Velocimetry studies at present are not capable of predicting thrombosis, but they can identify flow features conducive to thrombosis. Thus, whilst we are addressing the issue of haemodynamic characteristics of our test chamber, it would be possible to use this technique in its present form to act as a guide to regions for detailed flow investigation.

SUMMARY

An in-vitro milk clotting procedure is shown to result in clot formation in the same regions around mechanical valves as is thrombus in-vivo. Some evidence of additional clotting is also found. This test, perhaps conducted in conjunction with tests involving velocimetry (PIV or LDV), may provide a useful adjunct to animal trials for mechanical valves.

INTRODUCTION

Cavitation associated with mechanical heart valve closure can damage valve materials and blood elements and remains poorly understood mechanistically. Evidence of cavitation in vivo has been noted in the form of pitting on explanted mechanical valve occluders (Kafesjian et al., 1989) and through high frequency pressure signatures (Chandran et al., 1998). In vitro cavitation studies attempt to simulate the fluid mechanical environment of valves in vivo in order to determine the mechanisms of cavitation. There are, however, aspects of the in vivo environment that have not been adequately simulated in vitro. In particular, CO₂, the most soluble blood gas, is not normally present in blood analog solutions and the gaseous nuclei present in the test fluids have not been fully characterized. The current study focuses on cavitation studies in blood analog fluids with varying nuclei content that have been supplemented with CO₂ to illustrate the influence of dissolved gas on cavitation intensity in vitro.

METHODS

To assess mechanical heart valve cavitation associated with a Bjork-Shiley monostrut valve, a “single-shot” heart valve chamber simulating the left side of a natural heart was constructed as described in Kini et al. (2000). Cavitation energy was measured in the atrial chamber utilizing a 1 MHz high fidelity pressure transducer (PCB Electronics) while in the ventricular chamber a similar high fidelity pressure transducer was used along with a Millar pressure catheter. All transducers were suspended within 4 mm of the valve’s major orifice in their respective chambers. Visual evidence of cavitation was collected through the use of a KODAK Ultra-SR high-speed video camera at an acquisition rate of 3000 frames per second. Blood analog mixtures consisted of 40% glycerin and 60% water to mimic blood’s viscosity and density. The fluid nuclei content and dissolved gas concentration were varied using tap water and distilled water supplemented with various concentrations of carbonated water to elevate CO₂ concentrations to physiologic conditions and higher. A CDI 300 blood gas monitoring system (3M HealthCare) measured CO₂ and O₂ concentrations. All analog fluids were filtered at various cutoffs in the micron range, and nuclei counts were determined through the use of a Coulter Counter. An algorithm developed by Johansen et al. (2002) was employed to calculate the cavitation energy spectrum for a range of ventricular pressure gradients (dP/dt).

RESULTS AND DISCUSSION

Cavitation may be quantified by examining the energy spectrum associated with valve closure as well as by observing cavitation bubble formation and collapse visually. The energy spectrum associated with valve closure may be separated into a deterministic part driven by vibration of the solid mechanical structure of the valve, a signature of the valve, and a non-deterministic portion associated with the cavitation events. Our results show that the cavitation energy spectrum is sensitive to changes in CO₂ concentration and nuclei characteristics. Shifts at the low and high ends of the frequency spectrum (up to 1 MHz) were noted with changes in pCO₂ in the range 0 to 100 mmHg. With increasing pCO₂, low frequencies increase in magnitude while high frequencies are attenuated. This would appear to reflect a shift in the bubble size distribution toward larger bubbles that cannot be detected readily in video images. Preliminary results also suggest that nuclei density plays a role in the cavitation energy developed, but the nuclei size distribution is not well characterized.

CONCLUSIONS

To simulate cavitation in vitro special attention should be paid to the dissolved gas content, especially the CO₂ concentration that is not normally present in analog fluids in equilibrium with room air. Dissolved CO₂ can affect the energy distribution associated with cavitation and this could have an impact on both valve material and blood damage characteristics. Gaseous nuclei also play a vital role in the development of cavitation and should be characterized carefully in vitro. The nature of cavitation nuclei in blood in vivo remains poorly understood and thus it is difficult to properly simulate this critical factor in vitro at the present time.

MIXED-ELEMENT ALE METHOD FOR SIMULATION OF MECHANICAL HEART VALVE FUNCTION

Yong G. Lai¹ and K.B. Chandran²

University of Iowa, Iowa City, Iowa

¹IHR-Hydrosience & Engineering, yong-gen-lai@uiowa.edu

²Department of Biomedical Engineering

INTRODUCTION

The numerical simulation of heart valves is quite challenging as it demands a numerical model capable of addressing several difficult issues. Two approaches are often used for heart valve simulations: The Eulerian method and the arbitrary Lagrangian-Eulerian (ALE) method. The Eulerian method uses the fixed computational mesh in space while the motion of the leaflet is incorporated using several means. One popular Eulerian implementation is the fictitious domain method of Glowinski et al (1994). The analysis was based on the finite-element formulation and the imposition of velocity constraints for the moving boundaries through Lagrangian multipliers. The major uncertainty of the method is its accuracy – inadequate mesh representation for flows near the leaflet and when leaflet is near closure. The ALE method, on the other hand, has been quite popular in the heart valve simulation. The method allows the computational mesh to deform in space in an arbitrary way to conform to the leaflet motion, thus offers an accurate and general way of treating the flow near the moving leaflet. The major drawback of the ALE method is its need to incorporate a mechanism to adapt (or deform) the mesh to conform to the leaflet motion at each new time step. Therefore, the merit of the ALE method largely depends on the mesh adaptation procedure. Most previous studies used the structured mesh and the large motion of the leaflet made the mesh adaptation quite difficult.

METHODS

In this presentation, the mixed-element ALE method is proposed for the blood flow simulation within prosthetic heart valves. The method is based on the arbitrarily shaped element method of Lai (2000) for mesh representation and the ALE method of Lai and Przekwas (1994) for the leaflet motion. As discussed, the ALE method has many advantages and is the preferred method if mesh adaptation can be carried out easily and the mesh quality can be maintained. Previous models for the heart valve simulation used the structured grids (quadrilateral elements in 2D and hexahedral elements in 3D), which severely limited the success of the mesh adaptation and often led to poor mesh quality. The proposed mixed-element ALE method is intended to overcome these difficulties by using a more flexible mesh system. The objective is that the mesh adaptation can be carried out in a much-simplified manner while the required accuracy near the leaflet and at valve closure can be maintained.

RESULTS AND DISCUSSION

The proposed method is implemented and the mechanical heart valve closure dynamics in two-dimensional space is simulated as a verification and test of the proposed method. One sample mixed-element mesh is shown in Fig. 1 in which a quadrilateral O-grid is used to represent the near-leaflet flow while the rest of the domain is filled with the triangular elements. Such a mixed mesh has several desirable features for the simulation of heart valves. Firstly, the O-grid can rotate or deform together with the leaflets easily as the O-grid is not tied to the overall mesh topology. The remaining triangular elements are known to be naturally suited to adaptation. Secondly, the proposed mixed mesh provides much needed accuracy for the heart valve simulation: finer mesh can be used in the O-grid to resolve the flow near the leaflet and when leaflet is near closure. Such flexibility has been difficult with the Eulerian method in general, and the ALE mesh often leads to mesh distortion.

Figure 1: Mixed Element Mesh for Mechanical Heart Valves

The computed results will be compared to previously published results and the proposed method will be assessed for its success during the presentation.

HIGH-FREQUENCY PRESSURE FLUCTUATIONS MEASURED IN HEART VALVE PATIENTS

Hans Nygaard, Tina S. Andersen, J. Michael Hasenkam, Peter K. Paulsen
Department of Cardiothoracic and Vascular Surgery, Skejby Sygehus, Aarhus University Hospital, Denmark
nygaard@iekf.au.dk

INTRODUCTION

In contrast to bioprosthetic valves, mechanical heart valve patients require life-long anticoagulant therapy due to the risk of thromboembolic complications. The reason for this is still not fully understood. In vitro studies have demonstrated the presence of cavitation bubbles in the vicinity of mechanical heart valves, but not in the vicinity of bioprosthetic valves. When cavitation bubbles collapse, they release a significant amount of energy, which may damage the formed elements of the blood. Cavitation has been extensively studied in vitro and a correlation between the presence of cavitation bubbles and high-frequency pressure oscillations has been established in vitro. However, there is a lack of in vivo studies to confirm these findings thus, the aim of this study was to measure and quantify high-frequency pressure oscillations in patients with normal, bioprosthetic or mechanical aortic valves, using both invasive and noninvasive techniques.

METHODS

Measurements were performed in 10 patients with normal aortic valves after coronary bypass surgery, in 5 patients with a Carpentier-Edwards pericardial bioprosthesis implanted and 16 patients with a St. Jude Medical valve. High-frequency pressure fluctuations were measured intraoperatively using a hydrophone (B&K 8103) placed near the aortic annulus at the low aortic/left arterial junction. Simultaneously, blood pressure, heart rate, cardiac output and blood gasses (PO_2 and PCO_2) were registered. Postoperative measurements were performed on the 4th postoperative day using a specially designed "hydrophone in a water sound chamber" – transducer placed on the precordium in the left intercostal space 4, close to the sternum. The root mean square (RMS) value of the high-frequency pressure signals was calculated in the frequency range 50-150 kHz within 5 ms time windows. Data acquisition and signal analysis was performed by a dedicated LabView-program at a sampling rate of 500 kHz. The frequency distribution was evaluated with and without 50 Hz high-pass filtering using FFT.

RESULTS AND DISCUSSION

High-frequency pressure fluctuations with intensities significant above the noise floor were registered intraoperatively in the vicinity of only mechanical heart valve prostheses, and not in the vicinity of normal or bioprosthetic valves. The mean value of RMS pressure fluctuations was 2 Pa for normal aortic valves, 4 Pa for bioprosthetic valves and 61 Pa for mechanical valves. The corresponding RMS values for the postoperative measurements were 0.1, 0.2 and 3 Pa, respectively implying damping of the high frequency pressure

fluctuation through the thoracic tissue of about 30 dB. Female patients with mechanical heart valves had lower postoperative RMS-values compared to the male patients – probably because the transducer (11 cm in diameter) interfered with mammae, so the membrane could not in all cases fit closely to the skin.

During the intraoperative measurements the hydrophone was handheld by different surgeons, which could introduce some variations in the magnitude of the recorded pressure signals, because the distance to the valve is important.

The RMS values of the HFPP for all three patient groups measured intra- and postoperatively disclose a significant difference between the mechanical valves and the two control groups. Indicating that there is no cavitation in the vicinity of the biological or the genuine valves. In this study, the various hemodynamic parameters and valve size are correlated to the intraoperatively measured RMS values. In vitro studies have shown that larger valves generate more cavitation by evaluating the pressure changes during the valve-closing phase. In this study a correlation may be present between RMS values and valve size if the mean values are considered, where the larger valves give a larger mean RMS values. Though, it would need further elaboration before any firm conclusions can be drawn. No relation was found in regard to blood pressure or blood gasses either.

HFPP can be due to natural mechanical resonance and cavitation. When the highest frequencies for the mechanical resonance are known, a high-pass filtering of the signal makes it possible to remove the natural resonance, extracting the signal due to cavitation. The chosen high-pass filtering in this study is 50 kHz. In vitro studies have shown that the mechanical resonance may reach frequencies above the 35 kHz that has been used in other cavitation studies. By using 50 kHz, most of the natural mechanical resonance components in the recorded signal were removed. However, as the resonance frequencies and cavitation frequencies overlap a small part of the cavitation signal would be removed as well. This study cannot with certainty establish whether the recorded signals are due to the mechanical resonance, cavitation or both. It is assumed, however, that most of the energy in the signals above 50 kHz is due to cavitation based on previous studies.

SUMMARY

High-frequency pressure fluctuations are present in the vicinity of mechanical aortic valves and can be measured in patients both invasively and non-invasively. This phenomenon is not present in patients with either normal or bioprosthetic aortic valves.

EVALUATION OF BILEAFLET MECHANICAL HEART VALVE INDUCED BLOOD DAMAGE DURING LEAKAGE FLOW USING LASER DOPPLER VELOCIMETRY AND INDICATORS OF PLATELET ACTIVATION

INTRODUCTION

Mechanical heart valves (MHVs) are far more durable than bioprosthetic alternatives; however, patients with mechanical heart valves are predisposed to thromboembolic disorders and must undergo lifelong anticoagulation therapy. Despite this therapy, some patients still develop thromboembolic complications. The exact cause of these complications is unknown, but they could be due to the design of bileaflet MHVs, which includes some degree of leakage flow upon valve closure in order for the reverse flow to wash the hinge/pivot region of the valve. It is believed this reverse flow helps prevent areas of stasis and inhibit micro-thrombus formation. However, the magnitude of this retrograde flow may also give rise to unacceptable levels of blood element damage and lead to platelet activation and/or hemolysis, as a result of the increased flow velocities through the hinge region. In two separate studies, bileaflet MHVs have been evaluated using laser Doppler velocimetry (LDV) and indicators of platelet activation in blood during leakage flow through a MHV. LDV was used to analyze the blood flow patterns during leakage flow and to quantify the shear stresses and velocities of the flow. Platelet activation indicators were used to determine the effects of hinge design on platelet damage.

METHODS

For the LDV experiments, two-dimensional laser Doppler velocimetry was used to measure the velocity and turbulent shear stress fields in the hinge regions. In order to conduct these measurements, exact dimensional models of the bileaflet hinge regions were cast and/or machined from transparent plastic materials. The experiment was conducted in a pulsatile flow loop with the measurement taken at different levels within the pivot and hinge regions.

For the blood studies, a centrifugal pump was used to drive whole, human blood anticoagulated with PPACK through a circuit containing various MHVs in the closed position for the experimental runs or a MHV in the open position for the control runs. Samples were taken at set time intervals after the start of the pump. These samples were analyzed by cell counting and flow cytometry to quantify the presence of annexin V and platelet factor 4 binding. Annexin V binding indicates the presence of anionic phospholipids on cell surfaces, which indicate cell damage. By isolating the platelet population before and at various intervals during the test, it is possible to determine the percentage of platelets that are damaged throughout the experiment. In a similar fashion, platelet factor 4 indicates the degree of platelet activation.

RESULTS AND DISCUSSION

In the LDV experiments, the velocity and shear fields were animated in order to visualize the flow structures within the hinge regions. Animations at the flat level revealed that certain designs created areas of stasis throughout the cardiac cycle, while others such as the Regent valve had very good wash out. Shear stress measurements revealed that certain hinge designs caused elevated levels of turbulence (>3000 dyne/sq.cm) that could cause platelet activation and/or hemolysis.

In the blood experiments, it was found that leakage through the MP design caused 17% more secretion of platelet factor 4 and 14% more anionic phospholipid expression on platelet surfaces than the SJM Standard design after two hours of run time. The effect of pivot gap width was shown by using a SJM 27 Standard valve, High Leaker valve, and Low Leaker valve. The results were that leakage through the High Leaker valve caused 25% more platelet factor 4 secretion than the Standard valve. In addition leakage through the High Leaker valve caused 96% more platelets to be positive for expression of anionic phospholipids and significantly more anionic phospholipid exposure on platelet surfaces than leakage through the SJM Standard valve at all sampling times after 5 minutes.

The LDV studies clearly demonstrate that the actual design/shape of the hinge/pivot region influences the degree of washing, the levels of turbulent shear stresses and/or unsteadiness within the hinge. Such micro flow field studies are critical to clinical outcomes and should be conducted in the pre-clinical evaluation phase of all new MHV designs.

The blood studies indicate that bileaflet valve leakage flow causes significant platelet disruption. Also, although pivot design was not shown to result in a significant difference in secretion of platelet factor 4 or anionic phospholipid expression, gap width did have a significant effect on platelet damage. The leakage flow rate through the High Leaker is twice the leakage flow rate through the SJM Standard valve. Increasing leakage flow rate exposes more blood to the stresses encountered during leakage flow. Leakage gap width also influences the likelihood for turbulence in the jets created by flow through the pivots.

Although these studies were performed independently, the advantages of using them together is evident. LDV is able to pinpoint the locations at which Reynolds stresses exceed the limit for blood damage, and platelet activation indicators can determine whether or not blood damage has occurred.

STRETCH-AND-FOLD FRACTAL-LIKE AEROSOL BOLUS SPREADING IN THE RHYTHMICALLY EXPANDING ALVEOLATED DUCT

Akira Tsuda¹, James P. Butler¹, and Frank S. Henry²

INTRODUCTION

In current theories, transport of submicrometer aerosols in the pulmonary acinus is described as a dispersive (diffusion-like) process in the context of reversible alveolar flow. Recent experimental data, however, have questioned the validity of the basic assumptions -kinematically reversibility of acinar flow- that formed the basis of the dispersive theories. The objective of this study was to demonstrate through numerical simulation of bolus experiments that the behavior of particles in a cyclically ventilating alveolar duct and multiple alveolus is not consistent with the predictions of any dispersive theory characterized by an effective diffusivity.

METHODS

We developed a computational fluid mechanics model with rhythmically expanding and contracting multiply-alveolated walls. Geometric model: The model comprised a closed-end central circular channel around which are placed nine tori, equi-spaced in the axial direction, representing the alveoli. The duct and alveolar walls move in a perfectly kinematically reversible, simple sinusoidal manner with a specific volume excursion of 25% and a cycle period of 3 seconds. Flow solver: The flow field was defined by the full, incompressible, Navier-Stokes equations with no-slip condition on all solid surfaces, which are solved numerically on a multi-block, body-fitted, moving grid using the finite volume code CFX-4 (CFDS, AEA Technology, Harwell, UK). Lagrangian particle tracking: Approximately 16,000 massless particles were placed on radial line across the central channel midway between alveoli. Regarding these massless tracer particles as marked fluid elements, this line of particles represents the front of incoming tidal gas or a tracer bolus facing the host alveolar residual gas. The behavior of the tracer was tracked over the first few cycles.

RESULTS AND DISCUSSION

Similarly to our previous study performed in the single-alveolus model (Tsuda, et al., 1995), the results showed that the acinar flow patterns become highly complex if the walls are not stationary (i.e., expand and contract). There are stagnation saddle points near the alveolar openings that are associated with slow alveolar recirculation. Lagrangian tracking of fluid particles indicated that the fluid motion exhibited unpredictable and irreversible stretched and folded patterns, characteristic of chaotic flow (Ottino, 1989). To quantify the extent of axial spreading of the tracer, we analyzed the cycle-by-cycle evolution of the variance (σ^2) of axial particle distribution. We found that σ^2 increased exponentially, rather than linearly, with increasing cycle number (i.e., time). This demonstrates that axial bolus spreading in the acinar duct does not follow the basic additive

of variance, which is characteristics of classical dispersive transport theories (Taylor, 1953). Further analysis on tracer pattern showed the following remarkable phenomena. As the tracer sampled irreversible multiple alveolar fields, the shape of the tracer progressively evolved into “finger-like” protrusions located especially near the duct walls. Each protrusion consisted of complex stretched-and-folded patterns, and moreover, as the scale became finer, similar and finer stretched-and-folded patterns were revealed. Thus, the observed patterns seemed to be at least qualitatively self-similar over a wide range of length scales. Such self-similarity is characteristic of fractal geometry which is often observed in many chaotic systems (Mandelbrot, 1982). Indeed, fractal analysis with the method of box counting technique (Sommerer, 1994) revealed that the distribution of tracer particles evolved in a fractal-like manner, with a fractal dimension of $D \approx 1.2$. The fact that the tracer pattern exhibited fractal characteristics is not entirely surprising since the origin of particle irreversibility is due to chaotic alveolar flow and deterministic chaos often manifests a fractal geometry (Sommerer, 1994). It is important and remarkable, however, that the observations in these simulations are strikingly similar to findings in animal experiments. These similarities strongly suggest that the numerical simulations – though they were based on highly idealized assumptions – captured the fundamental features of the underlying mixing mechanism, namely that low Reynolds number chaotic flow in the acinus determines particle transport in the lung.

SUMMARY

The results suggest that (i) kinematic irreversibility is the origin of aerosol transport, (ii) axial transport cannot be characterizable by an effective diffusivity, and that (iii) fractal trajectories can occur, in most of the alveoli in the acinar tree. The alternative mechanism of aerosol transport that we propose here may in fact be the dominant mechanism determining deposition of submicron particles deep in the lung.

mshimizu@mei.titech.ac.jp

INTRODUCTION

Respiration is attained despite small tidal volume breathing and large dead space in the trachea. Uneven inner surface configuration by cartilage of trachea may influence on the effective diffusivity. Ye had reported augmentation of diffusion by oscillatory flow of water in a lateral grooved tube. Measurements of CO₂ concentration in the oscillatory flow in tubes with several groove widths have been carried out.

METHODS

Inner diameter of the test tube was 18mm, and inner surface configuration was composed by combination of aluminum rings with rectangular cross section as shown in figure 1. Depth of the groove of each configuration was 2mm and Bottom width and top width of it are described in table 1. Total length of the test tube was 3025mm, consisting of the part from the entrance to injecting point of 1260mm and from there to sensing point of 500mm, and further 1265mm to the open end. Oscillatory flow was generated by piston($\phi 50$) connected with a reciprocating block double slider-crank mechanism driven by AC servomotor. CO₂ gas was injected simultaneously with the lower dead point of the piston. Non-dispersive infrared analyzer measured CO₂ concentration.

Figure 1: Inner surface configuration along the grooved tube.

RESULTS AND DISCUSSION

Values of $(D_{eff}/D_{mol}-1)/(V^2/a^6)$, where D_{eff} is effective diffusivity, D_{mol} is molecular diffusivity, V is stroke volume and a is the inner radius of the tube, are shown in figure 2. The difference between the effective diffusivity obtained and the theoretical one in the oscillatory flow in a straight tube is increasing with the increase of Womersly number. As for the bottom width of the groove, wide width of groove gives relatively large augmentation on the effective diffusivity.

Figure 2: Evaluation index derived from non-dimensional effective diffusivity and non-dimensional stroke volume. Solid curve indicates the theoretical value for laminar flow in a straight tube.

SUMMARY

The effective diffusivity of CO₂ in oscillatory flow along tubes with the lateral grooves has been measured. The difference between the effective diffusivity through the lateral grooved tube and one through the smooth straight tube is increasing with the increase of Womersly number. The effective diffusivity is more augmented by each inner surface configuration with the increase of the width of the groove within the region of the present experimental condition.

MODELING THE INTERSUBJECT VARIABILITY OF OZONE UPTAKE INTO HUMAN AIRWAYS

Gregory Zugates¹ and James Ultman²

¹Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, MA

²Department of Chemical Engineering, Penn State University, University Park, PA, jau@psu.edu

INTRODUCTION

Ozone (O₃) is an inhaled air pollutant that causes decrements in pulmonary function and promotes airway inflammation. These health effects are variable among different individuals, making some people particularly susceptible to O₃ exposure (e.g., McDonnell *et al.*, 1995). One source of this intersubject variability in physiological response is a corresponding variability in O₃ dose. The hypothesis of the current study was that variations in O₃ dose between subjects occur because of differences in breathing patterns (*i.e.*, frequency and tidal volume). This hypothesis was tested by comparing mathematical simulations of O₃ transport to measurements of O₃ uptake performed on human subjects under four different short-term exposure conditions.

METHODS

In the experiments, ten healthy adult nonsmokers inhaled an ozonated air mixture through an oral mask while exercising continuously on a cycle ergometer. Each subject participated in four sessions with respective O₃ concentrations, workloads, and durations as follows: A) 0.4 ppm, light, 1 hour; B) 0.4 ppm, moderate, ½ hour; C) 0.2 ppm, light, 1 hour; and D) 0.2 ppm, moderate, ½ hour. In each session, O₃ concentration and respiratory flow was continuously monitored by instruments positioned at the oral mask, and fractional uptake of O₃ (FU) was determined on a breath-by-breath basis as the ratio of O₃ uptake to the amount of O₃ inhaled. Further details can be found elsewhere (Rigas *et al.*, 2000).

In the simulations of FU, the airways were modeled as a single conduit of expanding flow cross-section and surface-to-volume ratio. Transport along the airways occurred by bulk flow and longitudinal dispersion. Lateral uptake was governed by an overall mass transfer coefficient that accounted for convective diffusion in the gas phase and reactive diffusion in mucus. Respired flow was modeled as a rectangle wave such that breathing pattern could be defined in terms of frequency and minute volume (MV). Whereas these ventilation parameters were specified from experimental measurements of each breath, anatomical and transport parameters were fixed at values previously found for this model (Bush *et al.*, 2001).

RESULTS AND DISCUSSION

FU data were obtained for each subject from about 70 breaths in each of sessions A and C and 35 breaths in each of sessions B and D. These breath-by-breath FU values were then averaged for each person within each session (Fig. 1). The

resulting subject-average FU values were averaged across all subjects to obtain a session-average FU and its variance (σ^2) for each of the four exposure conditions (table 1).

Figure 1: Intersubject Variability Grouped by Session

Simulations of FU were obtained for each individual breath and were then averaged across breaths and across subjects to obtain session-average FU and σ^2 values (table 1). In comparison to the measurements, the simulations systematically overpredicted FU by about 5%. Variances in the simulated FU induced by the breathing pattern explained about 50% of the intersubject variances observed in the data. The unexplained portion of the variances may be due to intersubject differences in anatomy and mucus chemistry not yet included in the diffusion model.

Table 1: Distribution of Subject-Average FU

Session	Ave. FU (meas.)	σ^2 (meas.)	Ave. FU (simul.)	σ^2 (simul.)
A	0.8465	0.0028	0.9053	0.0018
B	0.8754	0.0016	0.9334	0.0005
C	0.8563	0.0020	0.9132	0.0012

ANATOMICALLY BASED MODELS OF GAS FLOW AND GAS EXCHANGE IN THE HUMAN LUNG

Merryn Tawhai and Peter Hunter

Bioengineering Institute, The University of Auckland, Auckland, New Zealand
m.tawhai@auckland.ac.nz

INTRODUCTION

An anatomically based model of the human lung airways and vasculature is being defined as part of the Lung Physiome (<http://www.bioeng.auckland.ac.nz/physiome/physiome.php>). The airway model includes a 60,000 element description of the conducting airways, terminating in lumped parameter acinar models. The lumped parameter models are targeted to specific function, with parameters derived from simulations in anatomically detailed respiratory airway models (Tawhai and Hunter, 2001a). Similarly, the pulmonary vasculature is modeled at the whole organ scale with a branching finite element network and coupled to lumped parameter models of the capillary bed, where these are based on a detailed model of blood flow and gas exchange at the alveolar level. The airways and blood vessels are coupled to a 3D finite deformation soft tissue model of the lung parenchyma.

METHODS

The conducting airway and large blood vessel models are generated into an accurate volume mesh of a human lung, using a bifurcating-distributive algorithm (Tawhai et al., 2000). The algorithm has been customized to generate branching trees with geometric properties similar to the real lung. The pulmonary acinus is modeled as an asymmetric bifurcating mesh, with mean dimensions from Haefeli-Bleuer and Weibel (1988). The alveolar structure is modeled using a Voronoi mesh that fills a given volume, with faces removed to form alveolar ducts, alveoli, and sacs. A capillary network is texture mapped to each alveolus, using a 2D Voronoi network generated over a $\frac{3}{4}$ sphere as the generic capillary mesh.

Advective-diffusive transport equations for relatively inert gases are integrated over the cylindrical airway cross-sections (Tawhai and Hunter, 2001a), and are solved using a Lagrangian Finite Element method. This solution can be applied at the acinar level through coupling of a detailed acinar model and a symmetric conducting airway model, or at the whole lung level through coupling of the detailed conducting airway model and lumped parameter acinar models.

By embedding the conducting airways in a soft tissue deformation model of the lungs, breath-like boundary displacements of the lungs can be solved to produce mechanically-coupled pressure fields in the respiratory zone. These pressures provide boundary conditions for solution of Navier Stokes equations to describe the air distribution. Similarly, blood flow in the large vessels is described by solution of Navier Stokes equations with pressure boundary conditions at the pulmonary artery and vein, and a lumped parameter model of pulmonary capillary pressure changes.

RESULTS AND DISCUSSION

Figure 1: Asymmetric conducting airway model.

Almost all respiratory disorders result in an impairment of gas exchange, often through some effect on ventilation-perfusion matching. A predictive model that is capable of investigating these complex interactions must include detailed structural information (geometry, tissue properties) and the ability to couple different processes over a range of spatial scales (air flow, blood flow, tissue mechanics, gas exchange).

We have developed structural models based on detailed anatomy, then have identified simplified forms of the detailed models to facilitate their coupling to large-scale structural and functional models. For example, the coupled airway model has been used to investigate the effect of conducting airway asymmetry on gas mixing (Tawhai and Hunter, 2001b) utilizing a hierarchy of airway models. The study highlighted the importance of accurately representing airway structure at both the conducting and respiratory level, and the need to couple gas mixing models to accurate solutions of airflow distribution.

Models of airway and vasculature smooth muscle at both the cellular and tissue levels are being developed to include in the anatomically based lung models described above. This hierarchy of models at several spatial scales (cell, tissue and organ) has the potential to provide a link from the level of protein expression to whole organ function.

A MODEL OF VENTRICULAR ANATOMY BASED ON STRUCTURAL MEASUREMENTS FROM PIG HEARTS.

Carey Stevens, Ian LeGrice, Bruce Smaill and Peter Hunter
Bioengineering Institute, The University of Auckland, Auckland, New Zealand
c.stevens@auckland.ac.nz

INTRODUCTION

Models of ventricular mechanics have been developed over the last 20 years to include finite deformation theory, anisotropic and inhomogeneous material properties and an accurate representation of ventricular geometry. Anatomically based models of dog and rabbit heart have been developed previously (Le Grice et al. 1997, Vetter 2000) but since the pig is now the preferred large animal model for many physiological studies we have recently measured and modeled the geometry and fibrous-sheet structure of the pig myocardium using the finite element techniques and data fitting algorithms reported in Hunter et al. (1997). Material properties were also measured using a purpose-built shear testing rig to complement earlier measurements with a biaxial rig. Stress and strain distributions throughout the cardiac cycle were then determined using the anatomical model together with finite deformation elasticity theory and ventricular pressure boundary conditions.

METHODS

A finite element model of the left and right ventricular myocardium in rectangular Cartesian coordinates was developed with tri-cubic Hermite basis functions (Hunter et al. 1997). Geometric measurements from the potassium arrested pig hearts were obtained with the cylindrical polar measurement rig described previously (Nielsen et al. 1991) and with a Faro Arm (Faro Technologies Inc) which allowed more accurate measurements around the base and apex of the heart. Fibre orientation measurements were obtained by shaving layers off the heart in the measurement rig, as previously reported for canine myocardium (Nielsen et al. 1991). Sheet orientations were obtained by cutting and drying 100 μ m transmural base-apex segments then using digital image analysis to quantify the sheet orientations as previously reported (Le Grice et al. 1997).

RESULTS

The model captures the anatomy of the basal and apical regions of the heart more accurately than any previous model. Figure 1 shows a crosssection of the apex and Figure 2 shows the fitted model geometry and fibre fields.

Figure 1: A sagittal cross-section of the left ventricular apex.

Figure 2: Fitted geometry and fibre fields. The left ventricular endocardium (left) and the complete pig heart model (right).

APPLICATION OF MODEL

The material properties of pig myocardium were also determined by mounting 5mm cubes in a purpose-built rig and loading the blocks in shear at various states of compression (Dokos, 2001). The shear behaviour was successfully fitted with the “pole-zero” law and the active myofilament properties were based on the HMT model (Hunter, McCulloch and ter Keurs 1998). The passive and active constitutive laws are referred to the anisotropic fibrous structure of myocardium and the tissue is assumed to be incompressible. Three-dimensional finite deformation, finite element analysis was used to determine the stress and strain fields during diastolic pressure loading and systolic contraction using methods reported in Nash and Hunter (2000).

INTRODUCTION

We have developed a system for measuring regional mechanics and spatially registered epicardial potentials in the canine heart.

METHODS

In the MR scanner, tagged cine images and nearly simultaneous electrograms and LV pressure recordings can be acquired for sinus rhythm and different pacing schemes. Unipolar electrograms are recorded at 1 kHz from an epicardial sock. MR tagging is performed on a GE Signa CV/i 1.5 Tesla scanner yielding movie sequences with a time resolution of 12-15 ms, 1.25 x 1.25 mm pixels, 7-pixel tag spacing. The trigger to begin MR scanning was delivered 40-80 ms prior to the ventricular pacing stimulus or simultaneous with the RA pacing stimulus so that the image sequence included the onset of mechanical shortening. After imaging is complete, the animals are euthanized and a T1-weighted scan is obtained in order to locate Gd-DTPA beads sewn onto the electrode sock for registration of the electrodes with the MR data.

Figure 1: Example short (super-imposed stripes) and long axis images (RA pacing) showing tag deformation characteristic of asynchronous contraction, and example electrograms from the epicardial sock (LV pacing).

After imaging, hearts are excised and electrode and bead locations are digitized using a 3D digitizer (Microscribe, 3DLX). Electrograms are correlated spatially to the MR

images by registration of the bead coordinates and all data is referenced in time to the pacing stimulus. Tag locations are segmented using two in-house programs: XBS¹ and Findtags².

The motion of the myocardium is modeled using a 4D B-spline tensor field with 7x7x7 control points in the volume containing the heart and 20 to 30 control points in time³. 3D strain is calculated through time over a subepicardial surface, and at points corresponding to electrode locations. Electrical activation times (minimum dV/dt) are evaluated for electrode signals from each pacing protocol and used to make maps of electrical activation.

RESULTS

The existence of the electrode sock around the heart does not interfere with the MR image quality to a significant degree. Clean electrical signals are also available even with the long cable runs from the MRI control room to the scanner. Spatially registered maps show an excellent correlation between the spatio-temporal pattern of mechanical activation and the electrical activation in the normal heart under different pacing conditions.⁴ Specific definitions of “mechanical activation time” derived from the local myocardial deformation are now being explored.

CONCLUSIONS

A measurement system now exists for examination of the electromechanical behavior of the heart in vivo. The change in this relationship under different conditions is now under investigation.

PRINCIPAL COMPONENT ANALYSIS OF CARDIAC FUNCTION

Kevin F Augenstein and Alistair A Young

Departments of Engineering Science, Anatomy and Physiology, University of Auckland, Auckland, New Zealand

INTRODUCTION

Heart wall motion can be efficiently and accurately estimated from magnetic resonance (MR) tagged images using finite element models of ventricular shape and motion [IEEE]. However, statistical analysis of the resulting deformation fields is a unsolved problem. We show how the model parameters from a number of subjects can be directly incorporated into a principal component analysis (PCA) of the dominant modes of shape and motion. This allows a statistical characterization of subpopulations of healthy and diseased subjects and may allow further understanding of the mechanical effects of disease and remodeling processes.

METHODS

Tagged MR images of fifteen normal volunteers were analyzed with a four by four element mesh using the methods described in [1]. The model parameters were converted into 3D Bezier control points which completely describe the shape of the LV at each time point. The location of these points can be regarded as consistent between subjects due to the automated process in which the models are registered to each subject.

Let \mathbf{U} be a vector of model parameters describing a subject's LV shape at end-diastole (ED) and end-systole (ES). We use a frame-wise ordering system in which all the ED parameters are followed by all the ES parameters. These vectors can be placed in a data matrix, \mathbf{X} , in which each row, \mathbf{X}_i , of the data matrix contains a separate case at ES and ED (i.e. $\mathbf{X}_i = \mathbf{U}_i^T$). The difference between each subject and the mean is

$\delta_i = \mathbf{X}_i - \bar{\mathbf{X}}$ and the covariance matrix of the model parameters is $C_{ij} = \frac{1}{n} \delta_i \cdot \delta_j$ where n is the number of

subjects in the database. The principal modes of variation are found using the eigenvalue decomposition $\mathbf{C} = \mathbf{P} \mathbf{\Lambda} \mathbf{P}^T$ where $\mathbf{\Lambda}$ is a diagonal matrix of eigenvalues and \mathbf{P} is an orthonormal matrix of eigenvectors. Assuming the modes are normally distributed about zero, each row of \mathbf{P} describes the shape variation of the mode while the corresponding eigenvalue is the associated variance. The resulting (orthogonal) modes and variances describe the statistical variation present in the database. Similar formulations have been used previously in the construction of point distribution models [2].

RESULTS

The strength (variation) in each mode drops rapidly with the mode number, with approximately 6 modes containing most of the variation in the distribution. The modes obtained contain information about ED shape as well as deformation from ED

to ES. To visualize the deformation separate from the initial geometry, we performed a PCA of the difference between the ED and ES parameters.

Figure 1: First three modes of variance in the ES shape after performing a PCA on the displacement parameters. The shapes have a common mean ED shape and the middle column is the mean displacement from that shape.

The first mode appears to vary the twist at the apex, the second the position of the base (i.e. longitudinal shortening) and the third mode appears to signify the size of the cavity (and therefore the ejection fraction and circumferential shortening).

SUMMARY

PCA describes heart motion with a small number of parameters (modes). Although the fitted models have hundreds of parameters, by using PCA on a training set we hope to distinguish the modes which truly differentiate the hearts, and remove the modes that are insignificant. A new heart model could be compared with the database distributions to see if statistical evidence of abnormal function exists.

INTRODUCTION

Numerical models of cardiac electrophysiological and mechanical mechanisms may be of great help to understand the consequences of various pathologies related to cardiac failure. In the present study we investigated the timing between moment of electrical depolarization and onset of myofiber shortening using integrated finite element models of electrical depolarization and mechanics in the normal canine left ventricle (LV) and compared the results with measurements from literature.

METHODS

In the reference state, when transmural pressure is zero, the LV is represented by a thickwalled truncated ellipsoid (Bovendeerd, 1992) and a realistic myofiber distribution (Rijcken, 1999).

The spatial variation of electrical activation is computed by the solution of a transversely isotropic eikonal-diffusion equation (Colli-Franzone et al, 1990; Tomlinson, 2000). The calculated moments of electrical activation are used as moment of onset of active stress generation.

LV mechanics is computed by solution of the momentum equation. Passive material was modeled nonlinearly elastic, transversely isotropic, and virtually incompressible. Active stress is generated in the fiber direction, depending on myofiber strain, strain rate and time (Arts, 1982). LV afterload during ejection is computed using a 3-element Windkessel model.

RESULTS

Figure 1 shows the results of a simulation for the LV depolarization wave during sinus rhythm for a dog. The results are well in agreement with measurements of Scher et al (1953). Figure 2 shows global hemodynamics during the cardiac cycle.

Onset of myofiber shortening as a function of electrical depolarization time from simulations and measurements are plotted in figure 3. Applying linear regression, a slope of 2.5 is found from the simulations. Wyman et al (1999) found a slope of 1.06 in their MRI tagging experiments in dogs.

DISCUSSION AND CONCLUSIONS

Simulation of electrophysiological conduction and mechanics yields results, which are in agreement with experimental results. However, when linearly relating timing of electrical activation and onset of myofiber shortening, the slope in the simulation differs from the slope in the experimental results. We conclude that the coupling of electrical activation to the

moment of mechanical activation is insufficiently described by the current knowledge on excitation contraction coupling, as included in the model.

ASYNCHRONOUS ELECTRICAL ACTIVATION IN A THREE-DIMENSIONAL MODEL OF CARDIAC ELECTROMECHANICS

Taras P. Usyk and Andrew D. McCulloch

Department of Bioengineering, The Whitaker Institute for Biomedical Engineering, University of California, San Diego
La Jolla, CA 92093-0412, USA, e-mail: amcculloch@ucsd.edu

INTRODUCTION

Asynchronous electrical activation, induced by an ectopic focus or ventricular pacing, can cause abnormalities in perfusion and pump function and, when chronic, can lead to asymmetric ventricular hypertrophy. These may be caused by local abnormalities, such as heterogeneity in regional workload and shortening.

Assessing the magnitudes of regional myocardial work requires knowledge of regional myofiber stress and strain. While some variables, such as regional strains and epicardial activation patterns have been measured in the intact heart (Wyman et al., 1999), practical experimental methods for mapping three-dimensional distributions of other important variables such as stress, strain energy, or transmembrane potential are still not available.

To investigate the mechanical effects of altered cardiac activation sequence, associated with external pacing or conduction abnormalities, it is necessary to integrate the biophysics of ventricular myocytes and realistic mechanical properties of myocardial tissue into detailed three-dimensional models of the ventricular walls during the whole cardiac cycle, using realistic anatomic, morphologic, and constitutive properties of myocardial tissue.

METHODS

A three-dimensional model of canine left and right ventricular anatomy with detailed myofiber and sheet architecture was based on measurements in the canine heart (Nielsen et al., 1991). We added a model of the Purkinje fiber network as an anisotropic, non-homogeneous, two-dimensional continuum, based on measurements in the dog heart (Pollard et al., 1990; Usyk et al., 2002). Finite element equations for time-dependent excitation and recovery variables were assembled using a collocation finite element method (Rogers et al., 1994) and solved using adaptive Runge-Kutta integration with pacing from the His-Purkinje bundle, left ventricular free wall or right ventricular wall. The computed activation time was used to trigger regional mechanical contraction following constant delay. The model also included length-, time- and calcium dependent active contractile stresses with transverse active stress components. A Windkessel model for arterial impedance was coupled to ventricular pressure and volume to compute the hemodynamic boundary conditions. Ventricular cavity volume constraints were imposed during the isovolumic phases (Usyk et al., 2002).

RESULTS AND DISCUSSION

Electrical propagation velocities obtained from the model were 2.36, 0.48, 0.18 m/s along Purkinje fibers, along ventricular muscle fibers and transverse to muscle fibers, respectively, consistent with experimental measurements. Using the model to compare the mechanical effects of pacing from left and right ventricular sites, close agreement was obtained with spatio-temporal distributions of three-dimensional strain observed experimentally in dogs by Wyman et al (1999) using tagged MRI.

Computed strains show that the tissue shortened rapidly at the early activated regions and shortening was preceded by prestretching of the tissue. This prestretching was a result of passive stretching of the late-activated regions in response to the contraction of the tissue activated earlier. Contraction in the prestretched regions did not begin until a delay about 40 ms after the earliest activation time.

External work was very small (or even negative) at the pacing site and increased up to twice that normal values in regions remote from the site of pacing.

SUMMARY

These results suggest that a coupled model of ventricular electromechanics could be useful for investigating the mechanical consequences of different pacing protocols in patients with conduction abnormalities. The computational techniques developed for the model provides a foundation for more biophysically detailed models.

CYCLE-INDUCED FLOW AND TRANSPORT IN AN ALVEOLUS FOR PARTIAL LIQUID VENTILATION

Hsien-Hung Wei and James B. Grotberg

Department of Biomedical Engineering,
University of Michigan, Ann Arbor, MI 48109-2125, USA.
E-Mail: grotberg@umich.edu

INTRODUCTION

The flow and transport in an alveolus are of fundamental importance to partial liquid ventilation, surfactant transport, pulmonary drug administration, and potential delivery of genetic material into the lung. We propose two simplified models for alveolar liquid undergoing cyclic stretching which mimics breathing motions.

METHODS

When the fluid layer is thin compared with the size of an alveolus, we model the system as a two-dimensional extensible slot. The presence of insoluble or soluble surfactants is considered. See Figure 1(a). We apply scaling analysis and asymptotic theory to describe the interface profile and surfactant distribution during the oscillation cycle for either insoluble or soluble surfactants.

We also model the case when the liquid is partially filled in the alveolus and has a comparable thickness to the size of the alveolus. See Figure 1(b). The surfactant-free case is first investigated. By assuming a spherical interface due to small capillary number, we solve the Stokes flow analytically in the toroidal coordinate system.

Figure 1: Alveolar models for (a) thin fluid layer (b) thick fluid layer. Red lines are the alveolar walls. Blue shading indicates fluid layers.

For the thin fluid layer case, Figures 2 show typical non-zero cycle-averaged flows for both insoluble (Fig. 2(a)) and soluble surfactants (Fig. 2(b)). For insoluble surfactants, the upper (lower) portion of the fluid tends to the extensible end (pinned end). However for a soluble surfactant with higher solubility, the stream pattern is different. Their turning directions near the pinned wall depend on the parameters of the system.

Figure 2: Cycle-averaged streamlines for thin layer model with (a) insoluble (b) soluble surfactants.

For the thick layer case, sufficiently large liquid volume the flow leads to re-circulations near the alveolar opening. This preliminary model, without surfactants, shows no steady streaming due to the reversibility of the Stokes flow. However it is anticipated that adding surfactants will lead to non-reversible Marangoni stresses that will cause steady streaming.

RESULTS AND DISCUSSION

COVARIANCE AMONGST RESPONSE TERMS WILL MAGNIFY THE EXPERIMENTAL ERROR THAT IS INHERENT IN MECHANICAL TESTS ON MYOCARDIUM

John C. Criscione

Department of Biomedical Engineering, Texas A&M University, College Station, Texas, USA
<http://biomed.tamu.edu/faculty/Criscione/>

INTRODUCTION

In the cardiome and similar projects that try to bridge the knowledge gap between myocyte physiology and heart mechanics, it is helpful to characterize myocardium as a continuum. Toward this end and as a graduate student in the lab of Dr. William C. Hunter at Johns Hopkins, this author began a series of extension and torsion tests on papillary muscles with the hopes of further defining the constitutive properties of myocardium. Using a conventional elasticity framework (Humphrey et al., 1992), however, there was tremendous error (> 100% of the mean values) in our response function calculations with much variation amongst specimens.

Upon further analysis it became evident that conventional elasticity theories themselves are excessively sensitive to experimental error for high-strain materials. We have become accustomed to large variations in parameters for biotissues. To our surprise yet clearly present in the elasticity literature, separate batches of rubber also exhibit large variations in response function forms. In short, when conventional theories are used, small perturbations in data are greatly magnified.

Consequently, we sought and discovered a high-strain elasticity theory for rubber that was not sensitive to error (Criscione et al., 2000). This theory has response terms that are mutually orthogonal (the minimum of covariance), and we noticed that Ogden's approach is similarly orthogonal and insensitive to error. Believing that minimal covariance amongst response terms is necessary for reducing any propagation of measurement error, we subsequently developed such theories for materials with microstructures that are transversely isotropic (Criscione et al., 2001) and laminar with one family of fibers (Criscione et al., 2002) as is myocardium.

In these works and at meetings in the last 5 years, we have conjectured that covariance amongst response terms should be avoided because theories with orthogonal response terms are insensitive to error. Here we show rigorously that covariance amongst response terms will always cause a magnification of measurement error. Whereby, we can now say with certainty that constitutive theories must minimize the covariance amongst response terms or else compromise the results of tests on myocardium, soft tissue, or any other high-strain material. Currently, most elasticity theories for myocardium and high-strain materials have response terms with much covariance.

COVARIANCE MAGNIFIES ERROR

In order to mathematically define covariance amongst tensors \mathbf{A}_1 and \mathbf{A}_2 , consider the covariance ratio $R_C(\mathbf{A}_1, \mathbf{A}_2)$ as follows:

$$R_C(\mathbf{A}_1, \mathbf{A}_2) = \frac{\text{abs}(\mathbf{A}_1 : \mathbf{A}_2)}{|\mathbf{A}_1| |\mathbf{A}_2|} .$$

where ' $:$ ' denotes inner product and e.g. $|\mathbf{A}_1| = \sqrt{\mathbf{A}_1 : \mathbf{A}_1}$. It follows that (1) $R_C(\mathbf{A}_1, \mathbf{A}_2) \in [0, 1]$; (2) $R_C(\mathbf{A}_1, \mathbf{A}_2) = 1$ iff \mathbf{A}_1 and \mathbf{A}_2 are colinear; (3) $R_C(\mathbf{A}_1, \mathbf{A}_2) = 0$ iff \mathbf{A}_1 and \mathbf{A}_2 are mutually orthogonal; (4) $R_C(\alpha_1 \mathbf{A}_1, \alpha_2 \mathbf{A}_2) = R_C(\mathbf{A}_1, \mathbf{A}_2)$ with $\alpha_{1,2}$ as scalars.

Consider a constitutive law for the true stress \mathbf{t} as follows:

$$\mathbf{t} = \alpha_1 \mathbf{A}_1 + \alpha_2 \mathbf{A}_2 + \alpha_3 \mathbf{A}_3 + \alpha_4 \mathbf{A}_4 + \alpha_5 \mathbf{A}_5 + \alpha_6 \mathbf{A}_6$$

where \mathbf{A}_{1-6} are symmetric, 2nd order, kinematic tensors and α_{1-6} are scalar response functions. Here we assume $\mathbf{t} = \mathbf{t}^T$ (i.e. there are no body torques). We do not assume elasticity. \mathbf{A}_{1-6} and/or α_{1-6} could depend on strain, strain-rate, or strain-history. As new terminology, let the i^{th} term in \mathbf{t} be considered as the i^{th} response term. It is necessary that \mathbf{t} not depend on more than 6 response terms because there cannot be 7 linearly independent, symmetric, 2nd order tensors. Hence, linearly dependent terms could be grouped into the 6 (or fewer) linearly independent terms. For isotropic elasticity there are 3 terms. For transverse isotropy there are 5 terms. With fewer terms (i.e. < 6), our results are analogous yet easier to obtain.

For homogenous tests, \mathbf{t} is the same everywhere and thus known pointwise. To obtain 6 equations to solve for the 6 response terms, separately contract \mathbf{A}_{1-6} onto \mathbf{t} above. These equations will be poorly conditioned (condition number large) if $R_C(\mathbf{A}_i, \mathbf{A}_j)$ is not small for all $i \neq j$. For poorly conditioned systems, small perturbations in \mathbf{t} give rise to large perturbations in the solution for the response functions. Hence, unless the covariance amongst the response terms is minimized, there will be a magnification of error for homogenous tests. Inhomogenous testing further complicates matters because the \mathbf{t} field is not known pointwise. Yet, as shown above, for each possible solution for \mathbf{t} , locally there will be ambiguity in determining the response functions if covariance is not minimized. It follows that a large range of response functions will give nearly the same solution.

INTRODUCTION

In cardiac physiology, genetically modified mice have provided unique tools to study the role of important proteins in Excitation-Contraction Coupling and helped investigators to understand molecular alterations that lead to diseases. Nevertheless, the mouse is a relatively recent animal model in cardiac physiology and little is known about underlying processes of force generation. Data published in the literature are often contradictory and, therefore, subject to controversies. We examined in mouse two fundamental relations that govern the functioning of the cardiac pump in mammalian species: 1) the force-frequency (FFR) and 2) the force-sarcomere length relationships.

METHODS

24 trabeculae (length~1mm, thickness~ 100 μm) were isolated from mice hearts (~120 adult males CF-1), mounted horizontally between a force-transducer and a servo-controlled motor arm and superfused with HEPES buffer solution containing 1 mM $[\text{Ca}^{2+}]$. The stress (σ) was measured with a silicon strain gauge (res: ~ 0.5 μN). Sarcomere Length (SL) was determined by laser diffraction technique (res: ~ 4nm). We measured, first, the force response to different stimulation frequencies (*Freq*'s) (0.07-10Hz). Second, different SLs were tested randomly between slack length and 2.3 μm . Each individual value of σ was expressed in % of reference measured at 1Hz ($\sigma_{1\text{Hz}}$). Interpretation of the results required the determination of Ca^{2+} amount carried by the L-type Ca^{2+} current ($I_{\text{Ca,L}}$). The action potential (AP) and $I_{\text{Ca,L}}$ were measured in mouse ventricular myocytes using patch-recording techniques. The amount of Ca^{2+} entering the cell was calculated by integration of $I_{\text{Ca,L}}$ measured under AP clamp condition.

RESULTS & INTERPRETATION

σ and *Freq* followed a biphasic relationship in mouse cardiac trabeculae: from 0.1 to 1 Hz, σ decreased, whereas it increased from 1 to 5 Hz with raising *Freq* (Fig.1). Negative segment was sensitive to ryanodine (0.1 μM), whereas the positive segment was abolished by nifedipine (0.1 μM). Consequently, the shape of the FFR was dictated by the combination of 2 sources for activating Ca^{2+} : 1) Ca^{2+} release function of the Sarcoplasmic reticulum (at low *Freq*) and by $I_{\text{Ca,L}}$ (at high *Freq*). This conclusion was supported by modeling the descending and the ascending branches of the FFR.

increased exponentially with SL and σ_p - SL curves suggested that, like in the rat, passive properties of mouse trabeculae are dictated by titin and collagen. **Fig.2** shows that σ increased with SL and with $[\text{Ca}^{2+}]_o$. σ_{active} -SL curves measured $\geq 4\text{mM}$ superimposed showing that production of force in mouse muscles becomes independent on Ca^{2+} above 4 mM. In contrast, the force obtained using post extra-systolic potentiation at the same SL was ~50 % larger. This result suggests that Ca^{2+} load of the SR is a limiting factor for the production of force in mouse cardiac muscle.

The high tolerance for Ca^{2+} seems to be a characteristic of mouse that probably relates to particularities in the SR function. Extrapolation of results obtained in other mammalian species to the mouse (genetically modified or not), therefore, requires caution.

CANDIDATE MECHANICAL STIMULI FOR HYPERTROPHY DURING EARLY VOLUME OVERLOAD

Kathryn A. Guterl and Jeffrey W. Holmes

Cardiac Biomechanics Group, Department of Biomedical Engineering, Columbia University
jh553@columbia.edu <http://www.columbia.edu/~jh553/>

INTRODUCTION

Pressure overload and volume overload of the left ventricle induce different gene expression patterns, cellular dimension changes and gross geometric remodeling. While systolic wall stress has been proposed as the control variable driving pressure overload type hypertrophy, Emery and Omens demonstrated that diastolic strain is a more plausible control variable for volume overload type hypertrophy (Emery 1997). Since expression of genes associated with both hypertrophic phenotypes has been demonstrated within hours of in vivo overload, hypertrophic mechanical or hormonal signals must appear early after the overload is initiated.

METHODS

All studies were performed according to the American Association for Accreditation of Laboratory Animal Care guidelines and approved by the Columbia University Institutional Animal Care and Use Committee. Sprague-Dawley rats weighing approximately 250 g were anesthetized with ketamine and xylazine (80 mg/kg and 12 mg/kg initial doses respectively, with supplemental doses as required) and ventilated with room air. The chest was opened via midline sternotomy and the heart instrumented with sonomicrometers to measure ventricular volume (Sonometrics, London ON, Canada) and a fluid-filled catheter connected to a pressure transducer (TRN050, Kent Scientific, Torrington CN) to measure ventricular pressure. The chest was loosely closed and covered with moist gauze.

Five seconds of continuous volume and pressure data were acquired digitally every five minutes at a sampling rate of 200 Hz. Following 45-60 minutes of control data acquisition, the abdomen was opened in the midline and an infrarenal aortocaval fistula was created using the method of Garcia and Diebold (Garcia 1990). Presence of a patent fistula was confirmed visually by dilation and streaming of arterial blood in the abdominal vena cava. The abdomen was irrigated with 5 ml of saline and closed. Volume and pressure data were recorded for an additional two hours and analyzed off-line to calculate minimum volume, maximum volume, mean volume, stroke volume, heart rate, and rates of volume change during at least five cardiac cycles for each sampling period.

Figure 1: Left ventricular volume (including wall volume) during typical beats 40 minutes prior to (open symbols) and 40 minutes after (closed symbols) creation of an infrarenal aortocaval fistula.

RESULTS AND DISCUSSION

At the cellular level, increases in diastolic strain such as those reported by Emery and Omens might be transduced as increases in time-averaged cell length, maximum cell length, amplitude of the length variation, or rates of length change. In the present study, acutely opening an aortocaval fistula increased maximum volume (14%) more than time-averaged volume (7%). Minimum volume and rates of volume change remained stable (Figure 1). These preliminary findings appear more consistent with a role for maximum cell length or amplitude of cell length variation as stimuli for hypertrophy.

The acute response to volume overload likely includes both compensatory regulatory responses and large volume shifts. In this study, increased stroke volume was offset by a decrease in heart rate, producing an overall drop (15%) in left ventricular cardiac output. Additional study is needed to better define the subacute responses that lead to a significant increase in left ventricular mass at three days in this experimental model.

SHEAR PROPERTIES OF VENTRICULAR MYOCARDIUM

Ian LeGrice, Socrates Dokos, Bruce Smaill and Alistair Young

Department of Physiology, University of Auckland, Auckland, New Zealand. i.legrice@auckland.ac.nz

INTRODUCTION

Ventricular myocardium has a characteristic laminar structure (LeGrice et al., 1995a). Myocytes are organized in branching layers separated by extensive cleavage planes. The orientation of layers varies across the ventricular wall, but is relatively uniform in the midwall. At any point in the myocardium, the laminar structure may be characterized by identifying orthogonal axes aligned i) with the myocyte direction, ii) transverse to the myocyte axis within a layer, and iii) normal to the layer. Separate families of perimysial connective tissue are associated with these different material directions. Shearing between layers is believed to be important in active (LeGrice et al., 1995b) and passive (Spotnitz et al 1974) ventricular function. However, there have been few attempts to characterize the shear properties of cardiac tissue. The aim of this study was to determine the shear properties of passive ventricular myocardium with respect to its three principal material axes.

METHODS

We have developed a novel device for this purpose (Dokos et al., 2000). Simple shear deformations can be applied to isolated segments of soft biological tissue in two orthogonal directions simultaneously while resulting forces along the three associated axes are measured. Six pig hearts were arrested in diastole and perfused with 2,3-butanedione monoxime to maintain the tissue in a passive state. Three samples, approximately 3x3x3 mm with sides parallel to the principal material directions, were removed from adjacent regions of the lateral LV midwall of each heart. Because only two of the six different modes of simple shear deformation can be imposed in a single sample, the three specimens from each heart were tested in different orientations to cover all possible modes. Four cycles of sinusoidal (30 sec period) displacement were applied separately in each direction for maximum shear strains from 0.1 to 0.5. On completing sinusoidal testing, rapid 50% shear step displacements were imposed in each direction and the resultant forces were recorded for 300s.

RESULTS AND DISCUSSION

Our study demonstrates that passive myocardium has nonlinear viscoelastic shear properties at physiological levels of deformation with reproducible, directionally dependent softening as strain is increased. Shear properties were clearly anisotropic with respect to the three principle material directions: Passive ventricular myocardium is least resistant to simple shear displacements imposed in the plane of the myocardial layers and most resistant to shear deformations which produce rotation and extension of the myocyte axis. Comparison of stress strain relations for the six different shear modes suggests that simple shear deformation is resisted by elastic elements initially perpendicular to the direction of the shearing motion.

CYTOSKELETAL DEFECTS ALTER MYOCARDIAL MECHANICS BEFORE THE HEART FAILS

Ilka Lorenzen-Schmidt, Andrew D. McCulloch, Jeffrey H. Omens

Department of Bioengineering, University of California, San Diego, La Jolla, California, USA
jomens@ucsd.edu

INTRODUCTION

Cytoskeletal defects may play an important role in the development of dilated cardiomyopathy and heart failure [1]. Targeted deletion of the cytoskeletal protein MLP (muscle LIM protein) consistently leads to typical signs of dilated cardiomyopathy in mice greater than two weeks old. These signs include decreased ejection fraction and depressed diastolic and systolic performance [2]. It is not known, however, whether the dysfunction is directly due to the lack of MLP through a structural defect or whether it is indirectly caused by MLP deficiency. We examined diastolic and systolic behavior of papillary muscles in two-week-old MLP knockout (MLPKO) and control mice, when echocardiography showed normal cardiac function and no clear signs of heart failure.

METHODS

12-to-17-day-old MLPKO and control mice were used for this study. After anesthesia, the chest was opened, the heart arrested and excised. The left anterior papillary muscle, still attached to the wall, was placed in an apparatus that allowed muscle force measurements, continuous superfusion with oxygenated solution and motor-controlled length change of the muscle. Titanium dioxide markers were arrayed on the muscle to observe local length changes during the experiment. Diastolic and systolic length-tension relations were recorded as well as force time course and force-frequency relationship.

RESULTS AND DISCUSSION

The diastolic length-tension relations in both groups revealed that muscles from young MLPKO hearts were softer than controls (Fig. 1a), although stiffness is elevated in adult MLPKO [3]. Systolic stress was decreased in the MLPKO muscles compared to wildtypes at comparable length (Fig. 1b). Time to half relaxation was prolonged in the MLPKO, also indicating depressed cardiac function. No difference in force-frequency relation was detected between the genotype groups.

The decreased stiffness in the young MLPKO muscles is striking, since it stands in contrast to typically elevated stiffness in adult muscles in dilated cardiomyopathy. The softer properties could be caused directly by the lack of MLP and may contribute to the progression of cardiomyopathy through increased ventricular dilatation during filling. Mild cardiac dysfunction, shown by decreased systolic tension and slightly prolonged relaxation time, is already present at two weeks of age. Therefore, it is unclear whether these changes are primary or secondary effects of the disease.

Figure 1: a) Diastolic and b) systolic length-tension relation in MLPKO and wildtype muscles. Young MLPKO papillary muscles are softer than wildtype controls and develop less systolic tension than controls at the same length.

MECHANICAL EFFECTS ON CARDIAC MYOCYTE ELECTROPHYSIOLOGY

Peter Kohl

Cardiac MEF Group, Department of Physiology, University of Oxford, Parks Road, Oxford, United Kingdom
<http://www.physiol.ox.ac.uk/~pk>

INTRODUCTION

Electro-mechanical regulation of cardiac myocytes consists of control (Excitation-Contraction Coupling) and feedback pathways (Mechano-Electric Feedback, MEF). The latter is much less investigated – even though there have been abundant phenomenological reports, over the past 120 years, about the mechanical induction and termination of cardiac arrhythmia by pre-cordial chest impact (Nesbitt et al 2001). The lack of insight into MEF at the cellular level is largely caused i) by the difficulty of simulating cardiac mechanical stimulation in isolated cells, and ii) by the absence, until last year, of selective blockers of underlying ion channels (Bode et al 2001). Here, we review recent advances in our understanding of the cellular basis of cardiac MEF, and highlight the role that detailed mathematical models of cardiac mechano-electrical interactions have played in the process.

EXPERIMENTAL METHODS

Studies of cardiac cellular MEF are based on electrical recordings from isolated cardiomyocytes during mechanical stimulation. Recordings are mostly made in patch-clamp, cell-attached or whole-cell mode (although sharp-electrode recordings have been performed in isolated cells and tissue). Mechanical stimulation in the patch-clamp setting is via deformation of the membrane patch under the pipette by application of a pressure gradient (pipette suction). Cell-attached and whole-cell cell studies tend to use local membrane deformation (poking, compression), cell volume changes (swelling, inflation), or axial elongation (stretch by probes attached to the cell); for review see (Kohl et al 1999).

MATHEMATICAL MODELS

Models of cardiac cellular MEF range from simple three-equation-outlines to detailed representations of mechanically-activated ion channels and their interactions with the ‘standard’ set of cardiac cellular electrophysiological mechanisms; for review see (Kohl, Sachs 2001).

RECENT FINDINGS

Out of the methods used to mechanically challenge isolated cardiac cells, axial stretching is best suited to reproduce pathophysiological responses like, for example, the increase in spontaneous beating rate of the natural cardiac pacemaker (Cooper et al 2000). Cell swelling, in contrast, reduces pace-making in isolated cells (Lei, Kohl 1998). This is caused by differences in ion channel sub-populations activated by interventions that primarily affect i) cell volume (volume-activated channels) or ii) cell length (stretch-activated channels, SAC). Extrapolations from experimental findings have to take this

into account (swelling is a feature of ischaemia/ reperfusion, but not of cyclical cardiac loading/contraction).

Various SAC have been described. They can roughly be divided into potassium-selective and cation non-selective channels. The former will abbreviate action potentials but have little effect in diastole, while the latter serve as potent triggers of diastolic depolarisation/excitation (Craelius 1993).

Apart from sarcolemmal ion channels, mechanical stimulation affects cellular Ca^{2+} handling; for review see (Calaghan, White 1999). Modelling suggests that Ca^{2+} -mediated stretch effects on action potential duration may be opposite to those brought about by stretch-activated channels (Kohl et al 1998), which may explain some of the contradictory findings in experimental work, particularly using the whole-cell patch clamp technique (where Ca^{2+} buffers reach the cell interior).

SUMMARY

In gross simplification: stretch of cardiac myocytes shortens action potential duration, depolarises resting cells, and promotes automaticity. Other important effects emerge only at the level of cardiac tissue, like those caused by gradients in electro-mechanical parameters, or effects on conduction.

KEY QUESTIONS

At present, it is not known how external forces reach mechano-electrical transducers at the cellular level, and whether it is primarily stress or strain that affects sub-cellular behaviour. Furthermore, the question of how SAC and Ca^{2+} -handling effects are linked is open, to the extent that we cannot confirm or reject at present, whether Ca^{2+} travels via SAC in mammalian cardiac myocytes.

INTRODUCTION

Stimulation of α -adrenergic receptors on cardiac myocytes initiates complex signaling pathways that enhance contractility and accelerate relaxation. These effects are mediated by cAMP-dependent protein kinase (PKA), which phosphorylates a host of intracellular substrates, including accessory proteins on the thin and thick filaments (e.g., TnI and MyBP-C). In addition to the thin and thick filaments, striated muscles also contain a third filament system composed of the giant protein titin. Individual titin molecules span the distance between the M-line and the Z-line to form an elastic connection between the A-band and the ends of the sarcomere. As muscles are passively stretched from their slack length, titin's I-band spanning segment extends and generates an opposing force, referred to as passive tension (Granzier and Irving, 1995). In the present work, we investigated whether the α -adrenergic pathway can also modulate the properties of titin.

METHODS

Cardiac myocytes were isolated from rats. Passive tension-SL curves were measured in relaxing solution (RS) as explained in Wu et al. (2000). 1U/ μ l PKA was achieved by changing 200 μ l of RS within the experimental chamber (total volume 600 μ l) with 200 μ l of RS containing 3U/ μ l PKA solution. Myocytes were stretched and released at 7 min intervals to facilitate diffusion of the kinase, and passive tension was measured after 35 min. Phosphorylation assays were carried out with myocytes as well as with recombinant fragments that represent the extensible region of human cardiac titin, see Labeit and Kolmerer (1995). Cells or protein samples were incubated in a buffer containing ATP- γ -³²P and PKA. Samples were electrophoresed, stained, destained, dried and exposed to autoradiographic film.

RESULTS AND DISCUSSION

Findings indicate that PKA phosphorylates titin and causes a decrease in passive tension in skinned rat cardiac myocytes. *In vitro* phosphorylation assays with recombinant titin fragments suggest that a region of titin expressed only in cardiac titins, referred to as the N2B spring element, is the target site for PKA. The N2B spring element is a 572-residue sub-domain of titin's elastic segment that allows cardiac titins to function as adjustable springs. Our findings suggest that its phosphorylation in response to α -adrenergic stimulation can also alter titin's elasticity. Because the N2B spring element is differentially spliced into only the cardiac titin isoforms (Labeit and Kolmerer, 1995), these results suggest that like TnI and MyBP-C, titin contains a cardiac-specific domain that serves as a PKA substrate. Because titin-based passive tension is a determinant of diastolic function, our results suggest that titin phosphorylation may modulate cardiac function *in vivo*.

INTRODUCTION

The three dimensional (3-D) organization of cardiac tissue *in vivo* is for efficient mechanical function. This organization combines the proper orientation of cellular components, cardiac myocytes and fibroblasts, with extracellular matrix (ECM) components in relation to the overall geometry of the heart. In this manner, the mechanical properties of the heart are dependent upon the ventricular fiber architecture in relation to the chamber walls. Specific receptors, integrins, link the cellular components with the ECM making a hierarchically coupled interacting 3-D structure (Ross and Borg, 2001). Experimental and mathematical models suggest that the distribution of myofiber orientations, ECM organization (patterning) and cellular alignment are all integral to maintaining uniform fiber stress and strain during the filling and ejection of the ventricles. To investigate this hypothesis, a 3-D model of cellular and ECM arrangement has been developed and subjected to various mechanical and electrical stimuli.

METHODS

Neonatal cardiac myocytes were isolated, subjected to Percoll gradients, and plated on aligned collagen (Simpson et al 1999). This method produces a cardiac phenotype that is similar to myocardium *in vivo*. Multilayers of cells and connective tissue are then layered to form laminae similar to those found *in vivo*. Multilayers, usually consisting of collagen-myocyte-myocyte-collagen, were then subjected to a variety of mechanical forces including static and cyclic stretch (Yost et al, 2000) and field stimulation. Morphological analysis was done by confocal microscopy using specific antibodies for myocytes, fibroblasts, integrins and connexins.

RESULTS AND DISCUSSION

Analysis of the multilayers showed that myocytes and fibroblasts had a similar phenotype to that observed *in vivo*. With time in culture, the collagen became modified into networks similar to the endomysium. (figs. 1). Confocal analysis showed that the fibroblasts were tightly associated with the cardiac myocyte in a non-random fashion. When

multilayers were subjected to mechanical force, myocytes demonstrated increased growth. Biochemical analysis confirmed these morphological observations. Multilayer systems that were subjected to electrical pacing also demonstrated an increase in size as well as actin and myosin.

Figure 1: Multilayers consisting of collagen (FITC-Green) associated with myocytes (Phalloidin-Red). The arrangement is consisted of aligned collagen-myocyte-myocyte-aligned collagen.

SUMMARY

These data demonstrated the feasibility of the culturing cardiac myocytes and fibroblasts in 3-D that showed a *in vivo* like phenotype and responded to mechanical and electrical stimulation. These procedures are suitable for morphological, biochemical and molecular analyses of the cellular and acellular components to determine how these properties are altered by mechanical stimulation.

FORCE AND SARCOMERE SHORTENING VELOCITY IN RAT HEART

Henk EDJ ter Keurs, Nathan Deis, Mei L Zhang, Amir Landesberg*

Departments of Medicine Physiology and Biophysics, Cardiovascular Research group, Faculty of Medicine, University of Calgary, Canada. *Dept of Biomedical Engineering, Technion-Israel Institute of Technology, Haifa Israel.

INTRODUCTION

Sarcomere shortening determines ventricular ejection. The velocity of sarcomere shortening depends on the load on the cross-bridges on the one hand and the effect of shortening on the number of force generating cross-bridges on the other. Further, this interplay between load and shortening depends on the myosin iso-enzyme composition in the muscle. The myosin iso-enzyme expression varies depending on effects of prolonged loading on the heart and on the effects of thyroid hormone, especially in rodents. The maximal velocity of sarcomere shortening in muscle the rapid V1 myosin isoform exceeds that of the V3 isoform 2.5 fold. Little is known about the effect of shortening on the number of force generating cross-bridges, and on its consequences for the shape of the force velocity relationship in cardiac muscle containing different myosin isoforms. In this study we have analyzed the relationships between force and velocity in Cardiac Trabeculae from the Rat containing either V1 or V3 myosin.

METHODS

We used trabeculae from the right ventricle of 3 month-old LBN Rats. Rats were either pre-treated with propylthiouracil (PTU) 0.8g/l in their drinking water for 6 weeks or pre-treated with 30 µg Triiodo-thyronine (T3)/100g bw s.c. per day for 14 days.

Myosin isoenzyme composition was identified by non-denaturing pyrophosphate poly-acryl-amide gel electrophoresis (PPi-PAGE) using a procedure similar to that of Hoh and co-workers (Hoh et al., 1977).

The trabeculae were suspended between a silicon strain gauge and a motor arm. Sarcomere Length (SL) was measured using laser diffraction techniques. The muscles were stimulated at 0.5 Hz in $[Ca^{2+}]_o$ 1.5 mM at 26 C. The velocity of sarcomere shortening was measured at SL 2.0 µm in order to avoid effects of elastic forces opposing shortening. SL was controlled until 70% of peak force of the twitch was reached; then, a quick release was applied followed by a controlled release at constant velocity of sarcomere shortening, yielding constant force. Alternatively a shortening ramp was imposed that caused linear sarcomere shortening and biphasic decline of force. The rate force decline during the slow phase was normalized to isometric force (F_{isom}) at the same moment during the twitch and correlated with the velocity of sarcomere shortening (V_{SL}). The slope (G1) between the force deficit (ΔF) and V_{SL} was interpreted as a velocity dependent rate of weakening of the cross-bridges. The number of force generating cross-bridges was estimated independently using the modulus of stiffness at 200Hz sinusoidal length perturbations of the muscle. G1 was used to calculate the

parameters a_H and b_H in the Hill's hyperbola fitted to the force velocity relations of muscles with V1 or with V3 myosin isoforms.

RESULTS

Treatment with T3 increased the V1 fraction of myosin in young rats from 90% to 100%. PTU eliminated V1 and left the muscles with only V3 myosin.

Maximal stress development at SL 2.0 µm was $98 \pm 8 \text{ mN/mm}^2$ in V1 muscle following T3 treatment and 35% lower following PTU treatment. The maximal velocities of sarcomere shortening (V_0) were $17.6 \pm 1.4 \mu\text{m/s}$ and $8.2 \pm 0.7 \mu\text{m/s}$ for V1 and V3 myosin respectively. The Hill coefficients a and b (in $\%F_{max}$ and $\mu\text{m/s}$, respectively) calculated from the force velocity relationship were 8 ± 2 and -1.2 ± 0.5 and 5 ± 0.8 and 0.6 ± 0.6 for V1 and V3 muscles, respectively.

The normalized force deficit following sarcomere shortening ramps at varied velocity, in both T3 and PTU treated muscle increased linearly with time and was proportional to the velocity of shortening:

$$\Delta F = G1 \cdot F_{isom} \cdot \Delta t \cdot V_{SL} \cdot (1 - V_{SL}/V_0)$$

The modulus of stiffness declined during the shortening ramps and G1 was $6.15 \pm 2.1 \mu\text{m}^{-1}$ in predominantly V1 muscle.

CONCLUSION

the linear interrelationship between ΔF and V_{SL} suggest that the kinetics of weakening of both V1 and V3 cross-bridges depends on V_{SL} . The feedback of V_{SL} to the number of attached cross-bridges provides a description of the interrelationship between force and shortening in muscle with V1 and V3 iso-enzymes explaining the nature of the force velocity relationship may be used for a general description of the energetic behavior of cardiac muscle.

ENGINEERED TISSUES AS MODEL SYSTEMS FOR STUDYING MYOCARDIAL BIOMECHANICS

Eun Jung Lee, Vedran Knezevic, Jeffrey W. Holmes and Kevin D. Costa

Cardiac Biomechanics Group, Department of Biomedical Engineering, Columbia University, New York
kdc17@columbia.edu, <http://www.bme.columbia.edu/research.html>

INTRODUCTION

Evaluation of ventricular wall stress, which influences myocardial growth and remodeling, requires a mechanical constitutive law relating stress and strain in the tissue. Biaxial testing has been widely used to investigate the constitutive properties of passive and active myocardium [review by Costa et al., 2001]. However, due to variability in tissue structure and damage during dissection of the test specimen, several fundamental biomechanics questions remain unresolved. Tissue engineering, while not yet capable of producing fully functional myocardium [Mann and West, 2001], may be useful to design rudimentary cardiac tissues with geometry, structure and composition ideally suited to overcome some of the practical limitations of biaxial testing of myocardium. This study examines the potential of this novel approach.

METHODS

Adult rat cardiac fibroblasts (ARCF) and human foreskin dermal fibroblasts (HFF, gift from Dr. Steven Nicoll) were harvested by serial collagenase digestion of minced tissue (and 30 min panning to separate attached ARCFs from floating myocytes) and cultured in polystyrene flasks (Fisher) for several days at 37°C and 5% CO₂ in DMEM with 10% fetal bovine serum and 1% penicillin-streptomycin (Gibco BRL).

Square cell-populated collagen gels were created as detailed elsewhere [Knezevic et al., 2002]. Briefly, a suspension of $2\text{-}6 \times 10^5$ cells/ml in 2.0 mg/ml purified bovine dermal collagen type-I (Vitrogen 100, Cohesion Technologies) was mixed on ice, and 10 ml placed in a 4x4-cm square mold. Secured at the edges of the mold are 6x20x2-mm bars of hydrophilic porous polyethylene (PE, Small Parts) threaded with 5-0 monofilament suture. After 1 hour incubation, 10 ml of media was added to “float” the gels, and the sutures were either held fully constrained in both directions (FULL), or uniaxially constrained in only one direction using either single solid PE bars (UNIsolid) or PE bars cut into 3 short segments to permit lateral freedom of the gel boundary (UNICut).

After 72 hours incubation, gels were fixed in 3.7% formaldehyde for 24 hours. The central region of the gels was then imaged at 100x magnification on an inverted phase contrast microscope (IX-70, Olympus) with a digital video camera (Sensicam, Cooke Corp). The distribution of cell orientation in each image was automatically measured on a Unix workstation (O2, Silicon Graphics Inc) using software specifically designed for quantifying alignment [Karlson et al., 1999] using circular statistics to obtain a mean and angular deviation (ANGDEV) of local cell orientation.

Biaxial mechanical testing of one UNIsolid gel was performed at 24 and 48 hours incubation by applying equibiaxial 50, 100,

and 200 mg weights to the loading sutures and photographing the positions of small markers affixed to the top surface of the gel [Knezevic et al., 2002]. From the digitized marker coordinates, Lagrangian finite strains were computed in the constrained direction (Exx) and in the unconstrained direction (Eyy), as well as the shear strain (Exy).

RESULTS AND DISCUSSION

In FULL gels, cells were randomly oriented in the plane with an average angular deviation of $36.1^\circ \pm 2.3^\circ$. In UNI gels, cells became aligned parallel to the lateral free boundaries with a mean orientation within $\pm 5^\circ$ of the constrained X-axis. However, the UNIsolid gel had a broader distribution of cell orientation (ANGDEV = $18.8^\circ \pm 0.57^\circ$) compared to the UNICut gel (ANGDEV = $14.8^\circ \pm 0.7^\circ$). Thus, by altering loading constraints at the gel boundaries, cell alignment could be regulated as random, moderately aligned, or highly aligned.

In the equibiaxial loading of a UNIsolid gel, Exx < Eyy (Exy negligible) and the degree of anisotropy increased from 24 to 48 hours of incubation (Fig. 1). This reflects mechanical anisotropy created in the tissue construct by controlling cellular alignment, with the constrained direction stiffer than the unconstrained direction.

Figure 1: Strain vs. incubation time for 200 mg load.

SUMMARY

A method has been developed to generate rudimentary tissues composed of cardiac cells embedded in a three-dimensional collagen matrix, in an ideal geometry for biaxial material testing, with integrated attachment points and control of cellular alignment and mechanical anisotropy. These engineered tissues overcome some of the fundamental limitations of biaxial testing of natural heart tissue, and offer a promising new model system for interrogating fundamental aspects of myocardial biomechanics.

WAVE INTENSITY IN THE PULMONARY CIRCULATION

Aoife B O' Brien and Kim H Parker

Physiological Flow Studies Group, Dept. of Bioengineering, Imperial College of Science, Technology and Medicine, London, U.K. (a.obrien@ic.ac.uk)

INTRODUCTION

The pulmonary circulation is very different from the systemic circulation and has been much less extensively studied. It operates at a much lower pressure and resistance, branching distances are shorter, pulmonary arteries are thinner and more compliant allowing larger pulsation of the vessels. We studied wave propagation, in the time domain, in both directions, in the proximal pulmonary circulation using wave intensity analysis, which also allowed the determination of wave speed and vessel distensibility.

METHODS

Pressure, flow, and diameter were measured simultaneously in the main and left pulmonary arteries in anaesthetised, open chest dogs during baseline and hypoxia (>1hour, 10% O₂) and during occlusion of the right pulmonary artery. Data were analysed using wave intensity analysis. The theory is based on the 1-dimensional conservation equations and considers waves to be the resultant of successive, infinitesimal wave fronts. Wave intensity is defined as the product of the change in pressure and the change in velocity ($dI = dP dU$) across the wave front. The theory provides an analytical expression for local wave speed, c , in terms of density, ρ , and vessel distensibility, D , ($c = \sqrt{1/\rho D}$) and leads to the water-hammer equation, relating changes in pressure to changes in velocity $dP_{\pm} = \pm \rho c dU_{\pm}$. Thus, c can be determined experimentally from the slope of a pressure-velocity loop. This allows the separation of pressure and velocity waveforms into their forward (mainly generated by the ventricle) and backward (mainly due to reflections from bifurcations or terminal vessels) components.

RESULTS AND CONCLUSIONS

The usual forward compression and expansion waves were observed during ventricular contraction and relaxation respectively. Expansion reflections were observed in both the main and left pulmonary arteries in early systole during ejection. They had the effect of lowering pressure and augmenting flow thus assisting right ventricular ejection. This is unlike the systemic circulation where reflections are normally compressive. The time of arrival of these reflections suggests that the reflection sites must be in the proximal vessels. Compression reflections, originating from more distal and terminal sites were observed in late systole under all conditions.

During occlusion of the right pulmonary artery, the expansion reflections were abolished and compression

reflections were observed in early systole. During hypoxia, expansion reflections were augmented but were of shorter duration due to the earlier arrival of compression reflections in mid-systole. These earlier and increased compression reflections were probably due to hypoxic vasoconstriction of the distal pulmonary vessels. Determination of local wave speed allows the study of vessel distensibility and thus can help to explain complex vessel behaviour, which is influenced by both mean pressure and vascular tone.

Figure 1: Pressure (—), velocity (--) and wave intensity (below) in the canine pulmonary artery during control and occlusion. (note change of scale during occlusion). Early systolic backward expansion waves (negative, green/grey) during control conditions are replaced by backward compression waves (negative, red/black) during occlusion.

SUMMARY

Wave intensity analysis, is well suited to the study of waves in the pulmonary circulation. It allows the determination of local wave speed, which is related to vessel distensibility, and, allows the separation of waveforms into their forward and backward components in the time domain. Application of the analysis to measurements in the dog show that reflected expansion waves (lowering pressure and augmenting flow) exist in the main and left pulmonary arteries in early systole during right ventricular ejection.

INTRODUCTION

We extend our previous work, by demonstrating how an affine structural model for aortic valve tissue may be recast as a strain energy function with a finite number of fiber families that is readily implemented in an explicit finite element environment. Computational efficiency is achieved with a modified single-point Hughes-Liu shell. Transverse behavior is updated separately to match experimental internal shearing data.

METHODS

Constitutive Equations: Membrane behavior is adapted from a seminal structural model for aortic valve tissue by Billiar and Sacks. In terms of the 2nd Piola-Kirchhoff stress:

$$\mathbf{S} = p\mathbf{J}\mathbf{C}^{-1} + 2J^{-2/3}\text{DEV}\left[\frac{\partial\tilde{W}}{\partial\tilde{\mathbf{C}}}\right]$$

$$\frac{\partial\tilde{W}}{\partial\tilde{\mathbf{C}}} = \mu + \int_{-\pi/2}^{\pi/2} A \left[\exp\left(\frac{B}{2}[\tilde{\mathbf{N}}\tilde{\mathbf{C}}\tilde{\mathbf{N}} - 1]\right) - 1 \right] R(\theta)\tilde{\mathbf{N}} \otimes \tilde{\mathbf{N}} d\theta$$

where $\tilde{\mathbf{N}}$ is implicitly a function of θ , and $R(\theta)$ is a Gaussian that determines fiber splay. The integral is performed discretely on 18 intervals over the domain.

Cauchy stresses for the transverse components are adapted from Carew *et al.*:

$$\sigma_{i3} = r\mu E_{i3} + sE_{i3}(\exp[tE_{i3}^2] - 1); \quad i = 1, 2$$

Finite Element Formulation: The constitutive equations are implemented in a modified single-point, co-rotational Hughes-Liu shell. Our finite element formulation has been described elsewhere (Einstein, et al.). Significant additions include a Newton-Raphson search to determine the thickness strain component to accommodate nearly incompressible behavior, and a partitioning of the co-rotational deformation gradient into membrane and transverse terms.

Simulations: The following parameter values, corresponding to mean values of 4 mm Hg fixed tissue, were used: $A = 25.42$ kPa, $B = 11.5$, $\sigma = 14.9$ deg, $\mu = 1.4$, $K = 2.1\text{E}04$ kPa. Simulated biaxial tests followed closely the protocol in Billiar and Sacks. The complete set consisted of seven Lagrangian membrane tension controlled tests: $T_{11}/T_{22} = 10:60, 30:60, 45:60, 60:60, 60:45, 60:30$ and $60:2.5$ (mN/mm).

Clamped inflation simulations (10 x 10 mm) to 80 mm Hg. were performed to demonstrate the influence of transverse stiffness on membrane stresses. Parameters were: $r = 5$ kPa, $s = 2$, $t = 5$ or $t = 10$.

RESULTS AND DISCUSSION

Results from the simulated biaxial load tests showed excellent agreement with analytic values, for all protocols, over the entire range of motion (Fig. 1). Addition of the small “linear” term, μ , had the greatest influence at low values of strain. Both experimentally observed strain reversal, and strong in-plane coupling were correctly predicted.

Peak stresses for the clamped 80 mm Hg. inflation tests were 306.0 kPa corresponding to $t = 5.0$, 360.7 kPa for $t = 10.0$ and only 199.4 kPa for a pure membrane response.

Two ultra-structural features of the aortic cusp - the presence of the compliant spongiosa and the macroscopic radial corrugations of the fibrosa - may serve to further reduce the bending moment that gives rise to the higher peak stresses seen in the two inflation tests with respect to a pure membrane solution. Neither of these features were included in the present formulation, but are a logical evolution.

Figure 1: Results from biaxial simulations, showing correct prediction of in-plane coupling and strain reversal.

SUMMARY

We have successfully implemented a structural constitutive equation for aortic valve cusp in a computationally efficient shell. The formulation allows for the separate inclusion of an experimentally driven stress-strain equation for transverse shear. Inflation tests demonstrate the detrimental effect of greater transverse stiffness assumed to be associated with chemical cross-linking.

TENSILE VS. COMPRESSIVE GLYCOSAMINOGLYCAN PROFILES IN NORMAL AND MYXOMATOUS MITRAL VALVES

K. Jane Grande-Allen, Ph.D., Ivan Vesely, Ph.D.

Heart Valve Laboratory, Department of Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland, Ohio, USA
grandej@bme.ri.ccf.org

INTRODUCTION

The extracellular matrix composition of heart valves is believed to be determined by the load patterns imposed during valve function, such as the varying tensile and compressive loading in the leaflets and chordae of the mitral valve. Consequently, alterations to the normal tissue loading patterns will locally affect the cellular phenotypic production of extracellular matrix (including glycosaminoglycans (GAGs) and structural proteoglycans (PGs)) and hence transform the valve morphology, mechanics, and function. PGs consist of one or more long chains of repeating disaccharides (GAG chains) that branch off central protein cores. PGs and GAGs serve several structural, regulatory, and cellular roles in connective tissues. To examine the link between GAG composition and mechanics, we measured the concentrations of the different GAG classes in leaflets and chordae from normal and myxomatous (diseased) mitral valves.

METHODS

Leaflets and chordae from normal human mitral valves (n=31, obtained at autopsy) and myxomatous mitral valves (n=71, obtained following surgical repair) were weighed and dissolved using Proteinase-K. Sample aliquots were further digested using hyaluronidase SD, chondroitinase ABC, and chondroitinase ACII. Fluorophore-assisted carbohydrate electrophoresis was then used to quantify the GAG types and the chondroitin/dermatan sulfate chain lengths (Calabro 2000). Both of these can be used to identify the type of proteoglycan.

RESULTS AND DISCUSSION

Normal chordae, which typically experience high tensile loads and contain highly aligned collagen, contained primarily the GAG dermatan 4-sulfate in chains approximately 50-60 disaccharides in length. This pattern is suggestive of the proteoglycan decorin, which binds to type I collagen fibrils. Normal leaflets, which experience a combination of tensile, bending, and compressive loads, contained mainly the GAGs hyaluronan and chondroitin 6-sulfate in GAG chains approximately 80-100 disaccharides in length, indicative of the water- and hyaluronan-binding proteoglycan versican. The relative amounts and distributions of these GAGs are consistent with the tensile and compressive loads that these tissues bear. The myxomatous tissues contained elevated concentrations of hyaluronan and

chondroitin 6-sulfate as compared to normal mitral valve tissues. The makeup of these diseased leaflets and chordae thus appears to have shifted away from the tensile loading pattern. Furthermore, all differences between the myxoid and normal tissues were far more pronounced in the chordae than in the leaflets.

Figure 1: GAG classes in normal and myxoid mitral valves

(nmol/mg dry weight). HA = hyaluronan, OS = unsulfated chondroitin, C6S = chondroitin 6-sulfate, C4S = chondroitin 4-sulfate, D6S = dermatan 6-sulfate, D4S = dermatan 4-sulfate, XS = di- and tri-sulfated chondroitin/dermatan sulfate. *p<0.05

SUMMARY

These findings support reported observations that chordal rupture due to myxomatous degeneration is the leading cause of mitral valve regurgitation, and illustrate the roles of GAGs and proteoglycans in heart valve mechanics.

IN VITRO EXPLORATION OF SYNERGIES BETWEEN FATIGUE DAMAGE AND PROTEOLYSIS IN BOVINE PERICARDIAL BIOPROSTHETIC MATERIALS

J. Michael Lee, Sean D. Margueratt, and Rajesh A. Khanna

School of Biomedical Engineering, Dalhousie University, 5981 University Avenue,

INTRODUCTION

Most failed bioprosthetic heart valves show signs of the tearing and perforation the leaflet material; however, the mechanism behind this degeneration remains unclear. There is analytic and experimental evidence that simple fatigue can lead to local collagen disruption in regions of high bending or tensile stresses, perhaps with denaturation of the collagen triple helix [1]. Ultrastructural studies have also demonstrated the presence of host inflammatory cells in regions of collagen degeneration [2]. Moreover, it is clear that there is substantial metalloprotease activity (cellular or non-cellular in origin) in bioprosthetic heart valve materials [3]. Taken together, these observations suggest a potential mechanism whereby fatigue damage and enzyme-driven proteolysis combine to disrupt leaflet collagen. We have developed in vitro experimental methods to explore this hypothesis and have demonstrated both: (i) synergies between fatigue and proteolysis, and (ii) dependence on the nature of both fatigue loading and chemical processing of the bioprosthetic material.

METHODS

Bovine pericardium was obtained fresh from slaughter, cleaned of fat, and prepared as 10 x 10 cm anatomically oriented squares overlying the ventral surface. The tissue was then crosslinked in 0.5% glutaraldehyde (GA, pH 7.4 in 0.1 M phosphate buffer) or 1.15% by weight EDC carbodiimide solution with a 2:1 molar ratio of EDC to NHS maintained at a pH of 5.5 (without buffering). In both cases, the tissue was subject to 250 kPa uniaxial load during crosslinking to remove collagen crimp in the loading (base-to-apex) direction [4]. GA-crosslinked samples were also prepared without tensile loading to preserve crimp. In all cases, a glycine solution was used to quench any unreacted crosslinking groups.

Strip samples 16 x 4 mm were subject to 20 million loading cycles at 30 Hz (antibiotic and antiproteolytic protection) in a custom-built fatigue system. Fatigue loading included either: (i) simple refolding producing buckling as per Broom [5] or (ii) refolding alternating with tension so as to emulate systolic/diastolic loading cycles in vivo. Fatigue-damaged and non-damaged tissue strips were then incubated in (i) Tris CaCl₂-buffered, bacterial collagenase (20 U/ml) solution (pH 7.4) or (ii) buffer only, while being subjected to a 1 Hz sinusoidal tensile loading profile (mean 60 g, amplitude 20 g) for 48 hours [6]. Afterwards, tensile testing was performed on an

MTS servohydraulic system. The incubation solution and the tissue samples were examined for hydroxyproline content as a measure of collagen content and the percent collagen solubilized during enzymatic degradation was calculated.

<i>Fatigue Type</i>	<i>Treatment Group</i>	<i>UTS (MPa)</i>	<i>% Collagen Solubilized</i>
Refolding only	Buffer	21.2 ± 3.8	0.02 ± 0.01
	Fatigue Only	15.6 ± 2.2	0.10 ± 0.04
	Collagenase Only	16.4 ± 1.7	0.09 ± 0.19
	Fatigue/Collagenase	6.6 ± 1.1	0.98 ± 0.19
Refolding & Tension	Buffer	17.5 ± 4.3	0.09 ± 0.02
	Fatigue Only	13.4 ± 2.3	0.15 ± 0.04
	Collagenase Only	22.2 ± 6.9	0.14 ± 0.02
	Fatigue/Collagenase	5.2 ± 1.5	0.26 ± 0.08

Table 1: Changes in Ultimate Tensile Strength (UTS) and Collagen Solubilization in GA-Treated Materials Crosslinked Under Uniaxial Stress

RESULTS AND DISCUSSION

When crosslinked under stress, the collagen crimp typically seen in juvenile bovine pericardium was lost. Cyclic refolding produced compressive buckling and bundle disruption after 20 million cycles. As seen in Table 1 above, the result was not simply a loss of tensile strength, but a synergistic susceptibility to bacterial collagenase. Use of a more complex fatigue protocol (with refolding and tension) modulated the observed results—in particular, reducing the collagen solubilized by 75%—suggesting that the loading protocol used for fatigue simulation is important. However, the synergy was preserved.

In materials crosslinked *without* stress, a similar loss of UTS was observed, suggesting that the preservation of crimp is not particularly protective against fatigue-enhanced proteolysis. Interestingly, however, EDC carbodiimide stress-crosslinking produced significantly better resistance to fatigue and the fatigue/proteolysis synergy, demonstrating the importance of the crosslinking chemistry—even with complete crimp collapse.

RATIONALE FOR BIOMECHANICAL MIMICRY IN THE DESIGN OF ARTIFICIAL HEART VALVES

Vladimir A. Kasyanov¹ and Richard T. Schoephoerster²

¹ Latvian Academy of Medicine, 16 Dzirciema St., Riga, LV-1007, Latvia, kasyanov@latnet.lv

² Florida International University, 10555 West Flagler St., Miami, FL 33199

INTRODUCTION

There are many types of prosthetic heart valves, which have achieved clinical success (Barton 2001). Nevertheless neither is a perfect solution to the problem of a suitable replacement for defective natural valves (Vesely et al. 2001; Bernacca et al., 2002; Sodian et al., 2000). Stress concentrations in bioprosthetic or tissue engineered valves typically results in tissue and cell injury with sequential calcification, tearing of the leaflets and thrombosis for polymeric valves. Soft tissue is a composite material (Kasyanov et al., 2001), and this structure is a critical factor in the biomechanics of the human natural valve. Therefore, the mimicry of natural valve structure is a keystone in the design of novel prosthetic valves (Schoephoerster et al., 2001). From this point of view the biomechanical properties and structure of individual elements of human valves were investigated, and the novel soft stent for bioprosthetic valve and polymer trileaflet aortic heart valve have been designed and tested.

METHODS

The mechanical and structural studies were carried out on human aortic and pulmonary valves (to understand implications of the Ross procedure) of individuals from 35 to 45 years old, which died not as the result of cardiovascular disease. The material was removed from the cadavers no later than 24 h after death. The valves were cut into rectangular strips and tested in a specially designed tensile testing stand. During testing, the strips were immersed in a chamber of physiological solution heated to 37°C. All strips were 3 mm wide. The structure of the individual valve elements was studied by transmission electron microscopy using the ultrathin slice method for an accurate interpretation of the scanning and transmission electron microscopy data. A parallel study was carried out on the same material by light microscopy.

On the basis of experimental data, a novel braided soft stent for bioprosthetic valves was designed, and fatigue tests using porcine bioprosthetic heart valves with rigid and soft stents were made in a pulse duplicator.

A novel polymer composite trileaflet aortic heart valve was designed. The proposed valve design incorporates a new polymeric material, polystyrene–polyisobutylene–polystyrene (SIBS), with the thread architecture and geometry mimicking the natural valve leaflet. Reinforcement fibers in the leaflets emanate from the top of the post, and coincide with collagen bundles in the natural leaflet. Spherical and elliptical valves were manufactured. The regurgitation and pressure gradient were measured and compared with a St. Jude valve.

RESULTS AND DISCUSSION

The stress-strain curves of individual elements of valves demonstrated the typical non-linear, progressive increase in the stress as the tissue was strained. The leaflet material of valves has an anisotropy: it is stiffer in the circumferential than in the radial direction. The fibrous ring is more rigid than another areas of the aortic valve. The structure of valve elements depends on function which they perform and has specific orientation and composition in each element of the valve. All elements of the valve: leaflets, commissures, sinus wall and arched ring work together as a common construction that minimizes leaflet stress.

Morphological investigation of the porcine leaflet treated by glutaraldehyde and fixed on the rigid stent after fatigue testing showed a destruction of the collagen fibers. Structure of the leaflets on the novel soft stent was more organized and practically unchanged in comparison with the rigid stent. The soft stent in conjunction with other valve elements minimizes the tensile stress in leaflets to maintain their structure integrity. Polymeric trileaflet valves were mounted in the aortic position of a left heart and systemic circulation simulator for acute performance evaluation of pressure gradient and regurgitation in comparison with St. Jude valve. The elliptical geometry produced equal pressure drop compared with the spherical geometry, but provided reduced backflow. Finally, for the composite elliptical valves, pressure gradients compared favorably with the St. Jude valve.

SUMMARY

The arrangement and orientation of the fibrous structure and their packing in the elements of the human valve are a function of the load acting on these elements. Biomechanical mimicry of the features of valve elements gives promising results in the design of novel heart valve prostheses. It is the main ingredient for the creation of a fully bio-integrated valve (bioprosthetic, polymeric and tissue engineered valves) with long-term durability and ideal hemocompatibility in the future.

