mantle *in vivo*. For failure to occur over many years, either crack growth rates must be extremely low or failure must occur as a result of very unusual overloading, and neither of these is normally represented in laboratory fatigue tests.

POSTURE DEPENDENT TRUNK STRENGTH AND EMG ACTIVITY

Amy L. Roy and Tony S. Keller

Musculoskeletal Research Laboratory, University of Vermont, Burlington, Vermont, aroy@emba.uvm.edu

INTRODUCTION

Low back pain is a common occurrence that 80% of the population will experience in their lifetime (Gomez et al 1991). The direct cause of chronic low back pain (LBP) is unknown, yet it is believed that trunk muscle function plays an important role. Current studies indicate a possible gender-specific difference in muscle strength and activation patterns. However, the majority of experiments that evaluate trunk muscle strength and EMG activity include only healthy male subjects. In addition, other studies have compared trunk muscle EMG activity and extension torque using only a small range of flexion angles (Shultz et al 1982, Shultz et al 1987, Seroussi et al 1987, Zetterberg et al 1987). As a result, the postural relationship between trunk extension strength and EMG activity over a large range of sagittal postures has not yet been quantified. The current study was designed to evaluate the relationship between sagittal plane posture, trunk muscle extensor activity, and isometric trunk extension torque, while emphasizing gender-specific differences.

METHODS

Twenty healthy adult subjects, 10 male and 10 female, having no previous history of back pain participated in this study. Each subject was positioned and restrained in a tri-axial trunk dynamometer. A series of isometric flexion (F) and extension (E) tasks were performed at 10-degree increments over a 70° range-of-motion (50° F to -20° E). Myotrace 10 electromyographic amplifiers were used to condition and linear-envelope raw EMG signals from the left and right erector spinae muscles at the L3 level during each of five trials. EMG signals and isometric trunk extension torque were recorded using a Biopac MP100 16-bit data acquisition system and Acknowledge software. Peak extension torque and EMG amplitude were determined at each posture.

RESULTS AND DISCUSSION

Trunk muscle EMG activity during isometric extension tasks increased with increasing flexion angle, and differed appreciably at the various sagittal plane trunk posture angles examined. The mean isometric trunk extension torque at a flexion angle of 40° was 64% and 71% greater than that at upright for the female and male groups respectively. Differences between left and right side EMG output were most marked at extended postures for the male subjects and at more flexed postures for the female subjects (Table 1). Significant differences were found between male and female isometric trunk extension torque at all angles except -20 degrees. Linear regression of the normalized torque (T_n) and EMG data for each of the subject groups revealed a significant positive correlation between the two parameters, as did the correlation for the combined group (Figure 1). This finding is consistent with several previous studies (Lavender 1994, Tan 1993).

Table 1. Left and right side peak EMG and extension torque values (both normalized to upright) for male subjects (n=10) and female subjects (n=9). *Indicates a significant difference between the male and female groups ($p < 0.01$). †Indicates a significant difference from upright ($p < 0.01$).

Angle (degrees)	FEMALES			MALES		
	EMG (right side)	EMG (left side)	Extension Torque	EMG (right side)	EMG (left side)	Extension Torque
-20	*0.78	0.79	*0.57	*0.59	0.88	*0.45
-10	0.95	0.91	*0.70	*0.73	0.91	*0.68
0	1.00	1.00	*1.00	1.00	1.00	*1.00
10	1.02	0.97	**1.22	1.05	1.10	**1.22
20	1.17	1.02	*1.37	1.07	1.08	*1.41
30	1.25	1.13	*1.48	1.12	1.15	*1.62
40	1.39	1.24	*1.64	1.19	1.18	*1.71
50	1.51	1.16	*1.78	1.31	+1.38	*1.73

Figure 1. Relationship between erector spinae EMG and isometric trunk extension torque (both normalized to upright) combined for all subjects. Linear regression results: $y = 0.293x + 0.696$ ($R^2 = 0.14$, p -value < 0.001).

SUMMARY

In order to increase the knowledge of trunk muscle function and its role in low back pain, researchers must include both men and women subjects in their studies, and should extend their focus to include subjects who suffer from chronic LBP. Results of this study indicate that experiments should incorporate the entire range-of-motion and gender-specific differences for studies that use EMG activity to model trunk muscle activation patterns.

KNEE LOADING DURING GAIT AND EARLY SIGNS OF KNEE OSTEOARTHRITIS IN A MENISCECTOMY POPULATION

Daina Sturnieks¹, David Lloyd¹, Thor Besier¹, Gwidon Stachowiak², Pawel Podsiadlo², Karl Stoffell² and Stephen Davis³

¹Department of Human Movement & Exercise Science, University of Western Australia, www.hm.uwa.edu.au

²Department of Mechanical and Materials Engineering, University of Western Australia

³Perth Radiological Clinic, Western Australia

INTRODUCTION

Knee osteoarthritis (OA) is the cause of more disability than any other joint condition, imposing large social and economic costs (Guccione et al., 1994). The risk of developing knee OA is considerably increased following meniscectomy (Sommerlath et al., 1991). Understanding the mechanisms contributing to the development of knee OA is an important first step for prevention and moderation of disease. The purpose of this study was to examine differences in gait patterns and knee radiographic features in young, pre-osteoarthritic adults who recently had a partial meniscectomy.

METHODS

Preliminary data from 45 meniscectomy patients (~6 weeks post-surgery) and 20 controls has currently been analysed from a larger cohort of 180 people. Subjects were aged 20 to 45 years and screened for previous or current knee joint pain, stiffness, laxity, disease and injury (excepting meniscus tear in patient group). AP weight-bearing knee radiographs were taken in normal standing and 30 degrees flexion positions. An experienced orthopaedic surgeon assessed radiographs according to a validated OA scoring system (Derek et al. 1999), using a published OA atlas (Burnett et al., 1994). Subjects were categorised as positive (+ve) or negative (-ve) to pathologic radiographic features. The +ve group were further categorised by the grade of change in joint space narrowing (JSN) and/or grouped bony changes (BC) (i.e. osteophytes and tibial erosion), in medial and lateral compartments. Subjects with greater than grade 2 changes were excluded from the study. Remaining +ve group subjects were considered free of knee OA due to the absence of pain and stiffness, precluding the clinical diagnosis of knee OA. Three-dimensional gait analysis was performed using a 50 Hz, six-camera VICON motion analysis system, with AMTI force platforms. Joint kinematics and kinetics were calculated using a custom seven-segment lower limb model. External knee moments were normalised to individual's height and weight, and analysed over stance. Data was statistically tested using two-way repeated measures ANOVA, Bonferroni corrected for multiple comparisons, p value for significance set at <0.05 .

RESULTS AND DISCUSSION

Compared to controls, the meniscectomy group was more likely to have +ve radiographic features indicative of early degenerative joint changes (see Figure 1.). This increased proportion was true for lateral and medial compartment joint space narrowing (LatJSN and MedJSN, respectively), and

bony changes in medial and lateral compartments (LatBC and MedBC, respectively), of the tibiofemoral joint. However, the only difference to reach statistical significance was bony changes in the medial compartment ($p<0.05$).

Figure 1: Radiographic changes between groups

Analysis of gait data revealed that the meniscectomy group had larger knee adduction moments ($x=0.032$), when compared to the control group ($x=0.027$) ($p<0.05$). The knee adduction moment loads the medial tibiofemoral joint and may account for the significant difference in MedBC between groups.

SUMMARY

Radiographic features indicative of degenerative joint changes were more commonly noted in the meniscectomy group. Furthermore, larger than normal knee adduction moments were experienced by the meniscectomy group. It is anticipated that inclusion of data from the remainder of the cohort will provide power for regression analyses to determine whether a relationship exists between these variables. Furthermore, examining progression of knee OA and changes in gait is suggested.

EXPERIMENTAL ANALYSIS OF FLOW THROUGH TILTING DISK VALVE

Sagi Raz, Idit Avrahami, Uri Zaretsky, Moshe Rosenfeld and Shmuel Einav
Faculty of Engineering, Tel-Aviv University, Tel-Aviv, Israel. sagiraz@eng.tau.ac.il

INTRODUCTION

Tilting disk mechanical heart valves (MHV) are commonly used in new developments of artificial heart pumps. The fluid dynamics associated with tilting disk MHV plays a critical role in determining the longevity of these devices. The present study simulated experimentally the flow across tilting disk valves in a straight tube. The objectives were to establish the time dependent global flow field for several typical cases, to track down time histories of individual platelets, to locate the regions where activated platelets might be found, and to evaluate the significant of the third dimension on the flow.

METHOD

The experimental method was based on the *continues digital particle image velocimetry* (CDPIV) method. This optical method uses visualization techniques to measure quantitatively the velocity field.

CDPIV methods were used to map the flow field in time for two models of tilting disk MHV: the first was a 3D model of Bjork-Shiley MHV ($\varnothing 28$ mm) installed inside a cylindrical glass tube. The second model was a two dimensional Perspex channel (size 10X60X2.8cm) with glass windows. A glass leaf connected to a hinge modeled the 2D tilting disk. Mitral inflow conditions were imposed using computer controlled pump, keeping both Reynolds and Womersley dimensionless numbers as in the physiological flow conditions.

For the 2D model, a case with constant inflow of $Re=3800$ and fully opened valve ($\theta = 57^\circ$) was analyzed. For the 3D, model three flow conditions were measured: (a) Constant inflow with $Re=4300$ (at fully opening angle of $\theta = 57^\circ$); (b). Constant inflow with $Re=800$ (at opening angle of $\theta = 23^\circ$); and (c) pulsating flow with moving valve, according to the mitral physiological waveform.

RESULTS AND DISCUSSION

Continuous visualizations of the flow field in all cases through the different models were captured. The flow downstream the valve was calculated using DPIV software. Velocity, vorticity and shear rate contours of the time-dependent flow were extracted and compared with numerical simulations. In the pulsatile case, the motion of the valve was measured and compared to previous results. Pertinent trajectories of the particles were established from the CDPIV measurements and their shear stress histories computed to evaluate the platelets level of activation.

Figure 1 exemplify typical vectors plot (a) and shear rates contours (b) as obtained for peak flow through the 3D model.

Figure 1: flow field calculated in 3D model, peak inflow (a)
vectors plot (b) shear rate contours

The flow through the tilting disk valve was characterized with two high velocity jets that are passing through the valve orifices, causing two shear layers that roll into counter-rotating vortices near the valve.

As the valve opened, the large vorticity created by the upper orifice jet was shed downstream and the flow coming from the lower orifice dominated the flow near the valve. As the incoming flow decreased, the vortices were more pronounced. With the closing valve, the flow field near the valve directed backward and the flow was still until a new cycle started. Excessive high shear stresses regions were found downstream the disk, and for some particle trajectories in the flow field along the cycle, platelets level of activation reached critical values.

SUMMARY

The results of the present study indicate two regions of high shear stress and a very disturbed flow downstream the valve. The secondary flow of the third dimension strongly affects the flow in the high Reynolds velocities.

The comprehension of the global flow field across 2D and 3D models of valve in a straight channel can assist in studying several hemodynamical and clinical aspects of the flow across valves inside heart assist devices.

MECHANISMS FOR CELL ACTIVATION IN THE CARDIOVASCULAR SYSTEM DURING PHYSIOLOGICAL SHOCK

Geert W. Schmid-Schönbein, Erik Kistler, Hiroshi Mitsuoka, Tony Hugli*
Department of Bioengineering, University of California San Diego, La Jolla, CA.

*The La Jolla Institute for Molecular Medicine, La Jolla, CA.
gwss@bioeng.ucsd.edu

INTRODUCTION

Physiological shock is one of the most life threatening condition. In shock the level of cell activation in the cardiovascular system dramatically raises within a few hours [1]. The cell activation can be detected by a wide variety of cell activities, including actin polymerisation with changes in cell shape and cytoplasmic stiffness, expression of membrane adhesion molecules, production of oxygen free radicals, a reduction of muscle contraction as well as eventual cell death. Under shock conditions the transport in the microcirculation and the biomechanics of cells is fundamentally altered.

In the past it has been hypothesised that cell activation in shock is due to intestinal bacteria and their products (endotoxin) after transport from the lumen of the intestine into the circulation. But there is no agreement whether this mechanism is the primary cause for cell activation in human or experimental forms of shock. The source and mechanisms of the powerful cell activation encountered in shock remains an important unresolved problem. In this communication we present a selected set of experiments designed to examine the origin of humoral cell activators in experimental shock.

LOCALIZATION OF THE CELL ACTIVATORS

Humoral cell activators in shock can be detected by incubation of plasma from central arteries with naive donor cells (e.g. leukocytes, platelets). The cell activators are already detectable within 1 hour after occlusion of the superior mesentery artery, indicating that no significant new protein synthesis of these mediators is required. We prepared tissue homogenates from a variety of different organs and exposed naive leukocytes to their supernatants after centrifugation. While all organ homogenates produced relatively low levels of leukocyte activation (less than 20%), the *pancreatic* homogenates generated a level of cell activation that reached close to 100%. Remarkably, organs with low levels of cell activation also started to produce high levels of cell activation after addition of pancreatic enzymes, especially serine proteases [2]. Administration of pancreatic homogenate into the circulation of rats produced not only leukocyte adhesion to the endothelium, but also parenchymal cell apoptosis [2] and high levels of mortality [3]. This evidence indicates that the reaction of digestive enzymes with autologous tissue serves to produce a set of powerful cell activators.

THE CENTRAL ROLE OF DIGESTIVE PROTEASES

Since pancreatic enzymes after discharge from the pancreatic duct become fully activated in the small intestine as part of normal digestion, we examined the hypothesis that these enzymes may be involved in the generation of activators during intestinal ischemia. The *lumen* of the small intestine

was continuously perfused with saline containing a broadly acting pancreatic protease inhibitor (ANGD, 0.37 mM) before and during ischemia of the small intestine by splanchnic artery occlusion [4]. This procedure served to inhibit activation of circulating leukocytes during occlusion and reperfusion. It also prevented the appearance of cell activators in portal venous and systemic artery plasma and served to attenuate symptoms of multiple organ injury in shock. Intestinal tissue produces only low levels of activators in the absence of pancreatic enzymes while in the presence of enzymes, activators are produced in a concentration and time dependent fashion. The significant protection provided by blockade of digestive enzymes in the lumen of the small intestine can also be achieved with other pancreatic protease inhibitors [5].

SUMMARY

These surprising results indicate that pancreatic digestive proteases in the ischemic intestine serve as an important source for cell activation, inflammation, and multiple organ failure. While the pancreatic enzymes, capable to digest human tissues, are restricted to the lumen of the intestine by the epithelial mucosal barrier, this barrier may be compromised in shock. Escape of pancreatic enzymes into the wall of the intestine leads to the production of significant levels of cell activators, which are then transported via the intestinal microcirculation and lymphatics into the central circulation [6]. The presence of high levels of digestive enzymes in the intestine compared to other organs may be the reason for the central role of the intestine in shock recognized in the past.

RESIDUAL STRESSES ANALYSIS AT THE INTERFACE BETWEEN HYDROXYAPATITE COATING AND TITANIUM SUBSTRATE

B.Cofino, P. Fogarassy, P. Millet, R. Taiar, A. Lodini

INTRODUCTION

Hydroxyapatite coatings on titanium alloy Ti-6Al-4V have shown for several years a great interest for implantology. Ti-6Al-4V presents good mechanical properties and is biocompatible. Hydroxyapatite has low mechanical strength, but very good osteointegration and biocompatibility. The use of plasma sprayed hydroxyapatite coatings on titanium substrates leads to a structure which has good mechanical strength and good osteointegration properties at the surface. However, the porous structure of the coatings gives failures in the implantation and it appears that the problem happens at the interface between the ceramic and the metal. These failures could be due to stresses created in the materials at the interface during plasma deposition [1]. Knowledge about these residual stresses is very important to predict the location of the failure. To determine the residual stresses induced, both in the substrate and in the coating during the plasma thermal spraying process, some samples were prepared, as presented in figure 1.

Figure 1 : Samples dimensions (mm)

High purity hydroxyapatite (HA) powder with particle sizes between 80 and 160 μm was used for the plasma spraying coating. Plates of Ti-6Al-4V alloy, 2.7 mm thick, were used as substrates and pure titanium powder with particles sizes between 25 and 75 μm was used as porous bondcoat.

In this study, two techniques have been used to determine the residual stresses near the interface between plasma sprayed hydroxyapatite coatings and titanium substrates, a numerical and an experimental method.

RESIDUAL STRESSES EVALUATION BY SYNCHROTRON RADIATION

The experimental technique is based on X-rays diffraction with a synchrotron radiation. These X-rays, with high energy (40 keV), can enter deeply into the material (0.5mm) and the diffraction gauge volume can have very small dimensions, down to 10 μm with synchrotron radiation compared to 300 μm for neutrons. Synchrotron radiation, using Beamline BM16 at the European Synchrotron Radiation Facility (Grenoble, France), has been used to determine residual stresses near the interface [2]. Now it is possible to determine very local thermal induced residual stresses near the interface between hydroxyapatite and titanium by synchrotron radiation measurements.

RESIDUAL STRESSES DETERMINATION BY FINITE ELEMENT ANALYSIS

During plasma spraying, molten particles cool down to the metal temperature within a few milliseconds. The thermal contraction of the particles is constrained by their bond to the substrate resulting in tensile stresses in the coating. If this contraction is totally inhibited, higher stresses than the ultimate tensile stress should develop. So a microcracking causes a stress relaxation in the ceramic coatings. There are two origins for the stresses : the speed of cooling to the substrate temperature (primary cooling), the thermal properties mismatch of the materials during cooling to the room temperature (secondary cooling).

The simulation by finite elements determines the residual stresses near the interface between titanium and hydroxyapatite induced by the plasma spraying process considering the primary and the secondary cooling during a layer by layer deposition.

RESULTS

The results are presented in figure 2 below.

Figure 2 : residual stresses analysis

Compressive residual stresses exist in the substrate near the interface and also in the coating. The compressive residual stresses are weak after 100 μm in the substrate. Plasma spraying and important cooling rates cause residual stresses near the interface. The thermal properties mismatch of the materials with a higher thermal conductivity for Ti-6Al-4V creates compressive residual stresses near the interface in the substrate and in the coating. The elasto-plastic simulation is comparable with the experimental results obtained with synchrotron radiation.

ACKNOWLEDGMENTS

The authors express appreciation for assistance from Dr. A. FITCH, European Synchrotron Radiation Facility (Grenoble, France).

INTRODUCTION

Fracture around the femoral component of a total hip arthroplasty is a serious complication. The frequency of these fractures is increasing as more procedures, particularly revision operations with loss of bone stock are performed. Internal fixation is the recommended management of a periprosthetic fracture adjacent to the tip of a well fixed femoral component (Wilson 2001). The purpose of this investigation was to compare the interfragmentary motions of six different fixation methods in a cadaveric model.

METHODS

A cemented femoral hip prosthesis was implanted in to six cadaveric femora. A fracture adjacent to the tip of the prosthesis was simulated by a transverse osteotomy, which is possible the “worst case” scenario around a well fixed femoral prosthesis.

The simulated transverse fracture was fixed with the following six constructs in a randomized sequence (Figure 1):

1. Lateral plate with 4 proximal cables and 4 distal bicortical screws plus anterior 20cm strut graft and 4 distal cables.
2. Lateral plate with 4 proximal cables, 2 proximal unicortical screws and 4 distal bicortical screws plus anterior 20cm strut graft and 4 distal cables.
3. Lateral plate with 4 proximal cables and 4 distal bicortical screws.
4. Lateral plate with 4 proximal cables, 2 proximal unicortical screws and 4 distal bicortical screws.
5. Two 20cm strut grafts lateral and anterior held with 8 cables, cables uniformly positioned, equal separation, four above and four below the fracture level.
6. Two 12cm strut grafts lateral and anterior held with 8 cables, cables uniformly positioned, equal separation, four above and four below the fracture level.