MODELLING THE NONLINEAR ANISOTROPIC PORCINE HEART VALVES

Jue Li¹ and XiaoYu Luo²

¹School of Civil Engineering and Mechanics, Xi'an Jiaotong University, Xi'an, China, leejewel@hotmail.com

²Department of Mechanical Engineering, University of Sheffield, x.y.luo@shef.ac.uk

INTRODUCTION

Biotissue valves such as porcine valves are used due to their excellent hemodynamic properties. This is no need for patient to have immunosuppressive therapy as tissue is accepted by the body, unlike with mechanical valves. The main disadvantage of the biotissue valves is the durability. It was generally believed that the majority of structural failures of biotissue valves resulted from tensile stress developed during valve closure. Stress analysis using numerical modeling has been used to understand the loading of natural and prosthetic heart valves during the closing phase. Most of the modeling, however, assumes that the valves are isotropic material, with but a few exceptions. The anisotropic and nonlinear properties of porcine aortic valve leaflet have potentially significant effects on its mechanical behavior and the failure mechanisms. This paper studies behavior of porcine valves using a nonlinear anisotropic model.

METHODS

The model is based on the uniaxial experimental data of porcine aortic heart valve leaflet and the properties of nonlinear composite material. A finite element code is developed to solve this problem using the 8-node nonlinear shell elements and the update Lagrangian method. The leaflets of porcine aortic valve are reinforced with collagen and elastin fibers, and behave like the anisotropic fiber-reinforced composite. We assume that both the fiber and the matrix are isotropic and incompressible materials with the same Poisson ratio of 0.45, and that the coupling between the longitudinal and the transverse elasticity to be negligible. This allows us to determine the longitudinal and the transverse elastic moduli from the experimental data by Mavrilas & Missirlis (1991).

RESULTS AND DISCUSSION

The pattern of the stress distribution can be strongly influenced by the thickness variation of the leaflet. This is investigated by varying the thickness of the anisotropic leaflet from 0.2mm to 1.4mm. In addition, valves with stent height from 16-20mm, and stent diameter between 19-27.8mm are also studied. The

results of the nonlinear anisotropic leaflet are compared with the stress contours from the corresponding linear anisotropic leaflet. It is found that the stress distribution of the non-uniform leaflet seems to be more uniform due to the non-uniform thickness. For isotropic case, the site of the maximum principal stress remains the same. However, there is a secondary maximum principal stress located at the belly of the valve when the thickness of the valve is non-uniform. This phenomenon is even more pronounced in the anisotropic case, where the peak principal stress actually locates in the belly zone, and the stress at the commissures is reduced by 43%. This is in agreement with the pathological examination of excised valves by Carpenter et al. (1976) that the leaflet's belly zone to be a common site of tissue rupture and disruption.

SUMMARY

To evaluate the model as a tool for valve assessment, valves with variable thickness, different ratios of stent height/diameter are examined both for isotropic and nonlinear anisotropic material. Compared with the isotropic valve at the same loading condition, it is found that the site of the peak stress of the anisotropic leaflet is different; the maximum longitudinal normal stress is increased, but the maximum transversal normal stress and in-plane shear stress are reduced. We conclude that it is very important to consider the anisotropic property of the porcine heart valves in order to understand the failure mechanism of such valves in vivo.

BIOFLUID EFFECTS OF THERAPEUTIC ULTRASOUND ON BIOLOGICAL TISSUES

Eitan Kimmel^{1,2} and Boris Krasovitski¹

Departments of Agricultural Engineering¹ and Biomedical Engineering², Technion IIT, Haifa 32000, Israel. agreita@tx.technion.ac.il

INTRODUCTION

This study has a long-term goal of utilizing therapeutic ultrasound for curing various pathologies in the cardiovascular system. It originates from experimental and theoretical studies on ultrasound-enhanced transdermal drug delivery in fish.

Micro alterations in fish epidermis, exposed to ultrasound (intensities of up to 2.2 W/cm^2 , frequencies 1 and 3 MHz, continuous mode), are observed using electronic microscopy. Five seconds of exposure to 1 MHz ultrasound (1 W/cm^2) result by hole formation in the membranes of the first cell layer. During longer exposures, deeper cell layers become affected and the level of damage increases as well. At the same time cells stay intact. This phenomenon is attributed to the behavior of gas bubbles near a rigid surface. Under conditions of unsteady cavitation the bubbles collapse towards the surface and high-velocity jets are formed. Interestingly, no isolated zones of damaged cells are observed. This type of cell damage is expected when bubbles are formed and collapse within an intact cell. Nevertheless, the epidermis is clearly divided by damage front, parallel to the skin, into two layers, damaged and undamaged. The front propagates inwards slowly in a diffusion-like process (Frenkel et al. 1999). The absence of damaged cells in the undamaged tissue is probably due to the fact that bubbles do not collapse in intact cells. We speculate that at first cell membrane ruptures from outside and only then cell contents change and conditions for bubble formations develop. The absence of cavitation damage from inside out in intact cells is probably due to the cell content and not its constraining size. This prediction is supported by a theoretical study of unsteady bubble collapse in semi-confined space. The bubble is located between two parallel and rigid surfaces, at equal distance from each surface. The distance is comparable to bubble size. In this case, under certain conditions, the bubble split into two parts and two high-velocity jets are formed aiming at both surfaces (Krasovitski and Kimmel, 2001). Those jets are similar in size to the jets created by bubble collapse in semi-infinite medium. Note that Chanine et al. (1982) observed similar bubble split.

Exposures to 3MHz ultrasound stimulate creation of intercellular spaces, which take place primarily between the two outermost cell layers. When exposure time increases, the number and size of spaces increase (Frenkel et al. 1999). At the same time cells stay intact. It is still unclear why intercellular spaces are formed and what is the reason they are concentrated at such a thin layer of about $10 \mu\text{m}$. One possible explanation is the formation of transverse (shear) waves at the water-epidermis interface, waves that attenuate rapidly in the cellular tissue because of high viscosity of cells cytoplasm. Another possible mechanism for induction of intercellular spaces by quasi-steady bubble pulsations is hereby discussed.

METHODS

A simulation method is developed for the shear stress induced by a spherical bubble, located near a rigid surface, when it is subjected to ultrasound field of relatively small intensity (about 0.01 W/cm^2) and pressure amplitude (20kPa). The pulsations of a bubble near a rigid surface generate steady flow field, known as acoustical microstreaming. Nyborg (1958) suggested an approximate method for estimating the velocity profile in the boundary layer from the potential flow. We solve Laplace equation for potential flow field in a domain bounded by a sphere and a plane. The boundary condition on the bubble surface is obtained by solving the bubble dynamics equation in infinite medium for a bubble that stays spherical while pulsating. The relatively complex set of boundary surfaces is then transformed into a simple square. The transformed Laplace equation is solved numerically as an asymptote of the solution of Fourier equation. The described method provides quasi-steady and oscillatory shear stresses on the tissue surface. Evolution of the bubble with time is also studied by introducing rectified diffusion – accumulative effect of the diffusion of gas in and out of the pulsating bubble.

RESULTS AND DISCUSSION

Quasi-steady shear stresses on the surface reach a peak of about 1kPa intensity (corresponding to intensity of 0.01 W/cm^2) over a region comparable to bubble size. The shape and direction of the shear distribution can be viewed as obtained by two concentric rings that touch the surface and move in the radial direction outward (the inner one) and inward (the outer one). The magnitude of the shear stress increases with ultrasound intensity and decreases with increasing distance between the bubble and the surface. For comparison, microstreaming stresses are 1000 times greater than the normal shear acting on endothelial cells in blood vessels, and as such might induce micro alterations.

CONCLUDING REMARKS

This study applies to any liquid/solid interface. It explains some of our observations in fish (water/epidermis interface) and might shed some light on the effects of therapeutic ultrasound on blood vessels (blood/vessel-wall interface).

INTRODUCTION

Cerebrospinal fluid (CSF) moves in a pulsatile manner within the spinal and cranial subarachnoid spaces (SAS) and ventricular system. This fluid cushions the brain from impact on the cranial vault walls due to sudden motions. CSF also delivers nutrients and protein to/from the brain surface along with the removal of waste products. Recent developments in non-invasive flow measurement techniques, such as phase encoded magnetic resonance imaging (PCMRI), enable *in vivo* measurement of the velocity pulsation. We have previously shown the basic velocity patterns present within a healthy SAS using 2D numerical simulations [1]. Changes in the SAS anatomy are associated with pathological conditions such as Chiari malformation and syringomyelia. Therefore, patient specific 3D hydrodynamic analysis of CSF motion is warranted since it may be used to provide an evaluation of the Chiari malformation severity before and after surgical treatment.

METHODS

The SAS geometry of a 21-year-old healthy male volunteer was obtained axially along the spinal canal using MRI. In addition, the geometry of 35-year-old male patient with Chiari I malformation was obtained pre- and post-surgically. For the three geometries, velocity measurements were obtained using PCMRI at the level of the second cervical vertebra (C2). The 3D geometries were obtained using a commercial image processing software (MIMICS, Materialise). The geometries were smoothed and meshed using MATLAB (Figure 1) as described previously [2,3]. The incompressible unsteady Navier-Stokes equations were solved using a commercial CFD code (Star-CD, adapco Inc.) with rigid walls. The inlet boundary conditions were imposed to match the CSF flow waveform (Q) obtained from PCMRI measurements.

The difference in unsteady pressure (dP) from base of the cranium to a position below C2 (25 mm) was computed from the numerical simulations for each specific geometry and corresponding Q. The unsteady flow resistance or longitudinal impedance (Z_L) was computed by the ratio of the fast Fourier transform (FFT) coefficients of dP and Q. The Z_L modulus was computed using the magnitude of the real and imaginary components for each harmonic [4].

Figure 1: Healthy, pre- and post-surgical SAS geometries

RESULTS AND DISCUSSION

Peak Reynolds numbers (Re , based on hydraulic diameter) and Womersley numbers (α , based on hydraulic radius) varied with position along the SAS and between cases. The Peak Re and α values for the three cases ranged from 50 to 150 and 5 to 17, respectively for the region extending 6 cm below the cranium. The velocity profiles within these SAS regions were generally blunt and pulsatile in nature for the three cases with the exception of narrow regions in the diseased geometries. The Z_L modulus was computed for each case at different frequencies (1st - 9th harmonic). The mean Z_L modulus values for the healthy, pre-surgical and post-surgical cases were 28, 65, and 48 dynes-s/cm⁵, respectively. Hydrodynamic evaluation of the SAS resistance to pulsatile CSF flow motion may provide additional information to the surgeon in evaluating Chiari malformation severity before and after surgical treatment.

HORIZONTAL-TO-VERTICAL VELOCITY TRADEOFF IN HORIZONTAL JUMPING

Steven LeBlanc

School of Health and Human Performance, Dalhousie University, Halifax, Nova Scotia, Canada

Steve.LeBlanc@dal.ca

INTRODUCTION

In the long jump and the triple jump, the primary goal of the athlete is to build up horizontal velocity during the approach run and then to maintain as much of that horizontal velocity as possible while generating vertical velocity during the takeoff. Research has shown that some horizontal velocity will always be lost during the takeoffs in both long jump and triple jump. Yu (1999) examined the relationship between the loss in horizontal velocity and the gain in vertical velocity during the three takeoffs in the triple jump and found that there was a significant linear relationship between the two measures. Yu (1999) used the competitive triple jumps of elite athletes to examine this relationship. The purpose of the present study was to determine if a linear relationship could be found between the change in the horizontal velocity of the total-body centre of mass (dV_h) and the change in the vertical velocity of the CM (dV_v) under different jumping conditions. It was hypothesized that this linear relationship would be found.

METHODS

The study made use of two sets of data, one in a competitive setting and the other in a laboratory setting. Kinematic data for each data set was collected using standard two-dimensional video analysis techniques (60 Hz). For the competitive jumps, the best two jumps from four male long jumpers and three male triple jumpers were selected for analysis (LeBlanc, 1997). For the laboratory trials, five athletes (3 male, 2 female) performed five trials each of three- and four-step approach long jump-style takeoffs in a laboratory setting. Athletes in both sets of data were experienced non-elite jumpers.

A regression model (see Equation 1) was used to examine the relationships between dV_h and dV_v . It was deemed to be evidence of a significant relationship if the regression analysis resulted in a model with a large F-value, a large R^2 value, a significant p-value for dV_h , and a negative β_1 coefficient.

$$dV_v = \beta_0 + \beta_1 dV_h \quad [\text{Eq. 1}]$$

The regression model was applied to the two data sets separately to see if the competitive and laboratory trials differed in the relationship of dV_h and dV_v . A combined analysis was also performed using both data sets together.

RESULTS AND DISCUSSION

The regression analysis found that there was a significant linear relationship between dV_h and dV_v in the 50 laboratory trials ($F= 69.28$, $R^2= 59.1\%$, $p= 0.000$, $\beta_1= -1.23$) but not the 14 competitive trials ($F= 1.38$, $R^2= 10.3\%$, $p=0.263$, $\beta_1= -0.22$). This may have been due to technical differences between the short-approach laboratory jumps and the competitive LJ and TJ trials, particularly the TJ trials (see Figure 1). However, in both data sets a negative β_1 coefficient was found, indicating that the trend was for greater loss of horizontal velocity to coincide with greater gains in vertical velocity during takeoff. When the two data sets were combined, a significant linear relationship was found to exist ($F= 30.99$, $R^2= 26.3\%$, $p= 0.000$, $\beta_1= -0.68$). The results seem to support the notion proposed by Yu (1999) that there is a linear relationship between the loss in horizontal velocity and the gain in vertical velocity during a horizontal jump takeoff.

Figure 1: Change in horizontal versus vertical velocity during the takeoff in long jumps (LJ), triple jumps (TJ), 3-step approach jumps (3L) and 4-step approach jumps (4L).

DEGRADATION OF DRUG TABLETS AND MIXING IN THE STOMACH USING COMPUTER SIMULATION WITH THE LATTICE-BOLTZMANN ALGORITHM

James G. Brasseur^{1,3}, Anupam Pal¹, Bertil Abrahamsson²

³communicating author: brasseur@jazz.me.psu.edu

INTRODUCTION

Drug release from polymer-based extended release (ER) tablets in the stomach is controlled by surface degradation due to local surface shear stress [Abrahamsson et al 1999]. Recent high resolution concurrent manometry/MRI studies [Indireskumar et al 2000] have shown that slowed gastric emptying is confined primarily to periods of quiescence, suggesting that the primary function of antral contraction wave activity may be other than gastric emptying.

AIMS

Using numerical methods and computer simulation we seek to understand and quantify the gastric motions within the stomach in the fed state associated with dispersion of gastric content, gastric emptying, intragastric pressure variation (as measured manometrically, for example), and viscous stress. In particular, we aim to "measure" surface shear stress variation on tablets moving within the stomach and evaluate the dispersion and mixing of drugs released within the stomach.

METHODS

A sophisticated numerical code was developed based on the "lattice Boltzmann" algorithm and combined with a realistic stomach geometry model derived from MRI movies of the human stomach. Gastric fluid motions, tablet surface stresses on 1 cm diameter tablets, and drug dispersion were predicted in a simulated human stomach in two dimensions with fundic and antral contraction and pyloric opening representative of the fed state.

RESULTS

Antral contraction waves generate recirculating gastric fluid motions which create a "mixing zone" of high relative surface shear stress (figure 1). Frequency distributions of surface shear stress during tablet motion revealed 4 levels of stress: (i) low level shear stress (<1 dynes/cm²) when tablets move within the fundus, (ii) moderate shear stress (~ 10 dynes/cm²) when tablets move in the antrum between contraction waves, (iii) high shear stress (~ 35 – 50 dynes/cm²) generated as tablets encounter antral contraction waves, (iv) very high short-lived shear stress events (>300 dyne/cm²) as tablets are forced retrograde through advancing contraction waves. The frequency of high shear stress events from tablet-contraction wave encounters is much lower than during the moderate shear stress periods. Nevertheless, the relative contributions to overall, time-integrated, surface shear stress of the shorter-lived high stress periods vs. the longer-lived moderate stress periods were comparable. The coordination of pyloric opening with the space-time structure of antral pyloric contraction-

wave activity has a significant influence on particle motion, mixing and emptying.

CONCLUSIONS

Wave-like contractile activity in the antrum of the stomach is responsible for circulatory motions that underlie mixing, viscous stress and pressure, particle degradation, and mixing. The coordination of antral contraction waves with pyloric opening history is important for emptying and details of mixing. Both long periods of moderate shear stress and short periods of high shear stress contribute to the degradation of ER tablets, albeit in different ways. Whereas the extended periods of moderate stress will continuously degrade the tablet surface, shorter-acting high shear stress events may remove larger pieces of tablet surface and contribute to uneven wear, change in tablet shape, and tablet breaking. We conclude that drug release may result from both continuous and discrete surface degradation periods.

AQUEOUS HUMOR FLOW AND PASSIVE IRIS DEFORMATION

Jeffrey J. Heys¹, Eric C. Huang², and Victor H. Barocas³

³Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN USA

INTRODUCTION

Active deformation of the iris in response to available light is a well-studied and important phenomenon. Less attention, however, has been paid to passive deformation of the iris in response to changes in anterior eye geometry or aqueous humor (AH) flow dynamics. Extreme passive displacement of the iris can have pathological consequences. Anterior displacement of the iris leads to angle-closure glaucoma, in which the proximity between iris and cornea prevents AH outflow. Posterior displacement, in contrast, can lead to rubbing of the iris against the lens capsule and zonules, which in turn can lead to pigmentary glaucoma.

METHODS

The fluid-structure problem involving AH (the fluid) and iris (the structure) has been formulated based on available anatomical and physical data; the domain is shown in Figure 1. An inflow boundary condition was specified at the ciliary processes, and the intraocular pressure was subsequently set based on the outflow at the trabecular meshwork. The cornea was treated as a section of a spherical shell of known properties (Smolek 1994). For steady-state calculation, the lens was assumed to be rigid.

Once the model was complete and tested for steady-state problems, we examined the hypothesis that AH flow due to lens motion during accommodation (shift in focus to view near objects) causes the characteristic bowing of the iris seen in pigmentary glaucoma patients. Accommodation was modeled by specifying the motion of the lens (Koretz et al. 1989).

Figure 1: Domain and specifications for fluid-structure model of the anterior eye.

RESULTS AND DISCUSSION

Figure 2 shows the calculated AH velocity field at the start of accommodation and posterior bowing that results from interaction between the AH and iris. In the absence of an iris, AH displaced by the motion of the lens would flow around the lens into the space vacated by accommodation. The iris behaves like a flap valve (cf. Pavlin et al. 1996), preventing posterior flow of the AH. We found that the pressure on the anterior iris surface is in fact higher than that on the posterior surface (unlike the steady-state case). After accommodation, the system takes 3-5 minutes to re-equilibrate.

SUMMARY

Our computational model has shown that passive deformation of the iris due to AH flow during accommodation is a reasonable explanation for the posterior bowing of the iris observed during accommodation in pigmentary glaucoma patients. We have not yet elucidated the mechanism by which some people suffer from pigmentary dispersion but almost all do not, even though accommodation is a universal process.

UTERINE BIOFLUID DYNAMICS

Osnat Eytan¹, Sarit Yaniv², Ariel J. Jaffa¹ and David Elad²

INTRODUCTION

Uterine motility plays a central role in human conception which depends on a number of transport vehicles within the female reproductive tract. The detached ovum is transported to the fallopian tube. Spermatozoa are rapidly transported in the uterine fluid towards the ampulla where fertilization occurs. The newly born embryo is driven to the uterine cavity within four days of ovulation, and is then conveyed during another 3-5 days to an optimal implantation site in the fundal area at the upper part of the uterus. Fulfillment of these essential events within the time limits of fertilization and implantation depends on concomitant intrauterine fluid motion induced by spontaneous myometrial contractions. Myometrial contractions in non-pregnant uteri were studied from measurements of intra-uterine pressures with fluid-filled catheters and by visual observations of high-speed replaying of transvaginal ultrasound (TVUS) images of the uterus. The contractions propagate from cervix to fundus during the proliferative and secretory phases, with the direction being reversed and the contractions rate slowed during menstruation. This study presents an objective method to evaluate the characteristics of the uterine dynamics and a mathematical simulation of intra-uterine fluid transport pattern.

METHODS

Transvaginal ultrasound (TVUS) images of the sagittal cross-sections of the non-pregnant uterus were scanned with an vaginal ultrasound probe. Images at consecutive times (1 second apart) were digitized and processed by employing modern techniques of image processing (Eytan *et al*, 1999). The sets of images were compared to evaluate time variation of the fluid-wall interface in terms of amplitude, frequencies and passive width of the uterine cavity.

Figure 1. Description of a uniform two-dimensional channel with oscillating walls. Legend: L and $2a$ are the channel's passive length and width, b and λ are the amplitude and the wavelength of wall motility, ϕ is the phase between the walls.

Intra-uterine fluid flow in a sagittal cross-section of the uterus was simulated by wall-induced fluid motion within a two-dimensional channel. Fluid motion within the channel was induced by two rhythmic wall displacements that were simulated by an infinite train of sinusoidal waves that propagated along the channel walls (Fig. 1). The time-dependent fluid pattern and possible trajectories of massless particles were studied by employing the lubrication theory (Eytan & Elad, 1999). The intrauterine fluid flow pattern and trajectories of embryos were simulated for various amplitudes, frequencies, pressure gradients and phase shift between the channel's wall.

RESULTS

Analysis of TVUS images from 25 volunteers during end proliferative phase and early secretory phase revealed that myometrial contractions are fairly symmetric and are propagated from the cervix towards the fundus at a frequency of about 0.03 Hz. The amplitudes of the fluid-wall interface during a typical contractile wave are about 0.08 mm, and the passive width of the uterine cavity is about 0.5 mm. The averaged results from the *in vivo* measurements were implemented in a mathematical simulation to study the intra-uterine fluid flow patterns. The paths of massless particles (embryos) were curly and the particles generally propagated towards the direction of the peristaltic wave. As the phase shift between the walls decreased from π to zero (i.e., symmetric to asymmetric), the trajectories of the particles became more tilted towards the transverse axis (y) until they were completely perpendicular to the axial axis at $\phi=0$.

DISCUSSION

The newly born embryo is transported by intrauterine fluid motions towards the site of implantation at the fundus. The mathematical simulations showed that the embryo may reach the fundus within a few hours if uterine wall motility is normal and will stay there until hormonal conditions are suitable for its successful implantation in the endometrium. In a different situation one may imagine a case of asymmetric myometrial contractions that lock the embryo within a confined vicinity and, as a result, it cannot reach an implantation site within the allowable time. This may provide a partial explanation for the outcome of IVF that many of the embryos transferred to the uterus fail to implant in the endometrium within the critical time limits.

THE ROLE OF THE PASSIVE STRUCTURES IN THE MOBILITY AND STABILITY OF THE NATURAL AND REPLACED HUMAN ANKLE JOINT

Alberto Leardini¹, John J O'Connor², Rita Stagni³, Federico Corazza⁴, Vincenzo ParentiCastelli⁴, Fabio Catani¹, Sandro Giannini¹

⁴ Dipartimento di Ingegneria costruzioni meccaniche, nucleari, aeronautiche e di metallurgia - Università di Bologna, Italy

INTRODUCTION

Current unsatisfactory clinical results in ligament reconstruction and joint replacement at the human ankle joint have been related to designers' inability to restore adequately the original mechanisms which guide joint mobility and stability. Thorough experimental and modelling studies are necessary to elucidate the role played by the ankle passive structures in these mechanisms (Leardini et al., 2000). A recent extensive investigation from these authors (Leardini et al., 1999a,b, 2001b) is revealing that a close relationship between the geometry of the ligaments and the shapes of the articular surfaces is responsible for the physiological relative motion of the bones in passive conditions and for an accomplished resistance to this motion when load is applied.

METHODS

Ten skeleto-ligamentous lower leg preparations including tibia, fibula, talus, calcaneus and intact ligaments were analysed (Leardini et al., 1999a, 2001b). Motion of these bones during passive flexion, deviation tests and muscle strengthening was tracked using both optical (Elite, BTS, Milan) and roentgen stereo-photogrammetry. Geometry of ligament fibre arrangement and articular surface shapes was obtained with a 3D digitiser (FARO Technologies, Inc.). The instantaneous distance between corresponding fibre attachments was calculated. Articular contact area was estimated by modelling the surfaces as thin plate splines and setting a distance threshold (Corazza et al., 2002c).

A sagittal four-bar linkage model was formulated as formed by the tibia/fibula and talus/calcaneus bony segments and by fibres within the calcaneofibular and tibiocalcaneal ligaments (Leardini et al., 1999b). A mechanical analogue of the extensor retinaculum was devised to include the action of the main flexor and extensor muscles (Leardini et al., 2002a). The model was used also to analyse current and possible novel prosthetic designs, particularly to test the ability to reproduce the compatible mutual function between the articular surfaces and the ligaments retained (Leardini et al., 2001a). Non-conforming two-component and fully-conforming three-component designs with either flat, concave or convex tibial surfaces were analysed. A mechanical 3D model of the ankle was also devised to calculate ligament fibre recruitment and load/displacement curves at different flexion angles during a simulated anterior drawer test (Corazza et al., 2002b). Ligaments were modelled as three-dimensional arrays of fibres with non-linear stress/strain relationships from the literature.

RESULTS AND DISCUSSION

The articular surfaces and the ligaments alone prescribed joint motion into a preferred single path of multiaxial rotation. The ankle complex exhibited one degree of unresisted freedom, the ankle joint behaving as a single degree of freedom mechanism and the subtalar joint as a flexible structure. Fibres within the calcaneofibular and tibiocalcaneal ligaments remained most isometric throughout the passive range, with change in distance smaller than 1% (Stagni et al., 2002d). These two fibres must guide and all other fibres must only limit this motion. The contact area was calculated to move anteriorly and laterally with dorsiflexion on both articular surfaces.

The four-bar linkage model well predicted the sagittal plane kinematics observed in corresponding experiments. The mechanical analogue of the extensor retinaculum revealed that the displacement of the flexion axis guarantees a mechanical advantage for the muscle forces during gait. Among a large range of ankle prosthesis designs, a ligament-compatible, convex-tibia, fully-congruent, three-component showed the best features. A complete congruence over the entire range of flexion together with an acceptable degree of entrapment of the meniscal bearing were obtained while restoring exactly the original patterns of joint kinematics, ligament recruitment and tensioning and muscle lever arms. The mechanical 3D model for the drawer test elucidated the significant different response of the joint at different flexion angles, well comparing with previous experimental reports (Corazza et al., 2002b).

SUMMARY

The overall investigation is demonstrating that a profound knowledge of the changing geometry of the passive structures throughout the range of passive flexion (mobility) is mandatory for a successful mechanical analysis of the response to external load (stability). A 3D extension of the sagittal four-bar linkage model is now in progress.

IN-VITRO REPORTS ON ANTERIOR ANKLE LIGAMENT DAMAGE AND ANKLE-JOINT LAXITY: A REVIEW OF THE LITERATURE

GMMJ Kerkhoffs, L Blankevoort, D Van Poll, Rk Marti, CN Van Dijk

Orthopaedic Research Center Amsterdam, Department of Orthopaedic Surgery, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands.

INTRODUCTION

Diagnostic methods for inversion injuries of the ankle have remained controversial throughout the years. An instrumented test for anterior ankle-joint laxity could be a diagnostic tool for evaluation of anterior lateral ankle ligament function. The relation between ligament damage and anterior ankle joint laxity is the key to the validation of any diagnostic test. The purpose of this study was to provide a systematic review of the literature on this relationship as observed in cadaver experiments.

METHODS

An advanced electronic database search using MEDLINE and EMBASE was performed to find studies describing the correlation between lateral ankle ligament damage and ankle-joint laxity. Two reviewers assessed the methodological quality for each study and agreement was noted. Two reviewers extracted all relevant data with respect to methodology, motion constraints and laxity measurements.

RESULTS

The quality assessment resulted in 5 studies being scored as high quality and 5 as low quality, out of 19 studies that described ankle ligament cutting experiments. Different test devices were used to apply the load and measure the displacement. All in-vitro tests applied a load to the calcaneus and subsequently measured the translation of the talus and/or calcaneus relative to the tibial dome. Rotation in the transversal and frontal plane was restricted in 8 tests. After analysis of the results presented by nine different studies, the mean value of anterior ankle-joint laxity with intact ligaments is 4.2 mm. The mean laxity value after sectioning of the anterior talofibular ligament is 6.5 mm (Figure 1). The mean laxity value increases to 8.4 mm after sectioning of the calcaneofibular ligament. The mean anterior laxity value with the foot in dorsal flexion (3.1 mm) is less than the mean value with the foot in neutral position (4.5 mm) or in plantar flexion (4.7 mm). The applied load and the anterior laxity values between the different studies vary greatly.

CONCLUSIONS

Each ligament section results in significantly increased anterior ankle-joint laxity. Ankle-joint laxity can be used as a measure for damage to the anterior talofibular ligament (ATFL) or calcaneofibular ligament.

Figure 1: Scatter diagram showing anterior ankle laxity and applied force for intact and ATFL-deficient ankles from the different studies. The values represent tests with the foot in neutral flexion. This figure represents all 9 studies.

TWO INSTRUMENTED TESTS FOR ANTERIOR ANKLE-JOINT LAXITY: AN EVALUATION IN THE CLINICAL SETTING

Gino MMJ Kerkhoffs, Leendert Blankevoort, Ruby Corveleijn, Inger N Sierevelt, Mark JC Smeulders, C Niek van Dijk
Orthopaedic Research Center Amsterdam, Academic Medical Center, Amsterdam The Netherlands

INTRODUCTION

As a diagnostic tool and for postoperative follow-up studies, an objective measure for anterior ankle laxity can be obtained through the use of an instrumented tester. Two such testers were developed for the measurement of anterior laxity of the ankle joint complex. The purpose of this study was to evaluate the reproducibility of these testers and their functionality in a clinical setting.

METHODS

The two devices used for the study are a quasi-static ankle tester and a dynamic ankle tester. The test devices both comprise of a vertical construction to fixate the lower leg, a horizontal construction to apply a load to the calcaneus and to measure the amount of displacement. Movement of the footplate enables measurement of displacement in the anterior direction.

The dynamic ankle tester measures the anterior displacement of the calcaneus in relation to the tibia as a result of a hammer

determine systematical errors between the observers. Pearson correlation coefficients were determined to investigate the correlation between the two testers, manual testing and Telos® stress testing.

RESULTS AND DISCUSSION

Intra-observer reliability coefficients for the dynamic test and quasi-static test were 0.84 and 0.82 respectively ($p < 0.01$). Inter-observer reliability was 0.83 for the dynamic and 0.82 for the quasi-static test ($p < 0.01$). Small but significant systematical errors between the observers of 0.58 mm (6%) and 2.84 mm (12%) for the dynamic test and the static test respectively were found ($p < 0.01$ for both tests). The correlation coefficients of the two testers are shown in Figure 3. There were no correlations between the two testers on the one hand and the manual and Telos® test on the other, nor was there a correlation between the manual and Telos® test.

Figure 1. Dynamic ankle tester

Figure 2. Quasi static ankle tester

hitting the heel-plate. The impulse of the hammer pushes the foot forward. The resulting anterior-posterior and medio-lateral translation are measured. The load-displacement event takes place within the reflex time of the muscles, so involuntary muscle contraction cannot influence the test results. The translation values of the calcaneus in relation to the tibia as measured with the quasi static ankle tester are the result of a manually applied load up to maximally 150N.

Twenty-four volunteers visited the clinic twice with minimally 1 week in between. During the first visit, 2 different observers tested the patients with both instrumented tests. Stress-radiographs were made with help of the Telos® device. During the second visit, one observer performed the manual test; the second performed both instrumented tests.

Reliability coefficients were calculated to investigate inter- and intra-observer reliability. Paired t-tests were performed to

Figure 3. Comparison of displacement measurements between the dynamic and quasi-static ankle testers.

CONCLUSIONS

The reproducibility and repeatability of both test devices are good. The systematical errors represent low clinical significance but call for further improvement of the measurement procedure. Which test (device) is the best and most reliable is not yet clear. Also the manually performed test and the TELOS® test with radiographs need re-evaluation.

INTRODUCTION

Various pathological conditions of the foot and ankle affect its morphological, architectural, and mechanical properties. These parameters have a variability among individuals, which is known to be very large. Therefore, for those conditions in which only one ankle is affected it is desirable to develop diagnostic techniques based on a comparison with the unaffected contra-lateral side. In order to do so, the level of left to right symmetry of the ankle in healthy asymptomatic individuals must be established. This was the goal of the present study.

METHODS

The morphological and architectural properties of the ankle complex consisting of the truncated tibia and fibula (i.e., based on an isoshaping procedure) (1), the talus and calcaneus were determined from three-dimensional reconstructions of MR images using the 3DVIEWNIX software system (2). This procedure included segmenting and creating a 3D representation of the bones, and calculating their morphological and architectural properties (3). These included the lengths of the principal axes within the bone and their corresponding principal moments of inertia, location of the centroids, and distance between the centroids. Kinematic parameters (i.e., centroid displacement, the direction of the equivalent axis, and the net rotation about it) representing relative bone movement under various incremental loading conditions were calculated for each load increment. To apply the loads, a non-metallic arthrometer, was used (4). The ankle was first scanned in the unloaded configuration. A 2.26 Nm inversion moment was applied, the arthrometer was locked, and the ankle was scanned. This procedure was repeated for a 133.45 N anterior drawer force.

RESULTS AND DISCUSSION

The average percent difference between the principal moments of inertia and the lengths of the principal axes for five healthy

subjects are presented in Table 1. The distance between the centroids of the tibia and talus, tibia and calcaneus, and calcaneus and talus yielded percent difference of $1.20 \pm 0.78\%$, $0.64 \pm 0.29\%$, and $1.07 \pm 1.02\%$, respectively. These anthropometric data show a high level of symmetry.

The angle of rotation and the centroidal displacement for each bone were small and close in magnitude to the level of accuracy of the MRI kinematic technique (3). Therefore the left to right symmetry in these properties were reported in absolute values. The average difference between left and right rotations and translations were calculated for the talus and calcaneus relative to the tibia. In inversion, the average difference for the calcaneus and talus were $6.28 \pm 4^\circ$ and $4.94 \pm 2.89^\circ$, respectively. The average difference in displacement in anterior drawer for the calcaneus and talus were 2.82 ± 3.13 mm and 1.19 ± 1.63 mm, respectively. These parameters show a greater symmetry than those calculated based on external measurements (4).

SUMMARY

The level of symmetry in the anthropometric and mechanical properties of the ankle joint identified in this study established a threshold, which can be used when a diagnosis of a unilateral ankle pathology relies on comparison to the intact contra-lateral side.

SIMULATION BASED MEDICAL PLANNING FOR CARDIOVASCULAR SURGERY: RECENT DEVELOPMENTS

Charles A. Taylor

taylorca@stanford.edu

INTRODUCTION

We describe the results from a series of animal experiments used to test the accuracy of our three-dimensional and one-dimensional finite element methods for modeling blood flow by comparing predicted flow rates to *in vivo* measurements obtained using phase contrast magnetic resonance imaging (PC-MRI). Both 3D and 1D methods involve solving the governing equations of blood flow on a domain and prescribing boundary conditions to account for the vasculature downstream. A variational multiscale method to obtain boundary conditions applicable to blood flow will be discussed in the podium presentation. In this approach, a finite element method is used for the region where the governing equations are nonlinear or not amenable to analytic solution and a lumped parameter model or linear wave equation is used for the vasculature downstream.

METHODS

Experimental validation studies were performed using data collected from experiments involving eight pigs. In each animal, we created an aortic constriction, or stenosis, by tying polyester (Dacron) umbilical tape around the descending thoracic aorta to restrict blood flow and then attached a 10 mm diameter polyester (Dacron) graft to the thoracic aorta proximal and distal to the constriction to provide an alternate path for blood flow. Blood is divided between the native aorta and the bypass graft and combines downstream of the stenosis. Magnetic resonance angiography was used to acquire three-dimensional anatomic images, while phase contrast MRI (PC-MRI) was used to collect velocity data at four different locations: the proximal aorta (inlet), the mid-aorta (aorta), the graft, and the distal aorta (outlet). Numerical predictions of flow rate were compared with magnetic resonance imaging data in eight pigs.

RESULTS AND DISCUSSION

Figure 1 shows computed flow rates using 3D and 1D methods with empirically-derived stenosis and branch loss terms.

SUMMARY

We have demonstrated that both three-dimensional methods and one-dimensional methods can describe blood flow distribution in a porcine thoraco-thoraco bypass surgery.

PROSPECTS OF MICRO- FINITE ELEMENT ANALYSES OF BONE FOR CLINICAL APPLICATION

Bert van Rietbergen

Department of Biomedical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands

INTRODUCTION

Micro- finite element analysis (μ FE) enables a complete and precise evaluation of cancellous bone mechanical properties as they relate to its trabecular structure as quantified by high-resolution images. A tempting application of this technique is the analyses of structure-related mechanical properties of bone in-vivo. Such analyses potentially could improve the diagnosis of bone strength reduction with osteoporosis or increase the sensitivity of osteoporotic drug treatment efficacy studies. So far, however, the clinical application of this technique has been limited by the poor resolution of clinically available imaging methods.

Recently, high-resolution pQCT and MR imaging techniques have been introduced that enable the visualization of trabecular bone in-vivo. The resolution of these images, however, is still less than that commonly used for μ FE analyses and the question remains whether results of analyses based on such images are better than those of stochastic relationships based on DEXA bone density measurements, which is the most common predictive tool used nowadays.

In this paper, the results of two recent studies that addressed this question are summarized. Based on these results, the prospects of μ FE as a clinical application will be discussed.

μ FE FOR BONE FAILURE LOAD PREDICTION

In the first study [1], a special 3D-pQCT device that can be used for bone in-vivo was used to create μ FE models of 54 cadaver arms at 165 μ resolution. After imaging, the arms were compressed to failure to produce a collus' type fracture and the failure load was measured. Micro-FE analyses were used to simulate the experiments and the bone failure load was predicted from these FE results using a bone tissue failure criterion. To evaluate the predictive value of stochastic relationships structural indices were measured as well from the 3D-pQCT images and bone mass measurements were obtained from DEXA measurements.

The predicted failure loads calculated from the FE-analysis compared well with those measured in the experiments ($R^2=0.75$ $p<0.001$). Lower correlations were found with bone mass ($R^2=0.48$ $p<0.001$) and bone structural parameters ($R^2=0.57$ $p<0.001$). It was thus concluded that micro-FE results significantly improved the prediction of bone failure load.

μ FE FOR DRUG TREATMENT EFFICACY STUDIES

In the second study [2], high-resolution (195 \times 195 \times 500 μ) MR-imaging was used to create 3D μ FE models of a cancellous volume of interest (VOI) in the calcaneus of 56 postmenopausal women participating in a longitudinal clinical trial to

evaluate the effect of idoxifene (Fig. 1). Subjects received either a placebo or the idoxifene treatment. MR-images were acquired at baseline and after one year of treatment and μ FE was used to calculate changes in elastic properties of the VOI. DEXA measurements were performed at the heel as well.

Elastic moduli in the treated groups significantly differed from baseline after one year of treatment. Changes in bone mass, however, were not significant. Changes in the placebo group were not significant for any parameter. Since significant changes in moduli were obtained for the treated groups whereas no significant change in bone mass was found it was concluded that the application of these techniques may increase the clinical significance of these trials.

DISCUSSION

In both studies summarized here it was found that the results of μ FE analyses could improve upon predictions based on bone density measurements. Moreover, the μ FE analyses provide direct and very detailed information about (changes in) bone mechanical properties.

Some limitations should be mentioned as well. First, high-resolution in-vivo images presently can be obtained only for the peripheral skeleton and not for other important osteoporotic fracture sites such as the femur or vertebrae. Second, the results of these analyses do not reflect (changes in) the bone tissue material properties, the measurement of which would require invasive (biopsy) techniques.

Based on the encouraging results obtained so far, it is concluded here that μ FE potentially could lead to more accurate predictions of bone failure load, shorter follow-up periods and smaller population sizes in clinical studies.

THE MECHANISMS AND SIGNIFICANCE OF THE CORRELATION BETWEEN BONE STRENGTH AND STIFFNESS

INTRODUCTION

Bone stiffness is fundamental to the ability of a vertebrate to move (Wainwright 1982). Sufficient strength is also essential for the skeleton to withstand overloads (Wainwright 1982). These observations are similar but it is fundamentally more difficult to control strength than it is to control stiffness. The difference is caused by the fact that bone stiffness affects *deformation*, but strength is related to the *force* (stress) when failure occurs. Deformation can be measured and, therefore, stiffness can be controlled. Force is not directly measurable (*e.g.*, load cells measure the deformation of a calibrated structure). Therefore, strength is a property of bones that cells cannot measure and cannot directly control. This talk presents recent work on how, despite its apparent impossibility, vertebrates still manage to control bone strength.

STIFFNESS PREDICTS STRENGTH

The key observation that suggests how cells may control bone strength is the high correlation between apparent strength and stiffness (Fyhrie and Vashishth 2000). Consequently, any ability to control bone apparent stiffness (by controlling deformation) will translate into an ability to control apparent strength. It is odd, however, that strength and stiffness correlate at the *apparent* level. Apparent strength and stiffness are calculated from volume and area averages of deformation and force. It is not obvious how a bone could know these averages. We conclude that the correlation of strength and stiffness for cortical and cancellous bone tissue derives from microstructural and ultrastructural mechanisms.

MICROMODELS FOR STRENGTH

Strain distribution in cancellous bone is strongly affected by trabecular microstructure (Hou 1998). We showed that the average and standard deviation of trabecular shear stresses are correlated (Fyhrie et al, 2000). Control of the correlation between stress statistics is a mechanism that can affect the correlation of stiffness and strength.

For cortical tissue, tensile failure is by propagation of cracks. A micromodel of collagen bridged microcracks (Yeni 2002a) can predict the apparent failure strength of cortical bone from the apparent stiffness of the tissue and the failure strain of the collagenous matrix. This model shows the importance of collagen viscoelasticity to the creation of bone strength.

The key to the model (Yeni 2002a) was the viscoelasticity and *hidden length* (Thompson 2001) of the collagen fibrils. The hidden length of a macromolecule allows it to unfold (extend) under load and to dissipate energy. Reversible bond breaking "toughens" (adds strength to) a material and is a mechanism

that can correlate strength and stiffness. Energy dissipation manifests as viscoelasticity at the macroscopic level. Consequently, our observation that viscoelastic properties of bone can predict macroscopic bone strength (Yeni 2002b) may relate to reversible bond breaking in collagen.

VISCOELASTICITY AND MENOPAUSE

The correlation of apparent bone strength to bone stiffness is very good and is related to bone viscoelastic properties. Changes in bone viscoelastic properties with age or menopause may be important predictors of changes in bone strength. The dissipation of energy in ovine cortical bone

($\tan\delta$) is decreased at high frequency after three years of ovariectomy (Les 2002). This change in viscoelastic properties, along with our other observations, leads to the hypothesis that ovariectomy

(and possibly menopause) reduces the strength of bone under rapid loading. Testing this hypothesis is the next goal in determining the relationship of bone stiffness to strength.

Fig. 1: Frequency dependence of energy dissipation for ovine cortical bone after three years ovariectomy.

APPLICATION OF VIRTUAL EXPERIMENTS TO THE STUDY OF TRABECULAR BONE MECHANICS

Glen L. Niebur

Department of Aerospace and Mechanical Engineering and Center for the Study of Biocomplexity
The University of Notre Dame, IN, USA gniebur@nd.edu

INTRODUCTION

The development of high-resolution imaging modalities and the high-resolution finite element technique has greatly expanded our capability to study trabecular bone mechanics through the application of “virtual experiments” (Niebur et al. '00). Computer models have been applied as surrogates for mechanical testing to formulate relationships between fabric and the elastic properties of trabecular bone (Van Rietbergen et al. '98; Zysset et al. '98). Nonlinear models have been used to study multiaxial yield behavior (Niebur et al. '01). In both cases, these virtual experiments provided additional insight into both the apparent and tissue level mechanical behavior of trabecular bone.

TISSUE CONSTITUTIVE MODELING

The degree to which a computer model will reflect a true mechanical test depends on the validity of the assumed tissue level constitutive behavior, and the accuracy with which the parameters to the constitutive law can be determined. Direct assessment of the trabecular tissue behavior is limited due to the small size of the experimental material (Choi et al. '90). Virtual experiments complemented by apparent level measurements can be used to gain insight into these tissue level properties.

For most applications, the elastic behavior of the tissue can be described by a single modulus (Kabel et al. '99) that can be calibrated (Van Rietbergen et al. '95) from accurate mechanical measurements of the apparent modulus (Keaveny et al. '97).

Figure 1: Apparent shear yield strains for bovine tibial trabecular bone. A one-parameter tissue yield criterion cannot accurately predict the apparent yield behavior in shear.

The yield properties of the trabecular tissue can be calibrated using a similar approach. Initial experiments demonstrated that the tissue level yield criterion must incorporate tension-

compression strength asymmetry (Niebur '01) (Fig. 1), requiring at least two failure experiments to calibrate the constitutive behavior. However, aggregate tissue level yield properties can be calibrated by comparing computationally predicted apparent yield properties to mean values from mechanical measurements (Niebur '00).

MULTIAXIAL YIELD PROPERTIES

Accurate measurement of multiaxial yield properties of trabecular bone is complex. High-resolution finite element models can be used to apply arbitrary loading combinations without loading artifacts (Keaveny '97). More importantly, multiple loading conditions can be investigated for a single specimen. Thus, the general form of a multiaxial yield criterion can be considered without the confounding effects of inter-specimen heterogeneity and anisotropy (Fig. 2)

Figure 2: Complete Tsai-Wu (left) and multi-surface (right) failure envelopes characterized for a single specimen of trabecular bone using virtual experiments.

SUMMARY

Virtual experiments based on high-resolution finite element models of trabecular bone provide a powerful means to confront the issues of heterogeneity and anisotropy when studying trabecular bone mechanics. High-resolution finite element models allow data for multiple loading conditions to be obtained for a single specimen. It is thereby possible to control or isolate the effects of inter-specimen heterogeneity and anisotropy to gain improved insight into the mechanical behavior of trabecular bone.

INTRODUCTION

Bone subsidence has been identified as a cause of implant failure (Taylor, et al, 1999). We wish to characterize this phenomena and use it with finite element models to predict subsidence of implanted systems. During *in vitro* fatigue tests with non-zero mean loads, strain accumulation is noticed upon unloading under a variety of loading modes. This observation has been described by various researchers as “creep” (Carter and Caler, 1983), “plasticity” (Taylor, et al, 1999), and “strain drift” (Pattin, et al, 1996). Limited work has focused on characterizing this phenomena, while a number of researchers have quantified the accompanying stiffness loss.

We examine if this strain accumulation during fatigue in cortical bone is accurately described as creep. Although several researchers (Carter and Caler, 1985; Zioupos, et al, 2001) have related in fatigue and creep cycles and times to failure, respectively, this study examines the actual rate of strain accumulation in fatigue. In cancellous bone, such a relationship has been presented (Bowman, et al, 1998).

Under constant load conditions, creep has been reported in human cortical bone. A formulation derived (Fondrk, et al, 1999) proves useful, where the rate of creep strain is determined by

$$\dot{\epsilon}_c = \dot{\epsilon}_{c-th} (\sigma / \sigma_{th})^N$$

An arbitrary creep rate threshold is chosen and constants of a stress threshold, σ_{th} , and power, N , determine the creep rate as a function of stress.

METHODS

Bone samples (n=29) were taken from four individuals: females age 53, 69, and 79; a male, age 55. Samples were fatigued until failure in 0-T loading over a range of stresses, (Winwood, et al, 2001). The average creep strain per cycle was calculated from 10% to 90% of the fatigue life. Creep rate was converted from equation 1 to a “per cycle” basis by substituting stress as a sinusoidal function of time, and integrating over a cycle. Thus, the constants of equation 1 were determined for the experimental data. Creep rate threshold was taken, as Fondrk, to be 10^{-5} /sec.

RESULTS

Creep strain accumulated according to the classically described “three stage creep”. The portion from which creep strain rate was taken corresponded to the middle, constant rate regime (stage II creep). Creep rates per cycle were observed in the range of 10^{-10} to 10^{-4} and are shown as a function of stress in figure 1. These relationship fitted well to a power law.

Resulting stress threshold values and powers were determined for the four individuals and are shown in Table 1.

Figure 1: Creep strain per cycle as a function of stress.

	f69	f53	f79	m55	Combined
σ_{th}	56.3	74.3	65.4	60.5	64.4
N	14.5	19.6	16.3	20.0	14.8
R^2	0.86	0.58	0.85	0.83	0.62

Table 1: Results of fitted analysis.

SUMMARY

The non-zero strains accumulated at a rate well described by a stress power law used to describe creep. Constants are seen to be in the range of speculated values presented by Fondrk (σ_{th} of 68-79 MPa) and ($N = 12-17$), even though the creep rates are mostly lower than those seen by Fondrk, owing to the different time scales of the tests. Notable is the advanced age and gender (mostly female) of the samples.

A COMPUTATIONALLY EFFICIENT ALGORITHM FOR IN-VIVO BONE FAILURE PREDICTION ON THE TRABECULAR LEVEL: A COMBINED EXPERIMENTAL AND COMPUTATIONAL APPROACH

Martin Stauber, Steven K. Boyd, Ara Nazarian and Ralph Müller

Institute for Biomedical Engineering, Swiss Federal Institute of Technology (ETH) and University of Zürich, Zürich, Switzerland

INTRODUCTION

Osteoporosis is a major health disease characterized by low bone mass and micro-architectural deterioration of bone tissue. Eventually, the bone becomes fragile resulting in increased fracture risk. The fracture risk has traditionally been assessed by bone density measurements, however it is known that changes in trabecular morphology can lead to disproportionate decreases in bone strength (Goldstein, 1987). Experimentally, using image-guided failure assessment technique, Müller et al. (1998) showed that failure of individual trabeculae can lead to global bone failure. Therefore, failure prediction of individual trabeculae is important for global failure prediction.

Individual trabecular strains can be predicted by finite element (FE) analysis of high-resolution image-based models. One possibility is the use of a solid FE model (Verhulst et al., 2001), but this approach is computationally taxing, and hence is currently of limited use for clinical purposes. In this study, we propose a computationally efficient FE technique to predict local trabecular strains and displacements and validate it against real experimental dynamic failure visualization. The FE model uses beam elements derived from skeletonized micro-structural data, and may have future clinical potential for *in vivo* applications of bone failure prediction.

METHODS

A micro-compression device was used to measure unloaded and loaded porous structures (aluminum foam, whale and human vertebral bone). The specimens were step-wise compressed to 0, 2, 4, 8, 16, and 20 percent global strain, and then measured in the micro-tomographic system (μ CT 20, Scanco Medical AG, Bassersdorf, Switzerland) at a spatial resolution of 68 μ m. During compression, a data acquisition system recorded the displacement applied to the specimen and the corresponding load providing stress-strain curves for global modulus assessment.

The experimental approach to compute local strains was based on the six consecutively measured compression images. Each of those three-dimensional (3D) time-steps was spatially decomposed using a thinning approach leading to a homotopic skeleton of the structure (Figure 1). Corresponding elements were identified within the different time steps using a 3D correlation procedure. This method allowed us to track each trabecular element and its deformations within the structure during the compression procedure, and hence to compute the relative strain for each element.

The computational FE approach to assess local strain was based on the unloaded 3D structure. The skeletonized structure

was the basis for obtaining a list of nodes and connectivities that could automatically be translated in a homotopic beam model used for subsequent FE calculations. The beam model was imported into Marc (MSC Software Corporation, Los Angeles, CA), where all material properties and boundary conditions were specified. All elements were chosen to be of the same type and same diameter (466 μ m), but lengths depending on the original trabecular structure. Boundary conditions for the compression test simulated the axial compression used in the experimental approach: a plane at the bottom surface fixed the nodes in contact, and a parallel plane on the top surface displaced the nodes of the elements at increments of 0.2% global strain. As compression continued, nodes coming in contact with either plane were constrained to move within the plane in all subsequent steps.

Figure 1: Porous structure measured by μ CT (left) and the derived beam FE model from the skeletonized image (right).

RESULTS AND DISCUSSION

The presented method allowed spatial decomposition of trabecular structures into individual elements, thus enabling computation of local strains both from experimental data and the derived beam FE model. The advantage of this approach is the ability to directly validate the beam FE model.

Globally, the resultant stress-strain curves were in excellent agreement, but more interesting also local strains computed from the experimental approach were in good agreement with local strains computed by the FE model. Thus, it appears that this computationally efficient FE approach has the potential to predict local failure in bone, and may have future applications for risk assessment in upcoming 3D *in vivo* image data.

SENSORY TRANSDUCTION IN AN ARTHROPOD MECHANORECEPTOR SYSTEM

Andrew S. French

Department of Physiology and Biophysics, Dalhousie University, Halifax, Nova Scotia, Canada

E-mail: andrew.french@dal.ca

INTRODUCTION

Arthropods (insects, spiders and crustaceans) have provided a variety of model systems for studying fundamental mechanisms of sensory transduction and processing of sensory information. In addition to their ready availability and relatively simple nervous systems, the arthropods possess a class of sensory receptors, the Type I or cuticular receptors, that have their sensory neuron cell bodies located in close proximity to the sensory endings in the external cuticle. These receptors allow experiments to be performed that are currently impossible with most vertebrate mechanoreceptors.

Slit sensilla are specialized mechanoreceptors that detect mechanical strain in the spider cuticle. They occur singly and in groups, called slit-sense organs. We developed a preparation of the VS-3 slit-sense organ (Barth and Libera, 1970) in the tropical wandering spider, *Cuppienius salei*, that has allowed us to make intracellular recordings from primary mechanosensory neurons and to voltage-clamp the receptor current during sensory transduction.

METHODS

Figure 1 shows the experimental arrangement used for most of our studies on the VS-3 slit-sense organ. The organ consists of 7-8 slits in the cuticle, with each slit innervated by a pair of sensory neurons. Both the neurons of each pair are mechanoreceptors but they have different adaptation properties. Glass microelectrodes of about 60 M Ω resistance were inserted into the sensory neurons allowing measurement of the membrane potential or the receptor current by the switching single electrode voltage clamp technique (Juusola et al., 1994).

RESULTS AND DISCUSSION

Transduction occurs in the tips of the sensory dendrites that terminate in the slits. The tips are surrounded by a sodium-rich lymph, and recordings of the receptor current, including its current-voltage relationship and ion substitution experiments showed that mechanical stimulation opens sodium selective ion channels in the tips (Höger et al., 1997). Noise analysis of the receptor current indicated that there are probably a few hundred mechanoreceptor channels with comparatively small single-channel conductance (Höger and French, 1999).

The receptor current adapts with time after a step stimulus to the slits, but the adaptation is much slower than the rapid

adaptation of the action potential discharge, indicating that other membrane currents control the rapid adaptation.

VS-3 Spider Mechanoreceptor Organ

Figure 1: Mechanotransduction in the spider VS-3 slit-sense organ. The patella cuticle was dissected and the tissues removed to expose the sensory organ. Microelectrodes were inserted into neuron cell bodies while a mechanical stimulator pushed on the appropriate slit from below.

SUMMARY

The spider VS-3 organ has provided important new information about fundamental mechanisms of transduction in arthropod mechanoreceptors. Current experiments are aimed at further characterization of the receptor channels to allow comparison with families of mechanically-activated ion channels in other systems.

RECONSTITUTING A *C. ELEGANS* ION CHANNEL REQUIRED FOR MECHANOSENSATION

Miriam B. Goodman

Department of Molecular and Cellular Physiology, Stanford University, Stanford, CA., mbgoodman@stanford.edu

INTRODUCTION

The soil nematode, *Caenorhabditis elegans*, is an excellent animal for studying the molecular events that give rise to the sensation of force. Its response to force is simple: touching the animal in the head elicits backward movement and vice versa. This behavior depends on six specialized sensory neurons called touch cells, all of which can be identified in living animals and exposed for electrical recording. Genetic screens for touch insensitive animals identified twelve *mec* (mechanosensory abnormal) genes needed for the function, but not the development, of the touch cells. Except for *mec-5*, which encodes a collagen protein expressed in closely apposed hypodermal cells (Du, et al, 1996), all of the cloned genes are expressed in touch cells.

The protein encoded by *mec-4* is touch-cell specific and belongs to the DEG/ENaC superfamily of proteins that form amiloride-sensitive ion channels. The *mec-10* gene encodes another DEG/ENaC channel subunit expressed in touch cells and four additional mechanosensory neurons. Both channel proteins are needed for touch sensitivity and can mutate to cause neuronal degeneration. MEC-4 and MEC-10 are hypothesized to form an ion channel at the center of a sensory mechanotransduction complex that includes genes encoding two additional membrane proteins (*mec-2* & *mec-6*), three extracellular matrix proteins (*mec-1*, *mec-5*, *mec-9*), and two microtubule proteins (*mec-7*, *mec-12*) (for review, see Tavernarakis & Driscoll, 1997). As a first step in reconstituting this putative sensory mechano-transduction complex, we co-expressed the DEG/ENaC proteins, MEC-4 and MEC-10, in *Xenopus* oocytes and determined how channel activity was affected by the addition of the membrane proteins, MEC-2 and MEC-6.

METHODS, RESULTS AND DISCUSSION

A long-standing question is whether the putative ion channel subunits, MEC-4 and MEC-10, form channels similar to other DEG/ENaC channels. To address this question we measured whole cell currents in *Xenopus* oocytes injected with cRNAs encoding the channel subunits (Goodman et al., 2002). Co-expression of the mutant or 'd' forms of MEC-4 and MEC-10 produced a constitutively-active Na⁺ current that is blocked by amiloride with high affinity (at -60, K_i' = 0.2±0.1 μM). MEC-2, a membrane protein related to human stomatin, increased the activity of mutant channels by approximately 40-fold and allowed currents to be detected with wild-type MEC-4 and MEC-10. MEC-6 also increased the activity of mutant channels by ~10-fold. MEC-6 has limited sequence similarity to paraoxonases, a family of arylesterases. Neither

MEC-2 nor MEC-6 generated any detectable amiloride-sensitive current when expressed alone, indicating that they increase channel activity by interacting with MEC-4 and MEC-10. The picture that emerges from these functional interactions and previous evidence of interaction derived from genetic analysis is that MEC-4 and MEC-10 form an ion channel complex together with the accessory proteins, MEC-2 and MEC-6.

MEC-2 belongs to family of proteins with members expressed in bacteria, plants, and animals. The central domain of MEC-2 is highly conserved and is 64% and 46% identical to the human proteins, stomatin and podocin, respectively. To test the hypothesis that MEC-2 function is conferred by this conserved domain, we truncated MEC-2 and tested if truncated MEC-2, stomatin and podocin generated similar activities in *Xenopus* oocytes. While all three proteins could generate amiloride-sensitive currents when co-expressed with the 'd' form of MEC-4, none retained the activity of full-length MEC-2. These results suggest that the highly conserved central domain of MEC-2 is not sufficient for its function as an ion channel accessory protein.

SUMMARY

Screens for touch insensitivity in *C. elegans* have identified components of a candidate sensory mechanotransduction complex. We have taken the first steps in reconstituting this complex in *Xenopus* oocytes and understanding the function of its individual components. Current experiments are aimed at understanding how this channel is gated, understanding the mechanism by which the accessory proteins alter channel activity and testing whether or not this channel is necessary for transduction *in vivo*. Emerging strategies for studying channel function *in vivo* will be discussed briefly.

MYOSIN-1c IS THE HAIR CELL'S ADAPTATION MOTOR

Peter G. Gillespie¹

Oregon Hearing Research Center and Vollum Institute, Oregon Health & Science University, Portland, OR.
¹gillespp@ohsu.edu

INTRODUCTION

Hair cells, the sensory cells of the inner ear, transduce auditory and vestibular stimuli into receptor potentials, which initiate transmission of the sensory signal to the central nervous system. Mechanical transduction is carried out by the hair bundle, a crosslinked cluster of ~50 actin-filled stereocilia arranged in ranks of increasing height. This anatomical polarity corresponds to the physiological polarity of the bundle, so that deflections of the bundle towards the tallest stereocilia depolarize the cell, deflections towards the shortest stereocilia hyperpolarize the cell, and perpendicular deflections have no effect on the membrane potential. Hair-cell transduction is direct: bundle deflections stretch ~50 gating springs, which tug open 50-100 cation-selective transduction channels within microseconds and without second-messenger intervention. Although transduction channels open and close stochastically, changes in gating-spring tension alter the channels' open probability (P_{open}) and change the total receptor current flowing through them.

Hair cells adapt to sustained bundle deflections by adjusting the P_{open} of transduction channels back towards a resting level. Four lines of circumstantial evidence implicate myosin molecules in adaptation. First, adaptation is not merely a passive response to the stimulus; the adaptation motor actively generates force. Second, adaptation takes place within actin-rich stereocilia, and myosins are the only motor molecules known to move along actin. Third, adaptation requires Ca^{2+} and calmodulin, both of which control the activity of unconventional myosins. Fourth, ADP analogs and phosphate analogs, inhibitors of myosin activity, block adaptation. Candidates for the adaptation motor are therefore likely to belong to the extensive myosin superfamily. Although several myosin isoforms are present in hair bundles, the best-supported adaptation-motor candidate is myosin-1c (Myo1c).

METHODS, RESULTS AND DISCUSSION

To test the hypothesis that Myo1c participates in adaptation, we have applied a chemical-genetic strategy for selectively inhibiting its motor activity. We designed a mutation in Myo1c, Y61G, that greatly increased its sensitivity to inhibition by N^6 -modified ADP analogs. Because the adaptation-motor complex likely consists of dozens of myosin molecules working together, immobilization of only a fraction

of these molecules in an actin-bound state should be required to arrest adaptation. We therefore made transgenic mice that express Y61G-Myo1c, and found that slow adaptation is blocked when hair cells are dialyzed with N^6 (2-methyl butyl) ADP (NMB-ADP).

Figure 1: Block of adaptation in Y61G mice by NMB-ADP. Wild-type (left) or Y61G (right) hair cells were dialyzed with NMB-ADP; transduction and adaptation were assessed before (thin lines) and after (thick lines) diffusion of NMB-ADP to stereocilia. Asterisk, slowed closing kinetics.

SUMMARY

Myosin-1c has been proposed to mediate the slow component of adaptation by hair cells, the sensory cells of the inner ear. To test this hypothesis, we mutated tyrosine-61 of myosin-1c to glycine, conferring susceptibility to inhibition by N^6 -modified ADP analogs. We expressed the mutant myosin-1c in utricular hair cells of transgenic mice, delivered an ADP analog through a whole-cell recording pipette, and found that the analog rapidly blocked adaptation to positive and negative deflections in transgenic cells but not in wild-type cells. The speed and specificity of inhibition suggests that myosin-1c participates in adaptation in hair cells.

EXPERIMENTAL VERIFICATION OF THE ROLE OF INTERSTITIAL FLUID PRESSURIZATION IN THE FRICTIONAL RESPONSE OF BOVINE ARTICULAR CARTILAGE

Ramaswamy Krishnan and Gerard A. Ateshian¹

Department of Mechanical Engineering, Columbia University, New York, NY 10027

¹<http://www.columbia.edu/~ga29> ateshian@columbia.edu

INTRODUCTION

Articular cartilage functions as the bearing material in joints and provides low friction and wear over a lifetime. The cartilage lubrication mechanism has not yet been fully characterized though several theories have been proposed. In previous studies (McCutchen, 1959; Forster and Fisher, 1996; Ateshian, 1997) it was hypothesized that interstitial fluid load support contributes significantly to the reduction of the frictional coefficient due to load transfer from the solid to the fluid phase of the tissue. This study provides experimental verification for a theoretical model based on this hypothesis (Ateshian, 1997; Ateshian et al., 1998). The specific aim of this study is to experimentally investigate the correlation between frictional response and interstitial fluid load support.

METHODS

Six cartilage plugs (diam. 6mm) were harvested from the femur and tibia of bovine knee joints obtained from a local abattoir. (2 joints, ages 3 & 24 months). Using a sledge microtome (model 1400; Leitz, Rockleigh, NJ), ~1mm of tissue was removed from the deep zone to produce samples 1.13±0.19mm thick, with the articular surface left intact. All specimens were stored at -20°C in physiological buffered saline (PBS) solution. On the day of testing, each sample was thawed and equilibrated in PBS solution. The test protocol consisted of an unconfined compression creep test with intermittent sliding. Sliding motion was provided by a computer controlled translation stage (Model PM500-1L, Newport Corporation, CA). Normal loads were prescribed via a stepper micrometer (Model 18503, Oriel Instruments, CT) connected with a linear variable differential transformer to measure displacements (HR100, Shaevitz sensors, VA). All loads were measured with a multiaxial load cell mounted on the translation stage (Model 20E12A-M25B, JR3 Inc., CA). Fluid pressure measurements were made on the face opposite the articular surface (Soltz and Ateshian, 1998) using a microchip piezoresistive pressure transducer (NPC 1210 series; Lucas NovaSensor, CA). Data acquisition and control was performed using a personal computer equipped with a data acquisition card. The entire specimen and glass surface were immersed in 0.15M PBS solution, at room temperature, throughout the test. Cartilage-on-glass friction measurements were made under the configuration of unconfined compression creep with a prescribed load of 4.5N or 9N and simultaneous intermittent sliding over logarithmic time increments (range of translation ±2mm; sliding velocity 1mm/s). The test was terminated when the interstitial fluid pressure nearly reduced to zero. The normal force, frictional force, interstitial fluid pressure and displacement were monitored throughout this time. According to our model, the time-dependent friction coefficient μ_{eff} varies as a function of the interstitial fluid load support W^p/W as $\mu_{eff} = \mu_{eq} [1 - (1 - \phi)W^p/W]$, where μ_{eq} is

the equilibrium friction coefficient achieved when $W^p/W = 0$, and ϕ is the fraction of the porous contact area where solid-to-solid contact occurs. Thus μ_{eff} is a linear function of W^p/W .

Figure 1: μ_{eff} vs. W^p/W for a typical specimen.

RESULTS AND DISCUSSION

The friction coefficient μ_{eff} was observed to increase with time, from a minimum value of $\mu_{min} = 0.024 \pm 0.01$ to a near equilibrium value of $\mu_{eq} = 0.28 \pm 0.08$, over a period of $10,600 \pm 7,500$ s. Concomitantly, W^p/W decreased from a peak value of $93\% \pm 3\%$ down to approximately 9%. Plotting μ_{eff} against W^p/W produced a linear response as shown for a typical sample in Figure 1. A linear fit to the experimental data yielded an average coefficient of determination of $r^2 = 0.97 \pm 0.014$ over all specimens. To our knowledge, this is the first study to report the measurement of interstitial fluid load support simultaneously with the frictional response of cartilage. The observed inverse linear correlation between these variables supports the hypothesis that interstitial fluid load support is a major mechanism governing the frictional response of articular cartilage. Any mechanism that compromises interstitial fluid pressurization, such as tissue fibrillation or degradation, is thus likely to adversely affect the frictional response.

BIOMECHANICAL MODELING OF ARTICULAR CARTILAGE: FROM MACROSCALE TO MICROSCALE

John Z Wu¹ and Walter Herzog²

¹National Institute for Occupational Safety & Health, Morgantown, WV, USA., E-mail: jwu@cdc.gov

²Faculty of Kinesiology, The University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

It is generally accepted that cartilage adaptation and degeneration, such as observed during osteoarthritis, is mechanically mediated. Experimental evidence suggests that cartilage deformation caused by mechanical loading is directly associated with deformation and volume changes of chondrocytes, and stress and pressure concentrations around the chondrocytes. Therefore, it is feasible to speculate that changes in cartilage loading are associated with changes in the stress/strain states of the corresponding chondrocytes, which in turn influence the in vivo biosynthetic activity of the cells, and so, regulate cartilage adaptation. Chondrocyte stresses cannot be measured experimentally, thus requiring a theoretical approach to obtain this information. The purpose of this presentation is to describe our efforts towards developing a biomechanical joint contact model, which predicts stress/strain state and chondrocyte deformation in articular cartilage under physiological loading conditions.

METHODS, RESULTS, AND DISCUSSION

Six years ago, we developed an analytical model of the static axi-symmetric joint contact mechanics with biphasic cartilage layers (Wu et al., 1996), based on an asymptotic solution by Ateshian et al. (1994). This approach extended Ateshian et al.'s model to more general cases, and could account for the interactions of curved convex and concave surfaces of different radii of curvature, and for the effects of changing articular cartilage dimensions and mechanical properties in the contact mechanics. Later, the solution for axi-symmetric joint surface geometry for static loading was generalized to account for dynamic loading (Wu et al., 1999a). In our previous joint contact models, the articular cartilage was considered to be uniform and isotropic, therefore, the deformation behaviour of chondrocytes and the effects of substructures on the global mechanical characteristics were not simulated.

Fig. 1: Cell-matrix composite treated as a homogenized equivalent matrix.

In a theoretical or numerical joint contact model, it is technically intractable to take into account the effects of individual cells on the global mechanical behavior of cartilage. Therefore, we proposed a homogenization technique to account for the average effects of the distributed substructures on the global mechanical characteristics of cartilage layers. The approach involved three basic steps (Fig. 1)(Wu et al., 1999b, 2000): first, the cartilage was approximated as a macroscopically homogenized material having effective

material properties; second, the mechanical behavior of cartilage in a joint was calculated using the homogenized model; and third, the solution of the time-dependent displacement and fluid pressure fields was used as the time-dependent boundary conditions for a microscopic sub-model (Fig. 1c), to obtain the average, time-dependent mechanical behavior of cells in different locations within the cartilage. In our preliminary model, cartilage was considered to be composed of extra-cellular matrix and small, spherical cells. The cartilage was assumed to be uniform, and the effects of collagen fibers were neglected. Both, cartilage matrix and cells, were treated as biphasic materials.

Fig. 2: Anisotropic cartilage model

In an improved homogenization procedure (Wu and Herzog, 2001), we tried to include the effects of anisotropy induced by the substructures in the cartilage. The articular cartilage was represented by a four-phasic composite, comprised of matrix, cell inclusion, and horizontal/vertical collagen fiber inclusions (Fig. 2). In the superficial layer, collagen fibers were assumed to be, predominantly, parallel to the contact surface; in the middle zone, 1/3 of the fibers were assumed vertical to the contact surface and 2/3 of the fibers were assumed parallel to the contact surface; and in the deep zone, collagen fibers were assumed to be vertical to the contact surface. The shapes of chondrocytes were assumed to vary from flat in the superficial zone, to spherical in the middle zone and columnar in the deep zone.

Using our analytical/numerical models, we predicted the mechanical responses of a joint to static and dynamic loading, the dynamic deformation behaviors of chondrocytes during an unconfined compression of a cartilage specimen, and the effects of microstructures on the global mechanical properties of articular cartilage.

SUMMARY

The goal of our research is to understand the growth, adaptation and degeneration of articular cartilage. However, before being able to tackle the problem of cartilage adaptation, we have to know the stress-strain states of chondrocytes and articular cartilage matrix for physiological loading conditions.

RESPONSE OF THE CHONDROCYTE TO MECHANICAL STIMULI: PHYSIOLOGIC AND INJURIOUS COMPRESSION

INTRODUCTION

Cartilage is subjected to wide range of mechanical forces associated with joint loading *in vivo*. These mechanical forces can dramatically alter chondrocytes synthesis, assembly, and degradation of extracellular matrix (ECM). Recent studies suggest that there are multiple regulatory pathways by which chondrocytes in cartilage can sense and respond to mechanical stimuli. These pathways include upstream signaling and changes at the level of gene transcription, protein translation, post-translational modifications of newly synthesized macromolecules (Fig. 1). For example we recently observed that dynamic tissue shear deformation within the physiological range of 1-3% strain amplitude (with little macroscopic fluid flow) could stimulate synthesis of proteoglycans, total protein, and collagen relative to no-shear control explants. In addition, we found that dynamic tissue shear could activate the ERK1/2 pathway and caused an increase in mRNA levels for type II collagen and aggrecan core protein. In contrast, overload injury of cartilage can lead to chondrocyte death, direct matrix damage, and cell-mediated degradation of ECM. Interestingly, data from most *in vitro* models have thus far had limited success in demonstrating the steady progression of enzymatic matrix degradation that one might expect from models of osteoarthritis development. We have therefore focused on characterizing mechanical versus enzymatic degradation of ECM in conjunction with the effects of exogenous cytokines.

METHODS and RESULTS

Cartilage explants were prepared from the femoropatellar grooves of 1-2 week old calves as previously described and subjected to an injurious compression consisting of a ramp and hold compression to 50% strain at a strain rate of 1 s^{-1} .

Fig. 1. Mechanotransduction pathways

After injury, explants were replaced in culture, and selected groups were subjected to addition of 1 or 10 ng/ml of human recombinant IL-1 α . With no IL-1, GAG loss was slightly greater in injured tissue compared to controls by day 3. Addition of IL-1 to uninjured tissue caused a significant increase in GAG loss (Fig. 2). Explants subjected to IL-1 + injury showed significantly greater GAG loss compared to uninjured tissue with added IL-1.

Fig. 2. Combined effects of injurious mechanical compression and addition of graded levels of IL-1 α on loss of GAG from bovine cartilage explants

DISCUSSION

Chondrocyte mechanotransduction is critically important *in vivo* in the cell-mediated feedback between joint loading, the molecular structure of newly synthesized ECM collagens and proteoglycans, and the resulting functional biomechanical properties of cartilage. Here, Addition of IL-1 to injured cartilage was found to synergistically increase the loss of GAG from the tissue. It is likely that GAG release is mediated by a combination of cell-mediated processes and mechanical disruption of the ECM.

INTRODUCTION

Electromagnetic field visualization is important in multidisciplinary research on the molecular basis of therapeutic effects of pulsed electromagnetic fields (PEMF). We have compared classic PEMF representation by two-dimensional field lines and field magnitude contour plots (Schwinger 1998) with a field representation using three-dimensional field isosurfaces. Field simulations were performed for a clinically approved Spinal-Stim[®] Lite system (Orthofix Inc., McKinney, TX). The relatively simple coil system geometry and the predominantly dielectric properties of the surrounding medium (Foster 1989) allowed us to develop analytical expressions for the field and a closed-form PEMF model. Field isosurfaces, represented as three-dimensional solids, allowed for direct visualization of PEMF targeting of individual organs (lumbar spine), the extent of the therapeutic field value, and the directional field characteristics.

METHODS

The magnetic vector potential of a current-carrying loop is approximated by a sum of N finite-length current segments:

$$\mathbf{A}_N = \mathbf{A}_N(\mathbf{r}, t) = \frac{\mu I(t)}{4\pi} \sum_{i=1}^{N+1} \frac{\mathbf{r}_{i+1} - \mathbf{r}_i}{|\mathbf{r}_{i+1} - \mathbf{r}_i|} \ln \frac{|\mathbf{r}_{i+1} - \mathbf{r}|}{|\mathbf{r}_i - \mathbf{r}|} \frac{\cos \varphi_{i+1} + 1}{\cos \varphi_i + 1}, \quad \mathbf{r}_{N+1} = \mathbf{r}_1$$

where

$$\cos \varphi_i \equiv \frac{(\mathbf{r}_{i+1} - \mathbf{r}_i) \cdot (\mathbf{r}_i - \mathbf{r})}{|\mathbf{r}_{i+1} - \mathbf{r}_i| |\mathbf{r}_i - \mathbf{r}|}$$

$$\cos \varphi_{i+1} \equiv \frac{(\mathbf{r}_{i+1} - \mathbf{r}_i) \cdot (\mathbf{r}_{i+1} - \mathbf{r})}{|\mathbf{r}_{i+1} - \mathbf{r}_i| |\mathbf{r}_{i+1} - \mathbf{r}|}$$

and \mathbf{r} is the field position vector, \mathbf{r}_i are the loop vertices position vectors, $I(t)$ is the total current intensity in the loop at time t , and μ is the magnetic permeability of the medium. The magnetic field vector:

$$\mathbf{B}_N = \text{curl } \mathbf{A}_N$$

RESULTS AND DISCUSSION

Results of the of the closed-form field model were compared with results of the field modeling software package for electrical engineering applications (Amperes 5.2) and was verified experimentally using a search coil (Model 49935,

Magnetic Instrumentation, Indianapolis, IN) connected to an amplifier and signal integrator (Orthofix Inc., McKinney, TX) and a digital oscilloscope (Infiniium Oscilloscope Model 54810A, Agilent Technologies, Englewood, CO). Excellent agreement was obtained for $N = 14$. Momentary field lines show a pattern of a nearly-uniform field at the center of the coil system, a highly rotational field in the vicinity of the wire, and a dipolar field far from the coils, as expected, Fig. 1.

Fig. 1 Field lines of a closed-form PEMF model (flat coils).

The field contour plot of $B_N = 0.46$ mT at a peak PEMF signal was superimposed on the lumbar spine vertebrae, Fig. 2. The spinal vertebrae were modeled by circular discs. The field isosurfaces visualized well the spatial properties and the anatomical fit of the PEMF.

Fig. 2 Field isosurfaces of a closed-form PEMF model, fitted to lumbar spine vertebrae (curved coils configuration).

INTRODUCTION

In double-blind studies, pulsed electromagnetic fields (PEMF) have been shown to enhance bone healing (Eyres & Kanis, 1996; Mammi, 1993; Mooney, 1990; Sharrard 1990). However, the biological mechanisms underlying this PEMF-enhanced bone healing are still not known. One hypothesis is that PEMF stimulates bone progenitor cells at the osteotomy site to enter mitosis, proliferate, and differentiate into new bone-forming cells (osteoblasts). We tested this hypothesis using a novel, bone nonunion model utilizing bilateral fibula osteotomies in 9 month-old rats. In each rat, the right hindlimb was treated with PEMF, while the left hindlimb was kept as an “in-animal” untreated control. Fibula osteotomy tissue was then assessed for the *in vivo* expression of Proliferating Cell Nuclear Antigen (PCNA).

METHODS

Osteotomy, Nine month-old, Sprague-Dawley male rats were anesthetized with Nembutal (60 mg/kg I.P.). A 5-6 mm segment was resected from the mid-fibula diaphysis using a rotary saw blade pre-cooled to 4° C with an irrigation solution. The wound was closed with sutures and a topical antibiotic then applied. **PEMF**, 21 days after surgery, right hindlimbs received daily 3 h treatments from a PhysioStim PEMF coil, while left hindlimbs were magnetically shielded. **Histology**, Fibula were fixed in 2% paraformaldehyde/TBS, pH 7.5 for 16 h at 4° C, decalcified with 300 mM EDTA in fixative solution for 4-5 days at 4° C, and cyrosectioned at 10 μ m. **PCNA staining**, Sections were pretreated for 1 min. at 100° C in antigen unmasking solution (Vector Labs), blocked with 5% ovalbumin, treated with a 1:50 dilution of mouse anti-rat PCNA (PC10, DAKO), and treated with a 1:200 dilution of Alexa Fluor 594-conjugated secondary antibody (Molecular Probes). Sections were mounted in Vectashield + DAPI (Vector Labs). Slides were examined using a Nikon Microphot FX epifluorescence microscope. *Cell proliferation index* = % PCNA+ nuclei / total DAPI-stained nuclei.

RESULTS AND DISCUSSION

In Vivo X-Ray Imaging – After 20-days treatment, 5 of 10 rats (50%) exhibited evidence of PEMF-dependent bone healing by longitudinal X-ray imaging (0.58 ± 0.2 mm of new bone formed at the PEMF-treated osteotomy versus 0.55 ± 0.3 mm bone loss at the contralateral untreated osteotomy). Three of ten rats (30%) showed marginal PEMF-dependent differences (0.2 ± 0.3 mm of new bone formed in PEMF-treated osteotomy versus 0.51 ± 0.4 mm bone loss on the contralateral side). Two of ten rats (20%) showed no PEMF-dependent effects on osteotomy healing by *in vivo* X-ray imaging.

Fig. 1: H & E histology of the distal fibula osteotomy sites from a rat exhibiting a PEMF-dependent healing response.

Bone Tissue Histology – Proximal and distal fibula segments were recovered from the five rats that exhibited significant PEMF-dependent osteotomy healing, and were processed for decalcified bone tissue histology. A comparison of the mid-sagittal, longitudinal tissue sections from one of these rats is shown in Fig. 1; these results are typical for this group of rats. On the contralateral-untreated side, the osteotomy-end of the distal fibula appears thin and poorly stained by eosin. About 0.6 mm² of bone tissue area was measured within a 3 mm distance from the end of the bone. Compared to this contralateral control, the osteotomy-end of the distal fibula on the PEMF-treated side appears thicker and intensely stained by eosin. Close inspection revealed a uniform lamellar-quality bone tissue. About 3.9 mm² of bone tissue area was measured within a 3 mm distance from the end of the bone, which is 6.5-fold more than its respective contralateral control.

Cell Proliferation Index – Tissue sections adjacent to those shown in Fig. 1 were stained with an antibody that reacts specifically with rat PCNA. The cell proliferation index for PEMF-treated specimens (22/1945, or 1.1%) was ~20-fold higher than that for the contralateral untreated control (1/1887, or 0.05%). PCNA-positive nuclei were exclusively localized within the apical cell layers of the overlying periosteum in positions typically assigned to “pre-osteoblasts”. PCNA-positive nuclei were not observed in other surrounding connective tissues or in osteocytes within the bone tissue.

INTRODUCTION

The use of electromagnetic fields to promote healing in bone may be traced to the middle of the last century when the piezoelectric properties of dry bone (Fukada, E, 1995) and electrical properties of wet bone (Cochran, GV, et al 1968) were described. However, although evidence of altered cell activity following exposure to electromagnetic signals has been reported, the mechanisms by which electromagnetic fields are sensed, transmitted, and ultimately used by cells to influence physiologic activity have not been defined. Establishing causal linkages between responses of cells in a controlled cell culture environment and responses of cells in a complex *in vivo* organ environment is a daunting task. One common feature of cell culture and *in vivo* models is the presence of an extracellular matrix, which in osteoblast cells is composed mainly of Type I collagen. As part of a larger effort to understand the signaling pathway(s) by which cells respond to Pulsed Electro-Magnetic Fields (PEMF), we have detected a PEMF-dependent difference in the processing of Type I collagen in the mouse pre-osteoblast cell line, MC3T3-E1, subclone 30 (a non-mineralizing clone) (Wang, D, et al 1999).

METHODS

MC3T3-E1, subclone 30 was grown in α -MEM in 60 mm dishes until confluence. Cells were washed twice with Hank's Balanced Salt Solution, and grown in α -MEM supplemented with 50 μ g/mL freshly prepared ascorbic acid. The next morning, at Time = 0, cells were exposed daily to 8 hours of Physio-Stim[®] (Orthofix, INC.) PEMF, followed by 16 hours without stimulation. Conditioned medium (CM) was collected from cultures at 0, 24 and 48 hours, protease inhibitors were added, and the Type I collagen forms were detected by Western blot after PAGE through 6% gels.

RESULTS AND DISCUSSION

Exposure of MC3T3-E1 subclone 30 cells to two, eight hour periods of Physio-Stim PEMF resulted in an approximately 2-fold reduction in the amount of Type I collagen processing intermediates in conditioned medium compared to unexposed control cells. Procollagen is proteolytically processed at both the amino and carboxy termini, and our results suggest that either the kinetics of one or both processing steps are decreased, or that the mature form of collagen is more efficiently incorporated into the extracellular matrix. We will discuss the implications of this result with respect to the collagen processing pathway.

Figure 1: Effect of PEMF exposure (2 x 8 hours over two days) on amount of Type I collagen processing intermediate in conditioned medium of pre-osteoblast cells.

EFFECTS OF CUSTOM MOLDING AND POSTING OF FOOT ORTHOTICS ON LOWER EXTREMITY KINEMATICS

Anne Mündermann¹, Benno M. Nigg, and R. Neil Humble

Human Performance Laboratory, University of Calgary, Calgary, Alberta, Canada

¹ahau@kin.ucalgary.ca

INTRODUCTION

Foot orthotics are frequently used as treatment of running injuries. Foot orthotics usually consist of a custom molded shell with some amount of intrinsic or extrinsic posting with the goal to align the skeleton. Their biomechanical efficacy is commonly evaluated in terms of reduction in maximum foot eversion during the stance phase of running. However, most studies found very small and non-significant differences between custom orthotic and no-orthotic conditions [1] and to date little is known about the contribution of custom molding and posting to such changes [2]. Thus, the purpose of this study was to determine the effects of custom molding and posting of foot orthotics on lower extremity kinematics.

METHODS

21 recreational runners participated in this study (12 female, 9 male; weekly mileage: 15-40 km). All subjects were pronators and were free of injuries for at least 6 months prior to the study. Subjects were examined and casted by a podiatrist. Neutral shells and custom orthotics with 6mm extrinsic varus posting were fabricated for each subject. The non-molded conditions were the control inserts (3mm EVA) and varus inserts (6mm medial wedge). The top layer of all four inserts conditions consisted of 3mm Spenco®. All inserts were placed in running sandals thereby allowing for skin marker placement directly on the heel. Kinematic data were collected for 100 running trials (4.0 ± 0.2 m/s) per subject per condition (total: 8400 trials) during nine experimental sessions on a 30-meter runway. Maximum foot eversion (β_{\max}), time to maximum eversion ($t_{\beta_{\max}}$), and maximum eversion velocity ($v_{\beta_{\max}}$) were calculated for each trial. Values for the control inserts were subtracted from values for varus inserts, neutral shell and custom orthotics for each subject and session to eliminate between-subject and between-session effects. MANOVA for repeated measures was performed to detect significant differences in the effects of the orthotic conditions ($\alpha = .05$).

RESULTS AND DISCUSSION

Maximum foot eversion, time to maximum foot eversion, and maximum eversion velocity were affected by varus inserts, neutral shells, and custom orthotics (Figure 1). Maximum foot eversion decreased for the varus inserts by $1.7 \pm 0.2^\circ$ and increased for the neutral shells and custom orthotics by $0.8 \pm 0.2^\circ$ and $1.0 \pm 0.3^\circ$, respectively. Wearing neutral shells or custom orthotics reduced time to maximum foot eversion by $2.0 \pm 0.4\%$ and $3.6 \pm 0.6\%$ and maximum eversion velocity by $20.9 \pm 8.1^\circ/\text{s}$ and $22.8 \pm 9.2^\circ/\text{s}$, respectively. In contrast, wearing varus inserts increased maximum eversion velocity by

$47.8 \pm 9.4^\circ/\text{s}$. The results of this study showed that adding posting to neutral shells further reduces time to maximum foot eversion, however, maximum eversion velocity remains unaffected. Furthermore, extrinsic posting may have an effect on maximum foot eversion opposite to changes usually attempted. Based on the results of this study the function of custom orthotics to reduce maximum foot eversion has to be questioned. Further research should investigate the effect of custom molding and posting of foot orthotics on lower extremity integrity.

Figure 1: Mean differences (SE) in maximum foot eversion, time to maximum foot eversion, and maximum eversion velocity of varus inserts, neutral shells, and custom orthotics compared to control inserts. * = significant difference ($p < .05$; $n = 8$).

FOOT FUNCTION AFTER THE SHORT TERM USE OF CUSTOM MADE FOOT ORTHOSES

Craig Payne

School of Human Biosciences, La Trobe University, Melbourne, Australia
c.payne@latrobe.edu.au

INTRODUCTION

Foot orthoses (FOs) are widely used in clinical practice for what is assumed to be biomechanical dysfunction. Many studies have previously investigated the immediate kinematic effects of FOs, but little is known about the longer term effects of FOs on foot function. The aim of this project was to determine foot function when custom FOs were first used and then again at 4 weeks.

METHODS

Consecutive patients needing rigid custom FOs at a podiatry teaching clinic were recruited for this project. Custom made FOs were made over a negative plaster cast of the foot in its defined neutral position. When orthoses were first issued, foot function was determined using the Pedar in-shoe pressure measuring system. Subjects were measured walking for approximately 10 steps in canvas shoes with and without their FOs. This was repeated again at approximately 4 weeks after the subjects had been using the FOs. Using the NovelWin software, 6 steps of each trial were averaged. Masks were created over the hallux, first metatarsal head, lateral forefoot, arch and heel areas to calculate mean pressure and the pressure time integral in each masked area. Contact time for the averaged steps to check if velocity was consistent between trials.

RESULTS AND DISCUSSION

36 subjects were recruited (10 were lost to follow-up). The left foot of 26 subjects was used for the analysis. Mean time between baseline and follow up was 29.5 (± 10.3) days. Repeated measures ANOVA showed that the velocity within subjects of each trial were consistent enough for further analysis ($p=0.31$). The results of the pressure variables are reported in Tables 1 & 2. Post hoc analysis showed, as expected, differences between the use of FOs and no FOs both at baseline and at follow up. However, no differences were found between foot function at baseline and at follow up without the use of FOs. Similarly, no differences were found in foot function at baseline and follow up with the use of FOs, indicating that no adaptation or changes occur to foot function in the parameters we measured over a 4 week period of using FOs.

SUMMARY

This study has shown that there are no adaptive changes in foot function in the short term in the parameters used. This does not rule out the possibility of longer term changes.

Table 1: Mean pressure

	No orthoses at baseline	Orthoses at baseline	No orthoses at follow up	Orthoses at follow up	ANOVA

THE EFFECT OF FOREFOOT AND ARCH POSTING ORTHOTIC DESIGNS ON HALLUX-FIRST METATARSAL KINEMATICS DURING GAIT

Deborah A. Nawoczenski¹ and Paula M. Ludewig²

¹Movement Analysis Laboratory, Ithaca College - University of Rochester Campus, Rochester, New York, USA

dnawoczenski@ithaca.edu

²Department of Physical Medicine and Rehabilitation, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

Although the forefoot has been implicated in foot pathologies, little is known about how forefoot kinematics, particularly hallux-first metatarsophalangeal (MTP) motion are influenced by orthotic use. A common orthotic design used to control excessive pronation incorporates the use of a medial post in the forefoot and/or rearfoot locations, with the purported goal of 'bringing the ground up to the foot' during gait. It is unknown whether this design actually restricts normal first metatarsal plantarflexion motion and hallux dorsiflexion during late stance. An alternative design is an orthotic which incorporates an elevated arch support in combination with first metatarsal plantarflexion. The theory behind this design is that normal first metatarsal plantarflexion and hallux dorsiflexion are facilitated. The purpose of this study was to examine the effect of two different types of orthotic designs on first MTP joint kinematics, and on the kinematic coupling between first MTP and rearfoot rotation during gait.

METHODS

Twenty subjects between the ages of 18 and 45 participated in the study. All subjects were classified as pronators based on a clinical orthopaedic examination. Two different orthotic designs were custom-molded using either 5/32" or 3/16" polyethylene, depending upon the subject's weight. One design incorporated an extrinsic rearfoot and forefoot post (Fig.1). The second pair had a high medial longitudinal arch without extrinsic posting (Fig.2). The Flock of Birds® electromagnetic tracking device was used to collect three-dimensional position and orientation data of three modeled rigid body segments (hallux, first metatarsal, and calcaneus, during the stance phase of walking (Nawoczenski, 1999; Umberger 1999). Transformation matrices were generated that related the assumed constant orientation of the sensors to the anatomically based local coordinate systems established for the hallux, first metatarsal, and calcaneus.

Figure 1

Figure 2

A Cardan angle system of three ordered rotations (x-z'-y'') was used to extract angular information of the hallux, first metatarsal and calcaneus. Subjects wore identical sports sandals for all test conditions.

RESULTS

A repeated measures ANOVA was used to assess differences between orthotic conditions: no orthotic, forefoot/rearfoot posted orthotic and arch orthotic during standing and walking. The mean of three trials was used in the analysis. Preliminary findings for peak hallux-1st MTP dorsiflexion are presented in Table 1.

Table 1. None = no orthotic; FF/RF Post = posted orthotic and Arch = medial arch orthotic

Early findings suggest that 1st MTP dorsiflexion values increased under both orthotic conditions (mean 4°) with no differences detected between conditions. Similarities were also found for metatarsal head translations between orthotic conditions.

SUMMARY

Preliminary results indicate that an orthotic with a forefoot post does not have a negative effect on hallux-1st MTP kinematics during gait. Additional analyses are needed using a larger sample and to further test movement patterns under different orthotic conditions.

CUSTOM AND SEMI-CUSTOM ORTHOTIC DEVICES: A COMPARISON OF REARFOOT MOTION CONTROL AND COMFORT

A.T. DeLeo¹, I. McClay Davis^{1,2}, R. Ferber¹

¹University of Delaware, Newark, DE, USA 19716 atdeleo@hotmail.com

²Joyner Sportsmedicine Institute, Mechanicsburg, PA, USA 17111

INTRODUCTION

The cost of custom fitted orthotic devices has led many patients to buy off-the-shelf inserts. In response to this, some orthotic laboratories have begun creating semi-custom orthotic devices as a more cost-effective solution. Semi-custom orthoses can be fabricated in several ways, but all involve matching a “mold-of-best-fit” to an individual. While the primary function of orthotic devices is motion control, comfort is an important feature for patient satisfaction and long-term use. No studies have compared the function or comfort of custom versus semi-custom devices. Therefore, the purpose of this study was to assess differences in rearfoot motion control and comfort of a between these two types of orthoses. Since this is an ongoing, double-blind randomized study, the devices cannot be differentiated. They are therefore referred to as device A and device B. It was hypothesized that there would be no difference in rearfoot peak eversion (EV), eversion excursion (EVEXC), and peak eversion velocity (EVVEL) between device A and B. Additionally, these rearfoot variables were expected to be significantly reduced from the no orthotic (NO) condition. Finally, it was hypothesized that there would be no significant differences in comfort between the two orthotic conditions.

METHODS

Six injury-free recreational runners have volunteered for the study thus far. Plaster casting of their feet was performed using a neutral non-weight bearing supine method. The casts were sent to a single orthotic laboratory where two devices were fabricated. The custom orthosis was fabricated based on the plaster casts and the semicustom orthosis was made based on foot measurements taken from the casts. Both devices were made with semi-flexible graphite and vinyl covers. Following a two week accommodation period, the subjects returned to the laboratory for data collection. Kinematic data were collected from 5 running trials for each of 3 conditions: NO, device A, and device B. Comfort was measured with a 100 mm visual analog scale (VAS) after each orthotic running condition. VAS scores for the heel, arch, edges, forefoot, and overall comfort were collected. A repeated measures ANOVA was used to compare the variables of interest between conditions ($p < 0.05$).

RESULTS AND DISCUSSION

Device A provided greater rearfoot control (Figures 1 and 2) and greater comfort (Table 1) than device B. However, only EVVEL and heel comfort were significantly different. It is has been suggested by Smith et al, (1986) that EVVEL may be a more important indicator of orthotic control compared to EV

or EVEXC. Device A did provide significantly greater rearfoot control than NO device for all three variables. There were no significant differences in comfort between the two orthotic conditions with respect to the overall comfort, arch, forefoot, and edges. However, device B was significantly less comfortable than device A in the heel region (Table 1).

Figure 1: Peak EV and EVEXC for the three conditions. Note: *= sig. dif. from NO ($p < 0.05$).

Figure 2: Peak EVVEL for the three conditions. Note: *= sig. dif. from NO; += sig. dif. from device A ($p < 0.05$).

Table 1 Orthotic comfort (on 100 mm VAS)

	Heel	Arch	Forefoot	Edges	Overall
Device A	94.5	88.8	93.0	93.8	92.5
Device B	89.0*	86.6	87.0	91.0	87.6

SUMMARY

Based on these early results, there may be differences between the custom and semi-custom foot orthoses in terms of comfort and rearfoot control. These preliminary data need to be further validated with additional subjects as they are added to the study.

INTRODUCTION

Stroke is the third leading cause of death and the major cause of disability. In the US alone there are more than 730,000 stroke victims and 4.4 million stroke survivors annually [1]. Stroke is a syndrome of multiple etiologies. Emboli emerging from the heart, aortic arch and the large arteries, mainly carotids, account for about 60% of all stroke cases [2,3]. Atrial fibrillation (AF) is the most important precursor of embolic stroke. More than 2 million Americans have intermittent or sustained AF [4]. Protruding aortic arch atheroma (AAA), prevalent among the elderly, has emerged as an additional common cause of embolic stroke [5]. Plaques located in the aortic arch have been found in 60% of 60 years old patients with ischemic stroke. The association is particularly strong when the plaques are > 4 mm in thickness [6]. AF and AAA often coexist [7]. Currently, the treatment of choice for AF and AAA is anticoagulation with warfarin. The relative risk of stroke can be reduced by 70% in selected subgroups of patients with AF using anticoagulants [8]. However, anticoagulants are contraindicated in about 40% of patients over 65 years old [9]. Moreover, anticoagulation was repeatedly shown to be underused, about 30% of eligible patients [10], and quality of control in routine clinical practice is often poor. Carotid stenosis is a local disease accounting for 9% of stroke [2,3]. Current treatment modalities of carotid stenosis are carotid endarterectomy or carotid stenting, with or without a cerebral protection device. However, these treatments address only transient ischemic attacks and prevention of stroke attributable to carotid stenosis, but not to the prevention of stroke due to emboli originating from the heart or the aortic arch.

METHODS

A novel filtering device for stroke prevention is proposed. This permanent implant can prevent ischemic stroke by diverting proximally originating emboli that ascend in the carotid arterial system away from the anterior cerebral circulation to a non-hazardous territory, the systemic extra cranial circulation (Fig. 1). The diverter is of a tubular mesh like structure that is implanted at the carotid bifurcation traversing the common carotid artery into the external carotid artery (ECA) essentially jailing the internal carotid artery (ICA). The ECA supplies oxygenated blood to superficial extra cranial structures, an abundantly interconnected arterial network, insensitive to oxygenated blood supply. Therefore, emboli entering the ECA are typically asymptomatic and benign. In contrast, emboli entering the ICA often lodge in the

middle cerebral artery or its branches, and are the main source of disabling embolic stroke in the oxygen starved brain territory within seconds.

RESULTS AND DISCUSSION

The feasibility of arterial filtration by a permanent implant without the possibility of filter-originated deleterious consequences was examined both in vitro and in vivo. The main issues with such an implant include the possibility of the filtering section being occluded, and the activation of cellular blood elements, particularly the platelets, by the implant. The preliminary in vitro results suggest that the activation parameter of the platelets is two orders of magnitude below the established customary value while the in vivo results in the swine model show that the filtering section of the implant remained patent up to four months post implantation.

SUMMARY

Preliminary findings give hope to a novel therapy for patients at high risk of embolic stroke from proximal sources, and may serve as a new potential vascular approach for this devastating disease.

³Egleston Children's Hospital, Atlanta, GA, USA

INTRODUCTION

The total cavopulmonary connection (TCPC) is a palliative surgical repair performed on children with a single ventricle (SV) physiology. The surgical procedure involves anastomosis of the superior and inferior vena cavae to the unbranched right pulmonary artery. This results in a complete bypass of the right side of the heart with the single ventricle driving blood through the circulatory system.

Much of the power produced by the univentricular pump is consumed in the systemic circulation. When power consumption is excessive, the result is decreased circulation of oxygenated blood throughout the body. Consequently the minimization of power loss in the TCPC is imperative for optimal surgical outcome. In order to achieve configurations that promote minimal power loss, underlying factors must be understood and controlled. We have performed a comprehensive fluid dynamic evaluation of the TCPC using experimental modeling and numerical simulation studies in order to elucidate and analyze these underlying factors. Information produced by this research can be used to facilitate the creation of optimal TCPC configurations in patients.

METHODS

Experimental Simulations: Custom crafted glass prototype models of the TCPC were selected with varying anastomosis geometries. Specifically models possessing different characteristics in terms of caval diameters, caval offsets, and pulmonary artery planarity were constructed. These models were used in conjunction with a steady flow loop capable of varying the total cardiac output and pulmonary artery flow ratios over a range of physiologic values. Models were investigated using pressure measurements, flow visualization, digital particle image velocimetry (DPIV), and magnetic resonance (MR) imaging. An image extracted from one flow visualization data set is displayed in Figure 1. Figure 2 displays a similar plane acquired with MR imaging.

Figure 1. Flow visualization image of planar one-diameter offset TCPC model.

Figure 2. MR image of planar one diameter offset TCPC

Data acquired with these modalities were then used with control volume analysis to evaluate and study energy loss in TCPC model geometries. In all studies a blood analog fluid, composed of glycerine and water, with a kinematic viscosity of 3.5cSt was used.

Numerical Simulations: Numerical simulations were performed to supplement experimental data from TCPC models of varying anastomosis geometry. To this end, three-dimensional computational models were created and boundary conditions were specified to match experimental conditions. Energy loss information, obtained from control volume analysis and dissipation function analysis, was calculated and compared to experimentally determined power losses.

RESULTS AND DISCUSSION

Experimental and numerical energy losses compared well for similar TCPC models. Furthermore, velocity fields obtained from DPIV, flow visualization, and MR imaging showed similar flow patterns to those present in numerical simulations on a model-by-model basis. Based on these results conclusions regarding flow patterns deleterious to efficient circulation in the modified district could be identified and optimal TCPC design characteristics recommended. Numerical simulation combined with experimental modeling can provide an accurate prediction of flow conditions and subsequent energy losses in simple models of the TCPC. Future work will focus on continued development of the integrated methods described here, the use of more physiologic models, and further clinical interactions, all aimed at facilitating the surgical creation of optimal TCPC configurations.

LASER DOPPLER ANEMOMETRY IN THE EVALUATION OF MECHANICAL HEART VALVES' HEMODYNAMICS

Mauro Grigioni, Carla Daniele, Giuseppe D'Avenio and Vincenzo Barbaro
Laboratory of Biomedical Engineering, Istituto Superiore di Sanità, Roma, Italy
grigioni@iss.it

INTRODUCTION

Mechanical heart valves (MHVs) are nowadays very common devices in the clinical practice. This notwithstanding, they are still not free from problems (witnessed by the necessity of continuous anticoagulation therapy), which can be related mostly to their fluid dynamics: excessive turbulence shear stress levels must be avoided, in order to limit the incidence of hemolysis, platelet activation or other blood traumatic events. Laser Doppler anemometry (LDA) is, to date, the most powerful tool to investigate the finer details of a MHV's flow field and, thus, to evaluate its damage potential for blood components.

METHODS

A series of 19-mm (nominal diameter) bileaflet MHVs was tested in the aortic section of the Sheffield University pulse duplicator. A glassblown aorta, whose transparency is essential for LDA operation, was pressed against the valve's sewing ring. The tests were performed at a cardiac output of 6 l/min (exercise conditions): together with the small diameter of the valve, this constitutes the worst case for the generation of velocity gradients (and turbulence) for this kind of devices. A two-color LDA system (Aerometrics, USA) was employed to measure the local velocity all along the width of the aorta, at four distances downstream of the valve plane.

The velocities were gate-time weighted, in order to prevent the *velocity bias* which typically affect LDA measurements. The elliptical filtering (Baldwin et al., 1993) was also used to discard occasional data corrupted by noise.

Principal stress analysis (Fontaine et al., 1995; Grigioni et al., 2000) was subsequently applied to the velocimetric data, in order to quantify the highest turbulence shear stress (TSS_{max}) in each considered point, independently from the particular TSS value $\overline{\rho uv}$ associated with the adopted coordinate system ($\overline{\rho uv}$ can obviously provide a gross underestimation of the actual mechanical load on blood particles).

RESULTS AND DISCUSSION

The highest TSS_{max} values we found are below the threshold for hemolysis which, after the data reported in Sallam and Hwang (1984) and in Grigioni et al. (1999) can be quantified to be at least 600 N/m². Since the limit conditions of the tests, this result underlines the good hemodynamics of bileaflet valves. Apart from hemolysis, however, some problem can still be expected from the observed turbulence levels, since

also sublethal damage or platelet activation may have important clinical consequences, especially when artificial surfaces are in contact with blood. Nevertheless, the limited hemolytic potential of these devices is important, since this traumatic event, unlike other valve-related problems such as, e.g., thrombus formation, cannot be controlled pharmacologically after implantation.

The fine-scale investigation made possible by LDA enabled to bring to light some interesting features of bileaflet MHVs: it was seen for the first time, for instance, that the leaflets' curvature has a very important role in the turbulence development downstream of the valve, with a stabilizing effect with regard to the lateral jets. This effect might constitute the basis for further design improvements.

Due to the steady progress of echographic techniques, the possibility can be foreseen that turbulence measurements will be soon routinely performed also in vivo. In this view, we characterized the possibility of a monodimensional approach to the problem of determining the TSS_{max} , which is, generally, a quantity requiring three-dimensional measurements. Thus, in vivo measurements of the rms axial velocity u' , together with the data obtained from our in vitro LDA measurements, could provide a simple assessment of the turbulence production and the hemolytic potential of an implanted bileaflet.

SUMMARY

The evaluation of a bileaflet heart valve is very complex, due to its hemodynamics, characterized by high velocity gradients. The use of an advanced technique such as Laser Doppler anemometry (LDA) enabled to quantify the hemolytic potential of several bileaflet valves; moreover, the effect of design features was studied, and useful parameters for future in vivo valve evaluations were proposed.

INTRODUCTION

The activation of the hemostatic system is related to platelet activation, and may be initiated by a series of rheological and hemodynamic processes. Shear stresses and flow patterns (fluid dynamics factors), and concentration of coagulation factors and platelet agonists (biological factors) may lead to platelet activation and aggregation. As it passes through pathological geometries characteristic of arterial stenosis, a platelet is exposed to varying levels of shear stress. The cumulative effect of the shear stress level and the duration the platelet is exposed to it, will determine whether it is brought beyond its activation threshold [1,2]. Thus, time histories of individual platelets should be tracked down to locate the regions where activated platelets might be found and subsequently adhere to the wall.

METHODS

Numerical simulations (NS) of turbulent transient flow of non-Newtonian fluid through a 3D eccentric and axisymmetric models of a coronary stenosis was conducted. NS were validated by Continuous Digital Particle Image Velocimetry (CDPIV), in optically clear, scaled up (5:1) stenosis models. Turbulent trajectories of the platelets were computed using a stochastic model. The shear stress histories were quantified along the trajectories to determine their level of activation. Pertinent trajectories of the particles were established from the CDPIV measurements and their shear stress histories computed in the stenosis throat region. The experimental and numerical methods were conducted over a range of flow conditions, corresponding to the entire physiologically relevant range in coronary arteries.

RESULTS & DISCUSSION

The results indicated that platelets that were exposed to elevated stresses at the stenosis throat and then entrapped in the recirculation zone had a higher incidence of activation.

It was demonstrated that trajectories that exposed the platelets to the highest shear

Fig. 1 Velocity vectors and turbulent platelet trajectories in a 3D model of 84% arterial stenosis ($Re = 300$)

stress levels in the stenosis throat region, led them towards entrapment in the recirculation zone, where the shear stress levels decreased but exposure time increased. As platelet activation depends on the combination of shear stress and exposure time, this yielded higher incidence of platelet activation, compared to platelets flowing in the core flow region. The decrease in wall shear stress in the recirculation zone diminished the capacity of the geometry to embolize the deposits, allowed, at the same time for prolonged contact with the wall, and led to possible thrombus formation.

INTRODUCTION

It is suspected that flow disturbances created by the geometric irregularity of the vessel wall at sites of anastomoses are responsible for post-operative narrowing and occlusion of anastomosed vessels through the development of intimal hyperplasia. However, no direct correlation has been established between the flow and the exact sites of intimal hyperplasia. Hence we have studied the relationship between the flow and preferred sites of wall thickening in vessels that have undergone various types of anastomotic procedures.

MATERIALS AND METHODS

Adult mongrel dogs weighing from 17 to 45 kg were used as subjects for arterial reconstructive procedures. Under general anesthesia with Nembutal, both the left and right femoral arteries were exposed and one of the following 3 types of anastomosis was performed on both femoral arteries: (i) 90-degree or 45-degree end-to-end anastomosis, (ii) interposition with either a saphenous vein or a jugular vein, (iii) bypass grafting with either a saphenous vein or a common carotid artery. Anastomotic procedures were carried out using either a 7-O non-absorbable suture (Surgilene: a monofilament polypropylene suture, Sianamid Canada Inc., Montreal, Canada) or a 7-O absorbable suture (PDS: a monofilament polydioxanone suture, Ethicon Inc., Somerville, NJ) and the techniques of continuous over-and-over intramural stitching.

The dogs were kept alive for 3 or 6 months for recovery and healing, and then sacrificed. The vessel segments which had undergone anastomotic procedures were harvested keeping their original lengths *in vivo*, fixed under physiological perfusion pressure, dehydrated with ethanol, and finally rendered transparent by suspending them in oil of wintergreen (methyl salicylate) containing 5% ethanol. To visualize the flow in these vessels, dilute suspensions of 30 to 350- μ m diameter polystyrene microspheres in oil of wintergreen were subjected to a steady or pulsatile flow through the vessel, and the behavior of individual tracer particles was photographed on 16-mm cine films. The developed films were subsequently projected onto a drafting table, and the movements of individual tracer particles were analyzed frame by frame to obtain detailed flow patterns and distributions of fluid velocity and wall shear rate (shear stress) in various regions of these vessels under normal physiological and altered (pathological) conditions.

RESULTS AND DISCUSSION

It was found that a definite correlation exists between the preferred sites of intimal thickening and the regions of slow recirculation flows with low wall shear stresses. In both 90-degree and 45-degree cut and anastomosed vessels, intimal thickening developed only in those vessels in which formation of slow recirculation flows was observed. It was also found that although a pronounced and localized intimal thickening developed in 45-degree anastomosed vessels, the degree of circumferential constriction caused by both surgical procedures and development of intimal thickening was much milder in 45-degree than 90-degree anastomosed vessels. In vein graft-interposed vessels, anastomotic intimal thickening was found at the distal anastomosis in saphenous vein-interposed vessels as shown in Figure 1 and at the proximal anastomosis in jugular vein-interposed vessels where, in both cases, a large recirculation zone was formed because of a sudden enlargement of the vessel lumen caused by mismatching of vessel diameters. In bypass-grafted vessels, a large recirculation zone was formed at the dead end of the partially or totally occluded host artery adjacent to the flow divider of the bypass, at the toe of the bypass graft, and the distal mouth of the host artery, where the bypass met the host artery. Intimal thickening was found at the proximal leading edge (opposite the flow divider), distal edge (toe) of the bypass, and on the floor of the host artery opposite the flow divider and the distal apex of the bypass. These areas well corresponded to the regions of slow secondary and recirculation flows where wall shear stresses were low.

As the inner lining of the vessel wall, vascular endothelial cells are poised to act as a signal transduction interface for hemodynamic forces. The molecular mechanisms of the primary force sensing elements of the cell, and the cascade of events that are involved in the mechanochemical signal pathway remain unclear. Activation of the G protein G α q and the phosphorylation of platelet endothelial cell adhesion molecule-1 (PECAM-1) have been reported to be involved in the early events of shear-induced signaling pathways. Using immunofluorescence and co-immunoprecipitation techniques, we demonstrate here for the first time that G α q and PECAM-1 co-localize as a complex at the cell-cell junction in primary

human umbilical vein endothelial cells. Temporal gradients in shear stress lead to a rapid disassociation and re-association of the G α q-PECAM-1 complex within 15 sec (0.65 ± 0.059 ratio G α q/PECAM-1 versus sham control), whereas slowly transitioning fluid flow devoid of temporal gradients does not disrupt the complex (1.04 ± 0.08 ratio Gq/PECAM-1 versus Sham control). Inhibition of protein kinases and tyrosine kinases completely eliminated impulse flow induced G α q-PECAM-1 disassociation and PECAM-1 phosphorylation. Taken together, this data may represent a missing link between the primary force sensing elements of the cell, and the downstream mechanochemical transduction pathway.

A ROLE FOR MOLECULAR DYNAMICS OF ENDOTHELIAL CELL LIPIDS IN MECHANOTRANSDUCTION

Peter J. Butler¹, Benjamin P. Bowen², Neal Woodbury²

¹Department of Bioengineering, Pennsylvania State University, University Park, Pennsylvania, USA

²Department of Chemistry and Biochemistry, Arizona State University, Tempe, Arizona, USA

INTRODUCTION

Endothelial cells (ECs) form the inner lining of the blood vasculature and are therefore exposed to shear stress (τ), the tangential component of hemodynamic forces. Shear stress exerts potent changes in EC biology, possibly via EC-membrane perturbations, with consequent influences on vascular health. The role in mechanotransduction by ECs of shear-induced changes in membrane lipid dynamics is explored.

METHODS

The cell membrane's proximity to blood flow makes it a candidate shear-sensitive system. By adapting a confocal laser scanning microscope for measurements of fluorescence recovery after photobleaching (confocal-FRAP), we made, for the first time, quantitative, two-point, sub-cellular measurements of membrane fluidity (as quantified by the lipid lateral diffusion coefficient) on the apical membrane of ECs while they were subjected to shear stress (fig. 1). Bovine aortic endothelial cells (BAECs) were grown to confluence on glass, stained with DiI C16, and exposed to step- and ramp-changes in shear (max $\tau=10$ dynes/cm²).

We now use membrane phase-specific lipid dyes to probe the effects of shear stress on membrane sub-domains existing in liquid or liquid-ordered phases. Confocal, molecular spectroscopic tools are used to measure fluorescence lifetimes, polarizations, and rotations of lipid molecules (DiIs) in the membranes of confluent BAECs which are subjected to membrane-perturbing agents including shear stress.

RESULTS AND DISCUSSION

Previously, we have used confocal-FRAP to investigate the time- and position dependence of the effects of τ on EC-membrane lipid dynamics (Butler, et al, 2001a,b). We showed: (i) shear stress induces a rapid, spatially heterogeneous, and time-dependent increase in the lateral diffusion of a fluorescent lipid probe in the BAEC membrane (fig. 1) (ii) the location, magnitude, and persistence of these shear-induced increases in membrane fluidity depend on the shear magnitude and the rate of change of shear, and (iii) shear stress elicits a secondary (7 min) increase in membrane fluidity.

We now present evidence for phase specificity of lipid dyes (DiIs) in confluent endothelial cells using confocal molecular

Figure 1: Effects of **A** step-shear and **B** ramp-shear on the normalized diffusion coefficient of DiI C16-stained BAEC membranes. Blue diamonds and pink rectangles represent simultaneous measurements on the portion of the cell upstream and downstream of the nucleus, respectively (from Butler, 2001b).

spectroscopy (fig. 2). Our measurements of fluorescence lifetime and polarization are consistent with the partitioning of DiI C12 (a carbocyanine dye with dual 12-carbon alkyl chains) in a liquid phase, and of DiI C18 (a carbocyanine dye with dual 18-carbon alkyl chains) in the liquid-ordered or gel phase. These properties are used to probe the spatial and temporal aspects of the effects of shear stress on membrane sub-domains.

Figure 2: Spatial plots of fluorescence intensity, polarization, and lifetime of DiI C18 incorporated into BAEC membranes.

SUMMARY

Fluorescence spectroscopic tools along with membrane-phase specific lipid dyes allow the detection of position dependence of shear effects on the EC membrane and the quantitative measurements of changes in lipid dynamics which have been correlated to changes in biochemical processes in ECs.

CHANGES IN THE PROPERTIES OF THE ENDOTHELIAL GLYCOCALYX AFFECT THE DISTRIBUTION OF SHEAR STRESS AND SHEAR RATE ON ENDOTHELIAL CELLS

Wen Wang

Medical Engineering Division, Department of Engineering, Queen Mary, University of London, London, UK
wen.wang@qmul.ac.uk

INTRODUCTION

It is well established that shear stress on vascular endothelial cells, imposed by the blood circulation, plays an important role on vascular biology and pathology (e.g. Davies, 1995). Little attention, however, has been given to the function of the endothelial glycocalyx, which forms a continuous surface layer on endothelial cells, and the role it plays in these processes. As it represents the interface between the flow and the endothelium, the glycocalyx is likely to affect the permeability of the endothelium to solutes, such as plasma proteins. Changes in properties of the endothelial glycocalyx are also likely to alter the magnitudes of the shear stress and the shear rate, and more importantly, the way in which the stress is imposed on the cell membrane.

METHODS

At a microscopic level, fluid flow within the endothelial glycocalyx introduces shear stresses on luminal surfaces of the cell membrane via two different routes: 1) the stress imposed by fluid movement directly on the cell membrane, and 2) the drag force transferred by fiber-branches of the glycocalyx to the endothelial cell. To gain insight into the distribution of these contributing factors to the total shear stress on endothelial cells, we have developed a theoretical model based on a binary mixture theory and modelled the endothelial glycocalyx as a surface layer of fiber matrix (Wang and Parker, 1995; Wang and Michel, 2000). The matrix contains both solid and liquid phases and is assumed to be uniform. It has a thickness, ϵ , volume fraction of liquid is ϕ , the apparent viscosity of the liquid in the matrix is μ and the drag coefficient between the solid and liquid phases is κ . Mass conservation and momentum equations for the matrix are solved asymptotically. Flow and stress distributions within the matrix as well as on the cell membrane are calculated.

RESULTS AND DISCUSSION

When the structure of the glycocalyx is altered, e.g. by enzyme digestion, the thickness, ϵ , or the volume fraction of fibers in the matrix, $1-\phi$, or both will be reduced. From a force balance analysis, the overall (i.e. total) shear stress on the luminal surfaces of endothelial cells, τ , remains unchanged regardless of the structural alterations of the glycocalyx layer, provided that flow conditions in the vessel are kept constant. However, the stress that is imposed on the endothelial cells by the direct 'pulling' of fibre branches of the glycocalyx may be reduced significantly. This 'pulling' stress, through branches of the endothelial glycocalyx, can be expressed as $\tau_s = \lambda \tau$, where λ is a constant parameter which depends on the properties of the

glycocalyx and the radius of the vessel, R . λ has an asymptotic expression,

$$\lambda = 1 - \phi + \phi (1 - \phi) \{1 - \cosh^{-1}(\xi) + 2\epsilon/r [1 - \tanh(\xi)/\xi]\},$$
with the intermediate parameter $\xi = (\kappa/\mu)^{1/2}\epsilon$. Shear rate at the cell membrane due to flow inside the fiber matrix can be expressed as $\gamma = \theta \Gamma$, where Γ is the wall shear rate in the absence of the fiber matrix and θ is a constant depending on the structure of the glycocalyx,

$$\theta = \phi \{ \cosh^{-1}(\xi) + 2\epsilon/R [\tanh(\xi)/\xi] \}.$$

To demonstrate how changes of the glycocalyx, e.g. changes in the drag parameter ξ and the volume fraction of liquid, ϕ of the fiber matrix, affect the 'pulling' stress, τ_s and shear rate, γ at the cell membrane, we present in Figure 1 variation (in contours) of the λ and θ with ξ and ϕ , respectively.

Figure 1. Variation of λ (in a) and θ (in b) against ξ and ϕ .

It is shown that, as the property of the glycocalyx changes, fluid shear rate at the endothelial membrane alters significantly (as shown in Figure 1b). In addition, there are associated changes in the stress due to pulling of the glycoproteins (in Figure 1a), despite the presence of a constant total shear stress.

SUMMARY

The model enables us to analyse how changes in the properties of the glycocalyx alter the shear rate and the "pulling" stress on the endothelial cell membrane. It may be used to interpret experiments investigating the role of the glycocalyx in shear induced responses of the endothelium.

THE BIOMECHANICS OF THE WEIGHTBEARING KNEE

Braden Fleming¹, Bruce Beynnon¹, Per Renstrom², Robert Johnson¹

INTRODUCTION

The musculature and articular contact forces play an active role in maintaining knee joint stability. Thus, biomechanical investigations of knee function should be performed *in vivo* where physiological loading conditions can truly be examined. Cadaver studies have shown that compressive loads on the knee reduce laxity relative to the non-weightbearing state. These studies support the popular belief that the compressive load produced by bodyweight stabilizes the knee and protects the ACL by forcing the articular surfaces together and inducing co-contraction of the hamstrings and quadriceps muscles. Although there is a reduction in knee laxity with the application of a compressive load, the cadaver model of Torzilli et al (1994) also found that there was an anterior shift of the tibia relative to the femur as the knee made the transition from non-weightbearing to weightbearing. This finding questions the protective function of weightbearing. We designed two experiments to compare the biomechanical response of non-weightbearing and weight-bearing knees *in vivo*. These experiments involved measurements of tibio-femoral kinematics in ACL-deficient and ACL-intact knees (Beynnon et al 2002), and direct measurements of ACL strain in the ACL-intact knee (Fleming et al 2001a).

EXPERIMENTS

Experiment 1: The objective of this study was to measure the A-P translation of the tibia during the transition from non-weightbearing to weightbearing in eleven subjects with a normal and a contralateral ACL-deficient knee. The subjects were positioned on a custom loading fixture with their muscles relaxed and no compressive load applied across the knee. The knee was positioned at 20° of flexion to simulate the slightly flexed, double-legged stance position. A lateral radiograph of the knee, with the posterior aspects of the femoral condyles superimposed, was obtained to document the position of the tibia relative to the femur. A compressive load equal to 40% bodyweight was then applied to each foot, and a second radiograph was obtained to document the change in position of the tibia relative to the femur. The transition from non-weightbearing to weightbearing produced a significant increase in the mean \pm 1 standard deviation of the anterior translation of the tibia relative to the femur (3.4 ± 2.6 mm) for the ACL-deficient knee. These values for the ACL-intact knee were significantly less (0.8 ± 2.2 mm; $p < 0.01$).

Experiment 2: The objective of this study was to measure the ACL strain response of the ACL-intact knee during the transition from non-weightbearing to weightbearing. A strain transducer (DVRT; MicroStrain, Inc., Burlington VT) was

implanted on the anteromedial band of the ACL in eleven subjects. A device similar to that used in first experiment was used to apply the compressive loads to each foot (40% bodyweight) with the knee at 20° of flexion. A significant increase in the mean \pm 1 standard deviation for the ACL strain values were observed as the knee made the transition from non-weightbearing ($-2.0 \pm 1.78\%$) to weightbearing ($2.1 \pm 1.78\%$). These values were significantly different ($p < 0.01$).

CONCLUSIONS

The application of bodyweight across the knee joint causes the tibia to shift anterior relative to the femur in the ACL-deficient knee (Beynnon et al 2002). The four-fold increase in anterior translation of the tibia for the knees with ACL tears compared to the contralateral side is a concern because it is substantially greater than the 95% confidence limits for the side-to-side differences in anterior-posterior knee laxity values that are obtained from subjects with normal knees. This observation could explain, at least in part, one of the mechanisms that could initiate damage to the meniscus and articular cartilage in subjects that have suffered an ACL tear. The direct measurements of ligament strain verify that the anterior shift of the tibia that occurs during weightbearing strains the ACL in the intact knee, at least when the knee is near extension (Fleming et al 2001a). This shift is most likely due to a combination of factors: 1) the dominance of the quadriceps muscles even though the quadriceps and hamstrings are co-contracted in this position (Beynnon et al 1995; Torzilli et al 1994), 2) the activity of other muscle groups that span the knee (i.e. the gastrocnemius muscle) (Fleming et al 2001b), and 3) the orientation of the contact force vector relative to the inclination of the tibial plateau (Torzilli et al 1994). These data have important clinical ramifications in the development of rehabilitation protocols following ACL reconstruction since the anterior shift of the tibia produces strain, or load, in the injured ACL or healing ACL graft. This mechanism has been previously thought to protect the ACL.

TOWARDS UNDERSTANDING IN VIVO KNEE JOINT MUSCULOTENDON AND SKELETAL DYNAMICS

Frances T. Sheehan, Ph.D.

Mechanical Engineering Department-The Catholic University of America, Washington, D.C. USA (sheehan@cua.edu)
Physical Disabilities Branch and Diagnostic Radiology, The National Institutes of Health, Bethesda, MD. USA

INTRODUCTION

In order to achieve a greater understanding of the demands placed on the musculoskeletal system and the capabilities of tissue to withstand and adapt to these demands, we are developing an imaging and analysis package, known as virtual functional anatomy (VFA), for the quantification and visualization of 3D musculoskeletal dynamics. VFA is a tool for the creation of subject-specific, 3D total joint anatomy models, animated based on actual joint kinematics during volitional movement. In addition, this tool will quantify the loads placed on individual joint structures. The first phase of VFA development focused on adapting cine phase contrast magnetic resonance imaging (cine-PC MRI) to the non-invasive *in vivo* study of 3D musculoskeletal kinematics. After confirming the precision and accuracy of cine-PC, the kinematics of healthy knees were quantified. These data (i.e., 3D tibio-femoral-patellar kinematics and patellar tendon strain) became the springboard for ongoing studies of impaired knee joint function. For example, we have quantified altered knee joint kinematics and vasti contraction patterns in subjects diagnosed with patellar maltracking. Additionally, we have begun to define possible coping strategies after an ACL loss.

METHODS

Contrary to standard MR imaging, where subjects need to remain as still as possible, cine-PC MRI requires that subjects cyclically move the limb being studied. For the knee joint studies, subjects were placed in a supine position within a 1.5T MR imager and were asked to extend/flex their knee at a rate of 35 cycles/min from $\sim 40^\circ$ of flexion to full extension. Consistency was maintained with the aid of a metronome. Cine-PC MR images were taken in a sagittal plane, at the center line of the femur and patella (Figure 1). Anatomically based reference frames were defined using anatomical images taken in 3 axial planes during the movement. For the vasti studies, an axial imaging plane proximal to the insertion of the vasti lateralis was used. Using integration algorithms developed previously (Zhu, et al, 1996), regions were selected on the tissues of interest and tracked 3-dimensionally throughout the motion cycle. Skeletal data were then translated into 3D xyz body-fixed orientation angles. Using 3D patellar-tibial data, the strain in the patellar tendon was calculated.

RESULTS

Cine-PC MRI was shown to have an accuracy of better than 0.55mm for the 3D displacement measures and a precision of

Figure 1: A/B) Sample cine-PC MR anatomic images; C/D) anterior/posterior (A/P) velocity images (superior/inferior and medial/lateral images not shown). White/black pixels indicate maximum A/P velocity, respectively.

better than 1.1° in the measurement of orientation angles. The kinematic profiles of the unimpaired knees agreed with previous studies (Sheehan, Zajac & Drace, 1999), but the average maximum tendon strain (6.6%) was greater than typically reported. The kinematics of the impaired subjects studied were clearly altered from those of the unimpaired.

DISCUSSION

Despite the frequency of reported knee pain, especially patellofemoral, there is still a lack of specificity in diagnosing the pathology causing this pain. This leads to confusion when designing a treatment plan and to difficulty in assessing the efficacy of intervention. Broad categories such as maltracking, chondromalacia, and anterior knee pain are often too quickly accepted as a diagnosis without the underlying etiology being understood. VFA's ability to non-invasively measure 3D musculoskeletal dynamics *in vivo* offers us an opportunity to revisit these broad classifications in order to develop more definitive diagnoses that can be correlated with specific impairments. This in turn will allow for improved diagnosis, treatment, and eventual outcome.

INSIGHTS INTO IN-VIVO KNEE MECHANICS WITH MAGNETIC RESONANCE IMAGING

Mechanical and Manufacturing Engineering, Human Performance Laboratory, *Clinical Neurosciences
University of Calgary, Calgary, Alberta, Canada, jlrnsky@ucalgary.ca

INTRODUCTION

Understanding the complex relations between joint structure, dynamic joint function and joint health status have been hampered due to lack of technologies for probing the in-vivo joint under physiologic loading conditions. Magnetic resonance (MR) imaging has provided an excellent venue for non-invasively quantifying joint structures in-vivo. The assessment of MR imaging for accurate measurements has been limited and has focused primarily on the measurement of cartilage thickness and volume as an indicator of the progression of cartilage degeneration (e.g. Peterfy et al., 1994; Kladny et al, 1999). Cartilage volume and thickness have also been used to calculate cartilage deformation under load in an attempt to better understand cartilage material properties (e.g. Eckstein et al., 2000). Ronsky and coworkers (1994) assessed in-vivo contact characteristics in both intact and ACL deficient patellofemoral joints under loading with MR imaging at flexion angles ranging from 0° - 45°. However, evaluation of contact area is plagued by lack of an appropriate gold standard. Cohen et al. (1999) used MR images and digitization techniques to collect surface data to measure cartilage topography, cartilage thickness and contact area between the joint surfaces, and compared results with stereophotogrammetric measures on an unloaded knee joint. As the limits of MR imaging for joint mechanics assessments are probed, issues related to feature extraction, motion artefact, image registration and reconstruction, accuracy, and repeatability become increasingly important. Hardware and software limitations related to bore size and orientation, magnet strength, imaging coils, image resolution, partial volume effects and pulse sequences provide constraints. Additional challenges include relating in-vivo joint structures to dynamic joint loading associated with locomotion, stair climbing and other functional activities. Our recent progress focusing on quantification of error sources and accuracy in prediction of joint contact, as well as relations between anatomical structures and functional joint centres is presented.

METHODS

A method for quantifying patellofemoral (PF) joint contact stress under physiologic load, non-invasively and in-vivo has been developed (Ronsky, 1994). A T2 weighted sagittal plane FSE sequence with 2 mm thick slices and imaging time of 2 min 52 s was employed. To evaluate the influence of edge detection, image registration, surface modeling techniques and proximity threshold on joint contact location and magnitude, this technique was applied to five loaded fresh porcine joint specimens (Moss, 2001). Staining and multi-station digital photogrammetry were used for comparative analyses. In a second study, variations in muscle moment arms for determination of resultant knee joint forces were compared based on a functional joint centre location and two anatomical locations

(cruciate ligament intersection and tibiofemoral contact point). Subject specific functional joint centres were obtained by determining the instantaneous helical axis (IHA) piercing point based on kinematic data, and relating this location to the joint structures visible on MR images (Figure 1).

RESULTS AND DISCUSSION

Non-Maxima Suppression semi-automated edge detection technique provided the most repeatable contact area results (intra-user coefficient of variability 0.94%) with the smoothest edge representation (0.27 pixel resolution). Contact area was sensitive to selection of proximity threshold value, with the optimal threshold of 0.2mm resulting in an uncertainty in contact area of 13%. Accuracy is specific to image sequence, MR unit and coil, and results suggest that this approach can be used for accuracy evaluations of specific experimental setups. The functional joint centre was located more closely to the cruciate ligament intersection point. While improvements in accuracy and processing time are required, this technique provides an example of integration of functional joint mechanics with MR imaging to reveal new insights into relations amongst normal and injured joint structure and function. Advances in image integration, dynamic imaging and increased image resolution through custom coils and higher strength magnets are projected to make MR imaging an integral component in monitoring joint health status and in-vivo joint mechanics.

3D KNEE KINEMATICS FROM PICTURES: HOW'S IT WORK, WHY'S IT USEFUL, AND WHERE'S IT GOING?

Scott A. Banks

The Biomotion Foundation, 1411 N. Flagler Drive, Suite 9800, West Palm Beach, FL 33401, banks@alum.mit.edu

INTRODUCTION

In the late 1980's, frustrated by the inability to use skin-mounted markers to accurately determine dynamic tibiofemoral translations and rotations, research groups sought new techniques to measure how total knee replacements (TKR) moved. Roentgen stereophotogrammetric techniques were well known at the time, but the requirement for surgically implanted fiducial markers made these techniques inappropriate for retrospective studies of patients with knee replacements. Instead, new techniques were developed based on ready availability of fluoroscopic imaging hardware in hospitals and computer geometry information from prosthesis manufacturers. Almost fifteen years later, these techniques have provided a wealth of quantitative information on the function of knee replacements, and have been adapted for a variety of other applications. The purpose of this summary is to briefly describe the principals of performing a three-dimensional pose measurement from a two-dimensional image, describe a few direct applications of these techniques, and provide an overview of the many related applications to which image derived kinematics will contribute.

MEASUREMENT PRINCIPLES

Measuring knee motion from images is a 'model and match' process. Fluoroscopic video sequences, as well as x-ray film images, are central or perspective projections of the implant components such that the shadow cast by the implants in the image are (usually) unique functions of the imaging geometry and the pose of the implants. The optical geometry of the imaging hardware, and spatial distortions, can be measured and incorporated into an image synthesis routine for projecting surface geometry of the implant components. The synthesized images can be compared to the recorded images, and an iterative process or look-up table can be used to optimize the shape correspondence. The pose of the virtual implant is taken as the estimated pose of the physical implant in 3D space.

These techniques are monocular vision (for most applications) and have highly non-uniform errors. Uncertainty for linear displacements along the optical axis can be an order of magnitude higher than for displacements parallel to the image plane. Uncertainties for angular displacements are slightly more uni-

Figure 1. 3D Knee motions from pictures: fluoroscopic (top, middle) or x-ray film (bottom) images and shape models of skeletal (middle) or prosthetic structures (top, bottom) can be used for matching and pose estimation.

form, but are more sensitive to the shape and features of the implant components. Significant sources of measurement error can include discrepancies between the physical object and the computer model used for shape matching, residual geometric distortion in the image, uncertainties in the optical parameters, motion blur, and penumbra.

MEASUREMENT APPLICATIONS

Single plane fluoroscopy has been used to characterize the motions of many (>30) designs of total knee replacement during a wide variety of dynamic and static activities, e.g. stair step, deep knee bend, gait, kneeling, rising from a chair (Fig. 1). These data have contributed significantly to an improving understanding of how total knee replacements function, and towards the objective refinement of TKR designs. The identical measurement approach has been applied on a more limited basis to the anatomic knee, with shape models derived from either CT or MRI scans. The same techniques apply equally well to planar x-ray films for static studies. Model and match techniques have been used to characterize motions in other joints and have been used in bi-plane joint imaging, where the accuracy can be increased substantially.

ASSOCIATED APPLICATIONS

Although measurements of knee motions are, by themselves, interesting and useful, it is possible to use this same information to compliment a wide variety of other test, evaluation, and development methodologies. In vivo knee kinematics can be used as inputs or validation for TKR wear testing systems. Image based data can be used to better understand damage to retrieved implants or, in some cases, predict wear in implants *in situ*. In vivo data can be used to drive musculoskeletal models and tribology simulations. Fluoroscopy, marker based motion capture, forceplates and EMG can be performed simultaneously to provide extremely detailed assessments of intrinsic and extrinsic biomechanics.

SUMMARY

Kinematic data from image matching is helping to 'close the loop' in the design of improved joint replacements and assessing the efficacy of ligament reconstruction and other surgical procedures. Image based 'model and match' techniques are yet another tool in the biomechanists' toolbox that will find varied and diverse application wherever the measurement properties are appropriate to answer the questions being asked.

ACL STRAIN DURING REHABILITATION EXERCISES, IN VIVO

Braden Fleming, Bruce Beynnon, Robert Johnson

McClure Musculoskeletal Research Center, Department of Orthopaedics & Rehabilitation,
University of Vermont, Burlington VT 05405; Braden.Fleming@uvm.edu

INTRODUCTION

Disruption of the anterior cruciate ligament (ACL) has been shown to lead to the early onset of osteoarthritis (OA), and that OA may progress despite surgical reconstruction of the injured ligament. One variable that is thought to influence the outcome of ACL reconstruction is the post-operative rehabilitation program prescribed. It is through rehabilitation that the biomechanical environment of the healing graft (and articular cartilage) can be controlled. Thus, it is necessary to understand how the ACL, and hence ACL graft, will respond to different joint loading conditions and exercises. These data could then be used to design clinical studies and to develop rehabilitation programs with the goal of optimizing graft healing while minimizing OA progression. Our approach has been to measure ACL strains *in vivo* because the force balance between the ligaments, articular contact, musculature and bodyweight regulates the ACL strains. The interaction between these structures is difficult to simulate in cadavers.

EXPERIMENTS

We used a small displacement transducer (DVRT; MicroStrain, Inc. Burlington VT) that can be arthroscopically applied to the ACL to evaluate the strains produced under different muscle contraction sequences and other commonly prescribed rehabilitation exercises. All study participants had normal ACLs and were candidates for arthroscopic partial meniscectomy or diagnostic arthroscopy. We assumed that the exercises producing the greater strain values in the normal ACL would also produce greater strains in an ACL graft.

We found that contractions of the quadriceps muscles strained the ACL when the knee was between 50° and full extension, while that hamstrings muscles did not except when the knee was near full extension. Co-contraction of the quadriceps and hamstring muscles reduced ACL strain values compared to isolated contractions of the quadriceps muscles. We also revealed that contractions of the gastrocnemius muscles strained the ACL when the knee was between full extension and 30° flexion emphasizing the important contributions other muscle groups may have. “Closed-kinetic chain exercises” (e.g. squatting) are commonly prescribed following ACL surgery since they are thought to enhance muscle co-contraction, and utilize the tibiofemoral compressive load produced by bodyweight to increase knee stability and protect the ACL. “Open-kinetic chain exercises” (e.g. active knee extension) are thought to produce higher strains since they are quadriceps dominant and do not include the compressive load induced by bodyweight. However, direct comparisons of the peak ACL strain values produced during squatting and active knee extension found no significant differences. We have

shown that this may be due to the increase in strain produced by compressive loading and/or the inability of the hamstrings to fully protect the ACL when the knee is near full extension.

Unfortunately, the strain thresholds beneficial and detrimental to ACL graft healing remain unknown. We used the strain data to design a clinical study evaluating the relationship between ACL strain and the graft and articular cartilage healing responses.

The clinical study utilized a prospective randomized design to compare two different rehabilitation programs (an “accelerated” program versus a “non-accelerated” program). The same exercises were prescribed in both programs; however, those that were found in our biomechanical studies to produce high strains were delayed by 4- to 6-weeks in the non-accelerated program. 25 patients who underwent ACL reconstruction with patellar tendon grafts were utilized. We hypothesized that the two rehabilitation programs would not produce significant differences in anterior-posterior knee laxity, patient-oriented outcomes, and “biomarkers” of articular cartilage metabolism (synovial fluid markers evaluating Type II collagen and aggrecan degradation and synthesis). Altered cartilage metabolism is thought to be indicative of OA. All outcome measures were assessed at the time of surgery and at 6-, 12-, and 24-months post-operatively.

We found that the patients who underwent the accelerated program had twice the increase in knee laxity after 24-months when compared to those in the non-accelerated rehabilitation program. However, neither program produced significant differences in any of the other outcome measures. The biomarkers of articular cartilage metabolism did not return to normal for either treatment group by 24-months.

CONCLUSIONS

Our biomechanical studies have shown that the ACL strains produced during rehabilitation exercises can be regulated. Our clinical study then revealed that a rehabilitation program that permits high strain activities in the early phases of graft healing produced greater changes in knee laxity. This may place the knee at risk for additional articular cartilage and meniscal damage. We hope that our future assessments of the biomarkers of articular cartilage metabolism and the patient-oriented outcomes in these patients will shed light on the long-term consequences of this increase in knee laxity.

MEASURING SPRING CONSTANTS OF THE P-SELECTIN/PSGL-1 MOLECULAR COMPLEXES BY AFM

Bryan Marshall¹, Rodger McEver², and Cheng Zhu¹

¹Schools of Mechanical Engineering and Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA 30332, USA, cheng.zhu@me.gatech.edu, ²Warren Medical Research Institute and Departments of Medicine and Biochemistry and Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104, USA.

INTRODUCTION

P-selectin is a cell adhesion molecule induced on activated endothelial cells and platelets. It plays a critical role in the inflammatory and thrombotic processes. P-selectin glycoprotein ligand 1 (PSGL-1) is expressed on leukocytes, and its interaction with P-selectin mediates the flowing cells tethering to and rolling on the blood vessel wall. In this mechanically stressful environment, the P-selectin/PSGL-1 complex is subject to a wide range of forces. As such, how much it would be stretched by force is a relevant question to the function of this interaction. Also, measuring properties of a single pair of interacting molecules not only symbolizes a long-standing theoretical appeal but also represents quite a technical challenge. As such, the elasticity of P-selectin/PSGL-1 complex is of interest. Here we report molecular spring constant measurements using an atomic force microscope (AFM).

MATERIALS AND METHODS

Dimeric P-selectin and wild-type (wt) PSGL-1 were purified from human platelets and neutrophils, respectively. Monomeric soluble (s) PSGL-1 was secreted by CHO cell transfectants. P-selectin was reconstituted into a glass supported lipid bilayer cushioned with a polymer layer. Dimeric wtPSGL-1 or monomeric sPSGL-1 was coupled to the tip of an AFM cantilever via the antibody PL2. In some experiments, the AFM tip was coated with the anti-P-selectin antibody G1.

The spring constants of AFM cantilevers were measured by thermal fluctuations. The spring constants of the molecular complexes were measured by two methods. In the thermal method, the spring constants of the AFM cantilevers linked to the surfaces by molecular complexes subject to given tensile forces were measured by thermal fluctuations. These were then compared to the spring constants of the same cantilevers not linked to the surfaces to deduce the spring constants of the molecular linkages. In the stretch method, the molecular spring constants were directly measured from their force-stretch curves.

RESULTS AND DISCUSSION

Spring constants were measured by either thermal or stretch method for each of the three molecular complexes: P-selectin interacting with wtPSGL-1, sPSGL-1 and G1. These are grouped according to the number of rupture events observed as the linkage between the AFM tip and the surface dissociated. The results are summarized in Figure 1.

Figure 1: Spring constants for the three molecular systems were measured by the stretch or thermal method from single or double rupture events. Data are presented as mean \pm standard error of N (indicated on the top of the bars) measurements.

Good agreement was found between data measured by the thermal and the stretch methods, which are indifferent to the spring constant of the cantilever used, thus imparting confidence in our methods. The spring constant of P-selectin complexed with wtPSGL-1 (which forms a dimeric bond) is about twice that of P-selectin complexed with sPSGL-1 (which forms a monomeric bond) when both were measured from single rupture events. For all three molecular systems, the spring constants measured from double rupture events are about twice those of the corresponding values measured from single rupture events. This suggests that the observed discrete the spring constant of a single molecular complex bound by a monomeric bond (for the sPSGL-1 case) or a dimeric bond (for the wtPSGL-1 case) was measured from the single rupture events. The similar values of the P-selectin/sPSGL-1 and P-selectin/G1 spring constants suggest that G1 formed single monomeric bonds with P-selectin in the single rupture events. They also suggest that most of the compliance of the molecular complex comes from P-selectin and PSGL-1 is a much more rigid molecule.

⁴Departments of Physics and Pathology, University of British Columbia, Vancouver, British Columbia, Canada

INTRODUCTION

The formation of transient attachments between leukocytes and a sparsely-coated reactive surface under flow is a commonly used assay for measuring the dissociation kinetics of leukocyte adhesion molecules such as selectins (Alon, Hammer, and Springer, 1995). These cell tethering experiments yield rate constants which are quite different from independent measurements obtained from either dynamic force spectroscopy (DFS) or atomic force microscopy (Fritz et al., 1998). We reexamine recent tethering results (Park, et al., submitted to *Biophys. J.*) using a numerical simulation of cell tethering that incorporates new kinetic parameters and viscoelastic relations obtained from DFS for the P-selectin/PSGL-1 bond.

METHODS

Using micropipette aspiration, a biomembrane force probe (i.e., red blood cell) serves as a transducer spring to measure the force experienced by two functionalized surfaces brought into contact (Merkel et al., 1999; Evans, 2001). In contrast to cell tethering, where the bonds experience a constant tensile stress once cell motion has ceased, a steady retraction of the DFS probe produces a linear ramp in force. We measured the strength of the P-selectin/P-selectin glycoprotein ligand-1 (PSGL-1) bond using DFS. The force vs. displacement profile for the compression of unactivated polymorphonuclear (PMN) neutrophils with a glass bead was also generated for several rates of force loading.

Cell and bead tethering on a P-selectin surface under flow was numerically simulated using adhesive dynamics to determine whether DFS-measured kinetic rate constants and derived relations for cell deformation could reproduce behavior observed in prior tethering experiments, and most recently by Park and coworkers. Adhesive dynamics is a technique for simulating the adhesion of cells to surfaces by coupling a hydrodynamic calculation of one or more rigid spheres suspended in a viscous fluid interacting with a wall under an imposed flow, with a stochastic model of specific receptor-ligand adhesion (Hammer and Apte, 1992; King and Hammer, 2001). Each molecular bond between the cell and substrate is explicitly included as a linear spring with endpoints fixed on either surface. The instantaneous length and orientation of each bond determines both the total force and torque acting on the spherical cell, as well as each bond's probability for failure at that time step.

RESULTS AND DISCUSSION

The normal force resisting PMN compression was measured to be $f \sim (2\pi R P_0) \Delta x$, where R is the harmonic mean of the PMN radius and the radius of curvature of the opposing surface, $P_0 = 17 \text{ N/m}^2$,

and Δx is the relative displacement. The dynamics of tether extension was measured to consist of two regimes, with each regime ended by a stochastic unbinding process. The initial response obeys a linear elastic relation $f = k_{\text{int}} \Delta x$, defined by the interfacial elastic constant $k_{\text{int}} = 0.25 \text{ pN/nm}$ which is independent of pulling speed. The transition from the elastic regime to a plastic tether growth regime occurs due to cytoskeletal unbinding at a force f_{cl} and a rate v_{off} :

$$f_{\text{cl}} = f_{\beta} \log_e (k_{\text{int}} v_{\text{pull}} t_{\text{off}} / f_{\beta}) \quad (1)$$

$$v_{\text{off}} = (1 / t_{\text{off}}) \exp(f / f_{\beta}) \quad (2)$$

where $f_{\beta} = 15.7 \text{ pN}$, $1/t_{\text{off}} = 0.5/\text{sec}$, and v_{pull} is the pulling speed. After cytoskeletal unbinding, the force approaches a plateau in a quasi exponential fashion (i.e., $f \sim 1 - \exp(-t/\tau)$). Both the plateau force f_{lg} and the relaxation time τ were determined to depend on the

$$\tau \approx 0.4 \text{ sec} (v_{\text{pull}} / \mu \text{ m / sec})^{-0.83},$$

$$f_{\text{lg}} \approx 85 \text{ pN} (v_{\text{pull}} / \mu \text{ m / sec})^{0.17}$$

pulling speed, as

The final event is rupture of the PSGL-1/P-selectin bond which again follows the quasi-Bell model form of eqns. (1) and (2) with $f_{\beta} = 17 \text{ pN}$ and $1/t_{\text{off}} = 0.1/\text{sec}$.

DFS of P-selectin/PSGL-1 reveals a single transition state with a significantly slower off rate and significantly larger bond interaction length than measured by tethering. When all of these refinements were included in the adhesive dynamics simulation, the tethering results of Park et al. (submitted to *Biophys. J.*) were accurately reproduced. This implies that the common steady-state, unimolecular interpretation of cell tethering results can produce highly inaccurate estimates of unbinding kinetics, and that more direct measurement techniques such as DFS or AFM are better suited to characterize receptor-ligand interactions at the single-molecule level.

RHEOLOGICAL PROPERTIES OF THE BLOOD AND LOCAL HAEMODYNAMICS MODULATING LEUKOCYTE ATTACHMENT TO SELECTIN-COATED SURFACES

G.B. Nash¹, K.B. Abbitt¹, C.A. Skilbeck¹, S.M. Westwood², P.G. Walker² and T. David²

¹Department of Physiology, The University of Birmingham, Birmingham B15 2TT, g.nash@bham.ac.uk

INTRODUCTION

The local physical environment critically constrains the interaction between adhesion receptors expressed on flowing leukocytes and vascular endothelium. The rheological properties of the blood (haematocrit, red cell aggregation, viscosity) and the pattern of flow influence initial contact, formation of bonds and bond survival. Contact with the vessel wall is promoted by margination of leukocytes by aggregated, centrally flowing erythrocytes, with aggregation itself being more extensive at low shear rates. Shear rate at the vessel wall determines the velocity of leukocytes at contact and thus influences the probability of establishment of a receptor-ligand bond. Wall shear stress (the product of shear rate and fluid viscosity) applies force to cells once they have bound, and accelerates bond disruption. We examined how variation in blood rheology and characteristics of flow affected leukocyte margination and capture from flowing whole blood.

METHODS

Whole citrated blood was fluorescently labelled with rhodamine 6G and perfused at variable rate over glass surfaces coated with P-selectin, an adhesion receptor able to capture flowing leukocytes and support a rolling form of adhesion (Abbitt & Nash, 2001). We used either straight glass capillaries with rectangular cross-section (microslides), or a flow chamber which incorporated a backward-facing step. In the latter case, flow separation occurred downstream of the step. A region of recirculating flow, a reattachment point, and a region where simple laminar flow was re-established could be distinguished (Skilbeck et al., 2001). We measured surface density of adhesion (corrected for leukocyte numbers) and rolling velocity. To quantify leukocyte margination, we used a non-adherent surface and measured flux of leukocytes near the wall and cell velocity.

RESULTS AND DISCUSSION

Manipulation of haematocrit from 10% up to 50% caused an increase in velocity of margined leukocytes, but little change in their flux. Since volumetric flow rate was constant, this implied that the flow velocity profile became blunted and wall shear rate increased as haematocrit increased. The number of leukocytes adhering increased between 10 to 30% haematocrit, and was essentially constant thereafter. It seems that increasing red cell concentration promotes initiation and stabilisation of attachment, even in the face of increasing wall shear rate, blood viscosity and hence shear stress. To study the influence of red cell aggregation, blood was diluted to 20%

haematocrit with plasma, 40kD dextran (reduced aggregation) or 500kD dextran (enhanced aggregation). Increasing aggregation correlated with increasing numbers of adherent leukocytes, and was associated with an increase in slow-flowing leukocytes near the wall. These results demonstrate that the physical properties of the blood control movement of leukocytes toward and contact with the vessel wall, and influence the initiation and outcome of adhesive interactions that follow.

Examining flow over a backward-facing step, it was evident that adhesion to a selectin-coated surface could occur either side of the reattachment point. On the upstream side, cells rolled inward towards the step. On the downstream side cells rolled away from the step and could enter regions where attachment could not occur from the main flow, presumably because shear rate was too high ($>400\text{s}^{-1}$). Thus discontinuity in the 'vessel' wall allowed adhesion in a conduit which otherwise had too high shear rate, and rolling adhesion allowed population of regions where attachment could not occur directly. The patterns of adhesion in the recirculation zone also showed that local components of flow toward or away from the wall influenced attachment, as well as the local shear stress.

SUMMARY

These studies indicate that adhesion within the circulation depends on rheological characteristics of the blood, physical interactions between blood cells, and the local patterns of shear rate and stress, as well as expression of endothelial receptors. This accords with findings that adhesion is typically restricted to post-capillary venules where shear rates are lowest. Nevertheless, mononuclear leukocytes are found within arterial atherosclerotic plaque, and adhesion may also occur in arterioles in pathological states. Adhesion in such regions might be promoted by flow separation at discontinuities in the wall, causing localised low shear and a normal component of flow.

DIVALENT ION INDUCED ADHESION OF NEUTROPHILS TO ICAM-1 AND VCAM-1 COATED SURFACES

Richard Waugh,¹ Elena Lomakina, Christopher Spillmann and Philip Knauf

Department of Biomedical Engineering, University of Rochester, Rochester, New York ¹waugh@seas.rochester.edu

INTRODUCTION

The firm adhesion of neutrophils to endothelium in the complex mechanical environment of the microvasculature is a critical step in the body's response to infection or inflammation. This interaction is primarily mediated by binding of members of the β_2 family of integrins expressed on the neutrophil to ligands, principally ICAM-1, expressed on activated endothelium. Members of the β_1 integrin family, capable of binding to VCAM-1 on endothelium, are also found in smaller numbers on the neutrophil surface. Binding of integrins to their ligands occurs only when integrins are in an "activated" or high-affinity conformation. *In vivo*, this conformation is induced by signaling events within the cell, but this conformation can be induced *in vitro* by the presence of Mg^{2+} (and not Ca^{2+}) in the extracellular medium. We are using the latter approach to examine the influence of mechanical force on integrin-mediated cell adhesion to endothelial ligands immobilized on beads.

METHODS

A small blood sample was obtained by fingerprick and dispersed into sterile buffer (Hank's Balanced Salt Solution (Gibco) to which was added 4% heat-inactivated fetal bovine serum (Hyclone, Logan, UT) and either 5.0 mM Mg^{2+} or 1.5 mM Ca^{2+} , pH 7.4, 290 mOsm). The cell suspension was placed in a chamber on the stage of an inverted microscope kept at 37°C. Neutrophils were selected based on the multi-lobular morphology of the nucleus. Two micropipettes were mounted opposite each other. One was used to hold a small (4.5 μm diameter) bead (tosyl-activated, Dynal, Lake Success, NY) that had been coated according to the manufacturer's protocol with soluble ICAM-1, VCAM-1 (R&D Systems, Minneapolis, MN) or NCAM (Chemicon, Temecula, CA). The second pipette was used to manipulate a cell into repeated contact with the bead surface. The cell and the bead were held in contact for a specified length of time (typically one minute), then separated, and the formation of an adhesive contact was noted by a deformation of the cell surface during separation. The percentage of contacts that resulted in the formation of an adhesive bond was calculated.

Flow cytometry measurements were made to estimate the number of adhesive ligands on the cells and the beads. Cells were labeled with fluorescent antibodies against CD18 (β_2 integrin) or CD29 (β_1 integrin) then fixed and the fluorescence intensity was compared to that of cells treated with isotype control antibodies. The fluorescence signal was converted to the number of antibodies bound to the surface by comparison with Quantum Simply Cellular beads (Flow Cytometry Standards, Fishers, IN).

Figure 1: Adhesion probability for interaction of neutrophils with beads coated with the specified protein and in the presence of 1.5 mM Ca^{2+} or 5.0 mM Mg^{2+} , as indicated.

RESULTS AND DISCUSSION

The density of ICAM-1 on the bead surface was estimated to be 500 copies/ μm^2 and the density of VCAM-1 was estimated to be 1000 copies/ μm^2 . The density of β_2 integrins on the cells was approximately 300 copies/ μm^2 (~70,000/cell). Preliminary estimates of the density of β_1 integrins indicated 25 - 50 copies/ μm^2 or 6,000 - 12,000 copies/cell.) In Mg^{2+} -containing media, adhesion was more likely to occur with ICAM-coated beads than with VCAM-coated beads (Fig. 1). Under conditions in which the adhesive probability for ICAM was over 80%, the probability of adhesion to the VCAM coated beads was ~60%. This high level of adhesion to VCAM was surprising, as VCAM is not thought to be a prominent ligand in mediating neutrophil-endothelial interactions. (In fact, the VCAM experiments were originally performed as a non-adhesive control for the ICAM experiments!). For both ICAM and VCAM, the frequency of adhesion was dramatically reduced when Mg^{2+} was replaced with Ca^{2+} in the external medium. Experiments in which cells were contacted with beads coated with NCAM showed little adhesive interaction. Interestingly, the formation of adhesive contacts was found to depend strongly on the size of the contact zone produced during impingement of the cells on the beads. For example the rate of adhesive contact formation after brief (2 s) contacts with ICAM beads was 75% when the size of the contact area was greater than 13 μm^2 , but fell to less than 33 % when the contact area was less than 12 μm^2 . This corresponds to impingement forces of ~400 pN and ~175 pN respectively for the two groups tested.

THE NATURE OF MECHANICAL FORCES REGULATING SHEAR-INDUCED PLATELET ACTIVATION

Sriram Neelamegham¹ and Harish Shankaran

Bioengineering Lab., Chemical Engineering, State University of New York at Buffalo, Buffalo, New York ¹neel@eng.buffalo.edu

INTRODUCTION

Shear-induced platelet activation may occur under conditions of high blood flow, such as those encountered in stenosed arteries. This phenomenon is thought to contribute to thrombosis. The molecular mechanism controlling this process involves the binding of plasma protein von Willebrand factor (vWF) to platelet membrane receptor complex GpIb/V/IX under high shear conditions. For this process, it is speculated that fluid forces may cause conformational changes in either vWF or GpIb thereby promoting receptor-ligand interaction. In this paper, we aim to quantify the nature and magnitude of the fluid stimulus that triggers platelet activation.

METHODS

Platelets (in citrated/PPACK treated platelet rich plasma or in whole blood) were subjected to defined shear in a cone-plate viscometer. The extent of platelet activation was measured by quantifying the level of AnnexinV-FITC binding to phosphatidyl serine expressed on the activated platelet surface. Generation of microparticles and the level of platelet aggregation was also monitored over a range of fluid shear protocols. In selected experiments, human vWF was isolated from blood cryoprecipitate. This isolated vWF was subjected to hydrodynamic shear and analyzed using static and dynamic light scattering experiments, in order to assess the extent to which fluid shear may alter the macroscopic shape of vWf.

RESULTS AND DISCUSSION

In studies performed to determine a sensitive marker of shear-induced platelet activation, we observed that the binding of Annexin V to phosphatidyl serine expressed on the activated platelet surface was a more sensitive and reproducible marker of platelet activation than platelet microparticle formation and cellular aggregation. Statistically significant detection of cellular activation was observed within 10sec. of application of shear (Fig 1), and this was consistently blocked by antibodies against GpIb but not GpIIb/IIIa.

Experiments were further performed using a range of fluid shear protocols to assess the contributions of mechanical forces on the rates of platelet activation. Here, we observed that: **i)** platelet activation levels were low below a shear rate of 6000/s, beyond which they increased approximately linearly with increasing shear. **ii)** In experiments with varying cell concentrations, we observed that the extent of cell activation only doubled when we increased the cell concentration over a 30 fold range from 10 to 300×10^6 cells/mL, thus indicating that collisions between platelets is not a major contributor to shear-induced cell activation. **iii)** Experiments performed with increasing fluid viscosity further illustrated that it is fluid shear stress rather than shear rate that is the primary parameter controlling activation. In these runs, doubling the fluid viscosity by addition of high molecular weight dextran at a constant shear rate of 9600/s caused a 2.4 fold increase in cell

Fig 1: Citrated PRP subjected to shear at 9600/s in the presence of function blocking antibodies against GpIb or GpIIb/IIIa.

we varied the volume of our experimental sample. Recently, we have demonstrated that increasing sample volume at a constant cone rotational rate causes an increase in non-linear secondary flow in the cone-plate viscometer without markedly altering the average applied shear rate (1, 2). In these experiments we observed a ~20% decrease in platelet activation when non-linear shear was applied thus suggesting that time-varying fluid forces are not necessary for shear-induced platelet activation. **v)** Our experiments with static light scattering also revealed macroscopic changes in the shape of vWF upon application of hydrodynamic shear. Here, vWF molecules were observed to irreversibly change from a near spherical shape to an elongated conformation upon application of shear at 9600/s for 2 minutes.

SUMMARY

Our results suggest that fluid shear stress rather than shear rate, non-linear/time-variant flow or cell-cell collisions regulate platelet activation. Besides causing minor changes in the conformational domains of vwf, fluid shear can also cause dynamic irreversible changes in the macroscopic shape of vwf. Implications of our findings on our understanding of how physical forces may control GpIb/vWF function and contribute to thrombosis are discussed.

OF MICE AND PIGS: THE CORONARY MICROVASCULATURE

Ghassan S. Kassab

Center for Biomedical Engineering, University of California, Irvine, CA, USA; gkassab@uci.edu

INTRODUCTION

Inbred strains of mice are being used with increasing frequency as subjects in many experimental cardiovascular studies. In particular, the strain C57BL/6 is perhaps the most widely used and hence the best known of all inbred strains. Despite the tremendous progress in the genotypic characterization of the mouse cardiovascular genome, however, the phenotypic characterization of the morphometry of the coronary microvasculature is lagging behind. The goal of the present study was to obtain a systematic set of data on the morphometry of the first several orders of the coronary microvasculature.

METHODS

Four mice (25.3 ± 1.3 g) were pre-anesthetized to achieve requisite immobilization. The mice were anesthetized with an intra-peritoneal injection of sodium pentobarbital (40 mg/kg) and the carotid artery was cannulated for blood pressure measurement. A tracheostomy was performed and the mouse ventilated with a rodent respirator. The chest was opened with a mid-line sternotomy. The blood was heparinized with a 0.1 ml of normal saline with 200 U/ml of heparin via the carotid artery catheter. The animal was sacrificed with an injection of 0.5 ml of 3.3 M KCl via the jugular vein for diastolic arrest while the animal is deeply anesthetized. The heart was rapidly removed and cannulated via the thoracic aorta at the arch for retrograde perfusion of the coronary arteries. A solid cast of the coronary vasculature was made with elastomer that was catalyzed to solidify in 45 minutes (Kassab et al, 1993). The aortic perfusion pressure was maintained at physiologic value until the elastomer was completely hardened.

The morphometric data on the coronary arterial vessels of diameters < 50 μm was obtained from histological specimens as described in our previous studies on the pig (Kassab et al, 1993). Briefly, plugs of myocardial tissue were removed from the left ventricles of cast hearts. Each plug was mounted on a freezing microtome and serial sections of 60- to 80- μm thickness was cut. Each section was dehydrated with 100% alcohol and cleared with methyl salicylate to render the myocardium transparent and the elastomer-filled microvasculature visible in light microscopy. The distinction between arterioles and venules were made possible because of the differences in the branching pattern. The morphology of the coronary microvessels were reconstructed through optical sectioning as described previously by Kassab et al. (1993). The reconstructed vessels were ordered in accordance with the diameter-defined Strahler system to obtain a relationship between the diameter, length, connectivity and the order number (Kassab et al, 1993).

RESULTS AND DISCUSSION

We found the first four orders of the mouse arterioles vessels to have diameters of 9.1 ± 0.85 , 12.4 ± 1.1 , 17.9 ± 1.8 and 25.8 ± 3.6 , respectively. The data on the diameter were not different from the corresponding orders in the pig heart. The data on the length of the first four orders of elements are shown in Fig. 1. The data is compared to the published data of the pig coronary arterioles. We found the lengths of the first four orders of vessels to be significantly smaller in the mouse heart.

SUMMARY

Our preliminary results show that the vascular anatomy of the first several orders of vessels (microvasculature) to be very similar to those of the pig heart. The diameters of the first several orders of arterioles were found to be similar to the respective orders in the pig heart. The lengths however were found to be significantly smaller in the mouse heart as shown in Fig. 1. Since the diameter is hemodynamically a more important parameter than the length, it is important to establish that the mouse is similar to the pig which is considered an excellent model for the coronary anatomy of humans.

INTRODUCTION

Endothelial cells show smooth lumen surface and scanty organelles with flat nucleus. It is known that high-flow dilates blood vessel and low-flow narrows blood vessels (Thoma, 1893). Later Kamiya and Togawa (1980) showed that Thoma's principle works so as to keep wall shear stress constant in the artery and that blood vessels are in equilibrium to the flow. It is therefore considered that the endothelial cells in vivo represents the equilibrium state, if we observe blood vessels in the normal animals. However, there would be various states of endothelial cells according to the various states of flow. In this report, we show morphology of endothelial cells in flow alteration and discuss the relationship to flow.

ARTERIES IN HIGH FLOW

Arterial blood flow increases, when arterio-venous fistula (AVF) is made in the distal of the arteries (Kamiya and Togawa, 1980; Masuda et al., 1999). In the common carotid arteries of the dogs and the rats, artery dilated and endothelial cells proliferated (Tohda et al., 1992; Sugiyama et al., 1997). In the rabbit common carotid arteries (Masuda et al., 1999), artery dilated remarkably as compared to those of dogs or rats. At 2 days of AVF, endothelial cells protruded abluminally and basement membrane was degenerated. At 3 days, endothelial cells frequently attached with medial smooth muscle cells in the enlarged fenestrae of the internal elastic lamina. At 4 days, there appeared the gaps of the internal elastic lamina. The gaps of the internal elastic lamina enlarged thereafter and the artery dilated.

ARTERIES IN LOW FLOW

Increased blood flow induced by AVF was reduced by the closure of the AVF (Zhuang et al., 1997; Sho et al., 2001). In the rabbit common carotid arteries, which were dilated by the 4 weeks AVF, wall shear stress reduced remarkably near 0.1 to 0.2 Pa (control or normal, 1-2 Pa) by the closure. After closure of the AVF, endothelial cells became short (1 day after AVF closure) and became almost round (3 days after AVF closure). Number of endothelial cells decreased rapidly with apoptosis. Medial smooth muscle cells began to migrate into the intima through the gaps of the internal elastic lamina.

CAPILLARIES IN THE ELECTRICALLY STIMULATED SKELETAL MUSCLE

When skeletal muscle is electrically stimulated, capillaries increase with angiogenesis (Hudlicka et al., 1992). We observed extensor digitorum longus of the rabbits, which was electrically stimulated for 3, 7, and 14 days (Ebina et al., 1996). Tissue blood flow increased after stimulation. At 7 days stimulation, capillary sproutings appeared nearly 4,000 per cubic mm. When, in the electrically stimulated extensor digitorum longus of the rabbits for 7 days, electrical stimulation was stopped, some capillaries disappeared (Hoshi et al., 2000). After 4 weeks, capillary density became normal.

SUMMARY

Morphologic changes of endothelial cells in the arteries and capillaries were studied under flow alteration using arterio-venous fistula or electrical stimulation. Endothelial cells under high-flow usually proliferate and induce remodeling of the blood vessels. In the arteries, the remodeling is dilatation and in the capillaries, it is angiogenesis. On the contrary, endothelial cells under low-flow usually disappeared with apoptosis and induce regression of the blood vessels. In the arteries, the remodeling is narrowing and in the capillaries, it is angio-regression. Therefore endothelial reaction to flow alteration would be summarized as "High-flow induces angiogenesis and low-flow induces angio-regression."

CORONARY MICROVASCULAR RESISTANCE AS DERIVED FROM INTRACORONARY PRESSURE AND VELOCITY MEASUREMENTS IN HUMANS

Maria Siebes

Depts. of Cardiology and Medical Physics, Cardiovascular Research Institute Amsterdam
Academic Medical Center, University of Amsterdam
Meibergdreef 15, 1105 AZ Amsterdam, The Netherlands

INTRODUCTION

For the evaluation of coronary stenosis severity in the catheterization room, sensor-equipped guide wires have been developed that on the one hand serve as a classical guide wire over which, e.g., balloon catheters can be introduced in the coronary arteries, but which at the same time allow for the measurement of pressure or blood velocity distal of the lesion. Recently, wires have been developed that enable the combined measurement of these two quantities and thereby allow not only the quantification of stenosis severity but also of the resistance of the coronary microcirculation.

PHYSIOLOGICAL CONCEPTS

The evaluation of the physiological significance of a stenosis is based on concepts of the coronary circulation developed in physiology. A patient develops problems when blood supply is not sufficient to meet oxygen demand. Demand increases with exercise and hence, supply may be sufficient at rest but fails at exercise. With a sensor downstream of the lesion, one is able to quantify the response of the coronary circulation to a vasodilator as a substitute stimulus for exercise.

Until recently, only the velocity or the pressure could be measured clinically distal to a stenosis. The interpretation to the vasodilator stimulus measured by either signal is based on the same physiological concept: coronary flow reserve. The velocity-based index is simply the ratio of velocity at maximal dilation and at rest and results in CFVR. With the pressure sensor, the ratio of distal pressure and aortic pressure at maximal dilation is used as an index, FFR. This index represents the ratio of flow with a stenosis to that in the same vessel without a stenosis.

CORONARY MICROVASCULAR RESISTANCE

The problem with the traditional concepts, FFR and CFVR, is that these are based on a simplified concept of the coronary microvascular resistance. It is assumed that microvascular resistance at maximum vasodilation is independent of pressure and that it is similar between different perfusion areas of major coronary arteries in the same heart. It is therefore not surprising that these indices can result in rather conflicting outcomes in the prediction of the physiological impact of the stenosis (Meuwissen, 2001).

Figure 1: Distribution of microvascular resistance at rest (b-MR_v) and at maximal hyperemia (h-MR_v)

First, combined measurements of distal pressure and velocity demonstrate a rather large variation of microvascular resistance between hearts and between perfusion areas as demonstrated in Figure 1. These variations still hold when velocity-based resistance is corrected for vascular dimensions. These variations are in line with what is known about heterogeneous distribution of blood flow in animal studies, which was more recently confirmed in humans with PET (Chareonthaitawee, 2001).

FINALLY

At present we are evaluating a guide wire which has both a velocity and a pressure transducer at the tip that can be located downstream of the stenosis. In this way, information on the microcirculation can be incorporated in the clinical decision making before PTCA and/or stenting and the effect of the intervention on the microcirculatory resistance index can be evaluated.

INTRODUCTION

The recent advent of intravital microscopy has permitted to monitor microcirculation in vivo with minimal invasion. Here we report on the first findings made with the use of a pencil-lens intravital non-invasive technology(AJP-Renal 2001) as applied to ischemic rat kidney. The aims were to clarify visualize peritubular capillary(PTC) microcirculation contributed pathology on ischemic renal failure directly and whether does the transplantation of human umbilical venous endothelial cell(HUVEC) result hemodynamic improvement in the ischemic renal failure .

MATERIAL AND METHODS

Peritubular capillary and glomerular blood flow were monitored under basal conditions, during renal artery occlusion and immediately following release of the clamp. Erythrocyte velocity was calculated as an angle on consecutive spatio-temporal images(Methods Inf Med 2000)

After 45 minutes, the left renal artery was released, while the right renal pedicle and the right ureter were ligated and a right nephrectomy was performed. After release of the clamp, 10⁶/0.2 ml HUVEC labeled with Cell Tracker (Molecular Probes) and human embryonic kidney cells(HEK), HEK/2GA(Mutant) or HEK/eNOS(Wild type human endothelial nitric oxide synthase) were injected into the right jugular vein or the aorta (through a catheter inserted into the left carotid artery) to athymic nude rats(n=5) with the ischemic renal failure.

RESULTS

RBC velocity in peritubular capillaries averaged 1069±146 $\mu\text{m}/\text{sec}$ (n=15). As expected, clamping the renal artery resulted in a complete cessation of blood flow accompanied by blanching of the surface and visualization of individual RBC halted within the vessels. The release of renal artery occlusion consistently resulted in an almost instantaneous recovery of blood flow. Surprisingly, within 1-2 minutes blood flow seized and showed partial recovery by 60 min. Twenty-four hours post-ischemia, peritubular capillary blood flow remained significantly diminished, representing only 1/3-1/4 of control level(Fig.1). Blood flow was uniformly orthograde under control conditions, however, it

displayed retrograde direction of flow upon reperfusion. The patency of peritubular capillaries was partially compromised during early reperfusion period, but rapidly recovered. The recovery of glomerular microcirculation occurred faster than that of peritubular capillaries. HUVEC-injection kidneys displayed(Fig.2) a significant hemodynamic improvement. Microcirculatory hemodynamics was not affected by the transplantation of HEK or HEK/G2A cells. In contrast, HEK/eNOS cells afforded a significant hemodynamic protection to the ischemic kidney.

SUMMARY

We suggest that in superficial cortical microvasculature, a functional vasculopathy develops early in the course of ischemia-reperfusion. and the circulating exogenous endothelial cells could protect the kidney against ischemic injury.

INTRODUCTION

It is well known that coronary risk factor contribute to the development of atherosclerosis with endothelial dysfunction. Asymmetric dimethylarginine (ADMA), an endogenous inhibitor of nitric oxide (NO) synthase is elevated in vascular endothelial dysfunction with decrease of dimethylarginine dimethylaminohydrolase (DDAH) activity, which degrades ADMA. Oxidized-LDL inhibits the DDAH activity and tetrahydrobiopterin (BH_4) in vitro (Figure 1). The subendocardium (ENDO) is more prone to ischemia than the subepicardium (EPI) in the hypertensive hypertrophic heart. However, there is no study of evaluation of the endothelium-dependent, -independent vasodilation and inhibitor of NO synthase in ENDO in the time-course of hypertension (HT).

Figure 1 @NO synthase pathway

We evaluated the time sequential changes in endothelium dependent and independent vasodilator on subendocardial arterioles (Endo-A) in the renovascular hypertensive canine hearts and also evaluated ADMA, BH_4 and DDAH in both ENDO and EPI of hypertensive hearts.

METHODS

We measured the diameter of Endo-A and subepicardial arterioles (Epi-A) in renovascular hypertensive canine hearts using CCD intravital microscope. Vascular responses to acetylcholine (Ach) and papaverine (Papa) were compared in normotensive (N) and hypertensive (4th week HT, 4wHT and 12th week HT, 12wHT) hearts.

We also evaluated plasma and rat heart tissue ADMA, BH_4 and DDAH in WKY and SHR (both 14th-week). ADMA and BH_4 , and DDAH were evaluated by HPLC and ELISA.

RESULTS

The mean aortic pressure were higher than those of normotensive group in both renovascular hypertensive canine model and SHR model.

Renovascular hypertensive hypertrophic canine model

Percent diameter change of Endo-A in both 4wHT and 12wHT after Ach were smaller than that of N. In Epi-A, a significant difference was observed only between N and 12wHT. The vasodilation of Endo-A in 4wHT and 12wHT was smaller than that of Epi-A. Endothelium-dependent vascular responses of Endo-A were impaired in both 4wHT and 12wHT, but only in 12wHT in Epi-A.

There was no significant difference after Papa between N and 4wHT in both Endo-A and Epi-A, while the vasodilation in 12wHT was impaired only in Endo-A. Thus, the endothelium-independent vasodilation was impaired time sequentially only in Endo-A of 12wHT.

Spontaneous hypertensive rats model

Plasma and myocardial ADMA were significantly elevated, myocardial DDAH, plasma and myocardial BH_4 were significantly decreased in SHR compared with WKY. These factors of NO synthase inhibition in ENDO is greater than that in EPI (see arrowheads in Figure 1).

CONCLUDING REMARKS

In an early stage (4wHT), the endothelium-dependent response of Endo-A was impaired. In the later stage (12wHT), both the endothelium-dependent and independent responses of Endo-A were impaired.

NO synthase disturbance in hypertension may be exacerbated by increment of ADMA, and decrease of DDAH and BH_4 , causing endocardial ischemia and the advancement of ischemic heart disease.

THE PATTERN OF SCAPULOHUMERAL MOTION - HOW STABLE IS IT?

Andrew Karduna¹, David Ebaugh¹, Lori Michener³ and Phillip McClure²

INTRODUCTION

Scapular motion plays a fundamental role in the biomechanics of the shoulder complex. Experimental measures of scapular kinematics are important for a better understanding of shoulder function and for the development of computational models. Ever since the seminal paper of Inman et al. (1944) over a half-century ago, there have been over 50 published studies of scapular kinematics. Approximately half of these studies have examined the robustness of the scapulohumeral rhythm by looking at changes due to factors such as shoulder pathology, external load, velocity, posture, muscle fatigue, plane of elevation and rehabilitation. Recent models have only been able to account for changes in one or two factors (eg, de Groot and Brand, 2001). The purpose of this abstract is to review our experience with factors that can influence the stability of scapular kinematics.

MATERIALS AND METHODS

We have recently developed a non-invasive methodology for measuring scapular kinematics with a magnetic tracking device (Polhemus 3Space Fastrak, Colchester, VT) attached to the scapular spine and acromion process. This technique has been validated by comparison with measurements made by drilling pins directly into the scapula (Karduna et al., 2001). Additional surface mounted sensors were placed on the thorax and humerus. For each sensor, the arbitrary axes defined by the magnetic tracking device were converted to anatomic axes by digitizing bony landmarks. For each experiment, data were collected when subjects elevated their arms in the scapular plane. We have used this protocol to compare normal motion with motion under the following conditions:

- patients with impingement vs healthy controls
- patients with spinal accessory nerve palsy vs healthy controls
- effects of rehabilitation in patients with impingement
- effects of muscle fatigue in healthy subjects
- effects of external loads in healthy subjects
- active vs passive shoulder motion in healthy subjects

To help summarize the data from all of these studies, the maximum differences in the upward rotation motion of the scapula were calculated.

RESULTS AND DISCUSSION

The largest changes were observed in the two conditions in which the muscular control of scapular motion was the most affected – passive motion and nerve palsy (figure 1). Our results are consistent with the majority of studies in the literature, where differences of less than 5 degrees are observed for upward rotation with a perturbation to the system. To our knowledge, the only study reporting differences from controls in excess of 10 degrees of upward rotation was a study of patients who had sustained a stroke (Johnson et al.,

1998). The implication of our results and results from the literature is that the scapulothoracic motion is a robust system, requiring substantial compromise before it exhibits dramatic pattern changes. It still remains to be seen whether the modest changes observed under most conditions are clinically or biomechanically relevant. For example, Ludewig et al. suggest that in patients with impingement syndrome, even small changes in scapular rotation may result in detrimental decreases in the clearance in the suprahumeral space (Ludewig and Cook, 2000). Additionally, although the scapula moves in a complex three-dimensional pattern, we have chosen to only report the motion about one axis here.

Figure 1 Maximal effects of different factors on upward rotation of the scapula.

TOWARDS THE CREATION AND VALIDATION OF A LARGE SCALE MUSCULOSKELETAL UPPER LIMB MODEL

Germano T. Gomes¹, Garth R. Johnson

Centre for Rehabilitation and Engineering Studies (CREST), University of Newcastle Upon Tyne (UNUT), United Kingdom

¹communicating author, G.T.Gomes@ncl.ac.uk, CREST, <http://www.ncl.ac.uk/crest>

INTRODUCTION

The shoulder mechanism is arguably the most complex joint system in the human body. Among the main factors that have precluded the accurate 3D measurement of movement and the development of large scale musculoskeletal models of the shoulder are: complex bone geometry allowing for a uniquely large range of movement, high number of muscles, some with very large attachment sites and with bi-articular function, and existence of a gliding bone (scapula).

In the past 10 years these problems started to be dealt with, leading to the creation of large-scale shoulder/elbow models. Currently three of such models exist, namely the Dutch model (van der Helm, 1994), the Swedish model (Hogfors, 1989) and the Newcastle model (Charlton, 2001) to be discussed here.

METHODS

The construction of the model started with the appearance of accurate morphometric data obtained in detailed anatomical studies of the shoulder complex (Johnson et al, 1996) and from MRI and CT data from large general datasets (Visible Human Project). This has allowed the 3D reconstruction of all bone structures, identification of muscle attachment sites, subdivision of large muscles into different functional units and estimation of varying moment arms for each muscle.

The second aspect was the determination of the kinematics relations between scapula, clavicle and the humerus. Following the development of palpation techniques and instrumented linkages (Johnson, 1993) it was possible to derive 3D regression equations for both the scapula (Barnett, 1996) and the clavicle (Marchese, 2001) as functions of three angles of the humerus.

Third, an extensive database of daily activities (10 activities) directly involving the upper limb was gathered with the objective of estimating the forces/moments acting in the joints. In the process a robust upper limb marker attachment procedure and a method based in robotics for calculating joint forces/moments were developed. (Murray, 1999)

Finally, these have been integrated into an interactive shoulder/elbow model with (74 muscle elements) capable of estimating joint contact forces, joint stability, and muscle contact forces (Charlton, 2001)

Ongoing developments are towards the full integration of the model with the Matlab[®] environment and the development of muscle and proprioception models allowing for seamless inverse/forward dynamics control studies. Also, force/length perturbation experiments are being carried out to quantify stretch reflex for muscles crossing the elbow joint (Torres, 2002).

RESULTS AND DISCUSSION

1. The morphologic shoulder data obtained in CREST corresponds well with that obtained in other groups (Veeger, 1997) and is now part of a much larger database available to the entire biomechanics community.

2. The kinematics description of the scapula shows the same behaviour as that obtained in other groups. There is still the need to make it scalable as in the Dutch model and to increase its envelope of validity. The kinematic regressions describing movement of the clavicle agree well for 2 dof, the third (rotation) cannot be directly compared due to absence of similar data. (Marchese, 2001)

3. Our database of forces/moments during daily activities agrees with that obtained in (Cheng, 1996). Its uses are the assessment of disability, quantification of postoperative recovery and the design of rehabilitation equipment.

4. Computed moment arms agree largely with those found *in-vivo*; glenohumeral forces follow similar trends to those found in previous studies (Charlton, 2001).

5. The stretch reflex mechanism (posture maintenance) agrees well with experimental data for the cat soleus (Gomes, 2001). Transposition of methodology for elbow and shoulder remains to be considered after the model is (or can be) validated for elbow muscles.

In terms of direct and strict validation of the final model, the only two avenues currently available seem to be EMGs and, more promising, the inclusion of force sensors in shoulder prostheses. Indirectly, the use of forward dynamics can also be used to corroborate these models. Apart from these two aspects, the need for creation of individualized or highly scalable models has also been identified.

STRESS ANALYSIS OF THE ROTATOR CUFF: MODEL DEVELOPMENT AND VALIDATION

Mark E. Zobitz and Kai-Nan An

Biomechanics Laboratory, Department of Orthopedics, Mayo Clinic/Mayo Foundation
200 First Street SW, Rochester, MN 55905, e-mail: an.kainan@mayo.edu

INTRODUCTION

Rotator cuff injuries produce significant clinical sequelae and can impair joint functionality. Therefore, an understanding of the etiology of rotator cuff tears would be useful for devising treatment strategies that promote healing and prevent further damage. Although mechanical factors have been implicated as the initiator of rotator cuff tears, there is considerable debate whether damage is instead initiated intrinsically. Using a finite element model to predict the stress state of the rotator cuff tendons under various conditions would be useful for understanding how different variables contribute to the pathological condition. A model could also be used to predict how a cuff tear would progress from a clinically insignificant size to one that requires surgical intervention. A third utility of a model could be to simulate treatment strategies that maintain joint stability without compromising tissue integrity. Development of a representative finite element model involves three basic components: geometry, material properties, and boundary conditions. The purpose of this paper is to highlight some of the work we have done to characterize these components to help validate computer simulations.

ANALYTIC MODEL

A stress analysis of the rotator cuff was reported using a 2-D model of a coronal section through the rotator cuff (Luo, 1998). Although 2-D models have the advantage of being simple to construct, their utility is limited as the rotator cuff tendon geometry is not uniform (Halder, 2000a, 2000b, and 2001a; Itoi, 1995). Anatomic geometry of the rotator cuff can be obtained from MRI scans to produce a 3-D model. We created a 3-D surface rendering of the rotator cuff using Analyze image processing software (Mayo Foundation, Rochester, MN) to process the MRI slice data. Then, the surface information was imported into Patran (MSC Software, Santa Ana, CA) finite element software for meshing.

Proper representation of the material behavior of biological tissues is quite a challenge. Since the supraspinatus tendon is subjected to longitudinal stresses (due to muscle tension) and compressive stresses (due to acromial impingement), a material model has been described using an elastic fiber embedded within a hyperelastic extrafibrillar matrix (Luo, 1998). The elastic fiber component, which simulates the collagen fibers, is easily incorporated using the Rebar element in ABAQUS software (HKS, Pawtucket, RI).

To validate the material model, experimental test results are needed. We have measured the regional variations in tensile properties of the rotator cuff tendons (Zobitz, 2001a). In addition the compressive properties of the supraspinatus tendon were measured (Lee, 2000) and fit to a hyperelastic model (Zobitz, 2001b).

Due to the convergence of the rotator cuff tendons at the humeral insertion, force transmission is still possible in the presence of a rotator cuff defect, due to the concept of the rotator cable (Burkhart, 1993). We have undertaken a number of studies to characterize force transmission patterns through the rotator cuff in the presence of increasing supraspinatus and infraspinatus defects. In addition, we have studied how repairs using either native tissue or synthetic graft material can restore the force generating capacity (Halder, 2001b; Mura, 2002).

EXPERIMENTAL VALIDATION

Recent advances in medical imaging make the experimental measurement of the stress and strain distributions possible. The technique of magnetic resonance elastography (MRE) has shown promise for providing information on tissue properties and tension distribution under various loading conditions and identification of regions of tissue injury (Jenkyn, 2001).

Measuring tissue strain using a pattern matching technique also shows promise for characterizing regional variations in tissue strain (Bey, 2001). The method involves taking MRI images at different joint orientations and calculating the strain components of a particular region of pixels. Since regional strain values can be obtained this method could be used to validate the results predicted by the finite element model.

CONCLUSION

In conclusion, information from experimental measurements is available for establishing a reliable 3-D model for rotator cuff stress analysis. In addition, potential imaging techniques could possibly be used to validate the findings. Such models would be useful to understand the etiology and treatment of rotator cuff disorders better.

CELLULAR RESPONSES REGULATING SIGNALING AND GENE EXPRESSION IN TENDON CELLS

Albert J. Banes^{1,2,3}, Joanne Archambault⁴, Mari Tsuzaki¹, Michelle Wall^{1,2}, Joanne Garvin^{1,3}. Department of Orthopaedics¹, Biomedical Engineering², Curriculum in Applied and Materials Sciences³, University of North Carolina, Chapel Hill, NC 27599; Genetics Institute⁴, Boston, MA

ABSTRACT

Tendons are designed to transfer the force and are principally tensile load bearing. However, tendons may also be subjected to compression when passing through a pulley or travel around bone. Tendons are also subjected to shear as they glide through sheaths, past extratendinous tissue, as collagen fibrils slide past one another during torsional bending or as fluid flows amidst cells and fibrils during load bearing. Hence, tendon cells are subjected to multifaceted mechanical loading during routine use. These load fields are changed as a consequence of traumatic injury or overuse. Our lab has focused on tendon cell responses to mechanical loading in several different models in vivo, ex vivo and in vitro. Cells in each experimental model respond to applied load by signaling, usually through an increase in intracellular calcium. Cells may also act synergistically with a ligand to increase or decrease a response to load. IL-1b can act as a positive stimulus whereas ATP can act as a negative modulator of a load response. Moreover, cells have multiple mechanisms with which to respond to load including integrin contacts with extracellular matrix, cell-cell contacts at desmosomes, intracellular contractile proteins including actin but also titin and nebulin, classically associated with muscle. We will discuss the loading paradigms as well as cellular responses in tendon cells.

TENSILE LOAD MODULATES INHIBITION OF MMP-1 EXPRESSION IN TENDONS

SP Arnoczky, T Tian, M Lavagnino; Laboratory for Comparative Orthopaedic Research,
Michigan State University, East Lansing, Michigan 48824

INTRODUCTION

The deleterious effects of immobilization on the material properties of ligaments and tendons are well-known. Previous work in our laboratory has demonstrated a progressive and significant decrease in the tensile modulus of stress-deprived tendons in an *in vitro* system. However, this effect was inhibited by application of low level (frequency and magnitude) cyclic strain. While the exact mechanism by which stress-deprivation decreases tensile modulus is still unclear, several investigators have implicated the role of collagenase (MMP-1) in this process. It was the purpose of this study to examine the effect of various levels of tensile load on the inhibition of MMP-1 expression in rat tail tendons. It was our hypothesis that tensile load will inhibit MMP-1 expression in a dose dependent manner.

MATERIALS AND METHODS

Tendons were obtained from the tails of adult ACI rats. The tendons were maintained in DMEM media supplemented with 10% fetal bovine serum, antibiotic/antimycotic solution, and ascorbate at 37°C and 10% CO₂ for the duration of the experiments. Tendons were divided into the following groups: *Group 1* (n=20): stress deprived (no load) for 24 hrs; *Group 2* (n=20) statically stressed @0.16MPa for 24 hrs; *Group 3* (n=20) statically stressed @0.75MPa for 24 hrs; *Group 4* (n=20) statically stressed @25MPa for 24 hrs; *Group 5* (n=20) cyclically loaded (6% strain @0.017Hz) for 24 hrs. The 6% strain coincides with a tendon stress of 25MPa. At the end of the experimental period total cellular RNA was extracted from the tendon cells and processed for Northern blotting. The RNA blots were hybridized with a cDNA probe for rat MMP-1 generated in our lab and a human G3PDH cDNA control probe. The exposed films were scanned and MMP-1 expression was quantified by optical density measurements and standardized as a ratio of G3PDH expression. The effect of load magnitude was evaluated using an ANOVA with significance set at p<0.05).

RESULTS

Stress deprivation for 24 hours resulted in a marked up-regulation of MMP-1 expression in tendon cells. Static loading resulted in a significant dose-dependent (but not complete) inhibition of MMP-1 expression (Figure 1). These loads corresponded with a progressive loss of tissue crimp and an increase in fiber recruitment (Figure 2). Cyclic loading (6% strain @0.017Hz [1 cycle/minute]) for 24 hours completely inhibited MMP-1 expression.

Figure 1: Northern blot showing mRNA expression of MMP-1. Lanes 1-fresh tendon (0 time); 2-no load, 24h; 3-0.16MPa, 24h; 4-0.75MPa, 24h; 5-25MPa, 24h; 6-6% cyclic strain @0.017Hz 24h.

DISCUSSION/CONCLUSION

The results of this study demonstrate that stress deprivation in tendons results in an immediate (within 24 hrs) up-regulation of MMP-1 expression in tendon cells. This expression appears to be inhibited by tensile load in a dose dependent manner and coincides with the progressive recruitment of collagen fibers. The importance of cell matrix interactions in maintaining normal tissue homeostasis has been well-documented. Studies from our lab have shown that there is a significant correlation between tendon strain and cell nucleus deformation. This stress-induced deformation is probably important in the MMP-1 inhibitory mechanism in tendon cells as cytoskeletal alterations have been implicated in the regulation of MMP-1 expression in fibroblasts grown in monolayer. While static load (and cell deformation) partially inhibited MMP-1 expression, low frequency cyclic loading completely inhibited MMP-1 expression; suggesting the importance of repetitive signaling. Thus, the effect of loading history on *in situ* cytoskeletal adaptations and matrix interactions may provide a key to understanding the effect of various exercise regimes on tendon health. This is the subject of ongoing investigations in our lab.

MOLECULAR AND CELLULAR ANALYSIS OF ROTATOR CUFF TENDINOSIS IN A RAT OVERUSE MODEL

Laura Gamer^{*}, Kelly McDermott[#], Karen Cox[#], Maureen Mertens⁺, Louis J. Soslowsky¹, Vicki Rosen^{*}
McKay Orthopaedic Research Laboratory, University of Pennsylvania. ¹soslowsk@mail.med.upenn.edu

INTRODUCTION

Tendinosis, often caused by overuse, can lead to microtrauma and weaken the structural and vascular elements of tendon. As tendinosis progresses and the intrinsic reparative ability of the tendon is overwhelmed, the tissue degenerates, often leading to tendon rupture, joint instability, and/or degenerative arthritis. Little is known about the mechanisms responsible for tendinosis and this lack of knowledge has hindered therapeutic advances in treatment. The objective of this study was to use a rat overuse model [1] to begin to profile the cellular and molecular changes associated with repetitive tendon injury.

METHODS

Sprague-Dawley rats were subjected to treadmill running to model a rotator cuff tendon overuse injury [1]. Rats were sacrificed at 4, 8, 13 and 16 weeks. For histologic analysis, both left and right supraspinatus tendons from 3 rat runners and 3 cage activity controls were removed, processed for histology, stained with toluidine blue, and analyzed by light microscopy. For Northern Blot analysis, both supraspinatus tendons from 5 additional rat runners and 5 additional cage activity controls were pooled and total RNA was extracted using the TRIspin method [2]. Ten microg of total RNA was used for each group. Blots were consecutively hybridized with rat cDNA probes specific for collagen type I, collagen type III, biglycan, decorin, TGF-B1, and GAPDH.

RESULTS

Control supraspinatus tendons showed low cellularity, long spindle shaped cells, and well organized linear collagen fibers (fig 1.). Tendons from rats run for 4 weeks showed some slight changes. Tendons from 8 week rats showed more degenerative changes, potentially reflecting the progression of tendinosis. Large numbers of cells were rounded up and bunched together, with a disorganized collagen fiber network. Tendons from 13 to 16 week rats showed focal areas of damage as well as an increasing number of blood vessels in the tendon body, consistent with that seen in later stages of human tendinopathy (fig. 1). From Northern blot analysis, we found significant changes in tendons from rats run for only 4 weeks. Collagen type I, collagen type III, and TGF-B1 gene expression were downregulated while biglycan and decorin levels were unchanged (fig. 2). Similar changes were seen in tendons from 8 week rats. In tendons from 13 week rats, levels of collagens I and III remained repressed, while biglycan levels began to fall and TGF-B1 expression levels returned to that of control (fig. 2).

Figure 1. Histology of control, 4 and 13 week supraspinatus tendons

Figure 2. Northern Blot analysis of control, 4 and 13 week supraspinatus tendons

DISCUSSION

Molecular changes consistent with degeneration were present at the earliest time point studied and over time consistent with a tissue injured early in overuse and repeatedly damaged. As a result, the tissue cannot mount a successful repair response. The molecular data is consistent with previous data from this model [1] which showed decreased mechanical properties of exercised tendons between 4 and 16 weeks. In that study, exercised tendons showed an increase in the amount of tissue present over time, suggesting an increase in the production of matrix components [1]. This fact was not reflected in our gene expression analysis as most of the matrix mRNAs examined were downregulated. One explanation for this discrepancy is the limited number of genes evaluated in this initial study. Further study is necessary to identify important factors in the disease etiology/pathogenesis so that appropriate prophylactic and/or therapeutic treatment modalities can be developed.

EXTRACELLULAR MATRIX WITHIN MUSCLE AND MUSCLE CELL – ECM INTERACTIONS IN RELATION TO MECHANICAL FUNCTION

Peter P. Purslow* and Moira A. Lawson†

*Department of Biological Sciences, University of Stirling, Scotland, UK, and Department of Dairy & Food Science, Royal Veterinary and Agricultural University, Frederiksberg, Denmark.

TISSUE ARCHITECTURE AND FUNCTION

The internal organisation of muscles into fascicles and fibres by intramuscular connective tissue (IMCT) is highly variable between muscles and is accepted to be a structural adaptation to the varying mechanical function of the muscles. Discussion of mechanical roles for IMCT has traditionally been limited to the passive elastic response of muscle. However, it is now clear that IMCT provides a matrix to integrate the contractile function of the whole tissue. Mechanical forces are co-ordinated and passed between adjacent muscle cells via cell-matrix interactions and the endomysial connective tissue that links the cells together. The highly compliant tensile nature of the collagen network that comprises the bulk of the endomysium easily permits changes in muscle length, but force transduction is by shear through this layer.

A mathematical analysis of the translaminal shear moduli of endomysial connective tissue networks has been constructed from composites science theory (Purslow, 2002) and shows that the efficiency of this network in transmitting force laterally between muscle fibres is only marginally dependent on the working length of the muscle.

An emerging concept is that division of a muscle into fascicles by the perimysial connective tissue is related to the need to accommodate shear strains as muscles change shape during contraction and extension. An analysis of shear between fascicles caused by muscle contraction shows that local shear strains within muscle may be considerable (Purslow, 2002). Experiments involving the deformation of rigor muscle show that fascicular boundaries, delineated by perimysial connective tissue, provide “slip planes” to relieve shear (Purslow, 1999).

CELL-MATRIX INTERACTIONS

IMCT also has a number of clearly defined roles in muscle growth and development. In developing muscles, proliferation and growth of muscle cells is stimulated and guided by cell-matrix interactions. Recent work has shown that the topography of collagen fibres is an important signal in this (Lawson et al., 2000). Muscle cells grown on fibrous collagen

are more irregularly shaped than cells grown on solubilised collagen. Cells deposit talin-rich focal adhesions where they touch collagen fibrils. The timing and rates of expression of connective tissue proteins also show clear differences between muscles (Lawson & Purslow, 2001). Expression of type I collagen starts earlier and continues at a higher level in chick quadriceps than in pectoralis, a difference maintained into post-hatch maturity. Studies on tissue sections using immuno-labelling indicate that integrin linkages at the cell surface are more rapidly degraded by the calpain enzyme system than dystroglycan linkages (Lawson & Schäfer, 2002).