Figure 1. Schematic drawing of the different fixation constructs (A: anterior, P: posterior, M: medial, L: lateral).

One hundred cycles of a craniocaudal (1Hz) and anteroposterior (0.5Hz) sinusoidal load at 1.5 and 0.3 times body weight respectively were applied. The interfragmentary motions at the fracture site were measured using an optoelectronic camera system. Offset and amplitude of the rotation about the helical axis and the length of the translation vector were averaged for each specimen between the 93rd to the 97th cycle. The constructs were compared using non-parametric Friedman ANOVA. For individual comparison a Wilcoxon matched paired analysis was used.

RESULTS AND DISCUSSION

In general, the plate-strut constructs had less interfragmentary motions compared with the others. This was significant for the rotation amplitude compared with the plate only and struts only constructs. Significantly higher rotational offset was found for the plate-only constructs compared with the plate-strut constructs. The translation offset of strut-plate construct with two proximal screws (2) was significant lower than the plate-only and strut-only constructs. A significantly lower interfragmentary rotational amplitude of the two 12mm struts (6) compared with the plate only constructs was found.

There were no significant differences in interfragmentary motion between the different plate-strut constructs, the plate only and the struts only constructs with one exception. The plate-only construct with two proximal screws had a lower interfragmentary translation amplitude compared with the plate without the proximal screws.

SUMMARY

Internal fixation is the recommended treatment of a periprosthetic fracture around a well fixed femoral component. Six different fixation methods were compared using a transverse fracture model in cadaveric femurs. Interfragmentary motions were measured under physiological loads. The results support the use of a combined plate and strut construct rather than a single plate or a two-strut construct.

INTRODUCTION

To determine the body's COM, the segmental method is a the more accurate approach (Eng and Winter, 1993). The precision of the COM location is then lying on the validity of the segment inertia parameters (SIP). The segmental method requires the knowledge of the segment's COM location relative to specific bony landmarks. The SIP most widely used in balance studies are derived from cadavers' data. The major limitation of these cadavers' data is that they were gathered from only few older frozen specimens. Zatsiorsky and Seluyanov (1990) used gamma-scanning techniques to determine the SIP from 115 young caucasian adults. These SIP may provide a better estimation of COM because of the technique used and the sample of living subjects. The objective of this study is to compare the Zatsiorsky-Seluyanov's data and the Dempster's data on the COM position during quiet standing.

METHODS

Twenty five young adult subjects (8 males and 17 females) participated in this study. An OPTOTRAK[®] position sensor (Northern Digital, Waterloo, Ontario, Canada) was used to collect kinematic data of the 21 infrared emitting diodes positioned on specific bony landmarks. During the data collection, the participants were instructed to keep their arms hanging at their side and to focus on a fixed target located at eyes height. The experimental session was composed of 120 seconds standing trials with a 120 seconds seated rest period. The segmental method was used to estimate the body's COM based on 14 segments (COM14), 8 segments (COM8), 6 segments (COM6) and 3 segments (COM3). The COM location and mass fraction of body segments used to define COM-models are presented in an accompanying paper. For instance, the Dempster's data was selected from Winter's table (Winter, 1990) and the Zatsiorsky-Seluyanov's data was selected from the paper of de Leva (1996). The RMS error was used to evaluate the difference between the COM calculated from Dempster and from Zatsiorsky-Seluyanov.

RESULTS AND DISCUSSION

The RMS error values in antero-posterior (AP) and vertical are presented in Figure 1 for both genders. In AP direction, the global average difference is 12.3mm (± 1.3) and 3.4mm (± 0.6) for male and female respectively. In vertical direction, the average difference is 14.4mm (± 7.3) for male and 29.0mm (± 9.9) for female. The results for ML direction are not presented because the segments COM longitudinal location do not affect very much the ML body's COM position (global RMS error < 0.7mm).

Figure 1. RMS error of Dempster's compared to Zatsiorsky-Seluyanov's parameters in AP and vertical direction.

Using a precise reaction board, de Leva (1993, 1996) found an error of 53 mm (± 18 mm) and 38 mm (± 13 mm) along the longitudinal axis in young male and female subjects respectively. However, Zatsiorsky-Seluyanov SIP showed a smaller average error of 16 mm (± 17 mm) and -4 mm (± 13 mm). Our results agree with those of de Leva (1993). We conclude that the Zatsiorsky-Seluyanov SIP provide a better estimation of the body's COM location than cadavers based SIP for young adult subjects.

SEGMENTAL MOBILITY OF LUMBAR SPINE DURING A PRONE PRESS-UP MANEUVER IN SYMPTOMATIC AND ASYMPTOMATIC SUBJECTS: ASSESSMENT USING DYNAMIC MRI

Kornelia Kulig¹, (kulig@usc.edu) Christopher Powers¹, Robert Landel¹, Hung Wen Chen¹, Michael Fredricson², Marc Guillet² and Kim Butts²

¹Department of Biokinesiology and Physical Therapy, University of Southern California, Los Angeles, California, USA

²Departments of Radiology, Athletic Medicine and Physical Therapy, Stanford University, Palo Alto, California, USA

INTRODUCTION

Altered spinal mobility is thought to be contributory to low back pain. With the advent of dynamic MR imaging methods and open bore systems; the study of spine kinematics *in-vivo* is now possible (Harvey 1998; McGregor 2001). The purpose of this study was to quantify the amount of lumbar extension during a passive voluntary maneuver in a prone position (press-up). We hypothesized that the quantity of voluntary motion in the sagittal plane would differ between symptomatic and asymptomatic subjects.

METHODS

Twenty pain-free and 45 symptomatic individuals (ranging in age from 19 to 45) consented to participate in this study. Dynamic imaging of the lumbar spine was performed using a vertically open MR system (0.5 Tesla, Signa SP, General Electric Medical Systems, Milwaukee, WI, USA). Images were obtained at a rate of 1 Hz using the following parameters: repetition time (TR): 200ms; echo time (TE): 18 ms; number of excitations: 1.0; matrix: 256 x 256; field of view (FOV): 28 x 21 cm; and a 7 mm section thickness with an interslice spacing of 1 mm. Subjects were positioned with their lumbar spine centered within the magnet. A surface coil was secured to the anterior and posterior lower torso. The subjects were instructed to do a prone press-up (i.e., arch the back into extension) "as far as you are able to, without causing additional pain". Extension of each lumbar segment was quantified using the intervertebral angle (defined as the angle formed by lines delineating adjacent vertebral endplates). Segmental lumbar motion was defined as the difference between the inter-vertebral angles measured from the resting and the end-range extension image. The same investigator made all measurements. Intra-tester reliability of the measurements was performed on repeated measurements on 5 healthy volunteers. Intraclass Correlation Coefficients (ICC; 3,1) were found to be excellent, (0.95 to .99). The standard error of measurement was determined to be 0.9 degrees.

RESULTS AND DISCUSSION

A sagittal image of the lumbar spine at rest and during a press-up is presented in Figure 1. Total and segmental spine motions, as well as contribution of the individual segments to total mobility [%], are presented in Table 1. There was no difference in the mean total mobility between symptomatic and asymptomatic subjects, however the symptomatic subjects demonstrated greater relative extension at L4-L5 and less relative extension at L3-L4.

Figure 1: Sagittal plane MRI images of the spine during rest (left) and during a press-up (right) maneuver.

SUMMARY

These data provide unique insight into the in-vivo spinal kinematics during a voluntary press-up maneuver. Although total spine extension did not vary between symptomatic and asymptomatic subjects, a difference in individual segment mobility was observed. It is possible that the increase in segmental extension observed at L4-L5 in the symptomatic group was to compensate for diminished segmental extension evident at L3-L4. Further research is necessary to determine how altered spine mechanics relate to the development of pain.

^{1,2}Center for Military Biomechanics Research, Natick, MA

INTRODUCTION

Soldiers are required to perform many actions that involve linear and angular accelerations while carrying backpack loads. The inertial properties of loads may have an effect on the energy expenditure of individuals and their ability to maneuver (Hinrichs et al., 1982). Previously, our lab found a relationship between the sagittal plane location of the center of mass (COM) of a loaded backpack and the metabolic cost of walking while carrying a heavy load (Obusek et al., 1997). The influence of backpack moment of inertia (MOI) on metabolic cost was not determined. The purpose of this study was to examine the system (torso & pack) MOI in relation to 9 COM positions and the metabolic cost of walking while carrying the loaded backpack.

METHODS

A custom external frame backpack (35 kg) was constructed. Within the backpack, a 24.9-kg lead brick could be placed in 3 horizontal positions (close, central, and away) and 3 vertical positions (high, intermediate, and low) relative to the trunk, for a total of 9 different COM positions. COM position 1 represents high and away and position 9 represents low and close (Fig. 1). Twelve soldiers (Mean \pm SD: 22.1 yrs, 79.4 \pm 13.6 kg, 1.73 \pm 0.1 m) walked on a level treadmill at 5.6 km/hr for 5 minutes while wearing the pack in each of the 9 COM positions. Rate of O₂ consumption was found while walking (Obusek et al., 1997).

An MOI Instrument (Model XR250, Space Electronics, Inc.) was used to determine the MOI for the pack's 9 COM positions. The backpack was placed in a holder to stabilize it. The composite's (pack & holder) COM was centered over the axis of rotation of the MOI device for each plane. Subtracting the MOI of the holder and applying the parallel-axis theorem, the MOI of the backpack itself was determined for the 9 COM positions. Male cadaver torso COM and MOI data (Chandler et al., 1975) represented the soldier's COM and MOI. The torso data were combined with the backpack COM and MOI to estimate the system COM and MOI about the principal axes for the 9 COM positions by applying parallel-axis theorem.