MECHANOTRANSDUCTION

Mechanotransduction via cell-surface integrins is implicated as a signalling mechanism in muscle development, growth, hypertrophy and turnover. Current work indicates that cyclic shearing of muscle cells adhering to matrix proteins promotes the deposition of integrin-rich focal adhesions. Alternative mechanostimulation regimes, including fluid shear, are currently under development.

THE INFLUENCE OF AGEING AND EXERCISE ON TENDON MATRIX – HYPOTHESES FOR THE INITIATION AND PREVENTION OF STRAIN-INDUCED TENDINOPATHIES.

Smith RKW* and Goodship AE
Royal Veterinary College, University of London, U.K.

Tendon strain injuries are common in human and equine athletes. In horses, *in vitro* strain measurements at rupture are close to *in vivo* measurements at the gallop. Small decreases in matrix 'quality' will therefore increase the risk of tendinopathy substantially. Epidemiological studies in horses and man have demonstrated a close association between age and exercise, and ultrasonography has shown bilateral tendinopathy commonly in both species. Therefore progressive tendon degeneration may precede clinical tendinopathy. Our studies on the tensional region of equine digital flexor tendons have demonstrated a regional reduction in the collagen fibril crimp angle and length with exercise and age, with a synergistic effect. A higher proportion of small collagen fibrils was found in long-term exercised older horses, but not in short-term exercised, or younger, horses. This did not correlate with new collagen formation and thus may result

from disassembly of larger diameter fibrils. Cartilage Oligomeric Matrix Protein (COMP) levels were low in the neonate, increased in response to loading until they peaked at skeletal maturity. Mechanical properties were related to COMP levels at this age. Levels subsequently declined which was accelerated by exercise. There was high expression of TGF- β in young equine tendon, declining after skeletal maturity, while tenocytes recovered from digital flexor tendons showed similar although reduced responses to growth factors *in vitro*. We hypothesise that tensional weight-bearing tendon can adapt to exercise during development but has poor or no ability to do so after skeletal maturity, which may be, at least in part, due to a relative lack of growth factors. Exercise accelerates the ageing effect of cumulative degeneration after skeletal maturity.

DYNAMIC CELL/SCAFFOLD INTERACTIONS:IMPLICATIONS FOR BONE TISSUE ENGINEERING

Alicia J. El Haj

Centre for Science and Technology in Medicine, School of Medicine, Keele University, North Staffordshire Hospital, Staffs, UK

INTRODUCTION

The development of tissue engineering and the reconstruction of autologous complex *in vivo* environments has been advanced by studies assessing the role of cell-cell and cell-matrix interactions following the introduction of implants. However, the role of dynamic mechanical interactions in this process has often been ignored. Our work has involved identifying key mechanotransduction pathways which can be manipulated for enhanced tissue engineering (El Haj et al 1999; Walker et al 2000). Our aim is to investigate ways by which we can regulate and augment the mechanical conditioning of bone tissue constructs both *in vitro* in bioreactors and *in vivo* following implantation by 1) design of mechanical bioreactors capable of process engineering of autologous tissue implants, 2) creation of 'mechano-active' scaffolds which augment specific load pathways previously shown to be involved in bone mechanotransduction and 3) investigate how surface modifications to biodegradable scaffolds can influence or facilitate the ability of the cell to respond to mechanical cues.

METHODOLOGY

In this report, we present our recent investigations into optimising PLLA type biodegradable materials for enhancing load transduction pathways in bone tissue engineering. Using primary human bone cells derived from tibia fracture, distraction osteogenesis (10-30 yr) patients (LREC # 1293) or the MG63 bone cell line, we report on the interactions between cells seeded on varying scaffold materials with altered surface topography, varying coatings such as collagen or tri-calcium phosphate and addition of slow release agonists of load transduction pathways. The constructs are cultured in short or long term culture using 2D four point bending or 3D compression perfusion bioreactor. The effects of using specific peptide ligands e.g. RGD or coatings such as collagen in biomaterial design on mechanotransduction pathways will also be described.

RESULTS AND CONCLUSIONS

Our results demonstrate the enhancing effects of biomechanical conditioning on bone matrix production in a compression perfusion bioreactor. By addition of chemical membrane channel agonists released from porous scaffolds, we can further enhance the production of bone. Figure 1a shows the human bone cells grown within the PLLA porous matrix following static conditioning for 3 weeks. Figure 1b show elevated mRNA expression of the bone cell differentiation factor, CBFA1, in scaffolds with and without agonist release following cyclical compressive loading.

Figure 1 a) Bone cells cultured in a PLLA based porous scaffold coated with collagen type 1 after 3 weeks in static culture. b) Level of the bone differentiation factor, CBFA1 mRNA in cell seeded constructs cultured in a compression perfusion bioreactor. Scaffolds are PLLA with collagen type 1 coating (PLLA/C) and PLLA with collagen and slow release membrane channel agonist (PLLA/C/BAY)

In addition, surface topography and composition can effect the ability of cells to transmit the load signal which is important in considering the balance between conditioning in bioreactors and static cultures with osteoinductive materials. Furthermore, the question of whether coatings or peptide binding motifs are an important feature for improved biomechanical conditioning both *in vitro* and *in vivo* will be discussed. Work is currently in progress to determine if we can influence the sites of bone deposition by combining scaffold design with the appropriate loading environment.

EFFECT OF PERFUSION RATE ON CELL SEEDED 3D CONSTRUCTS *IN VITRO*

Blaise Porter, Sarah Cartmell and Robert Guldberg

Georgia Institute of Technology, Atlanta, GA 30324 robert.guldberg@me.gatech.edu

INTRODUCTION

Cell viability at the center of tissue engineered constructs in static culture may be decreased due to diffusion limitations. We have designed a 3-dimensional perfusion system (fig. 1) that has the ability to simultaneously perfuse culture media through porous cell seeded constructs, as well as apply axial mechanical loads between 0 and 25lbs. This study tested the effects of media perfusion rate on cell viability, proliferation and gene expression on cell seeded 3D bone scaffolds.

Figure 1

Figure 2

METHODS

MC3T3-E1 osteoblast-like cells were seeded onto 56 human trabecular bone cylindrical scaffolds measuring 0.25" in diameter and length. Eight constructs were perfused at each of the following flow rates: 0.01, 0.05, 0.1, 0.2 and 1ml/min for one week. Two non-perfused controls included cell seeded scaffolds in 6 well plates and cell seeded scaffolds placed into stainless steel chambers in 6 well plates (fig. 2). Media was changed on days 2 and 4 consisted of α -MEM with glutamax (GIBCO), 10% fetal bovine serum, 1% penicillin/streptomycin, 50 μ g/ml ascorbate, 3mM β -glycerophosphate, and 10^{-8} M dexamethasone. Laser scanning confocal microscopy was performed at one week to visualize calcein (viable cells) and ethidium homodimer (non-viable cells) staining of the scaffolds. Real-time quantitative RT-PCR using an ABI PRISM 7700 (Applied Biosystems) sequence detector was performed on 5 of the constructs at each perfusion rate. Runx2, osteocalcin (OCN), alkaline phosphatase (ALP) and bone sialoprotein (BSP) were quantified using real-time RT-PCR and were normalized to 18S. A DNA assay using Hoechst dye fluorescence was performed on scaffolds at each perfusion rate.

Figure 3

Figure 4

Figure 5

Figure 6

RESULTS

Confocal microscopy revealed that flow rates of 1ml/min showed cell necrosis, while 0.01 and 0.05 ml/min showed consistent cell viability after one week of perfusion. Real-time RT-PCR showed that cells perfused at 0.2ml/min and less produced all four genes analyzed. There was a significantly higher amount of OCN produced at 0.05ml/min than at higher flow rates (fig. 3). There was also significantly more Runx2 and ALP produced by the cell seeded constructs perfused at 0.2 ml/min than at lower flow rates (fig. 4 and 5). BSP had significantly increased at one week in the cellular scaffolds perfused at 0.01ml/min compared to the 1 day seeded and 0.05ml/min perfused constructs (fig. 6). DNA analysis showed increased cell proliferation at flow rates of 0.01 and 0.05ml/min compared to 0.2ml/min and static controls (fig. 7). Constructs perfused at 0.01ml/min showed significantly higher cell proliferation than bone only (no cells), 1 day seeded constructs and 0.2ml/min perfused constructs.

Figure 7 (* - p<0.05).

DISCUSSION

Altering the perfusion rate through the cellular scaffolds showed an effect on the amount of osteorelated genes produced, cell viability and cellular proliferation. This effect of media perfusion may be the result of enhanced nutrition to cells and/or flow induced mechanical stimuli. The perfusion rate must be kept relatively low to enhance cell viability. Cell proliferation was also higher at lower flow rates; however, expression of OCN, Runx2 and ALP was decreased at the 0.01ml/min flow rate compared to higher flow rates. These short-term studies suggest a perfusion rate of 0.05ml/min maybe optimal in this system for developing 3D bone constructs. Previous *in vitro* studies have shown that mineralized matrix formation on 3D scaffolds is limited to the outer 150-250 μ m of the scaffold². A perfusion system may allow mineralization to develop throughout tissue engineered constructs. Longer-term studies to investigate matrix mineralization on 3D constructs in the perfusion system are ongoing.

INTRODUCTION

Enhancement of peri-implant bone growth by growth factors may improve indication and success of implant use. Calcium phosphate as a material for implants or for coating of implants is known for its good biological interaction with bone. A calcium phosphate implant combined with a growth factor like transforming growth factor- β 1 (TGF- β 1) might improve bone regeneration and subsequently osseointegration.

Calcium phosphate in cement¹ form can be used as a carrier for TGF- β 1 and applied as a paste in vivo to fill micro- and macroscopic bone defects. The effectiveness of a calcium phosphate cement (CPC) combined with TGF- β 1 for bone regeneration needs to be determined in a biological environment, such as cell or tissue culture experiments and animal studies. After showing its usefulness and safety in pre-clinical studies, then clinical studies can be initiated.

In a series of studies we have demonstrated the capability in bone regeneration of calcium phosphate cement (CPC) that was intermixed with TGF- β 1.

MATERIALS AND METHODS

First, a method was developed to incorporate recombinant human TGF- β 1 (rhTGF- β 1) during setting in CPC. CPC was prepared by mixing calcium phosphate powder with liquid. The liquid for rhTGF- β 1 containing CPC was mixed with HCl and albumin. A release study was performed to determine the amounts of rhTGF- β 1 released in surrounding medium.

In a subsequent study², two cell populations were obtained from adult rat long bones: pre-osteoblastic cells, and osteoblastic cells. After preculture the cells were plated on a layer of CPC containing 0, 10 or 20 ng rhTGF- β 1. Bone cell differentiation was analysed by measuring alkaline phosphatase (ALP) activity, as well as protein content of the cell layer.

The following study was set-up to determine the possible intervening effects of rhTGF- β 1-intermixing on the clinical compliance of two comparables CPCs by assessing their physicochemical properties. Both CPCs, with and without modification for rhTGF- β 1, were examined for setting time, compressive strength, crystallinity, Ca/P ratio, porosity, and microscopic structure.

A final study³ was performed to examine whether the identical enrichment with rhTGF- β 1 (as *in vitro*) affected the replacement of CPC by bone (osteotransduction) in calvarial defects of adult rats. Two bone defects were filled with CPC without rhTGF- β 1 (control) at one side, and with 10 or 20 ng rhTGF- β 1 at the other side. Defects with surrounding skull were analysed histologically and histomorphometrically.

RESULTS

A gradual release was found into tissue culturing medium leading to 20% of rhTGF- β 1 of the amount added, after 24 hr. Incorporation of 10 ng rhTGF- β 1 increased ALP activity in pre-osteoblastic cells by 3-fold, and 20 ng rhTGF- β 1 per CPC layer by 5-fold. ALP activity in osteoblastic cells was not affected by rhTGF- β 1.

Both CPCs became a dense, micro porous structure of calcium deficient apatite with a compressive strength of over 20 MPa within 24 hrs. The setting time differed greatly between the two CPCs; for slow setting CPC, 18 min at 37°C was needed vs. 5 min for fast setting CPC. The modification for rhTGF- β 1 hardly affected the physicochemical properties.

Addition of rhTGF- β 1 to fast setting CPC stimulated bone formation as indicated by an increased bone volume of 50% and an increased bone/cement contact of 65%. In addition, rhTGF- β 1 *reduced* the remaining volume of cement, by 11 % at 10 ng rhTGF- β 1, and by 20 % at 20 ng rhTGF- β 1 in the cement.

DISCUSSION AND CONCLUSION

In a series of step by step development we have demonstrated the improved bone regenerative properties of the appropriate CPC by the addition of certain concentrations of rhTGF- β 1. The intermixed concentrations of rhTGF- β 1 in the cement were released and stimulated bone cell differentiation. Subsequently, the addition of identical concentrations of rhTGF- β 1 in fast setting cement increased the amount of bone and osteotransduction of the cement.

For bone regeneration procedures around endosseous implants, calcium phosphate cement with rhTGF- β 1 might be an appropriate combination for early osseointegration and implant use.

INTRODUCTION

During the past decade, many polymeric scaffolds have been created for bone tissue engineering applications (Agrawal C.M. et al 2001; Mikos A.G. et al 2000; Holy C.E. et al 1997). Some of these materials are not only biocompatible and biodegradable, but also mimic the trabecular bone morphology, which allows efficient host tissue invasion. However, one problem with those scaffolds which permit ubiquitous 3-dimensional cell colonization is that when these materials are implanted into bony defects, they may shrink when clot contraction occurs during the early stages of the wound healing cascade. One of the strategies used to overcome the problem of contraction of polymeric scaffolds involves modification of these materials with calcium phosphates. Although such a modification often improves the physical properties of the scaffold, it also undesirably reduces the scaffold macroporosity which is essential for effective tissue ingrowth. We have recently produced a biodegradable PLGA scaffold modified with calcium phosphate (CAP) particulate which has both the required physical properties and a macrogeometry that mimics trabecular bone. We compared the geometric stability of this composite scaffold with that of the traditionally employed PLGA formulation alone, both *in vitro* and *in vivo*, and demonstrated that improvements in the mechanical properties can be attained by the addition of the CAP phase without compromising the biological requirements for optimal *in vitro* and clinical performance of the scaffold.

MATERIALS AND METHODS

Poly(lactide-co-glycolide) 75:25 (PLGA) was purchased from Birmingham Polymers (Birmingham, AL, USA). Dimethylsulfoxide (DMSO) was purchased from BDH Inc. (Toronto, ON, Canada). Sugar crystals were purchased from Redpath Sugar (Toronto, ON, Canada). Dicalcium phosphate anhydrous (DCPA) and tetracalcium phosphate (TTCP) were purchased from Sigma-Aldrich Inc. (Oakville, ON, Canada) and Inui Corp. (Osaka, Japan), respectively. The starting PLGA/CAP 3-dimensional scaffold blocks were prepared by dispersing an equimolar mixture of DCPA and TTCP powders with glucose crystals in a solution of 10% (wt/v) PLGA in DMSO. The sugar/polymer/calcium phosphate mixture was then placed in a Teflon®FEP-coated aluminium mould and allowed to set. Following polymer precipitation, the glucose crystals were extracted, which resulted in a 3-dimensional scaffold block having macroporous, interconnected porosity. Pure PLGA scaffold blocks were prepared as described above to function as controls. Cylindrical scaffolds were cut from the starting scaffold blocks such that the porosity was

maintained to the outer margins. *In vitro* testing of the scaffolds was performed by seeding scaffolds (6.7 mm diameter and 6 mm length) with 1.9×10^5 rat bone marrow-derived cells, and culturing the cells for 4, 7, and 21 days under osteogenic and non-osteogenic conditions. Control scaffolds were exposed to the same medium conditions as their parallel experimental samples, but in the absence of cells. *In vivo* testing was done using a rat animal model. Bone defects (2.5 mm diameter) were made in the mid-diaphysis of the femurs of young male Wistar rats (Charles River, QC, Canada). At various time points, the femurs were removed and processed for histology. Sections, perpendicular to the long axis of the implant, were stained with Masson's Trichrome stain.

RESULTS AND DISCUSSION

Modification of the polymeric scaffold with a CAP phase improved the physical properties of the material without affecting the trabecular bone morphology of the resultant PLGA/CAP scaffold. *In vitro* experiments demonstrated that our PLGA/CAP scaffolds did not show a quantifiable amount of shrinkage in the presence of cells or media alone. Improved physical performance of the PLGA/CAP scaffolds was further demonstrated *in vivo*. Histological results in Figure 1 show that the PLGA scaffold contracted *in vivo*, as was expected based on our *in vitro* data; in contrast, the PLGA/CAP scaffold retained its original cylindrical shape and macroporosity throughout the implantation period, as a result of which bone tissue invasion was observed inside the macropores of this composite construct.

Figure 1: Transverse sections of rat femora containing scaffolds at 7 days *in vivo*: (A) PLGA, (B) PLGA/CAP. FW 2.5 mm (white areas represent the space occupied by the scaffold, blue areas are bone).

SUMMARY

Polymeric scaffolds, which mimic trabecular bone morphology, when modified with a calcium phosphate phase offer improved handling characteristics and physical performance while supporting rapid bone tissue invasion *in vitro* and *in vivo*.

THE EFFECT OF PULSATILE BUBBLE MOTION ON SURFACTANT DISTRIBUTION DURING AIRWAY REOPENING

INTRODUCTION

Pulmonary surfactant is a complex mixture of phospholipids with hydrophobic and hydrophilic surfactant-associated proteins that dynamically modifies the surface tension of the lung through molecular interactions and multilayer resspreading during interfacial area cycling. When lung surface tension is high, as is the case with premature newborn Respiratory Distress Syndrome, mechanical stresses applied to the airway walls during ventilation can damage the airway epithelial tissue. Our goal is to analyze surfactant transport in computational models of steady and unsteady pulmonary airway opening to determine if physicochemical hydrodynamic interactions can be used to optimize this process and minimize tissue damage.

METHODS

To investigate surfactant transport behavior during oscillatory flow, we have computationally modeled the pulsatile motion of a semi-infinite gas bubble in a horizontal channel of width $2a$ filled with a Newtonian liquid of viscosity μ and surface tension γ . We investigate the fluid mechanical responses to a volume flux $Q(t)$ with non-zero mean (Q_0) and an oscillatory component of magnitude Q_ω and frequency ω . Stokes equations are solved using a mixed boundary element and lubrication analysis technique and are time-stepped using a fully implicit method. The fluid dynamics are characterized by several dimensionless parameters:

- o $Ca = \mu Q_0 / (2a\gamma)$, a steady-state Capillary number, which represents the ratio of viscous to surface tension forces;
- o $Ca_\Omega = \mu Q_\Omega / (2a\gamma)$, an oscillatory forcing magnitude, and
- o $\Omega = \omega \mu a / \gamma$, a non-dimensional frequency that represents the ratio of oscillatory-forcing to viscous-draining timescales.

RESULTS AND DISCUSSION

An oscillatory forcing component superimposed over a steady-state Capillary number caused significant modifications in the air-liquid interfacial behavior as well as the surrounding fluid flow field. Multiple case analysis revealed the importance of a ‘stroke length’ parameter, $A = 2Ca_\Omega / \Omega$, that describes the forced oscillatory amplitude of the system. Using systems with simple surfactant transport models, ‘optimized’ frequencies (Ω) for interfacial surfactant concentration in the bubble tip region could be found for cases of given Ca_0 and stroke length, A . Such a case can be seen in Fig 1.

**Surfactant Concentration on Pulsatile Bubble Tip,
 $Ca_0=0.1, A=1.0$**

Figure 1: The effect of oscillation frequency on surfactant sorption to the bubble tip. $Ca_0 = 0.1, A = 1.0$.

Additionally, analysis of multiple amplitudes, A , over a range of oscillatory frequencies, Ω , for a given Ca_0 provided a quantitative comparison of the relative increase in interfacial surfactant transport gained by each amplitude case as compared to the steady state Ca_0 value. We will expand these studies to investigate surfactant multi-layer dynamics.

SUMMARY

Our analysis of pulsatile pulmonary airway reopening shows that interfacial surfactant transport can be improved in comparison to the transport characteristics of similar steady-state systems. Quantitative comparisons of interfacial surfactant transport show that there exist optimized oscillation frequencies that will maximize surfactant concentrations in the bubble tip region. This increased surfactant concentration serves to lower lung surface tension, thereby decreasing necessary ventilation pressures, which should minimize ventilator-induced lung injury.

BIOPHYSICAL AND BIOLOGICAL RESEARCH IN LUNG SURFACTANT DRUG DEVELOPMENT

INTRODUCTION:

In 1959 Avery and Mead described high minimum surface tensions on Wilhelmy balance testing of lung extracts from premature infants who had died of the Respiratory Distress Syndrome (Avery and Mead, 1959). Although this directly linked lung surfactant deficiency to disease in these infants, effective surfactant replacement therapy was not available for another 30 years. This compares to an interval of less than 5 years between the discovery of insulin deficiency in diabetes and availability of insulin replacement therapy. Difficulties linking biophysical and biologic research explain the prolonged delay in developing effective surfactant replacement therapy, and it was the eventual ability to relate biophysical and biological results that eventually allowed development of the therapy.

METHODOLOGIC CONSIDERATIONS:

Development of effective surfactant therapy was delayed because of a series of false scientific assumptions. The composition of active lung surfactant is complex, not simple; there are multiple essential biophysical properties, not one; biophysical activity is a necessary, but not sufficient standard; biologic evaluations ultimately require experimental testing in animals *in vivo*, not just in bioassays. Finally, since lung surfactant acts on an internalized, but ultimately exterior epithelial surface, accurate evaluation of replacement surfactants also requires assurance of adequate quantitative delivery of the material to the airspace and its appropriate deposition among the 3×10^8 alveoli.

RESULTS

In the early 1960's, following relatively little biophysical study and virtually no biological evaluations, a clinical trial was conducted evaluating the aerosolization of dipalmitoylphosphatidylcholine (DPPC, a major phospholipid component of lung surfactant) into the incubators of premature babies with RDS (Chu *et al.*, 1967). The lack of success of that effort, which is now known to be due both to inadequate surface activity and inadequate delivery, was misinterpreted to imply that surfactant deficiency was not the cause of RDS.

In the 1970's, replacement studies in premature animals reaffirmed original insights about lung surfactant and RDS. However, the material complexity of lung surfactant and limitations on the parameters evaluated in biophysical testing still left unresolved conflicts in biophysical and biological research until the Enhorning Pulsating Bubble Surfactometer was introduced in the early 1980's. The ability to study a

physiologically-relevant combination of adsorption and dynamic activity, and correlations between biophysical and biological testing, improved understanding of surfactant function and the crucial roles of lipid-protein interactions in activity. Effective synthetic and natural surfactant drugs for premature newborns were developed and tested in the 1980's. They have now become standard therapy.

Since the 1960's it has been assumed that surfactant has a significant role in the Acute Respiratory Distress Syndrome (ARDS) that causes respiratory failure in children and adults. Basic research has identified how lung surfactant can be inhibited (inactivated) biophysically or chemically degraded in these clinical syndromes (Notter, 2000). Development of surfactant therapy in ARDS has repeated some of the missteps of the past (Anzueto *et al.*, 1996). However, basic science and clinical data exist that surfactant replacement therapy can modify the course of ARDS (Notter, 2000; Willson *et al.*, 1999).

SUMMARY

Development of optimal surfactant replacement therapy for newborn infants was not achieved until biophysical and biological testing matured and complementary assessments were combined. That achievement must be replicated if it is going to be possible to develop equivalent therapy for ARDS.

3D AIRWAY REOPENING: THE STEADY PROPAGATION OF AN AIR FINGER INTO A STRONGLY COLLAPSED ELASTIC TUBE

Matthias Heil¹ and Andrew L. Hazel²

Department of Mathematics, University of Manchester, UK

¹M.Heil@maths.man.ac.uk; <http://www.maths.man.ac.uk/~mheil>

²ahazel@maths.man.ac.uk

INTRODUCTION

Many pulmonary diseases result in the collapse and occlusion of parts of the lung by viscous fluid. The subsequent airway reopening is assumed to occur via the propagation of an 'air finger' into the collapsed, fluid-filled part of the airway. A complex 3D fluid-structure interaction governs this problem (a free-surface flow interacting with a strongly collapsed elastic tube), and hence the mechanics of airway reopening are still poorly understood. Previous work (e.g. Gaver *et al.* 1996, Heil 2000) has been restricted to 2D models, which fail to capture some potentially important features of the 3D system.

Figure 1: An air-finger propagates into a strongly collapsed elastic tube. Only one quarter of the domain is shown.

THE COMPUTATIONAL MODEL

Fig. 1 illustrates the model problem. The bubble pressure, p_b , drives an air finger at constant speed U into a strongly collapsed, thin-walled elastic tube of undeformed radius R . The collapsed part of the tube is filled with viscous fluid of viscosity μ and surface tension σ . The air finger reopens the tube, depositing a thin layer of fluid on the walls. We assume that the flow is governed by the free-surface Stokes equations and describe the wall deformation by geometrically non-linear shell theory. The governing equations are solved by a fully coupled finite element method.

RESULTS

Fig. 2 shows a typical computational result. At small propagation speeds, the air finger 'pushes' a large volume of fluid ahead of the bubble tip and a decrease in bubble pressure, p_b , is required to increase the speed of the steadily propagating finger. At larger bubble speeds, the finger tip is nearer the tube wall and an increase in bubble pressure is required to increase the bubble speed. The resulting two-branch behaviour implies

the existence of a minimum pressure below which there is no steady bubble propagation. These results are surprisingly similar to those found in previous 2D models. We present a simple model for the behaviour on the 'pushing' branch to explain this observation. In contrast to previous 2D models' predictions, we find that an increase in the degree of collapse *decreases* the bubble pressure required to drive the air finger at a given speed. This could have important physiological ramifications. Furthermore, the stresses that the fluid exerts on the airway walls are found to be so large that they have the potential to cause damage to the lung tissue.

Figure 2: Non-dimensional bubble pressure $p_b / (6/R)$ vs. the non-dimensional bubble speed $U\mu/\sigma$.

STRUCTURAL AND FUNCTIONAL ASPECTS OF ALVEOLAR AND AIRWAY SURFACTANT

Samuel Schürch^{1,2}, Marianne Geiser² and Peter Gehr²

¹Department of Physiology and Biophysics, University of Calgary, Calgary, Alberta, Canada. schurch@ucalgary.ca

²Institute of Anatomy, University of Berne, Switzerland

INTRODUCTION

The extracellular fluid lining the airways and alveoli exists as a continuum from the larynx to the alveolus. In the alveolus, the extracellular layer consists of a thin hypophase covered by a dipalmitoylcholine (DPPC)-rich surfactant film. In the airways it consists of sol and gel layers surmounted by a surfactant film of unknown composition. The direct demonstration of a surfactant film in the airways is relatively recent, although a surfactant film had been inferred by electron microscopic studies by Weibel and Gil about 30 years ago. Recently, non aqueous fixation techniques in conjunction with electron microscopy (EM) have demonstrated a continuous film covering the entire airway and alveolar surfaces. The film appears frequently multilaminated with a variable number of lipid layers at its surface (eg Schürch *et al*, 1998). This is consistent with studies in the captive bubble surfactometer (CBS), which indicate that the film can form a reservoir of surface active material.

The function of the alveolar surfactant film in stabilizing the gas exchange area and keeping the alveolus relatively dry has been well documented. Direct measurement of surface tension in intact lungs confirmed that the surface tensions within alveoli at lung volume levels of normal breathing are very low, varying from near zero to approximately 10 mN/m (eg Bachofen *et al* 1987). A surface tension of approximately 32 mN/m has been recorded in large airways, this suggests the presence of a surface film in large airways. This film promotes the displacement of particles into the aqueous phase (Schürch *et al*, 1990, Gehr *et al*, 1990). In small airways, where the surface tension is probably much lower, close to that in the alveolar spaces, surfactant is likely important in maintaining small airway patency. In addition a surface tension gradient will likely promote particle and fluid transport between the alveolus and the ciliated airways.

SURFACE ACTIVITY & STRUCTURE FUNCTION RELATIONS

The surface activity of pulmonary surfactant, including therapeutic surfactants, used for replacement therapy, encompasses at least three physical properties essential for normal lung function: (1) rapid film formation (within a few seconds) by adsorption from the hypophase; (2) low film compressibility (less than 0.01 mN/m) with a fall in surface tension to a value of less than 2 mN/m upon a maximum surface compression of approximately 20%; (3) effective replenishment of the surface film on expansion by the incorporation of reserve material associated with the surface. In general, rapid film formation (within 1 s) to an equilibrium surface tension between 23 and 25 mN/m is followed by a low

film compressibility close to 0.005 mN/m, the value for pure DPPC, and stable minimum surface tensions around 1 mN/m on quasi-static and dynamic compression. Such film properties suggest that these films are highly enriched in DPPC formed by preferential adsorption. If such films are not compressed beyond the area at which minimum surface tension is obtained, there is negligible hysteresis upon repeated cycling between surface tensions of 25 and 1-2 mN/m. In contrast to films formed from surfactant at relatively high phospholipid (PL) concentrations, films formed from surfactant with low PL concentrations below about 1mg/ml, may show a “squeeze-out plateau” upon area compression and thus demonstrate increased compressibility and substantial hysteresis in their surface tension-area relations. At relatively low concentration only a faint and amorphous film can be visualized by EM although the film may produce near zero surface tension upon its compression. With suspensions at higher concentrations, a more distinct film is seen. It is of variable thickness with frequent multilayer formations, consistent with the concept of the surface reservoir. These multilayers form de novo, upon film adsorption. After repeated cycling with over-compression at near zero minimum surface tension the bubble shape may become asymmetrical (non-Laplacian) after mechanical distortion. Such bubbles may revert slowly, within a few seconds into a Laplacian shape.

SUMMARY

There is “surplus” surfactant material in excess of a monolayer at the liquid- air interface upon de novo adsorption from surfactants derived from natural sources. Films from surfactants at high concentrations show high surface activity *i.e.*, very low compressibility, near zero and mechanically stable minimum surface tension obtained upon area compressions below 20%. They appear highly enriched in DPPC by preferential adsorption. Electron micrographs of such films are frequently multi-laminated. By repeated dynamic cycling, highly surface active films may show visco-elastic behavior, which may be important in vivo for clearing mechanisms.

DYNAMICS OF WOUND HEALING IN AIRWAY EPITHELIAL CELLS: GFP-ACTIN REMODELING

³email: cwaters@physio1.utmem.edu

INTRODUCTION

Mechanical ventilation of patients is often necessary in order to provide adequate gas exchange, but considerable damage to the lungs can occur. One of the prominent features of ventilator-induced lung injury is damage to the epithelium lining the airways. We have previously demonstrated that cyclic mechanical stretching and compression of wounded airway epithelial cells delays wound closure (Savla and Waters, 1998; Waters et al., 2001). Tracking wound closure by video microscopy demonstrated that wound closure was inhibited due to decreases in cell spreading and cell migration. Both of these processes involve remodeling of cytoskeletal components. Therefore, we sought to develop techniques to visualize actin remodeling in live cells. In this study we describe the development of a cloned cell line of human airway epithelial cells that we have stably transfected with a gene expressing a fusion protein that combines enhanced green fluorescent protein (EGFP) and human β -actin.

METHODS

We transfected a cell line of SV40-transformed human bronchial epithelial cells (16HBE14o-, from Dr. D. Gruenert, UCSF) with an EGFP-actin vector obtained from Clontech. During selection with G418, we identified individual cells that expressed the highest levels of EGFP-actin and transferred these cells to individual wells to initiate colonies. Several stable transfectants have been cloned. To visualize EGFP-actin in live cells, we grew cells in coverslip chambers and then placed the chambers on a motorized stage enclosed within a heated box. Wound closure was observed after scraping wounds across confluent monolayers.

RESULTS AND DISCUSSION

To directly visualize de-polymerization of f-actin, cells were treated with cytochalasin D (1 μ g/ml) and disruption of F-actin was observed within minutes. Fig. 1 shows the progression of disruption from the initial time until 10 min later. Similar experiments were performed to demonstrate membrane ruffling, pseudopodal extensions, and cell migration in response to epidermal growth factor (EGF) and keratinocyte growth factor (KGF).

Two hours after wounding monolayers we observed formation of a strong, uniform band of actin at the wound edge that was parallel to the wound. Pseudopodal extensions emanated from this band and contained actin filaments perpendicular to the wound edge. Cells away from the wound edge were observed to remodel, elongate, and extend toward the wound front. These images can be used to measure the kinetics of actin remodeling.

INTRODUCTION

Cellular mechanical properties can now be evaluated by a variety of micromanipulation techniques. These techniques implicate a variety of probes (e.g., micropipettes, beads, plates, poker, microscopic tip) of very different sizes (from nm to μm) which, in general, are physically connected to the cytoplasm through molecular junctions, the adhesion plaques. However, different types of probe-cell coupling may lead to probing of different subcellular structures, e.g., RGD-coated beads were used to measure cytoskeleton properties through the molecular linkage that integrin transmembrane mechanoreceptors constitute (Wang *et al.*, 1993). In addition, the large variety of probe diameter might also contribute to the scatter of reported experimental data based on a tensegrity length scale that would fit the probe diameter (Maksym *et al.*, 2000; Wendling *et al.*, 1999). But some other factors may contribute to influence the cellular response. Because spherical probes are most often partially immersed, e.g., in case of bead attachment to the extracellular extremity of a transmembrane protein, the effect of incomplete bead immersion in the cytoplasm must be considered (Laurent *et al.*, 2001). We presently analyze theoretically and experimentally the effects of partial bead immersion, in relation with the type of loading, e.g., a force and a torque respectively generated by two micromanipulation techniques implicating beads: Laser Tweezers (LT) and Magnetic Twisting Cytometry (MTC).

METHOD

Theory: At equilibrium, the displacement (translation and/or rotation) of a rigid spherical bead, was calculated for various degrees of bead immersion in a homogeneous elastic medium, when submitted to either a force F , or a torque C , applied to its center. Assimilating the true displacement x (or rotation angle θ) of a bead (radius R) to the free displacement of the medium alone, we obtained reliable relationships describing the behavior of x (or θ) versus the elastic force F_e (or elastic torque C_e) exerted by the intracellular medium, α being the half-immersion angle of the bead, i.e.,

$$x = -\frac{3}{4\pi E R} \left(\frac{3}{2\sin\alpha} + \frac{\cos\alpha}{\sin^3\alpha} \right), \text{ and } \theta = -\frac{3}{4\pi E R^3 \sin^3\alpha} C_e$$

These formulae which are used to determine the equivalent Young modulus E , are basically established at small α , but their validity extends to $0 < \alpha \leq \pi/2$. Both formulae show that the degree of bead immersion, α , greatly affects the x - F_e and θ - C_e relationships, the smaller α , the larger the α -dependency, and that this effect depends on the nature of the load. Moreover, x - F_e formula takes into account the fact that a unidirectional

force applied to partially immersed beads results in both translation and rotation (LT case).

Experiments: we performed specific measurements of the CSK mechanical properties in a given type of living adherent human epithelial cells with two independent bead micromanipulation techniques, the laser tweezers already described by (Hénon *et al.*, 1999) and the magnetic twisting cytometry initiated by (Wang *et al.*, 1993). Discrepancies between the two techniques were minimized using beads of similar sizes ($\approx 5\mu\text{m}$), i.e., silica beads for LT and ferromagnetic beads for MTC, same cellular substrate and same bead coating. We determined α from spatial reconstructions of the F-actin cytoskeleton for a representative sample of beads during MTC, while α was measured bead by bead from each bright field microscopic image during LT.

RESULTS and DISCUSSION

Direction and nature of efforts differ between the two techniques since a torque is applied during MTC while both a force and a torque are applied during LT. Analyzing the data obtained with each technique using the theory described above, shows that bead deviation angles and applied external torques get comparable but are on average larger in MTC ($\theta^\circ = 21\text{-}32^\circ$; $C = 444\text{-}1205 \text{ pN}\times\mu\text{m}$) than in LT ($\theta^\circ = 0\text{-}25^\circ$; $C = 0\text{-}400 \text{ pN}\times\mu\text{m}$). Concerning the degree of bead immersion, we measured on average, $\alpha = 62^\circ$ in LT and $\alpha = 67^\circ$ in MTC. The values of equivalent Young modulus E obtained from above theoretical relationships appeared roughly in the same range of magnitude, i.e., $E \sim 34\text{-}58 \text{ Pa}$ in MTC and $E \sim 29\text{-}258 \text{ Pa}$ in LT. E -values in MTC appear one order of magnitude larger than those reported in previous MTC studies (Wang *et al.*, 1993). Compared to LT, a number of reasons may contribute to explain the smaller E -values in MTC, including (i) heterogeneity in bead rotation already pointed out by (Fabry *et al.*, 1999), (ii) reinforced non linearity and plasticity due to higher stress values in MTC possibly making inadequate the use of linear theory of elasticity. On the whole, this study is a contribution to define reliable transducers of cellular mechanical properties.

THE EFFECT OF PRESTRESS ON MECHANICAL PROPERTIES OF ADHERENT CONTRACTILE CELLS

Dimitrije Stamenović¹, Zhuangli Liang¹ and Ning Wang²

INTRODUCTION

Rheological properties of cells play essential roles in various cell functions including spreading, interacting with the extracellular matrix or maintaining an appropriate tone (e.g. airway wall hysteretic properties). It is well established that rheological behavior of adherent cells can be characterized as viscoelastic. Cells exhibit creep, stress relaxation and hysteresis (cf. Sato et al., 1990; Thoumine and Ott, 1997; Maksym et al., 2000). However, adherent cells also exhibit features that characterize stress-supported structures (Wang et al., 2002). The prime feature of these structures is that their deformability is strongly influenced by pre-existing tensile stress (prestress) carried by their structural components. In the cell, the prestress is carried primarily by the actin cytoskeleton (CSK) and is generated either actively by the cell contractile apparatus or passively by cell distension on the substrate and by swelling pressure of the cytoplasm. It is not known, however, whether the origin of these two distinct types of rheological behaviors, the rate of deformation-dependent ones and the prestress-dependent ones, can be traced to common mechanisms. The goal of this study is to answer this question.

METHODS

We measured cell dynamic modulus (mechanical impedance) (G^*) and prestress (P) at different states of cell contraction. Measurements were done in cultured human airway smooth muscle cells. Cell contractility was modulated by graded doses of histamine (0.1, 1, 10 μ M) or isoproterenol (0.01, 0.1, 1, 10 μ M). Measurements were done at each dose and at the baseline. G^* was measured using the magnetic oscillatory cytometry technique (Maksym et al., 2000). This technique applies an oscillatory twisting field to small ferromagnetic beads attached to integrin receptors on the cell apical surface. Integrins are physically linked to the CSK. Thus by twisting the beads, stresses and strains are induced into the CSK. Form a known applied specific twisting torque and measured corresponding angle of twisting, G^* is obtained as the complex ratio of the two. The real part of G^* is the elastic modulus (G') and the imaginary part is the frictional modulus (G''). Measurements were done at 0.1 Hz and amplitude of 6 Pa. P was measured using the traction microscopy technique (Wang et al. 2002). This method measures traction that arises at the cell-substrate interface in response to cell contraction. Since traction balances contractile stress, P can be obtained.

RESULTS AND DISCUSSION

G' , G'' and P gradually increased/decreased with increasing doses of histamine/isoproterenol. At a given drug dose, G' was greater than G'' by a factor of 3-4. This, in turn, suggests

that the cell behavior is predominantly elastic. Both G' and G'' increased linearly with increasing P (Fig. 1).

Figure 1: Elastic (G') and frictional (G'') moduli increased linearly with increasing prestress. Data, mean \pm SE.

The most significant finding of this study is that both G' and G'' depend on the level of P . The linear dependence of G' on P is a known property of adherent cells and could be traced to mechanisms of stress-supported structures (Wang et al. 2002). However, the dependence of G'' on P is a novel result. To investigate whether its origins can be traced to mechanisms of stress supported-structures, we modeled the CSK as a prestressed structure composed of linear Kelvin-Voigt bodies. The model could mimic the relationships shown in Fig. 1. However, we cannot rule other biophysical and biochemical mechanisms that may also explain the observed behavior.

SUMMARY

This study shows that rheological properties of contractile adherent cells reside within the CSK and that they can be modulated by the CSK contractile stress in a dose-dependent manner. This behavior is consistent with the notion that the CSK is organized as a stress-supported structure.

MICRORHEOLOGY OF THE LIVING CELL: ARE WE BUILT OF GLASS?

Jeffrey J. Fredberg¹, Ben Fabry and James P. Butler

Physiology Program, Harvard School of Public Health, Boston, MA 02115

¹ jfredber@hsph.harvard.edu

INTRODUCTION

Mechanical stresses and resulting deformations play central roles in cell contraction, spreading, crawling, invasion, wound healing and division, and have been implicated in regulation of protein and DNA synthesis and programmed cell death. If the cytoskeleton were simply an elastic body, it would maintain its structural integrity by developing internal elastic stresses to counterbalance whatever force fields it might be subject to. However, those same elastic stresses would tend to oppose - or even preclude altogether - other essential mechanical functions such as cell spreading, crawling, extravasation, invasion, division and contraction, all of which require the cell to “flow” like a liquid. A liquid-like cell, however, would be unable to maintain its structural integrity. The classical resolution of this paradox has been the idea that cytoskeletal polymers go through a sol-gel transition, allowing the cytoskeleton to be fluid-like in some circumstances (the sol phase) and solid-like in others (the gel phase). The data presented here suggest that, rather than being thought of as a gel, the cytoskeleton may be thought of more properly as a glassy material existing close to a glass transition. If so, then disorder and metastability may be essential features underlying cell mechanical functions (Fabry et al. 2001).

METHODS

We used optical tracking of ligand-coated, magnetically twisted ferrimagnetic beads that were bound to integrin receptors on adherent cells: human airway smooth muscle cells, human bronchial epithelial cells, F9 mouse embryonic carcinoma cells, J774A.1 mouse macrophages and human neutrophils. We used this system to measure the complex elastic modulus over bead displacement amplitudes ranging from 5 to 500 nm and twisting frequencies ranging from 10^{-2} to 10^3 Hz.

RESULTS AND DISCUSSION

The complex modulus did not change with displacement amplitude, implying linear mechanical behavior in this range. Elastic stresses dominated at frequencies below 300 Hz, increased only weakly with frequency, following a power law. Frictional stresses were also weakly dependent on frequency below 10 Hz, but approached a viscous limit at higher frequencies.

Surprisingly, data for all cell types, frequencies, and interventions studied could be scaled onto universal master curves (Fabry et al., 2001). This scaling identified these cells as soft glassy materials existing close to a glass transition,

with an effective noise temperature, x , of about 1.2, where trap models of glassy materials use the effective noise temperature to express the level of mechanical agitation, or noise, in the matrix relative to the depth of the energy wells in which metastable elements are trapped (Sollich, 1998).

Fig. 1a: Ferrimagnetic beads (arrow) bind avidly to the actin cytoskeleton (stained with phalloidin) of HASM cells via cell adhesion molecules (integrins). 1b: Scanning EM of a bead bound to the cell surface. 1c: A magnetic field introduces a torque which causes the bead to rotate and to displace. M denotes the direction of the bead's magnetic moment.

SUMMARY

These results stand in contrast to current concepts in cell rheology in that 1) relaxation processes exhibited no intrinsic time-scale, implying stress relaxation going as the power law t^{1-x} , and 2) frictional stresses did not correspond to a viscous process.

These findings support the novel hypothesis that cytoskeletal proteins can regulate cell mechanical properties by modulating the effective noise temperature of the matrix and, thereby, the ability of cytoskeletal elements to hop out of energy wells. The practical implications are that the effective noise temperature is an easily quantified measure of the ability of the cytoskeleton to deform, flow, and reorganize.

A MODEL OF NON-UNIFORM LUNG PARENCHYMA DISTORTION

E Denny and R C Schroter

Department of Bioengineering, Imperial College of Science, Technology & Medicine, London SW7 2BX, UK
r.schroter@ic.ac.uk

INTRODUCTION

Non-uniform distortion of lung parenchyma is a ubiquitous phenomenon in lung mechanics. Important examples include parenchymal distortion around constricted airways and support of airways by surrounding parenchyma during forced expiration. It is common to model the lung as a homogeneous elastic continuum undergoing small distortions from a state of uniform inflation with a single bulk modulus and shear modulus. However this simple model of lung parenchyma undergoing non-uniform distortion is a poor description of the real case in many circumstances – distortions cannot be considered as small or be modelled using linear elastic theory. Distortion of parenchyma causes re-orientation and a change in strain distribution of the load bearing components. The parenchyma becomes physically inhomogeneous with anisotropic properties and different elastic moduli in different directions.

THE MODEL

The parenchyma is modelled as an assemblage of truncated octahedra arranged in a cuboidal block; the model is a development of our earlier work [Denny & Schroter 2000]. A finite element computer model is used to study the effect of large non-uniform distortion on the elastic behaviour. The distortion is a uni-axial stretch from an initial state of uniform pressure expansion. (Figure 1). For large distortions, the anisotropic non-linear elastic properties are described by five independent elastic moduli, each dependant on the initial pressure and degree of distortion.

Figure 1: Alveolar assembly of 91 truncated octahedral alveoli: (a) block inflated and undistorted; (b) block uni-axially strained in the z direction.

RESULTS

When the distortion is zero, the five elastic moduli reduce to the two moduli for small distortions. The Young's modulus in the direction of stretch (E_z), increases significantly with distortion while the Young's modulus in the plane perpendicular to the stretch (E_x), is approximately constant. The higher the initial pressure, the greater the difference

between the two moduli at larger distortion strains. For an initial pressure of 5 cmH₂O, E_z rises from 10.4 to 13.2 cmH₂O and E_x falls from 10.4 to 9.3 cmH₂O as the uni-axial distortion strain (ϵ_z), increases from 0 to 0.1. At 20 cmH₂O, E_z increases from 55 to 115 cmH₂O and E_x increases from 55 to 55.6 cmH₂O as ϵ_z increases from 0 to 0.05. The shear modulus (G_{xz}) is approximately independent of degree of distortion except at the highest initial pressure. At 5 cmH₂O, G_{xz} increases from 5.05 to 5.07 cmH₂O as ϵ_z increases from 0 to 0.1. At 25 cmH₂O, G_{xz} falls from 37.3 to 32.2 cmH₂O and as ϵ_z increases from 0 to 0.05. The Poisson's ratio, (ν_{xz}) is approximately constant with distortion strain for lower initial pressures, but increases significantly with ϵ_z at higher pressures. At 10 cmH₂O, ν_{xz} increases from 0.26 to 0.3 as ϵ_z increases from 0 to 0.1, but at 20 cmH₂O, ν_{xz} increases from 0.29 to 0.45 as ϵ_z increases from 0 to 0.05.

In general, both fibre bundle realignment and a change in strain distribution of individual fibres occur with increasing ϵ_z . At high inflation pressures, some individual fibres their approach maximum strain (~ 0.85) at $\epsilon_z = 0.08$. Despite this, the average individual fibre strain remains virtually unchanged at ~ 0.62 as the distortion ϵ_z increases from 0 to 0.08 (Figure 2). However, at low to moderate inflation pressures, maximum fibre bundle strains are not reached for $\epsilon_z = 0.2$ because they have lower initial strains.

Figure 2: Effect of distortion strain on individual fibre strain distribution at an initial inflation pressure of 20 cmH₂O.

BIOMECHANICAL MEASUREMENTS AND DYNAMIC MODELING OF THE RHESUS MONKEY ARM

Gary T. Yamaguchi

Department of Bioengineering, Arizona State University, Tempe, AZ 85287-9709, USA

INTRODUCTION

An accurate, quantitative, dynamic model of the upper extremity is an important asset to analyses of reaching movements. The process of creating such a model involves detailed anatomical studies of the musculoskeletal system, 3D digitization, and computerized reconstruction of bone surface geometries. Adding dynamic capabilities to the anatomical model requires the definitions of reference frames, inertial parameters, joint motions, and dynamic equations. An overview of the process of model creation is given.

METHODS

Over the past decade, four young rhesus monkeys between 2.0 and 2.2 kg were dissected and used to determine typical segment lengths, muscle paths, and muscle parameters. Frozen monkey right upper extremities were pinned to a plexiglass board and digitized with an Optotrak 3D Bar (Northern Digital, Waterloo, Canada). 39 musculotendon paths were identified and measured to determine origins, insertions, and via points, muscle volumes, and fiber lengths. Left side arms were dismembered to determine weights and center of mass locations for the upper limb, forearm, and hand. To get the surface geometries, the bones were dried, mounted, and hand or laser digitized. Currently, a laser diffraction method (Lieber and Friden, 2000) is being used to measure average sarcomere lengths and optimal fiber lengths.

A seven degree of freedom (7-DOF), 3D dynamic model of the arm was constructed using vector methods as described in Yamaguchi *et al.* (1995). The shoulder was modeled as a fixed point, with the humerus revolving about the shoulder through three successive rotations. The humeroulnar joint defined elbow flexion and the proximal location of the radius. The distal radius pronates naturally about an axis drawn through the proximal radius and the distal ulna. Two additional degrees of freedom were defined for wrist flexion-extension and ulnar-radial deviation. This model features separate rigid bodies for the radius and ulna, with distinct inertial properties.

The final step of model development was to display the muscle pathways simultaneously with the bone surface geometries. Software for Interactive Musculoskeletal Modeling (SIMM, Musculographics, Inc., Evanston, IL) was used to display and adjust the results. When muscle pathways were incompatible with the surface geometries, small numerical corrections were made to improve the appearance of the model when viewed as a light-shaded, 3D surface model (Figure 1).

RESULTS AND DISCUSSION

The model has been used in pilot optimal control studies to compare predicted muscle tensions with EMG and *in-vivo*

Figure 1: 7-DOF model of the monkey upper extremity.

force measurements. Force predictions made using the pseudoinverse optimal control method (Yamaguchi, 2001) compare favorably with *in-vivo* force measurements, but do not compare favorably with EMG (Figure 2). The latter discrepancy may be due to the optimization's preference for minimizing energy expenditure, while the monkey maximizes the likelihood of receiving a reward.

THE DEPENDENCE OF WRIST EXTENSION MOMENT ON ELBOW AND WRIST POSITION AFTER BRACHIORADIALIS TENDON TRANSFER

Wendy M. Murray¹, Kevin L. Kilgore^{2,3,4}, and Michael W. Keith^{2,3,4}

¹Rehab R&D Center, VA Palo Alto HCS, Palo Alto, CA, murray@rrdmail.stanford.edu

²Louis B. Stokes Veteran's Affairs Medical Center, Cleveland, OH, ³Case Western Reserve University, Cleveland, OH,

⁴MetroHealth Medical Center, Cleveland, OH

INTRODUCTION

Brachioradialis is the most commonly utilized donor muscle for tendon transfers that restore some upper extremity function after cervical spinal cord injury. Because brachioradialis shortens substantially with elbow flexion, function restored by brachioradialis transfers is thought to be weak in flexed elbow postures (Wilson 1956; Brand 1985). However, Fridén and Lieber (1998) demonstrated that surgeons frequently attach donor muscles at relatively long lengths, suggesting transferred muscles operate on the descending limb of the isometric force-length curve. If this is true, the transferred brachioradialis would produce *more* force at shorter fiber lengths (i.e., with the elbow flexed), rather than *less* force as is generally assumed.

After transfer to the paralyzed ECRB or ECRL, brachioradialis is essentially the only muscle that powers wrist extension. Thus, it is likely that differences in the wrist extension moment produced during maximal effort in different elbow positions reflect the force-length properties of brachioradialis. For example, if the wrist extension moment generated with the elbow flexed is greater than the moment produced with the elbow extended, it would suggest the transferred brachioradialis operates on the descending limb of the force-length curve (i.e., the muscle produces more force at a shorter length). Conversely, smaller moments when the elbow is flexed would imply the muscle operates on the ascending limb. The objective of this work is to determine if the isometric moment produced at the wrist increases or decreases with elbow flexion following brachioradialis tendon transfers that restore wrist extension. Because brachioradialis length also depends on wrist position after transfer, we evaluated how elbow position influences wrist extension strength in different wrist postures.

MATERIALS AND METHODS

We quantified the isometric wrist extension moment produced during maximal effort in seven individuals (eight limbs) following transfer of the brachioradialis to ECRB ($n = 7$) or ECRL ($n = 1$). Data was collected in two elbow postures (maximum elbow extension, 120° elbow flexion) and 3 wrist positions (30° flexion, neutral, 30° extension). Four trials were collected for each combination of elbow and wrist positions. The order the positions were tested was randomized across subjects. Subjects received visual feedback of the moment they produced on an oscilloscope which also displayed a target moment just beyond their capability to encourage maximum effort. All subjects provided informed consent. Results were analyzed using a 2x3 two-factor ANOVA with repeated measures on both factors.

RESULTS

The relationship between wrist extension strength and elbow position depended on the position of the wrist for the eight limbs in this study ($p = 0.01$). With the wrist flexed, the isometric moment produced with the elbow flexed was greater than the moment generated with the elbow extended (c.f., Fig. 1, black bar). On average, wrist extension moment increased by 13.7 Ncm with the elbow flexed, a 67% increase from the average moment produced with the wrist flexed and the elbow extended (20.6 Ncm). In contrast, wrist extension moment tended to decrease with elbow flexion when the wrist was in neutral (gray bar) or was extended (white bar).

Figure 1. The difference between the wrist extension moments produced with the elbow flexed and with the elbow extended in three wrist postures. A positive difference indicates the wrist extension moment was larger when the elbow was flexed. Error bars indicate one standard error.

DISCUSSION

While few studies investigate joint moment-joint angle relationships after tendon transfer, understanding the moment-generating capability of transferred muscles can provide insight into the *in vivo* function of a single muscle. Our data indicate that the transferred brachioradialis tends to operate on the descending limb of the force-length curve when the wrist is flexed and shifts toward the ascending limb as the muscle shortens with wrist extension. These results provide direction for future biomechanical simulations aimed at improving surgical outcomes.

AN EMG-DRIVEN BIOMECHANICAL MODEL OF THE HUMAN ELBOW: FITTING A GENERIC MODEL TO SPECIFIC SUBJECTS

Thomas S. Buchanan, Kurt Manal and Richard Heine

Center for Biomedical Engineering Research, University of Delaware, Newark, Delaware USA
buchanan@udel.edu

INTRODUCTION

We have developed a biomechanical model of the human elbow that takes EMGs as inputs and yields estimates of joint moments in real-time as outputs (Manal et al., 2002). One factor that impacts the accuracy of the model is the relationship between the generic musculoskeletal parameters with which we begin, and the actual musculoskeletal properties of the specific subject being examined. In this abstract we will examine ways to scale (or tune) generic models so that they accurately represent specific subjects.

METHODS

EMG data from eight elbow muscles were collected during cyclic flexion-extension using fine-wire EMG electrodes. EMG data were rectified, filtered, and normalized to maximum effort. The elbow joint moment was simultaneously recorded.

The transformation from EMG to joint moment requires several steps, each of which can be described as a type of model. First, activation dynamics transforms each processed EMG signal to muscle activation, expressed as values between zero and one. Next, a model of muscle contraction dynamics transforms the muscle activation values to muscle force values. Finally, a musculoskeletal geometry model is used to transform the muscle force values to joint moment values. These can be compared with the measured value to assess the accuracy of the model

Muscle contraction dynamics is based on Hill-type models, requiring knowledge of musculoskeletal parameters such as optimal fiber length, tendon slack length, pennation angle, and maximum muscle force. It also requires values for the time varying muscle and tendon lengths, as well as muscle velocity. These come from the musculoskeletal geometry model, which, in addition, must compute the time varying (angular dependent) value of each muscle's moment arm. These parameters, as well as the parameters involved in modeling muscle activation dynamics, are the ones that must be adjusted if the model is to be tuned for a particular subject.

RESULTS AND DISCUSSION

For each subject, the parameters of the model are tuned by comparing the measured moment and the estimated moment and minimizing the differences between them. Typically, tuned parameters that are rooted in actual measurements are allowed to vary between plus or minus one standard deviation of the mean reported values used in the generic model. This

Figure 1: Elbow flexion-extension moment measured during a time varying task compared to that estimated from our EMG-driven model before and after tuning the model.

allows each subject specific model the ability to accept anatomical variability without introducing parameters into the model that fall outside the normal physiological range. In Fig 1 we see the results of this tuning. Once the model has been tuned for a subject, it can be used without further tuning to predict joint moments from EMGs during novel tasks.

An analysis of the importance of each parameter has been performed to examine which most substantially impact the model's ability to accurately predict joint moments. The model was found to be rather sensitive to changes in the values of tendon slack length, whereas other parameters such as pennation angle were found to have little effect in joint moment estimation, even when substantially modified. This information is being used to determine the minimum number of parameters necessary to adjust in the model tuning process.

SUMMARY

An EMG-driven biomechanical model has been created to estimate muscle forces and, from these, joint moments. The model can be tuned for specific subjects by adjusting a few important anthropometrical parameters over physiological ranges and can yield very good results.

WHEELCHAIR PROPULSION BIOMECHANICS WITH UPPER EXTREMITY IMPAIRMENT AND FATIGUE

Mary M. Rodgers and Margaret A. Finley

University of Maryland School of Medicine, Baltimore, MD USA
Baltimore Veterans Administration Medical Health Care System, Baltimore, MD, USA
Communicating Author: mrogers@umaryland.edu

INTRODUCTION

A fatigue protocol is one model used to study the potential risks for overuse injuries in wheelchair users. Rodgers, et al (2000) has shown that several biomechanical characteristics of manual wheelchair propulsion change with fatigue. Many manual wheelchair users (MWCU) have upper extremity impairment (UEI) due to paralysis or motor control deficits, yet are functionally independent. The purpose of this study was to compare biomechanical characteristics in functionally independent MWCU, with and without UEI, during fresh and fatigued states. It was hypothesized that 1) MWCU with UEI would demonstrate different biomechanical values compared with those without UEI and 2) fatigue would magnify the differences.

METHODS

Subjects included 43 MWCU (14 with UEI, 29 without UEI, mean age = 39.1 ± 9.1 yrs, WC use = 10.4 ± 8.3 yrs, height 169.5 ± 14.6 cm, weight 71.6 ± 14.8 N). Diagnoses included spinal cord injury (24), spina bifida (4), cerebral palsy (3), multiple sclerosis (3), and other (9). Following informed consent and medical screening, propulsion mechanics were measured during a maximal exercise test to exhaustion (defined as volitional inability to sustain the target velocity of 3km/hr). Peak power output (POpeak) for the test corresponded to 60% of the maximal load achieved during a prior graded maximal exercise test. Three Peak 3D Charge Coupled Device (CCD) cameras and a video acquisition system (Peak Performance Tech., Colorado Springs, CO) were used to measure upper extremity and trunk movement. Temporal features of propulsion were determined from this kinematic data (60 Hz). A wheelchair ergometer instrumented with a PY-6 six-component force/torque transducer (Bertec Corp, Worthington, OH) in the wheel hub was used to measure handrim forces and moments. Orientation of the x-y-z transducer coordinates was tangential (forward+), radial (up+) and medial-lateral (into the wheel+), respectively. Peak joint angles during wheel contact and at release, temporal data and handrim data (360 Hz) were collected when the load was applied (fresh) and at exhaustion (fatigued), and averaged over three cycles. Joint kinetics were calculated using a 3-D linked segment Newton-Euler method based on body segment coordinate systems. Inputs to the model included 3-D angular displacement, velocity, acceleration and linear acceleration, handrim kinetic, temporal, and anthropometric data. A 13 item functional test called Wheelchair Users Functional Assessment (WUFA©) was used to assess level of independence (Feliciano, 1994). ANOVA was used to determine if differences existed between the groups and states

($p \leq 0.05$). ANCOVA determined differences in Mz between groups with POpeak covaried.

RESULTS

UEI demonstrated less wrist extension ($p=0.02$), elbow extension ($p=0.01$), shoulder flexion ($p=0.01$) and abduction ($p=0.01$ with a more upright trunk position at release ($p=0.04$). Contact time was shorter ($p=0.01$). Kinetically, the UEI had smaller handrim Mz ($p=0.003$) and elbow extension power ($p=0.03$). When POpeak was covaried, there was no difference in handrim Mz between the groups. Both groups had decreased radioulnar range with fatigue at contact ($p=0.04$) and release ($p=0.05$). As shown in the figure below, UEI demonstrated a greater decrease in shoulder flexion power from fresh to fatigue ($p=0.04$).

DISCUSSION

Although both groups were functionally independent, overall kinematics and kinetics were decreased for the UEI. MWCU with UEI were able to propel at the same proportion of their maximum effort as those without UEI. The primary effect of fatigue was to decrease wrist range used for propulsion for both groups. The combination of decreased joint excursion and no change with fatigue may provide UEI MWCU some amount of protection from overuse types of stresses.

IN VIVO MEASUREMENT AND BIOMECHANICAL MODELING OF THUMB CIRCUMDUCTION RANGE OF MOTION

Peter Braido and Xudong Zhang

Department of Mechanical and Industrial Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, USA

INTRODUCTION

Thumb function is often regarded as accounting for 40-50% of hand usefulness (Emerson et al., 1996). A normative database along with a clear understanding of the biomechanics of thumb movement can aid in clinical evaluation of thumb functional impairment and ergonomic design of hand-held devices. Data obtained from in vitro studies (Imaeda et al., 1994) have limited applicability. This study aimed to explore the use of a contemporary motion capture system for measuring in vivo maximum thumb circumduction, and through biomechanical modeling and statistical analysis, to establish a normative database of 3D functional thumb ROM.

METHODS

Twenty-eight anthropometrically diversified subjects (14 males & 14 females) were selected according to stature through a rigorous screening process. A Vicon motion capture system (Oxford Metrics Ltd.) recorded the movement of 21 miniature reflective markers secured over the bony landmarks of the thumb and hand during the motion of right-hand maximum thumb circumductions in the counterclockwise (CCW) and clockwise (CW) directions.

A globographic representation method (Engin & Chen, 1986) implemented in MATLAB (MathWorks Inc.) was used to first calculate three best fitting concentric spheres for the metacarpophalangeal (MCP), interphalangeal (IP) and distal phalanx (DP) marker trajectories of the thumb and determine the carpometacarpal (CMC) joint center (JC). A plane was then fitted to each marker trajectory to identify a reference axis around which the thumb circumducts (Figure 1).

Figure 1: Fitted sphere and plane for a DP marker trajectory.

The thumb range of motion was quantified using (1) the volume that the thumb is capable of sweeping through defined by a cone with an irregular base, and (2) the included angles with respect to a reference axis, expressed as the joint sinus. To examine the effects of stature, gender and direction of circumduction on the ROM measures, two-sample t-tests and analysis of variance (ANOVA) were carried out using SAS (SAS Institute Inc.).

RESULTS AND DISCUSSION

The mean (\pm SD) root-mean-square-error (RMSE) between the estimated MCP, IP and DP sphere radii and marker trajectories are 1.31 (\pm 0.50), 1.21 (\pm 0.65) and 1.41 (\pm 0.60) mm respectively, and the kinematic JC occurs within the thumb near the CMC joint. Gender has the most notable effect ($p < 0.05$) on the JC location. Direction has the most significant effect on the orientation of the reference axis, followed by stature and gender respectively. The orientation of the reference axes of the more distal markers display a pattern that suggests an involuntary tendency to oppose the thumb to the palmar surface of the hand. The marker trajectories of thumb circumduction form a saddle shape in 3D that produces a joint sinus profile resembling a sine wave. Only direction has a significant effect on the computed angular values of the joint sinus. Anthropometry is the dominant factor in determining the cone volume, while gender and direction both have statistically significant effects.

SUMMARY

The validity of the globographic approach to quantify the maximum functional thumb ROM in vivo was supported by the low RMSE of the fitted spheres and the plausible physical location of the CMC joint center. The results of this study led to useful insight for future biomechanical modeling of thumb motion as well as implications on clinical diagnosis of impairment and ergonomic hand-tool design.

INTRODUCTION

Effective methodologies for experimentally investigating computational principles of the brain are in short supply (Ito, 2000). Two competing demands dominate the design of experiments to study the cortical foundation of dexterous manipulation: (i) the biomechanical versatility of the hand requires that the experimental task be sufficiently constrained mechanically to reduce inter- and intra-subject variability. And, (ii) the task must be complex enough to be representative of dexterous manipulation. Functional MRI studies have shown that primary motor cortex, premotor and parietal areas are important for control of fingertip forces during static precision grip (Ehrsson, et al, 2000), but we lack dynamic tasks to study sensorimotor integration during dynamic manipulation. We present a novel well-defined dynamical task to identify cortical areas involved in sensorimotor integration during dynamic precision pinch.

METHODS

Task: Ten healthy, right-hand dominant subjects (avg. age 27 yrs) used three-point pinch to repeatedly compress a slender spring that requires a specific combination of pinch force magnitude and directional accuracy to compress without buckling. In a modified version of the Strength-Dexterity test (Valero-Cuevas et al., 2001), two smooth plastic end caps flanked a 25 mm long, 10 mm diameter compression spring. The pads of the second and third digits opposed the pad of the thumb to compress the spring without buckling by simultaneously and dynamically regulating fingertip positions and forces to keep the end caps parallel and aligned (see Figure). The pinch force needed to fully compress the spring was 2.5 N, which could be repeated continuously for 50 s without fatigue in each experimental condition. We presented four experimental conditions twice at random to study cortical activity during spring compressions as we varied the presence of vision and the quality of tactile input: (1) Eyes Open (2) Eyes Closed (3) Eyes Open with Sandpaper, and (4) Eyes Closed with Sandpaper. In conditions 3 & 4 coarse sandpaper covered the smooth end caps. **Brain Imaging:** A 1.5 tesla Magnetic Resonance Scanner and a standard head coil (General Electric) were used to obtain T2*-weighted images (sensitive to deoxygenation accompanying neuronal activation) and conventional high-resolution T1-weighted images for anatomical reference. We collected 21 contiguous slices that covered the entire cortex for all subjects. Analysis of Variance compared the activity of brain regions that were active across all subjects and conditions (Hirsch et al., 2000).

RESULTS & DISCUSSION

Regions that co-varied significantly ($p < 0.05$) with the visual input included the inferior parietal lobule (Brodmann's Area [BA] 40), inferior occipital (BA 18) and middle occipital (BA 19) gyri, the medial frontal gyrus (BA 6), and the cingulate Gyrus (BA 24, see Figure). The parietal and occipital regions showed the most activity when visual input was present. The medial frontal and cingulate gyri, in contrast, were more significantly activated when vision was occluded, perhaps reflecting a requirement for increased preparation and attention when visual feedback was unavailable. Regions that co-varied with the tactile input included the pre-central motor (BA 4), and post-central sensory (BA 1,2,3) gyri. The interaction between visual and tactile data was strongest in the inferior parietal lobule, consistent with the known associative role of this structure. These findings suggest that fine-tuned motor tasks are mediated by a network of several cortical regions where the relative contribution of these regions varies depending on the type and quality of sensory input available.

SUMMARY & SIGNIFICANCE

Part of the internal model theory predicts that the occlusion or enhancement of a sensory channel will cause a complementary enhancement or downgrading of other channels, respectively, to maintain an appropriate level of sensory feedback (Wolpert et al, 1995). Our novel dynamic manipulation task has allowed us to detect changes in associative regions (e.g., BA 24) that may reflect the cortical activity necessary for the internal model to adapt to the presence and quality of sensory input.

MODEL-BASED DEVELOPMENT OF A NEUROPROSTHESIS FOR HIGH CERVICAL SPINAL CORD INJURY

Robert F. Kirsch¹ and Ana Maria Acosta²

INTRODUCTION

Individuals with high cervical spinal cord injury (C1-C4) are highly disabled, with all movements below the level of the neck paralyzed except for shoulder shrug. We are developing a neuroprosthesis based on functional neuromuscular stimulation (FNS) of paralyzed muscles to restore arm function to these individuals. The challenges are significant because of the sheer number of paralyzed motions and, in particular, because the shoulder complex is involved. We are making extensive use of simulations with a musculoskeletal model to develop this neuroprosthesis, beginning with an evaluation of its basic feasibility. Here we describe the minimal muscle set needed to restore a series of simple yet critical arm motions, and the minimum muscle forces needed to produce these movements.

METHODS

We used the 3D musculoskeletal model of the shoulder and elbow developed by the Dutch Shoulder Group, (van der Helm 1994). Inverse static simulations were performed at several arm postures to find the muscle forces needed to balance the weight of the arm and an external load. Shoulder and elbow input kinematics were measured on an able-bodied individual using an established method (van der Helm and Pronk 1995). Three simple tasks were chosen for simulation: arm elevation from resting to horizontal (90°) in the coronal and scapular planes, and hand movement from a tabletop to the mouth. These dynamic tasks were approximated by a series of 5-6 fixed postures along each of the 3 trajectories so that inverse static simulations could be used. Simulations were performed

(i.e., made the muscles “paralyzed”) until one or more of the postures could no longer be maintained, taking care to determine if previously discarded muscles could substitute for the remaining muscles. This process converged to the minimum muscle set needed across all of the postures.

RESULTS AND DISCUSSION

We found that the minimum muscle set obtained from the simulations was unique and included only six muscles: scapular head of trapezius, serratus anterior, clavicular head of deltoid, infraspinatus, subscapularis, and brachialis. Five of these were essential, i.e., no combination of other muscles could substitute for the actions of any one of them. Clavicular deltoid could be replaced by scapular deltoid plus teres minor (i.e., a larger muscle set). Of these six muscles, 5 would be paralyzed in an individual with a C3-C4 spinal cord injury, while the scapular trapezius would retain voluntary control. The muscle force magnitudes required of these muscles for the unloaded conditions were always less than 68% of maximum and typically 20-40% of maximum. For the loaded conditions, the required forces increased only modestly (less than 22%). These simulation results indicate that the minimum number of muscles that would need to be stimulated (five) to restore arm movements is well within existing FNS technology. Further, the muscle force magnitudes required for the simple tasks simulated are likely to be low enough for stimulated muscles to generate in individuals with disuse atrophy due to chronic paralysis. Thus, we believe that a neuroprosthesis to restore simple arm movements in individuals with high cervical spinal cord injuries is feasible.

SUMMARY

To evaluate the feasibility of restoring arm movements to individuals with high cervical spinal cord injuries via FNS, model-based simulations were used to identify the minimum number of muscles needed to move the arm in a set of simple tasks. We found that both the number of muscles (6) and required strength (typically less than 40% maximum) were low enough to indicate that such an approach may be feasible.

A FORCE-FIELD APPROACH TO THE ADAPTIVE CONTROL AND LEARNING OF ARM MOVEMENTS

Ferdinando A. Mussa-Ivaldi, Michael A. Conditt, Jonathan B. Dingwell, Amir Karniel, Christopher D. Mah,
James L. Patton, and Robert A. Scheidt

Northwestern University Medical School

Sensory Motor Performance Program, Rehabilitation Institute of Chicago, Chicago, Illinois, sandro@northwestern.edu

When we learn to move our arm and to act upon the environment, our brains become to all effects “experts in physics”. How can such expertise come about from experience? What kinds of representations are used by the brain to control the arm dynamics? How can we handle objects with inherent instabilities and internal degrees of freedom? How can arm movement control be recovered after stroke? We have addressed these questions in a set of experimental and theoretical studies. The theoretical framework is based on the idea of representing a complex control function as a superposition of “basis fields” representing the action of primitive controllers. The experimental studies make use of a simple robotic device, which alters the dynamics that the brain must control in order to execute the desired movements. Taken together, these studies present a new perspective on the control, learning and recovery of multi-joint arm movements.

THEORETICAL FRAMEWORK: MOTOR LEARNING AND CONTROL THROUGH THE COMBINATION OF PRIMITIVES

Microstimulation of the spinal cord in spinalized frogs and rats provided evidence for a modular organization of the spinal cord function [1]. A spinal module is a functional unit of the spinal cord circuitry that generates a motor output by producing a muscle synergy - a specific pattern of muscle activation. The output of a spinal module can be characterized as a force field - a mapping that associates each position of the frog's limb with a corresponding force generated by the neuromuscular system. Remarkably, these studies demonstrated that the simultaneous activation of spinal sites results in the vector summation of the corresponding fields. Arm dynamics are described by a set of nonlinear differential equations, which may be summarized as:

$D(x, \dot{x}, \ddot{x}) = C(x, \dot{x}, t)$, where D represents the passive (inertial, viscoelastic, gravitational) dynamics and C represents the time varying controller dynamics, which also include state-dependent terms. The finding of vector summation of spinal force fields suggests that under descending supraspinal commands, the fields expressed by interneuronal modules in the spinal cord may form a broad repertoire of control fields $C_s(x, \dot{x}, t | c_\alpha)$:

$$\Gamma = \{C_s(x, \dot{x}, t | c_\alpha) = \sum_{\alpha} c_{\alpha} \phi_{\alpha}(x, \dot{x}, t)\}$$

where each element of Γ is generated by the descending neural commands selecting a group of synergies through the weighting coefficients, c_{α} . Following this view, the neural control system may approximate a target field implementing a

desired behavior, by finding the element of Γ that is closest to the target field. We have developed experimental techniques with robotic manipulandum and human subjects to reveal the capabilities and limitations of this internal representation of the external force perturbations.

EXPERIMENTAL FINDINGS

Experimental studies of motor learning involve the mechanical interaction of subjects with a 2-joint robotic manipulandum. Typically, in these studies, subjects execute reaching movements holding the handle of the manipulandum, which applies a preprogrammed field of forces. The following main results have been obtained by our group:

- 1) When subjects execute arm movements against a field of forces that depend on the state of motion of the hand, they learn to compensate the field by constructing an internal representation of the perturbing field. The clearest evidence for that are the predictable erroneous movements that are observed as the field stopped unexpectedly.
- 2) When forces depend upon time but not upon state, a correct representation is not learned. Instead subjects tend to substitute the time-varying force with a state-dependent force, which generate similar effects on the training movements. This is in contrast to artificial systems that typically use clocks, counter and switches and not state mapping.
- 3) The mechanism of adaptive control may be exploited to induce the implicit learning of a desired movement as an after-effect of adaptation. This method is investigated for the design of force fields that can facilitate the recovery of motor skills lost to stroke and other disorders.
- 4) Time-series analysis of motor adaptation has revealed that the perturbing state-dependent field is learned based only on recent memories of the perturbation and of past performance. The same model fits both predictable and random sequences of perturbations.
- 5) When interacting with an object with internal degrees of freedom (such as a spring in series with a mass), subjects learn to control the kinematics of the object by forming an internal model that specified the forces that the hand must exert at the point of contact to induce a smooth motion of the object's endpoint.

IMPEDANCE MODELS OF FINGER JOINTS DURING TYPING

Devin L. Jindrich and Jack Tigh Dennerlein (jax@hsph.harvard.edu)

Harvard Occupational Biomechanics, Harvard School of Public Health, Boston, MA, USA

INTRODUCTION

One possible risk factor for the development of computer work-related musculoskeletal disorders (MSDs) is mechanical load to the soft tissues resulting from extensive keying. Predicting the mechanical load on the soft tissues of the finger and hand is difficult because of the complex musculoskeletal structure and the dynamic nature of the finger during a keystroke. Simple mechanical impedance models of animal locomotion, however, have revealed principles of musculoskeletal design, and lead to specific motor control hypotheses (Farley *et al.*, 1993). Our approach therefore, is to build a lumped-parameter model of the finger to test the hypothesis that joints of the finger behave like a relatively simple mechanical impedance system.

MATERIALS & METHODS

Subjects tapped with the index finger of the right hand on a computer keyswitch mounted on a bi-axial force sensor, which measured vertical and sagittal forces (Figure 1). An optical measurement system measured the position of the keyswitch using an infra-red LED glued to the side. Miniature finger goniometers (Model S720 Shape Sensors, Measurand, Inc.) placed across each joint measured joint kinematics. Output from the force, position and angle sensors were sampled at 10 KHz using a computer A/D system (National Instruments NB-MIO16E DAQ board, LabVIEW software).

Figure 1. Experimental apparatus.

Finger segment lengths were measured, and an inverse dynamic model of the finger was used to calculate joint torques from forces and kinematics (Craig, 1989).

A linear Voight model, (linear spring and damper in parallel), was fit to the kinematic and torque data from each joint. Using the model parameters, joint angles and angular velocities over the tap, the joint torque was re-constructed and compared to the measured torque to determine the effectiveness of the model. Proportional errors were calculated as the RMS value of the difference between measured and predicted torque relative to the RMS value of the input torque signal. Three subjects have been tested to date.

RESULTS

For the subjects tested to date, the distal finger joints of the index finger acted as simple spring-mass-damper systems during the contact phase of a keystroke. Torques at the Distal interphalangeal (DIP) and proximal interphalangeal (PIP) joints were re-constructed by a linear Voight model (Figure 2) to errors of less than 20%. A linear Voight model was not able to accurately model the mechanics of the metacarpophalangeal (MCP) joint during tapping on a keyswitch, suggesting a more complex motor control pattern.

The effectiveness of viscoelastic models in describing the behavior of some finger joints may simplify the analysis and prediction of tissue loading during keying. Monitoring only a subset of joints during different typing tasks may be sufficient to understand the tendon forces, which determine the movements of, and external forces on, the finger.

Figure 2. Measured (solid black curve) and predicted (dotted blue curve) joint-torque over time for a representative tap.

EFFECTS OF LOW-LOAD, HIGH REPETITION MOTION ON SCAPULAR KINEMATICS

Andrew Karduna, Chao-Yin Wu, David Ebaugh

Programs in Rehabilitation Sciences, MCP Hahnemann University, Philadelphia, PA

email: karduna@drexel.edu

INTRODUCTION

Although the National Institute of Occupational Safety and Health has identified a clear epidemiological link between repetitive arm motion and shoulder disorders in the workplace (Bernard, 1997), there are few scientific data available regarding the biomechanics of this connection. On theory is that repetitive motion leading to scapulothoracic muscle fatigue may result in abnormal scapular kinematics that are potentially dangerous to a worker. There is evidence that high load, low repetitive activity is associated with muscle fatigue and abnormal scapular motion (McQuade et al., 1998). The purpose of this study was to investigate the consequences of low load, high repetition activities frequently associated with workplace shoulder disorders.

METHODS

Kinematics The Polhemus 3Space Fastrak (Colchester, VT) was used to collect kinematic data. A thoracic receiver was placed over T3 using double sided tape, a humeral receiver was placed at the deltoid tuberosity using an elastic strap, and a scapular receiver was fixed to a so-called scapular tracking device that was attached to the scapular spine and acromion process using Velcro strips. We have previously demonstrated the validity of the technique for measuring scapular kinematics (Karduna et al., 2001). Data were collected during three trials of elevation in the scapular plane, with data averaged over the three trials. Data for 3 scapular rotations were analyzed: posterior tilting, upward rotation, and external rotation.

Measurements of Fatigue Force, EMG and perceived stress data were collected in order to assess the effects of a simulated work task on fatigue. Pre-amplified surface electrodes were applied to the anterior deltoid, upper trapezius and serratus anterior. Data were collected at 1200 Hz, amplified and bandpass filtered (10-750 Hz). Force and EMG data were collected during a 5 second maximum isometric contraction. A spectral analysis of the EMG data was performed and the median power frequency (MPF) was calculated. The Borg's rating of perceived exertion scale was used to measure the subjective physical intensity of the simulated work task. This is an interval scale scored with levels ranging from 6 (no exertion) to 20 (maximal exertion).

Protocol Sixteen healthy subjects were studied with IRB approval (mean age of 27 years). The first step was to collect baseline measurement of force, EMG, perceived fatigue and kinematics. The subject then performed a simulated work task for 15 minutes. The task required the subject to reach out and grasp a bar positioned at a height that resulted in 110 degree of shoulder flexion in the sagittal plane and then return to 0 degrees of flexion. The subject performed this task at a pace of 41 cycles/minute with no load in their hand. Immediately

after the completion of this simulate work task, force, EMG, perceived fatigue and kinematic data were collected again.

RESULTS

Signs of fatigue after the simulated work task were varied among the measurements. While there was no significant reduction in isometric force, the serratus anterior showed a significant reduction (10%) in MPF after the simulated work task. Also, there was a dramatic change in perceived exertion, going from 7 (extremely light) to 16 (hard). With respect to kinematics, there were no significant differences in posterior tilting and external rotation. However, there was a small but significant increase in upward rotation between 60 and 120 degrees of humeral elevation (figure 1).

Figure 1 Mean differences in upward rotation * $p < 0.05$

DISCUSSION

Clearly, the low load, high repetition task of this study resulted in a substantial perception of fatigue as indicated by the results from the Borg scale. However, the fact that there was only moderate fatigue in one muscle and no reduction in force production might help explain why only minimal changes in scapular kinematics were observed. Additionally the low load condition of the present study may have resulted in EMG activation levels less than 10%, which may not be high enough to elicit a shift in action potential velocity necessary for a decrease in MPF (Hagg, 1992). Other methods may be necessary for assessing muscle fatigue under these conditions. We are currently examining the effects of varying load intensity on fatigue and kinematics.

INDIVIDUAL LOAD LIMITATION OF THE GLENOHUMERAL JOINT AS A PREVENTION TOOL FOR MUSCULOSKELETAL INJURIES

Krystyna Gielo-Perczak and Tom Leamon

Liberty Mutual Research Center for Safety and Health, Hopkinton, MA U.S.A.

Krystyna.Gielo-Perczak@LibertyMutual.com

<http://www.libertymutual.com/research/>

INTRODUCTION

An important feature of workplace design is the creation of solutions for preventing excessive joint loading. Ergonomists apply quantitative methods during the search for optimal relationships between workers and their work environments, but these assessments are mainly based on anthropometry which often represents the main design criteria. An important need in workplace design is the creation of innovative ways to prevent excessive joint loading. The only methods for finding these different options are modeling and simulation.

METHODS

Musculoskeletal disorders of the upper extremities due to work factors are common and occur in nearly all sectors of our economy. The highest rates of these disorders occur not only in the industries with a significant amount of forceful work in high arm positions during concentric contractions, but also during eccentric contractions in arm positions of 0 to 30 degrees of abduction.

A new model of the glenohumeral joint has been proposed and investigated for its applicability to ergonomic studies (Gielo-Perczak, 1989). The most important feature of the proposed model is that the internal loading – which means the forces at the bone-on-bone contact point, or in the muscles, or in the ligaments – can be expressed as the multivariable function of its articular geometry. This method of analysis takes into account individual differences in geometry of the glenohumeral joint (GHJ) with different types of work. Central to the study is an investigation of the individual influence of joint geometry on the Maximum Acceptable Workload (MAW) applied to the hand.

The proposed model provides sets of humerus positions that are acceptable in terms of muscle and ligament strength and stresses at the bone-on-bone contact points. The maximum acceptable workload of each element of a joint can be calculated individually as a function of the external load, the geometry of the articulating surfaces, and the muscles and ligaments.

RESULTS & DISCUSSION

The load applied at the hand is a critical element in assessing individual force limitations during activities. Calculations have been performed for the different joints and loading, and the results show that when an individual pushes an object on a table, the bone-on-bone forces have the greatest influence on the MAW. In a pulling activity, if the arm is moved about 30° from the side, and the angular position of a handle is:

- 170°, then the maximum acceptable load can be 971 N;
- 160°, then the maximum acceptable load can be 414 N;
- 150°, then the maximum acceptable load can be 271 N.

The maximum weight of the pulled object depends on the geometry of a joint and position of the arm, and on the position

of the handle.

This method can be a useful tool for:

- minimizing incompatibilities between the capabilities of workers and the demands of their jobs,
- preventing likely shoulder injuries during work.

With this GHJ model, it is possible to reduce musculoskeletal injuries by assessing individual acceptable loads during carrying, pushing and pulling. This model can help reduce the risk of shoulder injuries during static and repetitive work, and can help researchers examine the forces in ligaments, selected muscles, and between bones for specific joint geometry.

SUMMARY

To understand human tolerance to work loads, it is necessary to calculate the stress and strain at specific points in the musculoskeletal system. Joint loading analyses, by application of computer simulation, imply the etiology of injury. The application of computer simulation can be useful for minimizing incompatibilities between the workers' physical capabilities and their job demands towards preventing work-related musculoskeletal injuries.

CONTRACTILE PERFORMANCE OF MUSCLES THAT GENERATE POWER VS MINIMIZE COST/FORCE

Andrew A. Biewener

Concord Field Station, Department of Organismic and Evolutionary Biology, Harvard University, Cambridge MA, USA

abiewener@oeb.harvard.edu

INTRODUCTION

Limb muscles are recruited and contract to carry out a range of mechanical functions. Many muscles shorten while generating force to do (concentric) work and generate mechanical power (work/time), while others lengthen (eccentric contraction) to absorb energy. Still other muscles may contract isometrically to transmit force, but do no work. Different modes of locomotion (flight and swimming vs running), as well as differing locomotor movements (level vs incline and steady vs acceleration & deceleration), emphasize these differing roles of muscles. Furthermore, in contrast to the quasi-steady nature of a muscle's force-length and force-velocity properties, the *in vivo* performance of muscles requires that they be cyclically activated in relation to time-varying changes in length and force.

This paper compares the dynamic *in vivo* force-length behavior of muscles that function to generate mechanical power (bird flight muscle) versus those (leg muscles of hopping and running animals) that minimize cost/force (Biewener & Roberts, 2000). It examines three aspects of muscle function: 1) how muscle architecture affects muscle function; 2) whether similar features of muscle activation relative to force development and length change apply to muscles that generate power vs those that minimize cost/force, and 3) how changes in grade, speed and gait affect the *in vivo* contractile performance of a muscle.

METHODS

In vivo patterns of muscle activation (EMG) were recorded in relation to fascicle strain (via sonomicrometry) and muscle force (via bone strain or tendon buckle) for the pectoralis (*Pect*) of birds during flight (Biewener et al. 1998a) and the lateral gastrocnemius (*LG*) and plantaris (*Pl*) of wallabies during hopping (Biewener et al. 1998b). EMG and fascicle strain were also recorded in the biceps femoris (BF) and vastus lateralis (VF) of rats (Gillis & Biewener, 2001) and goats (unpublished) during treadmill locomotion at different grades, speeds and gaits.

RESULTS & DISCUSSION

In contrast to the pigeon *Pect*, which undergoes considerable shortening (total fascicle strain: 35-40%) while generating force to produce mechanical power to move the wing during flight, the wallaby *LG* (not shown) and *Pl* muscles both contract under nearly isometric conditions (< 5% strain; Fig. 1), similar to the *LG* of running turkeys (Roberts et al. 1997). Near isometric contractile behavior favors greater force/ATP use and may often be related to tendon elastic energy savings.

A common feature of both contractile behaviors is that these muscles are all activated near the end of passive lengthening

Figure 1.

(wing upstroke or limb swing protraction), just prior to shortening. Eccentric activation of the muscles enhances both the rate and magnitude of force development, which favors both increased work and reduced cost/force.

The rate and magnitude of muscle force, and *not* muscle work, have been argued to be the main determinants of energy cost in terrestrial running gaits (Kram & Taylor, 1991). Direct experimental evidence for this relies largely on the observed isometric behavior of distal leg muscle-tendon units (Roberts et al. 1997). Measurements of muscle strain and EMG patterns in more proximal muscles of rats and goats (Fig. 2) however indicate that both the BF and VL undergo considerable strain (20 to 25%) during

limb support, indicating that they play important roles in modulating whole-limb work during limb support. In general, changes in speed and gait have only subtle

effects on the *in vivo* patterns of muscle strain and activation. In contrast, changes of grade strongly influence the contractile behavior of the BF and VL. Both muscles shorten more during incline running (VL: 9%; BF: 27%, $p < 0.01$), and the rat BF is generally 'turned-off' during downhill locomotion.

ELASTIC MECHANISMS IN EQUINE LOCOMOTION (*EQUUS CABALLUS*)

Wilson A.M.

Structure and Motion Lab, The Royal Veterinary College, North Mymms, Hatfield, Herts, AL9 7TA England

INTRODUCTION

Storage of elastic strain energy in the collagenous component of muscle tendon units of anti gravity muscles is important in reducing the mechanical work of locomotion (Minetti *et al*, 1999). This mechanism has been demonstrated in the gastrocnemius tendon of the wallaby (Biewener *et al*, 1998), the digital flexor tendons of the horse and the plantaris muscle of the human foot (Alexander & Bennet-Clark, 1977). These specialised muscle-tendon units have very short muscle fibres and long tendons. Short muscle fibres mean that there is limited scope for changing the length or the stiffness of the muscle tendon unit. The limb therefore acts as a passive elastic structure with fixed mechanical properties. We are interested in how the horse deploys this mechanically constrained limb under the varying requirements of locomotion.

In this talk I will summarise a series of experiments testing the following hypotheses:

1. The equine limb does not change stiffness as a result of changes in speed, gait or surface.
2. The short fibred muscles act not to control limb stiffness but as dampers of high frequency vibration within the tendons.
3. Elastic energy storage appears to also be used to initiate limb protraction.

METHODS AND RESULTS

1. We conceptually divided the equine limb into two compression springs, one extending from the elbow to the foot and the second from the scapula to the elbow. Length change was measured using video motion analysis (ProReflex, Qualysis) during treadmill locomotion. About 90% of the length change occurred in the distal portion of the limb where the highly adapted muscles lie. We speculate that the proximal limb is more involved with limb protraction.

Limb length change occurs as a result of metacarpo-phalangeal (MCP) joint extension. We used the relationship between MCP angle and limb force as a measure of limb stiffness. This relationship was almost unchanged as a function of surface properties, gait or muscle activation. Theoretical calculations indicate that the proximal limb is too stiff to make any significant contribution to changing whole limb stiffness.

2. The elastic and multi segmented nature of the equine limb make it susceptible to a secondary mode of vibration in a cranio-caudal direction – much like plucking a violin string. These oscillations are excited by foot impact, occur at a frequency of 30 – 40Hz and, we believe, are important in the development of musculo-skeletal injury. (Wilson *et al*, 2001) Such vibrations are damped by the surface and by the energy absorption properties of muscle. These oscillations can be

recreated by impacting a mechanical model of the equine limb; this enables us to study the relationship between musculo-skeletal arrangement, surface properties and limb oscillation. It transpired that whilst surface stiffness is important in tuning the primary resonant frequency of the limb it has little influence on vibration magnitude or frequency. The damping properties of the surface are however critical in determining the duration of limb vibration. The very short fibred digital flexor muscles, whilst of little value in controlling limb movement, appear ideal for damping the higher frequency oscillations of the limb. When a cross bridge model is subjected to small amplitude oscillations it demonstrates peak energy absorption around 50-100Hz and there are sufficient cross bridges in the digital flexor muscles to account for the damping response seen *in vivo*.

3. It is biologically important to maximise duty factor (fraction of stride time that foot is on ground) because this will minimise peak limb and muscle stress. Muscles are not very good at generating force at high contraction velocities. In the horse the biceps muscle (which has short fibres and a substantial internal tendon) is loaded by body weight during stance phase. The length of the muscle tendon unit peaks at the end of stance at which point the leg is de-stabilised and the biceps shortens, flexing the elbow and extending the shoulder, the movements required to initiate limb protraction.

CONCLUSIONS

The equine forelimb contains a large amount of collagenous tissue which is important for storage of elastic energy in the limb. The springs are loaded by gravitational and inertial forces during stance phase and energy is returned to lift the centre of mass and accelerate the limb forwards for the next stance phase. Despite the large contribution of passive mechanisms to locomotion horses are able to demonstrate a wide range of gaits and speeds. Understanding the deployment mechanisms for the limb may be important in the design of legged robots.

MECHANISMS OF FLIGHT FORCE ENHANCEMENT IN FLAPPING FLIGHT

Fritz-Olaf Lehmann

BioFuture Research Group, Theodor-Boveri-Institute, University of Würzburg,
Am Hubland, 97074 Würzburg, Germany, email: lehmann@biozentrum.uni-wuerzburg.de

INTRODUCTION

Insects display an impressive variety of flight maneuvers. Flies, in particular are capable of extraordinary aerial behaviors, aided by an array of unique sensory specializations including neural superposition eyes and gyroscopic halteres. Using such elaborate sensory input, flies steer and maneuver by changing many aspect of wing kinematics including angle of attack, the amplitude and frequency of the wing stroke, and the timing and speed of wing rotation. Conventional aerodynamic theory based on fixed-wing aircraft, however, may not explain how the flapping wings of insects control and produce flight forces that exceed twice the body mass while the animal is carrying loads or performing flight maneuvers. In addition to force production by flapping one wing, small insects such as fruit-, damsel- and butterflies may enhance total lift production and control by an interaction of both wings at the dorsal stroke reversal. The *clap and fling* is a close apposition of the two wings preceding pronation and is thought to enhance aerodynamic circulation at the beginning of the down stroke (Fig. 1). The purpose of this study was to estimate the contribution of clap and fling to total flight force production.

Figure 1. Kinematics of clap and fling during dorsal stroke reversal in insects (modified from Weis-Fogh 1973).

METHODS

The constraints of force measurements in the living animal can be circumvented by building a dynamically scaled robotic model of the 1.1 mg fruit fly. In this robot, the motion of the two wings is driven by an assembly of six computer-controlled stepper motors attached to the wings gearbox via timing belts and coaxial drive shafts. The 25 cm long model wings were constructed from clear Plexiglas (3.2 mm thick) to allow flow visualization on both sides of the wing. The base of the wing was equipped with a 2D force transducer consisting of two sets of strain gauges wired in full-bridge configuration. Each set measured forces parallel and normal to the wing, respectively. Wings, sensors, gearboxes and part of the coaxial drive shafts were immersed in a 1 m by 1 m by 2 m tank filled with high viscous mineral oil (density = $0.88 \times 10^3 \text{ kg m}^{-3}$, kinematic viscosity = 115 cSt). The length of the model wings, their translational velocity and the viscosity of the mineral oil were chosen to match Reynolds number of 134 typical for wing motion of fruit flies.

RESULTS AND DISCUSSION

The contribution of clap and fling to total flight force varies between 3.6 and 21% of total aerodynamic force production depending on the trajectory of wing motion (Fig. 2). In fruit flies *Drosophila* the clap and fling wingbeat contributes up to 16% to total flight force at a stroke amplitude of 160 degs - a high value considering the brief duration (~10% of the stroke cycle) over which dorsal wing interaction occurs.

Figure 2. Force contribution of clap and fling at various types of wing kinematics. v= ventral, d= dorsal.

SUMMARY

Aerodynamic force measurements in a dynamically scaled robotic insect have revealed that the enhanced performance of a flapping insect wing results from three distinct unsteady aerodynamic mechanisms: delayed stall, rotational circulation and wake capture. In addition to force production by flapping one wing, insects may enhance total lift production through the interaction of both wings at the dorsal stroke reversal. Instantaneous measurements of aerodynamic forces during the stroke of the robotic insect suggest that in the fruit fly *Drosophila*, clap and fling significantly contributes to total force production. Reconstruction of wing movement during yaw torque maneuvers in tethered flight indicates that the neuro-muscular system of fruit flies actively modulates the timing of wing rotation during clap and fling within a 0.2 ms range, whereas angular velocity of wing rotation does not change. Fruit flies might primarily use clap and fling to modulate flight forces in order to enhance both flight stability and maneuverability.

ADAPTIVE RESPONSES OF ENDOTHELIAL CELLS TO CYCLIC PRESSURE

Hainsworth Y. Shin¹, Michael L. Smith², Karen J. Toy³, Mickey P. Williams³, Mary E. Gerritsen³, and Rena Bizios¹

¹Dept. of Biomedical Engineering, Rensselaer Polytechnic Institute, Troy, NY

³Dept. of Molecular Biology and Dept. of Cardiovascular Research, Genentech, Incorporated, South San Francisco, CA

INTRODUCTION

In the vasculature, the pumping action of the heart as well as containment of blood within the blood vessel lumen exposes vascular endothelium to cyclic pressure. Although basic functions (specifically, proliferation and apoptosis) of endothelial cells are dependent on the applied cyclic pressure levels (Shin *et al.*, 2002), the modulatory role of this type of mechanical force on endothelial-specific phenotype (such as barrier function and gene expression) has not been elucidated.

The present study utilized an *in vitro* cell culture model and examined select functions (specifically, transendothelial permeability and gene transcription) of human umbilical vein endothelial cells (HUVEC) after exposure to cyclic pressure. These results elucidate the adaptive responses of endothelial cells to cyclic pressure.

METHODS

Cyclic Pressure Experiments

Well-characterized populations of HUVEC (passage 4 to 6) were exposed to either 60/20 or 140/100 mm Hg cyclic pressures at 1 Hz using a custom-made cyclic pressure system and procedures previously described (Shin *et al.*, 2002) for various time periods up to 24 hours. Controls were parallel cultures of HUVEC maintained under 0.15 mm Hg sustained hydrostatic pressure but, otherwise, similar experimental conditions.

Endothelial Cell Barrier Properties

Confocal microscopy and standard immunocytochemical techniques were used to assess ZO-1, VE-cadherin, and β -catenin localization using confluent HUVEC monolayers cultured on fibronectin-coated glass slides and exposed to either 60/20 or 140/100 mm Hg cyclic pressure at 1 Hz for 18 hours. The effects of cyclic pressure on macromolecular transport was investigated using confluent monolayers of HUVEC cultured on fibronectin-coated Transwell inserts (Costar) for 36 hours and, subsequently, exposed to either 60/20 or 140/100 mm Hg cyclic pressure for 18 hours. At that time, permeability of endothelial monolayers to fluorescein-conjugated bovine serum albumin (FITC-BSA) was monitored under control (0.15 mm Hg) sustained pressure conditions for 30 minutes. Concentrations of FITC-BSA transported across HUVEC monolayers were determined using fluorescence (490 nm excitation/520 nm emission) spectrometry.