RESULTS AND DISCUSSION

The system (torso & pack) MOI results indicate that COM position 7 (low and away) had the highest overall MOI about the principal axes and position 3 (high and close) and position 6 (intermediate and close) had the lowest (Fig. 1). In parallel with these findings, position 7 resulted in the highest metabolic cost per unit mass and position 3 resulted in the

lowest (Table 1). Positions 2 and 5 were also associated with relatively low MOI values and low metabolic costs. These findings indicate that the region encompassing COM positions 3, 6, 2, and 5 may be one in which soldiers should strive to keep their backpack COM to achieve low MOI and low energy cost.

Table 1: Mean Metabolic Cost/Total Mass (ml/min/kg) \pm SD by COM location.

Figure 1: MOI of system about system COM.

SUMMARY

Lower system MOI values appeared in the same region of COM positions that shared lower energy cost. The findings indicate that soldiers should strive to keep backpack COM high and close relative to the torso to achieve the lowest metabolic cost and the smallest MOI values while carrying the backpack. Future research will manipulate MOI while holding a pack's COM constant to further elucidate the relationship between load carriage mass properties and energy cost.

THE VISCOELASTIC BEHAVIOR OF MOUSE EXTENSOR DIGITORUM LONGUS SINGLE CELLS

Jennifer Davis, Sameer Shah, and Richard L. Lieber

University of California, San Diego and The VA Medical Center, San Diego

Email: rlieber@ucsd.edu

INTRODUCTION

Skeletal muscle fibers are inherently viscoelastic. While much is known about active muscle viscoelasticity, until recently, little had been known about the mechanical behavior of passive skeletal muscle. Magid and Law (1985) showed that myofibrillar structures are the source of elasticity at physiologic lengths and that the sarcolemma and extracellular connective tissue are responsible for passive tension only in highly extended muscles. Previous studies in rat, rabbit, and frog have shown that upon stretching, a single fiber exhibits viscoelastic behavior (Katz, 1939; Wang et al. 1993; Mutungi and Ranatunga, 1996; Minajeva et al. 2001). No one has characterized the passive mechanical properties in mouse muscle. Thus the purpose of this study was to quantify the viscoelastic behavior of mouse extensor digitorum longus (EDL) cells, especially in light of the powerful studies that are possible when performed on transgenic animals.

METHODS

The EDL muscle was slightly skinned in 30% glycerol storage solution incubated with a protease inhibitor. The EDL was submerged in relaxing solution and single fibers excised from the preparation. A single fiber was transferred into an apparatus containing relaxing solution at room temperature ($\sim 25^{\circ}\text{C}$). The fiber was mounted between a force transducer (400A, Aurora Scientific, Ontario, Canada) and length controller (318B, Aurora Scientific, Ontario, Canada). Sarcomere length was monitored during the course of the experiment by measuring first order diffraction patterns from a He-Ne Laser (LHR-007, Melles-Griot, Irvine, CA.).

Figure 1: Sample raw data from a stress-relaxation experiment. (A) Muscle fiber force after 30% deformation, (B) Sarcomere length (SL). T_1 , T_2 , T_3 represent decay time points measured.

Motor length, force, and sarcomere length were recorded via a 610E series DAQ board in the LabView environment (National Instruments, Austin, Texas). Every 4 minutes, fibers were stretched to 10, 20, and 30% strain within 30 ms. Stretched fibers were held for 2 minutes and released to the initial starting position.

RESULTS AND DISCUSSION

The time points measured (T_1 , T_2 , T_3) represented the peak force, middle decay, and steady state force of the stress-relaxation curve (Fig.1). The average force at each strain was expressed as a function of sarcomere length for T_1 , T_2 , and T_3 (Fig. 2). Despite the large decay in force, sarcomere length clearly remained constant throughout the entire duration of the stretch. A 2x2 two-way ANOVA revealed a significant effect of strain on force and sarcomere length ($p < 0.0001$), but the effect of time and interaction between time and strain were not significant. The source viscoelastic behavior of mouse muscle is still unresolved and that future investigations could lead to a complete characterization of mouse EDL passive mechanical properties.

Figure 2: Relationship between sarcomere length and force for three strains (symbols show strains) and three times (shadings show times) for mouse EDL fibers.

WHOLE-BODY POSTURAL CONTROL and TRUNK STABILITY DURING SUDDEN HAND LOADING PART 2: LOADS CAUSING COUPLED LATERAL BEND AND FORWARD FLEXION MOMENTS

Monica Haumann, Stephen Brown and Jim Potvin

Faculty of Human Kinetics, University of Windsor, Ontario, Canada

jpovtin@uwindsor.ca

INTRODUCTION

During activities of daily living, unpredictable circumstances results in challenges of equilibrium, including those that affect medial-lateral stability. The purpose of this study was to investigate the control of whole-body equilibrium, in coordination with spinal stability, in anticipation and response to sudden, asymmetric perturbations at the hands.

METHODS

Seventeen females volunteered for this study. Subjects were instrumented with EMG electrodes over 6 bilateral muscles pairs: lumbar and thoracic erector spinae (LES and TES), external and internal obliques (EO and IO), biceps femoris (BF), soleus (Sol) and the right tibialis anterior (TA). Subjects were situated on a force plate to measure Centre of Pressure (CoP) in the anterior-posterior (CoP_{AP}) and medial-lateral (CoP_{ML}) directions. CoP values were calculated with the vertical force and moments recorded on the force plate. These data were sampled at 1000Hz and dual low-pass filtered (10Hz). EMG signals (1000Hz) were rectified, low-pass filtered (3Hz) and normalized to MVC.

Subjects were asked to maintain an upright posture while holding a box with arms extended comfortably and handles at waist height. A curtain was placed in front of the subject so that they could not see the load or the box. A 6 kg load was delivered to the subject via a pulley system that applied the load into the center (Symmetry) or right side (Asymmetry) of the box. The current paper will focus on the data from the Asymmetric trials. For the purposes of this paper, data were collected under two experimental conditions: 1) asymmetrical load, with expected timing in which the experimenter counted down from 5 to 1 and released the load into the right side compartment of the box on the count of one; 2) asymmetrical, unexpected loading in which the load was dropped to the right side after random intervals with no prior warning to the subjects. Subjects performed 10 repetitions for each condition

For each condition the following dependent variables were calculated: 1) pre-average: average amplitude of the CoP_{AP} and EMG from each muscle, for the 15 ms prior to sudden load onset, 2) anticipatory response: change in amplitude from the baseline levels, averaged from 150 ms to 15 ms prior to loading, to the pre-average levels and, 3) peak response: maximum increase from the pre-average level to the peak amplitude during the first 500 ms following load onset. Averages were calculated with each of the 10 trials performed within each condition. A three-way ANOVA was performed with repeated measures (side, load placement and timing) to

determine experimental effects. Significance was evaluated at $p < 0.05$.

RESULTS AND DISCUSSION

The anticipatory response of the CoP_{ML} was not significantly affected by the lateral load placement or timing conditions. Absence of a lateral anticipatory postural adjustment was attributed to the substantial challenge to whole-body stability that the asymmetric perturbation evokes.

The right BF was the only leg muscle to show a significant anticipatory response prior to the asymmetric load onset. Recruitment of the BF may be indicative of the 'hip strategy', which is evoked in response to large, unpredictable perturbations (Horak and Nashner, 1986). In response to the asymmetric perturbation those leg muscles ipsilateral to the load placement (right BF, Sol, TA) were activated significantly higher than the contralateral leg muscles. It is concluded that, in response to the asymmetric perturbation, the shear forces acting at the surface were altered to regain whole-body equilibrium.

Lateral agonists of the trunk (left LES, EO) and lateral stabilizers (right TES, IO) each showed significantly higher pre averages to the asymmetric load onset. Similarly, significant asymmetries were noted for the activation of the lateral agonists (right LES, EO) and the lateral stabilizers (left TES). Co-activation of the lateral agonists and lateral stabilizers served to increase lumbar stiffness and compression acting on the spine. It was also found, in a case study of a completely unanticipated/surprise asymmetric perturbation, that the TES and IO were recruited to serve as lateral agonists as opposed to providing solely a stabilizing function. A plausible explanation for these asymmetrical stabilizers to be recruited to counter and resist the asymmetric perturbation was the degree of postural instability, given the unpredictability of the surprise perturbation.

SUMMARY

The observed increase in the ipsilateral leg muscles were concluded to control the displacement M-L CoP and prevent the lateral collapse of the trunk. Trunk stability observed increase in antagonistic co-activation, suggesting greater neuromuscular control is necessary to maintain medial-lateral stability.

PILOT STUDY OF INTRACELLULAR SIGNALING IN POST-OPERATIVE TENDONS

Jeng-Yu Lai¹, Krishna V Gumidyala², Aletta P. Houwink², Chunfeng Zhao², Peter C. Amadio², and Kai-Nan An²
Departments of Dermatology¹ and Orthopedics², Mayo Clinic, Rochester, MN, USA

INTRODUCTION

Early mobilization is necessary after tendon surgery to regain maximal function of the tendon. Studies suggested that soft tissues may require proper stimulation to maintain their integrity at the tissue as well as cellular level.

At least part of the signal transduction pathway that mediates responses to mechanical forces is coupled to activation of extracellular signal-regulated kinases (ERK) and c-Jun N-terminal kinase (JNK) which, in turn, regulate downstream transcription factors and nuclear events linked to specific cell responses (Banes *et al*, 1999; Xia *et al*, 1995; Yamauchi *et al*, 2001). Surgery should enhance JNK activation, which is a stress activated protein and whose activation leads to apoptosis. We hypothesize that the ERK and JNK activation after surgery may have an effect on the results of early motion therapy, specifically that therapy may affect ERK and JNK levels differentially, altering the balance between mitosis (ERK) and apoptosis (JNK). As a prelude to testing this hypothesis, we wished to determine if intratendinous ERK and JNK were affected by tendon surgery, and if so, when.