Endothelial Gene Expression

Total RNA was harvested from HUVEC following exposure to 60/20 mm Hg cyclic pressure for 24 hours using procedures described in Kahn *et al.* (2000) and analyzed using Affymetrix™ Gene Chip® HuGene FL arrays according to procedures described in Jin *et al.* (2000). The results of the microarray analysis were independently confirmed using quantitative reverse transcriptase-polymerase chain reaction following standard procedures (Kahn *et al.*, 2000).

RESULTS/DISCUSSION

Select levels of cyclic pressure affected the barrier function of endothelial cells. Compared to cells maintained under control (0.15 mm Hg) sustained pressure conditions (controls), only HUVEC exposed to 140/100, but not 60/20, mm Hg cyclic pressures exhibited altered barrier properties which included changes in the localization of interendothelial junctional proteins and in transendothelial permeability.

Exposure of HUVEC to 60/20 mm Hg cyclic pressure at 1 Hz for 24 hours elicited an altered pattern of gene transcription. In addition to genes (such as, tissue plasminogen activator and cytosolic phospholipase A₂) known to be up-regulated in response to shear stress and cyclic strain, HUVEC exposed to 60/20 mm Hg cyclic pressure for 24 hours exhibited a gene transcription profile characterized by changes in the expression of a unique subset of cyclic pressure-sensitive genes.

CONCLUSIONS

The present *in vitro* study demonstrated that physiologically-relevant levels of cyclic pressures modulate select HUVEC functions, specifically, barrier function and gene expression. These findings provide novel insight into the fundamental importance of circulatory pressure to endothelial cell physiology.

LEG DESIGN AND JUMPING IN SPIDERS

Reinhard Blickhan¹, Jelena Zentner², Andre Seyfarth¹ and Michael Karner¹

¹Motion Science, Friedrich-Schiller-University, Jena, Germany, reinhard.blickhan@uni-jena.de

²Technical Mechanics, Technical University, Ilmenau, Germany

INTRODUCTION

Jumping represents a basic locomotory behavior in animals. In spiders the ability to jump is well known for *Salticidae* however less well described for hunting spiders or other groups. There, a surprisingly flexible performance can be observed. Simplified, the leg of a spider can be approximated by three slender segments connected via two hinge joints, the femuro-patellar and the tibio-metatarsal joint. In these joints extension is provided by hydraulic (hemolymph) pressure. In order to achieve high and robust performance the animals follow kinematic and design criteria.

METHODS

Experiments were made with 42 specimens of the South American hunting spider *Cupiennius salei* (Keyserling) from juveniles of about 1 cm body length to subadult animals (donation: F. G. Barth, Vienna, E. A. Seyfarth, Frankfurt am Main). Kinematic data were obtained using a high speed video system with three cameras (CAMSYS 500, mikromak at 500 frames per second. Three-dimensional analyses were carried out by use of WINalyze 1.3 (mikromak).

Numerical simulations (Bohmann and Blickhan, 1998) were performed using the software packages Mathematica (Wolfram) and Matlab (Mathworks).

RESULTS AND DISCUSSION

The spiders show a surprisingly flexible behavior. In unprepared jumps the animals might jump in any direction opposite to an approaching object. The remarkable flexibility in jumping directions is achieved by flexing the legs on the leading and extending them on the trailing side. In prepared jumps the spiders show characteristic leg positioning and the jumps are directed anterior. Jumping movements are initiated by a backward movement immediately before the acceleration phase. This is accompanied by a slight bending of the tibio-metatarsal joint. Only minor compression of the carapace is sufficient to generate the jump.

In simulations jumps generated by hydraulic leg extension are investigated. Reasonable jumps are only possible from a starting position similar to that observed in the animals. The backward movement in the early phases of the jump can be attributed to a lack of equilibrium in torque generated by the hydraulic pressure partly due to joint geometry and to delayed filling of the distal joint. The dimensions of the spider's leg are

optimized to provide jumps within a short time. This is relevant for flight situations. The slenderness of the leg of the hunting spider is optimum for high take-off-velocities (Fig. 1).

Three segmented legs are typical for most animals. Spiders prefer C instead of Z-shaped segment arrangements (Seyfarth et al., 2000). This results in a much higher leg compliance but is a save mode of operation for legs with imbalanced and softening joints.

Figure 1: Legs with large diameters provide more effective area for the hemolymph pressure. However, the weight increase compensates this advantage.

SUMMARY

Jumping is the most vigorous activity of spiders. The necessary performance combined with limits imposed by the hydraulic extension mechanisms may determine to a large extent the leg design in spiders.

MECHANICAL FUNCTION OF LEG MUSCLES IN RUNNING BIRDS

Richard L. Marsh¹, David J. Ellerby¹, and Cindy I. Buchanan²

Department of Biology¹ (r.marsh@neu.edu) and Department of Physical Therapy²
Northeastern University, Boston, MA

INTRODUCTION

Skeletal muscle serves a variety of functions during locomotion. During some activities the primary function is clear, e.g., in swimming and flying the main function of muscle is to produce mechanical power. However, muscle function during running has remained a puzzle. During level running at constant speed, considerable energy is used, but no net work is done. Work must be done during parts of the stride to move the center of mass up and down and to accelerate it slightly in the horizontal plane. Work is also done to accelerate the segments of the body during the stride. However, the potential exists for recovering much of this energy in elastic elements, thus reducing greatly the energy required for running. These facts led C.R. Taylor and associates to suggest the major function of most muscles during running was to support the weight of the body, not to produce work. They further suggested that muscles could most economically perform this function if they operated isometrically while active.

Evaluating this hypothesis has been hampered by a lack of information on the mechanical function of individual muscles. Muscle function has most often been studied using electromyography. Muscle length has been predicted using limb kinematics measured from light or x-ray cine and video. However, the complexity of the movements and of the architecture of the limbs limits the success of this approach.

Sonomicrometry has recently provided an alternative approach to measuring length change at the level of the muscle fibers (fascicles). Using this technique combined with electromyography we are evaluating the mechanical function of the bulk of the hind limb muscles in running helmeted guinea fowl *Numida meleagris*.

METHODS

Sonomicrometer transducers and electromyography electrodes were surgically implanted in individual hindlimb muscles. The birds were run on a motorized treadmill and data acquired while simultaneously recording limb movements using high-speed video.

RESULTS AND DISCUSSION

The lateral gastrocnemius in running Guinea fowl appears to function nearly isometrically while active during ground contact. In this regard, its function matches the prediction of C.R. Taylor and colleagues, and agrees with data collected on the ankle extensors of other birds and mammals. These data suggest that the ankle extensors of terrestrial vertebrates

generally may satisfy the conditions for economical force production.

In contrast to these data on the ankle extensors, none of the thigh muscles examined to date appears to operate mainly isometrically during activity. The posterior iliotibialis lateralis (PIL), the single largest muscle in the limb, is stretched during the bulk of its active period. The mechanics of the stride predict that the stretch of this bi-articular muscle (knee flexor and hip extensor) results from the co-contraction of knee flexors. Two of these flexors the flexor cruris lateralis (FCL) and the iliofibularis (IF) do indeed shorten while active. Intriguingly, the IF also shows a second period of activity during early swing phase when it is being lengthened by antagonistic muscles that produce hip flexion and knee extension. The only swing phase muscle examined so far, the iliotibialis cranialis (IC) is active mainly during shortening, but has a short period of active lengthening at the end of stance. The muscles measured represent approximately 40 % of the total mass of the hindlimb muscles.

CONCLUSIONS

A complex picture of muscle function during level steady speed running emerges from the data on guinea fowl. Some muscles function nearly isometrically to support the body weight during stance. However, many of the active muscles measured either shorten, producing work, or, conversely, lengthen, absorbing work. We hypothesize that considerably more muscle work is done during running than appears externally because active muscles absorb some work during stretch. Because the strain in the muscle fibers is large, this energy cannot be recovered elastically. We propose that this seemingly wasteful co-contraction of antagonistic pairs of muscles allows greater stability during running because the muscles that are stretched provide predictable forces against which the shortening muscles operate. The potential for instability may be greatest at the knee, which goes through a point of zero moment during ground contact. A major challenge for the future is determining the importance of the various types of mechanical activity for the overall energetic economy of running.

INSIGHTS INTO THE PROCESSION MOVEMENT OF MYOSINS V AND VI.

Lee Sweeney. Department of Physiology, Pennsylvania Muscle Institute, University of Pennsylvania School of Medicine, 3700 Hamilton Walk, Philadelphia, Pennsylvania 19104-6085, USA.(lsweeney@mail.med.upenn.edu)

SUMMARY

We have conducted kinetic and single molecule analyses of myosin V and VI. For both motors, ADP release is the rate-limiting step of the actin-activated ATPase cycle, and both motors have high duty ratios. The duty ratios combined with the structural coupling of the heads allows these motors to move processively. Surprisingly, the motors have similar step sizes. We will present data supporting a conventional lever arm mechanism for myosin V, but a completely different mechanism for the motility of myosin VI.

MYOSIN V TRUNCATION MUTANT WITH ONLY ONE IQ MOTIF CAN PROCESSIVELY MOVE ALONG AN ACTIN FILAMENT WITH 36 NM STEPS.

(Email: yanagida@beta)

INTRODUCTION

Class-V myosin is recently found by using an optical trap to processively move along an actin filament with large (~ 36 nm) steps. Since myosin-V has two heads, each of which consists of a motor domain and an expanded neck domain (23 nm long), it is postulated to stride along the helical repeat (36 nm) of an actin filament by using its long neck domain as a lever arm. This postulation agrees the widely-accepted lever-arm model. To test this postulation, here, we measure the mechanical properties of single molecules of deletion mutants of myosin-V, which has an extremely short (one sixth of the native one) neck domain.

METHODS, RESULTS AND DISCUSSION

The results show that the size and processivity of steps of short-necked myosin-V are both similar to those of myosin-V fully equipped with a long neck domain. Thus, the long extended neck domain is critical to neither the large step nor the processivity of myosin V, presenting evidence that calls into question the lever arm model. We propose that the myosin motor domain and/or actin-myosin interface determine the processive and large steps of myosin V.

OBSERVATION OF DISPLACEMENT STEPS BY SINGLE MYOSIN ID AND MYOSIN II MOLECULES

Christine Ruff¹, Danny Koehler², Martin Bähler² and Edgar Meyhöfer^{1,3}

¹Molecular and Cellular Physiology, Medical School Hannover, ²Institute for General Zoology and Genetics, University Münster,

³Department of Mechanical Engineering, University of Michigan (meyhofer@umich.edu)

INTRODUCTION

Considerable evidence from structural work and single molecule experiments suggests that the displacement generated by single myosin II molecules concurrent with ATP-hydrolysis is amplified by the lever-action of the light chain binding region of myosin. Myosins constitute a large family of actin-based motors¹ which differ substantially in their structural and physiological properties. It remains unclear if the same basic chemo-mechanical transduction mechanism operates in all myosins. For example, step sizes measured from rat liver and brush border myosin I did not relate directly to the length of the proposed lever². In the present study we characterized rat myosin ID, formerly known as myr 4, and compared it to myosin II.

METHODS

Using stably transfected HeLa cells we expressed three recombinant FLAG-tagged myosin ID proteins with either no, 1 or 2 light chain binding IQ-motifs and measured the single molecule step sizes of all constructs with a combined microneedle/laser trap apparatus.

RESULTS AND DISCUSSION

The step size of the myosin ID construct without IQ-motifs was 4.6 nm, while the step size of the comparable *Dictyostelium* myosin II motor is only 1.6 nm³. The step sizes of the two myosin ID constructs encompassing either 1 or 2 IQ-motifs increased in a linear manner, strongly suggesting that the myosin ID step size is determined by a lever mechanism. A rotation of approximately 90° about the same pivoting point as in myosin II is sufficient to explain our data. We conclude that the degree of lever arm rotation can vary considerably in different myosins. Lever arm rotation is an important determinant for the step size of myosin, and together with the length of the lever arm is sufficient to account for all reported step sizes on the basis of the same general mechanism.

REGULATED ACTIN-MYOSIN INTERACTION AND SARCOMERIC STIFFNESS

Kenneth Campbell, Yiming Wu, Robert Kirkpatrick, Henk Granzier

Dept VCAPP, Washington State University, Pullman, WA 99164
cvselkbc@vetmed.wsu.edu

INTRODUCTION

Muscle stiffness is the outcome of a large number of individual actin myosin interaction events. To understand stiffness in terms of these underlying actin-myosin events, it is necessary to accept that some details of the kinetics of an individual event will be lost in the population dynamics of large numbers of these events. However, it is also reasonable to expect that some essential features will be retained. In this report, we strive to extract essential features of the underlying events from measured cardiac muscle stiffness.

METHODS

Our fundamental assumption was that the force generated by a population of parallel, linearly elastic crossbridges, XB, is given by

$$F = \sum_{i=1,n} \varepsilon N_i X_i$$

where n is the number of attached XB states, N is the number of XB in each of the i attached states, X is the average distortion among all XB in each state, and ε is the elastic coefficient for each XB.

At the outset, we assume one attached state. Then, in the presence of changes in sarcomere length, dSL , the stiffness of this population of attached XB may be calculated. As has been shown (Kawai et. al., 1980, 1993), the stiffness of muscle fibers is a function of frequency; putatively, as a result of the underlying kinetics of actin myosin interaction. Thus, stiffness, as a dynamic transfer function, may be written in terms of its distortion and recruitment components as

$$\frac{dF}{dSL}(j\omega) = X_0 \frac{dN}{dSL}(j\omega) + N_0 \frac{dX}{dSL}(j\omega)$$

where the zero subscripted variables represent baselines around which variations occur and the two transfer functions on the right hand side of the equation represent respectively, the frequency dependence by which XB are recruited into the attached state when there has been a change in sarcomere length, and the frequency dependence by which the average distortion among attached XB change when there has been a change in sarcomere length.

We have shown elsewhere [Campbell et. al., 2001] that the distortional transfer function, $dX/dSL(j\omega)$, takes the form of a high-pass filter. Further, the coefficients of this dynamic transfer function depend entirely on sums, products, and sums of products of kinetic coefficients regulating steps leading away from the attached XB state. Of more interest in this work is the myofilament origins of $dN/dSL(j\omega)$ and how these

myofilament processes are expressed in the measured stiffness of cardiac trabecular muscle.

DISCUSSION

We can imagine three mechanisms by which XB may be recruited into attached states in response to dSL : 1) sliding filament mechanisms; 2) length-dependent myofilament kinetic steps; and 3) certain cooperative mechanisms by which transient changes in XB force influence the probability of state transitions. Mechanisms 1 and 2 result in **low-pass filter** type behavior in which $F(t)$, following a step increase in SL develops slowly and is sustained. Mechanism 3 results in a **band-pass filter** behavior in which $F(t)$ following a step increase in SL develops slowly but eventually dissipates and is not sustained. It has been shown in cardiac muscle that mechanism 1 is a small effect. Thus, it becomes important to distinguish between the relative importance of mechanisms 2 and 3 as means for length-dependent recruitment in cardiac muscle.

Mechanisms 2 and 3 are not confined to just the kinetic steps within the XB cycle but also involve the kinetics of regulatory protein steps in the transition between permissive states that allow myosin access to the actin binding site and nonpermissive states that do not (Campbell et. al., 2001). Thus, all the regulatory mechanisms on the thick and thin myofilaments may participate in length-dependent recruitment of force-bearing XB as seen through myocardial stiffness.

Constantly-activated, rat skinned trabecular muscle was subjected to ΔSL perturbations containing a broad spectrum of frequency components. The calculated cardiac muscle stiffness was decomposed into components representing high-pass, band-pass, and low-pass aspects of the response. The relative contributions of length-dependent kinetic steps and cooperative mechanisms in cardiac muscle length-dependence were assessed.

INTRODUCTION

Titin is a giant (up to 3,700 kDa) protein that constitutes an elastic half-sarcomere spanning filament system in vertebrate striated muscles. Titin is the major contributor to passive tension during physiological amounts of stretch in mammals such as humans, with the extracellular matrix (collagen) and the cytoskeleton playing secondary roles (Gregorio et al., 1999; Granzier and Labeit, 2002). A plethora of titin isoforms has been reported with expression that correlates with the tissue-specific diversity of myofibrillar elasticity (Freiburg et al., 2000; Cazorla et al., 2000). These differentially expressed titin isoforms have spring elements within their I-band segments that vary in composition and length. Because of titin's giant size, the molecular mechanisms that underlie differential splicing have remained unknown.

RESULTS AND DISCUSSION

To study splicing in more detail we determined titin's gene sequence in human and mouse. In both species we could identify only a single locus for titin. Titin isoform diversity results from this single gene locus by multiple splice cascades. The human titin gene contains 363 coding exons and two LINE-1 elements within the differentially spliced PEVK spring region. Their >99% similarity suggests that LINE-1 integration caused PEVK exon duplication in primates several million years ago. In mouse, one LINE element could be identified in the differentially spliced Z-disc region of the repetitive Z-repeat segment. Interestingly, a LINE integration was also recently identified in a mutant titin gene of the mdm mouse strain. This integration skips 4 exons from the N2A region and modifies splice patterns (Garvey et al., 2002). Thus, in both the mouse and human, integration of LINE elements in the titin gene has caused exon duplication and skipping events that can modify titin isoform splice patterns. This modification may influence titin's elastic properties since the PEVK exon duplication introduced additional spring elements.

SUMMARY

Significant differences between the mouse and human titin gene exist which point at recent evolutionary intragenic duplication events. These events contribute to the plethora of titin isoforms found today. Further characterization of titin isoforms expressed in different species is likely to provide molecular insights in how myofibrillar mechanics and titin structure are linked

A UNIQUE SEQUENCE OF TITIN, THE PEVK-DOMAIN, IS AN ENTROPIC SPRING THAT INTERACTS WITH ACTIN

INTRODUCTION

The PEVK-domain is a unique sequence within the giant muscle protein titin. The PEVK-domain, along with titin segments comprised of immunoglobulin-like (Ig) modules, earlier was shown to determine extensibility and passive-force development of skeletal and cardiac muscle sarcomeres (Linke et al., 1996). Recent results of several groups have also hinted at the possibility that PEVK-titin could interact with other sarcomere proteins. Here we studied functional properties of the PEVK-domain of cardiac titin by using a hybrid experimental approach.

METHODS

Single-molecule atomic force microscopy (AFM) was used to measure the force-extension behavior of cloned cardiac-PEVK polyproteins of the type (PEVK-Ig27)₃ (Fig. 1; cf., Li et al., 2001).

AFM Force Spectroscopy on PEVK Polyproteins

Figure 1: (A) (PEVK-I27)₃ construct stretched by AFM. (B) Force-extension curve and fit with wormlike-chain (WLC) model.

The AFM data obtained then were compared to the extensibility data of PEVK-titin previously established by immunoelectron microscopy in rabbit cardiac sarcomeres (Linke et al., 1999). To study whether the PEVK-domain and/or other regions of titin can interact with actin filaments, we employed the actin-myosin *in-vitro* motility assay (IVMA) (Fig. 2; cf., Kulke et al., 2001).

RESULTS AND DISCUSSION

We found that the results of AFM measurements could be readily applied to explain cardiac-PEVK extensibility in the sarcomere. The analysis revealed that both *in vitro* and *in situ*, cardiac PEVK behaves as an entropic spring with the properties of a random coil.

Possibly, however, the random coil exhibits mechanical conformations of different flexibility (Li et al., 2001).

Figure 2: Results of IVMA assays with titin constructs.

Actin-titin interaction was indeed detectable in the IVMA: cardiac-PEVK constructs slowed down the sliding speed of actin filaments over myosin; in contrast, Ig/fibronectin-like titin domains had no effect (Fig. 2). Interestingly, the PEVK effect was partially reversed in the presence of physiological concentrations of Ca²⁺. Co-sedimentation assays confirmed a weak Ca²⁺-modulated actin-binding propensity of the cardiac PEVK-domain. In the sarcomere, the actin-PEVK interaction may give rise to a viscous force component opposing filament sliding (Kulke et al., 2001). Thus, the PEVK-domain contributes not only to the extensibility of cardiac myocytes, but also affects contractile properties.

SUMMARY

Single-molecule AFM force spectroscopy and *in-vitro* binding tests show that cardiac PEVK-domain contributes to titin elasticity as a random coil exhibiting entropic-spring behavior, but—via binding to actin—also modulates contractile properties of cardiac-muscle sarcomeres.

TITIN INTERACTS WITH MURF-1 TO REGULATE SARCOMERIC M-LINE AND THICK FILAMENT STRUCTURE

Abigail S. McElhinny¹, Siegfried Labeit², and Carol C. Gregorio¹ (gregorio@u.arizona.edu)

¹Dept. of Cell Biology and Anatomy, University of Arizona, Tucson, Arizona, USA

²University Hospital, Mannheim, Germany

INTRODUCTION

The giant sarcomeric protein titin appears to have several essential roles in striated muscle. Recent studies have aimed to decipher titin's functions by investigating its unique ligands. Previously, a member of the muscle-specific RING finger protein, MURF-1, was found to bind titin's C-terminal A168-170 domains, located adjacent to the titin kinase domain in the M-line region of the sarcomere (Spencer et al., 2000; Centner et al., 2001). Structurally, this protein is comprised of an N-terminal RING domain, a MURF family conserved region, a B-box domain, coiled-coil domains, and an acidic tail. In this study, we aimed to investigate the functional significance of the interaction of titin with MURF-1 in cardiac myocytes.

METHODS

We expressed GFP-fusion constructs encoding defined regions of titin's M-line region and MURF-1 in primary cultures of embryonic chick cardiac myocytes. Immunofluorescence microscopy was utilized to examine potential phenotypes. MURF-1 bait constructs were used in yeast two-hybrid screens to identify novel MURF-1 binding partners.

RESULTS AND DISCUSSION

Strikingly, the majority of MURF-1 transfected cardiac myocytes exhibited severe disruption of the C-terminal region of titin compared to cells expressing GFP alone (Fig. 1). Triple labeling studies revealed that although titin's C-terminal region was disrupted in MURF-1 expressing cells, staining for titin's N-terminal region appeared in a regular, striated pattern. However, staining for myosin, myosin binding protein C (MyBP-C), and myomesin demonstrated that MURF-1 expression also perturbed thick filament structure. Unexpectedly, the structure of the actin-containing thin filaments, the I-band region of titin, and Z-line components appeared in typical striated patterns in the majority of MURF-1 transfected cells. An identical phenotype was observed in myocytes transfected with titin A168-170-GFP, but not in cells transfected with other titin M-line regions (domains M1-M2-M3 or M8-M9-M10), or with titin's Ser/Thr kinase domain.

Yeast two-hybrid screens of human heart and skeletal muscle cDNA libraries revealed that MURF-1 interacts with ubiquitin-conjugating enzyme-9 (Ubc-9) and isopeptidase-3 (ISO-T3), enzymes implicated in post-translational

Figure 1. Quantification of MURF-1-GFP and GFP expressing myocytes exhibiting disrupted staining for various sarcomeric components. Data presented as mean percentage of total transfected myocytes ($n > 50$ cells from > 2 experiments) with disrupted staining patterns \pm S.D. Titin epitopes are: A168-170 and AB5 (N-terminal), N2A (I-band) and T11 (N-terminal region).

modification pathways involving small ubiquitin-related modifier-3 (SUMO-3). MURF-1 also interacts with glucocorticoid modulatory element binding protein-1 (GMEB-1), a transcriptional regulator. Consistent with this, a portion of endogenous MURF-1 colocalized with GMEB-1-GFP fusion proteins in some nuclei.

SUMMARY

The results from our studies suggest that the interaction of titin with MURF-1 plays an important role in the structure of the sarcomeric M-line region and the thick filaments. Additionally, while disruption of titin's C-terminal region perturbs thick filament structure, it does not appear to affect the integrity of titin's I-band or N-terminal regions, the thin filaments, or the Z-lines. We speculate that MURF-1 may link myofibril signaling pathways with nuclear functions via its interactions with titin and GMEB-1.

MUTATIONS OF TITIN CAUSE DILATED CARDIOMYOPATHY

INTRODUCTION

Congestive heart failure (CHF) can result from various disease states with inadequate cardiac output. CHF due to dilated cardiomyopathy (DCM) is a familial disease in 20-30% of cases and associated with mutations in genes encoding cytoskeletal, contractile or inner nuclear membrane proteins (Seidman & Seidman, 2001). DCM is the most frequent indication of heart transplantation in young patients. We show that mutations in the giant muscle filament titin cause autosomal dominant DCM linked to chromosome 2q31 (*CM DIG*, Siu et al., 1999). The giant muscle protein titin serves several important functions in striated muscles: it directs assembly of contractile filaments, provides elasticity by its serial spring elements and, based on the presence of a C-terminal kinase domain, has a role in cell signaling. Furthermore a lot of splice isoforms in skeletal and cardiac muscles are known (Gregorio et al., 1999).

RESULTS AND DISCUSSION

Affected members of two large DCM kindreds (family A1, family MAO) suffer from autosomal dominant DCM with CHF of variable age of onset but absence of cardiac conduction defects or clinically detectable skeletal muscle disease. Linkage and haplotype analyses of DCM in both families revealed a 7.7 cM disease gene interval on chromosome 2q31. Among the more than 70 transcripts of the chromosome 2q31 DCM disease gene locus the gene for the giant muscle protein titin was considered an excellent candidate for DCM due to its high cardiac expression and central physiologic role in muscle assembly and function. On this base we deliberately chose titin and screened 313 of the 363 exons known to be expressed in cardiac muscle by direct sequencing of PCR amplified genomic fragments in both families.

In family A1, a segregating 2bp insertion mutation in titin exon 326 causes a frame shift, thereby truncating A-band titin. The truncated 2 mD protein is expressed in skeletal muscle but Western blot studies with epitope-specific antibodies suggest its proteolytic processing into a 1.14mD subfragment by site-specific cleavage C-terminally of the N2A domain, presumably within the PEVK domain. Interestingly, the N2A segment has been shown to interact with calpain 3 (Sorimachi et al., 1995).

Our data raise the possibility that the calpain 3 /titin complex may indeed cleave the titin polypeptide under specific circumstances, such as if the titin filament is damaged as in our case.

In another family (MAO) a titin missense mutation (2920T→C) was found in all affected family members. This mutation results in the substitution of a highly conserved tryptophane by an arginine at amino acid position 930 within an immunoglobulin domain (Ig-Z4) located near the Z-disc/I-band transition zone. The functional consequence of this mutation is unknown, it is likely that the β -sandwich structure of the Ig-Z4 domain is disrupted. Possibly, Ig module Ig-Z4 is a key domain for organizing the Z-disc, maintaining I-band elasticity or has other yet unknown functions.

SUMMARY

We have shown that mutations in the giant muscle filament titin (*TTN*) cause autosomal dominant dilated cardiomyopathy linked to chromosome 2q31. The identification of titin mutations should provide further insights into the pathogenesis of familial forms of congestive heart failure and myofibrillar titin turnover.

CHARACTERIZING TRANSIENT LOWER EXTREMITY KINEMATICS DURING THE IMPACT PHASE OF RUNNING

Mark Lake

Research Institute for Sport and Exercise Sciences, John Moores University, Liverpool, United Kingdom.
Email: M.J.Lake@LIVJM.AC.UK

INTRODUCTION

Transient loading of the lower limb during running ground contact has been implicated in many overuse-type injuries although the mechanism of load attenuation during impact remains to be established. Adequate characterization of impact transients can help further our understanding in this area. Rapid loading during running can be readily detected using a force platform and examining the rate of increase in the ground reaction force. But also detected from this data are oscillations in the trace which correspond to rapid movement phenomena occurring during the initial 10-30 ms (Lees, 1998). Undulations in the Fz curve are seen in a wide variety of published literature and several peaks are usually obtained in the initial portion of the continuous differential of Fz. These biological vibrations occurring during force loading are the focus of the present discussion.

METHODS

We have examined the oscillations by tracking high frequency movements of individual body segments using high speed displacement data (1000 Hz) and three dimensional accelerometry (e.g. Lake et al., 2001). Damped high frequency oscillations of 30-45 Hz were detected in the angular acceleration of the shank. These were typically damped within 100 ms of ground contact and were significantly modified by footwear. Using displacement data sampled simultaneously at 240 Hz and established data processing techniques (low pass butterworth filtering followed by numerical differentiation) to obtain movement velocities and accelerations, no oscillations in segmental motion were detected. In addition, the peak magnitudes of these lower limb movement transients were substantially attenuated. Filter cut-off frequencies (determined using residual analysis) were 15 Hz and 50 Hz for the 240 Hz and 1000 Hz displacement data, respectively. Therefore, it is not surprising that higher frequency signal above 30 Hz was completely removed from the 240Hz information. For analysis of high-frequency loading, such as impact or vibration, improved data processing techniques in the time-frequency domain have been proposed (e.g. Giakas et al., 2000). By adjusting filtering parameters according to the frequency content over time higher frequencies can be maintained in the derivatives of displacement data without sacrificing the signal to noise ratio.

VIBRATION DAMPING AND JOINT STIFFNESS

Oscillations and higher magnitudes of movement transients influence the calculation of joint kinetics using the traditional inverse dynamics procedure. To evaluate movement adaptation to loading conditions during locomotion, joint 'stiffness' has often been quantified by assuming a linear relationship between joint moment and angular displacement. We have found highly non-linear vibrations in such joint stiffness measures during running. To adequately determine the control and damping of these high frequency vibrations, improved calculations of dynamic joint stiffness are required that are frequency dependent. Frequency domain sinusoidal models of muscle-tendon-mass systems have recently been used to predict the damping of limb vibration during hoof impact in horses (Wilson et al., 2001). Such approaches should enhance our understanding of natural shock attenuation mechanisms to protect the body from injury and how we adapt to changes in external loading conditions during running.

SUMMARY

High frequency oscillations of the lower limb have been found during the impact phase of running. They are modified by external loading conditions and characterise movement adaptation to the severity of foot-ground impact. Methodological considerations needed to adequately capture these spring-like joint vibrations include suitable sampling frequency and/or processing of the kinematic data. Developments in the calculations of vibration damping and joint stiffness setting during running are likely to occur in the frequency domain.

SPRING-LIKE FORCE GENERATION BY THE LEG IN RUNNING

Claire T. Farley¹ and Cassie Shigeoka²

¹Dept. of Kinesiology and Applied Physiology, Univ. of Colorado, Boulder, Colorado, USA. Claire.farley@colorado.edu

²Department of Integrative Biology, Univ. of California, Berkeley, California, USA.

INTRODUCTION

When humans and other animals use running gaits, their legs generate force in a spring-like pattern during the ground contact phase. The leg is often modeled as a linear spring because a simple spring-mass model, consisting of a linear “leg spring” that represents leg behavior and a point mass that represents the runner’s body mass (McMahon & Cheng, 1990), mimics the *pattern* of movement of the center of mass in many quadrupedal and bipedal mammals, including humans (Farley et al., 1993). Indeed, a runner’s leg exhibits a spring-like force-displacement relationship. Although the model’s leg spring is passive, the muscles in a runner’s leg generate force actively to produce the spring-like behavior. Thus, the leg’s spring-like force-displacement relationship can be interpreted as representing a rule for the control of leg force generation.

Because this force-displacement relationship is produced by active muscles, humans can modulate its slope (i.e., “leg stiffness”) to control running dynamics. For example, when runners use faster stride frequencies or encounter softer surfaces, they increase leg stiffness dramatically (Farley & Gonzalez, 1993; Ferris et al., 1998). As a result of leg stiffness adjustment, the series combination of leg and surface stiffness remains the same regardless of surface stiffness. Thus, by controlling the force-displacement relationship of the leg, runners adjust their dynamics.

The qualitative similarity between the movements of a runner and a spring-mass system inspired the development of a spring-mass model for running (McMahon & Cheng, 1990). Our goal was to quantify the accuracy of a spring-mass model’s prediction of the trajectory of a runner’s center of mass. This information will allow us to assess whether a spring-mass model provides a rigorous quantitative framework for understanding the rules underlying the control of running.

METHODS

Ten subjects (body mass = 55.5 ± 5.6 kg, mean \pm S.D.) ran at 3.7 m/s on rubberized foam surfaces covering two force platforms while being videotaped in sagittal view. We used three surfaces: a continuous “hard” foam surface ($k_{\text{surface}} = 505.6$ kN/m), a continuous “soft” foam surface ($k_{\text{surface}} = 37.3$ kN/m), and a surface comprised of alternating hard and soft sections sized so that a runner’s footfalls alternated between hard and soft sections. We determined the trajectory of the center of mass (COM) by double integration of its acceleration

derived from the vertical and horizontal components of the ground reaction force.

We used Matlab to simulate the spring-mass model. We input body mass, leg length, COM velocity at touchdown, and leg angle at touchdown. We iteratively found the leg spring stiffness value that predicted the COM trajectory with the least error. We quantified the error by expressing the average difference between the predicted and actual COM vertical displacement for all the timesteps in a trial as a % of the actual vertical displacement.

RESULTS AND DISCUSSION

On each surface, the spring-mass model predicted the center of mass trajectory with remarkable accuracy. The mean error was 4.3% ($\pm 0.9\%$, S.E.M.) and 6.1% ($\pm 0.9\%$) for the hard and soft continuous surfaces respectively. The error was not larger on the alternating surface: 4.2% ($\pm 0.7\%$, hard sections) and 5.7% ($\pm 0.8\%$, soft sections). Runners maintained normal spring-like dynamics despite surface property differences by using a greater leg stiffness on the soft versus the hard surface (16.1 ± 3.5 kN/m vs. 12.1 ± 2.5 kN/m, $p < 0.05$) as observed previously (Ferris et al., 1998).

SUMMARY

A spring-mass model predicts the COM trajectory with errors less than 6.1% regardless of surface properties. Thus, it is reasonable to model leg force generation with a linear spring. This observation suggests that runners somehow coordinate the force generation by many muscles so that the overall leg behaves like a spring on a range of surfaces. The spring-mass model should provide quantitative information about the determinants of running dynamics, and thus advance our understanding of the control of locomotion.

PLANTAR PRESSURES, SHOCK AND REARFOOT MOTION DURING RUNNING ARE THESE MEANINGFUL QUANTITIES FOR THE PREDICTION OF RUNNING INJURIES ?

Ewald M. Hennig
Biomechanics Laboratory, Universitaet Essen
Essen, Germany, ewald.hennig@uni-essen.de

INTRODUCTION

Injury surveys on runners have concluded that the occurrence of overuse injuries is the most common reason for runners to quit running and to continue with other kinds of physical exercise (Koplan et al., 1995). Among many other authors Messier et al. (1988), Duffey et al. (2000), Hreljac et al. (2000), and Bennett et al. (2001) showed that excessive rearfoot motion and increased shock can be identified as risk factors for injuries in runners. Therefore, pronation control and cushioning are still considered to be the main concepts for injury prevention in running shoe design. However, conclusive epidemiological and clinical proofs for these concepts are still missing. Plantar in-shoe pressure measurements provide comprehensive information about the interaction of the individual foot anatomy with the shoe. No studies, however, have identified specific pressure patterns with running injury risk to date.

METHODS

During the last 12 years our laboratory has performed 7 running shoe tests for a consumer product test agency in Germany. On the basis of more than 12000 measurements (140 runners) the biomechanical properties of 116 different shoe constructions were evaluated with regard to plantar in-shoe pressures, shock, and pronation properties. All products in the shoe tests were also worn by each of the participating runners for a distance of 10 km on varying terrain. Perception scale (15 point) shoe property ratings were given by the participants after completion of the 10 km run. All shoes were also tested mechanically, using an impacter devices to quantify midsole material properties. Comparing the technical and biomechanical data with the subjective evaluations from the runners in a questionnaire, several conclusions could be drawn.

RESULTS

Data from 17 pairs of shoes (test from the year 2000) showed that neither the subjective rating of shock ($r^2 = 0.01$) nor the peak tibial accelerations from the biomechanical tests ($r^2 = 0.08$) showed relationships to the impacter peak g results. The subjective perception of rearfoot motion control revealed only low correlations with the biomechanically determined maximum pronation ($r^2 = 0.20$) or pronation velocity ($r^2 = 0.01$). From the biomechanical tests it was found that maximum pronation ($r^2 = 0.04$) and peak pronation velocity ($r^2 = 0.01$) did not show any relationship to shock, as measured by the peak acceleration. This finding defies assumptions that good shock absorbing shoes do not provide sufficient support

against overpronation. The highest correlations between any of the perception against the biomechanical variables were found for plantar pressure data (figure 1). Footwear with reduced forefoot pressures were rated by the runners as better overall performing shoes.

Figure 1: Shoe Performance Rating vs. Forefoot Pressures

Our shoe tests during the last 12 years showed that overall performance rating is closely related to the perception of comfort. Therefore, peak plantar pressures seem to be a key variable for the perception of comfort. It is unlikely, however, that this variable is a strong indicator for the occurrence of injuries. The influence of running shoe design on the loading behavior of the foot is best described with a relative load analysis. Such an analysis will identify percentile load bearing of anatomical structures across the plantar surface. Relative load analyses would be well suited to draw conclusions from load patterns of specific shoe designs with running shoe based injury surveys.

INDIVIDUAL VS. GROUP ANALYSES IN DISTANCE RUNNING BIOMECHANICS

Keith R. Williams

Human Performance Laboratory, University of California, Davis, Davis, CA, USA (krwilliams@ucdavis.edu)

INTRODUCTION

The goal of much research in distance running biomechanics is to identify mechanical mechanisms involved in injury occurrence or in metabolic energy expenditure (economy). In addition to the general goal of furthering knowledge, there is the ultimate aim of understanding more about how to improve an individual's ability to perform or to run injury free.

Clinicians have often used a case-study approach to identify relationships with injury, but these methods have been little used in scientific studies due to an inability to statistically verify implied relationships. Many biomechanical studies have involved groups of runners, sometimes using subsets based on injury, sometimes comparing groups differing in economy or the magnitude of impact forces. While such studies have identified some likely causal relationships, statistical results are often relatively weak and usually provide few specific guidelines applicable to individual runners. This paper addresses some of these issues as they relate to furthering our understanding of the relevant mechanisms in distance running.

METHODS

Examples of published and new data are used to examine the relevance of relationships among variables to individuals, focusing on interactions between selected biomechanical data and measures of economy or incidence of injury.

RESULTS AND DISCUSSION

An example of group analyses related to injury can be found in work published by Viitasalo and Kvist (1983) and Messier and Pittala (1988), who found shin splints to be related to excessive pronation or pronation speed. Table 1 shows several biomechanical measures for a subset of elite female distance runners who all had a history of shin splints. Maximum pronation angles were not excessive, and while two showed high pronation speed values, most pronation measures were within normal ranges. The general premise from the group studies did not hold well for these individuals.

Another example can be found for group studies evaluating biomechanical measures and running economy. Heise and Martin (2001) and Williams and Cavanagh (1987) both found relatively weak but significant correlations between ground reaction force (GRF) measures and economy. The vertical force patterns from two trained runners with similar economy measures shown in Figure 1 illustrate that large differences can exist in GRF's with little effect on metabolic costs.

Figure 1: Vertical ground reaction forces from 20 trials for each of two subjects who had similar running economy.

SUMMARY

These and other examples highlight the difficulty in applying results from group studies to individuals. An alternative that can be more successful is to evaluate specific relationships within the individual. This method may also provide a further and perhaps more successful means of identifying mechanistic relationships between biomechanical measures and injury or metabolic energy expenditure.

DYNAMIC VARIABLES AND RUNNING INJURIES

Gert-Peter Brüggemann, Adamantios Arampatzis, Wolfgang Potthast Institute for Biomechanics, German Sport University of Cologne, Cologne, Germany, brueggemann@dshs-koeln.de

INTRODUCTION

Excessive impact forces, overpronation, excessive mileage and previous injuries have been proposed as major factors for acute and chronic running injuries (e.g. van Mechelen 1992, Robbins et al. 1990). The running shoe was identified to influence impact forces, foot eversion and hence the eversion moments at the ankle joint. Consequently running shoes have been designed to control the impact forces, the eversion moment at the ankle joint, and the torsional moment at the tibia. Recent prospective studies did not support the general and strong association between impact force, eversion moment, tibia shear stress, and running injuries.

The purpose of this paper is to approach to an understanding of a possible association between dynamic variables in heel-toe running, running injuries and performance enhancement.

DYNAMIC VARIABLES

Impact forces in heel-toe running occur when the foot hits the ground and reach their maximum earlier than 50ms after the first ground contact. The magnitude of the vertical impact force peak varies substantially for different running velocities. Unexpected results are that the hardness of the shoe midsole has only a minimal systematic influence on the external impact force peaks (Bates 1989). The resultant internal forces and moments in the structures of the lower extremities are not systematically determined by the hardness of the midsole of running shoes (Cole et al. 1995). Calculations indicate higher joint contact forces in the push-off phase than during the impact. Based on these calculations it was speculated that non excessive impact forces and the related internal joint contact forces during running might not be a major factor for the development of injuries in running (Scott & Winter 1990). Results of a prospective study do not show differences of short term running injuries between subjects with high or low external impact force peaks (Bahlsen 1989). Foot inversion does not act as predictor for an increase in running injuries. From the findings on impact peak forces and the associated foot eversion one can speculate that the eversion moment has no strong relation to running injuries.

INJURIES AND FUNCTIONAL ADAPTATION

Runners did not show a higher incidence of osteoarthritis than non-runners (e.g. Eichner 1989). Some studies showed that in certain cases shock-absorbing insoles reduce the frequency of injuries (e.g. Milgrom et al. 1992). A decrease of impact forces or internal joint loading due to the insoles was not quantified in these studies. Interestingly shock-absorbing insoles did not reduce the incidence of stress fracture (Gardner et al 1988). The unsystematic results lead to the conclusion that shock attenuation might not be the ultimate reason for running induced injuries.

Biological responses to impact loading have been shown to improve bone quality (Grimston & Zernicke 1993). While the

thickness of cartilage was not found to adapt to mechanical stimulation through running, the joint size was shown to be modulated during growth (Eckstein et al. 2001).

Based on these findings one cannot conclude that the dynamic variables impact force and loading rate are the most important factors in the development of chronic or acute running-related injuries.

DYNAMIC VARIABLES AND PERFORMANCE

The surface stiffness affects significantly the running economy (Kerdok et al. 2002). Running with comfortable and cushioning shoes might be combined with less energy consumption (Nigg 2001). From that one can conclude that muscle force production must be more efficient under the more comfortable footwear conditions. A comfortable shoe condition can be assumed to be associated with a cushioned midsole or a lateral crashpad. Recent in vivo measurements of Achilles tendon force indicate a faster and more pronounced decrease of the Achilles tendon stress during impact phase in running with harder and non comfortable shoes than in comfortable and cushioning shoes. From the pronounced plantar flexion of the ankle joint at foot strike with the non cushioning footwear one can conclude that the triceps surae muscle shortens and works at the ascending limb of the force length relationship. When running in comfortable shoe condition the contractile element can work at a length closer to the plateau of the force length relation.

The deformation of the midsole or the crashpad of a running shoe decreases the plantarflexion moment at foot strike, the rate of length change of the muscle tendon unit of the triceps surae and allows the contractile element to work more close to the optimal length. From that one can conclude that a decrease of impact peak force and the loading rate through a cushioning midsole or a lateral heelpad of a running shoe will increase the force production potential of the plantarflexors of the ankle joint and therefor increase the economy of muscular work and performance.

THE INFLUENCE OF VEHICLE ROLL RATE ON NECK LOADING DURING CONTROLLED VEHICLE-TO-GROUND IMPACTS

Catherine Ford Corrigan¹, Peter A. Crompton¹, Jeffrey Croteau²
Exponent Failure Analysis Associates, ¹Philadelphia, PA; ²Natick, MA

INTRODUCTION

Cervical spine injury potential during vehicle rollovers is a function of numerous variables, several of which are associated with the dynamics of the rolling vehicle. Significant roof-to-ground impacts that occur adjacent to an occupant's seated position have been associated with the potential for severe cervical spine injury in both crash test series and field studies (Orlowski, 1985, Bahling, 1990, Huelke, 1983). Consultants in the applied biomechanics field are often asked to determine the cervical spine injury mechanisms associated with a specific rollover accident. However, the extent to which specific dynamic parameters associated with the rolling vehicle contribute to cervical spine injury potential has not been well-documented. This is in large part due to limitations in previous rollover test procedures, which did not allow for controllable and repeatable roof-to-ground impacts. In this study, a novel and highly accurate rollover test apparatus was used to produce pre-defined vehicle to ground impacts. We report on the first use of this apparatus to investigate the effect of vehicle roll rate on neck loading.

METHODS

The Controlled Rollover Impact System (CRIS) (Cooper, 2000) utilizes a modified semi-trailer to release a suspended vehicle from a pre-determined drop height and roll angle. The CRIS apparatus incorporates mechanisms that allow the vehicle's initial roll, pitch, yaw, lateral translational and vertical kinematics to be predetermined by the investigators. Two tests were performed using the same make and model vehicle to examine the effect of vehicular roll rate on neck axial loading. To mitigate potential differences in roof deformation between the tests, each vehicle was tested with a reinforced roof. Both tests utilized a nominal 6.7 m/sec lateral translation velocity (passenger-side leading), a 46 cm drop height, and impacted the ground at a roll angle of 190 degrees. In the first test (Trans-Drop), the vehicle was released with zero roll velocity. In the second test (Spin-Drop), a constant 360 degree per second roll rate was introduced, with all other variables associated with the roof-to-ground impact held constant.

Hybrid III 50th percentile anthropomorphic test devices (ATDs) instrumented with upper neck load cells were restrained in the driver's seated position for each test. The ATDs were held in position by additional harnesses while the desired translational and rotational velocities were achieved. Once vehicle velocities were stabilized prior to vehicle release, the harnesses were pneumatically released so that the ATDs would be restrained only by the vehicle's three-point belt system during the roof-to-ground impact. Both onboard and ground-based high speed cameras were utilized to capture details of the roof-to-ground impacts. All data were collected in accordance with Society of Automotive Engineers J211.

RESULTS

In both tests, the ATD's head was in contact with the vehicle's roof just prior to vehicle release. In the Trans-Drop test, release of the vehicle resulted in a small displacement of the ATD's head away from the roof, after which the ATD and the vehicle fell at essentially the same velocity. Peak axial neck load occurred 24 msec after impact in the test and 22 msec after impact in the Spin-Drop test. Addition of the 360 degree per second roll rate increased the peak axial neck load 21.6% relative to the Trans-Drop test (9120 N versus 7500 N, Fig. 1).

Figure 1: Axial neck load versus time

DISCUSSION

Biomechanical studies have identified velocity-based injury criteria when the neck is called upon to stop the moving torso (McElhaney, 1979). In the case of vehicular rollovers, a vehicle's roll rate can add substantially to the roof's and to the occupant's velocity relative to the ground just prior to impact, thus increasing the injury potential that results from the moving torso transmitting force to the cervical spine. The data presented here directly demonstrate the importance of considering a vehicle's roll rate, in addition to its translation rate and drop height, when evaluating injury potential of specific rollover accidents.

Future testing with the CRIS apparatus will allow detailed study of occupant, vehicle, restraint and injury prevention parameters in a controlled and repeatable fashion. This will result in an improved overall understanding of neck injury mechanisms that occur during rollover accidents.

BIOMECHANICAL ANALYSIS OF ACUTE LUMBAR INTERVERTEBRAL DISC LOADING

Dan Girvan and Elaine R. Serina

Piziali and Associates, San Carlos, California, USA

INTRODUCTION

Lumbar intervertebral disc (IVD) injuries are often claimed as a result of vehicular, industrial, or other types of incidents. These injuries can result in significant financial costs, physical disability, and loss of productivity. Biomechanical testing can be used to determine the magnitude and type of loading experienced by the lumbar spine in a particular incident or during a specific activity. In particular, acceleration measurements can be useful to assess lumbar loading on subjects exposed to sudden vertical motions. A biomechanical analysis can then be performed to assess whether the claimed lumbar IVD injuries resulted from a particular incident.

METHODS

Because axial compression tends to be a significant factor in causing lumbar IVD injuries, it is most useful to measure z-axis (vertical) accelerations. For seated vehicle or equipment occupants, an accelerometer (Kistler Type 8304B10 10 g) was placed between the operator's buttocks and the seat to measure vertically applied accelerations. The accelerometer was mounted in an ISO 7096-1982 seat pad. In tests with a standing occupant (e.g., elevator emergency stops), the accelerometer was mounted to the floor next to the test subject. The data was collected with an IOTech DaqBook 216 16-bit data acquisition system (1000 Hz sampling frequency).

RESULTS AND DISCUSSION

The tested activities included operating a fork lift in which a wheel dropped through a wooden floor, operating a railroad tie remover/insert machine, driving over railroad tracks and speed bumps, and emergency elevator stops. Figure 1 shows the vertical acceleration time-history produced at the seat-buttocks interface while operating a railroad tie remover/insert machine.

Figure 1: Tie Insert/Remover -- Operation

These measurements can be compared to the accelerations produced during typical activities such as sitting down into a seat. The results show that sitting down in the operator's seat produced higher peak vertical loading than the machine operation (Figure 2). The forces applied to the spine in the

incident under study can be determined by multiplying the measured accelerations by the effective mass (i.e., the upper body mass). The peak applied force can be compared to static spinal forces produced during daily activities. The lumbar compressive forces during activities such as lifting and postural changes can be predicted by computer models of the low back (Chaffin and Andersson, 1991).

Figure 2: Tie Insert/Remover--Sit into Seat

This analysis technique can be a useful tool in determining whether a lumbar IVD was injured in a particular incident. If the measured loads in a particular incident are comparable to or less than the loading experienced during activities of daily living, there is no biomechanical rationale for how the given incident could have caused the lumbar IVD injury. Further analysis may be necessary if the incident loads are greater than activities of daily living.

This methodology analyzes the magnitude of loads applied to the lumbar spine. Further evaluation of the nature of the loading and IVD disc injury mechanics should be considered. Some studies indicate that disc bulges and herniations result primarily from degeneration or fatigue loading (Adams and Hutton, 1985; Gordon, *et al.*, 1991). Investigators that have produced disc injuries from acute loading have found that these injuries are accompanied by other bony or ligamentous injuries (Adams and Hutton, 1981). Therefore, a comprehensive biomechanical evaluation should consider IVD injury mechanisms as well as an analysis of the loading.

SUMMARY

Vertical acceleration measurements can help in assessing whether a particular event caused lumbar IVD injuries. The measured accelerations can be compared to accelerations produced in typical activities. Additionally, the forces applied to the spine can be estimated and compared to forces produced by lifting and postural changes.

BIOMEDICAL ASPECTS OF HELMET DESIGN

James McElhaney¹ and William Newberry²

¹Department of Biomedical Engineering, Duke University, Durham, NC, USA

²Exponent® Failure Analysis Associates, Phoenix, AZ, USA, wnewberry@exponent.com

INTRODUCTION

Brain and cervical injuries from contact sports and vehicular accidents are a continuing major problem in our high-speed society. The use of helmets is an attempt to reduce the risk of injury in various activities including motorcycle, bicycle and equestrian riding, football, baseball, ice hockey, rock climbing, certain hazardous industrial operations and, of course, the military. Helmets are quite effective in distributing the force of a head impact over the head thus reducing the risk of skull fractures. Their spherical shape sheds blows changing what would have been a direct blow into a glancing blow. The deformation of the helmet liner manages the energy of the blow and reduces the force or stress applied to the head. But helmets offer little protection to the cervical spine. This paper will discuss the limitations of designing a helmet that offers both head and cervical spine protection in head impact situations.

METHODS

Head and neck injury criteria were developed from the literature. Experiments that developed load-deflection criteria for representative helmet types were performed. Experiments that developed cervical spine deformation and force transmission characteristics were performed. Experiments that compared neck loads in the helmeted and unhelmeted Hybrid III ATDs when swung into a rigid barrier were performed. These various experimental data were analyzed to better understand the biomechanical limitations of helmets to provide significant protection from catastrophic cervical injuries.

RESULTS AND DISCUSSION

Load-deflection tests indicate that the typical football, bicycle, equestrian, baseball and motorcycle helmet with a deformable liner produce a stiffening curve when loaded between an external surface and the head. Since the area under the load-deflection curve is the energy/work expended in producing the deformation, this is an undesirable characteristic that occurs because the area of the crush surface increases during deformation.

Using head deceleration of 250 g as a brain injury threshold, the available helmet crush stiffness would be optimized by having the liner bottom out at a force equivalent to 250 g times the head and helmet weight. For the 50% male head, this would equate to approximately 14,500 N applied to the helmet. A typical motorcycle helmet liner bottoms out at approximately 2 cm deformation. This establishes an energy management level of approximately 150 Nm for the liner, when optimized for head protection. However, because in an axial compression mode the average male's cervical spine

fails at approximately 3,800 N, the linear helmet only manages approximately 10 Nm before a compression fracture of the cervical vertebrae occurs.

In addition, catastrophic axial compression of the cervical spine occurs when the neck is aligned with the head and torso and trapped so that the inertia force is transferred through the cervical spine. This so-called torso augmentation means that instead of simply managing the kinetic energy of the head and helmet to protect the neck, the helmet must also manage the dynamic mass of the neck and torso. To further compound the problem, cadaver tests and mathematical models indicate that the head starts to rebound before the peak neck loads occur.

This analysis was verified by experiments using a Hybrid III ATD with a six-axis cervical load cell. The dummy was swung like a pendulum into a wall with and without a helmet. The results indicate that a helmet reduces HIC values by 86% but reduces neck compression by only 22%. Since our tests indicate the Hybrid III neck is much stiffer than a human neck, neck loads in humans under similar circumstances would be reduced by a lesser amount.

SUMMARY

Helmets cannot provide significant protection to the cervical spine in axial compression because: 1) the tolerance levels of the brain and skull are so much higher than the cervical spine; 2) the torso augmentation factor requires the helmet to manage four to five times more energy for cervical spine protection; and, 3) the phasing of cervical spine loading lags the peak helmet loads so that the helmet is unloading before cervical failure occurs.

THEORETICAL MODEL STUDIES OF FLUID-SOLID INTERACTIONS IN THE CERVICAL SPINE DURING LOW-SPEED POSTERIOR SHOULDER IMPACTS

Peter F. Niederer¹, Kai-Uwe Schmitt¹, Markus H. Muser², Felix H. Walz²

¹ Institute of Biomedical Engineering, ETH Zurich, Switzerland

² Working Group for Accident Mechanics, Zurich, Switzerland

INTRODUCTION

Minor soft tissue injuries of the cervical spine which are caused by posterior shoulder impacts at a low loading level represent an important public health issue because they are sometimes associated with long-term impairment (“Whiplash-Associated Disorders”). Such injuries are typically conveyed during low-speed rear-end automobile impacts. A number of hypotheses has been formulated in order to explain the occurrence of potentially harmful neck injuries at apparently subtraumatic loading levels. Among them, interactions between fluid compartments and solid structures have been postulated, in that relative motions of fluids vs. solids cause viscous shear stresses and pressure peaks which may have an adverse influence, *e.g.*, on cellular membranes. This hypothesis is supported by a number of experimental findings [1, 2].

METHODS

Mathematical modeling approaches lend themselves for a quantification of fluid/solid interactions under loading conditions which have to be expected under typical impact situations of interest here. In the present study, two modelling strategies have been applied. First, an idealized fluid/solid system is considered which is exposed to an acceleration pulse. The geometry (Figure 1) is chosen such as to represent a fluid-filled tube whereby an analytic solution can be found. Second, a neck model on the basis of a Finite Element formulation has been developed which includes vertebrae, discs, muscles, tendons as well as a representative fluid space (part of the *plexus venosus*, Figure 2). Initial and boundary conditions are applied which correspond to typical low-speed rear-end impacts (change of velocity $\Delta v = 15$ km/h, maximal acceleration level $a_0 = 5$ g).

Figure 1. Fluid-filled tube [radius r_0 , axial flow velocity $v(r, t)$] which is subjected to an acceleration pulse, a_0 .

Figure 2. FE model of the human neck: Calculated motion sequence resulting from a $\Delta v = 15$ km/h posterior impact. The model of a venous blood vessel is included which runs along the cervical spine (The “S-shape” configuration characterizes a momentary shape of the cervical spine during the impact response and corresponds to the phase which is presently assumed to be critical).

RESULTS

The analytical model shows, that the level of shear stresses caused by fluids and acting on accelerated surfaces in fluid-filled bodies depends essentially on the size and orientation of the fluid space under consideration. Accelerations thereby exhibit a stronger influence than the duration during which they act [3]. On the basis of the presently available information with respect to cellular tolerances it cannot be excluded that critical levels are reached even in a low speed impact scenario. Calculated pressure peaks, in turn, were compared [4] with measurements performed in animal (pig) as well *post mortem* human subjects and they were found to remain within physiological limits.

Stephen W. Rouhana

Ford Motor Company, Dearborn, Michigan, USA

INTRODUCTION

Crash test dummies are important tools in the development and assessment of automotive safety systems. However, to obtain reasonable results, the mechanical response of these devices to impact should be similar to that of the human body, a characteristic known as biofidelity (Rouhana 2001). The objective of this work was to develop a dummy abdomen with injury assessment capability and good biofidelity. This was a multi-faceted research program encompassing biomechanics, instrumentation and mechanical design (Rouhana et al 2001).

METHODS

Previous biomechanical studies demonstrated the need for rate-sensitivity to achieve abdominal biofidelity and some past efforts with fluid-filled elements gave promising results. Therefore, a fluid-filled bladder concept was chosen for the new crash dummy abdomen. After a significant development effort, a silicone gel-filled, silicone shell abdominal insert design was selected for further test and evaluation (Figure 1).

The biomechanical response targets (force-deflection corridors) used to design the new abdominal inserts were obtained from a human cadaver study performed under contract at the University of Michigan Transportation Research Institute (UMTRI; see Hardy et al 2001). This study utilized a variety of loading conditions that might be encountered in an automotive collision. The new abdominal inserts were tested on the bench and *in situ* in Hybrid III dummies. Most of the in-dummy tests were performed at UMTRI, under identical test conditions as the cadaver study, utilizing a powered pendulum, pneumatic lap-belt loading device and/or airbag impact simulator.

RESULTS AND DISCUSSION

Figure 2 shows the force-deflection response of the silicone gel-filled, silicone shell abdominal insert compared with the force-deflection corridor developed from the UMTRI lap belt loading condition tests.

SUMMARY

While the amount of rate-sensitivity achieved was not large, when tested as a system with abdomen *in situ* and the dummy chest jacket on, the rate sensitivity was adequate and appropriate for the automotive environment. Moreover, the biofidelity of the abdominal insert in rigid-bar, seat belt and simulated airbag loading conditions was good.

Figure 1: Front view of abdominal insert with electrodes bonded inside of the bladder for deflection measurement.

Figure 2: Force-deflection response of abdominal insert in a belt test compared with the human cadaver belt corridor.

The response of the abdominal insert was an aggregate response of the dummy's entire abdominal area and did not address differences in upper versus lower abdominal response, or solid versus hollow organs. While the abdomen developed demonstrated good biofidelity, some work remains to be done before it can be used in crash testing.

CUMULATIVE LOADING AS AN INJURY MECHANISM: TISSUE CONSIDERATIONS

Jack P. Callaghan

Department of Human Biology and Nutritional Sciences, University of Guelph, Guelph, Ontario, Canada jcallagh@uoguelph.ca

INTRODUCTION

Research examining cumulative loading of the spine has demonstrated the potential to identify individuals more likely to report low back pain (LBP) (Kumar, 1990; Norman et al., 1998). These studies have examined cumulative exposure in the workplace and compared the reporting of low back pain in case subjects to the magnitude of exposure in a control population. This approach, while beneficial for establishing a relationship between LBP and cumulative loading, has done little to develop a standard or threshold tolerance value for cumulative loading exposure. To date cumulative loading is calculated as the unweighted integration of low back joint forces without any consideration to tissue modifying factors such as magnitude (percent of maximum strength) or rate (rest work interaction).

Historically the investigation into tissue tolerance has primarily focused on single cycle destructive compressive testing of spinal motion segments in-vitro. While it is acknowledged that compressive tolerance values can be modified by factors such as loading rate, gender, and age a single tolerance has been adopted for acute compressive loading (i.e. NIOSH). Repetitive loading has recently gained increased attention by both ergonomists and researchers. While there has been a relative scarcity of in-vitro tissue testing, it has been examined by researchers as early as the 1950s (Hardy et al., 1958). Both Liu et al. (1983) and Adams and Hutton (1983) demonstrated that in-vitro repetitive compressive loading can generate injuries at a submaximal level. However, neither of these studies reported the relationship between magnitude of loading and the number of cycles to failure.

The purpose of this paper is to examine current tissue research to determine if there is support for the cumulative injury scenario and provide a tissue-based rationale for developing a single threshold tolerance value based on tissue injury mechanisms in the low back.

METHODS & RESULTS

An examination of data from recent research was performed, in some cases additional calculations were performed to determine the cumulative spine loading. The work of Hansson et al. (1987) and Brinckmann et al. (1988) demonstrated a non-linear relationship between the repetitive in-vitro compressive testing and cycles to failure (Figure 1). When cumulative loading to failure is calculated for the data of Brinckmann et al. (1988) a linear trend is evident in the samples that failed within 5000 loading cycles (Figure 1). This lack of a single cumulative compression magnitude linked to injury was also present in the work of Callaghan and McGill (2001) examining disc herniation in a repetitive loading scenario (Figure 2).

Figure 1: Left Y Axis: Non-linear trend between magnitude of compressive loading and cycles to failure. **Right Y Axis:** Cumulative compression and cycles to failure (adapted from Brinckmann et al., 1988).

Figure 2: Cumulative loading for two spine specimens.

DISCUSSION & CONCLUSION

An unweighted single cumulative threshold tolerance value is not supported by current in-vitro research. The interplay between magnitude and cycles to failure (Hansson et al., 1987; Brinckmann et al., 1988) when taken together with the lack of a single cumulative value corresponding with injury (Callaghan & McGill, 2001), indicates that the magnitude of cumulative exposure will need to be incorporated in work towards setting a standard for cumulative exposure.

USING CUMULATIVE SPINAL LOADING TO ASSESS JOBS, ENGINEERING, AND ADMINISTRATIVE CONTROLS: A SPINAL PERSPECTIVE

Mardy Frazer

Ergonomics Initiative, Faculty of Applied Health Sciences, University of Waterloo, Waterloo, Ontario, Canada

INTRODUCTION

Peak and cumulative forces on spinal structures have been identified as significant and statistically independent risk factors for reporting low back pain (LBP) (Norman et al., 1998). However, current field tools do not account for cumulative spinal loading explicitly so this risk factor is not easily quantified. Thus, when making change to reduce risk, the impact of any specific engineering or administrative control remains unknown. For example, job rotation is often cited as an administrative control for reducing cumulative loading risk, but, evidence of this is difficult to find. This presentation uses a software based, biomechanical modeling approach to calculate, combine and interpret both peak and cumulative spinal loading parameters for two manufacturing jobs to illustrate the risk of injury associated with peak and cumulative loading. The effect of job rotation, and a specific engineering intervention are also evaluated.

METHODS

A 2-D link segment model is used to estimate the L4/L5 moment and reaction forces. The job being analyzed is broken down into specific actions. The number of repetitions, and duration of, each action are entered. For each action the mannequin is positioned to match the job's posture. The direction and magnitude of the forces acting on each hand are entered. The model then estimates the peak and cumulative spine loads. Cumulative spinal loading is estimated by modeling the spinal load time history as a sequence of square waves. These values are compared against an epidemiological database for the reporting of low back pain and presented as a Low Back Pain Reporting Index (LBPRI) score ranging from 0.0 to 1.0 (the lower the score the better). A Combined LBPRI score is also produced from peak (hand load, reaction shear) and cumulative (moment) variables. Two automotive manufacturing jobs were assessed using the software. The effect of a specific engineering change, which stood workers more upright, was assessed for one of the jobs. Finally, a series of job rotation scenarios were simulated and evaluated.

RESULTS AND DISCUSSION

The peak and cumulative spinal loading parameters and their respective LBPRI are presented in Table 1. If only peak

loading is considered, the risk of reporting LBP is minimal. For job B-Pre the cumulative moment LBPRI of 0.88 reflects a different scenario. The Combined LBPRI of 0.81 indicates a high probability of LBP being reported due to the demands of this job. The engineering intervention reduced the Combined LBPRI to 0.54 (Job B-Post). Job rotation did not result in an even redistribution of risk (Figure 1). A worker that spends 99% of their time on job A and only 1% on job B-Pre has a Combined LBPRI of 0.61, a 33% increase compared to the 0.46 score if they only worked at Job A.

Figure 1 Combined LBPRI scores, as a result of job rotation, calculated pre and post engineering intervention, using a linear time weighted average model and a biomechanical model.

SUMMARY

It is not sufficient to only consider the impact of a single peak. The cumulative effect of many small peaks that are held for long durations and/or performed many times in a shift must also be considered. Measuring cumulative loading allows the effects of interventions to be quantified. Biomechanical diversity of tasks is needed for success with job rotation.

TOWARDS THE DEVELOPMENT OF A CUMULATIVE TRAUMA METRIC FOR OCCUPATIONALLY-RELATED MUSCULOSKELETAL DISORDERS

W. S. Marras

Biodynamics Laboratory, Institute for Ergonomics, The Ohio State University, Columbus, Ohio
Professor and Director, marras.1@osu.edu

INTRODUCTION

A continuing problem for society has been the control of occupationally-related musculoskeletal disorders. It is well established that most occupationally-related low back disorders (LBDs) are associated with manual materials handling (MMH) tasks. However, our ability to characterize overall risk associated with the various dimensions of LBD risk is rather poorly understood. For example, a recent study compared the ability of two commonly used risk metrics for LBD against a database of industrial injury data and found the ability of these tools to characterize risk to be moderate at best [1]. A evaluation of the structure of these metrics indicated that these tools were particularly weak at characterizing risk associated with cumulative trauma. This discussion will consider the contributions to work-related LBD in an attempt to better understand the components of cumulative trauma disorders (CTDs) that must be considered to characterize risk.

LOAD-TOLERANCE AND CTDS

The physical requirements of a lifting task, psychosocial pressures of work, as well as individual factors have all been implicated in the causality of LBDs [2]. Hence all of these risk dimensions should have some influence on cumulative trauma of the low back. If we accept the premise that all risk of LBD is related to a load-tolerance imbalance within the tissues of the trunk then we can begin to formulate how these various dimensions of risk might influence cumulative trauma. The concept of load-tolerance suggests that cumulative trauma may influence this relationship in several ways. Tolerance levels can be exceeded by: 1) increases in the applied load on a tissue; 2) decreases in the tolerance over time; or 3) a combination of both mechanisms occurring simultaneously.

LOAD DETERMINATION

The literature suggests that there may be several mechanisms responsible for increased tissue loading as a result of cumulative trauma. Recent literature indicates that a common link between the various risk dimensions (physical loading, psychosocial factors, and individual factors) involves increases in trunk muscle coactivation. We have known for some time that changes in the physical requirements of work can influence spine loading. However, we must understand how the temporal aspects of exposure to repeated trauma might affect this loading. For example, repeated exertions have demonstrated that the nature of spine loading changes from compressive loading to shear loading [3]. In addition, factors such as task experience, personality, psychosocial stress, mental concentration, and age can all influence how the

muscles are recruited and subsequently affect spine tissue loading. We must begin to understand how the quantifiable components of these various dimensions can interact and increase loading of the spinal structures in 3-D space.

TOLERANCE SPECIFICATION

In a similar manner, these same risk factors can affect tolerance of the spinal tissue. It has been well established that individual factors such as age, gender, and conditioning can influence the tolerance of spinal tissues [4]. We also know that tolerances are diminished with greater frequency of exposure [5]. Recent work by the McGill group has also shown how the combination of spine position and frequency is an important component of spine tolerance [6]. Here again, it is well established that the better we can quantify these parameters the better we can understand and quantify the risk dimension.

ADAPTATION

One characteristic that makes the quantification of risk particularly challenging is our poor understanding of adaptation. We must begin to understand how components of these risk dimensions influence our ability to strengthen or weaken tissue due to exposure and rest cycles. Human adaptation may influence either the loading or tolerance. .

CONCLUSION

In summary, we must begin to precisely quantify the influence of physical work requirements, psychosocial influences, and individual factors upon both the loading of the spinal tissue and the tolerance of these tissues if we are to develop meaningful metrics of risk. These metrics will be truly useful if they are able to determine how much exposure to work is too much exposure given individual characteristics and the multidimensional work environment. The real challenge in this endeavor is to account for the dynamic nature of the exposure and the individual's ability to adapt to stress.

LOCOMOTION RESEARCH WITHIN AN ORTHOPAEDICS FRAMEWORK: SUCCESSES AND CHALLENGES

Janet Ronsky, Barbara Loitz-Ramage, Carol Scovil, Anne Gildenhuys, Jessica Maurer, Craig Good, and Ron Zernicke
Mechanical & Manufacturing Engineering, Human Performance Laboratory, McCaig Centre for Joint Injury and Arthritis Research,
University of Calgary, Calgary, AL, Canada, jronsky@ucalgary.ca

INTRODUCTION

A person's locomotion forms a distinct signature that can be recognized qualitatively by a trained observer, but a quantitative description that captures the continuous nature of that locomotion and enables inter-subject comparisons and evaluation of interventions remains a significant challenge. Human locomotion studies have investigated normal gait and elucidated cause-effect relations leading to abnormal gait. Increasingly, gait and locomotor function assessments are being incorporated into orthopaedic diagnoses, treatment planning and evaluations. While we acquire vast quantities of data, questions remain whether the appropriate advantages and insights are being gained for the purpose of influencing orthopaedic decisions and functional outcomes.

ADVANCES

During the past few decades, key advances have enabled new research questions to be tackled, and new linkages to be forged between locomotion analyses and clinically oriented orthopaedic questions. Technical improvements in hardware associated with acquisition of kinematic, kinetic, strength, and muscle activation patterns have enabled simultaneous collection of signals related to external loading, 3D movement, and muscle activation, with recent improvements enabling more accurate analyses in real time. Computers and software advances facilitate rapid data processing and analysis, with user-friendly interfaces that broaden the range of potential users. Increased data storage capacities and computational speed have enabled analysis of larger sample sizes in reasonable cost and time. More advanced statistical approaches have enabled more sophisticated data analyses and identification of key factors relating gait characteristics to an orthopaedic condition (e.g., Deluzio et al., 1997). Computational advances have also led to the development of complex numerical simulations of 2D (e.g., Pandy and Berme, 1988; Piazza and Delp, 1996) and 3D gait simulations (e.g., Scovil et al., 1999). Locomotion studies with animal injury models have also been used successfully by our group (e.g., Frank et al., 2002) and others to investigate relations among joint injury, joint mechanics alterations, and development of degenerative joint disease.

ACCOMPLISHMENTS

Pioneering work with cerebral palsy treatment planning and evaluation (e.g., Gage et al., 1984) assisted in establishing the role of gait analysis in orthopaedics. Successes in providing objective treatment planning and evaluation of outcome in that patient population prompted the widespread development of clinical gait laboratories. Integrated approaches to assessment of joint health and functional status using multiple imaging modalities and dynamic methods are providing promising new insights. Andriacchi and coworkers (e.g., Hurwitz et al., 2002)

have reported numerous insights by examining key relations between static alignment, radiological measures of joint degeneration, pain scales, and measures of dynamic function to identify linkages with predictors of dynamic joint function (e.g., knee adduction moment). In a population with tibial rotational malunion, we recently applied similar approaches to identify dynamic variables (ankle eversion moments, hip vs. knee moment) that provide the best indicator of interlimb tibial rotation (Ronsky et al., 2000). Despite these accomplishments, however, clinicians, biomechanists, and orthopaedic specialists continue to have difficulty achieving consensus on interpretation and utility of gait analysis data.

CHALLENGES AND DIRECTIONS

Key challenges related to current movement analysis approaches stem from the fundamental simplifying assumptions associated with representing the complex biological system with a rigid body dynamics model. All such biomechanical models rely on the choice of appropriate geometries and properties for elements of the musculoskeletal system in healthy and clinical populations. Determining these values is currently a barrier to the effective use of locomotion measurements for orthopaedics. Other barriers include person-specific geometry, funding for clinical studies, validation of numerical simulations of locomotion, and appropriate tracking and evaluation of outcome measures. Current and future research that will enable locomotion studies to play a more effective and central role in orthopaedic treatment planning and evaluation must be focused on: 1) techniques for person-specific multi-modal imaging, integration and fusion of anatomical data (obtained with medical imaging) under functional loading, 2) improved technical and computational techniques for representing bony segmental motion based on non-invasive external markers, and 3) standardized, clinically relevant outcome measures.

NEURAL CONTROL OF LOCOMOTION: PRESENT KNOWLEDGE & FUTURE DIRECTIONS

Jaynie F. Yang

Department of Physical Therapy and University Centre for Neuroscience
University of Alberta, Edmonton, AB, Canada, T6G 2G4, jaynie.yang@ualberta.ca

INTRODUCTION

Locomotor movements performed by all animals are graceful, rhythmic, efficient and adaptable. Evolution has perfected these movements that are essential for survival. Much progress has been made to understand how the nervous system produces these movements. Much also remains to be done. In this abstract, I will focus on the main principles that have emerged from this body of work. Emphasis will be placed on the generation of rhythmic movements. Equilibrium and goal-directed aspects of locomotion will not be considered here.

PATTERN GENERATORS

The rhythmic movements of locomotion are produced by a group of interneurons, called the pattern generator. The pattern generator requires only tonic excitation to operate. Patterned input is unnecessary.

The design and operation of pattern generators for locomotion have been explicitly shown in invertebrates and lower vertebrates. Key elements in the pattern generator, their intrinsic and network properties important for the production of the behaviour are known (Marder & Calabrese 1996). In mammals up to lower primates, the existence of these generators have been confirmed (Grillner 1981). Elements in the generator, however, remain to be identified. Evidence from the last few years have provided strong support for the existence of these generators in the human. One of the challenges for the future will be the identification of key elements in the pattern generator for mammals, and their working principles.

ROLE OF SENSORY INPUT

The output of the pattern generator is strongly molded by sensory and descending input in the intact animal. Indeed, the output patterns of the generator in isolation are never identical to that in the intact animal. The ability of the pattern generator to adapt on a moment-to-moment basis to changes in the environment is essential for the animal to navigate through changing environments.

Considerable progress has been made in understanding the role of peripheral sensors in locomotion, for both simple and complex animals (Rossignol 1996). Sensory input contributes to the timing, amplitude and dynamics of motoneuron activity. Sensory input can initiate or terminate locomotion. Phase transitions in locomotion (such as transition from the stance to the swing phase in walking) are controlled by sensory input. Interestingly, in animals as diverse as insects to humans,

similar sensory inputs are used for controlling phase transitions (Prochazka 1996).

ADAPTABILITY OF THE PATTERN GENERATOR

Pattern generators are not dedicated for one type of movement. In both invertebrates and lower vertebrates, elements in pattern generators can be reconfigured to produce different motor behaviours. These reconfigurations can be brought about by descending input and their neuromodulators, or by specific types of sensory input (Marder 2000). Indirect evidence supports a similar type of flexibility in mammalian pattern generators for different forms of walking in the cat, and for different directions of stepping in the human infant.

Pattern generators also adapt to sustained changes in the nervous system, such as occurs with maturation, injury or disease. After either central or peripheral lesions in the nervous system, the remaining system adapts to allow locomotion to continue. For example, after peripheral lesion to a muscle nerve, the synergistic muscle and the strength of its afferents change to allow functional compensation. These changes are dependent on use of the neural pathways (Pearson et al. 1999). Similarly, after spinal cord transaction, locomotor training can partially restore this function in a variety of mammals (Rossignol 2000).

FUTURE DIRECTIONS

What does the mammalian pattern generator look like? How does it operate? What aspects can we manipulate, particularly after injury? Which neurotransmitters alter its function? How can it be altered with use? These are all questions for the future. Although much remains to be done, our current knowledge has already led to the development of new treatment strategies for individuals with injury to the nervous system (Barbeau et al. 1998). Exciting developments are likely in the near future.

LOCOMOTOR RESEARCH: PRESENT STATE AND FUTURE DIRECTIONS FOR REHABILITATION

Sandra J. Olney

School of Rehabilitation Therapy and Human Mobility Research Group
Queen's University, Kingston, ON, Canada, K7L 3N6, olneys@post.queensu.ca

INTRODUCTION

Research in locomotion is relevant to the field of rehabilitation to the degree that it can assist with the rehabilitation process. There are four primary ways in which the rehabilitation process can use information about locomotion in normal and pathological conditions: to provide a basic understanding of locomotion; to assist in movement diagnosis; to inform treatment selection, and to evaluate effectiveness of treatments. In each of these categories we can consider the information as being applied either to a group of people with similar conditions, or to individual patients. In each circumstance we can also consider whether locomotion analysis techniques or simpler clinical methods, including observation, are being used. The purpose of this presentation is to evaluate the present state and future direction of research in locomotion in rehabilitation.

BASIC UNDERSTANDING

From Muybridge, through Eberhart and Inman, Perry, Gage, Winter, Andriacchi, and so many more, each has contributed uniquely to this body of knowledge, with the need for knowledge inseparably linked to the introduction of new methods and technology. Basic understanding also includes evaluating the change naturally occurring over time, such as the recovery of persons with stroke (Richards, 1996). From a rehabilitation perspective, information related to kinetics, which can be influenced by therapeutic methods, has provided more useful information than spatio-temporal or kinematic methods. A number of investigators have made landmark contributions by establishing methodologies for understanding locomotion in cerebral palsy, stroke and other specific pathologies. Methodologies are frequently condition-specific.

Future directions for providing basic understanding include relating biomechanical measures to other performance measures such as metabolic analyses.

ASSIST MOVEMENT DIAGNOSIS

Two approaches are used: direct application of gait analysis, usually including kinematic, kinetic and frequently EMG data, with interpretation of findings by a skilled team, and indirect application, using visual observational analysis sometimes assisted by simple aids.

Important future directions for locomotor research to assist movement diagnosis include development of less complex methods of analysis.

INFORM TREATMENT SELECTION

Research in locomotion has made many contributions that can inform selection of treatment. One area that has made a very large contribution is the use of power analyses in identification of compensations and adaptations in pathological conditions (Winter et al., 1990).

Some important future directions of research to inform treatment selection are the development of clinically applicable analytic methods; routine use of power analysis for treatment of cerebral palsy and stroke and computer modeling to predict the results of training interventions.

EVALUATE EFFECTIVENESS OF TREATMENT

To effectively determine difference in treatments, it is important to have methods that are as precise as possible, and recent technical and procedural innovations have facilitated this. Included here are improved methods of determining joint centers and methods of minimizing the effects of skin motion artifact (Andriacchi, 1998). This capacity has been well used by researchers in rehabilitation, and well worth the expense involved.

Important future directions to aid evaluation of effectiveness of treatment include further advances in accuracy of motion analysis techniques, use of combinations of performance measures with locomotor analyses and general use of investigations of locomotion on sloped, rough, and other natural surfaces and on stairs.

CONCLUSION

Analysis of locomotion has provided powerful methods to analyze locomotion, assist in diagnosis, inform treatment and evaluate effectiveness of treatment, but is limited in application in all of these ways. Future research that targets these applications will assist in solving locomotor problems in rehabilitation.

INTRODUCTION

Knee and shoulder joint injury frequently occurs through different forms of activity. However, in order for physicians to properly treat the injuries to the structures in the joint, knowledge of joint mechanics and specific function of the ligaments are needed in order to understand injury mechanisms, improve surgical procedures and design better post-surgical rehabilitation protocols.

THE ROBOTIC/UFS TESTING SYSTEM

A robotic/universal force-moment sensor (UFS) testing system was developed in order to examine joint kinematics in multiple degree-of-freedom (DOF) and the *in situ* forces in normal ligaments as well as the distribution of these forces in a non-contact manner. A major advantage of the robotic/UFS testing system is the ability to determine and repeat the paths of motion. When operated in the force control mode, the testing system applies a known load to the intact joint while the motion and force data are recorded. After transection of a ligament, the system is used in position control mode and the recorded motion for the intact joint is repeated while new force and moment data is recorded by the UFS. Since the robot reproduces the identical initial position as well as path of joint motion before and after a ligament is transected, the *in situ* force in the ligament is indeed the difference in the two sets of force and moment data measured by the UFS. Additionally, changes in kinematics can be measured when a known force is applied to the intact knee while the kinematics are recorded. After transection of a ligament, the same force is applied while the kinematics are again recorded. Testing in this mode is similar to the clinical examination in diagnosing ligament injury or deficiency. Also, the procedure can be extended to examine those for the replacement grafts by using the same specimen, so as to limit the inherent specimen-to-specimen variation.

Using this system, the distribution of *in situ* forces in the anterior cruciate ligament (ACL) as well as the effects of axial compression, quadriceps and hamstring co-contraction and rotatory loads on *in situ* forces in the ACL can be determined. In addition, variables of ACL reconstruction such as location of graft fixation, type of graft, and type of reconstruction are also examined. Similar studies have been performed in the posterior cruciate ligament and shoulder.

3D FINITE ELEMENT MODEL

Currently, a three-dimensional finite element model has been constructed based on serial CT/MRI scans of a knee specimen.

The same specimen was tested on the robotic/UFS testing system and the *in situ* forces in the ACL in response to an anterior tibial load were determined. Based on the same anterior tibial load, the model was used to calculate these forces and the values matched well with those from the experiment. Thus, this model was validated and is now being used for predicting knee joint behavior under other external loading conditions. This combined experimental and computational approach has also been used for the shoulder, forearm, and spine.

IN VIVO APPLICATION

Future developments will focus on *in vivo* applications. Input data will be collected during gait analysis or throwing activities using the point cluster technique in order to yield accurate kinematic data. The robotic/UFS testing system can be programmed to reproduce these joint kinematics on young human cadaveric specimens in order to generate a database for *in situ* forces in the ligaments, or ligament replacements grafts. With appropriate computational models, the stresses and strains in these tissues *in vivo* can also be predicted for more complex loading conditions such as sports activity or rehabilitation. Potential application of this combined approach includes pre-operative surgical planning, improvement of surgical procedures as well as development of appropriate post-operative rehabilitation protocols. (Fig 1)

FUTURE DIRECTIONS

In the future, it is hoped that we can use this technique to study injury mechanisms, as well as examine the validity of arthrometers and other instruments. However, greater

Figure 1: Flow chart describing future directions

emphasis will also need to be placed in research on rehabilitation and neuromuscular training. The ultimate goal of this strategy is to improve patient outcomes following ligament reconstructions.

DYNAMIC, IN-VIVO FUNCTION OF HEALTHY, ACL-DEFICIENT AND ACL-RECONSTRUCTED KNEES: NEW INSIGHTS USING HIGH FRAME-RATE STEREO-RADIOGRAPHY

Scott Tashman and William Anderst

Bone & Joint Center, Henry Ford Hospital, Detroit MI USA, tashman@bjc.hfh.edu

INTRODUCTION

Accurate in-vivo assessment of skeletal kinematics is essential for understanding normal and pathological joint function. We have developed techniques combining kinematics from high frame-rate stereo-radiography with bone geometry from static CT for precise assessment of in-vivo joint behavior.

We are applying these techniques to the study of ACL insufficiency and reconstruction. Preliminary results from an ongoing study of ACL-deficient human subjects indicate that significant dynamic abnormalities may persist even after ligament reconstruction. Parallel studies with an ACL-deficient canine model suggest that these abnormalities may be related to the increased risk of osteoarthritis associated with ACL loss and reconstruction.

METHODS

Kinematic data is collected using a unique biplane radiographic system. A minimum of three radiopaque markers are implanted into each bone to be tracked. Stereo pairs of radiographs are acquired during movement at up to 1000 frames/s, using synchronized high-speed video cameras coupled to 30cm image intensifiers. 3D coordinates of the markers are reconstructed using a modified DLT method, with

Biplane X-ray configuration for human running trials.

3D tracking accuracy of $\pm 0.1\text{mm}$.

To interpret this data in an anatomically relevant context, high-resolution knee CT scans are acquired after marker implantation. Bone surface geometry is determined, and related to the coordinates of the implanted markers. Thus, the anatomical motion of the joint surfaces can be completely reconstructed from the dynamic stereo-radiographic data.

For the human study, three 1.6mm tantalum spheres were implanted into the distal femur and proximal tibia of the both the ACL-deficient and uninjured limbs of subjects undergoing ACL reconstruction. Kinematic data was acquired at 250 frames/s during the impact phases of downhill running (2.5 m/s) and forward one-legged hopping. 3D knee kinematics were determined for both limbs and compared. For the canine study, markers were implanted in the right hindlimbs of 23 female foxhounds. Kinematic data was acquired during treadmill gait before and serially for 2 years after ACL transection. Joint condition was assessed visually at the conclusion of the study, and related to knee kinematics.

RESULTS AND DISCUSSION

For the human studies, anterior tibial translation curves were similar for intact and reconstructed limbs. No significant differences were found during running or hopping. Though internal/external tibial rotation plots were also grossly similar in appearance between intact and reconstructed limbs, the reconstructed curves were shifted towards external rotation. The effect was greater during hopping than running (see figure below), but all differences were significant (paired t, $p < 0.05$) except for run min. This shift towards external rotation suggests that common reconstruction techniques may fail to restore normal rotational motion, leading to altered interactions of the articulating joint surfaces.

Though the long term effects of these abnormal motion patterns are not known, they could have important implications for long-term joint health. Our canine studies have shown that there are distinct patterns of abnormal joint motion after ACL loss that are predictive of rapid cartilage degeneration. With the combined dynamic X-ray/CT method, we are able to estimate the path of joint contact (see figure below); the average velocity of the contact point on the medial femoral condyle 2 months after ACL loss is highly correlated ($r^2 = 0.81$) with femoral cartilage damage at 2 years.

Estimated femoral contact point paths for 2 ACL-deficient dogs. Note differences in medial path length. Two years later, dog on left had full-thickness cartilage loss; dog on right had healthy femoral cartilage.

Our preliminary results suggest that these techniques have great potential for identifying mechanical factors responsible for increased risk of joint disease after ACL injury. This may assist in the development of improved treatments and better long-term outcome.

INTRODUCTION

Knee replacement is now a highly successful operation, with the clinical survivorship of some devices reported to be greater than 96% at 7–10 years (Biomet, 2002). However, complications such as infection, wear, loosening, and patellar instability and pain do occur, particularly in younger patients.

Over the years, we have completed a number of in vitro experiments and theoretical modelling studies of both the intact and replaced knee joint (e.g. Gill and O'Connor, 1996; Feikes et al., 2000; Lu et al., 1998; Miller et al., 1998; O'Connor et al., 1990; Wilson et al., 1998; Wilson et al., 2000; Zavatsky et al., 1999). These studies have shown a relationship between the geometry of the knee ligaments and articular surfaces and passive knee kinematics. They have also highlighted the importance of retaining the cruciate ligaments in medial uni-compartmental knee arthroplasty.

In addition, we have found that some total knee replacements which are very successful clinically have abnormal kinematics when compared to intact knees in vitro (Miller et al., 1998; Zavatsky et al., 1999). This result is a puzzling one, given that the abnormal in vitro kinematics might be expected to translate into serious clinical problems after implantation in vivo. In vitro studies are, of course, limited in that only simple activities using a small number of muscles can be simulated, and resultant joint forces tend to be low compared to those in vivo. Nevertheless, they provide a controlled environment in which specific hypotheses about knee mechanics can be tested. A full picture of knee replacement biomechanics requires an understanding of experimental results both in vitro and in vivo and an explanation of how such data relates to clinical outcomes.

In our present work, we are addressing the problem of patellofemoral complications in total knee replacement by performing studies both in vitro and in vivo. We will be using theoretical models of the knee joint to help us understand the relationship between the two sets of results. At the same time, we will be looking more carefully at relevant clinical outcomes, such as patient satisfaction, mobility, and pain.

METHODS

We have measured simultaneously the tibiofemoral kinematics and patellofemoral kinematics and forces in a supine leg-extension rig in fifteen post-mortem knee specimens both before and after knee arthroplasty (Oppold, 2000). The motions of the patella, tibia, and femur were measured using a five-camera Vicon 370 (Vicon Motion Systems, Oxford, UK). The simulated quadriceps force was measured with a uniaxial

tension transducer, and a custom-built six degree-of-freedom force transducer, based closely on the design of Singerman et al. (1994) was used to measure the three forces and three moments acting upon the posterior surface of the patella.

We are using sagittal plane fluoroscopy and image analysis to study knee replacement motion in vivo. So far, a number of patients have been tested in supine leg-extension, and we are currently developing a protocol for stair climbing. A force plate is being incorporated into the step, so that an inverse dynamics type model (Gill and O'Connor, 1996; Lu et al., 1998) can be used to calculate the forces and moments at the knee joint. A software tool is being developed which will fit CAD models to the fluoroscopy images for a more accurate determination of the joint position in vivo. A motion analysis system will be used in conjunction with the fluoroscopy to provide information about any out-of-plane motions.

RESULTS AND DISCUSSION

The in vitro results show that the total knee replacement caused an increase in tibiofemoral adduction and decreases in tibial rotation and patellar tendon angle relative to the intact knee. A sharp change in patellar flexion occurred near 60° tibiofemoral flexion, along with a sharp increase of nearly 100 N in the quadriceps force. Fluoroscopy results on five patients with total knee replacements also show an abnormal patellar tendon angle. The theoretical modelling of the knee joint associated with this experimental work is in progress.

BIOMECHANICAL SIMULATION OF FRACTURE HEALING

Patrick Prendergast and Damien Lacroix

Bioengineering Group, Department of Mechanical Engineering, Trinity College, Dublin 2, Ireland. pprender@tcd.ie

INTRODUCTION

To better understand the influence of mechanical loading on the differentiation of tissues in the fracture callus, finite element modelling has been used to determine the spatial variation of biophysical stimuli and correlate it with tissue phenotype; e.g. Carter et al (1989) and Claes et al (1994). However, no study has yet addressed whether or not (i) the healing process can be simulated using biophysical stimuli as regulators of tissue differentiation and (ii) the healing process can be simulated in realistic 3D fractures.

The hypothesis to be investigated in this paper is that fracture healing can be simulated over time in three-dimensional model of a fractured tibia using the biphasic mechano-regulation rule presented in Prendergast et al (1997). If this would be true then it opens the possibility of using such biomechanical analyses to assess the possibilities of using finite element models to pre-operatively predict the best fixation treatments for healing of a patient's fracture.

METHODS

The concept of biphasic mechano-regulation is that both solid phase and fluid phases may contribute to stimulation of mesenchymal stem cells (MSCs)– high values of these stimuli cause the cells to differentiate into fibroblasts forming fibrous connective tissue, intermediate values stimulates chondrocytes and cartilage, and low values stimulate osteoblast differentiation and therefore bone formation. Depending on the combination of these two stimuli, differentiation of the MSCs is then determined.

A finite element model was used to represent a bone fracture. The model was constructed based on a CT scan of a composite tibia. An external fixator was used to fixate the fracture, as shown in Fig. 1. The properties of the callus was specified as “granulation tissue” at the beginning and an iterative procedure was used to change the properties of the callus according to the combination of biophysical stimuli in each element.

RESULTS AND DISCUSSION

Richardson et al (1994) proposed that sagittal plane bending could be used as a measure of the success of fracture healing. For that reason, the sagittal plane bending stiffness (in Nm/deg) was calculated during the simulation. The simulation was carried out with under two different loading magnitudes: 300 N and 500 N, see Fig. 2. In addition, the simulations predict the change in tissues appearing and disappearing in the external callus and the fracture gap during healing.

Fig. 1: 3D FEM of the fractured tibia with external fixation.

Fig 2: Predicted change in bending stiffness under loading of 300 N and 500 N.

SUMMARY

In conclusion, fracture healing can be simulated using tissue strain and interstitial fluid flow as mechano-regulatory variables. 3D models of real fractures can be generated, and these can predict the influence of loading magnitude. This makes the use such computer simulations a clinical possibility.

MONITORING OF THE REHABILITATION OF PATIENTS AFTER FRACTURE

THE MONITORING CONCEPT

Transducers to assess locomotion structures are poorly represented in the classification of diagnostic instruments. Mechanical measurements of the locomotion system, however, represent a diagnostic tool. A pioneer work has been done by our group in clinical application of the monitoring of implant deformation as a diagnostic tool (Burny et al., 1993, 2000). We present the results of some twenty-five years of monitoring using "smart implants". In this review abstract we present the two main applications of monitoring in our department. We aim to accelerate the rehabilitation (early weight bearing) while avoiding the risk of overloading.

METHOD

The monitoring of patient rehabilitation allows avoiding dangerous overloads. For this it is mandatory to know the ultimate mechanical characteristics of the fixation (a plate, an external fixation) and limit values which must never be surpassed during exercise to avoid a failure of the system. The implant deformations are measured with a Wheatstone bridge and the signal is transferred to a personal computer for processing and display via a hard-wired connection (a telemetry system is being implemented).

External fixation monitoring

Figure 1: the concept, external fixation

The deformation measurements, throughout the healing process help to quantify the mechanical strength of the callus, an information complementary to the X-ray images. The measurement of the bending and torsion moments at the articulations of a frame fixation is straightforward, once the necessary coefficients are introduced into the system. The dynamic monitoring of the patient rehabilitation is a unique tool to identify hazardous overloads and to anticipate failure during rehabilitation and daily living activities.

The monitoring may also take place after the achievement of a limb lengthening procedure, to control the effectiveness of a distraction osteogenesis.

Conclusion 1:

Early controlled weight bearing, when possible, significantly reduces the healing time (table 1).

Table 1: tibia fracture, retrospective study, and delay of healing

Healing	Monitoring -	Monitoring +
N	75	74
Mean time	180 days	142 days
Variance	4081	1470

P < 0.001

Internal implant monitoring

Femoral implants have been instrumented with a "sensing cell" (resistive strain gauges), and carefully calibrated in vitro, before implantation. The fatigue limit is defined for each implant as the half of the signal at the elastic limit. The clinical data already available are presented in table 2.

Table 2: failure of internal fixation, retrospective study

R : regular osteosynthesis
MO : monitoring, measured overloading
MNO : monitoring, no overloading

	R	MO	MNO
N total	618	17	144
N failure	53 (7,9 %)	7 (29,2 %)	3 (2,0 %)

P < 0.001

Conclusion 2:

The monitoring of internal implants reduces the rate of failure, when the patient respects the instruction (MNO).

CLINICAL RELEVANCE

Extensive clinical experience has been built up using orthopaedic implants instrumented with strain gauges. This shows the relevance of the monitoring of the deformation of implants to assess nursing and rehabilitation exercises, to identify dangerous overloads and to anticipate implant failure. We consider now combining the results of the mechanical evaluation and of the imaging as a decision making aid.

INSTRUMENTATION OF A HEAD FOR THE DETECTION OF LOOSENING BY VIBRATION ANALYSIS

Michael Catrysse¹, Michel De Cooman¹, Robert Puers¹, Siegfried V.N. Jaecques², Georges Van der Perre², Monique Donkerwolcke³ and Franz Burny³

INTRODUCTION

The functional life of orthopedic implants is generally limited to 10-15 years due to aseptic loosening and mechanical failure. Conventional imaging based techniques do not have satisfactory diagnostic sensitivity to detect loosening (Georgiu & Cunningham 2001, Li et al 1995). Therefore, vibration analysis is proposed as a diagnostic method for the monitoring of total hip replacement (THR) loosening.

METHODS

A well-fixed implant and the surrounding bone behave as a linear dynamic system when subjected to a mechanical stimulus. When the implant gets loose, non-linear behavior develops. Loosening is diagnosed by detecting distortion of a sinusoidal excitation signal applied externally to the condyle.

The distorted response is captured by an accelerometer, placed in the THR head. In this way, distortion, introduced by soft tissue between the prosthesis and an externally applied accelerometer are avoided. A telemetry circuit is also implanted, to transmit the measured data to a base unit.

The packaging of this implanted circuit should be biocompatible, hermetic and sufficiently strong and the dimensions minimized (Barbosa et al 1993).

RESULTS AND DISCUSSION

The circuit is placed on hybrid boards inside a Ti can (Figure 1). For telemetric readout, coils are wound around the can, connected to the circuit by feedthroughs in the can. The can is mounted in a cavity of a dedicated ZrO₂ THR head, allowing telemetry and protecting the circuit from mechanical stress. The cavity is filled with Epotek 301.

He leakage tests were performed, according to the MIL-STD-883. 80% of the assembled packages passed the test. The static compression resistance of the heads is higher than the FDA standard (Stryker Howmedica Osteonics 2000). The instrumented head has not been implanted in patients and hence the detection protocol has not been tested yet in a clinical situation. However, on model femora with well-controlled simulated loose stems, it was possible to discriminate between secure, early and late loose stems with an elaborate analysis protocol (Jaecques et al 2001). In a clinical situation, resonance frequency shifts could also be used as an indication of early loosening.

Figure 1: Schematic overview of the instrumented THR

SUMMARY

The presented instrumentation of the THR head fulfils the requirements for implantable systems. The detection method proved to be successful on model femora. Future work will include per-operative testing of the instrumented THR head.

BONE CONSOLIDATION

In vivo evaluation of bone consolidation is clinically relevant for the monitoring of fracture healing and assessment of bone consolidation after distraction osteogenesis. In both cases, the evaluation of the effect of BMP's has become of recent interest.