METHODS

Dogs were anesthetized for tendon surgeries. The surgical forepaw was immobilized by a combination of radial neurectomy and external casting. The contralateral paw served as a mobile, normal control. The side of immobilization was randomized. On the immobilized paw 2 tendons were used. The first was lacerated (Lac) and then repaired with a modified Kessler repair suture technique. The other was surgically approached in the same manner as the Lac tendon, but no laceration or repair was performed (Sham). Tendon within 7 mm proximal and distal to the operated site was discarded. Tendons were harvested at 1, 3, 5, or 7 days (3 dogs each group) after surgery and fresh frozen in liquid nitrogen before being stored.

Tendons were weighed and ground with Trizol. Proteins were dissolved in MAPK solution (Auclair *et al*, 1999), loaded onto a 12% polyacrylamide gel for electrophoresis, and transferred to a nitrocellulose membrane. The membrane was blotted against activated ERK 1/2, total ERK 2, and phospho-JNK.

The images were scanned and measured by Scion Image software. All the signal intensities were calibrated based on intensity and band area of total ERK from the normal tendon. The changes in expression were calculated against the amount of expression in the normal tendon of the contralateral limb.

RESULTS AND DISCUSSION

Since the image software determined the amounts of protein by measuring the pixel number in the band area, exposure of the film and size of the scanned image would affect the

reading. Therefore, the results were presented as ratios to the control tendon.

The ERK expression is shown in Figure 1. ERK expression decreased after 3 days in the Sham tendons. However, ERK expression was relatively unchanged, as compared to controls, in the Lac tendons. However, the expression of JNK was not consistent, possibly due to technical difficulties. We had intended to examine and compare the expressions of ERK and JNK as an indicator for post-operative rehabilitation. However, our intention was hindered by the difficulties in preserving phospho-groups during protein extraction and photo imaging.

Nevertheless, this study presents an initial effort to design a rehabilitation protocol for tendon surgeries based on cellular signaling.

A larger sample size may be needed to demonstrate statistical differences. Also, technical improvement in the extraction process is needed. Phosphorylation is unstable unless the protein is stored in a reducing agent, which was not achievable with MAPK buffer. Therefore, some activated ERK and JNK might have lost in the process. Finally, a better imaging system could greatly increase the accuracy of the measurements.

Figure 1. ERK expression..

DETERMINATION OF THE OPTIMAL FOREARM MUSCLES TO MONITOR WITH EMG IN ERGONOMIC STUDIES

Matt MacPherson, Diane Grondin and Jim Potvin

Faculty of Human Kinetics, University of Windsor, Windsor, Ontario, Canada,
jpotvin@uwindsor.ca

INTRODUCTION

Jobs that require large grip forces and repetitive handgrips are linked to the occurrence of tendon-related disorders (Mital & Kilbom, 1992). Therefore, it is important to quantify the forces required by the muscles of the forearm during work. However, no efforts have been made to indicate which muscle(s) of the forearm best represent the demands on the hands. Also, many gripping studies do not even specify which muscles of the forearms were monitored. Many portable EMG systems used in ergonomics allow for the monitoring of only four muscles. The purpose of this study was to determine if one forearm flexor and one extensor muscle were sufficiently active during a wide variety of hand exertions to warrant the monitoring of only two EMG channels, bilaterally, when wanting to represent overall hand demands during work activities.

METHODS

Six male and four female subjects volunteered to participate in the study. Pairs of Ag/Cl bipolar surface electrodes were placed over three forearm flexors: flexor carpi ulnaris (FCU), palmaris longus (PL) and flexor carpi radialis (FCR), and three forearm extensors: extensor carpi ulnaris (ECU), extensor digitorum (ED) and extensor carpi radialis brevis (ECRB). EMG data were collected at 1024 Hz and the signals were amplified (x500) and full-wave rectified. Maximum voluntary contractions (MVCs) were obtained for each flexor and extensor muscle. The experimental trials consisted of five different hand exertion types often observed in work environments (pinch grip, lateral key grip, power grip, thumb press and finger press), with each held in three different wrist postures (flexed, neutral and extended). Trials lasted 20s with five cycles, each cycle consisting of 2 s of a maximum exertion and 2 s of rest. EMG signals were low-pass filtered using a second order Butterworth filter ($f_c = 2.5$ Hz) and then normalized to MVC amplitudes. The average EMG amplitude was calculated for each muscle/trial combination. In addition, each flexor was renormalized to the highest mean of the three for each trial. The same was done for the extensors. Three-way ANOVAs with repeated measures (3 muscles, 5 hand exertions, 3 postures) were calculated for the normalized and renormalized EMG amplitudes for both the flexor and extensor groups (significance at $p < 0.05$).

RESULTS AND DISCUSSION

When the EMG data were pooled across postures and hand exertion types, the ECU and FCU were the extensor and flexor muscles, respectively, with the highest average amplitudes ($p < .05$ for both, Figure 1). Interestingly, the extensor activity

Figure 1: Pooled average EMG amplitudes, with standard error bars ($n=150$). Different letters or numbers indicate significant differences within flexors or extensors ($p < 0.05$).

was generally higher than the flexor activity, with the most active extensor (ECU) being approximately 31% higher than the most active flexor (FCU). Moreover, for the significant Grip*Posture*Muscle interaction of the extensors, the ECU was the highest extensor in 11 out of 15 conditions, and was at least 85% of the highest extensor muscle in the other four conditions. With the renormalized data, the ECU was an average of 90% of the ultimate maximum over the 15 conditions. The FCU was higher than, or equal to, the other flexor muscles in 13 of 15 conditions, and was at least 80% of the highest muscle in the other two conditions. With the renormalized data, the FCU was an average of 89% of the ultimate maximum over the 15 conditions.

SUMMARY

It was concluded that it sufficient to collect surface EMG from only the ECU and FCU muscles when monitoring the hand and forearm demands in occupational tasks. These muscles were almost always the most active, or nearly the most active, for the 15 combinations of posture and hand exertion type. Given the higher activation levels of the forearm extensor muscles, it is important to note that these muscles cannot be ignored, even when the dominant hand motion seems to be in flexion. The extensor muscles of the forearm likely have an important stabilizing role during hand exertions and are, consequently, very important to monitor in ergonomic studies.

THE EFFECTS OF BACKPACK LOADS ON PELVIS AND UPPER BODY KINEMATICS OF ADOLESCENT FEMALES DURING GAIT

Chriss Stanford¹, Peter Francis², and Hank Chambers¹

¹Motion Analysis Laboratory, Children's Hospital, San Diego, California, cstanford@chsd.org

²San Diego State University, San Diego, California

INTRODUCTION

Children carry schoolbag loads of 15% to 25% of their bodyweight (BW)¹. Though carrying 20% BW has been associated with increased symptoms of back pain in schoolchildren², few studies have examined the specific effects of backpack carrying on posture and gait characteristics in children. The purpose of this study was to examine the kinematics of the pelvis, trunk, and upper extremities in the adolescent female during loaded gait.

METHODS

Reflective markers were attached to the skin overlying the feet, pelvis, trunk, shoulders, and elbows of ten healthy females, aged 13-15 years. Subjects walked down a 10 m runway, while carrying each of five randomized loads, listed in Table 1. Positions of the markers were captured using an 8-camera Motion Analysis System (Motion Analysis Corp., Santa Rosa CA), sampled at 60 Hz.

Table 1: Description of load conditions

BW	Unloaded/no backpack
D10	10% BW load carried with both shoulder straps
D20	20% BW load carried with both shoulder straps
S10	10% BW load carried on the right shoulder
S20	20% BW load carried on the right shoulder

Trunk and pelvis motion were calculated relative to a global coordinate system. Pelvis kinematics were measured in the coronal and transverse planes only, as the presence of the backpack on the dorsal surface of the pelvis prevented accurate analysis of sagittal plane motion. Shoulder motion was measured in the sagittal plane, relative to the trunk.

For each subject, data were normalized as a percentage of the gait cycle. Mean angle and range of motion (ROM) were compared across load conditions using repeated measures ANOVAs, with a Bonferonni correction. For each comparison, $p < .007$ was considered significant.

RESULTS AND DISCUSSION

Figure 1 displays mean trunk and pelvis kinematics throughout the gait cycle for BW, D20, and S20. Load carriage using a single shoulder strap induced a significant trans-planar adjustment in posture, including increased lateral tilt and rotation of the trunk in the opposite direction to the load-bearing shoulder. Increased obliquity of the ipsilateral hemipelvis and increased pelvic internal rotation was also

observed when carrying as little as 10% BW on one shoulder. These changes appear to represent a strategy to center the load over the hips in an attempt to preserve the normal gait pattern. Assymetry in arm swing was also observed: a significant increase in left shoulder ROM and decrease in right shoulder ROM was observed with S10 and S20.

An increase in forward lean was the only observed significant difference between D10 and unloaded walking. This finding was not previously observed in boys³, suggesting that the flexion response may be more pronounced in girls.

D20 significantly increased trunk flexion, reduced pelvic rotation, and increased right and left shoulder flexion, relative to unloaded walking.

Figure 1: Trunk (top row) and pelvis kinematics (bottom) during the gait cycle for BW, D20, and S20.

SUMMARY

The results of this investigation indicate that carrying 20% BW poses additional postural consequences over 10% BW in female adolescents. Changes in posture were most evident when the load was asymmetrically distributed in the coronal plane. The resulting internal moments acting to stabilize the trunk through this mode of carriage may be of concern in the development of injuries, particularly in teenage females.

MUSCLE DEMANDS AND TORQUE REACTIONS ASSOCIATED WITH AIR AND ELECTRIC HAND TOOLS

Jim Potvin¹, Mike Agnew¹, Cherrie Ver Woert²

¹Faculty of Human Kinetics, University of Windsor, Ontario, Canada, jpotvin@uwindsor.ca

²Ford Motor Company, Dearborn, Michigan, USA

INTRODUCTION

Recently, electric (or DC) tools have been introduced as a potential replacement for pneumatic (or air) tools in manufacturing environments. While DC tools can be transducerized and programmed with many variables to improve the torque reactions during drilling, they do have a potential ergonomic liability of being heavier than air tools. Thus, the purpose of this study was to determine if differences exist between the ergonomic demands and injury risks associated with air and DC pistol grip hand tools during the run down of horizontal joints.