Clinical measurements were made after tibia elongation, and showed interesting correlation between US-velocities measured at different sites within the elongation zone and consolidation time (Lowet 1993). A practical limitation is that tibia measurements can only be taken at the medial face, limiting the relevance of the measurement to that side, while the healing progress could differ over the cross section. On top of that, due to the surgical procedure, a small gap can develop at that site, affecting the precision of determination of the US pathway and hence the velocity. Combining US with Vibration Analys (VA) could solve those problems, since vibration analysis measures the stiffness of the bone as a whole (hence the whole cross-section).

However, although convincing clinical data on the feasibility of vibration analysis for monitoring of fracture healing were published (Nakatsuchi et al. 1996), skepticism in leading fracture research circles against VA is even stronger than that against US, the leading idea being that the future for bone assessment is in advanced imaging techniques combined with advanced FEM. Apart from the cost of such an approach, the first proof that it can produce a quantitative prediction of bone stiffness or strength remains to be given. In the meantime, ultrasound acoustic imaging (i.e. based upon mechanical properties) has already produced promising clinical results (Moed et al. 1998)

MONITORING OF PROSTHESIS STABILITY

RoentgenStereophotogrammetric Analys (RSA) is applied to monitor prosthesis migration in clinical studies. Ryd (1992) provided data proving that long-term success or failure of prosthesis can be predicted from migration in an early stage. Hence, it makes sense to use RSA in animal studies and clinical evaluations of prosthesis designs. Routine clinical application of RSA (or rather simplified versions of it) could be justified by the argument that if loosening is predicted in an early stage, it is better to remove the prosthesis before bone damage is caused. Furthermore, it is argued that such a

generalized application would contribute significantly to our knowledge on long-term prosthesis behavior.

An alternative to RSA is the so-called "smart" prosthesis, integrating sensor(s) to monitor loosening directly. Such an approach is developed in the STIMULUS project, based upon vibration measurements (Denayer et al, 2000). Two different principle approaches are evaluated. One is based upon the distortion of a sine wave as a result of a non-linear contact between prosthesis and bone. The other is based upon changes in resonant frequencies and damping values, and is similar to the approach used in the monitoring of dental implant fixation (Meredith et al., 1996)

From all these studies, it has become clear that there is a lack of understanding of basic phenomena and mechanisms. What is loosening, or better, which different types of loosening can be distinguished and how can they be identified and detected mechanically? What is the interaction between residual mobility (as measured by vibration analysis), migration (as measured by RSA) and loosening?

MONITORING OF BONE LENGTHENING. AN EXPERIMENTAL STUDY IN SHEEP.

Francisco Forriol

Orthopedic Research Laboratory, Department of Orthopedic Surgery, Clinica Universitaria de Navarra
Facultad de Medicina, Universidad de Navarra, Pamplona, Spain, fforriol@unav.es

AIM OF THE STUDY

The aim is to investigate the mechanical behavior of the lengthening process, and to discern whether any characteristic pattern is followed.

MATERIAL AND METHOD

Four two-to three-month- old sheep, weighting 20-25 Kg, were operated on, by performing a 3cm progressive lengthening of the left tibia. The surgical procedure was performed under general anesthesia. A unilateral external fixator was fitted to the tibia (Monotube-Triax[®], Stryker Trauma, Geneva).

Strain gauges were incorporated into the external fixator by replacing a section of the lengthening bar with a sensor consisting of a metal piece instrumented with four strain gauges to form a complete Wheatstone bridge. The 5mm diameter pins were attached to the bone at the proximal and distal metaphysis of the tibia, using an image intensifier. A longitudinal incision 2 cm in length was performed on the lateral side at the middle third of the posterior leg.

Distraction was performed at the same time on six days each week in four sheep that were kept in isolated cages. The lengthening was carried out at a rate of 1 mm/day in one step and the lengthening procedure commenced one week after the operation.

The fixator was connected by means of a cable to a computer (Macintosh IIfx) with an analogical-digital converter for the acquisition and processing of data (Lab View2, National Instruments). This was equipped with an amplifier (San-ei) to pick up the microvolts transmitted through the bar of the fixator every 20 minutes for 24 hours a day, equivalent to 80 readings a day. For each reading, the program performed an average of 500 data points taken in 1 second, then transformed the information into the corresponding value in kilograms. This measurement was carried out without interruption over

the lengthening procedure, and always at the same time of the day (10 AM).

The measurement system was checked every day before the lengthening was carried out. When a technical problem was detected, the experiment was stopped. Lengthening procedures performed for less than 3 weeks were not included in the results.

RESULTS

The forces began to increase around day 10, and were clearly higher once the third week after surgery had been reached, that is, after the bone had already been lengthened for a week. The forces continued to rise until day 21, to a value of over 8 Kg (40-50% of the animal's weight).

The force increases each day, rising dramatically after lengthening and then slowly falling until it reaches a value slightly greater than the final force on the previous days. The forces follow a common pattern in every case. The maximum daily force starts to drop one hour after distraction, and continues to decrease gradually throughout the day until it reaches a value slightly greater than the initial force on the previous day; the mean daily force thus increases little by little.

DISCUSSION

The progressive increase obtained is just the result of distracting the muscles and other soft tissues. In our study, the obtained pattern shows that no differences exist between day and night, because the sheep does not lean on the limb during the lengthening period. This pattern is produced by distraction of the soft tissues, which gradually adapt to their new situation owing to their elasticity, thus reducing the amount of tension.

LOADS ON AN INTERNAL SPINAL FIXATOR DURING SITTING

A. Rohlmann, F. Graichen and Georg Bergmann

Biomechanics Laboratory, University Hospital Benjamin Franklin, Free University of Berlin, Germany, rohlmann@biomechanik.de

INTRODUCTION

It is assumed that spinal load in the lumbar region depends on the degree of lordosis and the inclination of the pelvis. Sitting may involve different degrees of lordosis and pelvic inclination. Thus spinal load may depend on the type of seat and the sitting posture. The aims of this study were to measure implant loads in ten patients for sitting on different types of seats and to compare implant loads for sitting erect and relaxed.

MATERIAL AND METHODS

Telemeterized bisegmental internal spinal fixators were used for in vivo measurements of spinal loads (Rohlmann et al., 1994). The inductively powered fixators were implanted in ten patients and allowed the measurement of three force components and three moments. The patients were videotaped during the measurements, and the load-dependent signals of the two telemetries were stored on the same videotape. Forces and moments were calculated from the telemetric signals and shown online on a computer monitor.

During a measuring session, patients successively sat on a stool, a chair, an office chair, a bench, a physiotherapy ball, and a knee-stool. While sitting on a stool or chair, the patients were asked to sit relaxed and afterwards to straighten and extend their back. This exercise was repeated during several measuring sessions. Previous studies (Rohlmann et al., 1999, 2000) have shown that the bending moment in the sagittal plane is the most important load component. Thus, only the bending moments in the fixators are compared here.

RESULTS

The type of seats had only a minor effect on bending moments in the fixators. Implant loads differed considerably in some patients when they changed the type of seat. However, a significant difference was only found between sitting on a bench and on a knee-stool with slightly higher values for the latter.

Sitting erect and actively straightening the spine as taught in some back schools increased the bending moment in the fixators by an average of about 11% compared to sitting relaxed (Fig.1). There were marked interindividual differences in load changes.

DISCUSSION

Loads on internal spinal fixation devices caused by sitting were measured in ten patients. There was marked interindividual variation, partially due to differences in the

Figure 1: Comparison of normalised fixator bending moments for sitting relaxed (100%) and erect.

indication for surgery (compression fracture, degenerative instability) and the surgical procedure performed (compression or distraction of the bridged region) (Rohlmann et al., 1999, 2000). Load differences were negligible for sitting on different types of seats. Intradiscal pressure likewise varied only slightly for sitting on different types of seats (Wilke et al., 1999).

Sitting erect and actively straightening the spine led to higher implant loads than sitting relaxed. Intradiscal pressure was about 10% higher for sitting erect than relaxed (Wilke et al., 1999). Sitting erect requires additional muscle forces which cause higher spinal load and implant loads. The fact that the loads for sitting are lower than for walking and much lower than for lifting a weight (Wilke et al., 1999) argues against the assumption that the higher load for sitting erect is the reason for low back pain, which sometimes occurs during sitting.

INTRODUCTION

The United Kingdom Ministry of Defence is undertaking a programme of research to address issues raised by long term exposure to low level or novel electromagnetic fields. A key element of this is the development of a computer model of the whole human anatomy to serve as an input to electromagnetic simulation software. Such computer model of the human anatomy would similarly be valuable for the biomechanical analysis of anatomical structures.

METHODS

Magnetic Resonance Imaging (MRI) and Computed Tomography (CT) images of various parts of the human anatomy, including the head, thorax, arms, legs and feet, were utilised as the input data to an image processing software system. The general method used for processing available data included the processing of the images; the identification of anatomical tissues; the extraction of geometrical information; and the interface of the data to an appropriate file format. Parametric and polygonal modelling techniques were investigated.

RESULTS AND DISCUSSION

Most of the anatomical structures and tissues of the human anatomy were successfully processed and modelled. A specific methodology was investigated and satisfactory results were achieved (Fig. 1). Potential difficulties, when dealing with such large-scale modelling, were identified. Those were the image processing time and manual segmentation of medical data; the identification of tissue boundaries and tissue classification; the accuracy requirements of the resulting model; the file format for interfacing the model to a design or analysis code; and the required computer resources.

SUMMARY

The aim of this work has been the processing of medical images regarding the extraction of anatomical geometrical information and the development of a 3D human model.

Figure 1: Example of image processing and 3D modelling of the lower body: hard tissues are shown on the left, while identified tissues are depicted on the right.

INTRODUCTION

Ultra-high molecular weight polyethylene (UHMWPE), formed into a solid by compression moulding, has been in use for approximately three decades in total hip and knee joint replacement prostheses. Generally these perform well, but there is a small and significant failure rate from wear and fatigue. Evidence from retrievals has implicated "fusion defects", remaining in the UHMWPE from the moulding process, as possible initiators of failure. In an attempt to improve understanding of this problem and to develop a viable strategy to overcome it, a systematic study has been carried out of the integrity of a medical grade UHMWPE (Hifax 1900H) following compression-moulding.

EXPERIMENTAL METHODS

As-received powder was moulded at 20Mpa in instrumented, cylindrical, matched-die moulds, with maximum temperatures from 145°C to 200°C, and dwell times at the maximum temperature between 10 minutes and 90 minutes. Constant extension-rate tensile tests at 37°C were performed of specimens manufactured from material at the surface of the moulding and in the centre. Low voltage scanning electron microscopy (SEM) was used to study the specimens before and after elongation to break.

EXPERIMENTAL RESULTS

We identified two distinct forms of fusion defect. Type 1 defects were residual voids observed at the lowest moulding temperatures (up to 165°C) and shortest times. It proved impossible to manufacture tensile specimens from material from the centre of mouldings formed at 145°C.

No voids were found at higher moulding temperatures: mouldings were apparently defect-free, when observed in the SEM as-moulded. Moreover, in tensile tests at 37°C these samples showed highly ductile behaviour, with mean values of elongation to break exceeding 400% for each mould temperature. When the free surfaces were examined in the SEM, from samples after elongation to break, linear surface features were observed on the same length scale as the original particle size (ca 150 µm) where no such features had been observed prior to loading.

These markings were identified as Type 2 fusion defects, where there was incomplete inter-particle molecular diffusion during moulding, leaving compliant particle boundaries rendered visible on machining marks by their relative shearing displacement during the large elongations. The severity of these defects reduced with increase in mould temperature, as evidenced by a peak in elongation to break occurring near 175°C, beyond the point where voids ceased to be visible. The reduction at the highest temperatures was attributed to oxidation revealed by infra-red spectroscopy.

THEORETICAL METHODS

A strategy was devised for quantifying the severity of Type 2 fusion defects, for components of given shape, subject to a given process history. A numerical method was developed to compute the progress of interparticle diffusion, employing a finite element model of heat transfer during moulding, together with results from the theory of polymer self-diffusion by reptation. *Reptation Time* is the diffusion time required for the current conformation of a long-chain molecule to bear no correlation to its initial conformation. It depends on Molecular Weight to the power of 3.4. For a given length of time spent above the melting temperature during temperature rise and dwell and above the recrystallisation temperature during temperature fall, molecules above a certain molecular weight – the Maximum Reptated Molecular Weight (MRMW in g/mol) – will not have fully reptated. The distribution of MRMW was calculated for a variety of surface thermal histories (Rise, Dwell, Fall).

THEORETICAL RESULTS

As an example, we describe the calculated temperature and MRMW distributions in a cylindrical moulding 30mm diameter, 15mm thick, formed from powder of initial viscosity-average molecular weight 4.9 to 5.9 x 10⁶ g/mol and melting temperature 141°C. The assumed surface temperature rose from 20°C to 175°C in 25 minutes, followed by a dwell at 175°C for 15 min and a fall to 20°C in a further 28 min, a total processing time of 68 min. The material at the surface started to melt after 12 min, reaching a final MRMW of 2.23 x 10⁶. The material at the centre did not start to melt until 21 min, reaching a final MRMW of 1.96 x 10⁶. Both values of final MRMW lie far below the initial minimum viscosity molecular weight. Final MRMW increased with dwell time and temperature. Increasing the dwell time to 90 min gave a final MRMW of 3.37 x 10⁶ for the surface.

DISCUSSION

Compression moulding requires the polymer powder to be melted and fully compacted under pressure. Full integrity of the solid is then achieved only after the molecules in neighbouring particles have diffused across their interfaces, knitting the particles together and leaving no memory of the interfaces. The shearing movements detected in Type 2 defects after one loading, if repeatedly reversed under oscillatory loading, could lead to the initiation of fatigue cracks and subsequent failure. Our calculations explained the experimental observation of Type 2 defects, by showing that the moulding conditions, although spanning the range thought to be used commercially, were insufficient to allow reptation of the majority of the molecular population. The computational tool has potential in the design of components and process conditions, to achieve specified levels of integrity and MRMW in the UHMWPE components of knee and hip prostheses.

MOLECULAR BIOLOGY OF BIOMATERIAL INCORPORATION WITH BONE

Hannu Aro, Heli Salminen, Tajja Helminen and Eero Vuorio

Department of Surgery and Medical Biochemistry/Molecular Biology, University of Turku, Turku, Finland, hannu.aro@utu.fi

INTRODUCTION

Bioactive glasses (BG) are a group of surface-active silica-based synthetic biomaterials which are highly osteoconductive and their surface provides the bonding interface with the bone tissue. The surface reactions of BGs occur very rapidly within minutes and it involves a sequence of reactions - including ionic translocations, allowing an exchange of ions with the physiologic milieu. The process leads to the formation of two reaction layers: an internal silica-rich layer and an exterior biologically active hydroxyapatite layer. The hydroxyapatite phase is equivalent chemically and structurally to the mineral phase in bone and this equivalence is responsible for interfacial bonding. Determination of mRNA levels for specific bone matrix components and their degradation enzymes provides a novel way to accurately determine the bioactivity of the BG materials and to characterize remodeling of the bonded new bone. Using such an approach, this study compared the capacity of bioactive glass and titanium microspheres to serve as a substratum for new bone formation and subsequent remodeling.

METHODS

To create the bone defect 75 female Harlan Sprague Dawley rats (age 15-16 weeks, weight 195-274 g) underwent the following surgical procedure. The proximal metaphyseal areas of both tibias were exposed on the medial side. One hole (\varnothing 3-mm) and 5 mm distally another hole (\varnothing 1-mm) were drilled into the anteromedial cortex of the tibia below the medial collateral ligament. Bone marrow was removed by rinsing with 0.9% saline through both holes. The cortical holes and the marrow cavity were filled with bioactive glass microspheres (\varnothing 250-300 μ m) or titanium microspheres (\varnothing 250-300 μ m) through the \varnothing 3-mm hole using a pipet. Sodium hyaluronate (Healon® at 10 mg/ml) was used as the carrier for both microspheres. At a random order, one tibia of each animal received bioglass glass microspheres and the contralateral tibia titanium microspheres. The selected bioactive glass composition is an intra-institutional product for research purposes only. The study protocol was approved by institutional animal care committee. Paired comparison of bone healing was performed at 1, 2, 4, 8, and 18 weeks. Ten animals at each time point were used for molecular biologic analyses and five animals for comparative histologic analysis. The bone segment was cut above the \varnothing 3-mm hole and below the \varnothing 1-mm hole and immediately frozen in liquid nitrogen. For extraction of total RNA using the guanidinium isothiocyanate method, bone tissue was powderized under liquid nitrogen. This yielded sufficient amounts of material to allow analysis of individual animals and subsequent statistical

analysis. The expression of various genes for matrix components (type I, II and X collagens, osteonectin, osteocalcin) and proteolytic enzymes (cathepsin-K, MMP-9, MMP-13) were determined by Northern analysis of the respective mRNAs. The histologic hard-tissue specimens were analyzed for new bone formation using operator-assisted histomorphometry. The bone-biomaterial interface was delineated in DEXA mode with a scanning electron microscope. Means for bioactive glass and titanium microspheres were compared with paired Student's t-test at each time period.

RESULTS AND DISCUSSION

Histomorphometric analysis showed a significantly increased formation of new bone in bones filled with bioactive microspheres as compared with those filled with titanium microspheres. Significant differences in total bone-mass per cent of bone marrow became evident already at two weeks and was significant at eight weeks ($p < 0.01$). The difference in the amount of new bone was evident still at eighteen weeks ($p < 0.01$).

Significant differences in the mRNA levels for specific bone matrix components became evident at 8 weeks: type I collagen ($p < 0.001$) and osteonectin ($p < 0.01$) mRNAs were higher in defects filled with BG microspheres than in those filled with titanium microspheres. No expression of cartilage specific collagens (type II and X collagens) were seen in any of the samples. The mRNA levels for cathepsin K demonstrated a significant increase of in BG samples both at 4 weeks ($p < 0.05$) and at 8 weeks ($p < 0.01$). The MMP-13 mRNA levels tended to be elevated in BG samples throughout the healing period, reaching a statistically significant level at 8 weeks ($p < 0.01$). By 18 weeks, the differences between the mRNA levels of the BG and titanium samples became insignificant and approached the control mRNAs levels of intact bone specimens.

SUMMARY

The current study confirms that the cellular activities of biomaterial-bone interfaces can be quantitatively studied at the molecular level. The surface activities of the BG material were shown to significantly enhance the expression of genes coded for bone formation and resorption. The model described here is useful for systematic comparative studies of different bioactive materials as it provides sufficient material for measurement of specific mRNA levels for bone matrix components and proteolytic enzymes in individual samples.

ARE THERE THRESHOLD VALUES FOR SAFE PLANTAR PRESSURES ON NEUROPATHIC FEET?

Peter R. Cavanagh and Jan S. Ulbrecht
The Center for Locomotion Studies, Penn State University
University Park, PA 16802, USA
prc@psu.edu, jsul@psu.edu

INTRODUCTION

Plantar pressure measurement is becoming a more common part of the evaluation and screening for people with diabetes. Ideally, such screening would identify feet that are “at risk” for tissue injury because of high plantar pressures that are not perceived due to diabetic sensory neuropathy. Unfortunately, such a threshold has not yet been identified. This paper discusses issues involved in the definition of thresholds.

BAREFOOT MEASUREMENT

A number of authors have suggested threshold values to distinguish normal from abnormal feet based on the measurement of barefoot plantar pressures. Boulton et al. (1987) suggested that a value of 1080 kPa on an optical pedobarograph was such a threshold. Veves et al. (1991) used a value of 1207 kPa to make a similar distinction, and found in a prospective study (Veves et al., 1992) that patients who proceeded to ulcerate all had plantar pressures greater than 1108 kPa during walking. The only study that has attempted to define a specific threshold for ulceration is that of Armstrong et al. (1998) who used an EMED SF platform to collect plantar pressures during walking in controls and in patients with a history of ulceration. Peak pressures were significantly higher in patients with a history of ulceration compared to controls (831 ± 247 kPa vs. 627 ± 244 kPa). The optimal cut-off point, which balanced sensitivity and specificity in the data, was 700 kPa. However, this value was only 70% sensitive and 65% specific, leaving the authors to conclude that there was no clear value that could be used in screening to predict ulceration. Rather, the higher the pressure, the greater the risk.

As we have discussed elsewhere (Cavanagh et al., 2001) there are a number of reasons why threshold defined in this manner may differ between investigators. These include different element sizes of different platforms, different thresholds in different parts of the foot, different thresholds depending upon tissue status, variations in shear pressures, and the fact that the duration of loading is usually not accounted for. Duckworth et al. (1985) and Shaw and Boulton (1996) have included loading duration in their analyses.

It is reasonable to ask whether barefoot pressure measurement will ever be able to reliably predict an ulceration threshold. Ideally, neuropathic patients should never let their feet touch the ground without shoes. Indeed, in most clinics they are strongly urged to avoid barefoot walking. If this ideal were to be achieved, barefoot pressure would only be a predictor of the actual pressure experienced by the foot (the in-shoe pressure) in activities of daily living if all shoes reduced pressure by the same amount. This is clearly not the case – since there are patients in good shoes and those in bad shoes. It is, therefore, likely that we need to look toward the

measurement of in-shoe pressure to gain a better estimate of threshold.

IN-SHOE PRESSURE MEASUREMENT

It is now quite feasible to obtain accurate and reproducible measurements of pressure distribution inside the shoes of ambulating patients. In collaboration with our colleagues in Sweden (Cavanagh et al. 2002) we have used the PEDAR device to measure in-shoe pressure in a group of 53 patients with a history of ulceration, but who had remained ulcer free while wearing therapeutic footwear. Although barefoot pressure measured with the EMED SF revealed greater peak pressures at ulcer sites under the first metatarsal head (MTH1) compared to the hallux (692 ± 330 kPa, $n=18$ vs. 486 ± 242 kPa, $n=17$) this trend disappeared for the in-shoe measurements (unadjusted peak pressures of 204 ± 63 kPa vs. 214 ± 71 kPa at MTH1 and hallux respectively). In-shoe peak pressures at all of the different prior ulcer sites were remarkably close to 200 kPa, suggesting that the reduction of in-shoe pressure below this value is necessary to maintain healing. If such a threshold were to be prospectively validated, it would be extremely useful in footwear design as long as plantar pressure monitoring were available prior to the shoes being dispensed.

OTHER FACTORS

In-shoe plantar pressure measurement alone will never predict all of the variance in ulceration threshold. For example, patients with extremely low plantar pressures can injure their feet by non-compliant behavior, and those with extremely high pressures can prevent injury by inactivity. It is, therefore, likely that in addition to in-shoe plantar pressure and the factors mentioned above, both compliance and activity level would need to be taken into account.

PLANTAR PRESSURE MEASUREMENTS AS AN OUTCOME MEASURE FOR INTERVENTIONS USED TO TREAT FOREFOOT AND MIDFOOT PAIN

Thomas G. McPoil

Gait Research Laboratory, Department of Physical Therapy, Northern Arizona University,
Flagstaff, Arizona, USA, tom.mcpoil@nau.edu

INTRODUCTION

Forefoot and midfoot pain as a result of orthopaedic problems are both painful and debilitating. Although numerous interventions have been suggested for the management of forefoot and midfoot pain, the success of these treatment techniques is often based on patient self-reported pain reduction. Plantar pressure measurements offer the clinical researcher the ability to assess the effectiveness of the various interventions available for the conservative treatment of forefoot and midfoot pain. Just as importantly, pressure measurements serve as an effective outcome measurement tool to validate if a reported reduction in pain corresponds to a decrease or modification of the plantar pressures acting on the painful plantar region of the foot. The purpose of this presentation is to review the etiology of forefoot and midfoot pain as well as the use of plantar pressure assessment as both a research and outcome measurement tool.

FOREFOOT PAIN

Forefoot pain, or metatarsalgia, is defined as pain in or about the head of the metatarsal, the metatarsophalangeal joint, and surrounding soft tissue structures. Next to heel pain, metatarsalgia is one of the most frequent causes of pain in the foot. The causes of metatarsalgia fall into four major groups: 1) localized disease processes (i.e.; Morton's neuroma, interdigital neuroma, Freiberg's disease, stress fracture), 2) systemic diseases with specific symptoms in the forefoot region (i.e.; rheumatoid arthritis), 3) toe deformities (i.e.; claw toe, hammer toe, mallet toe), and 4) alteration in normal forefoot biomechanics. Groups 3 and 4 are often referred to as primary metatarsalgia, while groups 1 and 2 are considered secondary types of metatarsalgia. Specific factors that can influence and alter normal forefoot mechanics include: 1) overload of anterior support (i.e.; high heeled shoes, equinus foot, cavus foot) and 2) irregularity in the distribution of metatarsal head loading (i.e.; first ray overload syndrome, overload of a central ray, first ray insufficiency syndrome, Morton's toe).

FOREFOOT PAIN INTERVENTIONS

Both primary and secondary forms of metatarsalgia can respond well to conservative treatment interventions if initiated early in the course of the patient's symptoms. Common conservative interventions include: cushioned insoles, metatarsal pads, foot orthoses, cushioned hosiery, and external and internal metatarsal bars. Previous studies using both traditional research methods as well as single-

subject design models have demonstrated that: a) metatarsal pads and insole materials decrease plantar pressures effectively and in a similar manner but that arch taping to control first ray insufficiency actually causes an increase in plantar pressure (Childs, 1996), b) padded hosiery can significantly reduce forefoot plantar pressures but that pressure reductions were not uniform across the entire forefoot (Flot, 1995), c) total contact foot orthoses are effective in decreasing plantar pressures irrespective of whether rearfoot posting is utilized (Cornwall, 1992), and d) the use of foot orthoses constructed from lower density materials provide a greater reduction in forefoot loads during walking than higher density materials (McPoil, 1991). Clinical outcome studies using plantar pressure measurements have also shown that a) internal metatarsal bars can be effective in the management of forefoot pain associated with toe deformities and b) total-contact cushioned foot orthoses can decrease forefoot pressures in athletes with a cavus foot structure.

MIDFOOT PAIN

Midfoot pain can occur as a result of overuse repetitive stress in activities such as ballet and volleyball. A more common cause of midfoot pain is trauma to the region as a result of motor vehicle accidents, occupational/industrial injuries, and athletic competition.

MIDFOOT PAIN INTERVENTIONS

In most cases, the conservative treatment for midfoot pain as a result of overuse or acute injury is foot orthotics that provide both cushioning and stabilization to the joints and soft tissues in the midfoot region. Although plantar pressure assessment provides little information on the effectiveness of this type of treatment intervention, plantar pressure measurements serve as an important functional outcome tool to determine progress of the patient in their reacquisition of a normal gait pattern. In addition to temporal measures, plantar pressure data can also provide valuable information on the pattern and sequencing of plantar surface loading.

RELATIONSHIP OF PERCEPTION VS. THE MEASUREMENT OF PLANTAR PRESSURES – A NEUROSENSORY APPROACH

Thomas L. Milani & Stefan Kimmeskamp
University of Essen, Department of Human Locomotion
45131 Essen, Germany; thomas.milani@uni-essen.de

INTRODUCTION

Human balance is controlled by afferent information based on visual, vestibular and somatosensory input systems (van Deursen et al., 1999). Studies have focused on the specific role of vestibular, visual or muscular sensory information, but few research studies have been performed to date to investigate the role of cutaneous sensibility from the foot soles (Kavounoudias et al., 1998). The contribution of the plantar sensory systems to balance control has been discussed indirectly by researchers that studied sensory deficiencies based on neuropathic (e.g. diabetes) or artificial (e.g. icing/cooling) perturbations. Research with Diabetes patients revealed that diabetic neuropathy lead to a loss of protective sensation (Simoneau et al., 1996). The loss of protective sensation in combination with the continually repeated stress onto the plantar surface in daily walking have been observed as main factors for ulceration. Using anesthesia procedures the importance of cutaneous afferent input from the plantar surface in controlling rapid compensatory stepping reactions could be shown (Perry et al., 2000).

Since the foot mechanoreceptors are the boundary systems between the body and the ground it can be assumed that they play an important role in controlling the human balance. While mechanoreceptors of human skin are specific for different stimuli the identification and contribution of the specific foot sensors for balance control is of interest. Whereas Merkel corpuscles and Ruffini are sensitive for the intensity of pressure, vibratory stimuli are mediated by Meissner (low frequencies of 10 – 50 Hz) and Pacinian (high frequencies of 100 – 300 Hz) corpuscles.

METHOD

A direct approach for studying the relationship between foot sensation and posture control can be performed by using sensor stimulation procedures. For different groups of subjects, sensitivity and posture control measurements were performed. Healthy youth adults (mean age: 26y), senior adults (64y) and patients with Parkinson disease (67y) participated in these studies. Subjective sensibility thresholds under five foot structures (heel, midfoot, I. & V. metatarsus head and Hallux) of different mechanoreceptors (intensity, vibration) were determined by using a vibration exciter (30 Hz, 125 Hz) and Semmes Weinstein-microfilaments. The sensitivity of intensity mechanoreceptors were analyzed by using a 4-2-1-algorithm. Control of human posture was measured by pressure sensitive insoles (Novel GmbH, Munich). The postural stability was tested under various sensory conditions with increasing level of demand (one leg standing/eyes open – closed/head upright – tilted back/lean forward). A sensitivity parameter for each subject was determined by averaging vibration resp. intensity thresholds of five foot locations. Sensitivity

variables and balance control variables were evaluated by regression analyses.

RESULTS & DISCUSSION

Sensitivity threshold measurements revealed significant differences ($p < .01$) between the various foot areas for both stimulus modalities (intensity & vibration). Comparisons between the different groups revealed significant differences in sensory threshold data (Fig.1).

Fig.1: Vibration (30 Hz) threshold diff. between groups

Regression analyses of the threshold data and Center of Pressure (CoP) data revealed that subjects with more sensitive feet show less motion amplitudes of the Center of Pressure (Fig.2).

Fig.2: Sensitivity (SSC) vs. Length of CoP in students

PRESSURE PATTERNS UNDER THE FEET OF CHILDREN, ADULTS AND OVERWEIGHT PERSONS - THE INFLUENCE OF GENDER -

Ewald M. Hennig
Biomechanics Laboratory, Universitaet Essen
Essen, Germany, ewald.hennig@uni-essen.de

INTRODUCTION

Results from various plantar pressure studies on adults and children, performed at our laboratory and in cooperation with international partners are presented here. Specifically, the influence of gender on foot pressures will be discussed.

ADULTS

An early study determined the pressures during bipedal standing and walking (approx. 1 m/s) under the symptom-free feet of 49 women and 62 men (Hennig et al., 1993). During standing and walking the highest pressures under the forefoot were found under the third metatarsal head. It was concluded that during weight bearing no transverse arch across the metatarsal heads is apparent. Therefore, a tripod theory of foot loading as it had been mentioned in many anatomy text books can not be confirmed by plantar pressure measurements. Similar to findings of Cavanagh et al. (1987) under none of the investigated anatomical regions a relationship between peak pressures and body weight were found across subjects. When grouping the subjects according to gender, however, a relationship ($r = + 0.65$, $p < 0.01$) was found for the comparison of body weight against the peak pressures under the longitudinal arch of the women's feet during walking. Because this phenomenon was only present for the women, it was speculated that weaker ligamentous structures in women's feet result in a higher collapse of the longitudinal arch with increased body weight. This hypothesis has recently been supported by a study comparing foot function of women and men during running (Hennig, 2001). Midfoot loading as well as the amount of rearfoot pronation were increased for the women.

CHILDREN

Plantar pressures during barefoot walking and running were determined for 15 infants (7 male, 8 female) between the ages of 14 and 32 months (Hennig & Rosenbaum, 1991). Compared to the plantar pressures in adults, considerably reduced peak pressures in the infant group were observed. These could be attributed to the softer foot structure as well as a lower body-weight to foot-contact area ratio. An almost three times higher relative load under the midfoot of the infant foot shows that the longitudinal foot arch is still a weak structure in this age group. Across the age range of the children it was observed that with increasing age the relative load under the midfoot decreases while it becomes more pronounced under the third and fifth metatarsals. In a later study peak pressures and relative loads under the feet of 125 children (64 boys, 61 girls) between 6 and 10 years of age were determined (Hennig et al., 1994). These results were

compared to the data from adults. The school children showed considerably lower peak pressures under all anatomical structures. These lower pressures could mainly be attributed to the larger foot dimensions per kg body mass for the children. Reduced loading of the first metatarsal head in the younger children was attributed to a valgus knee condition with hyperpronation of the foot and a reduced stability of the first ray. No reduction in pressures under the longitudinal arch with an increase of age suggests that foot arch development is almost complete before the age of six. Contrary to the findings in adults, body weight was identified to be of major influence on the magnitude of the pressures under the feet of school children. Between boys and girls no differences in the peak pressure or relative load patterns were present.

OVERWEIGHT PERSONS

Hills et al. (2001) investigated the plantar pressure differences between obese and non-obese adults during standing and walking. Thirty-five men (67–179 kg) and 35 women (46–150 kg) were divided into an obese (body mass index (BMI) 38.8 kg/m²) and a non-obese (BMI 24.3 kg/m²) group. The obese subjects showed an increase in the forefoot width to foot length ratio, suggesting a broadening of the forefoot under increased weight loading conditions. In spite of the increased load bearing contact area of the foot with the ground, the obese men and women had substantially higher pressures under the heel, midfoot, and forefoot during standing and walking. In the static as well as the dynamic loading situations, the highest pressure increases for the non-obese group were found under the longitudinal arch of the foot. The influence of body weight on increased midfoot pressures was much stronger for the women as compared to the men. This gender related influence of body weight on the flattening of the arch may be the consequence of a reduced strength of the ligaments in women's feet.

PRESSURE DISTRIBUTION MEASUREMENT AND THE RHEUMATOID ARTHRITIC FOOT

James Woodburn
Rheumatology & Rehabilitation Research Unit, School of Medicine,
University of Leeds, Leeds, UK

INTRODUCTION

Rheumatoid arthritis (RA) is a chronic inflammatory arthritis associated with widespread synovial joint involvement and systemic features. It is both persistent and destructive and manifests itself early in the feet causing pain, deformity, functional impairment and disability. Synovitis, tenosynovitis, bursitis are responsible for pes planovalgus deformity, hallux valgus, claw and hammer toe deformity of the forefoot, subluxation of the metatarsophalangeal joints with plantar callosities, bursitis and ulceration, and more rarely neurological and vascular deficit.

The Rheumatology Research Unit at the University Leeds conducts a clinical research foot and ankle program for patients with RA foot disease. The gait laboratory utilises both platform (Emed- Novel GmbH) and in-shoe (Pedar- Novel GmbH) plantar pressure measurement (PPM) systems and the suite of NovelWin analytical software. The aim of this presentation is to provide a brief overview of RA and its common manifestations in the feet and to demonstrate justification for PPM. Application in routine clinical practice will be described, illustrated with case histories. An overview of past, current and future research projects will be provided.

CLINICAL APPLICATIONS OF PPM IN RA

PPM is used routinely in the RA foot clinic to evaluate overall foot geometry- midfoot collapse, forefoot splaying, absent toe contact, prominence of metatarsal heads, etc- (fig 1 & 2), foot loading patterns- medial heel loading, medial midfoot loading, antalgic gait, etc- (fig 2), the magnitude and distribution of forefoot pressures- Hughes loading patterns, peak and time integrals of pressure and force, etc. We derive a core set of quantifiable PPM measurements and combine this information with standard outcomes for foot pain, deformity and disease activity to both inform and evaluate diagnosis and therapy.

Fig 1. Abnormal plantar pressure distribution in RA showing elevated forefoot pressures, reduced toe contact and partial collapse of the medial longitudinal arch.

Fig 2. Antalgic gait pattern in RA- absent toe contact, elevated forefoot peak pressures and abnormal loading pattern (CoP).

PPM RESEARCH IN RA

Foot structure and function in RA

Various PPM and footprint parameters have been used in RA to study the structural and functional changes associated with RA disease. Results of these studies will be described. Our group is interested in the interaction between local inflammatory and biomechanical factors causing persistent localised disease activity. We are studying the ability of PPM in very early RA to predict future distribution and severity of localised forefoot synovitis and bone pathology, pressure lesions, pain, deformity and functional impairment.

Tissue Viability

PPM has been used to study the effects of tissue debridement for forefoot lesions in RA and findings will be presented².

Orthotic management

Redistributing plantar pressures is a stated goal in orthotic management. Literature will be reviewed and results from our own cross-sectional and longitudinal studies presented³.

Future research

An MRI-based method for determining foot structure in RA has been developed. Preliminary findings will be presented investigating the relationship between PPM/footprint derived structure and function and *in vivo* foot architecture derived from MRI analysis.

SUMMARY

PPM is a useful clinical and research tool to study foot structure and function in RA foot disease.

NEURONAL CO-ORDINATION OF ARM AND LEG MOVEMENTS DURING HUMAN LOCOMOTION

Karim Fouad^{1,2}, Catharina Maria Bastiaanse^{1,3} and Volker Dietz¹

¹ParaCare, Paraplegic Centre University Hospital Zurich, Switzerland,

²University of Alberta, Faculty of Rehabilitation Medicine, T6G 2G4 Edmonton, Canada, Karim.fouad@ualberta.ca

³Catholic University Nijmegen, Dept. of Medical Physics and Biophysics, Nijmegen, The Netherlands

INTRODUCTION

The evolution of upright stance and gait in association with the differentiation of hand movements represents the basic requirement for human development. An unresolved question of this development is whether or not there are still residual functions of quadrupedal locomotion during human bipedal gait reflected in a neuronal linkage between leg and arm movements. Therefore, the aim of this study was to examine the interlimb co-ordination between leg and arm movements in walking humans.

METHODS

To study the neuronal co-ordination of lower and upper limb muscles the effect of small leg displacements during gait on leg and arm muscle electromyographic (EMG) activity was evaluated. During walking on a split-belt treadmill (velocity 3.5 km/h), short accelerations or decelerations were randomly applied to the right belt during the mid or end stance phase. Alternatively, trains of electrical stimuli were delivered to the right distal tibial nerve. The EMG activity of tibialis anterior (TA), gastrocnemius medialis (GM), deltoideus (Del), triceps (Tric) and biceps brachii (Bic) of both sides was analysed. For comparison, impulses were also applied during standing and sitting.

RESULTS AND DISCUSSION

The displacements were followed by specific patterns of right leg and bilateral arm muscle EMG responses. Most arm muscle responses appeared with a short latency (65 to 80 ms) and were larger in Del and Tric than in Bic. They were strongest when deceleration impulses were released during mid stance, associated with a right compensatory TA response. A similar response pattern in arm muscles was obtained following tibial nerve stimulation. The arm muscle responses were small or absent and when stimuli were applied during standing or sitting. The arm muscle responses correlated more closely with the compensatory TA than with the compensatory GM responses. The amplitude of the responses in most arm muscles correlated closely with the background EMG activity of the respective arm muscle.

The observations suggest the existence of a task-dependent, flexible neuronal coupling between lower and upper limb muscles. The results showed a stronger connection between flexor activity in the legs and activity in arm muscles than between leg extensors and arm muscles. The results are

compatible with the assumption that the proximal arm muscle responses are associated with the swinging of the arms during gait, as a residual function of quadrupedal locomotion.

Figure 1: Comparing walking, standing and sitting. Rectified and averaged right TA and left Tric EMG response to a deceleration impulse during walking (A) a backward translation of the right belt during standing (B) and during sitting (C). Thin lines represent EMG recordings without perturbation.

CONCLUSION

In conclusion we would suggest a functional gating of neuronal pathways between lower and upper limb muscles during human locomotion. It remains a future task to define these neuronal connections more precisely.

ARE RHYTHMIC ARM MOVEMENTS CONTROLLED BY A CENTRAL OSCILLATOR?

E. Paul Zehr

Neurophysiology Laboratory, University of Alberta, Edmonton, Alberta, Canada, pzehr@ualberta.ca

INTRODUCTION

The neural control and sensory regulation of arm movement in humans has received comparatively scarce attention when compared to studies on the lower limb during locomotor movements such as treadmill walking or leg cycling (for reviews see Duysens and Tax, 1994; Brooke *et al.*, 1997). Such studies have shown extensive modulation of reflexes evoked by stimulation of muscular (e.g. H-reflexes) and cutaneous afferents during leg movement and have contributed greatly to our understanding of the sensory control of rhythmic movement. Mechanisms controlling the patterns of reflex modulation observed during leg movements (e.g. phase-dependent modulation, task-dependency, reflex reversal, and nerve specificity) have been ascribed to the activity of spinal central rhythm generating networks (Duysens and Van de Crommert, 1998). The working hypothesis in my laboratory has been that neural mechanisms controlling rhythmic movement are conserved between the human lumbar and cervical spinal cord. Therefore the neural control mechanisms and thus patterns of reflex modulation observed during rhythmic arm movement should be similar to that previously documented for leg movement during locomotor tasks. We have developed a model for studying rhythmic human arm movements and have been testing our hypothesis by evaluating the control of cutaneous and H-reflexes during these arm movements. Additionally we have also studied cutaneous reflex modulation during the rhythmic arm swing occurring during treadmill walking.

METHODS

All subjects participated in the experiments with informed, written consent. Subjects performed rhythmic arm cycling on a custom made hydraulic ergometer in which the two arms could be constrained to move together (180° out of phase) or could rotate independently. In different experiments, cutaneous reflexes were evoked with trains (5 x 1.0 ms pulses @ 300 Hz) of electrical stimulation delivered at non-noxious intensities (~ 2 x threshold for radiating parasthesia) to the superficial radial (SR), the median, and the ulnar nerves innervating distinct cutaneous fields in the hand. H-reflexes in forearm flexor carpi radialis (FCR) were evoked with single 1.0 ms pulses of constant current stimulation applied just proximal to the medial epicondyle of the humerus. Electromyographic recordings were made bilaterally from muscles acting at the shoulder, elbow, and wrist. Reflexes were evoked during rhythmic movement as well as during static contraction at matched positions. For the experiments during walking, subjects walked on a motorized treadmill

while the SR nerve was stimulated pseudorandomly throughout the step cycle. Analysis was conducted on specific sections of the step cycle after phase-averaging contingent upon the occurrence of stimulation in the step cycle.

RESULTS AND DISCUSSION

During arm cycling, cutaneous reflexes were modulated with the movement cycle (i.e. there was phase-dependency; Zehr and Chua, 2000, Zehr and Kido, 2001). Also prominent phase-modulated cutaneous reflexes were typically observed in arm muscles during treadmill walking (Zehr and Haridas, 2001). Nerve and task-specificity of cutaneous reflexes was also seen as cutaneous reflexes were of larger amplitude or inhibitory during arm cycling movement when compared to static contraction (i.e. reflex reversal; Zehr and Kido, 2001). Additionally, forearm H-reflexes were attenuated during arm cycling as compared to static contraction. Thus, task-dependent modulation of H-reflexes was observed in the arm as previously demonstrated in the leg (Frigon *et al.* 2002).

SUMMARY

It is concluded that reflexes are modulated similarly during rhythmic upper and lower limbs suggesting similar motor control mechanisms. However, there are some differences between this pattern and that previously observed in the lower limb. It is suggested that these small differences arise from the difference in biomechanical constraints seen when comparing articulation at the wrist vs. ankle joints in humans. The data support the assertion that mechanisms regulating reflex pathways during rhythmic movement are similar in the human upper and lower limbs.

INTER-LIMB COORDINATION IN HUMAN LOCOMOTION WITH ADDED MASS.

J. Duysens^{1,2}, S.F. Donker¹, S. M. P. Verschueren³ and S. P. Swinnen³

¹Sint Maartensclinic Research, Nijmegen, The Netherlands

²Dept. of Biophysics, K.U.Nijmegen, The Netherlands j.duysens@mbfys.nl

³Motor Control Laboratory, Department of Kinesiology, FLOK, Katholieke Universiteit Leuven, Belgium

INTRODUCTION

During gait there is a continuous interaction between sensory input and motor circuits generating the locomotor patterns (Duysens et al., 2000). From animal models it is known that proprioceptive information from a limb affects not only the kinematics of the limb involved but also the inter-limb coordination. During walking in crabs, for example, the activation of load receptors in one leg induced changes not only in the perturbed leg but also in the non-perturbed legs (Libersat et al. 1987). In human walking and running the addition of mass (load) to one leg leads to substantial changes in the structure of the step cycle (increased duration of swing; decrease in duration of double support period) although very little effect on cadence has been observed (Bonnard and Pailhous 1991; Cavanagh and Kram 1989). Little is known, however, concerning changes in the relation between upper limbs and between upper and lower limb activity as a result of selective loading to a single segment.

METHODS

In the present experiments, adaptations in arm amplitude and arm muscle activity to mass perturbations were studied in 7 participants during walking on a treadmill. Four different perturbation conditions (no perturbation, mass added to both wrists, to the right wrist, and to the right ankle) were employed randomly. During each experimental condition 10 different belt speeds (from 0.5 to 5.0 km/h) were tested, while the arm movements and the electromyographic (EMG) activity of the posterior and anterior deltoids were measured.

RESULTS AND DISCUSSION

No differences were found for stride frequency. However, loading the arm resulted in a significant decrease in movement for that particular arm. In addition, loading one arm increased the movements on the contralateral left arm. Loading the leg resulted in a significant increase of the movements of both arms as compared to the control condition. The highest increase in EMG activity was found for deltoids of the arm to which the weight was added. Remarkably, loading one arm yielded a significant increase in the (non-loaded) left arm. Additionally, in the condition in which a load was added to one leg a significant increase in EMG was found also in the deltoids of both (non-loaded) arms.

SUMMARY

The results indicate that during gait the added mass not only yielded an increase in arm muscle activity and in a decrease of movement amplitude of the perturbed arm, but also in alterations in the non-perturbed arm. The effects were not limited to the arms. Notably, adding mass to the ankle induced adaptive changes in both arms.

In conclusion, during gait the loading of one of the limbs induces adaptations in inter-limb coordination in the 3 remaining limbs despite rhythm constancy (stable cadence). This is in line with experiments on sitting subjects. Serrien and Swinnen (1998) showed that inter-limb synchronization remained possible after loading the limbs although the synchronization between homologous limbs was more robust than between non-homologous limbs. The results from the Swinnen laboratory along with the present ones point towards the existence of neural circuits which allow for stable interlimb coordination despite extensive changes in limb loading.

MUSCLE WORK AND FORCE: ENERGETICS OF HUMAN WALKING

Arthur D. Kuo¹, Jiro Dokeh¹, and J. Maxwell Donelan²

¹Dept. of Mechanical Engineering, University of Michigan, Ann Arbor, Michigan USA (artkuo@umich.edu)

²Centre for Neuroscience, Dept. of Physiology, University of Alberta, Edmonton, Alberta, Canada

INTRODUCTION

What determines the metabolic cost of walking? Movement is produced by muscles, and muscles consume energy to produce work and force. Although the muscle work is known to consume energy, work is insufficient to explain the net metabolic cost of walking. It also does not explain the relationship that step length and walking speed that humans typically prefer (Elftman, 1966). This may be due to the consumption of energy to produce muscle force without performing work. We use a simple mathematical model of bipedal walking, along with experimental measurements of metabolic cost, to examine how work and force might be used in human walking.

METHODS

We developed a simple model of actively powered bipedal locomotion, based on the passive dynamics of the legs (Fig. 1; Kuo, 2001). The model is actively powered by an impulsive toe-off push, applied along the trailing leg axis, just prior to heel strike of the leading leg. A torsional spring acts between the legs. This model walks stably on level ground, with the toe-off push providing propulsion, and the torsional spring adjusting step length and step frequency.

Figure 1. Bipedal walking model.

The model dissipates mechanical energy in the collision between the swinging foot and ground. During each step the center of mass (located near the hip) moves in an arc. Energy loss occurs between steps, as the center of mass is redirected from the downward arc of one step to the upward arc of the next. The redirection is due to negative work performed by the trailing leg. In order to walk at steady speed, an equal amount of positive work must be performed each step. The rate of positive and negative work due to collisions should increase with the fourth power of step length if step frequency is kept fixed, with a proportionate metabolic cost.

Collisions alone do not explain the metabolic cost of walking, because collisions could be minimized by taking very short but frequent steps. Instead, humans increase both step length and step frequency with walking speed, indicating that there is an energetic cost to high step frequencies, perhaps for the muscle activity required to move the legs quickly. We therefore examined the possibility that such movement, which is produced at no energetic cost by the model's torsional spring, comes at a substantial cost in humans. But the work needed to move the legs, if assumed to exact a proportionate metabolic cost, does not properly predict the preferred step length vs. speed (Kuo, 2001). Instead, an energetic cost for moving the legs—proportional to force and inversely proportional to duration of force—appears to predict optimal step length. This assumes that muscle force is the dominant cost, with work performed by elastic tendons. A prediction arising from this

model is that metabolic cost should increase with the fourth power of step frequency, if step length is kept constant.

We tested these predictions by measuring human metabolic energy consumption with three types of walking. First, we asked subjects ($N=7$) to walk at increasing speed by changing step length alone. Metabolic cost should increase with the fourth power of step length. Second, we asked the same subjects to walk at increasing speed by changing step frequency alone. Metabolic cost should increase with the fourth power of step frequency. Finally, we asked subjects to walk at increasing speed without restrictions. The combined metabolic costs at the preferred step length should increase approximately with speed raised to the 2.4 power.

Fig. 2. Net metabolic power vs. speed at freely selected step lengths, with model prediction (speed raised to 2.4 power).

RESULTS AND DISCUSSION

We found that when subjects increased speed by changing only step length, metabolic power increased with the fourth power of step length ($R^2 = 0.95$). When they increased speed by changing only step frequency, metabolic power also increased with the fourth power of step frequency ($R^2 = 0.91$). Finally, when they increased speed using their freely selected step lengths, metabolic power increased with speed raised to the 2.42 power (Fig.2; $R^2 = 0.96$).

CONCLUSION

These results are consistent with our predictions that mechanical work is performed to redirect the center of mass between steps (collisions), and mechanical force is produced by muscles to move the legs, with both contributions exacting a proportional metabolic cost.

INTRODUCTION

Numerous studies have described the differences in kinematic, kinetic and EMG variables between forward and backward human walking. Many aspects of the backward pattern appear to be a time-reversal of the forward pattern, with many similarities observed between initial and late stance in forward walking and late and initial stance, in backward walking, respectively. However, since initial and late stance are associated with net resistive and propulsive ground reaction forces, respectively, and the directions of joint rotations will be opposite during the two gait modes, it is unclear whether the observed similarities represent similar muscle actions. Winter et al. (1989) suggested that "temporal cycling of muscle contraction would be reversed: Concentric muscle activity in forward walking would become eccentric activity in backward walking, and vice versa." While their EMG results generally supported those findings, other studies have found the differences in muscle activity patterns between forward and backward walking more complex (e.g., Grasso et al., 1998). In the present study, we explicitly test the hypothesis that individual muscle activity will switch from from concentric to eccentric, and vice versa, in backward walking.

METHODS

Bilateral ground reaction forces, 3D kinematics, and unilateral EMG from eight muscles (tibialis anterior, soleus, medial gastrocnemius, vastus medialis, rectus femoris, biceps femoris, semimembranosus, and gluteus maximus) were collected from 12 subjects walking forward and backward at their self-selected speed. To assess muscle length, a forward dynamical simulation that emulated observed planar walking kinematics and kinetics of young adult subjects was produced. The musculoskeletal model and simulation were developed using SIMM/Dynamics Pipeline (MusculoGraphics, Inc.) and SD/FAST (PTC). The contact between the foot and the ground was modeled with discrete visco-elastic elements located on the bottom of the foot. The individual muscle excitation patterns were modeled as block patterns and an optimization framework systematically varied the muscle controls to replicate the experimental data.

RESULTS AND DISCUSSION

During backward walking, tibialis anterior, soleus, medial gastrocnemius, and gluteus maximus showed peak activity during muscle lengthening and the hamstrings, vastus and rectus femoris showed peak activity during shortening (Fig 1). During forward walking, only hamstrings showed peak activity during the same region, with all others being reversed.

Figure 1: EMG activity during backward walking (mean + SD), normalized as percent of max for forward walking. Gait cycle begins with ground contact and ends with final swing. Bars represent regions of muscle-tendon unit lengthening.

SUMMARY

The hypothesis of Winter et al. (1989) was mostly supported. A change from predominantly concentric to eccentric activity, and vice versa, was found in nearly all muscles when walking backward. Different mechanisms of propulsion and support were observed during forward and backward walking. Analysis of simulation results will be presented to contrast the mechanical effects of concentric and eccentric action by individual muscles in the two walking tasks.

QUADRUPLE JUMPS IN FIGURE SKATING

Deborah King, Ph.D.

Biomechanics Lab, Montana State University, Bozeman, Montana

Email: dking@montana.edu

INTRODUCTION

The "quad", a quadruple revolution figure skating jump, has become a commanding presence in figure skating. However, the completion percentage of quadruple jumps remains low, only 13 of 24 attempted quadruple jumps were successfully landed at the 2000 State Farm Figure Skating Championships analyzed for this study.

Successfully completing any figure skating jump requires, at a minimum, the skater to coordinate time-in-the-air with average rotational velocity. Albert and Miller (1996) found an increase in angular velocity from single to double Axels with only minor variations in time-in-the-air. The increase in angular velocity was predominantly due to decreases in moments of inertia of the skaters as opposed to increase in angular momentum (Albert and Miller, 1996). However, King (1997) found an increase in jump height and time-in-the-air from single to double to triple Axels with more highly rated jumps having higher jump heights than more lowly rated jumps. Moreover, due to physiological limitations in generating vertical velocity (maximizing jump height), minimizing moment of inertia, and generating angular momentum, completing triple jumps may require different strategies than completing quadruple jumps. Thus, the purpose of this study was to determine critical technique elements for successful completion of quadruple jumps.

METHODS

Data were collected during the 2000 State Farm Figure Skating Championships. Written informed consent along with age, height, and weight were obtained from participating skaters. The approach through landing of quadruple and triple jumps were recorded using four high speed (120-pictures/second) pan and tilt cameras (Peak Performance Technologies, Inc.). A calibration was performed at the beginning of each day of testing using survey poles. Data were manually digitized and 3D coordinates were calculated using the Peak Motus pan and tilt procedure. The 3D coordinates were filtered using a quintic spline algorithm and then analyzed using software written in LabView (National Instruments, Inc.). Four men attempted a total of 24 quadruple jumps resulting in a total of 6 landed and 6 fallen quads being

analyzed along with 7 corresponding triples. All jumps were toe-loops and Salchows. Results from 4 landed quad toe-loops, 4 fallen quad toe-loops, and 4 triple toe-loops are presented.

RESULTS AND DISCUSSION

Jump heights were similar between triple and quadruple jumps, though time-in-the-air (*FlightTime*) was longer for quadruple jumps (Table 1). This seeming incongruity is explained by a lower, or slightly seated, landing position for the quads. Similar to the findings of Albert and Miller (1996), the minimum moments of inertia (I_{min}) during flight were smaller for quad jumps as compared to triple jumps, and angular momentum values at take-off (H_{to}) were similar between jump types, especially after removing one outlying triple, which changes the H_{to} triple average to 29.9 kgm²/s (Table 1). Moreover, the average moment of inertia during flight (I_{avg}) was smallest for the landed quad jumps as compared to the fallen quads or triples (Table) allowing for faster angular velocities during flight. Smaller toe-pick distances (*PickDist*) at the instant of tap for the landed quads (Table), were likely influential for the skaters controlling their moments of inertia and angular velocities during take-off. Lastly, in landed quadruple jumps, skaters initiated on average 64 degrees more rotation on the ice (*PreRot*) as compared to triple jumps. The average number of revolutions for the landed quadruple jumps was 3.1 as compared to 2.5 for the triple jumps (Table), so that the quads were actually only 0.6 more revolutions than the triples.

SUMMARY

Additional revolutions during quadruple jumps were from a combination of increased time-in-the-air and smaller moments of inertia during flight. However, due to a more pre-rotation, the quad jumps in this study had only 0.6 more revolutions than the triples.

SEARCHING FOR OPTIMAL KNEE EXTENSION TIMING IN DIVES FROM THE REVERSE GROUP

Eric Springs¹ and Doris I. Miller²

¹College of Kinesiology, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

²Professor Emerita, University of Western Ontario, London, Ontario, Canada

INTRODUCTION

Reverse rotating dives require divers to face forward yet generate backward somersault angular momentum during the takeoff phase. These requirements place major importance on the positioning of the lower legs and timing of the knee extension. The optimal changes that should take place in these two variables when progressing from a reverse 1½ to a 2½ pike have yet to be determined. The purpose of this study was to develop a mathematical model to simulate the diver's springboard or platform contact during the takeoff phase of dives from the reverse group.

METHODS

The diver was modeled in 2-D space as a 5-segment linked system: feet, lower legs, thighs, head & torso, arms. The springboard was modelled as a mass-spring element with no damping (Springs et al., 1990). Effective mass and spring stiffness of the board model were set at 9.5 kg and 3500 N/m ('soft' board), respectively. Torque generators that adhered to activation rates and force-velocity properties of human muscle were inserted at ankle, knee, hip and shoulder joints allowing the model to control energy to the system. The force-length property of muscle was expected to play a 2nd order role in the outcome of the performance (Caldwell, 1995) and, as such, was not included in the simulation model. Activation rate and force-velocity properties associated with human muscle were implemented using calculated instantaneous isometric torque predicted from a linearized Hill model structure as input to the force-velocity approach described by Alexander (1990). Parameter values for segment lengths, masses and moments of inertia for a representative diver with body mass of 54.0 kg and standing height of 1.62 m, were obtained from de Leva (1996). Equations of motion for the diver-springboard system were written using a Newtonian formulation in combination with the known equations of constraint for a system linked with pin joints. A 5th order Runge-Kutta-Fehlberg algorithm with variable step size was programmed in FORTRAN and used to numerically solve the 2nd order differential equations for the corresponding angular position and velocity values of the 5 segments. Thirteen control variables, consisting of the times of onset and the length of activation time of each of the muscle torque generators, plus the body tilt angle, were used in the optimization process. The total angular displacement, as measured from the start of dive flight until the piked model's CG passed the level of the takeoff surface, along with any accrued penalties from inappropriate behaviour by the model, served as the objective function to be minimized.

RESULTS AND DISCUSSION

The simulation model suggested a controlled knee extension, which commenced late in the springboard's depression phase, was best. This is contrary to the fact that most divers begin

knee extension early in depression. Delaying knee extension until the board has nearly reached its maximum deflection due to the diver's downward momentum has the advantage of allowing muscular efforts to be exerted against a stiffer surface. The two-phase knee extension velocity strategy observed in a number of world class divers (Miller, 2000) may be related to the optimization results. From an energy perspective, delayed knee extension produces a greater deflection in the board, thus increasing the storage of strain energy to be returned to the diver during the recoil phase. The optimization process suggests that as the number of required somersaults increases both the angle of the lower leg with respect to the springboard and the angle of knee extension at the completion of the takeoff should decrease (Figs. 1 and 2).

EFFECT OF THE DIRECTION OF THE SOMERSAULT ROTATION ON THE AMOUNT OF TWIST ROTATION IN HIGH JUMPING

Jesús Dapena

Department of Kinesiology, Indiana University, Bloomington, IN 47405, USA (dapena@indiana.edu)

INTRODUCTION

At the end of the takeoff, a high jumper is upright, and facing approximately along the bar. For an effective bar clearance, at the peak of the jump the athlete needs to be horizontal and facing upward. This requires the athlete to make a twisting somersault rotation in the air. The twist rotates the body about its longitudinal axis, and the somersault rotates the body about an axis perpendicular to the longitudinal axis. The twist rotation is generated by the component of angular momentum aligned with the longitudinal axis (H_{TW}) and through rotational action-and-reaction ("catting") (Dapena, 1997). A defective twist rotation can produce a tilted position at the peak of the jump with one hip lower than the other. This will reduce the effectiveness of the bar clearance. To solve the problem, it is first necessary to understand its causes. A tilted position at the peak of the jump can be due to deficiencies in H_{TW} or in the catting (Dapena, 1995). The purpose of this project was to investigate the possibility that the tilt might also be affected by the direction of the somersault rotation.

THEORETICAL CONSIDERATIONS

Figure 1 shows an overhead view of a hypothetical high jumper at takeoff and after 90° of pure somersault rotation (no twist) in three different directions. A typical somersault about an axis parallel to the bar would produce the position shown in image b, which would require in addition 90° of twist for a face-up orientation. A somersault about an axis aligned with the final direction of the run-up would produce the position shown in image a, which would require only 45° of twist for a face-up orientation. A somersault about a horizontal axis perpendicular to the final direction of the run-up would produce the position shown in image c, which would require 135° of twist for a face-up orientation. The implication is that the somersault rotation of image c would require 90° more of twist in the air than the somersault rotation of image a to reach a face-up position at the peak of the jump.

PROCEDURES

Two trials with markedly different orientations of the angular momentum vector relative to the bar (overhead view) were selected for analysis. Body landmark locations were obtained using 3D film analysis. Center of mass location and angular momentum were calculated with a method based on Dapena (1978). The orientation of the longitudinal principal axis was computed for each airborne frame. The cumulative twist rotation of the hips about the longitudinal axis between takeoff and the peak of the jump was calculated, as well as the twist orientations of the hips at takeoff and at the peak of the jump.

Figure 1: Body positions after pure somersault rotations.

RESULTS AND DISCUSSION

The horizontal component of the angular momentum vector of subjects #1 and #2 pointed, respectively, 21° counterclockwise and 41° clockwise relative to the bar. At takeoff, the subjects' hips faced, respectively, 31° and 27° counterclockwise relative to the bar. In the air, subject #1 twisted through a cumulative angle of 76°, and his hips were level at the peak of the jump. Subject #2 twisted through a cumulative angle of 8°, and ended up with the hips 6° short of level at the peak of the jump. Thus, an additional 6° of twist rotation would have leveled his hips at the peak. If subject #2 had taken off facing the same direction as subject #1 (31° rather than 27°), he would have needed (8+6-4 =) 10° of twist rotation in the air to reach a level position at the peak of the jump, while subject #1 needed 76° of twist rotation for the same outcome.

The results indicate that high jumpers with angular momentum vectors oriented more counterclockwise relative to the bar in the view from overhead may need to twist through substantially larger angles to reach a level position of the hips at the peak of the jump. This could make it impossible for some jumpers to reach such a position.

THE CONTROL OF TWISTING SOMERSAULTS USING ASYMMETRICAL ARM MOVEMENTS

Maurice R. Yeadon

School of Sport and Exercise Sciences, Loughborough University, Loughborough, United Kingdom (M.R.Yeadon@lboro.ac.uk)

INTRODUCTION

Twist may be initiated during the aerial phase of a somersault by using asymmetrical arm movements to tilt the body away from the vertical plane of the somersault (Yeadon, 1993). A reversal of the asymmetrical arm movement can also remove the tilt and stop the twist. Since there will be some variation in the movement initiating the twist, it will be necessary to make in-flight adjustments in order to complete the required amount of twist. Adjustments in arm asymmetry have been shown to be capable of controlling twist in unstable non-twisting somersaults (Yeadon and Mikulcik, 1996). This study investigates whether the same type of control can control the twist in the final phase of a twisting somersault.

METHODS

An 11-segment computer simulation model of aerial movement (Yeadon et al., 1990) was used to produce a backward somersault with one twist. The arms each moved from an initial symmetrical position through 90° until one was by the side of the body and the other was overhead (Figure 1). The arm movements were later reversed so that the tilt was removed and the twist ceased after one revolution had been completed. The arm movement initiating the twist was perturbed by reducing the amplitude of the movement by 5° . This resulted in less tilt and a slower twist. The timing of the arm reversal in this perturbed movement was the same as that in the original simulation and lead to insufficient twist.

A control system was introduced into the model whereby arm asymmetry was adjusted with arm abduction acceleration being a function of twist angular velocity and acceleration (Yeadon and Mikulcik, 1996). With zero feedback time delay in the control system, the perturbation was accommodated with the required amount of twist being completed. With a time delay of 0.2 somersaults problems were encountered arising from the high rate of twist with the arms in the asymmetrical position. To overcome this difficulty the arms were abducted through 50° from the asymmetrical position before the control system was activated.

The procedure was repeated for a perturbation in which the simulation overtwisted.

RESULTS

The original simulation produced 1.00 twists with a final tilt angle of 0.2° after one somersault (Figure 1a). The perturbation resulted in a final twist angle of 0.86 revolutions and a final tilt angle of 7.0° (Figure 1b). With zero time delay the control system was able to compensate automatically for

the perturbation, producing final amounts of 1.01 revolutions of twist and 0.4° of tilt (Figure 1c). With a time delay of 0.2 somersaults and a spreading of the arms in mid-flight, the control system was at its limit in coping with the disturbance producing final amounts of 1.00 revolutions of twist and 2.3° of tilt (Figure 1d). Similar results were obtained when a perturbation was used to produce too much twist.

Figure 1: Simulation of a full twisting somersault (a) with change resulting from perturbation (b) and subsequent correction using control system with feedback delays of zero (c) and 0.2 somersaults (d).

DISCUSSION

There are few reports of difficulty in controlling the twist when gymnasts or trampolinists first attempt double somersaults in the straight position. This suggests that the method of control has been learnt prior to the attempt at the unstable movement. It may be speculated that gymnasts learn this method of twist control in single somersaults with twist.

SUMMARY

A feedback control system for making in-flight adjustments to the twist in twisting somersaults has been shown to be capable of effecting control for time delays of up to 0.2 somersaults.

ASSESSMENT OF TECHNIQUES USED IN CALCULATING CELL-MATERIAL INTERACTIONS

Y.F. Missirlis* and A.D. Spiliotis
Biomedical Engineering Laboratory, Department of Mechanical Engineering,
University of Patras, Rion Achaia, 26500, Greece

A review of the techniques used in measuring the forces of de-adhesion of cells that have been adhering on substrate surfaces will be presented. Two categories of techniques will be described. The first category involves techniques that utilize fluid flow against an adhered cell population and subsequently count the percentage of cells that detach (global tests). The second category of techniques involve manipulation of single cells in various configurations which lend themselves to more specific force application and provide the basis for theoretical analysis of the receptor-ligand mechanics.

Starting from the simple static assays, where centrifugation is used to detach the cells, the parallel-plate flow chamber technique is dealt with in some detail due to its popularity in study-

ing cell-substratum attachment. Steady-state or dynamic shear stresses are responsible for the detachment of cells in this case. The techniques of micropipette aspiration or the microplate versions are discussed next, with the new feature of handling single cells (one cell at a time) instead of populations of cells. Other techniques include the use of magnetic beads as a means of exerting the required force on the cell, the optical tweezers (utilizing optical forces) and the shear forces applied on single cells by manipulating microcantilevers (such as those used in atomic force microscopes).

The relative range of applied forces, and the merits and pitfalls of each technique are discussed in an attempt to make useful comparisons possible.

BIOMATERIALS AS EXTRACELLULAR (ECM) MATRICES

Dr. Tim McGloughlin

Biomedical Engineering Research Centre, Dept. of Mechanical & Aeronautical Engineering University of Limerick, Ireland.

INTRODUCTION

The loss or failure of organs/tissues remains one of the most severe human health problems. Standard treatment is organ transplantation but there is an inadequate supply of organs available for transplantation to meet the needs of the 36,000 patients on organ waiting lists, and in the last 5 years 10,000 people have died while on such lists (Fentiman 1994). There is an increasing need for an adequate alternative to transplantation. It is believed that tissue engineering has great potential to overcome the shortcomings of conventional treatment.

Tissue engineering is an emerging multi-disciplinary field, which embraces a diverse range of disciplines including cell biology, polymer chemistry and engineering. It is intended to be used in the development of bio-artificial organs/tissues and also to assist in the tissue remodelling process with the purpose of repairing or enhancing tissue/organ function (Nerem et al 1995).

Conventional cell culturing involves growing cells in an artificial environment, which enables them to proliferate into larger colonies. These cell cultures are intended for diagnostic use and do not become organised into tissues and organs. In the body cells are continuously bombarded with environmental cues including mechanical, chemical and electrical signals, which tell the cells how to behave. The cells are also exposed to structural cues due to the interaction with the extracellular matrix (ECM) (Ratcliffe 2000). It is believed that the physical communication between cells and their ECM directly and indirectly impacts cell shape and function. As a result it is believed that these signals are necessary for normal cellular activity. It is now usual to employ a 3-D ECM scaffold in the engineering of new tissues/organ.

Scaffold guided tissue regeneration involves seeding highly porous biodegradable extracellular matrix (ECM) scaffolds with donor cells and/or growth factors followed by culturing and implantation of the scaffolds to induce and direct growth of new tissue. These scaffolds are required to provide structural support and a suitable substrate for cell adhesion and proliferation to the new developing tissue. The scaffold may also be required to release bioactive substances at a controlled rate or to directly influence the behaviour of incorporated or ingrowing cells (Sundararajan 1999).

There a number of issues which must be considered prior to selection of a biomaterial as a tissue engineering scaffold including mechanical properties, surface morphology, porosity, degradation and chemistry of the material. Each of these parameters plays a significant role in cell attachment, proliferation, differentiation and secretion of proper ratios of ECM molecules. The ability of the material to perform the appropriate and specific function for which it is intended (biofunctionality) and also the compatibility of the material within the body (biocompatibility) must also be assessed (Marques 2002).

ECM scaffolds may be synthetic or natural in origin. Polylactide (PLA) and polyglycolic acid (PGA) are examples

of biodegradable synthetic polymers, which have been used in applications such as sutures, and orthopaedic fixation. Natural polymers include collagen, alginate, and heparin etc which have been used in cardiovascular applications and in the development of skin substitutes.. Recently biological scaffolds such as acellularised aortic conduits have been used (Chen 2001).

To date only tissue engineered skin has been commercialised. Tissue engineered skin products include epithelial replacements such as Epicel (Genzyme), dermal replacements such as Dermagraft (Advanced Tissue Sciences) and full thickness replacements (Organogenesis Inc.). These have met with varied success and there are still many issues relating to control of fluid loss, vascularisation etc. which need addressing (Seal 2001).

In orthopaedic applications donor bone cells have been seeded on hydroxyapatite (HA), which is a ceramic scaffold to create small-scale bone. It has been found that the microstructure of coralline HA is very similar to the mineralised component of natural bone ECM. Although this has shown some success there remains a need for improved scaffolding for orthopaedic applications, which address a number of issues relating to strength, toughness, osteoinductivity, osteoconductivity, controlled degradation and inflammatory response (Seal 2001).

Vascular tissue engineering has utilised natural polymer materials such as collagen, which is a tough fibrous protein matrix, and synthetic polymers such as polyglycolic acid (PGA). Attempts have focused on seeding tubular scaffolds with smooth muscle cells and endothelial cells (Hoerstrup 2001). However there remain numerous issues relating to thrombosis in these artificial vessels.

POTENTIAL FOR COMBINED AND SEQUENTIAL DELIVERY OF GROWTH FACTORS TO CONTROL RESPONSES AT THE CELL-BIOMATERIAL INTERFACE

David A. Puleo and Adrian T. Raiche

Center for Biomedical Engineering, University of Kentucky, Lexington, KY 40506
puleo@uky.edu

INTRODUCTION

Delivery of biomolecules having the ability to control bone cell differentiation and functions directly to the tissue-biomaterial interface has great potential for influencing the fate of implants. Although the optimal mode and profiles for delivering these molecules remain unknown, the natural cascade of growth factor release during fracture healing can be used as a guide. Zero-order release of single biomolecules does not occur. Instead, temporally varying profiles of multiple biomolecules are observed. We hypothesize that combined and sequential delivery of different growth factors with non-zero-order release profiles will more effectively alter cellular activity than zero-order delivery of a single molecule. As a first step in testing this hypothesis, the *in vitro* effects of simultaneously and sequentially delivering two bone growth factors, BMP-2 and IGF-I, were determined.

MATERIALS AND METHODS

A crosslinked gelatin coating system was used to control release of growth factors. BMP-2 and IGF-I were selected because of their roles in bone formation and repair. A mathematical model was used to determine loading and glutaraldehyde crosslinking needed to produce peak release at 2 and 11 days from the top and bottom layers, respectively, of two-layer coatings. Peaks consisted of BMP, IGF, or both if co-immobilized. Unloaded layers were used as controls.

Solutions of 5 wt% gelatin were dissolved in PBS, pH 7.4, at 37°C and BMP-2 and/or IGF-I were added. After adding glutaraldehyde, layers were cast in 24-well tissue culture plates. Free aldehyde groups were blocked by incubation in 200 mM glycine at 4°C for 1 hour. The plates were dried overnight under laminar airflow. Second layers were added on top of blocked dried layers. Finally, plates were sterilized under ultraviolet light for 5 hours.

Three models were used to assess cellular responses: SaOS-2 cells for IGF-I mitogenicity, C3H10T1/2 cells for BMP-2 activity, and bone marrow stromal cells (BMCs) for both growth factors' osteogenic effects. Cells were seeded directly on dried gelatin coatings at a density of 18,000 cells/cm² and cultured for up to 4 wk, with weekly feeding. Cell growth was determined using a Hoechst DNA assay, and osteoblastic differentiation was assessed by measuring alkaline phosphatase (AP) activity and matrix mineralization.

RESULTS AND DISCUSSION

Using the two cell lines, non-zero-order profiles were found to stimulate cell responses more effectively than zero-order release. Furthermore, use of both BMP-2 and IGF-I was more effective than either molecule alone. Although differences in responses were observed for the different cell types tested, simultaneous release of both growth factors generally was not as effective as sequential release. For example, using the pluripotent C3H10T1/2 cell line, release of BMP-2 followed by IGF-I induced a significantly greater response ($p < 0.01$) than all of the other coatings tested (Figure 1). Similarly, in BMC cultures, multilayered coatings delivering BMP-2 after 2 days and IGF-I after 11 days resulted in significantly greater AP activity compared to controls at 14 days, which subsequently enhanced mineralization at 28 days. Animal studies are being conducted to verify the observed *in vitro* findings.

CONCLUSION

Figure 1. Induction of alkaline phosphatase activity in C3H10T1/2 cultures in response to simultaneous and sequential release of BMP-2 and IGF-I.

More biologically relevant release of growth factors increased osteoblastic cell activity and matrix mineralization *in vitro*. Similar strategies may enhance bone formation *in vivo*, thereby improving implant fixation.

EFFECTS OF SURFACE TOPOGRAPHY ON CELL BEHAVIOUR AND TISSUE ORGANIZATION.

D.M. Brunette, M. Takekawa and B.Chehroudi. brunette@interchange.ubc.ca

Faculty of Dentistry, University of British Columbia, Vancouver, B.C. Canada

INTRODUCTION

Surface properties, including topography and chemistry, are of prime importance in establishing the response of tissues to biomaterials. Microfabrication techniques have enabled the production of precisely-controlled surfaces to investigate the response of cells to topography. The intent of such studies is to develop principles of cell response to topography that could be used to design surfaces for tissue interaction on implanted devices. Originally produced in silicon (Brunette et al. 1983) the microfabricated surfaces can be replicated in epoxy, and coated with the biocompatible materials such as titanium(Ti). The Ti surfaces can be used as substrata for cell or implanted *in vivo*. Microfabricated surfaces have been used to explore the effects of topography on cell shape, locomotion, and function for epithelial cells, fibroblasts and cells involved in the production of mineralized tissue. The work on cell behaviour and fabrication methods has been reviewed recently (Brunette 2001, Jaeger and Brunette 2001)

Epithelium: Attachment to titanium surfaces on implanted devices and culture substrata is similar and features hemidesmosomes. Epithelial cells have a tendency to be oriented by grooved surfaces but the behaviour of individual cells *in vitro* is modified by the number of cells with which an epithelial cell is in contact. Epithelial downgrowth on implanted percutaneous devices can be inhibited by grooves on the implant surface directed at right angles to the direction of downgrowth. In general it appears that epithelium attached to implants *in vivo* displays several aspects of behaviour similar to those that are apparent *in vitro*, but the behaviour is modified by the connections with other epithelial cells and leads to the epithelium behaving more as a tissue than as individual autonomous units.

Fibroblasts. Fibroblasts exhibit contact guidance *in vitro* and *in vivo*, but the shape of migrating cells differs markedly. Cell culture substratum topography can also alter fibronectin and matrix metalloproteinase expression, orientation of fibronectin and other extracellular-matrix proteins, and cytoskeletal organization.

Mineralized tissue. Micromachined grooved surfaces increase the frequency of bone-nodule production *in vitro* and *in vivo*. Moreover, orientation of the nodules occurs both in culture and on implants.

Harris and Stopak (1982) have demonstrated that fibroblast-generated tractional forces and positive mechanical feedback can evoke the formation of complex connective tissue structures such as ligaments. Our hypothesis is that as structural geometry of extracellular matrix is largely controlled by directed cellular traction, control of cell orientation and attachment on an implant by surface topography should enable control of soft connective tissue organization and the promotion of tissue integration. In this study we adapted the system of Harris and Stopak (1982) to assess the ability of Ti surfaces of varying topographies to promote attachment and orientation of connective tissue.

METHODS

Machined, grit-blasted and blasted and etched (SLA), and micromachined grooved surfaces were replicated in epoxy and coated with $\approx 50\text{nm}$ Ti as described by Wieland et al. (*in press*). The surfaces were embedded in a type I collagen gel containing human gingival fibroblasts and culture medium in a well constructed of filter paper on a polystyrene dish. Cell orientation was determined by nuclear staining with propidium iodide and confocal microscopy.

RESULTS

The collagen gel becomes embedded in the filter paper and, as cell tractional forces develop, the collagen gel contracts away from the Ti surface. The length of time the surface resists the cell-generated forces thus reflects the strength of the collagen gel-fibroblast system (sometimes called tissue equivalent) attachment. There was a statistically significant ($p < 0.05$) difference in the time of attachment between the surfaces in the order SLA > grooved > blasted > etched > machined. Moreover cell orientation differed between the surfaces with the machined surface showing the greatest tendency for orienting fibroblasts parallel to the surface.

CONCLUSION

The topography of Ti surfaces can markedly alter the attachment and organization of fibroblast collagen gel tissue equivalents. This *in vitro* model provides a convenient system to evaluate the ability of surfaces to support connective tissue attachment and organization and resist cell tractional forces. There is thus abundant evidence that microfabricated surfaces can control diverse aspects of behaviour of several cell types. Only a few of the many possible topographies that can be produced by microfabrication techniques have been investigated, and there is considerable potential for optimizing cell responses to implanted devices by topographic control of cell behaviour.

DESIGNING SYNTHETIC POLYMERS WITH CELL-ADHESIVE PROPERTIES: N-ISOPROPYLACRYLAMIDE POLYMERS CONTAINING RGD-PEPTIDES FOR OSTEOGENESIS

Hasan Uludag, Erin Smith and Jennifer Yang

Department of Chemical and Materials Engineering, and Department of Biomedical Engineering,
University of Alberta, Edmonton, AB, Canada T6G 2G6.

INTRODUCTION

Synthetic polymers are promising materials to support tissue regeneration. Being synthetic, one can easily manipulate material properties to optimize the properties critical for tissue regeneration. However, a critical drawback of synthetic biomaterials is their inability to interact with mammalian cells; cells simply do not possess cell-surface receptors for material recognition. This limitation can be circumvented by incorporating synthetic peptides, which are recognized by cell receptors, into the biomaterials. Towards this goal, Arginine-Glycine-Aspartic acid (RGD) peptides were grafted onto polymers for cell attachment via integrins [1].

We are designing RGD-containing *N*-isopropylacryl-amide (NiPAM) polymers for bone regeneration. The polymers are thermoreversible: i.e., solubility in aqueous medium varies as a function of temperature. This allows one to inject the biomaterial solution to a specific site, where the biomaterial becomes insoluble at the physiological temperature. These materials, in combinations with Bone Morphogenetic Proteins (BMPs), will direct *in situ* differentiation of osteoprogenitor cells into bone-depositing osteoblasts. The response of osteoprogenitors is expected to be influenced by the nature of the biomaterial, and, in this presentation, we will present data exploring correlation among the physicochemical properties of NiPAM-based biomaterials and *in vitro* osteogenesis in response to BMP treatment.

MATERIALS AND METHODS

NiPAM polymers were prepared by thermal polymerization and characterized by ¹H-NMR [2]. RGD-containing peptides were synthesized at Alberta Peptide Institute (Edmonton, AB) or obtained from Bachem. The polymers contained amine-reactive N-acryloxysuccinimide (NASI). Peptide conjugation was characterized by using ¹H-NMR and a RP-HPLC method. The bioactivity of the polymers was assessed using cell adhesion studies with C2C12 cells. The cells are myoblastic in origin and exhibit osteoblastic phenotype when treated with BMP-2. The cells were seeded onto multiwell plates, which had been previously coated with the desired polymers. The polymers contained NiPAM, hydrophobic alkylmethacrylates and, in some cases, NASI groups. The cellular response to the designed materials were based on (1) extent of cell attachment (direct cell counts and MTT assay); (2) cell proliferation (MTT assay), and; (3) cell differentiation (alkaline phosphatase, ALP, induction) in response to BMP-2 treatment.

RESULTS AND DISCUSSION

The NiPAM/NASI polymers were conjugated to GRGDYS by incubating the reagents in aqueous buffers. The NMR and RP-HPLC techniques indicated that as much as 8.4

peptides/polymer was obtained. The NiPAM/NASI polymer supported little C2C12 attachment in medium with or without serum. A significant increase in cell attachment was observed as a result of GRGDYS grafting (69.6% vs 3.1% after 24 hours). A dose-response study showed that cell adhesion was directly proportional to RGD concentration. An RGE-peptide did not support cell attachment, indicating that attachment was specific to the RGD sequence. Cell proliferation on NiPAM/NASI polymers was relatively slow. Although GRGDS-grafted surfaces enhanced cell proliferation, cells did not proliferate as much as the cells seeded on tissue culture surfaces (Fig. 1). Incorporating hydrophobic alkyl (hexyl and lauryl) methacrylates increased cell attachment and enabled better retention of activity on polymer surfaces up to 1 week in culture. Finally, C2C12 cells grown on tissue wells and treated with BMP-2 exhibited an alkaline phosphatase induction that was proportional to the dose of BMP-2. This osteogenic ability of cells were retained on surfaces grafted with GRGDS, albeit to a lower extent than the tissue culture surfaces.

Figure 1. Cell proliferation on tissue culture surface and surfaces coated with NiPAM/NASI polymers. The polymers were treated with either buffer or GRGDS.

CONCLUSIONS

RGD-containing polymers were effective in increasing C2C12 cell adhesion as compared to parent polymers. The cells were able to proliferate on RGD-surfaces and respond to morphogenetic signals (BMP-2). However, cell responses (proliferation and ALP induction) were not as strong as the cells grown on tissue culture polystyrene. Further engineering will be needed to enhance cell-compatibility of the polymers.

CORRELATES BETWEEN CONTINUUM AND MICROSTRUCTURAL DESCRIPTIONS OF CENTRAL NERVOUS SYSTEM WHITE MATTER

David F. Meaney

Department of Bioengineering, University of Pennsylvania, Philadelphia, Pennsylvania, USA

INTRODUCTION

With measurements of finite strain material properties for the CNS white matter¹, relationships between the continuum behavior and the underlying structure of the tissue can be developed. In the past, isotropic material descriptions have been used to describe the behavior of the white matter in different testing directions¹. In this report, we develop a structurally based model for the white matter and compare this description to the isotropic hyperelastic formulation used to model the material behavior of the white matter. For simplicity, we do not account for the time dependent behavior in this analysis. The long-term objective of this analysis is to estimate how properties of individual axons within the white matter can be approximated from continuum material descriptions.

MODEL DEVELOPMENT

In simple extension, the following stress (T) –stretch (λ) is obtained for a first order Ogden material:

$$T = \frac{2\mu}{\alpha} \left(\lambda^{\alpha-1} - \lambda^{-\alpha/2-1} \right) \quad [2]$$

where α and μ are parameters assigned to the material. This material description has been used to model the response of white matter tissue in shear¹. For the structural model, we use a form of the stress-stretch relationship developed from a single myelinated nerve fiber²

$$\sigma_{\text{fiber}} = C(\lambda_{\text{fiber}} - 1)^2 \quad [3]$$

We assume all axons are aligned in the direction of stretch, and examine simple extension along the axis of the axonal fibers. In the unstretched state, each axon has a unique microstructural appearance, where most axons are undulated ($U > 1.0$) and do not bear tensile force. As the white matter elongates in the direction of the axons, these axons will eventually straighten ($U = 1.0$) and begin to produce a tensile force according to the above relationship [3]. Summing the contribution of the individual axons at a stretch (λ_o), the resulting tensile force is

$$T(\lambda_o) = \sum f_i(U_i) \cdot \Delta U_i \cdot \sigma_{\text{fiber}} \left(\frac{\lambda_o}{U_i} \right) \quad [4]$$

where $f(U_i)$ denotes the fraction of axons at an undulation U_i . Measured microstructure of the axonal geometry was used to predict the response of the structural model to the applied tensile loading.

RESULTS AND DISCUSSION

Using the nonlinear constitutive relationship for single, myelinated PNS axons, general stress-stretch response produced by a structurally based model of the material behavior (Figure 1A) could be reproduced by the first order Ogden material. Unlike other simpler descriptions for the individual axonal elements, the tangential stiffness

characteristics between the two modeling approaches also agreed (Figure 1B)

Figure 1

SUMMARY

Continuum formulations used for brain tissue behavior show a general agreement with stress-stretch relationships derived based on individual fiber behavior. The correspondence between the material behavior developed using these two approaches will lend insight into how continuum descriptions can incorporate structural failure of axons, as well as predicting the deformation of axons at specified macroscopic deformation levels.

REDUCTION OF BLAST INDUCED HEAD ACCELERATION AND CONCUSSIVE HEAD INJURY POTENTIAL

Jean-Philippe Dionne, Jeffery Nerenberg, Aris Makris

Med-Eng Systems, Ottawa, Ontario, Canada
Corresponding author: jpdionne@med-eng.com

INTRODUCTION

When an explosive device detonates, a blast wave is generated, compressing the gases behind it and propagating away in all directions. The impact of the blast wave with a person can induce violent accelerative motion of the head. A previous systematic investigation to assess the relevance of this type of injury in the context of demining concluded that blast-induced head acceleration injuries can be fatal for an unprotected deminer facing typical mines (Makris et al, 2000). The present study extends these results to an explosive ordnance disposal scenario, where a bomb technician faces explosive charges of the order of 5 to 17.5 kg at standoff distances of few meters.

METHODS

Anthropomorphic test devices (50th percentile Hybrid II) were fully dressed in protective equipment (EOD-8 and EOD-7B from Med-Eng Systems) or only dressed in light fleece clothing and subjected to blasts from high explosives. The mannequins were supported in the standing position by means of an anchored steel pipe slipped underneath each armpit, allowing a natural response to the blast. Charge sizes ranging from of 5.1 to 17.5 kg of C4 plastic explosive were placed on a stand located 1 m off the ground at distances varying from 2 to 5 meters from the mannequin. Standard blasting caps were used to initiate the detonation. The mannequins were instrumented with a tri-axial cluster of accelerometers in their head and the signals were filtered using a four-pole Butterworth filter set to attenuate signals above 1650 Hz. For each test, the Head Injury Criterion (HIC) was calculated (Versace, 1971) and probabilities of injuries were estimated, based on the Prasad/Mertz probability curves (Prasad, 1985).

RESULTS AND DISCUSSION

The injury analysis based on the HIC indicates that protective equipment drastically reduces the injury outcome. For an explosive charge of 10kg at a 3m standoff, Fig. 1 indicates the probability of injuries, based on the AIS scale for both the protected (EOD-8 helmet) and unprotected cases. Instead of a significant probability of fatal injury, there is a 80% probability of at most a minor injury.

Given the explosive type, charge and distance from the mannequin, the theoretical incident impulse of the blast can be calculated. A linear correlation between the HIC values and the impulse was found, based on tests involving the EOD-7B

helmet (see Fig. 2). This linear behavior, which was also assumed for the EOD-8 helmet and unprotected tests, provides a predictive tool to estimate the likeliness and severity of blast-induced head acceleration injury.

Figure 1: Probability of head acceleration injury for mannequin facing a 17.5kg charge at 3m standoff distance, protected (EOD-8 helmet) and not protected

Figure 2: HIC vs Impulse curves for the protected cases (left) and unprotected (right)

SUMMARY

Injury analysis based on the head injury criterion indicates the significant reduction in injury outcome in an explosive ordnance disposal scenario when wearing adequate protection. Moreover, a correlation between the HIC values and the blast impulse was found, yielding a convenient predictive tool for blast-induced head acceleration injury for a general case of explosive charge and standoff distance.

ICE IN TISSUES

Locksley E. McGann

Department of Laboratory Medicine and Pathology, University of Alberta, Edmonton, Alberta, Canada

INTRODUCTION

Engineered tissues are being developed for a wide variety of applications in medical, agricultural, and food industries, but our ability to preserve these constructs for distribution is lagging significantly. Cryopreservation is often the only method for preserving physiological structure, viability and function in living tissues for long periods of time, therefore considerable research effort is now required to develop general methods for cryopreservation of tissue systems. Preservation of cell viability, cell-matrix interactions, and properties of the matrix are all required for post-thaw function of living tissues. Research in cryobiology has focused largely on the preservation of cellular viability, but it is now clear that cell-cell and cell-matrix interactions play a major role in low temperature responses of tissue systems.

METHODS

This paper is a synthesis of previous studies on ice in cells and tissue systems, designed to summarize the information and to point to future directions for cryopreservation of tissue systems.

RESULTS AND DISCUSSION

Cell adhesions affect intracellular freezing

Cell-cell and cell-matrix interactions change the responses of the cells at low temperatures (McGann 1993). Notable among these changes are the increased likelihood of intracellular freezing (Acker 1999), and the increased probability of intracellular freezing when an adjacent cell freezes (Acker 1998). Cell damage associated with intracellular freezing occurs during the formation of intracellular ice, but it is not clear whether intracellular ice is the cause or result of membrane damage (Acker 2001a).

Freezing damages cell adhesions

Monolayer systems have also been used to demonstrate that loss of cell adhesion is an independent type of cell damage that requires different modes of cryoprotection (Ebertz 2002).

Ice propagation between cells

For cells in a monolayer with close cell-cell contacts, intracellular ice formation does not necessarily result in the immediate disruption of the plasma membrane (Acker 2000). An equation for capillary freezing-point depression developed to describe the effect of temperature on the equilibrium radius

of an ice crystal supports the theory that gap junctions facilitate ice nucleation between cells (Acker 2001b). This introduces the potential for developing strategies to cryopreserve tissues using rapid cooling.

Direct and indirect damage by interstitial ice

Chondrocyte recovery in articular cartilage after cryopreservation is dependent on the location of chondrocytes within the cartilage (Shachar 1999). The observation that physical proximity to a surface leads to higher recovery of cells supports the hypothesis that planar ice growth into the cartilage, with exclusion of solutes by ice, leads to constitutional supercooling deep in the tissue (Muldrew 2000).

SUMMARY

From these studies, it appears that the use of high concentration of cryoprotectants to reduce the amount of ice in the matrix, with rapid cooling to limit movement of water and solutes, is a feasible approach for the cryopreservation of natural and engineered tissues, when coupled with methods to induce innocuous intracellular ice that provides cellular cryoprotection.

THERMO-MECHANICAL STRESS AS A LIMITING FACTOR OF LARGE SCALE CRYOPRESERVATION

Yoed Rabin

Department of Mechanical Engineering, Carnegie Mellon University, Pittsburgh, PA 15213, USA
Email: rabin@cmu.edu, Fax: 412 268 3348

INTRODUCTION

Cryopreservation technologies represent a potential long term and minimally damaging method to preserve both native and engineered tissues. This presentation addresses one of the limiting factors that hinder the widespread use of recent developments in cryopreservation technology to multicellular tissues, namely thermo mechanical stresses.

For example, conventional cryopreservation of allogeneic veins involving freezing is currently being used clinically. However, *in vivo* studies using these grafts in both animal models and patients have demonstrated poor long-term patency rates. Our industrial collaborators, Organ Recovery Systems, Inc., have demonstrated recently that an alternative approach to cryopreservation, involving vitrification that avoids the hazards of ice formation, leads to a markedly improved vascular product in terms of both structure and function. Vitrification (*vitreous* means glassy in Latin) is essentially the solidification of a supercooled liquid by adjusting the chemical composition and cooling rate such that the crystal phase is avoided. This new preservation technology is now being scaled up for clinical applications, and ultimately for use with engineered blood vessels.

Techniques have already been developed to preserve native blood vessels. However, while vitreous cryopreservation has been demonstrated to provide superior preservation compared with conventional freezing methods, cryopreservation of large tissue samples has been hampered by mechanical damage including fractures. Such fractures are attributed to stresses that can arise due to the non-uniform cooling of larger tissues. In fact, the higher cooling rates that facilitate vitrification will typically lead to higher mechanical stresses. The competing needs for vitrification and minimization of mechanical damage demand greater understanding of both vitrification and stress development. Although mechanical stress has long been recognized as an important mechanism of tissue destruction, it has received very little attention in the context of cryobiology.

The current presentation addresses three aspects of thermo mechanical stress in cryopreservation: mathematical modeling, physical properties measurements, and the mechanical response of the frozen tissue to an applied load.

MATERIAL PROPERTIES

The mechanical behavior of slowly freezing tissue specimens (conventional cryopreservation), and glass forming specimens, is inherently different. For the purpose of analyzing thermal

stress during conventional preservation, our group has measured thermal expansion, the elastic modulus, and the strength of various frozen tissues (Table 1).

The mechanical behavior of vitrified biomaterial can be modeled as that of a fluid with viscosity value that increases exponentially with the decrease in temperature. This behavior continues until the viscosity reaches such a high value that the material can be considered solid in a typical time scale relevant to cryopreservation. Our group is now focusing on quantifying mechanical properties of glass forming biomaterials.

Table 1: Typical properties of polycrystalline ice water and soft frozen biological tissues in conventional cryopreservation

	Polycrystalline Ice Water @ 101.3 kPa	Frozen Biological Tissues
Thermal Expansion Coefficient: $\beta_1 + \beta_2 T$ [1/°C]	$\beta_1 = 56.3 \times 10^{-6}$ $\beta_2 = 2.53 \times 10^{-7}$ -180 < T < 0°C (Powell, 1958)	$\beta_1 = 65 \times 10^{-6}$ $\beta_2 = 2.89 \times 10^{-7}$ -180 < T < -20°C (Rabin et al., 1998)
Elastic Modulus, E [GPa]	8.9 - 9.9 @ -5°C (Fletcher, 1970)	14 - 132 @ -196°C (Rabin et al., 1996)

MODELING AND SIMULATION OF MICRO-SCALE PHASE CHANGE AND TRANSPORT PHENOMENA IN CRYOPRESERVATION OF CELLS AND TISSUE

H. S. Udaykumar

Department of Mechanical Engineering, University of Iowa, Iowa City, IA 52242, USA

INTRODUCTION

Successful cryopreservation of cells and tissue critically depends on the thermophysics of ice-cell interaction. The rate at which extracellular ice forms and the resulting solutal environment in which the cell is placed in the cooling process determines cell death due to “solution effects” or “intracellular ice formation (IIF)”. The morphology of the extracellular ice crystals can determine the ability of the cell to navigate the freeze-thaw cycle. The interaction of the ice fronts with the cell membrane can also impact on the nucleation of lethal intracellular ice. Hitherto, modeling of ice cell interactions have relied largely on the theory developed by Mazur (1963), which provides a method to calculate the volume of the cell and the intracellular water content as a function of time (and temperature). Karlsson et al. (1994) have developed techniques to predict cell survival by combining Mazur’s approach with intracellular ice formation models. The present work goes beyond the analytical models of cell response to direct numerical simulation of ice formation and cell response, in order to include non-equilibrium effects on crystal growth and provide better visualization and understanding of the physics of ice-cell interactions.

METHODS

Diffusion-controlled growth of ice crystals from an aqueous salt solution is computed using a numerical method detailed in Udaykumar et al. (1999). The governing equations are solved using a finite-volume scheme that handles arbitrary moving boundaries, including phase change interfaces and membranes. Isothermal conditions are imposed in the computational domain, with cooling rates specified corresponding to typical cryo-protocols. The segregation and transport of salt from the advancing ice front is calculated. The cell is modeled as a fluid region bounded by a semi-permeable membrane. Water loss from the cell is computed using mass flux balance at the cell membrane. Properties of the solution and the cell are obtained from the literature.

RESULTS AND DISCUSSION

Figure 1 shows a sample calculation of the response of a modeled cell to the approach of an extracellular ice front. Initially the intra- and extra-cellular solutions are isotonic. Due to subsequent instability of the ice front the cell is finally attacked by a front with deep finger-like structures. The segregated solute is trapped in the deep grooves between the ice fingers and between the ice and the cell. As the extracellular medium becomes progressively salt-rich, the cell

loses water by exosmosis. The ability of the water to escape from the cell is determined by the permeability of the membrane. A detailed study of cell water loss as a function of the controlling parameters (cooling rate, membrane permeability, CPA content etc) will be presented.

Figure 1: The shrinking of a cell in response to an approaching unstable ice front (a) Early time, (b) Later time. The dark region corresponds to a salt-rich medium.

SUMMARY

A method for the direct numerical simulation of the interactions between a freezing (ice) front in an aqueous medium with a modeled cell has been developed. The method allows the computation of the ice-cell interaction where two-dimensional phase change and heat/mass transport is computed. The method has also been extended to study the interactions in a ternary medium and to predict cell death based on the IIF mechanism.