METHODS

Data were collected from 15 male and 15 female subjects. Each subject was instrumented with 7 pairs of surface EMG electrodes on the right arm: flex. carpi uln. (FCU), flex. carp rad. (FCR), ext. carpi uln. (ECU), ext. carpi rad. longus (ECR), biceps brachii (BB), ant. deltoid (AD) and trapezius (Traps). A triaxial accelerometer was also attached to the hand. Each subject performed drilling with five pistol grip tools from two tool suppliers. This resulted in two air tools, one non-transducerized electric (NTDC) and two transducerized (TDC) electric tools. Three types of joints were simulated: 1) 2 Nm, 720 degrees, 2) 7 Nm, 720 deg and 3) 7 Nm, 30 deg. For each of the 15 combinations of tool and joint, subjects were asked to drill five joints to completion within a 60 second period, and to repeat this 5 times for each condition (5 minutes). The order of joint and tool presentation was randomized. Each signal was sampled at 1000 Hz. The EMG signals were digitally full wave rectified, low pass filtered with a Butterworth filter ($f_c = 2$ Hz) and normalized to MVC. A resultant acceleration was calculated from the triaxial accelerometer and this was converted into an angular acceleration based on the moment arm to the tool joint axis.

EMG and acceleration time-histories were truncated to represent drilling periods. Median and Peak (90th %ile EMG, 99th %ile acceleration) values were calculated for each signal time-history, but only the peak data will be presented here. A 2 factor ANOVA with repeated measures was run to determine the effects of joint and tool type.

RESULTS AND DISCUSSION

In general, the 7 Nm/720 degree joint was shown to result in the highest demands for all muscles monitored in this study, with the ECU having the highest overall demands for each

condition studied. Muscle demands were similar for the other two joints. The effect of tool type could be divided into two groups: 1) the four forearm muscles monitored, 2) the biceps, shoulder (AD) and neck (Traps) muscles. For the forearm muscles, the activation levels were observed to be significantly lower in the non-transducerized and transducerized DC tools, when compared to the two air tools. However, given the greater weight of the DC tools, the BB, AD and Traps showed slightly higher amplitudes in the DC compared to the air tools. It should be noted that the highest demands were observed in the forearm ECU, ER and FCU muscles.

With regards to the hand acceleration (torque reaction) data, there was a significant interaction between tool type and joint (Figure 1). Generally, the DC tools always had lower torque reactions than the air tools, although these differences were larger for certain joints. For example, one air tool resulted in particularly high accelerations for the 7 Nm/30 deg (hard) joint.

Figure 1: Joint x Tool interaction for Peak acceleration. Standard errors are indicated. (n=30)

SUMMARY

It was concluded that, although DC tools are heavier, they actually result in a decrease in the risk of cumulative trauma disorders of the upper limb. They result in a significant decrease in the demands on the highly challenged forearms, a substantial decrease in the torque reaction at the end of the joint run-down and only a slight increase in the demands on the less challenged upper arm, shoulder and neck muscles.

EFFECTS OF MECHANICAL COMPRESSION ON ANABOLIC AND CATABOLIC GENE EXPRESSION IN A RAT TAIL MODEL

CR Lee^{1,2}, JJ MacLean¹, S. Grad², K. Ito², M. Alini², and JC Iatridis¹

¹Department of Mechanical Engineering, University of Vermont, Burlington, VT, USA, cyndi_lee@alum.calberkeley.org

²AO Research Institute, Davos, Switzerland

INTRODUCTION

Mechanical loads influence the health of the intervertebral disc (IVD) in large part due to the influence of physical forces on IVD cells. To elucidate the relationship between mechanical loading and IVD cell metabolism, the current *in vivo* study evaluated the IVD cell expression of anabolic (collagen I, collagen II and aggrecan) and catabolic (stromelysin and collagenase) genes after cyclic compression.

METHODS

Animal Model: Tails of 28 skeletally mature Wistar rats were instrumented with an Ilizarov-type device spanning caudal disc level 8-9 (i.e. instrumented level). Animals were separated into 4 groups as follows:

Real-time PCR Analysis: Instrumented (caudal level 8-9) and uninstrumented (i.e. internal control levels 6-7 & 10-11) discs were isolated and separated into annulus and nucleus regions, followed by mRNA extraction and reverse-transcription to cDNA. The relative expression of types 1 and 2 collagen, aggrecan, stromelysin (MMP3) and collagenase (MMP13) mRNA was measured with real-time PCR.

Statistical Analysis: Levels of mRNA in instrumented discs were normalized to the average levels measured in the 2 uninstrumented discs. Data are presented as mean \pm IQ range and 95th percentiles. A t-test was used to determine effects of surgery and loading. ANOVA and SNK post-hoc testing were used to evaluate differences among loading groups.

RESULTS

Immobilization (imm/imm) resulted in a slight decrease in relative mRNA levels of collagen 1 and 2 (2- to 3-fold) in the annulus (Fig 1a) and a marked increase in MMP3 mRNA (10-fold) in the nucleus (Fig 1d). Annular collagen 1 and 2 mRNA levels were also significantly reduced in discs that were immobilized for 72 hrs and then cyclically loaded at 1 MPa for 2 hrs (imm/comp; Fig 1a). The increase in nucleus MMP3

with immobilization was down-regulated back towards control levels with 2 hrs of cyclic loading (imm/comp), while cyclic loading applied to free discs (free/comp) up-regulated nuclear MMP3 (3-fold increase; Fig 1d). The imm/comp condition moderately up-regulated relative mRNA levels of MMP3 and MMP13 (2.5- and 4-fold, respectively) in the annulus (Fig 1b).

Fig. 1: Relative mRNA levels in annulus (a,b) and nucleus (c,d) of anabolic (a,c) and catabolic (b,d) genes. Data presented as mean \pm IQ and 95th percentile. (*t-test $p < 0.05$; +SNK vs free/free $p < 0.05$)

DISCUSSION

Immobilization of the motion segment led to a decrease in collagen 1 and collagen 2 gene expression in the annulus and an increase in MMP3 (stromelysin) expression in the nucleus. Immobilization plus cyclic compression (1MPa @ 0.2Hz for 2 hrs) down-regulated collagen 1 and 2 expression while up-regulating MMP3 and MMP13 expression in the annulus. Two hours of cyclic loading offset the MMP3 up-regulation in the nucleus that was induced by immobilization. Further work is necessary to determine the magnitude, frequency, and duration of cyclic loading that stimulate anabolic and catabolic responses of the disc cells.

GROUND REACTION FORCES TRANSMITTED TO THE UPPER EXTREMITY DURING THE YURCHENKO VAULT AND FLOOR EXERCISE

Matt Seeley and Eadric Bressel

Biomechanics Laboratory, Utah State University, Logan, UT, USA, sl63n@cc.usu.edu

INTRODUCTION

Women's gymnastics has increased in popularity, and injury rates within the sport have also increased. Female collegiate gymnasts consistently maintain injury rates similar to collegiate football players, and elite gymnastics injury rates are higher than all other levels of gymnastics (Meeusen, 1992). Research indicates upper extremity injuries may be more prevalent during the vault than during other gymnastic skills (Caine et al., 1992; Roy et al., 1985). Previous research has not quantified ground reaction forces (GRF) transmitted to upper extremities during the vault. The Yurchenko vault is a relatively new round-off entry vault involving increased risk. The purpose of this study was to observe peak vertical GRF transmitted to the upper extremity of high-level gymnasts during the round-off phase (the round-off just before the gymnast strikes the springboard) of the Yurchenko vault.

METHODS

This study observed one independent variable, the round-off, comprised of two conditions: (a) the round-off phase of the Yurchenko vault, and (b) the floor exercise round-off. Values for the Yurchenko vault were compared to the floor exercise round-off, an activity normally associated with fewer upper-extremity injuries. Peak vertical GRF served as the dependent variable. Fifteen high-level gymnasts ($M_{\text{age}} = 18 \pm 2.58$; $M_{\text{height}} = 159 \pm 6.22$ cm; $M_{\text{mass}} = 56.4 \pm 5.87$ kg) volunteered to participate in the study. Participants performed three trials of the Yurchenko vault and floor exercise round-off in randomized order, placing the trail hand on a 40 X 60 cm force platform. GRF values were collected at a sampling rate of 500 Hz and recorded GRF values were normalized to body weight (BW). The Yurchenko vault and floor exercise round-offs were performed in dimensions identical to a competition environment, which included a sting mat placed over the force platform. A paired t-test was used to examine the effect each round-off condition had on the dependent variable with the p-value set at .05.

RESULTS AND DISCUSSION

Mean peak vertical GRF during the round-off phase of the Yurchenko vault were $2.39 \pm .25$ BW (Figure 1) and were significantly greater ($p < .05$) than peak GRF values recorded during the floor exercise round-off (Figure 1).

GRF values during the round-off phase of the Yurchenko vault and floor exercise round-off were greater than GRF values observed by Markolf et al. (1990) during the pommel horse, an activity commonly linked to chronic upper extremity injury (Figure 1). Peak GRF values during the round-off phase of the

Yurchenko vault were also greater than values reported by McClay et al. (1994) and Cavanagh and LaFortune (1980) during the impact stage of running at speeds of 3.8 m/s (1.9 BW) and 4.5 m/s (2.2 BW) respectively (Figure 1). Each of the activities mentioned have been linked to overuse injury. Because upper extremities are poorly fit for weight bearing activities (Tuttle, 1969), peak GRF observed in this study may be a factor in upper extremity injury in gymnastics.

Figure 1: Mean peak vertical GRF values normalized to body weight. Yurchenko vault (YV), floor exercise (FE) round-off, and pommel horse show peak vertical GRF transmitted to upper extremities.

SUMMARY

Peak GRF values during the round-off phase of the Yurchenko vault were 2.39 BW and were significantly greater ($p < .05$) than peak GRF transmitted to the upper extremity during the floor exercise round-off (Figure 1). Peak GRF values during the round-off phase of the Yurchenko vault may be reduced through the implementation of safety equipment and/or a change in vaulting technique. Research conducted to decrease peak GRF transmitted to the upper extremities during the round-off phase of the Yurchenko vault may decrease the incidence of upper extremity injuries suffered by high-level gymnasts.