RATIONAL CONTROL OF ICE DURING VITRIFICATION OF EXTENDED SYSTEMS

Gregory M. Fahy and Brian Wowk

21st Century Medicine, Inc., Rancho Cucamonga, California, USA (www.21cm.com)

INTRODUCTION

The only way to meet the clinical demand for replacement vascularized tissues and organs is to create engineered bioartificial organs. Cryopreserving these organs is a challenge similar to the challenge of preserving natural organs. Current evidence suggests that adequate preservation of large systems will require the elimination of essentially all ice despite cooling to and warming from the glass transition temperature (about -110 to -135°C). This is problematic for several reasons. First, water is an essential constituent of living systems, and removing more than 50% of the water from an organ is normally damaging. Second, even though most ice formation may be prevented by using colligative agents, a few stray heterogeneous nucleators may produce ice crystals that, though occupying only a very small volume fraction of the system, are able to produce unacceptable injury to the system as a whole. To overcome these problems, we have designed solutions that, despite being very high in concentration, are low in toxicity and that, in addition, contain specific molecules that recognize and inactivate most heterogeneous nucleators.

METHODS

The toxicity of multiple candidate vitrification solutions was determined by exposing rabbit renal cortical slices to these solutions, washing the slices free of cryoprotectant, and assaying their K^+/Na^+ ratios after 90 min of incubation at an optimal temperature for ion transport. Solution stability was determined by heating vitrification solutions at a variety of warming rates in a differential scanning calorimeter (DSC) and determining the warming rate required to almost completely suppress ice formation on warming. The influence of solution composition on viability (K^+/Na^+ ratio) was studied by plotting viability against different global compositional variables. An overall figure of merit was constructed as the position of the results for a given composition on a plot of viability vs. stability. For the control of heterogeneous nucleation, a hanging vial technique was developed in which visual observations of the number and size of ice crystals under standardized conditions could be made and photographed. In addition, nucleation spectra were constructed by evaluating the behavior of populations of droplets tested for crystallization using the DSC. Furthermore, computer simulations of potential interactions between successful "ice blockers" and ice-like templates were carried out using Hyperchem.

RESULTS AND DISCUSSION

A polyvinyl alcohol-polyvinyl acetate copolymer (PVA) was found to have broad spectrum antinucleation capacity, whereas polyglycerol was found to specifically inhibit bacterial ice nucleation. The antinucleation effects were complementary, allowing synergistic protection from ice formation when the agents were combined. Molecular dynamics simulations showed an affinity of certain PVA oligomers for ice that may explain the effects of PVA as a disrupter of nascent ice crystals forming on heterogeneous nucleator surfaces.

A linear relationship was found between a compositional variable called qv^* and the K^+/Na^+ ratio of slices exposed to vitrification solutions. qv^* is the number of cryoprotectant polar groups per water molecule in the solution at the concentration needed to vitrify, and a high value was associated with both a high solution concentration and a high viability, quite contrary to normal expectation. It appears that the inclusion of poor glass formers is advantageous to glass formation, because such agents fail to compete successfully with biological molecules for water, thus allowing living systems to remain hydrated under water-poor conditions. The addition of ice-inhibiting polymers permitted the attainment of solutions that have very low toxicity despite extremely high stability (for example, VM3, which yields $\sim 95\%$ viability after 30 min of contact at 0°C , and yet which has a critical warming rate of $10^{\circ}\text{C}/\text{minute}$). These solutions are believed to be sufficiently stable and sufficiently non-toxic to enable vitrification of bioartificial organs, without electromagnetic warming requirements. Experiments showed that Cordis-Dow Artificial Kidneys could be vitrified and rewarmed at rates consistent with the stability of these solutions, whereas frozen-thawed CDAKs cracked.

SUMMARY

The combination of molecular ice control and biologically gentle water-replacing chemicals has permitted the realization of extraordinarily valuable vitrification solutions that may be equal to the task of permitting both natural and bioartificial organs to be successfully vitrified and recovered for clinical use.

THE BEHAVIOR OF INDIVIDUAL SARCOMERES AFTER STRETCH IN ACTIVATED SKELETAL MUSCLE MYOFIBRILS

Dilson E. Rassier¹, Walter Herzog¹ and Gerald H. Pollack²

¹ Human Performance Laboratory, University of Calgary, Calgary, AB, Canada

² Department of Bioengineering, University of Washington, Seattle, WA, USA

INTRODUCTION

Force enhancement after stretch is observed in skeletal muscle and has been associated with instability of sarcomeres (Edman et al, 1982; Morgan, 1994). It has been suggested that during stretch some sarcomeres shorten, being responsible for most of the active force, while other sarcomeres are overstretched, being supported by passive structures. The average force of these sarcomeres would be increased compared to the isometric force at the same length. However, evidence suggests that sarcomeres may be stable, and sarcomere non-uniformity may not account for the force enhancement solely (ter Keurs et al, 1978). Although there has been much controversy, this issue has never been resolved. By studying single myofibrils, and tracking individual sarcomeres, we should be able to resolve this issue.

METHODS

Myofibrils isolated from rabbit psoas muscle were attached to a glass needle at one end and to a nanolever at the other end. The displacement of the nanolever could be monitored, providing force measurements. The image of the myofibrils was projected onto a linear 1024-element photodiode array, which was scanned to produce tracings of light intensity vs. position along the myofibril. Due to the contrast between the A-bands and I-bands, the photodiode array output gave a striation pattern, and the sarcomere length (SL) could be calculated as the span between A-band centroids (Blyakhman et al, 2001). Starting from an average SL of $\sim 2.5 \mu\text{m}$, stretches (4% to 10% of average SL, at a velocity of $95 \text{ nm} \cdot \text{sec}^{-1} \cdot \text{SL}^{-1}$ to $350 \text{ nm} \cdot \text{sec}^{-1}$) were applied to the myofibrils in relaxing ($\text{pCa}^{2+} 8.0$) and activating ($\text{pCa}^{2+} 4.0$) solutions.

RESULTS AND DISCUSSION

When the myofibrils were activated, and then stretched, force was higher than before stretch (Fig. 1). Since the stretch was performed on the descending limb of the force-length relation, the final length was at a region of less filament overlap. The observed force is therefore higher than expected if the myofibril had been stretched passively to the final length and then activated. It is also higher than the pre-stretch tension (less overlap, but more tension). The passive force after stretch accounted for $\sim 2.5\%$ of total force, similar to what others have reported in this SL range (Bartoo et al, 1993), and was therefore negligible.

Fig. 2 shows that force enhancement was not accompanied by instability of sarcomeres. All sarcomeres in this myofibril stretched (not necessarily by the same amount), and remained

at constant length until the myofibril was shortened. There were cases in which some sarcomeres shortened modestly during stretch; however, that was observed in occasional sarcomeres in fewer than 5% of myofibrils.

Figure 1: Force enhancement during and after stretch in an activated myofibril. The initial average SL was $2.5 \mu\text{m}$. The myofibril was stretched to a final average SL of $2.7 \mu\text{m}$.

Figure 2: The behavior of all sarcomeres ($n = 16$) during and after stretch in an activated myofibril.

In conclusion, sarcomeres appear to be stable. Stretch-induced force enhancement in skeletal muscle cannot be explained solely by instability that results in sarcomere non-uniformity.

THE FORCE-SARCOMERE LENGTH- $[Ca^{2+}]_i$ RELATIONSHIP IN RAT HEART

Henk EDJ ter Keurs, Tsuyoshi Shinozaki⁺, Jun Sun, Ying M Zhang, Amir Landesberg^{*}.

Departments of Medicine Physiology and Biophysics, Cardiovascular Research group, Faculty of Medicine, University of Calgary, Canada. ⁺Tohoku Graduate School of Medicine Sendai Japan; ^{*}Dept of Biomedical Engineering, Technion-Israel Institute of Technology, Haifa Israel.⁺

INTRODUCTION

Sarcomere dependent (SL) Ca^{2+} sensitivity of the myofilaments underlies Starling's law of the Heart and fundamental changes in this interrelationship may be involved in heart disease. The steady state Force-SL relationship in skeletal muscle is determined by filament overlap, but little information is available on the steady state properties of Cardiac muscle. In this study we have analyzed F-SL- $[Ca^{2+}]_i$ relationships of intact and skinned Cardiac Trabeculae from the Rat.

METHODS

We used both intact and skinned trabeculae from LBN Rats. The trabeculae were suspended between a silicon strain gauge and a motor arm. SL was measured using laser diffraction techniques, $[Ca^{2+}]_i$ by fluorescence of Fura-2 injected by iontophoresis.

Tetani were elicited by 2 s stimulus trains at varied SL (1.85- 2.05 μ m) and at varied $[Ca^{2+}]_o$ (0.3-6 mM). The effects of SL and $[Ca^{2+}]_o$ and tetanic force (F_t) on auto fluorescence were measured. $[Ca^{2+}]_i$ was calculated from fluorescence of Fura-2 after subtraction of auto fluorescence corrected for effects of SL, $[Ca^{2+}]_o$ and F_t . the dependence of Fura-2 fluorescence on $[Ca^{2+}]$ was calibrated in skinned fiber solutions.

Trabeculae were skinned using 1% triton X-100 and activated by solutions with 6 different $[Ca^{2+}]$ with physiological free $[Mg^{2+}]$ (0.7 mM) and following correction for skinning induced myofilament lattice expansion by addition of Dextran. A biochemical scheme, which couples Ca^{2+} binding to troponin-C (Tn-C) with cross bridge (XB) cycling, was established in order to quantify the dependence of Ca^{2+} affinity and XB kinetics on the SL, free $[Ca^{2+}]$ and the generated force. The hypotheses that were tested included: i) SL-dependent Ca^{2+} affinity; ii) interfilament spacing dependent Ca^{2+} sensitivity; iii) force-dependent Ca^{2+} affinity and; iv) Ca^{2+} -dependent XB kinetics.

RESULTS

F_t , SL and $[Ca^{2+}]_i$ reached a steady state in 2s during tetani. Sub maximal activation at $[Ca^{2+}]_o$ 0.3-3 mM revealed F_t -SL relationships identical to those in skinned fibers. F_t at saturating $[Ca^{2+}]_i$ (6 mM) increased from 60 % of F_{max} at SL 1.65 μ m to 100% at SL=2.1 μ m, following a curve predicted on the basis of the cross-bridge theory, given the sarcomere geometry in rat trabeculae. The F_t - $[Ca^{2+}]_i$ relationship revealed a SL-dependent decrease in EC_{50} (0.95, 0.70 and 0.56 μ M at SL 1.65, 1.75 and 1.85 μ m, respectively) and increase in F_{max} (62, 85 and 98 mN/mm²) and increase in Hill coefficient (3.9, 4.7 and 5.5, respectively).

The shape of the F-SL relationship in skinned trabeculae was identical to that previously published. F_{max} , at SL 2.1 μ m, was lower in the control muscle than in Dextran treated muscle (78.7 \pm 8.1 mN/mm² vs. 107.6 \pm 6.2 mN/mm² (mean \pm s.e.m), $p<0.001$). EC_{50} decreased with increase of SL in both groups. EC_{50} decreased from 1.55 \pm 0.09 μ M at SL 1.90 μ m to 1.06 \pm 0.10 μ M at SL 2.15 μ m without Dextran and decreased from 1.41 \pm 0.06 μ M to 1.04 \pm 0.09 μ M over the same SL range in Dextran treated muscle. EC_{50} at corresponding SL were 0.18 \pm 0.03 μ M higher in Dextran free solution than that in the presence of Dextran ($p<0.05$). The EC_{50} from both groups were substantially higher than those of intact fibers (EC_{50} 0.56 μ M at SL \sim 1.85 μ m and 0.38 μ M at SL \sim 2.20 μ m).

Using the biochemical scheme, it appeared that SL-dependent and Ca^{2+} -dependent mechanisms were unable to explain the measured stress-length- $[Ca^{2+}]$ relationships. However, for all trabeculae, an identical, unique relationship between Ca^{2+} affinity and developed stress demonstrated that an increase in the generated stress is associated with a proportional increase in apparent Ca^{2+} affinity.

CONCLUSION

Filament overlap determines SL-dependence of cardiac force development at saturating $[Ca^{2+}]$. Correction of $[Mg^{2+}]$ and colloid osmotic pressure in the skinning solutions increases F_{max} , but neither eliminates SL-dependent Ca^{2+} sensitivity, nor does it increase Ca^{2+} sensitivity to the level of intact cardiac muscle suggesting the presence of a Ca^{2+} sensitizer in the cytosol of the cardiac myocyte. The dependence of Ca^{2+} affinity on the number of force generating XBs is the dominant mechanism that regulates XB recruitment and SL-dependent generated stress in cardiac muscle at physiological cytosolic $[Ca^{2+}]$.

CONTRACTION OF SINGLE MYOFIBRILLAR SARCOMERES OCCURS IN 2.7-NM STEPS AND INTEGER MULTIPLES THEREOF

Olga Yakovenko¹, Felix Blyakhman¹ and Gerald H. Pollack²

¹ Department of Physics, Ural State University, Ekaterinburg, Russia

² Department of Bioengineering, University of Washington, Seattle, WA, USA

INTRODUCTION

In deducing the underlying nature of contraction, considerable emphasis has been placed on determining the elemental contractile step. Early on, muscle contraction was noted to occur in steps (Pollack et al., 1977). Since then, we have continually refined methodologies, and are now able to follow the time course of shortening and lengthening in individual sarcomeres of single myofibrils, with nanometer resolution.

METHODS

Myofibrils isolated from rabbit cardiac muscle and honeybee flight muscle were attached between the tips of glass needles, one of which could be moved by a piezoelectric motor. The image of the myofibril was projected onto a linear 1024-element photodiode array, which was scanned to produce tracings of light intensity vs. position along the myofibril. Sarcomere length could be calculated as the span between A-band centroids (Blyakhman et al, 2001). Myofibrils were placed in activating solution, and put through ramp-stretch-release cycles, and the length of each sarcomere was tracked.

RESULTS AND DISCUSSION

Although the myofibril was programmed to change length by a ramp waveform, the sarcomere-length change was consistently stepwise. Examples are shown in Fig. 1. We computed step size by taking the sarcomere-length decrement between successive pauses, determined by least squares fit.

Results are shown in Fig. 2. Note that the primary step size is 2.7 nm. All other step sizes are integer multiples of that value. Thus, each sarcomere can step by any of a series of values, but the values are always integer multiples of 2.7 nm. The same was found for stretch—always integer multiples of 2.7 nm. And, the same paradigm was found in honeybee flight muscle. Hence, the 2.7-nm stepping paradigm appears general.

Why 2.7 nm? The value 2.7 nm is the molecular repeat along the thin filament. (Although the repeat along the individual actin strand is 5.4 nm, the two strands that make up the filament are displaced by half of 5.4 nm, giving a linear repeat of 2.7 nm.) Hence each step is related to the actin-monomer repeat. But, each step can be two, or three, or n times the repeat. A simple model to explain these results will be presented (see: Pollack, 2001).

Figure 1: Representative traces of sarcomere-length change during motor-imposed trapezoid in rabbit cardiac muscle. First, second and fourth traces show segments of record; third trace shows entire record.

Figure 2: Histogram of shortening steps obtained from activated rabbit cardiac muscle. Histogram includes 493 steps from 75 sarcomeres in 25 myofibrils.

Among a superfamily of at least 18 known classes of myosin, class VI myosin is recently found to move actin filaments backwards in the surface gliding assay (Wells et al., Nature 401, 505-'99). Here we observed movement of single molecules of myosin VI with GFP fused along actin filaments by total internal reflection fluorescence microscopy. Single myosin VI molecules moved processively towards the pointed (-) end of actin filament (backwards). Furthermore, using optically-trapping nanometry, it was found that myosin VI produces several successive steps along an actin filament with ~38 nm steps. These mechanical properties of myosin VI are

quite similar to those of myosin V, except for the directionality. The extended long (23 nm) neck domain (lever arm) of myosin V has been thought to be essential for its large processive step, based on the lever arm model. However, since myosin VI has only one IQ motif thus its neck domain is extremely short, it is unlikely that the myosin VI takes this scenario. Recently we have shown that the directionality of myosin VI is irrespective to the neck domain (Homma, *et al.* Nature 412, 831- '01). These results indicate that the motor domain and/or actin-myosin interface, not the neck domain, determine the processive 36 nm steps and directionality of myosin VI.

PASSIVE ELASTIC RECOIL OF TITIN ADDS TO THE SHORTENING SPEED OF SKELETAL MUSCLE FIBERS

Ave Minajeva, Ciprian Neagoe, Michael Kulke, and Wolfgang A. Linke

Institute of Physiology and Pathophysiology, University of Heidelberg, Im Neuenheimer Feld 326, D-69120 Heidelberg, Germany, wolfgang.linke@urz.uni-heidelberg.de, webpage: <http://www.physiologie.uni-hd.de/linke/>

INTRODUCTION

The shortening velocity of skeletal-muscle fibers is determined principally by actin and myosin. However, these contractile proteins are in parallel with elastic elements, whose main structural basis is thought to be the titin filaments. If titin is stretched, it may contribute to sarcomere shortening simply because it can recoil passively. Thus, titin truly is a 'contractile' protein. Here, the titin-based contribution to shortening velocity (V_p) was quantified in single rabbit psoas myofibrils. Results were used to estimate the importance of titin elastic recoil for the shortening speed of actively contracting rabbit psoas fibers.

METHODS

Single rabbit psoas myofibrils were suspended between a rigid needle and a micromotor, and the image was projected onto a linear CCD array (Fig. 1). Nonactivated specimens were rapidly released from different initial sarcomere lengths (SLs) by steps of 150, 250, or 450 nm/sarcomere. During buckling of the myofibril, the regular intensity-profile pattern disappeared, but was spontaneously restored as the slack was taken up. V_p was calculated from release amplitude and time to slack reuptake.

Method to Measure the Speed of Passive Elastic Recoil

Figure 1: Example of measurement of V_p of relaxed myofibril.

RESULTS AND DISCUSSION

V_p progressively increased (upper limit of detection, $\sim 60 \mu\text{m} \times \text{s}^{-1} \times \text{sarcomere}^{-1}$) between 2.2 and 3.0 μm initial SL (Fig. 2), albeit much steeper than passive tension (*cf.*, Linke, 2000). Already at very low passive-tension levels ($< 1\text{-}2 \text{ mN/mm}^2$), V_p could greatly exceed the active unloaded shortening velocity measured in fully Ca^{2+} -activated skinned rabbit psoas fibers

(11.8 (15°C) or 14.5 (23°C) $\mu\text{m} \times \text{s}^{-1} \times \text{sarcomere}^{-1}$), if release steps were sufficiently small. Degradation of titin by low doses of trypsin (0.05 $\mu\text{g/ml}$; 23°C, 5 min) drastically decreased V_p .

Summary of V_p Measurements on Single Myofibrils

Figure 2: Passive shortening speed (mean \pm SEM, $n=9\text{-}11$), calculated for release steps of 150, 250, 450 nm/sarcomere, and temperatures of 15°C or 30°C (Minajeva et al., 2002).

In intact myofibrils, average V_p was the faster, the smaller the release step applied. Also, V_p was much higher at 30°C than at 15°C (Q_{10} : 2.0-3.04-6.15, for releases of 150-250-450 nm/sarcomere, respectively). Viscous forces opposing the shortening are likely to be involved in determining these effects (Kulke et al., 2001). The results support the idea that the contractile system imposes a braking force onto the passive recoil of elastic structures. However, elastic recoil may aid active shortening during phases of high elastic energy utilisation (Minajeva et al., 2002), *i.e.*, immediately after the onset of contraction under low or zero load or during prolonged shortening from greater physiological SLs.

SUMMARY

Measurements of the passive elastic recoil of single psoas myofibrils revealed that stretched titin filaments are sufficiently powerful molecular springs to make a significant contribution to the shortening speed of Ca^{2+} -activated muscle fibers. Under physiological conditions this contribution may be important in that it acts as an additional driving force on the contractile system at small releases and during shortening from longer SLs.

ANGULAR MOMENTUM OF THE NON-THROWING ARM IN THE JAVELIN THROW

Michele LeBlanc
Pepperdine University, Malibu, CA 90263
michele.leblanc@pepperdine.edu

INTRODUCTION

Javelin throwers are instructed to “block” with their non-throwing side and to “reach for their wallet” during the final phase of the throw to enhance their throw’s distance. The purpose of this study is to determine the effectiveness of the motion of the non-throwing arm (NTA) during a javelin throw by examining its angular momentum.

METHODS

At the end of the run-up, a right-handed thrower makes a cross-over step, lands on the right foot (RTD), plants the left foot (LTD), and releases the javelin. The athlete is in single-support (SS) between RTD and LTD, and generally, in double-support (DS) between LTD and release. Two throws for each of eight elite-level male javelin throwers were used for this study. Data was collected at 100 Hz using standard 3D film analysis procedures.

Digitized data from the film images were used to calculate the coordinates of 21 body landmarks and three javelin landmarks. The 3D coordinates were expressed in a fixed orthogonal reference frame with the X-axis perpendicular to the run-up (pointing to the right), Y-axis along the run-up, and Z-axis pointing upward. The coordinate data were smoothed using quintic spline. Center of mass locations and angular momentum values of the body segments and of the javelin were calculated following a method based on Dapena (1978). The location of the javelin c.m. was computed using information from Hubbard and Bergman (1989).

The SS and DS phases were each divided into two equal time periods. The 3D angular momentum values of the system (body-plus-javelin) and the NTA, all relative to the whole-body c.m., were calculated for five instants: (1) RTD, (2) the midpoint of SS, (3) LTD, (4) midpoint of DS, and (5) release.

RESULTS AND DISCUSSION

Average angular momentum values for the 16 throws are shown in Table 1. To facilitate this discussion, the terms “clockwise” (CW) and “counterclockwise” (CCW) will replace the signs of the X, Y and Z angular momentum components; the directions will correspond to views from the right, from behind and from overhead for the H_X , H_Y and H_Z angular momentum components, respectively.

During SS and DS, the system obtains more and more CW H_X . The NTA minimally contributes to the system H_X . The c.m. of the NTA is located just slightly in front of the body c.m. and moves from shoulder level to approximately the height of

the body c.m., creating a small amount of CW H_X .

The amount of system CCW H_Y increases throughout SS, in large part due to the motions of the extended NTA as it sweeps horizontally across the thrower’s body, away from the throwing arm. During DS, the system CCW H_Y remains relatively fixed. The NTA transfers its CCW H_Y to the trunk throughout DS. The trunk transfers the CCW H_Y to the throwing arm-plus-javelin segment (TAJ) later in DS.

During SS, the system has a small amount of CCW H_Z and the NTA generates CCW H_Z by the sweeping motion of the extended arm across the body. During the early portion of DS, the NTA’s CCW H_Z is transferred through the trunk to the TAJ.

CONCLUSIONS

During SS the motions of a javelin thrower’s NTA create angular momentum that is transferred to the TAJ via the trunk during DS. The NTA has little angular momentum at release. The effectiveness of a javelin thrower’s NTA action can be assessed by noting the amount of angular momentum generated and transferred, as well as noting the timing of the transfer of angular momentum to the trunk and TAJ.

OPTIMAL DISCUS RELEASE CONDITIONS INCLUDING PITCHING-MOMENT-INDUCED ROLL

Mont Hubbard

Sports Biomechanics Laboratory, University of California, Davis, California, USA
mhubbard@ucdavis.edu

INTRODUCTION

Besides its roughly parabolic flight path, the next most apparent feature of discus flight to the keen observer is the slow rolling of the discus attitude from right to left (when viewed from behind). Although this motion has apparently not yet been measured quantitatively, it appears that tens of degrees of roll occur in a typical flight and that the women's discus is perhaps more susceptible to it than the men's. This rolling motion changes the direction of the lift vector and consequently the trajectory from an otherwise vertical plane, and the smaller vertical component of lift reduces range. Most previous discus simulation studies have assumed that attitude is unchanged during flight, however, relying on the assumption that large angular momentum due to spin about its axis of symmetry will resist completely the effects of aerodynamic torques and maintain the initial release discus attitude constant. Even Frohlich (1981), who clearly described the precessional effects of torques due to any offset between centers of pressure and mass, neglected these in simulations.

Only the calculations of Soong (1976) have considered the possibility of general rotational motion. He derived equations for flight including not only large axial spin, but also wobble about the other two axes, and used experimental lift and drag force data of Stilley (1972) for a frisbee-like disc. Because he was unable to find information in the literature on discus pressure distributions, Soong calculated these using the classical velocity potential for an approximate rotating ellipsoid. These were used to calculate aerodynamic moments in the trajectory integrations. Unfortunately, no numerical results were given for the dependence of the moments on translational and rotational velocities that would allow for comparison with experimental data.

METHODS

In this work, equations of motion were derived for discus flight including the assumption that attitude changes (mainly in roll) due to precession of spin angular momentum by nonzero pitching moments. The initial angular velocity vector is assumed parallel to the axis of symmetry, i.e. there is no initial wobble. Although other authors have measured discus lift and drag (Cooper, et al., 1959; Ganslen, 1964), for consistency we use the experimental aerodynamic force results of Kentzer and Hromas (1958), who also measured pitching moment as a function of angle of attack, α . Other realistic features observed in their data are stall and consequent abrupt decrease in lift near $\alpha = 28$ deg. Recent studies of the aerodynamics of Frisbee and other similar circular planform objects (Potts and

Crowther, 2000; Hubbard and Hummel, 2000) support the assumption that even large spin produces negligible rolling moment. Thus, in the calculations, the precession of spin angular momentum is due only to pitching moment, and discus attitude changes occur in roll only. Optimization in the initial condition parameter space allows calculation of release conditions producing maximum range including initial pitch and roll attitude, and angle of attack.

RESULTS AND DISCUSSION

It is optimal to release with the discus rolled significantly to the right ($\phi_0 = 15$ deg) so that the lift vector remains near vertical throughout much of the flight. Maximum range (when $v_0=25$ m/s and $h_0=1.8$ m) is more than 73 m. Roll angle excursions during the optimal trajectory exceed 35 deg ($-20 < \phi(t) < 15$ deg). Optimal release conditions found here neglect the possible dependence of release velocity and spin, since no such dependence has yet been documented. It is also likely that release velocity is dependent on release angle as in the shot put (Hubbard, et al., 2001) and even angle of attack. This motivates further study of these dependencies.

SUMMARY

Discus roll changes substantially during flight as a result of the precessional effects of nonzero pitching moments and must be accounted for in simulations. Optimal release conditions include non-zero initial roll and allow the mean lift to stay nearly vertical, especially near the end of flight.

TWIST ANGULAR MOMENTUM DURING THE POLE VAULT TAKE OFF

Peter M. McGinnis

Department of Exercise Science and Sport Studies, SUNY College at Cortland, Cortland, New York, USA (pmcginnis@cortland.edu)

INTRODUCTION

Pole vaulting is an exciting and complex athletic event. During a successful vault, rotations occur about several axes. Following takeoff, rotation around the transverse or somersault axis occurs as the vaulter swings on the pole and continues to rotate into an inverted position. This somersaulting rotation reverses direction later in the vault as the vaulter pushes off the pole. Just prior to this, rotation about the vertical or twist axis occurs as the vaulter extends and prepares to push off the pole. On initial examination, it appears that this is the only time during the vault when a vaulter has angular momentum about the vertical or twist axis. However, upon closer examination, it seems that a pole vaulter might have some angular momentum about the twist axis during the takeoff phase of the vault as well, due to the forward swinging action of the lead leg at the instant of takeoff. This angular momentum would be in the opposite direction of the twist angular momentum the vaulter possesses when he turns and pushes off the pole.

Most analyses of the pole vault have only been 2-dimensional, a few have been 3-dimensional, and even fewer have reported the angular momentum of a vaulter in 3-dimensions. Morlier and Cid (1996) did measure the angular momentum of a pole vaulter in 3-dimensions. Their results indicated that the vaulter had a slight amount of twist angular momentum at the instant of takeoff. Their study was limited to only one vault at 4.80 m, however.

The purpose of this study was to measure the twist angular momentum generated during the takeoff phase of successful competitive vaults by elite pole vaulters.

METHODS

Two gen-locked video cameras operated at 60 hz recorded the last step and take off phases of vaults during the men's pole vault competitions at the USA Track and Field Championships in 1999 and 2001. A Peak Motus video digitizing system was used to manually digitize 20 anatomical landmarks in each frame of the selected videorecords. The digitized coordinate data were filtered and then transformed into global 3-dimensional coordinates using the DLT method. The following global coordinate system was used: the X-axis was directed forward and horizontally along the direction of the runway, the Y-axis was directed to the left horizontally across the runway, and the Z-axis was directed upward. A total of 9 vaults (one by each by 9 different vaulters) were analyzed. These vaults represented the highest successful vaults by each vaulter in the two competitions. The heights of the analyzed vaults ranged from 5.50 m to 6.02 m. The average height of the analyzed vaults was 5.71 m.

The vaulter model included the following 11 segments: head, neck, and trunk; 2 forearms and hands; 2 upper arms; 2 thighs; 2 legs; and 2 feet. Anthropometric data from Zatsiorsky and Seluyanov (1983) and Plagenhoef et al. (1983) were used to describe the inertial characteristics of the vaulter. The angular momentum of the pole vaulter about his center of mass was computed using the technique described by Dapena (1978). A composite history of the angular momentum was computed by averaging the angular momentum of the 9 vaulters using the instant of takeoff as the synchronizing event.

RESULTS

The angular momentum about the Z-axis was negative at foot strike and generally changed toward positive throughout the stance phase of the takeoff foot for all 9 vaulters. All 9 vaulters had positive angular momentum about the Z-axis at the instant of takeoff as did the vaulter in Morlier and Cid's (1996) study. This angular momentum reached a maximum at takeoff or within one frame of takeoff in 7 of the 9 vaults. The composite angular momentum about the Z-axis was minimum and negative at the instant of foot strike ($H_z = -3.9 \text{ kg.m}^2\text{s}^{-1}$) and maximum and positive at the instant of takeoff ($H_z = 7.3 \text{ kg.m}^2\text{s}^{-1}$). The most significant contribution to the positive angular momentum about the Z-axis at takeoff came from the swing leg.

DISCUSSION AND CONCLUSIONS

The positive angular momentum about the Z-axis possessed by pole vaulters at takeoff is not large, but it must be reversed later in the vault to execute the turn. The total change in angular momentum about the Z-axis during the vault may thus be significant. This change in momentum may be difficult for some vaulters to produce. Qualitative examination of videos of the elite vaulters in this study indicates that this is not a problem for them. However, some less skilled vaulters may have difficulty producing this change in momentum. As a result, their turning action may be incomplete or late, thus adversely affecting their performance.

KINEMATICS AND KINETICS IN POLE VAULTING: ENERGY STORAGE AND RETURN

Gert-Peter Brüggemann, Adamantios Arampatzis, Falk Schade

Institute for Biomechanics, German Sport University of Cologne, Cologne, Germany, brueggemann@dshs-koeln.de

INTRODUCTION

Pole vaulting at national and international levels was subjected to numerous biomechanical studies in the past (e.g. Gross & Kunkel 1990, Angulo-Kinzler et al. 1994). Most biomechanical analyses were restricted to the description of selected parameters of the performance. Only a few model oriented studies were carried out to explain the effect of energy storage by pole bending and of energy re-utilization by the athletes in a later stage of the movement (McGinnis & Bergmann 1986, Ekevad & Lundberg 1997). Due to the fact that calculations of the energy of the pole based on pure kinematic sources are extremely sensitive to noise and errors, most of the energy and power research is based on a relatively restricted data base. No kinetic data are available from elite pole vaulters in training or competitive situations. Only a very small amount of kinetic data (ground reaction forces at the pole box) has been reported from sub-elite athletes in training situations (Woznik 1992).

The objective of the study is the explanation of the effect of energy storage in the pole by bending, and of energy re-utilization by the athletes in a later stage of the movement, on the final performance in pole vaulting.

METHODS

For the analysis, the pole vault was divided into the following phases: (1) The energy production phase. This phase starts with the approach and ends with contact of the jump foot against the ground at take-off. (2) The energy exchange phase. This phase is from the first contact of the takeoff foot with the ground at take-off to the athlete's release of the pole at the end of the jump. During the first part of the energy exchange phase, elastic energy is transferred into the pole while decreasing the athlete's energy. The difference between the decrease in the athlete's energy and the maximum pole energy indicates if the pole elasticity was effectively used (Criterion 1). During the second part of the energy exchange phase the stored energy is re-utilized through transfer from the pole to the athlete. The athlete's energy increases. The difference between the returned energy and the energy gain of the athlete indicates to what extent the athlete used muscular work to increase his/her energy (Criterion 2). The two criteria were applied to identify energy storage and return strategies of elite athletes in two separate competitions.

In the study, 6 top national jumpers (5 male, 1 female) performed 4 to 11 trials each, at 90% of their respective personal records. All trials were recorded using four synchronized and genlocked video cameras operating at 50 fps. The ground reaction forces exerted on the bottom of the pole were measured with an instrumented planting box (three 3D Kistler force transducers). Pole deformation and force data allowed the calculation of energy transmitted into the pole and re-utilized by the athlete.

RESULTS AND DISCUSSION

From the energy data, one can derive an energy loss of 7–10% during pole bending and extending (Fig. 1). Different athletes use different energy storage and return strategies while reaching similar energy amounts at the end of the pole phase. Differences in the final energy at release can be determined through different motor behavior in the two phases.

The results show that the chosen criteria are sensitive to differentiate between top athletes and to identify individual deficits (Figs. 1, 2). The criteria are repeatable and reliable.

Figure 1: Mechanical energy of the athlete and of the pole during pole bending and extending of two athletes (means of 4 and 7 trials, respectively). Criteria 1 (Cr_1) and 2 (Cr_2) are completely different in the two athletes.

Figure 2: The two criteria (Cr_1 and Cr_2) and the energy loss analyzed

in the trials of six athletes demonstrate subject-dependent energy storage and re-utilization strategies. The numbers in the graph indicate significant ($p < 0.05$) differences between the individual athletes: (1,2) different from athletes 1 and 2; (1,2,3) different from athletes 1,2,3.

ORTHODONTIC BRACKET DEBONDING: IN VIVO AND IN VITRO DEBONDING STRENGTH AND THE RELATED TOOTH DAMAGE

Tamar Brosh, Ofer Sarne, Alexander D Vardimon

Department of Orthodontics, School of Dental Medicine, Tel Aviv University, Tel Aviv Israel

INTRODUCTION

Debonding strength of orthodontic brackets and their related tooth damage are of concern to bracket developers, engineers, dental material researchers and orthodontics. The in vitro studies, as well as numerical models, cannot simulate the oral environment and its affect on the debonding characteristics. This presentation introduces results obtained from in vivo and in vitro bracket debonding and their related tooth damage.

METHODS

Orthodontic debonding pliers were modified and a strain gauge was bonded to one of its handles. After calibration, in vivo bracket debonding force measurement could be performed.

In vivo study: Metal brackets were debonded after full orthodontic treatment (about 24 mo) from 50 patients using pliers. Brackets from 30 of these patients were scanned using SEM and EDAX and scaled for Adhesive Remnants Index (ARI) (0-3) and Calcium Remnant Index (CRI) (0-3). Only premolars were used for comparison.

In vitro study: Metal brackets were bonded to the buccal side of 20 premolars after acid-etching procedure and then divided into 2 groups which differed in water storage duration: Group A - 48 h, Group B - 12 mo. Before bracket debonding using the pliers connected to a loading machine, all specimens underwent thermo-cycling procedure. All brackets were scanned and scaled as in the in vivo study.

Student t-test was applied to evaluate differences between debonding strengths, ARI and CRI. Correlations between debonding strength and ARI or CRI were performed for both studies.

RESULTS AND DISCUSSION

Table 1 presents the mean values of the determined parameters of all tests. No significant differences ($p>0.05$) were found between debonding strength or ARI. However, calcium remnants on brackets debonded in the in vivo study were significantly higher than those observed in the in vitro study after 48 h ($p=0.05$) and also higher than the 12 mo water storage of specimens. One of the brackets debonded with a large enamel chip is presented in Figure 1. Significant negative correlations were found between debonding strength and ARI or CRI (Table 2).

Debonding strength was not affected by the clinical environment (orthodontic forces, saliva ect.) compared to in vitro measurements. This fact alone allows further determining strength values by using laboratory models. However, more tooth damage was observed when brackets were debonded after the long orthodontic treatment.

Higher debonding strength values do not indicate higher tooth damage (Table 2). Debonding site can occur at various locations: (i) cohesive at the adhesive-bracket interface, where the adhesive remains on tooth enamel; (ii) adhesive through the adhesive layer; and (iii) cohesive at the adhesive-enamel interface. Almost none of these categories appear alone and a combination of more than one appears. If debonding occurs according to (i) no tooth damage occurs. Most importantly, debonding strength between the bracket and the adhesive is higher than required to debond the bracket according to (ii) or (iii). This conclusion is an outcome of the negative correlations found between debonding strength and ARI or CRI. However, high values of debonding strengths indicate large amounts of adhesive remnants on tooth enamel. In these cases, scaling using orthodontic tools should be performed and damage may occur.

SUMMARY

Teeth are prone to damage when low debonding strength is required, since debonding occurs at the enamel-adhesive interface. This interface is weaker than the bonding interface between the adhesive material and the metal bracket. Moreover, in vitro studies can indicate debonding strength, however, their indication for tooth damage is limited.

Table 1: Debonding strength, adhesive (ARI) and calcium (CRI) remnant index (mean \pm SD)

	In vivo study	In vitro study	
Test after	24 mo	48 h	12 mo

EXPERIMENTAL AND NUMERICAL STUDY ON THE MECHANICAL BEHAVIOUR OF THE PERIODONTAL LIGAMENT UNDER ORTHODONTIC LOADING

Christoph Bourauel

Department of Orthodontics, University of Bonn, 53111 Bonn, Germany
Head Orthodontic Biomechanics Laboratory, bourauel@uni-bonn.de

INTRODUCTION

Initial tooth deflections under orthodontic loads are the mechanical key stimulus to trigger bone remodeling processes in the dento-alveolar complex. In particular the elasticity properties of the periodontal ligament (PDL) have a great impact on stresses and strains induced in the PDL and the surrounding bony structures and thus control the orthodontic tooth movement. It was the objective of the presented study to determine linear and nonlinear elasticity parameters describing the mechanical behaviour of the PDL regarding the initial tooth mobility. Though the parameters are well known for teeth and bony structures, a wide range of values for Young's modulus of the PDL can be found in literature. In a combined experimental and numerical approach, the behaviour of different human and animal models was determined.

MATERIALS AND METHODS

Ten non-fixed preparations of human front and canine teeth, five canines from mini pigs (genus Yucatan, Troll), each with surrounding bone and ligament, and twelve mandibular segments of Wistar rats were investigated. The specimens were measured in a 3-D laser-optical set-up (**MO**bility **M**eaurement **S**ystem, *Hinterkausen et al.*, 1998) to determine force/deflection characteristics. The crowns of the teeth were loaded with forces of up to 0.1 N (rat specimens), 1.0 N (human) and 3.5 N (pig). A very slow force rate was chosen to simulate the orthodontic load case and to ensure that hydrodynamic flow processes have decayed. The maximum load was applied in up to 100 steps within one hour of measurement time.

Subsequently, the specimens were cut into sections, microphotographs were taken and 3-D finite element (FE) models were generated semi-automatically with a specialized software (*Vollmer et al.*, 2000). Using measured force/deflection diagrams and the FE models of the experimentally investigated preparations, material parameters of the PDL have been determined in an iterative procedure. Constant values of the material parameters were assumed for all other structures (tooth: 20 GPa, cortical bone: 15 GPa, spongy bone: 1 GPa). Calculations were performed with the FE package COSMOS/M (Versions 2.5 – 2.6) using its 3D solid element.

RESULTS AND DISCUSSION

Initial tooth deflections under orthodontic loads is dominated by the material parameters of the periodontal ligament.

Figure 1: FE model of a human canine (left) and numerical load/deflection curve fitted to the experimental one (right).

However, the experimental load/deflection curves could not be reproduced satisfactory with the assumption of a linear behaviour (Young's modulus $E = 0.1$ MPa, Poisson's ratio $\nu = 0.3$). A bilinear approach representing the nonlinear behaviour of the PDL could be fitted to the force/deflection curves of all preparations. Two Young's moduli separated by an ultimate strain ϵ_{12} were determined. The first, E_1 , represents an initial regime with high mobility, and the second Young's modulus, E_2 , is approximately four times higher and the tooth reacts stiffer on force application. The means and standard deviations of the parameters are listed in the table below for all preparations. Only minor variations were determined between human and pig material parameters of the PDL, while the values for the rat seem to differ significantly especially with respect to the start value (ϵ_{12}) and the modulus (E_2) of the second elastic regime.

ON THE RELATIONSHIP BETWEEN BONE-REMODELING RATE AND ORTHODONTIC STRAINS WITHIN THE PERIODONTAL LIGAMENT

Christopher G. Provatidis

Mechanical Engineering Department, National Technical University of Athens, Athens, Greece
Associate Professor, prowaton@central.ntua.gr
9, Heroes of Polytechnion Avenue, GR-15773, Athens, Greece

INTRODUCTION

Analytical closed formulas for the calculation of strains within the periodontal ligament (PDL) in case of intrusion were previously reported by Provatidis (1999). In this particular (and very simple) case it was shown that if the bone remodeling rate along the interface between the PDL and the alveolar bone is assumed to be proportional to *both* the normal and the tangential strain components, the PDL reserves its shape and it continuously follows the tooth during its long-term orthodontic movement". This result is in the opposite direction to bone remodeling assumptions for long bones; a differentiation firstly made by Middleton et al (1996). This paper extends the theory to bodily tooth movement.

METHODS

Following Provatidis (2001), translation (u) of a tooth with a paraboloidal root is related to only a normal (ϵ_{nn}) and two shear strains ($\gamma_{nt}, \gamma_{n\vartheta}$), which are approximated as follows:

$$\epsilon_{nn} = -\frac{u_n}{\delta}, \gamma_{nt} = -\frac{u_t}{\delta}, \gamma_{n\vartheta} = -\frac{u_\phi}{\delta} \quad (1)$$

where δ is the PDL thickness and u_n, u_t, u_ϕ are tooth displacement components with respect to local coordinate (tooth-fixed) system.

It is here hypothesized that the PDL reserves both its shape and thickness and it continuously follows the tooth during its long-term orthodontic movement. This assumption establishes a relationship between bone remodeling rate (\vec{u}_{bone}) and tooth displacement (u) given as ($\lambda = \text{constant}$):

$$\vec{u}_{bone} = \lambda \vec{u} \quad (2)$$

A combination between (1) and (2) leads to ($c = -\lambda\delta$):

$$\begin{bmatrix} \dot{u}_n \\ \dot{u}_t \\ \dot{u}_\phi \end{bmatrix}_{bone}^T = c \begin{bmatrix} \epsilon_{nn} \\ \gamma_{nt} \\ \gamma_{n\theta} \end{bmatrix}^T \quad (3)$$

The theory is here validated by a numerical example on an upper central incisor using FEM analysis. A structured mesh of 1156 nodules and 768 elements was generated by cutting root in 24 equidistant slices. The PDL/bone interface was moved in accordance to (3) using $c=1000$, mainly for visual purposes.

RESULTS AND DISCUSSION

It is clearly shown in **Figure 1** that the interface between PDL and alveolar bone reserves the shape of the tooth.

Figure 1: Initial tooth-root surface (blue) and new position of the alveolar bone (pink). The tooth is then shifted to depict that tooth shape is reserved (yellow).

The limitation of the proposed approach is that it is reduced to linear elastic considerations. It is remarkable that according to the above considerations, if the bone displacement is larger than its corresponding on the adjacent tooth surface in such a way that these displacements are related through a common *constant* ratio, then the PDL is *uniformly* enlarged according to the same ratio.

SUMMARY

Closed-formed analytical formulas for single-rooted teeth offer the background for the development of a simple bone remodeling theory in orthodontics. Tooth roots characterized by more complex geometries can be further analyzed using finite element analysis. Comparison with clinical and histological findings will further validate the proposed theory.

DELAYED VERSUS EARLY VERSUS IMMEDIATE LOADING OF ORAL IMPLANTS

INTRODUCTION

The classic osseointegration method is based on a two-stage surgical protocol and delayed loading (3-6 months). Over the years this has proven to be a highly successful and predictable treatment. However attempts have gradually been made to simplify the protocol and to reduce the treatment time. Techniques have e.g. been suggested for one-stage approaches as well as early (weeks) and immediate loading (days) of the oral implants. Loading is an important factor concerning implant success/failure. In a clinical study these three treatment concepts are prospectively followed during the first year of loading, concerning type of loading and the related effect on (re)modelling of the peri-implant bone. At the same time the effect of mechanical loading on early loaded implants is investigated in an animal study. Both studies are part of a larger project to analyse adaptive bone (re)modelling around implants, using a combination of clinical and animal experiments and individualized finite element models.

METHODS

In the clinical study a miniature bite force is used to measure bite forces. Strain gauged supra-osseous parts on the implants measure the accompanying type (axial/moment) and amplitude of loading of the implants. Digital intra-oral peri-apical and tomographic radiographs are used to follow the peri-implant bone (re)modelling.

In the animal study percutaneous titanium implants are placed in both tibiae of skeletally mature guinea pigs. Using an electromechanical shaker implants are mechanically stimulated with a sinusoidally varying bending moment, frequency 30 Hz, for 1800 cycles. Already 4 experimental groups with a force amplitude of 10 Nmm, 20 Nmm, 40 Nmm and 80 Nmm respectively are performed. Stimulation was applied unilaterally, during 4 weeks, starting one week post-operatively. The contra-lateral leg was used as control. Bone(re)modelling of both test and control implants are followed by in vivo (1 week post-op, before loading and two weeks after loading) and post mortem micro-focus computer tomography.

RESULTS AND DISCUSSION

Both clinical and animal study are not completed yet, but interim results show that bite forces increase during the first year of function in all three patient groups. Marginal bone loss takes place mainly during the first three months of loading. In the early and immediate loading patient groups mean marginal bone loss (1.07 mm) is larger than in the delayed loading group (0.47 mm).

In the animal study micro-CT images are qualitatively scored on the amount of new bone formation. Using a non-parametric test, mechanical stimulation has a positive effect on bone (re)modelling around early loaded implants in guinea pigs for the 10, 20 and 40 Nmm group. Using a 80 Nmm force amplitude, test implants showed non-integration, probably due to overload.

SUMMARY

Although bite forces increase over time, the rate of mean marginal bone loss decreases during the first year of function. Early and immediate loaded implants show more bone (re)modelling than delayed loaded implants.

In an animal study stimulation of bone(re)modelling can be shown. Quantification of the positive effect will be done by means of histomorphometric analysis of the post mortem bone with implant specimens.

NUMERICAL SIMULATION OF THE POLYMERIZATION OF TOOTH/RESIN INTERFACE FOR CLASS V RESTORATIONS

Estevam Barbosa de Las Casas¹, Tulimar Pereira Machado Cornacchia², Fabiano de Carvalho Filho¹, Priscila Azeredo² and Carlos Alberto Cimini Jr.¹

¹School of Engineering and Dentistry, Federal University of Minas Gerais, Brazil

²School of Dentistry, Federal University of Minas Gerais, Brazil

INTRODUCTION

Composite resins are nowadays the most used materials in dental restorations, due to their aesthetic advantages and mechanical characteristics. These materials are usually light-cured and their polymerization induces a significant volumetric shrinkage, varying between 1 and 3%. The process of polymerization and its related constrained shrinkage produces a state of residual stresses which can lead to failure in the involved materials, post-operative pain or fracture of the margins of restoration, leading to leakage of fluids and caries.

In order to reduce the effects of the shrinkage, incremental techniques were developed as an option to the unique incremental procedure. Different manners of filling the restoration cavity have shown to result in different stress distributions of the residual stresses, as observed by the clinical results in terms of success. The choice of the best filling technique is the dentist-surgeon function, and there are not very clear guidelines as to how to proceed.

METHODS

In this paper, step-by-step analysis of the transient stresses induced for different filling techniques is performed. In the model the accumulated stresses are considered, as well as the leakage in the event of reaching local stresses higher than the shear bond between tooth and resin. Mastication load is then introduced, to improve understanding of the behavior of the restoration with residual stresses under functional loads. The three techniques are shown in Figure 1 - uniform, WI and bulk.

A similar analysis procedure was described by Winkler and co-workers in 1996. Our results show that the final stress distribution is dependant on the filling technique, as expected in a nonlinear phenomenon.

RESULTS AND DISCUSSION

The results indicate that the bulk technique results in larger interfacial stresses, while the WI provided the best results.

Figure 1: Filling techniques - uniform, WI and bulk

A larger number of failures is expected when using the bulk filling, which agrees with clinical practice. High values of principal tensile stresses are obtained in all cases. The first principal stresses that arise during the polymerization and the final residual stresses are shown in Table 1.

Table 1: Stresses during filling and at the end of the process.

A NONLINEAR ELASTIC TRANSVERSELY ISOTROPIC CONSTITUTIVE LAW FOR THE PDL: ANALYTICAL AND COMPUTATIONAL ASPECTS

Georges Limbert and John Middleton

Biomechanics Research Unit, University of Wales, College of Medicine, Cardiff, UK, LimbertG@cardiff.ac.uk

INTRODUCTION

A thorough knowledge of the periodontal ligament (PDL) is vital in understanding the mechanics of tooth mobility, soft tissue response and proposed treatment plans (Middleton et al., 1996). In order to overcome the limitations exhibited by the existing constitutive models of the PDL (Pietrzak et al., 2002), we propose a new model of the PDL that captures simultaneously its essential mechanical features: non-linear behaviour, large deformations, anisotropy, distinct behaviour in tension and compression, and fibrous characteristics.

METHODS

Due to the composite nature of the PDL (collagen fibres embedded in a gel-like solid matrix) the framework of a continuum theory of fibre-reinforced composite (Limbert and Taylor, 2002) was used. Let \mathbf{F} be the deformation gradient and J its determinant. \mathbf{C} , the right Cauchy-Green deformation tensor admits three principal invariants I_1 , I_2 and I_3 . To model the preferred mechanical direction from which anisotropy arises a local unit vector \mathbf{n}_0 defining the fibre direction is introduced. This leads to the definition of a fourth invariant I_4 : $I_4 = (\mathbf{n}_0 \otimes \mathbf{n}_0) : \mathbf{C}$. The following notations are introduced:

$$\bar{\mathbf{F}} = J^{-\frac{1}{3}} \mathbf{F}, \det(\mathbf{F}) = 1 \Rightarrow \bar{\mathbf{C}} = J^{-\frac{2}{3}} \mathbf{C} \quad (1)$$

\bar{I}_1, \bar{I}_2 and \bar{I}_3 are the principal invariants of $\bar{\mathbf{C}}$. The existence of a strain energy density $\psi(\bar{I}_1, \bar{I}_2, \bar{I}_3, \bar{I}_4)$ is postulated. It is further hypothesised that the strain energy function can be represented by the uncoupled sum of the isotropic deviatoric, anisotropic deviatoric and isotropic volumetric strain energy functions:

$$\psi = \psi(\bar{I}_1, \bar{I}_2, \bar{I}_3, \bar{I}_4) = \psi_{dev}^m + \psi_{dev}^f + \psi_{vol}^m \quad (2)$$

For the matrix contribution a simple Mooney-Rivlin type strain energy function is chosen:

$$\psi_{dev}^{matrix} = c_1(\bar{I}_1 - 3) + c_2(\bar{I}_2 - 3) \quad (3)$$

To capture the distinct behaviour of the PDL in tension and compression (Pietrzak et al., 2002), the following convex function I_3 is used:

$$\psi_{vol}^m = \kappa f(I_3) = \begin{cases} \frac{\kappa}{4\alpha^2} (I_3^\alpha - 1 - \alpha \ln I_3) & \text{if } I_3 \leq 1 \\ -\frac{\kappa}{4\beta^2} (-I_3^{-\beta} + 1 - \beta \ln I_3) & \text{if } I_3 \geq 1 \end{cases} \quad (4)$$

To represent the mechanical contribution of the collagen fibres the following convex function is proposed:

$$\psi_{dev}^f = g(\bar{I}_4) = \begin{cases} 0 & \text{if } \bar{I}_4 \leq 1 \\ \frac{c_3}{2c_4} [e^{c_4(\bar{I}_4-1)^2} - 1] & \text{if } \bar{I}_4 \geq 1 \end{cases} \quad (5)$$

$c_1, c_2, c_3, c_4, \kappa, \alpha$ and β are material parameters that were determined by identification with experimental/analytical curves (Pietrzak et al., 2002). Stress and elasticity tensors are respectively obtained by first and second differentiation of ψ with respect to \mathbf{C} .

The constitutive law was implemented into the finite element (FE) code ABAQUS/Standard (HKS Inc., Pawtucket, RI, USA) via a customized subroutine. An idealized FE model of the PDL was then built and several FE analyses were carried out in order to simulate various mechanical physiological conditions the PDL is subjected to.

RESULTS AND DISCUSSION

The constitutive law exhibited the typical non-linear stiffening in the fibre direction as well as being capable of capturing the distinct highly non-linear stress-strain characteristics in tension and compression. Essential constitutive requirements were also verified. Excellent agreement was found between the analytical and numerical solutions therefore providing a solid basis for further FE analyses. The FE analyses of the PDL model demonstrated the relevance of the continuum mechanics formulation adopted in this work. The anisotropy of the PDL has also provided a much more accurate insight into the complexity of its mechanical behaviour. The proposed model adds significant improvement to the current analytical and numerical models of the PDL through being able to capture the directional and non-linear properties of the ligament for the finite strain regime. Further experimental data will permit the constitutive law to be extended to encompass both time-dependent and transport effects. Accurate geometrical definition of the PDL-tooth-bone complex will also be required for the simulation of more realistic *in-vivo* physiological conditions.

SIMULATION OF OVERLOAD-INDUCED MARGINAL BONE RESORPTION USING ANATOMICAL FINITE ELEMENT MODELS

Hans Van Oosterwyck¹, Tom De Wilde¹, Jos Vander Sloten¹, Joke Duyck², Ignace Naert²

¹Division of Biomechanics and Engineering Design, KU Leuven, Leuven, Belgium, hans.vanoosterwyck@mech.kuleuven.ac.be

²Department of Prosthetic Dentistry, KU Leuven, Leuven, Belgium

INTRODUCTION

Pathological overload has been suggested as an important etiological factor for marginal bone loss around oral implants. (Duyck et al 2001). Recently overload-induced marginal bone resorption was simulated for a simple non-anatomical finite element model of a cylindrical implant (Van Oosterwyck et al 2001). In order to compare simulated resorption with in vivo observed resorption into more detail anatomical finite element models are needed. In the present study the simulation algorithm was applied to anatomical models. The hypothesis was tested whether pathological overload alone is sufficient to explain marginal bone loss.

METHODS

An iterative feedback algorithm was developed to simulate bone adaptation around an oral implant (Van Oosterwyck et al 2001). It was assumed that the rate of change of apparent bone density can be expressed as a function of the difference between the actual strain and a reference strain (fig. 1). The corresponding change in (isotropic) E-modulus was then calculated (Carter & Hayes 1977).

Figure 1: Bone adaptive response, expressed as the rate of change of apparent bone density as a function of strain.

The algorithm was applied to anatomical finite element models. A first model was taken from a previous study that investigated the influence of adverse dynamic loading on the bone response around a screw-shaped implant, placed in a rabbit tibia (Duyck et al. 2001). The interface between bone and implant was assigned a finite tensile strength. A second model was created from spiral tomographic images of an implant, placed in a patient's mandible. For the latter model the implant was simplified to a cylinder and a fixed bond was assumed between implant and bone. For both models a bending moment was applied to the implant.

RESULTS

The implementation of a finite strength resulted in debonding at the proximal (tensile) side for the model of the rabbit tibia. As a result, an asymmetric resorption pattern was predicted

(fig 2, left). In reality resorption craters were present at both the proximal (tensile) and distal (compressive) side. The discrepancy between simulated and observed resorption pattern could indicate that overload was not the only factor, responsible for marginal bone loss. Possibly, relative motion could also play a role in bone resorption, as was already previously hypothesised (Duyck et al. 2001). Relative motion was not yet included in the algorithm as a stimulus.

A symmetric resorption pattern was predicted for the model of the patient's mandible: resorption craters were predicted at the mesial and distal implant side. The simulated resorption could however not be validated due to the lack of radiographic data of sufficient quality.

Figure 2: Simulated distribution of E-modulus in rabbit tibia (left) and human mandible (right) around an oral implant. Dark zones in the marginal bone region represent a decrease in bone density, light zones represent an increase.

CONCLUSION

Marginal bone resorption was predicted for both a clinical and animal experimental case. Based on the animal experimental case it is hypothesised that other factors, apart from pathological overload, might be responsible for marginal bone loss.

BIOMECHANICAL MODELING OF OVERLOAD AT THE BONE-ORAL IMPLANT INTERFACE

John B. Brunski¹, Do Gyoon Kim², Ajit Prabhu¹ and Chia-Ju Yang²

Department of Biomedical Eng.¹; Department of Mechanical, Aeronautical and Nuclear Eng.²
Rensselaer Polytechnic Institute, Troy, NY 12180-3590

INTRODUCTION

Several studies have suggested that it is possible to “overload” the bone-oral implant interface (e.g., Isidor, 1999). While clinical overload seems to involve bone loss at the crestal region, mechanisms underlying that bone loss remain unclear. Possible mechanisms have been explored in experiments and computer-simulations, and here we outline a recent series of computer simulations of possible biomechanical mechanisms. A major distinction between our simulations and related previous models of bone adaptation at interfaces (e.g., van Rietbergen *et al.* 1993) is that our model accounts for changes in the bone microstructure during the remodeling process itself, i.e., we account for the fact that remodeling occurs via A-R-F = Activation of osteoclasts, Resorption by osteoclasts, and Formation of bone by osteoblasts. Also, we assume that microdamage (MDx) occurs in bone when maximum or minimum principal strain reaches $\sim 0.5\%$ ($5,000 \mu\epsilon$), and that MDx triggers A-R-F.

METHODS: REALITY VS. SIMULATION

An unrealistic aspect of some previous models of bone adaptation is that once a certain stress/strain signal is presumed to trigger remodeling, A-R-F (and its presumed adaptive effect on bone properties) is assumed to happen essentially instantaneously, with no recognition of the step-by-step A-R-F cycle that unfolds over weeks to months (Roberts, 1988). Therefore, such models do not allow for the possibility that bone near a site of A-R-F might respond to signals during the weeks to months required for a remodeling cycle. To address this shortcoming, our model explicitly simulates the A-R-F process; it allows for the possibility that holes from the initial A-R- step may alter local stress-strain states, and in turn, subsequent remodeling events. Using this idea, we have formulated several finite element models of bone-implant interfaces in 2- and 3-dimensions. We have simulated remodeling events under the rule that A-R-F is triggered at

regions where the maximum or minimum principal strains exceed a magnitude of $\sim 0.5\%$ ($5,000 \mu\epsilon$).

RESULTS AND DISCUSSION

Examples simulations (Figs 1-2, plus others to be reviewed) illustrate that one outcome consistent with overload is a situation of *positive feedback*, which develops as follows: 1) implant loading produces high strain levels and MDx at some osteons in the interfacial microstructure; 2) A-R- is triggered at MDx sites, thereby producing a hole in the bone; 3) the hole from step 2) may then concentrate strain nearby, possibly inducing new high strains, new MDx, and new sites of A-R- (which outpaces the -F stage); and 4) increasing A-R- causes another cycle of high strains, more MDx, more A-R-, etc., causing diminished bone support and, eventually, frank failure of the majority of the interfacial bone.

NEW INSIGHTS INTO ORTHODONTIC LOAD TRANSFER AND ALVEOLAR BONE REMODELING

Michel Dalstra¹, Paolo M. Cattaneo¹, Felix Beckmann² and Birte Melsen¹

¹Dept. of Orthodontics, Royal Dental College, University of Aarhus, Aarhus, Denmark

INTRODUCTION

Moving teeth through the use of orthodontic appliances, like braces etc., is perhaps one of the most direct applications of biomechanical principles in clinical practice. By carefully choosing a force system (forces & moments) for a particular tooth, the orthodontist can provoke this tooth to move (translate & rotate) in the desired direction. The tooth can actually move inside the jaw, because the alveolar bone around the tooth starts to remodel due to the perturbations in the normal loading pattern caused by the presence of the orthodontic load.

In the orthodontic field, the classical view on alveolar bone remodeling still largely persists that, if a tooth is pushed against one side of the alveolus, on this side the bone is in a state of compression, while on the opposite side the bone is in tension. As the tooth moves in the general direction it is loaded in, bone in compression must thus be getting resorbed, while bone in tension gives rise to new bone formation. This, however, is in total contrast with bone remodeling laws, which are employed in the field of orthopaedics. By using new techniques to, on the one hand, create highly geometrically accurate finite element (FE) models of tooth/bone configurations and on the other to determine the alveolar bone architecture, it is the aim of this study to shed new light on orthodontic load transfer mechanisms and give new insights into alveolar bone remodeling.

METHODS

Segments of human mandibles containing three or four teeth were obtained at autopsy and embedded in blocks of methyl-metacrylate. These blocks were scanned with a table-top micro-CT scanner at a spatial resolution of 30 µm. These scans were used for the creation of FE models. First they were read into Mimics software (Materialise, Leuven, Belgium). With this visualization/CAD software, masks were created of the different anatomical structures, which could be transformed into 3D geometrical entities. These shapes were then read into the COSMOS/M FE package (SRAC, Los Angeles, CA), where a mesh was then automatically generated. The material properties of the periodontal ligament (PDL) were assumed to be non-linear (Bourauel et al., 1999), while the Young's moduli of the individual bone elements were directly linked to the local bone densities given by the

gray values in the CT-scans (Cattaneo et al., 2001). External loading simulated various orthodontic loading regimes.

The same blocks were scanned with a micro-tomograph attached to the DORIS synchrotron-ring at HASYLAB/DESY at a spatial resolution of 7 µm. The individual scans were read into VGL software (Volume Graphics, Heidelberg, Germany) for three-dimensional (3D) reconstruction and further analysis.

RESULTS AND DISCUSSION

The orthodontic load transfer is more complex than the classical view of having opposite zones of tension and compression. Firstly this is caused by the very shape of the jaw. Due to its irregular form, the teeth are not supported uniformly by the alveolar bone. Especially near the alveolar edge, the cortical bone can be very thin and when this shell is loaded perpendicular to its thickness, secondary load transfer mechanisms become activated causing the bone to behave almost like a Roman arch. This means that normal tensile stresses are transformed into circumferential compressive stresses and vice versa, and that the nature of loading becomes the opposite of what one might expect intuitively. Secondly, the inner surface of the alveolar bone is not smooth and homogeneous. The 3D reconstructions of the micro-CT scans show a very porous surface with rough and sharp edges. This means that the stresses here are much higher than previously assumed.

SUMMARY

By using state-of-the-art techniques the orthodontic load transfer from teeth to alveolar bone has been re-examined and compared to the traditional views. The classical zones of tension and compression in the alveolar bone, still believed by many in the orthodontic field to be the origin for alveolar bone remodeling during orthodontic loading, can no longer be identified as such. This means that new hypotheses on alveolar bone remodeling must be raised, more in line with those in use in the orthopaedic view (Melsen et al. 2001).

THE DEVELOPMENT OF ABFRACTION LESIONS IN TEETH

J S Rees, M Hammadeh and D C Jagger

University of Bristol Dental School, Lower Maudlin Street, Bristol BS1 2LY, UK

Corresponding Author: j.s.rees@bristol.ac.uk

INTRODUCTION

Cervical tooth surface loss is particularly common resulting in poor aesthetics and sensitivity and this problem is likely to increase as the population ages and retains their teeth for longer. This type of tooth surface loss has traditionally been attributed to gingival recession and toothbrush abrasion. More recently, Grippo (1996) has suggested that occlusal loading causes strains in the cervical region of the crowns of teeth. These high surface strains initiate microcracks and eventually propagate, resulting in bulk enamel loss. Grippo has coined the term “abfraction” to describe this process.

Clinically, abfraction lesions are sharp, angular wedge-shaped defects that occur more commonly on the buccal surface of teeth compared to the lingual surface. They are also found more commonly in bruxists and are more commonly found on incisor and premolar teeth (Rees, 2000).

METHODS

The Bristol group has carried out a number of finite element studies to broaden understanding of this clinical problem. Various aspects have been investigated, including:

- Varying the position and magnitude of the occlusal load
- Comparison of cervical stresses in incisor, canine and premolar teeth
- Effect of undermining of the amelo-dentinal junction by erosive liquids on the buccal aspect of teeth
- The exacerbating effect of an occlusal restoration.

RESULTS AND DISCUSSION

Initial studies found that a typical bruxing load of 500N produced cervical shear stresses of 30 MPa, a figure that is close to the known failure stresses for enamel. Obliquely applied loads also produced much higher cervical stresses.

A comparison of the cervical stresses in different tooth types found that the highest stresses were evident in the premolar, followed by the incisor, with the lowest stresses in the canine. This correlates well with clinical studies that show a higher prevalence of abfraction lesions in premolar and incisor teeth and is likely to be related to variations in tooth morphology and the area of the supporting periodontal ligament.

The effect of the presence of a coronal amalgam restoration was modelled and it was found that the cervical stresses increased by a factor of 2 or 3. This effect is probably due to the weakening effect of the amalgam restoration, resulting in increased cuspal flexure under occlusal loading. This ultimately produces greater cervical stresses.

SUMMARY

In conclusion, high occlusal loads, obliquely applied occlusal loads, and the presence of coronal amalgam restorations seem likely to contribute to the development of abfraction lesions. Incisor and premolar teeth also seem more susceptible to the development of abfraction lesions compared to canine teeth, due to the natural variation in their morphology.

REGISTRATION METHODS FOR COMPUTER-ASSISTED SURGERY

RE Ellis PhD, Departments of Computing and Information Science, Mechanical Engineering, and Surgery, Queen's University, Kingston, Canada K7L 3N6

Computer-assisted surgery allows a surgeon to navigate inside a patient's body through tiny incisions. Figure 1: Navigation from a CT image and a 3D model to excise a deep bone tumor in the tibia.

Figure 1: Navigation from a CT image and a 3D model to excise a deep bone tumor in the tibia.

Registration is the process of finding a transformation equation from patient data to a medical image. Typically, the patient data are gathered in the operating room by touching bone surfaces with a calibrated probe that is tracked by a three-dimensional localizer (such as the Optotrak optoelectronic system of Northern Digital, Waterloo, Canada). The transformation is found by optimizing an objective function, such as the least-square error, between the patient data and the medical image. The image is commonly a computed tomography (CT) or magnetic resonance image (MRI) of the patient, taken days or weeks before the surgical procedure.

Early registration methods matched pairs of points, so the locations of pre-implanted markers [0] or distinct anatomical landmarks needed to be selected from the medical image. Examples of markers and landmarks are shown in CT images in Figure 2.

Figure 2: A tantalum bead used as a marker in a patient's tibia, and distinctive landmarks on a plastic model of a lumbar vertebra. These are matched to points on a patient's anatomy for image-guided surgery.

Current registration methods use numerous surface points from the bone, which are matched to a triangulated mesh derived from the medical image. The iterated closest point (ICP) algorithm [0] iteratively solves the matching problem, determining the mesh point closest to the data, and the optimization, which is a least-squares process. Our preferred method for registering a patient to his/her preoperative image is mathematically robust [0], and automatically discards statistical outliers (which are poorly collected data).

Figure 3: A mesh of a tibia, surface data, and the data registered by our robust method. The spurious data were automatically discarded; the blue “spotlight” areas guide the surgeon in finding an initial registration.

Our most recent method is a deformable transformation to an *atlas*, which is an average model developed from images of volunteers. This method does not require a scan of the patient, which saves time, cost, and is logistically simpler for both the patient and the medical team.

IMAGING TECHNOLOGY FOR COMPUTER AIDED SURGERY

Gabor Székely

Computer Vision Laboratory, Swiss Federal Institute of Technology Zürich, Switzerland

INTRODUCTION

Computer aided surgical procedures critically depend on available information about the anatomy, physiology and pathology of the patient, which can be generated by pre- and inter-operative imaging procedures. The talk will provide a short introduction of available radiological methods and their applicability for optimally supporting surgical interventions.

IMAGING METHODS

The basic principles of interaction between electromagnetic radiation and human tissue will be summarized. The resulting properties and limitations will be discussed for the most important imaging modalities like X-Ray, Computer Tomography, Magnetic Resonance Imaging or Ultrasound.

IMAGE PROCESSING

A short overview will be given about the most important methods of image analysis allowing the preparation of raw image data for optimal usage during interventions. The most important concepts of segmentation and registration will be explained.

VISUALIZATION

The results of the whole image acquisition and processing scheme discussed above must be presented in an intuitive and non-obstructive manner in order to enable the surgeon to fully utilize the information extracted from the radiological data. Recent achievements in computer graphics, especially in virtual and augmented reality technology will be presented, together with selected examples about their utilization in minimizing the invasiveness of medical interventions

SIMULATION-BASED DESIGN OF KNEE REPLACEMENT SURGERY

INTRODUCTION

The primary goal of most three-dimensional planning systems for total knee replacement is to align the centers of the hip, knee, and ankle. We have developed a system that extends the capability of the surgical planning process by allowing one to study the effects of implant design and placement on knee kinematics and stability. We illustrate the utility of our technique by analyzing effects of implant design parameters and posterior tilting of the tibial component on the kinematics of posterior-cruciate substituting knees.

METHODS

Planar implant kinematics were determined from sagittal-plane profiles of the component geometry (Piazza et al, 1998). Three assumptions were employed to simulate motion of the implant during knee flexion: first, the most inferior point on the femoral condylar profile contacted the tibial well at its most inferior point when the knee was extended and remained there until the knee was flexed enough for the cam to contact the spine; second, contact – either condylar or between cam and spine – was maintained once initiated as the knee flexed; and third, tangents to sagittal implant profiles at points of contact were collinear. These assumptions can be stated as kinematic constraint equations. Vector addition (Fig. 1) gives

$$\mathbf{p} + \mathbf{f}(v) = \mathbf{t}(u), \quad (1)$$

and collinearity of tangents yields

$$\frac{d\mathbf{t}}{du} \times \frac{d\mathbf{f}}{dv} = 0, \quad (2)$$

where u and v are the tibial and femoral spline parameters used to fit the implant geometry. These vector equations were converted to a system of three scalar equations and solved for the position of the femoral component relative to the tibial component as knee flexion angle was increased from full extension to maximum flexion in 1° increments. Equations similar to Eqs. (1) and (2) described contact between the cam and spine and were solved to determine both the knee flexion angle at which the cam initially contacted the spine and the tibiofemoral kinematics once this contact had occurred.

We used the simulation to study the effects of five design parameters (tibial spine height, spine anterior-posterior position, femoral component posterior radius, and femoral cam anterior-posterior and distal-proximal position) on tibiofemoral kinematics and prosthesis stability. Prosthesis stability was characterized by a “dislocation safety factor,” defined as the

vertical distance from the bottom of the femoral cam to the top of the tibial spine. We also studied the effect of posterior tilt of the tibial component on the flexion angle at which the cam and spine engaged.

Figure 1. Sagittal plane implant geometry.

RESULTS AND DISCUSSION

Computer simulations revealed that posterior substituting knees are most likely to dislocate at maximum knee flexion. Prosthesis stability can be improved by increasing the tibial spine height and moving the femoral cam posteriorly. Our results suggest there is a tradeoff between maximum knee flexion and prosthesis stability. We found that relatively small gains in maximum knee flexion, made through design changes, may cause substantial decreases in prosthesis stability (Delp et al., 1995). (1)

The simulations revealed that even small degrees of posterior tilt of the tibial component reduced rollback by limiting the interaction between the cam and spine; tilting the component posteriorly by 5° caused the cam to contact the spine at a flexion angle that was 18° higher than in the untilted case. The results suggest that posteriorly tilting the tibial component in posterior-cruciate substituting knee replacement may not produce the same beneficial effects that have been reported for tilting in posterior cruciate-retaining knee replacement.

Incorporating kinematic models into the surgical planning process reveals the relationships between implant design, surgical technique, and knee kinematics.

SURGICAL NAVIGATION

Lutz P. Nolte

Center for Computer Assisted Surgery, M.E. Müller Institute for Biomechanics, University of Bern, CH
E-mail: Lutz.Nolte@memot.unibe.ch

INTRODUCTION

The recent advent of new computer assisted surgery technology has bridged the gap between preoperative diagnosis and planning and intraoperative manipulations. This is achieved by a so-called navigator that establishes a link between preoperative images and the intraoperative anatomy (registration), and maintains that link during motion of the patient (referencing). Surgical navigation technology allows to perform accurate and safe surgical actions through image-interactive control of tools actions.

TECHNICAL ASPECTS

Initially the focus of research and development was on navigation technology, which is purely based on preoperatively acquired 3D tomographic image data sets. These techniques require intraoperatively a surgeon-generated transformation between the surgical object and the associated image based virtual object, the so-called registration procedure. A wide variety of associated matching algorithms have been developed adapted to different clinical applications. Free-hand navigation systems using active or passive optoelectronic tracking technology are then used to image-interactively perform various surgical actions.

The need for an often additional CT scan, the applied X-ray radiation dose and the rather difficult and time-consuming registration procedure has led to a novel approach to computer assisted orthopaedic surgery, in which intraoperative images, such as fluoroscopy complement or replace preoperatively acquired 3D tomographic image data. For this purpose the imaging devices or device components had to be integrated into the rigid body navigation concept. In addition internal and external device calibrations had to be realized in order to overcome physical image distortions. The resulting so-called registered 2D images can effectively be used for navigation by superimposing onto them the action of tracked surgical tools.

Also the concept of 'surrogate variables' was introduced into surgical navigation. By identifying important morphological landmarks from registered patient images or by direct digitization on the available bony anatomy or even indirect through pivoting procedures, variables, such as clinical axes, orientations (anteversion, inclination,...), etc. can accurately be determined at the OR table and then related to the subsequent surgical action. This has led to a variety of successful image-free surgical navigation systems.

Another challenge is the use of surgical navigation for novel minimal access surgery in orthopaedics. This requires accurate and reliable percutaneous registration procedures. Various research groups currently investigate the effectiveness of co-registering preoperative CT scans with intraoperatively acquired registered fluoroscopic and ultrasound images.

CLINICAL APPLICATIONS

Various clinical applications for both strategies will be presented in different anatomical areas, such as spine, hip, shoulder, and knee. Surgical interventions ranging from joint reconstruction and replacement to trauma treatment will be covered. A variety of systems have emerged from the laboratory and are being clinically used.

Figure 1: Example of an early CT based surgical navigation system - Transpedicular screw holes are prepared interactively using tracked surgical instruments.

Figure 1: Example of a novel CT free navigation system – The spatial position of both joint components is optimized (anteversion, varus, ...) in registered fluoroscopic images.

FUTURE PERSPECTIVES

Future surgical navigation systems will bring (a) automated cross-registration and complementary use of 1D, 2D, and 3D imaging modalities, (b) see-through vision for the surgeon during the whole treatment process, and (c) a new breed of computer based implants and instruments.

COUPLING INFORMATION TO ACTION IN THE 21'ST CENTURY

Russell H. Taylor, Ph.D.

Center for Computer-Integrated Surgical Systems and Technology, Johns Hopkins University, Baltimore, Maryland, USA
Center Director, rht@cs.jhu.edu

INTRODUCTION

The impact of Computer-Integrated Surgery (CIS) on medicine in the next 20 years will be as great as that of Computer-Integrated Manufacturing on industrial production over the past 20 years. A novel partnership between human surgeons and machines, made possible by advances in computing and engineering technology, will overcome many of the limitations of traditional surgery. By extending human surgeons' ability to plan and carry out surgical interventions more accurately and less invasively, CIS systems will address a vital national need to greatly reduce costs, improve clinical outcomes, and improve the efficiency of health care delivery.

The evolution of these systems will be synergistic with the development of patient-specific surgical simulation for planning as well as for training and surgical augmentation systems transcending human sensory-motor limitations in the performance of surgical tasks.

THE INFORMATION FLOW OF CIS SYSTEMS

Figure 1 shows the information flow associated with CIS systems [1, 2]. Information from medical images and other sources is combined with generic information in anatomical atlases to produce patient-specific models that are used to develop optimized surgical plans. The plans, models, and images are combined in the operating room with intraoperative images and other sensing to update the models and register them to the patient. Once this is done, the plans can be updated and a variety of appropriate means, including robots, navigational aids, and interactive displays can be used to assist the surgeon in carrying out the surgical plan. The same system components can also be used intraoperatively to verify that the plan has been executed and also to assist in postoperative assessment and follow-up.

SURGICAL CAD/CAM SYSTEMS

We refer to the process described in the previous section as *Surgical CAD/CAM*, stressing the analogy with Computer-Integrated Manufacturing. Indeed, the analogy can be taken further by noting that the greater consistency and information gathering made possible by computer-integrated planning, execution, validation, and follow-up can enable us to improve surgical processes and evaluate new therapies more efficiently. We refer to this process as *Surgical Total Quality Management (Surgical TQM)*.

This talk will provide numerous examples of Surgical CAD/CAM, but will emphasize the development of "one stop shopping" systems that integrate modeling, planning, and therapy delivery in an interventional scanner, as shown in Figure 2 (Left).

SURGICAL ASSISTANTS

A second way of looking at CIS systems emphasizes their role as *Surgical Assistants* that work cooperatively with surgeons in carrying out highly interactive surgical procedures. This talk will also discuss examples of such systems, emphasizing our work on cooperatively controlled systems for microsurgical augmentation such as shown in Figure 2 (right).

MECHANICAL ENERGY OUTPUT BY RED MUSCLE FIBRES

Nancy Curtin^{1*}, Roger Woledge² and Fang Lou³

¹Biomedical Sciences, Imperial College, London SW7 2AZ UK

²University College London, Institute of Human Performance, Stanmore HA7 4LP UK

³Dept. Biosciences, University of Hertfordshire, Hatfield AL10 9AB UK

*Email: n.curtin@ic.ac.uk

Dogfish myotomal muscle consists of three fibre types, white, red and superficial fibres. Each fibre type has a distinct histological, biochemical and energetic profile, which at least for white and red fibres seems well matched to its function during swimming.

Two questions are addressed: (1) Are red fibres as strong as white fibres during isometric contraction? (2) Can we predict the force and power output during sinusoidal movement (work-loops), which mimic swim-like contractions of red fibres? Successful predictions have been made for the white fibres of dogfish based on observations of the behaviour of crossbridges and series elasticity of the fibres, and a reasonable assumption about the time-course of activation (Curtin et al, 1998).

Experiments were done on bundles of red and white fibres isolated from dogfish, *Scyliorhinus canicula* (L.). Intact fibre bundles were stimulated electrically and their length controlled by a motor, while force, length change and stimuli were recorded.

Maximum isometric tetanic force produced by red muscle fibres was $142.4 \pm 10.3 \text{ kN.m}^{-2}$ ($N=35$); this is significantly less than that produced by white fibres $289.2 \pm 8.4 \text{ kN.m}^{-2}$ ($N=25$). (All values mean \pm S.E.M.) Part, but not all, of the difference is due to the higher mitochondrial content of the red fibres (Lou et al, in press).

The stiffness of the elasticity in series with the contractile component (crossbridges) was measured in step-and-ramp shortenings of fully active fibres. Force was measured during shortening and lengthening at different velocities (Lou et al, in press). The force-shortening velocity

relationship was hyperbolic, as expected, with force intercept of $P_0^*/P_0 = 1.228 \pm 0.053$, velocity intercept, $V_{\max} = 1.814 \pm 0.071 \text{ L}_0/\text{s}$, and other constants, $a/P_0^* = 0.225 \pm 0.024$, and $b = 0.404 \pm 0.041 \text{ L}_0/\text{s}$ ($N=7$ for all values). The maximum power was $0.107 \pm 0.005 P_0 V_{\max}$ and was produced during shortening at $0.297 \pm 0.012 V_{\max}$.

These results show that although the red fibres have a lower P_0 (49%) and V_{\max} (48%), compared to white fibres, the shapes of the force-velocity curves are very similar (Curtin & Woledge, 1988). Thus the white and red fibres have equal capacities to produce power within the limits set by the isometric force and maximum velocity of shortening of each fibre type.

In separate experiments, force and power output were measured during patterns of movement and stimulation that mimic what occurs during swimming. (Sinusoidal movement at 0.75 Hz with stimulation during 0.33 of each mechanical cycle, starting at different times in the cycle.). These results will be compared with predictions based on the elastic and force-velocity properties of red muscle, and an assumed time-course of activation.

NEW ENERGETICS APPROACHES TO ELUCIDATING MECHANISMS OF CONTRACTION AND RELAXATION

*Email: lrome@sas.upenn.edu

Vertebrate muscle must perform mechanical work to power locomotion, pump blood or produce sound energy. The frequency at which the work must be generated varies dramatically from less than 1Hz for some slow-twitch skeletal and cardiac muscles to more than 200 Hz for super-fast sound producing muscles. We have found that no single muscle fiber type can perform all activities (Rome & Lindstedt, 1998; Young & Rome, 2001) rather that specific molecular modifications are necessary to enable different muscles to operate at different frequencies

It is clear from our previous studies (Rome et al, 1996; 1999) that the kinetics of the crossbridges and the kinetics of sarcoplasmic reticulum (SR)-Ca²⁺ pumping are two major determinants of twitch speed: to relax quickly you must have a fast crossbridge detachment rate constant and a fast Ca²⁺ uptake rate. Because crossbridge force generation and Ca²⁺ pumping involve rapid utilization of ATP, measurement of ATP utilization during contraction can serve as an important window on understanding these mechanisms. For ATP utilization measurements to be useful, however, it is necessary to be able to partition the contribution made by crossbridges and the SR-Ca²⁺ pumps. For nearly a decade, specific and potent SR-Ca²⁺ pump blockers (e.g., TBQ, CPA) have been used extensively to knock out the SR-Ca²⁺ pump ATPase (Stienen et al. 1995). This has permitted the direct measure of crossbridge ATPase, which in turn, has permitted the determination of crossbridge detachment rate constants (i.e., ATPase / number of attached crossbridges; Rome et al. 1999).

Until now, there has not been an analogous crossbridge blocker that could be used to knock out crossbridge ATPase so that ATP utilization of SR-Ca²⁺ pumps could be measured directly. SR-Ca²⁺ pump ATPase is generally measured indirectly as the difference of total ATPase and crossbridge ATPase (Stienen et al., 1995), or directly over a limited range of Ca²⁺ concentrations [Ca²⁺]_i in toadfish swimbladder muscle (Rome & Klimov, 2000) because of its low affinity force-[Ca²⁺]. Recently Young *et al.* (2002) have shown that the crossbridge blocker BTS (N-benzyl-P-toluene sulfonamide; Cheung *et al.* 2002) can be used at low concentrations in skinned toadfish fibers to eliminate at least 96% of the force

and crossbridge ATPase, without affecting the SR-Ca²⁺ pump ATPase. Thus, by measuring the SR-Ca²⁺ pump ATPase one can determine the total Ca²⁺ pumping rate as well as the pump turnover rate (ATPase / number of pumps) in an intact SR.

Using BTS in intact fibers has opened up additional opportunities to study Ca²⁺ release and reuptake. Although Ca²⁺ transient measurements are very useful in determining free [Ca²⁺]_i, they do not measure the amount of Ca²⁺ released. Using a combination of high-energy phosphate measurements as well as recovery metabolism measurements, we are able to determine how much Ca²⁺ is released per stimulus. In addition, we can determine the fate of the released Ca²⁺, that is, whether it is pumped back into the SR immediately or left bound temporarily in the myoplasm at the time of mechanical relaxation. This information, coupled with measurements of the muscle stimulation pattern in calling toadfish, permits unprecedented insights into muscle Ca²⁺ usage and budgeting during normal motor behaviour.

THE RELATIONSHIP BETWEEN FILAMENT MOVEMENT AND ATP SPLITTING IN SKELETAL MUSCLE: CROSS-BRIDGE STEP SIZE AT DIFFERENT SHORTENING VELOCITIES

C. J. Barclay

School of Physiotherapy and Exercise Science, Griffith University, Gold Coast Campus
PMB 50 Gold Coast Mail Centre, Queensland 9726, Australia, Email: C.Barclay@mailbox.gu.edu.au

INTRODUCTION

Worthington & Elliott (1996) described a method for quantifying the contractile filament sliding generated per ATP hydrolysed in skeletal muscle by calculating the ratio of the velocity of filament sliding to the rate of ATP splitting along a single actin filament. Using this analysis, the amount of filament movement per ATP used was necessarily 0 in an isometric contraction (*i.e.* no filament movement) and increased as the load against which the muscle shortened decreased, reaching ~2 nm for unloaded shortening. Those authors used these data to support a model of muscle contraction in which only a single cross-bridge was attached to a thin filament at any instant (*i.e.* cross-bridges work sequentially); in this case, the filament movement per ATP used corresponds to the amount of movement generated in each cross-bridge cycle. They further claimed that the small amount of filament movement generated for each ATP split was inconsistent with the more generally accepted cross-bridge models of the type proposed by Huxley and colleagues in which the amplitude of the fundamental power stroke is typically assumed to be 10-15 nm (Huxley & Simmons, 1971).

The purpose of this study was to demonstrate that the relationship between net filament sliding per ATP used and load can be explained quantitatively in terms of a cross-bridge model in which multiple cross-bridges are attached along each thin filament simultaneously.

METHODS

The amount of movement each cross-bridge imparts to the thin filament in one ATP-splitting cycle (cross-bridge step size, D_{ATP}) was calculated from the net filament movement per ATP used (z) and the number of cross-bridges attached simultaneously along one thin filament (N):

$$D_{ATP} = z \cdot N$$

z was calculated from published measurements of the rate of enthalpy output from shortening frog sartorius muscle (Hill, 1964) and the fast-twitch EDL and slow-twitch soleus muscles from the mouse (Barclay, 1996) and making corrections for non-cross-bridge energy use and the extracellular fraction of fibre volume. N in an isometric contraction and its variation with shortening velocity were estimated by assuming that (i) 50 % of all cross-bridges were attached in an isometric contraction (Linari et al. 1998), (ii) muscle fibre stiffness decreased linearly with load (Julian & Sollins, 1975) and (iii) 50 % of sarcomere compliance was due to cross-bridges and the remainder was due to other compliant structures in series with the cross-bridges.

RESULTS AND DISCUSSION

D_{ATP} was estimated for each muscle shortening against a range of loads. In an isometric contraction (load = $1P_0$) D_{ATP} is 0, by definition. D_{ATP} increased as load decreased (that is, as shortening velocity increased) reaching values over 20 nm when load was $< 0.1P_0$ (Fig. 1). Over much of the load range, D_{ATP} was between 10 and 15 nm in all three muscles and the dependence of D_{ATP} on relative load was similar for all three muscles, despite distinct differences in their energetic profiles.

Figure 1: Variation in estimated cross-bridge step size with relative load.

At loads $> 0.2P_0$, the magnitude of D_{ATP} is consistent with the magnitude of the cross-bridge power stroke estimated from a variety of experiments. Assuming these estimates are accurate, then over this range each power stroke must be associated with hydrolysis of one ATP. The high values of D_{ATP} at low loads is consistent with the idea that under these conditions cross-bridge cycles can occur without ATP use (*e.g.* Barclay, 1999).

SUMMARY

The relationship between net filament displacement and load described by Worthington & Elliott (1996) is consistent with a model in which many cross-bridges attach simultaneously along each thin filament and in which cross-bridges produce 10-15 nm of movement for each ATP split across much of load range.

QUANTIFYING ISOMETRIC FORCE-DEPENDENT ENERGY RELEASE IN WHITE MUSCLE BY COMPARING CONTRACTION ENERGETICS IN INTACT AND SKINNED FIBRES

Tim West^{1*}, Nancy Curtin¹, Mike Ferenczi¹, He-Zhen He², Yin-Biao Sun³, Malcolm Irving³ & Roger Woledge⁴

¹Imperial College, London SW7 2AZ; ²National Institute for Medical Research, London NW7 1AA;

³King's College London SE1 1UL, ⁴UCL Institute of Human Performance, Stanmore HA7 4LP, UK, *Email: t.west@ic.ac.uk.

INTRODUCTION

Energy release in contracting muscle is complex because force-dependent and force-independent components are enmeshed into the time-course of total energy output. We have compared isometric contraction energetics in intact and skinned fibres to (i) establish the time-course of force-dependent energy production and (ii) quantify the actomyosin ATPase contribution to total energy output.

METHODS

White fibres were isolated from the dogfish (*Scyliorhinus canicula* L.). Energy release during a 3.5s tetanus was monitored as heat production in intact fibre bundles (4 – 12 fibres) at optimal length (Lo). Force-dependent energy release was determined from heat production at Lo and at longer fibre lengths (i.e., decreased filament overlap). Plots were made of relative energy release at selected time-points in the tetanus vs. relative force production and the slopes from these plots were used to model the force-dependent component of total energy release.

Energy production was also monitored in single Triton-permeabilised fibres using two independent fluorescent assays. These fibres contain the contractile filament array but no functional membrane ATPases. Initial rates of energy release were calculated from the binding of Pi to MDCC-labelled protein following initiation of contraction by the photolytic release of ATP from NPE-caged ATP (He *et al.* 1997). The final, stable rate of energy release was determined from NADH oxidation coupled to ADP production in a linked enzyme assay (Sun *et al.* 2001). Comparisons with intact fibres were made by assuming 34 kJ/mol Pi or ADP released (Woledge *et al.* 1985) and fibre density = 1.06 g/ml.

RESULTS & DISCUSSION

Initially energy is released by intact fibres at a high rate (210 $\mu\text{J}/\text{mg}\cdot\text{s}$, slope in Fig 1); this declines to a slower stable rate (45 – 50 $\mu\text{J}/\text{mg}\cdot\text{s}$, data not shown) by about 1.5s. The initial rate of energy release by skinned fibres was 150 $\mu\text{J}/\text{mg}\cdot\text{s}$ (Pi-binding protein assay, Fig 1A). It is likely that activation processes involving Ca^{++} account for the difference in the initial rates.

Fig. 1A also shows that energy release in the Pi-binding study agrees with the force-dependent energy release in intact fibres, indicating that the ATP hydrolysis in skinned

fibres matches the actomyosin ATPase activity in the intact system. Fig.1B shows that the rate of force-dependent energy release by intact fibres declines during an isometric tetanus. The ATPase activity late in the contraction time-course (31 $\mu\text{J}/\text{mg}\cdot\text{s}$; NADH-assay, $n = 4$) is 1/5th of that determined in the first 0.1s (Pi-binding assay). The two independent skinned-fibre assays concur with the intact fibre result.

Figure 1: **A.** Mean energy release in intact (black triangles, $n=8$) and skinned (black line, $n=15$) fibres. Force-dependent energy release (open circles) from a separate group of intact fibres ($n=9$). **B.** Rates of force-dependent and skinned-fibre energy release during contraction.

CONCLUSIONS

- The initial energy turnover is greater in intact than in skinned fibres; probably due to activation processes.
- The actomyosin ATPase rate slows down during isometric contraction.

APPLICATIONS OF MAGNETIC RESONANCE TECHNIQUES TO SKELETAL MUSCLE ENERGETICS AND BIOMECHANICS

Robert W. Wiseman

Molecular Imaging Research Center, Departments of Physiology and Radiology,
Michigan State University, East Lansing, MI 48824
Email: rwiseman@msu.edu

Magnetic resonance studies of skeletal muscle can provide unique information useful for biomechanical studies that may be otherwise unattainable. Magnetic resonance imaging (MRI) methods can provide quantitative morphometry on parameters such as cross-sectional area and tissue composition (e.g. muscle, fat, connective). In addition, more specialized “functional” MRI techniques provide information on the relative involvement (recruitment) of individual muscle groups in a particular mechanical task (Meyer & Prior, 2000). Magnetic resonance spectroscopy (MRS) provides invaluable information on the metabolic aspects of muscle function. For example, phosphorus MRS can be used to measure muscle content of ATP, PCr, Pi and free ADP as well as intracellular pH (Wiseman & Kushmerick, 1995; Wiseman et al, 1996). Thus the control and regulation of ATP free energy homeostasis and direct measurement of some of the key reactions in cellular energy metabolism are possible *in vivo* (Jeneson et al, 1997). When coupled with concurrent measurements of force production estimates of contractile costs can be derived.

In muscle, ATP production during the first few seconds of contraction is known to be almost entirely via the creatine kinase reaction (Harkema et al, 1997). Thus, the ATP cost of contraction can be estimated from the initial PCr change. In this study to investigate the ATP cost associated with contraction, we examined the initial rate of PCr depletion during stimulation using gated NMR, which enables sub-second time resolution of metabolic events (Foley & Meyer, 1993). C57B mice were anaesthetized with 50 mg/kg sodium pentobarbital and prepared for *in situ* stimulation via the sciatic nerve. ^{31}P -NMR spectra were acquired at 162 MHz by gating the acquisitions (8000 Hz sweep width, 1K data) to times 200 ms and 20, 40, 60, 80, 100, 120, and 140 s after a 2 s burst of isometric twitch contractions at 5 Hz (10-11 twitches total). After a final 20 s delay, the sequence was repeated for a total of 8 scans per time point. In addition, time-averaged spectra (8 scans, TR=2 s) were acquired during 2.1 min of continuous stimulation at 5 Hz. Relative changes in PCr were computed by the method of natural linewidths (Heineman et al, 1990).

The resting PCr/ATP ratio was 2.97 ± 0.13 , mean \pm SE (n=7). Assuming an ATP content of $7.5 \mu\text{mol/g}$ muscle, these changes correspond to initial PCr hydrolysis rates of $1.08 \pm 0.17 \mu\text{mol/g/s}$. Peak twitch force after 2 s of 5 Hz stimulation was $95.6 \pm 1.6 \%$ of initial in control muscles. Thus, in this study, as in previous studies of rat muscles (Foley & Meyer, 1993), the result is about $0.2 \mu\text{mol/g/twitch}$.

BIOMECHANICAL ASPECTS OF TUMOR MICROCIRCULATION: WITH SPECIAL EMPHASIS ON LEUKOCYTE-ENDOTHELIUM INTERACTIONS

Norio Ohshima¹, Chika Miyoshi, Toshishige Suzuki, Kennichi Yanagi

Department of Biomedical Engineering, Institute of Basic Medical Sciences, University of Tsukuba,
Tsukuba Science City, Ibaraki, Japan. ¹ohshima@md.tsukuba.ac.jp

INTRODUCTION

Blood flow in the microvasculature plays an important role in governing the growth of the tumor tissue. Thus, more detailed knowledge of hemodynamics in the microcirculation is needed to obtain sound guidelines for diagnosis and treatment of malignant tumors. Direct observation of these dynamic processes *in vivo* has been extremely difficult mainly due to methodological limitations of the microscope optics. On the other hand, recent development in technologies of intravital microscope system, in particular, the use of a confocal laser-scanning microscope (CLSM) system combined with the use of a variety of fluorescent tracers has made it possible to visualize the microcirculatory blood flow *in vivo* even in a solid tumor tissue with a considerable depth.

As an experimental animal model to observe tumor microcirculation intravitaly, the authors have established a solid tumor model called "peritoneal disseminated tumor model rat." This model has a distinct advantage to allow observation of the three-dimensionally grown-up tumor microcirculation under physiological conditions.

Using CLSM and the peritoneal disseminated tumor model, we have performed a series of experiments to analyze quantitative features of the vascular architecture of the tumor microvasculature, hemodynamics of the blood flow and behavior of leukocytes in the tumor microcirculation.

MATERIALS AND METHODS

Tumor model:

Tumor cells of a tumor cell line; RCN-9 (Riken Cell Bank, Tsukuba, Japan), established from Fischer 344 rat colon carcinoma, were intraperitoneally inoculated according to the method developed by the authors. Briefly, 1×10^7 cells were inoculated into the peritoneal cavity of 7 week-old male Fischer 344 rats (Charles River, Kanagawa, Japan).

Intravital microscopic observation:

The mesenteric microvasculature was observed under an intravital microscope system (BHWI; Olympus Optical Co., Tokyo, Japan) equipped with a real time confocal laser-scanning optics (InSIGHT plus; Meridian Instrument Inc., Okemos, MI) and an image processing unit. Microvascular architecture and microhemodynamics of the formed elements were fluorescently visualized selectively by injecting a bolus of an appropriate fluorescent dye through the right jugular vein. Hemodynamic parameters were determined off-line by play-back analysis of the videotape.

RESULTS AND DISCUSSION

Angiogenic growth of the microvasculature:

After inoculation of the tumor cells into the peritoneal cavity of rats, tumor growth with an angiogenesis was microscopically observable within a few days. The inoculated tumor cells were then gradually became to be supplied by the mesenteric microvasculature with the progression of angiogenesis.

The branching pattern of the vascular network was analyzed based on the Horton's law of bifurcation. Arterioles and venules were given an order of branching separately according to the Strahler's nomenclature, and the number of vessel segment (*N*) having the same order number was counted. A vascular density index (VDI) and a bifurcation

ratio (BR) were calculated from a semilogarithmic plot of the vessel density against the vessel order. Values of VDI in both arterioles and venules showed a significant increase with time after the tumor cell inoculation. The rate of increase in the venular VDI was larger than that of the arteriolar VDI. Moreover, the arteriolar BR remained almost constant, whereas the venular BR showed an increase with time.

Microhemodynamic parameters in the tumor microvessels:

As a consequence of morphological abnormality, tumor microvessels also showed an altered hemodynamics. Fluorescent labeling of the erythrocytes (labeled by fluorescein isothiocyanate (FITC)), leukocyte (labeled by rhodamine 6G) and blood plasma (labeled by FITC-dextran) enabled quantitative measurements of microhemodynamic parameters such as flow velocity, blood cell flux and vessel diameter in both the normal and tumor microvasculatures. In the vessels of the tumor-bearing mesentery, the centerline velocity of erythrocytes was significantly lower than that of the tumor-free rats. The wall shear rate of the tumor microvasculature also significantly decreased as compared with the normal control.