EFFECTS OF EXPECTATION DURING SUDDEN UNLOADING OF THE HANDS

PART 1: ANTICIPATORY POSTURAL ADJUSTMENTS

Stephen Brown, Monica Haumann and Jim Potvin

Faculty of Human Kinetics, University of Windsor, Windsor, Ontario, Canada
jpotvin@uwindsor.ca

INTRODUCTION

In whole-body control, anticipatory postural adjustments (APAs) are utilized to counteract the effects of an oncoming perturbation (Massion, 1992). These APAs appear to be more significant under self-triggered, rather than externally triggered, perturbations (Aruin & Latash, 1995). This study examines the anticipatory and responsorial whole-body adjustments made during sudden unloading of the hands with various expectancies

METHODS

Eleven male subjects volunteered for this study. All measurements were made using an EMG system and force plate. Surface Ag/AgCl electrodes were used to detect the activity of four muscles on the right side: biceps femoris (BF), rectus femoris (RF), soleus (Sol), and tibialis anterior (TA). Trunk muscles were also examined but will be dealt with in a separate abstract. Forces plate data were used to calculate anterior-posterior centre of pressure (CoP_{AP}) time-histories.

The experimental procedure was as follows: the subject stood upright on the force platform, with feet separated at shoulder width, holding a box at waist height with handles at shoulder width. A 6.8 kg load was placed in the center of the box. Three experimental conditions were examined: a voluntary timing (VT) condition in which the experimenter counted down from 5 to 1 and then the subject dropped the box; a known timing (KT) condition in which the experimenter counted down from 5 to 1 and rapidly removed the load from the box via a pulley system; and a random timing (RT) condition in which the load was rapidly removed from the box with no countdown. Ten repeat trials collected for each condition. The order of each timing condition was randomized.

Raw force plate signals (1000 Hz) were dual low-pass filtered (10 Hz). Raw EMG signals (1000 Hz) were rectified, low-pass filtered (3 Hz) and normalized to MVCs. The following statistics were calculated for each EMG amplitude and the CoP_{AP} : 1) preparatory adjustment: the change in amplitude from baseline levels to the level just preceding the load removal or drop and, 2) dominant response: the maximum increase or decrease in amplitude from the pre-perturbation level to the post-perturbation level (within 500 ms). Averages were taken across the 10 trials for each subject. A one-way ANOVA, with repeated measures, was used to determine the effect of expectancy for each dependent variable ($p < 0.05$).

RESULTS AND DISCUSSION

The magnitude of the CoP_{AP} APA was highest in the VT condition. The lack of significance between the KT and RT conditions indicates that knowledge of when the unloading will occur may not have a large effect on APAs, if the perturbation is externally triggered. The dominant CoP_{AP} response was observed to become more negative with an increase in uncertainty of the perturbation timing (Figure 1). The BF was the only muscle to show significantly larger preparatory adjustments in the VT compared to both the KT and RT conditions. The dominant responses of the BF, Sol and TA each significantly increased from the VT to KT to RT conditions ($p < 0.05$).

Figure 1: Responses of the CoP_{AP} for the three experimental conditions. Positive values represent displacements in the anterior direction. Standard error bars are indicated. ($n=11$).

SUMMARY

As knowledge of the timing of unloading increased, subjects were better able to adjust their CoP_{AP} to prepare for the perturbation. This resulted in smaller CoP_{AP} displacements in response to the unloading. The BF was the monitored muscle most responsible for adjusting the CoP_{AP} in the posterior direction prior to unloading. This adjustment seemingly enabled the BF, as well as both anterior muscles (Sol and TA), to respond to the perturbation with lower activation levels as knowledge of the timing of the unloading increased.

HEAD, TRUNK AND PELVIS KINEMATICS DURING RAPID HEAD TURNING IN STANDING AND WALKING

Caroline Paquette, Sunil Garg, Nicole Paquet, Joyce Fung

Jewish Rehabilitation Hospital Research Center and McGill University, Montreal, Quebec, CANADA (caroline.paquette@mail.mcgill.ca)

INTRODUCTION

Maintaining balance in quiet stance is not a trivial task as it requires complex coordination of all body segments. The task can be more demanding during walking as it also requires the accurate synchronization with voluntary anterior disequilibrium to allow forward progression (Winter, 1995). The demands increase when a voluntary movement, such as an arm or head motion, is executed simultaneously. Our purpose was to evaluate the impact of a rapid head turn on the kinematics of the trunk and pelvis segments during step stance and walking.

METHODS

Six young healthy subjects (22 to 30 years) walked at their naturally preferred speed across a 10-meter walkway. They were instructed to turn the head as quickly and as fast as possible in the direction indicated by an illuminating arrow (right, left, up, down or none, randomly presented), during step stance or walking. Head turning was maintained with the aid of visual targets. A full body model (38 markers positioned over head, trunk, pelvis, arms and legs) was used to record and analyze body motions in 3-D with a 6-camera Vicon 512 system.

Paired t-tests were used to compare horizontal and sagittal excursions of the trunk and pelvis with and without head turning.

RESULTS AND DISCUSSION

Subjects responded to the arrow signal (reaction time) faster during standing as compared to walking (225 ± 43 vs. 323 ± 28 ms). The reaction time was similar within the different head turn directions and did not interact with standing and walking. Head movement amplitude was larger during walking as compared to standing (75 ± 16 vs. $60 \pm 12^\circ$). The amplitude of head motion was significantly larger in horizontal movements as compared to up-down motions ($78 \pm 11^\circ$ vs. $57 \pm 13^\circ$). However, in the up direction there was no significant difference between standing and walking ($53 \pm 11^\circ$ vs. $50 \pm 11^\circ$, significant interaction effect). These head motions were executed at high velocity in both standing and walking, on average $408 \pm 144^\circ/\text{s}$. Velocities were significantly different within head turn direction: $516 \pm 119^\circ/\text{s}$ horizontal vs. $300 \pm 62^\circ/\text{s}$ sagittal.

Figure 1A shows that when a head turn was executed during standing or walking, trunk rotations occurred in the same direction of the head turn. The excursions were markedly larger in walking as compared to standing.

Figure 1B shows that in standing, there was very little pelvis motion associated with head turn. However, in walking, pelvis rotation is executed in the direction opposite to the head and trunk rotation.

Figure 1: Maximum horizontal angular excursions of the A) trunk and B) pelvis in walking and standing for with and without head turns.

The differences observed between step stance and walking might be due in part by relative target location, since the angle separating the subject's gaze with the target was continuously increasing as the subjects were moving forward. This is consistent with the head movement amplitude difference reported between standing and walking.

Analyses for the flexion-extension motions of the trunk and pelvis revealed that they were not influenced by up-down motions of the head during walking. However, a small but significant trunk flexion accompanied a head-down movement during standing as compared to no head turn ($4 \pm 5^\circ$ vs. $1 \pm 2^\circ$), whereas pelvis extension occurred with head-up movement ($3 \pm 2^\circ$ vs. $0 \pm 1^\circ$).

SUMMARY

When a horizontal head turn is executed during walking, the trunk follows the motion of the head, whereas the pelvis moves in the opposite direction. This kinematic strategy is likely used to maintain a straight trajectory while looking to the side. This strategy is not used when head turn is executed during a similar posture in quiet stance, when trunk and pelvis stability is paramount to maintain balance.

DETERMINATION OF ELASTIN AND COLLAGEN CONTENT IN PORCINE AORTA

Namrata Gundiah¹, Kim Dao², Karen King²³, Lisa Pruitt¹²

¹Dept. of Mechanical Engineering, lpruitt@newton.berkeley.edu

² Dept. of Bioengineering, University of California Berkeley, Berkeley, CA 94720

³ Dept. of Medicine, University of California San Francisco, San Francisco, CA 94143.

INTRODUCTION

Elastin and collagen are the primary passive components of arterial wall and their relative amounts contribute to the highly nonlinear stress-strain behavior of elastic arteries (Wolinsky, 1967). Because arterial diseases like atherosclerosis and aneurysms directly correlate with changes in the amounts vessel wall constituents, it is important to develop methods to quantify their amount and study their architecture. In this study, we use biochemical analyses to quantify the relative amounts of collagen and elastin in porcine arteries and study their architecture using histological methods.

MATERIALS AND METHODS

Thoracic aortae from two healthy female sows were harvested from UCSF and rings from each were stored in methanol for collagen content determination, saline for elastin isolation, and formalin for histology respectively. **Collagen Content:** Hydroxyproline (Hyp) makes up 14% of total collagen content in porcine tissue (Gosline, 1996). Hyp content was determined using the Chloramine-T assay. The sample was hydrolyzed in 6M HCl for 20 hours in a 2 ml. sealed glass tube. Hyp was then oxidized and reacted with p-dimethylamino benzaldehyde to form a chromophore, detected using a spectrophotometer at 550 nm (Stegemann, 1967). **Elastin Isolation:** Elastin was isolated by repeated autoclaving of the tissue followed by treatment in 6M guanidine hydrochloride (Lillie, 1990). **Histology:** Samples were embedded in OCT, cryo-sectioned into 8 μ m sections and stained using three methods. (i) Hematoxylin & Eosin (H&E) was used for the detection of nuclei (stained purple) and fibers (in pink). (ii) Masson's trichrome was used to stain collagen (blue) and muscle cells (red). (iii) Verhoeff stain counterstained with picroponceau was used to identify elastin (brilliant blue-black) and collagen (red).

RESULTS AND DISCUSSION

Trans 4 hydroxy L Proline was used to obtain the standard curve for Hyp concentration. Standard concentrations in excess of 0.03 mg saturated the absorbance curve (Reddy, 1996). A linear fit of the standard curve (Fig 1a) was used to estimate the Hyp concentrations in the sample. Based on this and data from all samples in the study (Fig 1b), we obtained % collagen of $9.52 (\pm 3.33)$ for the first animal and $17.16 (\pm 5.31)$ for that of the second animal. Elastin content for the first animal was 81.51% and that for the second animal was 63.5%. The histological images show that the elastin isolation procedure eliminates collagen and smooth muscle cells from the tissue samples.

Figure 1a: Standard Absorbance curve.

Figure 1b: Absorbance curves for all samples in study.

Figure 1c: Histology of control (left) and purified elastin (right)

The amount of elastin decreases away from the aortic arch while collagen content increases. The relative differences in the amounts of elastin and collagen from the two specimens in our study may occur since the samples originate from different regions of the thoracic aorta.

SUMMARY

We evaluated methods to quantify the amounts and architecture of elastin and collagen in arterial walls. These techniques will be combined with mechanical tests of elastase and collagenase digested arteries to study their biomechanical role in healthy and diseased arteries.

EFFECT OF SHEAR STRESS ON THE ACTIVATION OF THE PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS (PPARs)

Kitty Formentin, LingFang Zeng, Andre P Morgan, and John Y.-J. Shyy
Division of Biomedical Sciences, University of California, Riverside, CA, USA, 92521-0121.
Email address: kitti.formentin@ucr.edu

INTRODUCTION

Located at the interface between the vessel wall and the circulating blood, the vascular endothelial cells (ECs) are constantly subjected to hemodynamic forces. Ample evidence has shown that shear stress, the frictional force of the flowing blood, plays an important role in atherosclerosis through the activation of many signaling pathways. PPARs, belonging to the superfamily of nuclear transcription receptors, are now emerging as potential key players in metabolic disorders leading to atherosclerosis. Therefore, the aim of this work is to study the effect of shear stress on the activation of different nuclear receptors such as PPAR γ , PPAR α , RXR and LXR.

METHODS

Monolayers of ECs cultured on glass slides coated with 2% gelatin were subjected to a laminar shear stress of 4 or 12 dynes/cm², using a parallel-plate flow chamber as described previously (1).

To measure the effect of shear stress on the activation of various nuclear receptors, the plasmid constructs pCMX-GAL-L-hRXR α , pCMX-GAL-L-mPPAR α , HN-GAL-L-PPAR γ , or CMX-GAL-L-hLXR α were co-transfected with 5Gal-luciferase reporter construct, using the Eugene reagent (Roche). Twenty-four hours after transfection, the EC monolayers were subjected to shear stress or kept under static conditions for 6 hr. The cells were then trypsinized and resuspended in a buffer containing 0.6% NP-40, 0.1 M NaCl, 10 mM Tris-HCl, pH 8.0, 1 mM EDTA and incubated on ice for 20 min. After a further centrifugation, the luciferase activity was measured.

Nuclear extract and gel electrophoresis mobility shift assays were performed as previously described (2). The nucleotide sequence of the probe is as follow: 5'-GGGGTCAGTAAGTCAGAGGCCAGGGA-3' that contains the core PPAR γ responsive element (PPRE) in CD36 promoter. The binding level was quantified by scanning the autoradiograph, followed by densitometric analysis.

RESULTS AND DISCUSSION

We transfected ECs with plasmids containing the specific sequence of various ligand binding domains (LBDs) of PPAR γ , PPAR α , RXR, and LXR. Unidirectional shear stress of 12 dynes/cm² induced a 0.3-fold increase in the activity of the LXR LBD, 2.2-fold increase in the RXR-LBD, 1.6-fold increase in PPAR α LBD and 121-fold increase in the activity of the PPAR γ LBD, compared to static controls. Moreover, gel shift mobility assay demonstrated that the binding activity of nuclear extracts to the CD36 PPRE sequence, a specific binding site for PPAR γ , was already increased 2 hr after EC

exposure to a unidirectional flow (4 dynes/cm²) and the increased binding lasted for at least 24 hr. Taken together, these results suggest that unidirectional flow increases the production of ligands for PPAR γ in ECs, thus enhancing the expression of the PPAR γ -mediated genes such as CD36.

Figure 1: Laminar shear stress (12 dynes/cm²) induces the activation of the ligand-binding domain (LBD) of PPAR γ , PPAR α , RXR, and LXR (n=6).

SUMMARY

In this study, we find that laminar flow, the flow pattern characteristic of atherosclerotic plaque-free regions, highly increases the PPAR γ LBD activity with concurrent increased PPAR γ -mediated transcription activity. These results suggest the release of specific PPAR γ ligands in ECs induced by this flow pattern. The role of the unidirectional flow-activated PPAR γ in vascular biology remains to be determined.

A NON-INVASIVE APPROACH FOR MEASURING SAGITTAL BALANCE OF THE SPINE

Chriss Stanford, Michelle Marks, and Peter Newton
Motion Analysis Laboratory, Children's Hospital, San Diego, California
cstanford@chsd.org

INTRODUCTION

Accurate measures of spinal alignment are vital in making proper treatment decisions and evaluating surgery outcomes. Postural deformities such as adolescent idiopathic scoliosis (AIS) are often classified based on regional measurements, including kyphosis and lordosis. Global measures of spinal alignment, such as the sagittal vertical axis (SVA) are also necessary for thorough assessment of spinal balance. Though researchers have investigated non-invasive measurement methods for spinal curvature¹, no attempts have been made to develop a technique for measuring SVA without the use of a radiograph. The purpose of the present investigation was to validate a non-invasive procedure for estimating SVA.

METHODS

Fifteen adolescent females without spinal deformity received standing lateral radiographs, while the positions of markers on the skin overlying the spinous processes of C7 and L4 were monitored using an 8-camera motion capture system (Motion Analysis Corp., Santa Rosa, CA). SVA was measured on radiograph as the horizontal distance between the posterior superior corner of the sacrum and a vertical plumb line through the center of the C7 body. SVA was also calculated using the difference between coordinates of the markers in the anteroposterior direction (SVA_{virtual}), and anthropometric corrections ($C7_{\text{correction}}$, $L4_{\text{correction}}$) between the markers and anatomical points used for SVA measurement obtained on radiograph, as shown in Figure 1. For each subject, SVA was estimated with the following equation, using mean correction values for all subjects:

$$SVA = SVA_{\text{virtual}} \times MF + C7_{\text{correction}} - L4_{\text{correction}}$$

MF is the magnitude of image magnification on radiograph.

Predicted and measured SVA values were compared using a Pearson's correlation and intraclass correlation coefficient (ICC).

RESULTS AND DISCUSSION

Subjects had a mean age of 12.09 ± 1.9 years, a height of 156.6 ± 10.8 cm, and a mass of 45.0 ± 9.8 kg. Mean predicted SVA was -4.23 ± 2.4 cm, and mean SVA, measured on radiograph, was -4.18 ± 2.3 cm. There was a strong relationship ($r = 0.86$) and good agreement ($ICC = 0.93$) between measurement techniques. The average difference between predicted and measured SVA was 0.95 cm, with a range of 0.0 to 2.7 cm.

Mean difference in SVA between radiographic measurement and non-invasive estimation was less than 1 cm, despite considerable variability in subjects' height and mass. Though variability in anthropometric corrections was low between subjects, this technique was most accurate in estimating SVA in ectomorphic subjects. Thus, the non-invasive procedure may be particularly useful in the AIS population, where most female patients tend to be slender and repetitive radiographs are indicated.

Figure 1: Estimation of Sagittal Vertical Axis (SVA).

SUMMARY

Lateral radiographs must be obtained with the patient in an unnatural standing position, to allow for adequate visualization of the spine. This introduces variability in measurement of SVA². SVA can be effectively estimated using the non-invasive technique, as indicated by high correlations between calculated SVA and radiographic measures of SVA. The proposed method may be useful in reducing the number of repeated radiographic follow-up evaluations and allows a measure of SVA to be obtained with the patient in a functional position.

INTRODUCTION

Spasticity, one of the most common motor impairments associated with cerebral palsy, alters gait patterns in children with cerebral palsy, and, as the children age, gait degenerates (Johnson et. al., 1997). Treatments of botulinum toxin injections alone or strength training alone have previously shown to have positive impacts on gait in children with spastic cerebral palsy (Yang, 1999; Damiano & Abel, 1998). However, the effect of the two interventions coupled together has not been tested. The goal of this study is to contrast the effects of a combined botulinum toxin and strength training intervention versus strength training alone on the gait patterns of children with cerebral palsy

METHODS

A sample of six children (7-13 years) with spastic diplegic cerebral palsy who ambulate independently were selected for these preliminary results. Each child had at least 20 degrees of knee flexion bilaterally, with popliteal angles of no less than 40 degrees (first catch), and with no contraindication to botulinum toxin injections. Subjects were randomly assigned to the botulinum toxin plus strengthening group (BTX, 4 subjects) or to strengthening alone (STR, 2 subjects). For subjects in BTX group, injections were performed in the hamstring muscles using 8 units per kilogram, 60% to the medial hamstring and 40% to the lateral. Two weeks after initial data collection, all subjects were instructed in a program of wall slides for strengthening. All subjects received weekly phone calls to encourage compliance.

Clinical assessments of the children were obtained pre-intervention, at two weeks, and at completion of intervention (8 weeks) by a physical therapist who was blinded to group assignment. These measures included: (1) spasticity, determined through a Modified Ashworth Scale (MAS), (2) range of motion (ROM) at the hips, knees, and ankles, and (3) strength in the flexor and extensor muscles of the hips, knees and ankles using a dynamometer. Furthermore, prior to intervention and at the completion of intervention, gait kinematics were recorded in each of the subjects as they walked at their preferred speed four times along a 3.66m walkway. A six-camera (60Hz) Peak Performance Motion Motus Analysis System was used to capture the kinematic data, and sagittal plane hip and knee angles were calculated and filtered using a quintic spline. Further gait kinematic parameters, including step length and walking speed, were determined using a 60Hz GAITRite walkway mat.

RESULTS AND DISCUSSION

All subjects complied with the exercise program. Preliminary results suggest that subjects generally improved in knee