Leukocyte-endothelial cell interactions in the angiogenic vessels:

Selective labeling of leukocytes with rhodamine 6G enabled visualization of leukocytes even in the complexed microvasculature of the tumor tissue. Measurements of the flux of the rolling leukocytes and density of the adhered leukocytes revealed that these values were significantly lower in the tumor microcirculation than in the normal controls. Decrease in the baseline levels of these leukocyte-endothelial cell interactions was prominent in the venules located inside the tumor nodule.

Effect of NO inhibition on microhemodynamics:

To elucidate the mechanisms of these hemodynamic changes in the tumor microcirculation, effects of inhibition of nitric oxide (NO) production were examined. Although reduction of the baseline levels of leukocyte-endothelial cell interactions that was observed in the tumor venules were markedly suppressed by inhibition of NO synthase (NOS), these increases in leukocyte interactions were scarcely found in the tumor-free rats. These results suggest that exposure to a high level of NO creates the tumor-specific micro-environment, thereby modulating leukocyte behavior in the angiogenic tumor vessels.

SIMULTANEOUS MEASUREMENT OF RED CELL VELOCITY AND PRESSURE IN MICROVESSELS REVEALED ADVANCEMENT IN PHASE OF FLOW PULSE RELATIVE TO THE PRESSURE PULSE BY $\pi/4$

Junji Seki¹, Yasuhiko Satomura^{1,2} and Yasuhiro Ooi³

INTRODUCTION

Red cell velocity in microvessels especially in arterioles has been found to pulsate rather largely originating from heart beats, and it propagates along the vessel as a pulse wave with phase delay (Seki, 1994). It is predicted theoretically that the flow pulse in microvessels advances the pressure pulse in phase by $\pi/4$ (45°) unless the microvessel is completely rigid, assuming that the Reynolds number and the frequency parameter of blood flow in microvessels are much smaller than one. However, the experimental results obtained so far showed the coincidence between the two within 10 - 15° (Intaglietta, et al., 1971). In this study, the red cell velocity in the rat pial arterioles was measured by the laser-Doppler method which has a higher temporal resolution than the dual-slit method used by Intaglietta et al. (1971) to reconcile the discrepancy between the experimental results and the theoretical prediction.

METHODS

Five male Wistar rats weighing 220-250 g were used for cerebral preparations. After animals were anesthetized and the respiration was controlled by a respirator, a cranial window of 3×5 mm² was created in the parietal region. Systemic arterial pressure was monitored in the femoral artery. Pressure in the pial arterioles was measured with a servonull pressure measuring system (IPM, San Diego, USA). Red cell velocity was measured with the fiber-optic laser-Doppler anemometer microscope (FLDAM) (Seki, 1990) in the upstream vicinity of the micro-pipette used for the pressure measurement. Temporal resolution of the velocity measurement was 5-10 msec. Time lag of the velocity relative to the pressure was calculated from cross-correlation.

RESULTS AND DISCUSSION

Measurements were made in 7 pial arterioles with diameter ranging from 41 to 53 μ m. The Reynolds number based on the temporal mean velocity ranged from 0.04 to 0.15, and the frequency parameter ranged from 0.05 to 0.08, both of which were actually much smaller than one.

An example of the experimental results obtained in a pial arteriole with 44 μ m in diameter is shown in Fig. 1. The microvascular velocity and pressure, and the femoral arterial pressure in this example all show distinctive pulsation with the same period. As estimated from the cross-correlation between the velocity and pressure (Fig. 1 (b)), the velocity wave preceded the pressure wave by 28.4 ms, which corresponds to 47.5° in this arteriole.

Figure 1: (a) Example of simultaneous measurement of red cell velocity and intravascular pressure in a rat pial arteriole of 44 μ m in diameter and the femoral arterial pressure. (b) Cross-correlation coefficient between the microvascular velocity and pressure, indicating precedence of the velocity pulse relative to the pressure pulse.

In all the measured arterioles, the velocity in the arteriole preceded the intravascular pressure by 18.7-43.6 ms. The precedence of the velocity to the pressure was statistically significant. The corresponding phase difference, which is calculated from the time difference and the pulsation period, ranged from 28° to 56° . The average phase difference was 42.2° with the standard deviation of 7.6° , which is in accordance with the theoretical prediction, 45° .

The difference in the experimental results between ours and Intaglietta et al. (1971) is considered to come from the difference in the temporal resolution of velocity measurements between the laser-Doppler method and the dual-slit method, since the method to measure microvascular pressure used in this study was the same as in theirs.

IMPLICATIONS OF A THICK ENDOTHELIAL CELL GLYCOCALYX FOR MICROVASCULAR FUNCTION IN MICE.

Hans Vink, Bernard van den berg, Alina Constantinescu, and Jos Spaan
Department of Medical Physics, Cardiovascular Research Institute Amsterdam

Academic Medical Center / University of Amsterdam, PO Box 22700, 1100 DE, Amsterdam, The Netherlands

INTRODUCTION

Vascular endothelial cells are shielded from direct exposure to flowing blood by a highly hydrated mesh of membrane associated proteoglycans, glycosaminoglycans, glycoproteins, and glycolipids. This anionic endothelial cell glycocalyx contributes to the selective permeability barrier of the vascular wall, regulates leukocyte- and thrombocyte- adherence, and specifically interacts with plasma proteins essential for vascular function. Numerous factors are described that may modulate the integrity of the endothelial cell glycocalyx. Elevation of vascular wall shear stress is reported to stimulate glycocalyx synthesis, while degradation of endothelial glycocalyx constituents is observed upon ischemia-reperfusion, during hypoxia, and by exposure to atherogenic plasma levels of oxidized low-density lipoprotein (oxLDL). Accurate assessment of glycocalyx thickness is therefore essential to relate dimensional glycocalyx changes to modulation of endothelial function. In the present study, we determined capillary glycocalyx dimension and tube hematocrit in Apo E3-Leiden mice supplied with an atherogenic diet for 3 months

METHODS

Mice (ApoE3-Leiden after 3 months of high fat diet, and wild type C57Bl/6 controls) were anesthetized with a single intraperitoneal injection of ketamine hydrochloride (125 mg/kg BW) and xylazine (7.5 mg/kg BW). The anesthesia was maintained with intraperitoneal injections of ketamine hydrochloride (15 mg/kg BW) administered at 1h interval. Atropine was supplemented subcutaneously. The trachea was cannulated to ensure a patent airway and the jugularis vein was cannulated for injection of lipoproteins. Body temperature was monitored with an intraesophageal thermometer and maintained at 37°C using a heating lamp. The right cremaster muscle was prepared for visualization of the microcirculation by longitudinal incision without cutting the connection with the epididymis. The muscle was continuously superfused at 34°C (5 ml/min) with a bicarbonate-buffered physiological salt solution (composition: 131.9 mM NaCl, 4.6 mM KCl, 2.0

mM CaCl₂, 1.2 mM MgSO₄, and 20 mM NaHCO₃) which was gas-equilibrated with 5% CO₂ and 95% N₂ to obtain a pH of 7.35 to 7.45. Succinylcholine (10⁻⁵ M, Sigma) was added to the superfusion solution to reduce spontaneous skeletal muscle contractions. In vivo glycocalyx dimension and capillary hematocrit were measured as previously described.

RESULTS AND DISCUSSION

In 9 out of 14 capillaries of Apo E3-Leiden mice (n=4), numerous lipid particles with diameters between 0.7 - 1.2 µm were present in the subendothelial space. In these capillaries, the dimension of the endothelial cell glycocalyx averaged 0.3 ± 0.1 µm, as compared to 0.5 ± 0.1 µm in non-fat Apo E3-Leiden capillaries, and 0.6 ± 0.1 µm in capillaries of wild type mice (C57Bl/6). Respective capillary tube hematocrits averaged 0.27 ± 0.03 , 0.17 ± 0.04 and 0.15 ± 0.02 during control conditions, and increased to 0.34 ± 0.02 , 0.34 ± 0.04 and 0.32 ± 0.02 after topical administration of bradykinine (10⁻⁵ M).

SUMMARY

It is concluded that reduced dimension of the endothelial cell glycocalyx in atherogenic Apo E3-Leiden mice is associated with increases in capillary tube hematocrit and subendothelial lipid accumulation.

³Department of Medical Physics, University of Amsterdam

INTRODUCTION

The interface between blood and the vascular endothelium represents one of the most complex, dynamic, and fundamentally important interfaces in mammalian physiology. Strategically located at this interface is a glycocalyx surface layer that is regulated by and expressed on capillary endothelial cells. In order to investigate the properties of this structure, we have combined analytical modeling with intravital brightfield and fluorescence microscopy. In our analysis, we have assumed that the glycocalyx consists of a mixture of electrostatically charged macromolecules hydrated in an electrolytic fluid. Disturbances arising from mechanical deformation are introduced as perturbations away from a nearly electroneutral equilibrium environment. In the case of mechanical compression of the layer, such as might occur on the passing of stiff leukocytes through capillaries, fluid flux into the compressed layer, driven by electrochemical potential gradients of the ions and glycocalyx macromolecules, results in rehydration of the layer and a restoration of its equilibrium dimensions. An analysis of the equilibrium configuration of the layer predicts that polyanionic fluorescent plasma tracers would be partially excluded by the glycocalyx by virtue of their charge. It further predicts, quantitatively, the degree to which this exclusion would occur as a function of tracer valence, glycocalyx fixed-charge density, and the ionic strength of blood plasma. This exclusion would result in a reduction in fluorescence intensity within the glycocalyx relative to luminal intensity levels, and could therefore be detected using epifluorescence illumination *in vivo*.

METHODS

To investigate the fixed-charge density and permeability of the glycocalyx, distributions of 20 and 40 kDa neutral and polyanionic plasma tracers were obtained over the cross section of capillaries in the mouse cremaster muscle using wide-field intravital fluorescence microscopy. Three-dimensional fluorescence recordings were made by moving the microscope objective lens through 150 steps along the z axis in 20 nm increments (where xy planes correspond to sagittal planes through the vessel). Out-of-focus light was removed from the three-dimensional recordings of the

capillaries using iterative constraint deconvolution software. Using different optical filters, fluorescence intensity distributions were obtained for both neutral and polyanionic tracers of the same molecular weight that were simultaneously present within the same capillary segment.

RESULTS AND DISCUSSION

Results reveal a charge-mediated exclusion by the glycocalyx of polyanionic tracers within an approximately 0.5-micron-thick region adjacent to the vessel wall. This exclusion was measured by the attenuation in fluorescence intensity of near-wall polyanionic tracers, which was found to be 46% relative to the centerline polyanionic tracer intensity and 30% relative to the near-wall neutral tracer intensity. When combined with our electrochemical model of the glycocalyx (Stace and Damiano, 2001), these measurements provide an estimate of the glycocalyx fixed-charge density of between 0.7 and 1.3 mEq/l. Based on this estimate of the fixed-charge density, and a recovery time of the layer of approximately 1 s after the passage of a single leukocyte (Vink et al., 1999), our mechano-electrochemical model of the glycocalyx (Damiano and Stace, 2002) estimates the glycocalyx permeability to be approximately 10^{-11} cm⁴/dyn-s. This result is consistent with an independent estimate of permeability made by Feng and Weinbaum (2000) using a fiber matrix model based on the Brinkman equation. Results under iso-osmolar conditions of low, normal, and high plasma ionic strength will also be presented.

RECONSTITUTION OF GPIb α -MEDIATED PLATELET BEHAVIOR IN MICROCIRCULATION

Makoto Suematsu, Tomihiro Katayama, Takako Nishiya, Satoshi Kashiwagi,
Mitsuru Murata, Makoto Handa, Yasuo Ikeda

Department of Biochemistry and Integrative Medical Biology, and Department of Internal Medicine, School of Medicine, Keio
University, Tokyo 160-8582, Japan
msuem@sc.itc.keio.ac.jp

INTRODUCTION

Analyses of behavior of circulating platelets in microvessels in vivo have been difficult technically through multiple reasons. High magnification and cell-specific labeling are necessary to visualize individual platelets, while such optical conditions causes difficulties in time resolution for visualization of the rapid-moving cells in circulation.

METHODS

To overcome these difficulties, we have established a novel method to stain platelets with the fluorophore and to visualize their individual traffics with a resolution sufficient enough to determine site-specific velocity and density in a single vessel of organ microcirculatory system. High-speed intensified video microscopy in rats allowed us to visualize fast-moving platelets at videorates of 300-1000 frames/sec, and normospeed replay of the video images at 30 frames/sec demonstrated that behavior of individual platelets in microvessels differ greatly between the cells flowing at centerline region and those flowing in the periendothelial space.

RESULTS AND DISCUSSION

Our results demonstrate that, under high shear rates greater than 600 sec⁻¹ (e.g. arterioles), platelets tend to form microaggregates and to flow along the periendothelial space, exhibiting transient skipping and rolling on the endothelium. They utilize GPIb α on their surface for these shear-dependent interactions with the surface of the endothelium through its affinity to vWF. In venules, GPIb α -mediated platelet adhesion appeared to occur transiently on the surface leukocytes. These specific events were reproducible in vivo by mimicking platelets with liposomal particles coated with human recombinant GPIb α were injected into circulation. Furthermore, liposomes coated with M239V GPIb α , the gain-of-function mutant protein losing shear-sensing ability showed transient adhesion not only to arterioles but also to venules, and most of them were captured finally on leukocytes immediately after the injection. These results suggest a critical role of GPIb α as a major determinant of shear-specific microvascular distribution of platelets and their behavior.

FORCE ENHANCEMENT DURING AND FOLLOWING ECCENTRIC MUSCLE CONTRACTION

Walter Herzog

Faculties of Kinesiology and Engineering, University of Calgary, Calgary, Alberta, Canada

INTRODUCTION

Cross-bridge models of muscle typically predict well the loss of force during concentric contractions, and the increase in force during eccentric contractions (Huxley, 1957). However, they do not contain, except in isolated cases, a description of the steady-state force depression/force enhancement that follows shortening/stretch contractions (Abbott and Aubert, 1952;Edman et. al., 1982), and no cross-bridge model contains a biological explanation of how such force depression/enhancement may be caused. For lack of understanding these well-accepted phenomena, structural mechanisms, not related to the mechanism of contraction, have typically been assumed to cause force depression/enhancement. The most widely accepted mechanism is the sarcomere length non-uniformity theory (Morgan, 1990). Although this theory was originally proposed on scarce evidence, it has provided a framework for hypothesis testing that has persisted in time. Here, we provide evidence that the sarcomere length non-uniformity theory alone cannot account for the observed phenomena.

HYPOTHESES:

One of the pillars of the sarcomere length non-uniformity theory is the hypothesis that force enhancement following muscle stretch cannot exceed the isometric force at the optimum muscle length (the length at which peak active isometric force is produced).

METHODS

Over the past five years, we measured force enhancement following muscle stretch in single fibres of frog tibialis anterior (TA) and flexor digitorum brevis (FDB), in cat soleus and semitendinosus, and in human knee extensors and adductor pollicis. Stretch contractions were always performed following achievement of the full active state, and forces following stretching were measured long enough for transient force changes to disappear. Force enhancement was defined as the steady-state isometric force following stretch minus the purely isometric force obtained at the same length and at the same time of contraction as that for the stretch tests.

RESULTS AND DISCUSSION

We found that the steady-state force enhancement can clearly exceed (10%) the purely isometric force at optimum length in frog single fibers (TA and FDB), in cat soleus, and in human adductor pollicis (Figures 1 and 2). Furthermore, we found a persistent passive component that contributed to the total force enhancement in all muscle preparations tested (Figure 1).

The results of this study indicate that force enhancement cannot be solely attributed to the development of non-uniformities in sarcomere length, because sarcomeres cannot

exert more force than they do at optimum length. Initially, we thought that perhaps force enhancement above the peak isometric force could be associated with the newly discovered passive force enhancement. However, preliminary analysis indicates that this is likely not the case.

Figure 1: Force enhancement (s) above optimal (o) and ifnal length (f) isometric force. Frog FDB; p = passive stretch

Figure 2: Force-length relation of frog FDB fibres (n=22) and the force enhancement following stretch exceeding the isometric force at optimum length.

CONCLUSION:

We conclude that although the sarcomere length non-uniformity theory cannot be dismissed as a mechanism to contribute to force enhancement, it appears unlikely that it can explain the full extent of force enhancement observed experimentally. We speculate that sarcomere length non-uniformity may play a minor (if any) role in force enhancement, and that force enhancement may be associated with the elementary, molecular mechanism of muscle contraction.

NEURAL CONTROL OF ECCENTRIC CONTRACTIONS

E. Paul Zehr

Neurophysiology Laboratory, University of Alberta, Edmonton, Alberta, Canada, pzehr@ualberta.ca

INTRODUCTION

Eccentric, or lengthening, muscle contractions have been suggested to require distinctive neural control strategies (Enoka, 1996). Supraspinal, spinal, and neuromuscular properties have been suggested as possible loci for mechanisms underlying the neural control of eccentric contractions although data has been lacking particularly for CNS mechanisms. Recently, however, numerous studies have identified altered features of both cortical (Fang *et al.*, 2001) and corticospinal tract excitability (Sekiguchi *et al.*, 2001) during eccentric contractions. Also, there are data to support altered H-reflex excitability during active (Nardone and Schieppati, 1988) and passive (Pinniger *et al.*, 2001) eccentric contractions of the human triceps surae. To address further the issue of spinal reflex mechanisms and muscle activation levels we have been studying cutaneous reflex modulation and EMG amplitudes during eccentric and concentric contractions of the human ankle flexor and extensor muscles.

METHODS

Subjects participated in the experiments with informed written consent. In separate experiments subjects performed both isolated and rhythmic isometric or isotonic plantar- (PF) and dorsiflexions (DF). To evaluate differences in the patterns of muscle activation (EMG) during eccentric and concentric contractions, subjects performed isotonic PF at different velocities (slow to near maximum) with loads of 40% of isometric plantarflexion MVC. Evaluations were made of peak and average EMG activity as well as temporal occurrence of the peak EMG during eccentric and concentric contractions. In the experiments focused upon reflex mechanisms, subjects performed eccentric and concentric contractions of the triceps surae and tibialis anterior (TA) muscles against a constant load (~20% MVC), while EMG was collected continuously. Additionally, both isotonic and isometric contractions were studied. Cutaneous reflexes were evoked by applying trains (5 x 1.0 ms pulses @ 300 Hz) of isolated constant current electrical stimulation to the sural nerve. The stimulation was typically applied pseudorandomly throughout the movement cycle. Reflexes were then phase-averaged dependent upon the time of occurrence of the stimuli within the movement cycle. Additionally, in some experiments stimulation was applied at the midpoint of the movement cycle and positions were matched when comparing eccentric and concentric contractions. Cutaneous reflexes were evaluated at early (~50-70 ms), middle (~75-110 ms), and late (>120 ms) latencies

post-stimulation. Additionally, the net effect of stimulation over a 150 ms post-stimulus window was calculated.

RESULTS AND DISCUSSION

Our results on EMG amplitudes extend to higher submaximal loads the observation that greater muscle activation is required to produce a concentric than an eccentric contraction. Interestingly, while the EMG amplitude scaled with contraction velocity during concentric contractions, there was no scaling during eccentric contractions (Gillies *et al.*, 2000). Cutaneous reflex amplitude was differentially modulated during eccentric and concentric contractions in triceps surae. Typically, reflexes were inhibitory during concentric but excitatory during eccentric contractions (Haridas *et al.*, 2000). Interestingly, cutaneous reflex reversal was not typically observed in the ankle flexor muscle TA (Haridas *et al.*, 2001). Taken together, our recent experiments suggest that EMG and cutaneous reflex amplitudes are differentially modulated during eccentric and concentric contractions, at least in extensor muscles of the leg. These observations fit with the observations on reflex control documented in other laboratories.

SUMMARY

The preponderance of evidence, particularly that obtained recently from many different laboratories, supports the assertion that eccentric contractions are treated as distinctly different actions by the nervous system. The biomechanical implications for this distinction as applied to functional motor tasks is currently the study of investigation.

EFFECTS OF CONTRACTION HISTORY ON FASCICLE BEHAVIOR IN SHORTENING CONTRACTIONS

Taija Finni, Janne Avela and Paavo V. Komi

Neuromuscular Research Center, Department of Biology of Physical Activity, University of Jyväskylä, Finland

INTRODUCTION

The force produced by a skeletal muscle is dependent on length, velocity and activity level, but also on previous contraction history. For example, enhanced force production following stretching phase is well established in the literature (Noble 1992). The stretch-shortening cycle of muscle function that occurs frequently in natural locomotion potentially benefits from the force enhancement mechanism, although the issue is controversial. In the present study, muscle-tendon interaction in the triceps surae muscle was examined during controlled ankle flexion-extension movements. On the basis of previous findings on the knee extensor muscles (Finni et al. 2001) it was hypothesized that the previous eccentric phase elongates muscle fascicles to a length longer than in corresponding isometric condition, thereby affecting force production in the consequent shortening phase (Meijer et al. 1997).

METHODS

Plantarflexion torque and fascicle lengths from gastrocnemius medialis muscle were measured from nine volunteers during isometric-concentric (IC) and eccentric-concentric (EC) contractions performed on a motor driven ankle ergometer. Subjects gave informed consent to participate in the study, which was approved by the University Ethics Committee. During the procedure, the subjects were seated in a chair with their right leg relaxed and fixed to the ergometer. The axis of rotation of the ankle was aligned with the axis of rotation of the ankle ergometer as well as possible. Plantarflexor muscles were activated by applying electrical stimulation via self-adhesive stimulation electrodes (5×5cm) that were placed over proximal and distal part of the muscle bellies. The intensity of the current was 10% MVC (ankle 90°), and was the same in IC and EC. Furthermore, IC contractions were repeated with an intensity that produced the same force as was recorded in the EC condition just prior to the shortening phase. Mean (SD) torques and fascicle lengths in different phases of the performance were calculated and the differences were tested with two-way ANOVA with Tuckey HSD Post Hoc Test.

RESULTS AND DISCUSSION

As expected, torque was significantly higher just before the concentric phase in EC as compared to IC (36 vs. 12 Nm, respectively, $p < 0.05$), when muscles were stimulated with the same intensity (Fig. 1). The fascicle lengths, however, did not differ (4.3 vs. 5.1 cm, ns.). When the torque level was the same in EC and IC, the fascicle length in the isometric phase of IC was 4.4 ± 0.9 cm (Fig. 2). The major difference in fascicle behavior in EC and IC was that during EC the fascicle continued to lengthen in the early plantarflexion phase although the length remained unchanged in IC. After the

Figure 1: Example of recordings from one individual. Two repetitions from both IC (left) and EC (right) conditions are shown. The shaded area indicates the concentric plantarflexion movement. Stimulation intensity was 10% MVC and the same in both conditions.

Figure 2: Group mean (SD) torque and fascicle length curves in IC (left) and EC (right) conditions. In IC, the stimulation intensity was set to produce the same force as in the end of eccentric phase of EC.

elastic tissues had shortened taking up the slack in the muscle-tendon unit, also the fascicles started to shorten. Shortening of the fascicles during the first 15° of plantarflexion movement was more pronounced in IC than in EC ($p < 0.05$). Consequent effects on force production, however, were not seen. The lack of observation of stretch-induced force-enhancement phenomenon is attributed to the low stimulation intensity used in the present experiment. In the measurements to follow we intend to use greater force levels to confirm our earlier findings that were done with the knee extensor muscles.

SUMMARY

Benefits of stretch-shortening cycle (SSC) muscle function may come through different interactive mechanisms. With controlled ankle flexion-extension movements this study showed that the fascicles of the gastrocnemius medialis muscle behave differently during plantarflexion movement when it is initiated from pre-stretched or pre-isometric contraction. In pre-stretch condition, the fascicles continued to stretch during early plantarflexion movement. Longer initial length may affect force production during shortening phase of SSC.

NEUROMUSCULAR FATIGUE DURING AND AFTER ECCENTRIC AND CONCENTRIC EXERCISES

Paavo V. Komi and Vesa Linnamo

Neuromuscular Research Center, Department of Biology of Physical Activity, University of Jyväskylä, Finland

INTRODUCTION

Considerable controversy exists regarding fatigue effects of repeated concentric and eccentric exercises. In discussing these controversies one should keep in mind that the maximal force produced during eccentric actions may sometimes be even twice that developed during concentric action and that the maximal EMG activities may not necessarily be different between these forms of actions. This high mechanical load concept in individual muscle fibres and connective tissues put Asmussen (1956) among the very first ones to quantify the performance and muscle soreness differences between fatiguing concentric and eccentric exercises. He was able to demonstrate for both arm (triceps brachii) and leg (quadriceps femoris) muscles that muscular soreness was always present 1 or 2 days after the eccentric exercise, but hardly ever after the concentric exercise. This finding has formed a basis – although often without reference to Asmussen's work – for the concept of delayed muscle soreness (DOMS), typically occurring in relation to unaccustomed exercises, including specifically eccentric exercises.

METHODS

The experiments of Asmussen (1956) on the “mechanical stress” concept for muscle soreness stimulated us to design studies, in which EMG activities and muscle forces were followed in forearm flexors and knee and leg extensors with repeated maximal eccentric and concentric actions with special dynamometers with controlled stretching and shortening velocities of the specific muscle groups (Komi & Rusko, 1974; Komi & Viitasalo, 1977; Linnamo et al, 2000). Depending on the study, the number of repeated maximal muscle actions were either 40 or 100. The two types of fatiguing exercises were separated by a minimum of two weeks. The individual contractions (either concentric or eccentric) were always produced by maximal preactivation.

RESULTS AND DISCUSSION

In the two earlier studies the fatiguability was clearly greater in eccentric than in concentric modes, and the eccentric induced reduction in performance was associated with DOMS. This is presented in fig. 1, which shows that both the force-time characteristics and EMG/force ratio during isometric actions presented a delayed recovery from eccentric fatigue but not concentric fatigue. This same association with DOMS and delayed recovery was confirmed in the later study by Linnamo et al (2000).

In all these studies the eccentric actions started with maximal preactivation similar to the model of Edman (1978) in isolated muscle fibres/sarcomeres. Linnamo et al (in preparation)

showed that if eccentric action is started with 50% or 0% preactivation, the maximal and average eccentric force remained lower compared with when maximal preactivation was used. Therefore, if the fatigue protocol in the eccentric mode is started with zero preactivation (e.g. Hortobagyi et al, 1996; Tesch et al, 1990) it is natural to expect that the overall eccentric loading is less than the full preactivated mode in our experiments. In the latter case the “mechanical load concept” of Asmussen (1956) is followed and the overall duration of eccentric action is much higher and the resulting fatigue response is usually greater than after concentric exercise. Equal metabolic loading between eccentric and concentric exercises in these conditions are in line with this observation as indicated by almost similar oxygen consumption (Komi & Rusko, 1974), blood lactate values, and muscle glycogen depletion (Komi & Viitasalo, 1977). Additional prerequisite in these fatigue studies is that the maximal EMG activation is similar in both exercise modes.

Figure 1: Influence of 40 repeated maximum concentric and eccentric actions on the isometric force-time curve of the bilateral leg extension (upper graphs) and on EMG-force relationship in unilateral knee extension (lower graph). Note the delayed recovery of muscle performance following the eccentric fatigue (from Komi & Viitasalo, 1977).

SCALING OF DAMPING: IMPLICATIONS FOR STABILITY

Robert J. Full¹, Anne M. Peattie¹, Mariano S. Garcia¹, Art D. Kuo², Paul C. Wang¹, Thomas M. Libby¹ and Daniel Dudek¹

¹Department of Integrative Biology, University of California at Berkeley, USA

INTRODUCTION

Rapid running insects are remarkable at negotiating rough terrain. Experiments have shown that animals maintain their preferred speed and gait, even when challenged with obstacles that exceed three times the height of their center of mass. Theoretical models of animals demonstrate passive, dynamic self-stabilization without sensing of the environment (Schmitt et al.). These horizontal plane models consist of a mass and a laterally projecting spring representing three legs acting as one. Biologically inspired robots or physical models using simple, damped-springy legs have become extremely effective at traversing irregular terrain (Altendorfer et al.; Cham et al.).

To determine one parameter often implicated in contributing to stability, we measured leg damping in the cockroach (*Blaberus discoidalis*). We hypothesized that damping provides stability by rejecting perturbations to legs in the swing phase, thus allowing simpler control of foot position. We wondered whether this hypothesized advantage was specific to insects or was a more general phenomenon based on size. Therefore, we determined the scaling of damping.

METHODS

We used three methods to measure damping in cockroach legs. First, we perturbed the free tibia and recorded its motion with a high-speed video camera until it returned to an equilibrium position. Second, we fixed the femur and attached the tibia to a lever. We oscillated the leg at a range of frequencies in the plane of the joint while measuring force. Damping in the plane of the joint was measured with and without passive muscles. Third, we fixed the body and attached the end of the tibia to a lever. We oscillated the whole leg out of the plane of the joint while measuring force.

RESULTS AND DISCUSSION

Insect joints and legs were highly overdamped, whether or not the perturbation occurred from the side in the plane of the joint or vertically out of the plane of the joint. The femur tibia joint was highly overdamped, both with and without passive muscles (damping ratio near 10). The exoskeleton was responsible for approximately 70% of the damping. Damping was independent of perturbation frequency.

When we modeled the limb as a cylinder oscillating at its natural frequency operating with a viscously damped joint, we found that stiffness and damping scaled proportionally with

length. Damping ratio scaled inversely with the length and mass. Therefore, as limb length decreases damping ratio increases. At large scales, damping is negligible and limbs swing like a pendulum. As size decreases, pendulum behavior gives way to self-stabilization without overshoot. Although data are insufficient to formalize a scaling relationship, measurements on humans lend support to the principle.

Figure 1. Damping ratio for segments that differ in size. Data from Garcia M.S., et al., 2000; Coveney V.A., et al., 2001; Lebiedowska M.K. & Fisk J.R., 1999; Milner T.E. & Cloutier C., 1998; Lacquaniti F., et al., 1982; Hunter I.W. & Kearney R.E., 1982; Hajian A.Z. & Howe R.D., 1997; Agarwal G.C. & Gottlieb C.L., 1977.

SUMMARY

Cockroach legs in the swing phase are overdamped. Damping ratio increases with decreasing limb mass and length. Large passive, damping in small appendages has implications for control. Perturbations to small limbs can be dissipated with less neural feedback. Muscle activation could be regarded more as a simple position or velocity command rather than a force command. A self-stabilizing limb favors the use of simple feedforward control strategies for locomotion.

SELF-STABILITY MECHANISMS FOR SENSOR-CHEAP LEGGED LOCOMOTION

Daniel Koditschek¹, Richard Altendorfer¹, Raffaele Ghigliazza², and Philip Holmes²

¹Department of Electrical Engineering and Computer Science, University of Michigan, Ann Arbor, MI 48109-2110

INTRODUCTION

It is now well established that running animals' mass centers exhibit the characteristics of a Spring Loaded Inverted Pendulum (SLIP) in the sagittal plane (Blickhan and Full, 1993). What control policy accomplishes this collapse of dimension by which animals solve the "degrees of freedom problem" (Bernstein, 1967)? How valuable might this policy be to gait control in legged robots?

A general framework for "anchoring" virtual spring loaded inverted pendulum (SLIP) mechanics in the far more elaborate morphologies of real animals' bodies (Full and Koditschek, 1999) has been motivated by successful implementation in laboratory robots (Buehler et al., 1990; Nakanishi et al., 2000; Rizzi and Koditschek, 1996). However these implementations appear to demand sensing, actuation, and computation that may be unrealistic relative to the resources that animals and practical robots might be expected to have on hand.

Can we account for stable running animal gaits without recourse to such "expensive" control techniques? If so, can we introduce such "cheap" controllers to robotics and hope to obtain similarly high performance legged locomotion?

METHODS

A new hexapedal robot, endowed with passive compliant legs and sprawled posture in essential conformance with the functional properties of exemplary cockroach runners (Full et al., 1998), exhibits mobility over general terrain exceeding that of any previous (scientifically documented) power autonomous legged machine (Saranli et al., 2001). When this machine's mechanical and control parameters are properly tuned, its mass center also exhibits pronounced SLIP characteristics (Altendorfer et al., 2001). Notably, this stable dynamical regime is achieved by a feedforward controller that drives the machine's few (only six) actuators without the benefit of any proprioceptive data (beyond the motor shaft angle measurements used to enforce the desired open loop hip position profile).

RESULTS AND DISCUSSION

At present, we do not understand enough about this robot's mathematical models to select desired gaits by first principles analysis. Stable steady state SLIP behavior is adjusted at present by systematic but almost purely empirical parameter tuning methods.

Mathematical analysis (Schmitt and Holmes, 2000) of the (simplified) horizontal plane mechanics of a running cockroach (Kubow and Full, 1999) has revealed that self-stabilization can occur in two and three degree of freedom lossless mechanisms. These models are mechanically very similar to a horizontal plane version of SLIP, motivating a

search for self-stabilized gaits in the sagittal plane. Analogous study of the sagittal plane SLIP model now reveals that it too indeed includes parameter regimes that yield self-stabilizing gaits. Algebraic approximations of this parameter regime suggest the possibility of computation- and sensor-cheap feedforward control by means of parameter set points appropriate to a desired control target.

SUMMARY

The wider range of maneuvers and larger stability margins active controls can afford may well justify a greater investment in sensory technology and internal models and computation on the part of robot designers. Similarly, there is growing evidence in the animal motor literature that biological solutions to these same problems span a design space that includes both active and passive stabilizing strategies (Klavins et al., 2001). A better understanding of the tradeoffs – of just how "cheap" a machine might suffice to accomplish just what level of locomotion performance – seems essential to better robot design as well as deeper insight into animal evolution. The talk will review our growing interest and slowly increasing understanding respecting the role of self-stability mechanisms in sensor-cheap "passive" locomotion behavior.

RUNNING STABILITY: LIMB ROTATIONAL CONTROL IN QUADRUPEDAL ANIMALS

Hugh M. Herr, Andre Seyfarth and Gregory T. Huang

Artificial Intelligence Laboratory, MIT, Cambridge, MA, USA

INTRODUCTION

Our goal is to understand the biological strategies used by humans and animals in locomotion. In running, the spring-like axial behavior of the limbs during stance is a well-known and remarkably general feature (e.g., Blickhan and Full, 1993). Here we consider how the *rotational* behaviors of limbs affect running stability. It is commonly observed that running animals retract their limbs just prior to ground contact (Muybridge, 1957) and exert proximal hip and shoulder torques throughout stance (Lee et al., 1999; Herr and McMahon, 2000). Measurements on trotting dogs show that just prior to touch-down the limbs retract towards the ground, and after touch-down, the stance-limb hip tends to exert a thrusting torque while the stance-limb shoulder predominantly brakes. More recently, a dynamic model of running quadrupeds constrained to give smooth, periodic solutions exhibited swing-phase limb retraction and stance thrusting and braking at the proximal limb joints over a wide range of body size (Herr et al., 2002). The mechanism by which these behaviors may influence stability is not fully understood. In this talk we discuss the idea that late swing-phase retraction, together with hip thrusting and shoulder braking during stance, improve quantitatively the stability of running quadrupeds (Figure 1). As a secondary issue, we consider the mechanical work expended at the hip and shoulder and test whether this work may be used by animals to stabilize gait with a manageable energetic cost.

METHODS

To address these questions, we study three dynamic models, each obeying the laws of Newtonian mechanics, in a hierarchy of complexity: (1) A structurally realistic quadruped model with distributed mass and ten degrees of freedom (DOF) (Herr and McMahon, 2000), where the mechanical assumptions are that stance limbs act as springs and forward motion is controlled by active hip and shoulder torques; (2) a simplified quadrupedal model with a rigid trunk, springy massless legs, and eight DOF; and (3) a further simplified spring-mass model with a single DOF. The models operate in two dimensions; motions are restricted to the sagittal plane. In the first and second models, we perform a linearized stability analysis for small perturbations of the state variables about periodic solutions and examine the eigenvalues of the system, and for the simplified third model, we compute a system return map to characterize model stability.

RESULTS AND DISCUSSION

For each model, simulations are run with and without the rotational control features. We find that limb retraction during the flight phase is a highly stabilizing strategy, independent of

model complexity. Results show that leg retraction compensates for errors in leg position and allows the system to adapt the angle of attack corresponding to internal (e.g. leg stiffness variations) and external disturbances (e.g. ground level variations). As for limb control during stance, the eigenvalue associated with body pitch is sensitive to the exact combination of fore and hind limb torques. If the legs are constrained to act (axially) in a passive spring-like manner, then there is a quantifiable advantage to commanding a torque to the animal's front end that generally acts to decelerate the mass of the body during early ground contact. Results suggest that this coordinated limb rotational control is crucial for pitch stability and may be used by animals to stabilize gait for a manageable energetic cost. These findings should be applicable to legged robots designed to traverse irregular terrain (Saranli et al., 2001). A control scheme for a robot that includes swing-phase limb retraction and thrusting and braking during each stance period may prove to be self-stabilizing.

Limb Rotational Control in a Trotting Horse

Figure 1: Stabilizing behaviors: limb retraction just prior to ground contact (left), thrusting torque at the hip and braking torque at the shoulder during early stance (center), and thrusting torques at both joints during late stance (right). The limbs behave as passive springs in the axial direction.

DOES LEG RETRACTION SIMPLIFY CONTROL IN RUNNING?

Andre Seyfarth^{1,2}, Hartmut Geyer^{1,2}, Reinhard Blickhan², Hugh Herr¹

¹MIT LegLab, 200 Technology Square, Cambridge MA 02139, USA (seyfarth@ai.mit.edu)

²Movement Science Group, University of Jena, Seidelstr. 20, 07749 Jena, Germany

INTRODUCTION

In fast locomotion (running, hopping, jumping) the leg operation during the stance phase can be described by a simple linear spring (Cavagna et al., 1964; Blickhan, 1989). For periodic running with a spring-like leg, the orientation of the angle of attack α_0 must be carefully adjusted to the chosen leg stiffness k (Seyfarth et al., 2002). For example in human running at 5 m/s the angle of attack must be kept within a range of $\pm 1^\circ$ (assuming fixed leg stiffness).

But how is the leg adjusted during the swing phase to guarantee such an angle of attack precision? Here we propose leg retraction (velocity ω_R , Fig. 1) as a simple mechanism to reduce the control effort in leg angle adjustment.

Using this approach we address following questions:

- (1) Is leg retraction capable to adjust the angle of attack?
- (2) Does leg retraction enhance the stability of running?
- (3) Does leg retraction support low running speeds?

METHODS

The trajectory of the center of mass in running is described by the gravitational acceleration (during flight and contact phases) and by the force produced by the stance leg (during contact) which is here represented as a linear spring.

Leg retraction (angular velocity ω_R) starts at the apex of the flight phase (Fig. 1) assuming a given initial retraction angle α_R . This allows a simple stride to stride analysis in terms of a *return map* of the apex height of two successive flight phases $y_{i+1}(y_i)$. Here self-stabilized running requires a stable fixed point with (1) $y_{i+1} = y_i$ and (2) $dy_{i+1}(y_i) / dy_i = (-1, 1)$.

The robustness of running is examined by measuring the number of successful steps after disturbance (e.g. change in ground level, leg stiffness etc.).

Fig. 1: Leg retraction (velocity ω_R) starts at apex with an initial retraction angle α_R . The angle of attack α_0 at touch-down is not a constant but influenced by the apex height y_{APEX} .

RESULTS

In Fig. 2A the return map $y_{i+1}(y_i)$ for a moderate retraction speed $\omega_R = 50^\circ/\text{s}$ in human running is presented. The control effort of the retraction angle is clearly reduced (α_R -range for stable running $> 12^\circ$) in comparison to the critical angle of attack adjustment without retraction.

The robustness of running with different retraction speeds ω_R is shown in Fig. 2B. Already a moderate retraction speed is sufficient to guarantee stable running for large stiffness variations. At high retraction speeds ($> 100^\circ/\text{s}$) lower leg stiffness is of advantage.

Moreover, the minimum speed for stable running is largely reduced by leg retraction (e.g. ca. 3.5 m/s without retraction, less than 2 m/s with $\omega_R = 50^\circ/\text{s}$).

Figure 2: **A** Return map $y_{i+1}(y_i)$ with stable fixed points (o) for human running with $\omega_R = 50^\circ/\text{s}$. **B** Area with 25 successful steps after a sudden change in leg stiffness by factor f_k .

DISCUSSION

Leg retraction proves to be a powerful strategy to adjust the appropriate angle of attack resulting in an increased robustness of running with respect to external and internal disturbances. It is a universal mechanism observed in nature and requires a further understanding.

STABLE STRATEGIES FOR MUSCLE SKELETAL SYSTEMS

Heiko Wagner, Tobias Siebert and Reinhard Blickhan

Institute of Sports Science, Dept. Motion Science, Friedrich-Schiller-University Jena, D-07749 Jena
heiko.wagner@uni-jena.de

INTRODUCTION

Voluntary movements of humans and animals are based on muscular contractions. In this view muscles are reduced to simple force generators and the skeletal system transfers the forces to the environment. Within the last few years several studies have shown that the muscle-skeletal system (MSS) is tuned in a way that it works not only as a simple force generator but as a controller system (Dickinson et al. 2001, Wagner and Blickhan 1999, 2001ab, submitted) stabilizing small perturbations without the need of a neuronal feedback. Here we give an overview of different studies in which we have been able to show the stabilizing ability of the muscle skeletal system.

METHODS

In order to quantify the stability of a system (e.g. muscle tendon complex, human leg, arm and trunk) we use the well established Ljapunovian method and calculate the eigenvalues of the systems equation of motion. These eigenvalues must be negative for a self-stabilized movement. If one eigenvalue is positive the system is unstable. In general we describe the force production of the muscles with a Hill-type muscle model including the force-velocity relation (FVR), the force-length relation (FLR) and a series elastic component (SEC). The geometric model is adapted to the different situations.

RESULTS AND DISCUSSION

Muscle (Fig. 1A): An isotonic contraction (e.g. of rat M. triceps brachii) can be interpreted as a simple perturbation with respect to a given external moment. We found that the system is stable and moves towards a new equilibrium point. The model calculations show that a FVR and operation at the ascending limb of the FLR is required.

Leg and arm (Fig. 1B,C): Here again, we found solutions where the MSS is able to self-stabilize the prescribed

trajectories. However, it was necessary that the system is adapted to the special tasks. For vertical knee-bends (simplification of walking and running) we have shown that i) bi-articular muscles, ii) co-activation of antagonistic muscles (quadriceps and hamstrings), and iii) the moving center of rotation of the knee-joint contribute to stability. For cyclic vertical arm movements (juggling) it is important that the biceps muscle works on the ascending limb of the FLR.

Trunk (Fig. 1D): For lateral bending of the trunk the geometric arrangement of the muscles represents an important factor for stability. The muscles should not be in parallel to the spine but should be arranged obliquely with a slope between $25^\circ - 40^\circ$. Nearly all muscles responsible for lateral bending of the spine have such a slope (multifidus, obliquus ext./int.).

SUMMARY

Surprisingly, all the properties necessary to generate self-stabilized movements are realized in the muscle-skeletal system, e.g. the negative slope of the FVR, the ascending limb of the FLR, the moving center of rotation of the knee joint, co-activation of antagonistic muscles, bi-articular muscles, the geometric arrangement of the muscles within the skeletal system (trunk). In conclusion, the muscle skeletal system should not be reduced to a simple force generator but it must be seen as a complex self-stabilized controller system unburdening the neuronal reflexive system.

PASSIVE DYNAMIC STABILITY IN HUMAN WALKING

Arthur D. Kuo

Dept. of Mechanical Engineering, University of Michigan, Ann Arbor, Michigan USA (artkuo@umich.edu)

INTRODUCTION

As shown by McGeer (1990), the passive dynamics of the legs are sufficient to walk down a gentle slope with no external control, and no external energy input save from gravity. Here we consider different models based on passive dynamics, including actively powered models that still make use of passive dynamic principles. We consider the stability of these models, and the implications on human central nervous system control.

MODELS

Fig. 1. Passive dynamic walking models. Left to right: planar stiff-legged model (McGeer, 1990; Kuo, 2001), planar kneeed model, 3-d stiff-legged model (Bauby & Kuo, 2000).

Models of passive dynamic walking (Fig. 1) use the natural pendular motion of the legs to generate a single stance phase that advances one step. At the end of that phase, the swing foot comes into contact with the ground. Modeled as a perfectly inelastic collision, the impact shifts weight onto the new foot and alters the velocities of the legs so that the conditions at the beginning of the previous step are repeated. This cyclical motion, known as a limit cycle in dynamical systems, is found by appropriate selection of inertial properties and initial conditions. The inertial properties of a human work well in generating a limit cycle.

Passive dynamic stepping is not necessarily stable. Perturbations to the system may cause it to veer away from the limit cycle, resulting in an unstable gait. But computational and physical models of passive walking show that, in the sagittal plane, the gait is stable in response to small perturbations. The stability is retained even with the addition of knees to the legs. However, frontal plane motion appears to be unstable in a 3-d model that can move side-to-side, even though the sagittal plane motion is still stable. In the absence of active control, bipeds would be expected to fall laterally. Of many possible stabilizing mechanisms, lateral adjustment of foot placement appears to be especially simple.

Experiments suggest that humans use lateral foot placement as part of their stabilization strategy (Bauby & Kuo, 2000). Human subjects exhibit higher variability of foot placement in the lateral direction than fore-aft, indicative of highly sensitive lateral dynamics. This difference is magnified when subjects walk with their eyes closed, perhaps because the feedback stabilization is operating on less than optimal information.

IMPLICATIONS

Passive dynamics have several implications for central nervous system control. We propose a reinterpretation of the role of central pattern generators, and examine how passive dynamics change at different size scales.

Central pattern generators (CPGs) are often interpreted as providing rhythmic commands to the periphery. But the legs themselves may already have an inherent rhythm. Mismatch between two rhythms will tend to adversely affect performance. Presumably sensory feedback (Fig. 2) allows the CPG to adjust its rhythm accordingly. But that feedback also implies that the CPG should not be interpreted as a feedforward controller. Instead, the need for an external rhythm generator is called into question, because feedback alone is sufficient to modulate and power walking. It is possible that the CPG's role is to help filter sensory information in the presence of noise (Kuo, 2002).

Fig. 2. Central pattern generator with sensory feedback.

At small size scales, mass becomes less dominant as viscous and elastic effects become more dominant. Geometric scaling predicts that small animals will have limbs that are more highly damped than their larger counterparts. This implies that smaller animals such as insects cannot rely on a pendular action to move the legs, and must instead move the legs quite deliberately. This drawback is offset by the possible advantage of greater self-stability in legs of small animals.

CONCLUSIONS

Passive walking highlights the importance of dynamics in walking. The natural pendular motion of the legs appears to have little use of a CPG as a command generator, but might instead use a CPG to filter sensory signals. These effects change in relative priority for animals of different size scales.

NONLINEAR TIME SERIES MEASURES FOR QUANTIFYING LOCAL DYNAMIC STABILITY DURING WALKING

Jonathan B. Dingwell

Department of Kinesiology and Health Education, The University of Texas, Austin, TX

Email: jdingwell@mail.utexas.edu Web: <http://www.utexas.edu/education/kinesiology/motorbe/dingwell.html>

INTRODUCTION

The basic control task in walking is to maintain stability across multiple consecutive strides. Gait analyses typically examine only a single “average” stride, inherently disregarding the continuous nature of gait. Understanding locomotor control requires understanding how the nervous system (CNS) controls locomotion *from one stride to the next*. Here, we describe a relatively new set of techniques that have been successfully used to quantify locomotor stability defined as the system’s capacity to respond to infinitesimal (i.e. “local”) perturbations (Dingwell & Cusumano, 2000). We believe these techniques can help illuminate important aspects of locomotor behavior and control that cannot be assessed by other means.

METHODS

First, an appropriate state space for each time series is constructed using delay-embedding (Fig. 1A&B; Kantz & Schreiber, 1997). The effects of local perturbations to the dynamics are tested by quantifying the Euclidean distance between initially “nearest neighbor” trajectories as the system evolves over time (Fig. 1C). The exponential *rate* of divergence, averaged over many neighboring trajectories, defines the maximum *finite-time Lyapunov exponent* (λ^*) for the time series (Fig. 1D; Rosenstein et al., 1993; Kantz & Schreiber, 1997):

$$\ln[d_j(i)] \approx \lambda^*(i\Delta t) + \ln[D_j] \quad (1)$$

Local dynamic stability (λ^*) was quantified in young healthy subjects during continuous over-ground and treadmill walking (Dingwell et al., 2001) and in a group of diabetes patients with peripheral neuropathy (NP) who have a far greater risk of falling than healthy controls (CO) (Dingwell et al., 2000).

Figure 1: **A:** Original time series, $x(t)$. **B:** Embedded time series. **C:** Local divergence in embedded time series. **D:** λ^* defined as the average exponential rate of local divergence.

RESULTS AND DISCUSSION

Local perturbations, on average, led to continued divergence of neighboring trajectories across ≥ 10 strides (Fig. 2A) in all subjects. Although NP patients exhibited increased variability relative to CO subjects (Dingwell & Cavanagh, 2001), they

were more locally stable (Fig. 2B). In fact, slower speeds appear to be a compensatory strategy used by NP patients to maintain upper body stability during level walking (Dingwell et al., 2000). Correlation analyses of mean standard deviations and λ^* in these patients revealed no discernable relationship between variability and local stability measures (Fig. 2C), similar to findings in younger subjects (Dingwell et al., 2001).

Figure 2: Mean exponential divergence curves (A) and λ^* exponents (B) for medio-lateral upper body accelerations in NP and CO subjects. C: Correlations between variability and stability measures for all subjects and variables recorded.

SUMMARY

The results of these studies demonstrate that: (1) Locomotor control of stability acts over multiple (≥ 10) strides; (2) Traditional measures of variability do *not* quantify the capacity of a system to respond to perturbations; and (3) in NP patients, λ^* may provide a better indicator of CNS compensatory strategies than more traditional gait analysis approaches. These and related techniques may provide important new insights into the control of locomotion and other similar movements.

LOCAL FEEDBACK MECHANISMS FOR STABLE BOUNCING

Hartmut Geyer^{1,2}, Andre Seyfarth^{1,2}, Reinhard Blickhan¹, and Hugh Herr²

¹Dept. Motion Science, Institute of Sport Science, Friedrich-Schiller University, D-07749 Jena, Germany

²MIT Leg Laboratory, Massachusetts Institute of Technology, Cambridge, MA 02139, USA (hartmut@ai.mit.edu)

INTRODUCTION

Most studies addressing local feedback mechanisms are focused on posture and walking (Orlovsky et al. 1999), but only little is known about their role in fast locomotion.

Fast periodic movements like hopping and running are characterized by an almost sinusoidal shape of the ground reaction force with its maximum approximately at half contact time. This global feature of leg operation can be described by a simple spring-mass template (Blickhan, 1989) and has been successfully applied to predictions of experimental results. But it remains unclear, how this behavior is generated by the biomechanical system on the muscle-skeleton level.

We investigate to what extent local muscle reflex loops can suitably adapt the dynamic properties of muscle actuators to result in spring-like behavior on the global leg level.

METHODS

A three-segment model using Hill-type muscles is equipped with sensory feedback pathways to analyze the contribution of simple, single loop muscle reflexes to the generation of spring-like leg operation during fast periodic movements.

Each proprioceptive reflex pathway transmits only one of three possible signals from the muscle receptors: muscle fiber length or velocity from the muscle spindles, and muscle force from the Golgi tendon organ (representing Ia, II and Ib afferences, respectively). The signals are applied either as positive or negative feedbacks. Multiple reflex signals affecting one muscle are summed.

The excitation-contraction coupling, delaying the muscle activation behind its neural stimulation, links proprioceptive signals to muscle force production. For each muscle a stimulation bias is considered.

The control parameters - feedback time delay and signal gain for each reflex pathway and stimulation bias for each muscle - are mapped to find an optimal adjustment for a stable periodic hopping pattern.

CURRENT RESULTS AND DISCUSSION

So far the model contains two Hill-type muscles: knee and ankle extensor. Without reflexes, the muscle stimulation must be centrally adapted to result in periodic hopping.

With a constant stimulation bias, i.e. lacking a central signal adaptation, the model leg can be tuned to operate spring-like, if both muscles are governed by separate positive force

feedbacks (Fig. 1). The movement pattern is robust with respect to changes in ground level.

This result coincides with former model investigations using a two-segment system including one Hill-type extensor muscle (Geyer et al. 2001) and suggests that positive muscle force feedback could be a powerful and fast mechanism to facilitate spring-like leg behavior in periodic movements.

However, in comparison to the system without feedbacks, the inner leg stability is not clearly improved using the separate force feedbacks. The system still tends to destabilize as predicted for a mechanical three-segment system (Seyfarth et al. 2001), if the muscle or feedback parameters are altered.

With a special focus on muscle reflexes, the goal of further investigations is to find the minimal neuromuscular architecture, which provides both spring-like leg behavior and inner leg stability in fast bouncing tasks.

Figure 1: Spring-like leg behavior in hopping using separate positive force feedbacks ($Ib(F)^+$). The three-segment model is equipped with knee and ankle extensor muscles. The feedback motor commands are not influenced by central adaptations during stance ($STIM0 = \text{const}$).

BIOMIMETIC APPROACHES TO STABLE SYSTEMS FOR FUNCTIONAL ELECTRICAL STIMULATION

INTRODUCTION

Humans learn to use their limbs for a wide range of tasks requiring dexterity, accuracy, efficiency and stability. Presumably their strategies take advantage of features of the muscle fibers, the musculoskeletal architecture, somatosensory feedback and spinal cord reflexes. Those structures form a hierarchy of control with the brain at the top. Neural prosthetic systems to reanimate paralyzed limbs by functional electrical stimulation (FES) have to anticipate the relevant features of the components that remain (muscles and their skeletal linkages) and replace those that are no longer available (sensors, feedback circuitry and motor planning). We hypothesize that subjects will find it easier to learn to control such prosthetic systems if they incorporate the same principles of operation as the biological components that have been replaced.

METHODS

Our general strategy is to build computer models of the subsystems that must be incorporated or replaced in an FES system and to conduct virtual experiments in model systems in order to understand how the properties of those subsystems contribute to the performance that we desire for our prosthetic systems. To this end, we are developing three modeling tools:

- Virtual Muscle™ (Cheng et al., 2000) is a program written in Matlab® that accepts morphometric data for musculotendinous structures and generates Simulink® blocks that reproduce accurately the force production and energy consumption of muscles responding to dynamic conditions of either neural or FES activation under the full range of physiological kinematics.
- Musculoskeletal Modeling in Simulink (MMS™; Davoodi and Loeb, 2001) is a program written in C++ that converts models of musculoskeletal anatomy and dynamics created in SIMM® (Musculographics, Inc.) and SD-FAST® (Symbolic Dynamics, Inc.) into Simulink blocks that can be linked to Virtual Muscle blocks and simulated sensors and control systems.
- A motion capture and animation environment that permits sensors of residual limb movements (e.g. shoulder and scapular motion) to be converted into command signals that operate a virtual prosthetic arm whose control systems can be adaptively trained to reproduce the desired limb trajectories.

SUBSYSTEMS CONTRIBUTING TO STABILITY

Mechanical Properties of the Musculoskeletal Subsystem:

Force production and energy consumption by muscles depend strongly on sarcomere velocity and the firing rates of motor units. Both of these reflect details of cross-bridge kinetics that appear to have evolved to improve the stability and efficiency of motor behavior. We use the term “preflexes” to identify force changes resulting directly from kinematic perturbations because they occur instantaneously, without the delays associated with synaptic transmission in reflex pathways, propagation of action potentials in nerve and muscle fibers, and excitation-contraction coupling (Brown and Loeb, 2000).

Adaptive Sensitivity Control of the Proprioceptive Subsystem:

Biological sensorimotor systems employ much higher aggregate data rates for sensing than for controlling muscle activation. Muscle spindles provide the most important kinesthetic information for stabilizing posture. They further optimize the information available by actively shifting the dynamic range of these sensors through fusimotor control.

Adaptive Gain Control of the Segmental Interneuronal Subsystem:

Most of the descending control from the brain to the motoneurons is routed through spinal cord interneurons, where it converges with somatosensory feedback and is distributed widely to increase or inhibit the activation of many different muscles. This pattern of connectivity also accounts for the often profound gating and even reversals of net reflex effects produced by external perturbations when delivered during different motor tasks or phases of tasks. Functionally, this subsystem appears to act as a programmable regulator (He et al., 1991).

STABILITY OF BIPEDAL STANCE; THE CONTRIBUTION OF CO-CONTRACTION AND SPINDLE FEEDBACK

W. P. (Wouter) Haenen and A.J. (Knoek) van Soest

Faculty of Human Movement Sciences and IFKB, Free University, Amsterdam, The Netherlands

INTRODUCTION

The human motor control system is hierarchically organized, and it is generally thought that control is delegated to the lowest possible hierarchical level. Thus, it is worthwhile to analyze the potential contribution of well-defined low level mechanisms when thinking about the control structure for any task. In this study, we investigate the contribution of two low level mechanisms often referred to, co-contraction and spindle feedback, to the control of bipedal stance in humans. Given the destabilizing effect of gravity in this "inverted pendulum" task, assuring local stability around an equilibrium is an obvious first objective for the control system. Therefore, the aim of this study is to assess the maximal contribution of co-contraction and spindle feedback to local stability.

METHODS

The 2-D forward dynamical model of the human musculoskeletal system used in this study consists of 4 rigid segments (foot, lower legs, upper legs, upper body), actuated by 9 Hill-type "muscles" (tibialis anterior, soleus, gastrocnemius, vasti, rectus femoris, hamstrings, biceps femoris caput breve, gluteus maximus, iliopsoas). Motion between foot and ground is neglected. Input of the open loop model is the stimulation of the muscles; output is the resulting behavior (kinematics and kinetics). First, a reference state was defined in which the joints are slightly flexed, and in which muscle stimulation is chosen such that equilibrium is maintained at a low level of co-contraction. Local stability of the open-loop controlled reference system around this equilibrium position was investigated by linearizing the state space model of the system at the equilibrium, and calculating the eigenvalues of the resulting system matrix. The effect of co-contraction was assessed by comparing the results for the reference state with those for a maximally co-contracted system. Spindle feedback was applied to the reference system; spindle feedback was modeled as local proportional time-delayed feedback of contractile element length and contractile element velocity. The time delay of 0.035 s. was modeled as a 5th order Padé filter. The 2 (length and velocity) x 9 (muscles) feedback gains were determined using a parallel genetic algorithm for optimization. As the sign of the maximum of the real parts of the eigenvalues is indicative of stability, the optimization criterion was chosen as $\max(\text{real}(\text{eig}(\text{Afb})))$, where Afb is the system matrix of the linearized feedback-controlled system.

RESULTS

In the reference state, $\max(\text{real}(\text{eig}(\text{A})))$ equalled +4.71, indicating an unstable system; imposing maximal co-contraction reduced this value to +2.62, again indicating an unstable system. For the feedback-controlled system with a time delay of 0.035 s, the optimal choice of feedback gains resulted in a $\max(\text{real}(\text{eig}(\text{Afb})))$ of +0.06, indicating a

marginally unstable system. The optimal feedback gains were also calculated for the system without time delays, resulting in a $\max(\text{real}(\text{eig}(\text{Afb})))$ of -0.97, indicating a stable system. As the (nonrealistic) nondelayed spindle feedback system is the only one considered that yields a stable system, we investigated for this system how well the behavior of the linear system matches with that of the nonlinear system. In the Figure, the response in terms of the horizontal position of the body center of mass is plotted for this system after application of a velocity perturbation of 0.01 rad/s to the trunk. Qualitatively, the responses are very similar.

DISCUSSION

In literature, co-contraction is often mentioned as an important first line of defense against destabilizing external forces (e.g. Hogan 1984). Here it is found that in the context of bipedal stance, co-contraction does contribute to joint stiffness, but to a limited extent. Moving up one level in the hierarchy of the motor control system, local muscle spindle feedback was considered. Given the strong emphasis on position feedback in several theories of motor control (e.g. Feldman 1986) it is surprising that locally stable bipedal stance cannot be obtained even when the spindle feedback gains are chosen optimally with respect to local stability.

As expected on theoretical grounds, the time delay limits the contribution of spindle feedback to stability; given the fact that transmission delays are inherent to neural conduction, it is unfortunate that in the comparable study by He et al. (1991) time delays were not included.

In future work we will investigate the potential contribution of non-local spindle feedback (afference of muscle A influencing stimulation of muscle B) and the potential contribution of force feedback, as mediated through Golgi tendon organs.

CLINICAL AND BASIC SCIENCE STUDIES OF THE DELTOID TO TRICEPS TENDON TRANSFER

Jan Fridén and Richard L. Lieber

Department of Hand Surgery, Department of Orthopaedics and Bioengineering
Göteborg University, SWEDEN and University of California, San Diego, USA

e-mail: jan.friden@orthop.gu.se

INTRODUCTION

The posterior deltoid muscle is surgically transferred to the triceps insertion to replace lost elbow extension in patients with C5 and C6 level tetraplegia (Freehafer et al. 1991; Hentz et al. 1983). Considering the large range of motion of both the elbow and shoulder joints, a risk exists for overstretching the repair sites, exceeding the range over which the muscle can operate and thereby jeopardizing the torque-producing capability of the new motor due to active insufficiency. For more than 15 years we have placed stainless steel markers into the tendons proximally and distally to the attachments during tendon transfer surgery. The distance between markers can be radiologically measured at various time intervals after surgery to provide quantitative measurement of repair site slippage. We have used this approach to evaluate two post-operative protocols—use of an arm restraint on the wheelchair that restricts shoulder adduction and nonuse of the arm restraint. In addition, we have developed methods to measure the detailed muscle fiber architecture of both the posterior deltoid and triceps muscles (Lieber et al. 1992). Thus, the purpose of this study was to quantify the magnitude of tendon slippage after postoperative deltoid-to-triceps tendon transfer and to mathematically model the transfer based on detailed architectural study of cadaveric specimens. .

METHODS

Twelve patients (mean 26, range 20 - 35 years, 10 males and 2 females) had thirteen tendon transfers of the posterior deltoid-to-triceps brachii muscle secondary to traumatic spinal cord injury. The average interval from the time of injury to the procedure was 3.4 ± 0.9 years. Surgery was performed under brachial plexus anesthesia combined with an axillary nerve block. The posterior deltoid border was mobilized and the interval between middle and posterior deltoid identified. The distal tibialis anterior was cut at its insertion, the tendon was then cut proximally at the myotendinous junction and removed through an anterior incision on the distal portion of lower leg. A subcutaneous tunnel was created from the level of deltoid insertion to the distal triceps tendon via a dorsal incision to the level of olecranon. The distal deltoid tendon and the tendon graft were placed with an overlap of 5 cm and sutured to each other using 5-0 Ethibond running sutures along the sides of the graft and host tendons. Stainless steel sutures (6-0) were placed in four positions: the deltoid tendon (marker #1), proximal tendon graft (marker #2), distal tendon graft (marker #3) and triceps tendon (marker #4) at a spacing of ~3 cm. Subsequently, 10 posterior deltoid and triceps muscles were harvested from cadaveric specimens for detailed quantification of muscle fiber length and cross-sectional area using methods previously developed for upper extremity muscles (Lieber et al. 1992).

RESULTS AND DISCUSSION

Total distance between markers, taken as a measure of muscle-tendon unit (MTU) length, measured 6 months postoperatively was 23 ± 3.7 mm for patients without arm rests while the corresponding value measured for patients with the arm rest was significantly lower (8.4 ± 3.0 mm, $p < 0.05$). Average muscle fiber length of the posterior deltoid was 113 ± 15 mm while that of the triceps was only 60 ± 10 (mean \pm SEM, $n=8$). Two cadaveric specimens were excluded due to poor quality of fixation.

The two main results of this study are (1) use of a shoulder adduction protection armrest significantly reduces slippage of the deltoid-triceps tendon repair and (2) the very long deltoid fiber length (113 mm) renders it highly suitable for this type of transfer in which high excursion is required, due to the large shoulder and elbow mobility of these patients.

The present data suggest that elongation of the deltoid-triceps transfer occurs secondary to overstretch of the muscle-tendon unit during recovery. Significant tendon elongation was found within the first 4-6 weeks after surgery but even more intriguing was the fact that the elongation continued over the next months. This could have been due to the fact that the plaster was removed after four weeks and caused an increased mobility (although restricted by orthosis) in many directions and thereby caused at the repair site. The fact that the posterior deltoid has very long (i.e., >100 mm) muscle fibers suggests that it would be difficult to suture the muscle in a position where it would not generate significant tension over the entire range of elbow extension. Of course, a definitive test of this comment requires the measurement of actual posterior deltoid passive tension as well as its normal and transferred sarcomere length operating range.

RELATIONSHIP BETWEEN JOINT MOMENT ARMS AND MUSCLE FUNCTION

Kai-Nan An, Ph.D.

Biomechanics Laboratory, Department of Orthopedics, Mayo Clinic/Mayo Foundation
200 First Street SW, Rochester, MN 55905, e-mail: an.kainan@mayo.edu

INTRODUCTION

Biomechanically, muscle is considered to be an actuator, which provides force and power for the movement and balance of the musculo-skeletal structures. The anatomic arrangement of the muscle in relation to skeletal structure determines the mechanical behavior and efficiency of the function. In general, a muscle can cross several joints, and there can be numerous muscles spanning one given joint. The recruitment of the muscle and also the magnitude of the muscle force exerted for a given task are therefore dependent on both muscle physiology as well as the mechanical arrangement of the musculo-skeletal system. Biomechanically, the function of muscle has been regarded as a segmental mover and also a joint stabilizer. The function of mover and stabilizer can be described respectively based on the moment arms and line of action considered in the equilibrium equations.

MUSCLE AS SEGMENT MOVER

To achieve equilibrium of rotation, the resultant moment generated by the external loading has to be balanced with the moment generated by the muscle contraction. The moment generated by the muscle is equal to the muscle force multiplied by the moment arm of the muscle force to the joint axis of rotation. The larger the moment arm, the greater the mechanical advantage of that muscle and thus less force is required to resist a fixed amount of external loading.

Muscle crosses a joint in a three dimensional fashion. In other words, in general, muscle contraction will generate moments about all three axes of rotation of a given joint. However, when the constraints of other peri-articular soft tissues are not available, the muscle will have primary responsibility for maintaining balance of the joint rotation. For example, the flexors and extensors of the elbow joint are the primary elements responsible for resisting any flexion and extension joint moment due to external loading. The contractions of elbow flexors and extensors will also generate valgus and varus moments about the elbow joint. However, within normal anatomic conditions, when the varus and valgus rotation of the elbow joint are restricted by the collateral ligaments and the joint articulating surfaces, the contribution of muscle moments are not manifested.

For joints with additional degrees of freedom, where the capsulo-ligamentous constraints are not important, the contribution of muscle moment in multiple planes is greater. For example, the wrist joint has two degrees of freedom, namely flexion-extension and radial-ulnar deviations. Contraction of FCR causes both flexion and radial deviation, and contraction of ECU causes both extension and ulnar deviation.

For muscles crossing multiple joints, muscle activity depends on the moments of all the joints spanned by the muscle. The concept of multiple-joints muscle is extremely important in the clinical setting. For example, the tendons of extrinsic flexors and extensors of the hand span both the wrist joint and as well as the metacarpal-phalangeal and inter-phalangeal joints. Contraction of the muscle coordinates the movement of all these joints. The concept of dynamic tenodesis effect has been adopted for controlling hand prosthetics and consideration in mobilization after tendon repair. Co-contraction of quadriceps and hamstrings, due to the principle of two joint muscle, at the knee joint results in reduced anterior joint shear force, hence reduced tension in anterior cruciate ligament considered in rehabilitation after reconstructive surgery.

MUSCLE AS JOINT STABILIZER

To achieve equilibrium of translation, the resultant joint forces due to external loading must be balanced by the summation of forces generated by individual muscles across the joint. In a three dimensional situation, such force equilibrium equations have to be satisfied along each of the three directions or axes. In other words, a given muscle force at a given joint can be decomposed into three components which are commonly used to represent the lines of action of the muscle. If the muscle force component is in the direction to contribute to the balance of the resultant joint force, then the muscle is a joint stabilizer. On the other hand, if the muscle force component is not in favor of balancing the resultant joint force, but rather in the same direction as the resultant joint force, then this muscle may even facilitate joint subluxation and dislocation.

COMPUTER SIMULATION OF THE EXTENSOR CARPI ULNARIS TRANSFER TO EXTENSOR CARPI RADIALIS BREVIS

Scott L. Delp and Ariel M. Herrmann

Biomechanical Engineering Division, Mechanical Engineering Department
Stanford University, Stanford, California, USA, delp@stanford.edu

INTRODUCTION

Tendon transfers are often performed to improve the functional capacity of the hand and wrist after spinal cord injury. The restoration of voluntary active grasp is one of the major goals of these procedures. To provide a stable platform for digital flexion, strong active wrist extension is necessary. Wrist extension strength can be augmented by transfer of the extensor carpi ulnaris (ECU) to the extensor carpi radialis brevis (ECRB). Keith et al. (1989) reported the effects of this transfer on the moment generated by the ECU at the neutral wrist position in one spinal cord injury patient. We developed a computer simulation of this procedure to study its affects on the moment-generating capacity of the ECU throughout a range of wrist positions. This computer model provides a basis for an inquiry into the elements of a successful tendon transfer design.

METHODS

A graphics-based computer model was developed from anatomical measurements of the muscle-tendon paths before and after transfer (Figure 1; Herrmann and Delp, 1999). This model, based on a model of normal wrist mechanics (Gonzalez et al., 1997), calculates the lengths and moment arms of the muscles over a range of wrist flexion-extension, and represents the muscles' force-generating characteristics from measurements of their physiologic cross-sectional areas, fiber lengths, and pennation angles (Lieber et al., 1990).

Figure 1. Musculoskeletal model depicting the path of the ECRB and of the ECU before and after transfer to the ECRB. The left window shows a frontal view in the neutral wrist position. The inset shows a medial view (wrist in 25° flexion). The right window shows a lateral view (wrist in 25° extension).

RESULTS AND DISCUSSION

Analysis of the computer model revealed that the maximum isometric extension moment of the ECU at the neutral wrist position increased from 0.50 N-m to 1.72 N-m after transfer to the ECRB. The deviation moment shifted from 2.72 N-m ulnar deviation to 1.42 N-m radial deviation. The extension moment generated by the ECU varied more with wrist flexion angle after transfer due to its greater range of operating length.

The simulations highlighted the need for proper intraoperative tensioning of the ECU to maximize the isometric force-generating potential of the transferred muscle over the functional range of motion (Figure 2).

Figure 2. Force vs wrist flexion angle curve of ECU postoperatively after adjustment of tendon slack length to yield maximum force at the neutral wrist position (solid line) and after a 1-cm increase (dashed line) and decrease (dot-dashed line) from this value. Preoperative force profile of ECU (dotted line) provided for comparison.

HUMAN UPPER EXTREMITY ARCHITECTURE: IMPLICATIONS FOR FUNCTION AND SURGICAL RECONSTRUCTION

Richard L. Lieber and Jan Fridén

Department of Orthopaedics and Bioengineering, Department of Hand Surgery
University of California, San Diego, USA and Göteborg University, SWEDEN
e-mail: rlieber@ucsd.edu

INTRODUCTION

Recently, the architectural differences between whole muscles have been investigated and quantified in a number of animal species (see reading list below). These studies suggest that skeletal muscle architecture is the most profound determinant of whole muscle function and that muscles are composed of different fiber types which reflect the developmental process and level of muscle use. This would obviously have significant implications for surgical procedures in which muscles are transferred from one position to another. The purposes of our studies in human upper extremity muscles has been to define the architecture of upper extremity muscles for use in surgical tendon transfer and to provide objective criteria for decision-making in tendon transfer cases.

METHODS

To perform architectural analysis, cadaver extremity specimens are typically amputated well above the elbow and skinned and mounted to a board with the elbow fixed at 90° of flexion, the wrist in the neutral position and the forearm supinated. The fingers are not immobilized and assumed a flexed position during fixation. Each specimen is immersed in 10% phosphate-buffered Formalin for 24 to 48 hours to fix the muscle tissue and then rinsed in phosphate buffer for another 24 hours to remove residual Formalin. Muscles are then placed in mild sulfuric acid to partially digest both the connective tissues surrounding the muscles and especially the endomysium around the muscle fibers. Muscle fiber bundles (consisting of 5-50 muscle fibers) are isolated from the proximal, middle and distal muscle regions and fiber length measured. It is important to normalize architectural properties to a reference sarcomere length which may be measured by optical microscopy or laser diffraction.

RESULTS AND DISCUSSION

Upper extremity skeletal muscles demonstrated a remarkable degree of architectural specialization in terms of fiber length and physiological cross-sectional area (PCSA). This specialization appears to be well-suited to each muscle in order that it might perform its task (Fig. 1). The longest and largest muscles, by far, are the digital flexors to the middle finger (mass=16.3±1.7 g, length=200±8 mm) and the brachioradialis (mass=16.6±2.8 g, length=175±8 mm). Individual digital and thumb extensors were very similar in architectural features and are characterized as relatively long muscles (100-150 mm) composed of moderately long fibers (40-60 mm) oriented at a small pennation angle (2-6°) relative to the axis of force generation and possessing a moderate PCSA (50-100 mm²). The individual muscles of the deep and superficial digital flexors are also similar to one another with a moderate fiber length (~60 mm) and intermediate PCSA (150-250 mm²).

Figure 1: Scatter graph of some of the major upper extremity muscles in terms of fiber length (FL) and physiological cross-sectional area (PCSA). FL is a good predictor of muscle excursion while PCSA is a good predictor of peak force.

In addition to improving our understanding of muscle anatomy and function, elucidation of human muscle architecture may ultimately provide information useful for selection of muscles used in tendon transfers. To substitute a lost muscle function, it would seem reasonable to select a donor muscle with similar architectural properties as the original muscle.

INTRODUCTION

Knowledge of forces produced by individual muscles during normal locomotion is important for understanding muscle mechanics, muscle physiology, musculoskeletal mechanics, neurophysiology, and motor control. Direct measurement of muscle force *in-vivo* has been performed using a buckle transducer surgically implanted around the Achilles' tendon (Komi 1990). A fiber optic method has also been developed for direct *in-vivo* tendon force measurements (Komi, 1996). This approach has been used to measure Achilles' tendon forces in a human during walking (Laitinen, 1997). However, most recently the accuracy of this fiber optic measurement system has been questioned (Erdemir, 2001).

Intramuscular pressure (IMP) is a measurable mechanical parameter related to muscle force that is less invasive to obtain. Hill (Hill 1948) showed that mechanical pressures develop inside a muscle when it contracts. This observation led to measurement of intramuscular pressure as a direct measure of muscle force. Numerous studies have shown a linear relationship between intramuscular pressure and joint torque. However, these studies have not confirmed the underlying physiologic mechanisms. Further, routine measurements of intramuscular pressure have been limited by the relatively large catheter diameter static pressure artifacts associated with using saline filled catheter lines. This abstract reports recent advances which have eliminated these limitations.

METHODS

A new fiber optic pressure microsensor has been developed that measures 360 μ m in diameter and is based on an extrinsic Fabry-Perot interferometric technique. The relationship between intramuscular pressure and muscle stress has been quantified during active isometric and passive conditions. The experimental model was the tibialis anterior of the New Zealand white rabbit. Muscle length, muscle tension, and intramuscular pressure were recorded at relative muscle lengths from $L_0 - 50\%$ to $L_0 + 50\%$.

RESULTS AND DISCUSSION

Microsensor performance characteristics of the were evaluated. The microsensor has an accuracy, repeatability, and linearity better than 2% full scale output (FSO) and a hysteresis of 4.5% FSO. The small size allows simple, minimally traumatic and highly precise measurement of intramuscular pressure.

The length-tension curve for isometric contractions (Figure 1) was mimicked by the length-pressure curve (Figure 2) for both active and passive contractions. The correlation between

muscle stress and intramuscular pressure was quantified for both active contractions and passive conditions. Pressure-stress coefficients of determination for active contractions ranged from 0.215 to 0.956 (mean = 0.70 ± 0.27) and from 0.045 to 0.948 (mean = 0.83 ± 0.05) for passive conditions. Correlations were higher for the descending limb of a length-tension curve compared to the ascending limb. These data demonstrate that intramuscular pressure reflects the total tension (active + passive) of muscle.

Figure 1

Figure 2

Measurement of intramuscular pressure provides a viable technique for *in-vivo* muscle force measurement. A linear relationship between IMP and muscle force exists during isometric muscle contraction. Therefore, IMP provides data which are more physiologically relevant than EMG. This technique may be used to gain insight into the function and mechanical behavior of human skeletal muscle during locomotion.

INTRODUCTION

The recent development of microminiature, single channel stimulators (BIONS) has provided a flexible tool by which weakened muscles can be stimulated intramuscularly. The leadless devices are controlled and powered from an external magnetic field. Implantations can therefore be conducted as outpatient procedures by injecting devices near nerve bundles or motor points through a large gauge needle. We are currently using BIONS in three pilot clinical applications in which safety and efficacy of the devices can be assessed with relative ease.

Table 1: Current sites of clinical trials

Subacute shoulder subluxation	Kingston, Canada
Chronic Shoulder subluxation	Los Angeles, CA
Knee Osteoarthritis	Milan, Italy

METHODS

Subacute shoulder subluxation: Hemiplegic subjects are randomized 3-12 weeks after stroke into a control or experimental group. In experimental subjects, two BIONS are implanted into the middle deltoid and supraspinatus muscles, respectively. These are used to stimulate muscles daily for 6 weeks. Treatment is followed by a 'non-stimulation' period of 6 weeks. Control subjects receive only conventional physiotherapy for 6 weeks. If control patients meet inclusion criteria after this 6-week period, they are offered BION therapy. Outcome measures included shoulder subluxation, arm strength, arm range of motion, pain (Visual Analogue Score) and muscle thickness measured by ultrasound.

Chronic shoulder subluxation: A longitudinal repeated measures design will be used for subjects with stable shoulder subluxation resulting from a stroke more than 6 months before they enroll in the study. The first patient is currently under baseline testing and will be implanted February 2002.

Quadriceps Stimulation for Knee Osteoarthritis: Using a repeated measures design, subjects are first observed for 12 weeks to determine baseline state. They are evaluated with the Western Ontario-McMaster (WOMAC) knee function scale, Knee Society Function tests and Visual Analogue Scale for pain. Muscle cross-sectional areas are assessed using MRI. A BION is implanted next to the femoral nerve.

In all studies, stimulation starts with 3 10-minute sessions per day, increasing gradually to 30 minutes per session. We use low frequency (2-5pps) trains of stimuli (2-5s on/1-3s off) at an intensity sufficient to recruit most or all of the motor units in the target muscles (typically 2-8 times motor threshold).

RESULTS AND DISCUSSION

Fifteen subjects implanted with BIONS have been satisfied with the simple implantation procedure and absence of complications. A single subject did not complete the trial because of worsening mental confusion following his stroke. One BION was removed from a second subject after completing the experimental phase of the osteoarthritis trial because she experienced unpleasant but not painful sensations when soft tissues folded around the device, in the groin. Stimulation thresholds remain constant over time, indicating a stable foreign body reaction and little or no migration of the BIONS. Autopsy tissue from one stroke patient who died of unrelated causes after two years of successful BION treatment showed a little foreign-body response. The main problem to date has been the sensitivity of devices to the position of the RF coil. This problem should be corrected by a new data transmission system developed recently.

Sub-acute subluxation: A significant decrease was found between subluxation levels before and after 6 weeks of BION therapy ($p < 0.05$). If no BION therapy was administered, no significant changes occurred. Muscle thickness stayed the same or improved slightly with BION therapy, but tended to decrease without the electrically induced exercise.

Knee osteoarthritis: Significant improvement of Knee Society Scores, WOMAC scores and pain levels were found after 12 weeks of BION therapy for the 3 patients who have completed the trial ($p < 0.05$). One subject has cancelled knee replacement surgery because of the improvement.

Typically, BION patients were compliant with their therapy and found it pleasant to receive. Patients self-administered the therapy at home, avoiding the cost of a medical professional administering the therapy and making it a practical treatment for patients who may need chronic electrical stimulation to maintain the health and function of muscles and joints that cannot be exercised voluntarily due to upper motoneuron damage.

A LEG-PROPELLED WHEELCHAIR: BIOMECHANICS, ENERGETICS AND MODELING

RB Stein¹, KB James¹, A Kido¹, SL Chong¹, LA Tubman², GJ Bell³

INTRODUCTION

Conventional wheelchairs have been widely accepted by persons with motor disabilities and sufficient arm strength for propulsion. However, problems remain: 1) Many, if not most long-term wheelchair users, develop overuse injuries of their arms, as a result of the strenuous and somewhat unnatural movements that are needed to propel a wheelchair with the arms. 2) The disuse of the legs for persons who spend much of their time in a wheelchair leads to atrophy of leg muscles and osteoporosis of the long bones of the legs and an increased rate of bone breakage. 3) The lack of whole body exercise leads to a decrease in cardio-respiratory fitness and an increased incidence of heart disease. 4) Sitting in a chair all day can lead to pressure sores and other skin problems that are difficult and costly to treat. The purpose of these studies was to test a new, leg-propelled wheelchair to see if it could provide increased mobility and fitness for wheelchair users who retained some voluntary leg movements or who required functional electrical stimulation (FES) to move their legs.

METHODS

A commercially available wheelchair (Pro-SA, Invacare Inc., Cleveland OH) was modified for these tests [1]. Essentially, a single mobile footrest, which allows flexion/extension of the legs around the knee center, replaced the two stationary footrests. Both legs were attached to the new footrest by straps at the toe and heel. Rotation of the lower legs was coupled to the wheelchair. A steering lever was added that attached to one of the front, castor wheels. Rotation of the lever turned the direction of this wheel and hence the chair.

Subjects wheeled with the arms or the legs and walked (where possible) for 4 min. periods in random order with approximately 10 min. rest periods in between. The subjects included persons with complete spinal cord injury (SCI; n=9), other motor disorders (retaining some voluntary control of the legs, n=13) and control subjects (n=13). The physiological cost index (PCI) and oxygen consumption were measured. PCI is computed as the change in heart rate during exercise divided by the speed of movement.

RESULTS AND DISCUSSION

Arm-wheeling took significantly more effort (mean PCI = 0.52 beats/m.) than walking (0.33) in control subjects [2]. Leg-wheeling was most efficient (0.23), requiring less than half the effort of arm-wheeling and 30% less effort than walking. For SCI subjects leg-wheeling with FES required less than half the effort (0.18) of arm-wheeling (0.40). This group could not

walk. The voluntary group walked, but with substantial effort (1.81) compared to arm- (0.76) or leg-wheeling (0.64). The effort required during leg-wheeling for the voluntary group depended on the presence or absence of spasticity. Results for oxygen consumption were similar to those for PCI

For individual subjects we measured the passive properties of the legs and foot at rest (effective stiffness and viscosity), the length-tension (torque-angle) properties of the active muscle groups, as well as their force-velocity curve and their activation and fatigue rates. The measured values were inserted into a model of the leg-propelled wheelchair. The model could predict the performance of individual subjects accurately and was used to optimize the thresholds for switching between stimulating knee extension and flexion and vice-versa for subjects using FES.

Finally, we tested the capabilities of the wheelchair using 9 able-bodied female subjects, who performed a graded exercise protocol up to maximal levels using leg-wheeling and arm-wheeling on custom-designed rollers that simulated the effort of wheeling over ground. Leg-wheeling elicited significantly higher peak cardio-respiratory values than arm-wheeling. Yet, leg-wheeling was more efficient, since the cardio-respiratory responses were significantly less than arm-wheeling at all levels of sub-maximal work. Thus, subjects could propel a wheelchair longer and faster with the legs than the arms.

CONCLUSION

Better efficiency and increased mobility can be obtained for many disabled individuals, while exercising the leg muscles voluntarily or with FES. Biomechanical measurements can be incorporated into a simple model that can be used to optimise the performance of individual subjects. The greater efficiency allows subjects to wheel further and faster with the legs than the arms, as well as getting a better cardio-respiratory workout. We are now testing the usefulness of this device in the community.

ARM STIFFNESS AND STABILITY IMPROVED BY FNS IN C5-C6 SCI

Robert F. Kirsch¹ and Eric J. Perreault²

¹Case Western Reserve University, Cleveland, Ohio, USA rfk3@po.cwru.edu

²Northwestern University, Chicago, IL, USA e-perreault@northwestern.edu

INTRODUCTION

Estimates of the dynamic endpoint stiffness of the human arm were obtained in this study to quantify the mechanical properties of the arm and to investigate arm stability. Endpoint stiffness, defined as the relationship between externally applied displacements of the hand and the resulting forces, characterizes the mechanical interface humans use to interact with their environment. Endpoint stiffness is thus closely related to postural stability. Numerous studies have quantified endpoint stiffness properties in able-bodied individuals (e.g., Mussa-Ivaldi et al. 1985). Recently developed techniques (Perreault et al. 1999) have allowed us to examine postural arm stability in individuals with spinal cord injuries.

METHODS

Two subjects (three arms) with complete cervical level spinal cord injuries (C5 or C6 level) function were examined. None had voluntary elbow extension and all had voluntary elbow flexion. A single electrode delivered biphasic, 20mA current pulses from an implanted stimulator to the triceps muscle, which was fatigue resistant due to months of electrical exercise. The endpoint stiffness of the arm was estimated using 2 cm peak-to-peak stochastic displacement perturbations applied by a two-joint robotic manipulator. All measurements were made at a single location: the arm was held in a horizontal plane passing through the glenohumeral joint, with the hand positioned between the sternum and acromion at a distance approximately 0.45m anterior to the acromion. Endpoint stiffness measurements made with the subject at rest and during combined voluntary and stimulated muscle activation that resulted in zero net endpoint force. Two-dimensional stiffness dynamics were estimated using a previously described nonparametric system identification algorithm (Perreault et al. 1999). A second order system model was then fit individually to each of the four resulting transfer functions to extract elastic stiffness, viscosity, and inertia for each. The directional qualities of the 2D endpoint stiffness were represented graphically by transforming the inertial, viscous and elastic matrices into ellipses, as was first demonstrated by Mussa-Ivaldi et al. (1985). 2D compliance impulse responses were generated by simulating the endpoint trajectories resulting from a 1N force impulse applied at 16 orientations in the measurement plane. The path length of the resulting endpoint displacement trajectories was used as a quantitative measure of endpoint stability.

RESULTS AND DISCUSSION

Figure 1 summarizes the effects of triceps stimulation on the stiffness, viscosity, and stability of the arm of a subject with a

C5 level injury. Results on the left are for when the arm was at rest, and those on the right are for when the triceps was being stimulated and subjects voluntarily contracted elbow flexor muscles to compensate for the FNS-induced elbow extension moment. The endpoint elasticity and viscosity are shown by the ellipses at the top of the figure. Arm position is indicated by the stick figures. The 2D compliance impulse responses are shown at the bottom. The number in the *FNS+Voluntary*

trajectory ring is the ratio of the average trajectory path length with no stimulation to that during stimulation. The average path length decreased by a factor of 3.0 for this arm, and across all arms by an average of 2.3.

Figure 1: Effects of triceps FNS on endpoint stiffness, viscosity, and stability.

SUMMARY

We found that the endpoint dynamics of the SCI-impaired arm can be adequately described by a linear model

with inertial, viscous, and elastic parameters, and that triceps FNS improved arm stability for all tested conditions. Our results indicate that the additional information regarding arm function provided by the stiffness estimates should provide valuable information for the development of task-specific FNS control mechanisms that provide high stiffness when desirable and low stiffness when that is more appropriate.

FUNCTIONAL INTRASPINAL MICROSTIMULATION FOR RESTORING LIMB MOVEMENTS AFTER SPINAL CORD INJURY

VK Mushahwar¹, DM Gillard², MJA Gauthier² and A Prochazka²

Departments of ¹Biomedical Engineering and ²Physiology, University of Alberta, Edmonton, AB, Canada

INTRODUCTION

Recovery of function after spinal cord injury (SCI) remains a daunting medical challenge. The difficulty in achieving regeneration of functional neural connections in the central nervous system prompted the development of systems that use electrical stimulation of muscles or nerves to improve respiration, micturition and motor function. However, the electrical restoration of whole limb movements remains elusive. Intraspinal microstimulation (ISMS) may provide an alternative. The spinal cord is distant from moving muscles, so electrodes implanted therein are less likely to be dislodged or damaged. Moreover, the lumbar enlargement of the cord is relatively short (~5cm in adult humans), allowing activation of the main limb muscles and spinal locomotor neural networks by electrodes implanted in a small, protected region. Since 1992 we have been testing the feasibility of using this novel approach for generating functional movements of the legs. We found that ultra-fine electrodes placed in the ventral horn can activate limb muscles through ensembles of interneurons and motoneurons. Smooth and graded muscle contractions with little fatigue are obtained. ISMS through some electrodes generates single-joint movements while stimulation through others produces coordinated whole-limb synergies. Generated extensor synergies are powerful enough to bear the cats' weight. The implanted microwires remain securely in place for long periods of time and the implantation procedure causes minimal neural damage. These results suggested that ISMS may be a feasible approach for restoring motor function after SCI. It could also be used in conjunction with other rehabilitation approaches (e.g., treadmill locomotor training, regeneration and pharmacology) to maximize the functional benefits after injury. However, the feasibility of using ISMS for restoring functional walking remained untested. The following experiments were conducted to address this issue.

METHODS

Under pentobarbital anesthesia, the lumbosacral region of the spinal cord in 3 adult cats was exposed. Twelve insulated microwire electrodes (30 μ m dia., 30-100 μ m bared tips) were implanted in each side of the cord. The electrode tips targeted motoneuronal and premotoneuronal regions within the ventral horn. These locations were chosen based on results obtained in awake chronically-implanted animals in which ISMS through wires in the ventral horn produced functional flexor and weight-bearing extensor movements with no apparent discomfort. However, ISMS through dorsally located wires generated paw shakes and flexion-withdrawals but no weight-bearing extensor movements. Behavioral responses indicated that the cats perceived the stimuli in these cases.

The electrodes were anchored to the spinous process of vertebra L3 or L4 with dental acrylic and terminated in an external connector. The back wound was sutured shut in layers.

The cats were then placed in a sling leaving all limbs pendant. Trains of electrical stimuli (biphasic, charge-balanced, 2-300 μ A, 200 μ s, 25 or 50 pulses/s) were delivered through each electrode separately and the elicited limb movements were documented. Two to four electrodes in each side of the spinal cord that generated limb flexion or extension were selected. An open-loop controller was used to modulate the timing and amplitude of pulse trains through each electrode, to produce bilateral alternating stepping.

RESULTS AND DISCUSSION

In most cases, limb movements elicited by stimulating through individual electrodes could be predicted based on the anatomical distribution of motoneuron pools. However, stimulating through 1/3 of the electrodes generated full limb flexor or extensor synergies which were primarily attributed to the activation of spinal interneuronal networks. Phasic, amplitude modulated, ISMS through as few as 2 electrodes in each side of the spinal cord (one eliciting limb flexion and the other limb extension) generated near normal bilateral stepping. Typical stride lengths were 25cm (cf. ~30cm in normal cats) and ample foot clearance was achieved during swing. Mean ground reaction force during stance was 36.4 N and was sufficient for lifting the animals' hindquarters. However, stimulation through only 2 electrodes in each side of the cord to produce bipedal stepping required that the stimuli be delivered at high repetition rates (50 pulses/s) to elicit fused muscle contractions. This resulted in the early onset of muscle fatigue (typically after 15 steps). Muscle fatigue was circumvented by stimulating through 4 electrodes in each side of the spinal cord (2 generating flexor movements and 2 extensor movements) and interleaving the stimuli (25 pulses/s) between the electrodes that elicited similar mechanical actions. At the expense of doubling the number of electrodes, this stimulation strategy resulted in no observable muscle fatigue throughout the duration of the experiments (15 hrs).

The results show that by stimulating through relatively few intraspinal microwires and using simple control strategies, load-bearing walking could be achieved. The efficacy of ISMS in restoring functional stepping after chronic SCI is currently under investigation.

INTRODUCTION

Many control schemes, such as optimal control, prediction control, sample-data control, model-based control, and adaptive control have been suggested often focusing on possible use on humans with disability [1]. Our hypothesis was that a neural prosthesis for upper extremities would contribute the most to the recovery of functions if it implements life-like control, that is, if it is integrated in the biological movement scheme. The reasons behind this hypothesis are that life-like control will maximise reorganisation, i.e. provide the augmentation to an inherent capacity to self-organise sensory-motor systems throughout life.

REACH / GRASP / RELEASE COORDINATION MODEL

The biological control of reaching and grasping relies on high connectivity between individual joint movement that is, muscle activation during functional movements. This connectivity is being developed through a skill acquisition procedure, mostly in childhood. This connectivity allows that a single decision at the brain level is appropriately distributed to end organs. This co-ordination is achieved by the hierarchical and parallel organisation of the CNS, yet it can be assessed in different phase spaces (e.g., force space, EMG space, angular velocity space).

The co-ordination model that we introduce comprises three automatic, and one biological control level [2]. The highest control levels (decision and planning) allow the user to select an action and the modality of operation. The top automatic level co-ordinates spatial and timing synergies between joints; it applies a discrete rule-based control. This rule-based controller implements the state model of movement that is heuristically cloned using data acquired in able-bodied humans; thereby mimicking life-like movement. The lower co-ordination implements synergies at the joint level, that is, machine determined mappings between the arm segment angular velocities. The lowest, actuator level deals with patterning functional electrical stimulation (FES) of muscle groups being responsible for the flexion or the extension of a single joint, or potentially biarticular muscles. The actuator level uses continuous feedback control, and is fully model-based [3].

The implementation of this model has two phases. Phase 1 is general: it applies machine learning with the inputs and outputs generated from able-bodied kinematics when performing slowed down reaching and grasping of daily utilities. Phase 2 is individual and relates to customising of the stimulation map to a specific user. The customising relates to biomechanical parameters and muscle properties (recruitment, force vs. length, and force vs. velocity nonlinearities) [3].

An example of the stimulation map designed for grasping of a can, bottle, or cup; drinking from it, and returning it to the original post is shown in Fig. 1. The user should voluntarily select the task (keypad), and the flexible goniometer measuring

the shoulder movement would then govern the whole sequence of stimulation required for the accomplishment of the task. The number of tasks is infinite, yet many of them can be accomplished with the same strategy; thus, it was possible to use a practical size keypad for selection of the activity. The shoulder sensor generates information that drives the elbow, forearm and hand; a threshold with hysteresis was applied to eliminate switching noise (Fig. 1).

Fig. 1: Stimulation pattern for drinking from a cup. The activations were normalized. Arrows show the timing. Spatial synergy was used for the elbow. Ext - extension (dark), Flex - flexion (light fields).

CONCLUSION

The co-ordination model of reaching and grasping that we developed for upper extremity neural prostheses relies on analysed behaviour of functional movements in able-bodied subjects. The model allows the design of life-like control for FES that is preferential specially for neurorehabilitation because it provides synchronised activation of both afferent and efferent sensory pathways with the voluntary activity of preserved sensory-motor mechanisms [4].

MAXIMAL CYCLING POWER CAN BE SLIGHTLY INCREASED BY CONSTRAINING LEG KINEMATICS

A.J. "Knoek" van Soest (1) and Andy Ruina (2)

INTRODUCTION

In steady state bicycle riding the average crank power equals average muscle power (neglecting the dissipation in the joints and other soft tissue). Muscle power depends on muscle length and muscle stimulation as a function of time. Modeling the bike-crank-leg system as a 2D 5-bar linkage, there are two degrees of freedom, e.g. the crank angle and the ankle angle. When a suitable pattern of muscle stimulation (as a function of crank angle) is prescribed, and given a load model for the crank, periodic kinematics and power output are obtained. To what extent is the muscular potential for power production compromised by the requirement of producing a kinematic pattern that does not, say, hyperflex any joints? In other words, by how much could power output be enhanced if the leg kinematics were fully prescribed as a function of crank kinematics? Constraining the leg to a kinematic pattern it is already following does not alter the energetics of its present muscle use, but does allow new choices in muscle use. Thus, prescription of the current kinematics and subsequent re-optimization of muscle stimulation has to lead to an equal or (most likely) greater power output. To quantitatively measure the effect of constraint addition we performed power optimizations for a model without and again with an extra kinematic constraint.

METHODS

Numerical simulations were performed using a model of the musculoskeletal system. The skeleton was represented by a rigid foot, lower leg, upper leg, trunk, with the ball of the foot being attached to the crank through a hinge joint. The skeletal model is actuated by 8 Hill-type "muscles" per leg. The input of the model is the stimulation of the muscles; the output of the model is the resulting kinematics, kinetics and power output. The neural inputs are optimized with respect to the mechanical power output (while demanding periodicity) using a genetic algorithm for optimization. Optimization results for a standard, unconstrained model of 120 RPM isokinetic sprint cycling (van Soest and Casius, 2000) are compared to those for a model in which the leg kinematics (taken from the optimal solution for the standard model) is prescribed as a function of crank kinematics. A similar comparison is made for an arbitrary suboptimal stimulation pattern that yields 50% of optimal power in the absence of a kinematic constraint.

RESULTS AND DISCUSSION

For the optimal solution, total muscle power per leg for the normal (N) model increases from 537.9 W to 550.2 W (a 2% increase) when kinematics is constrained (C), the improvement largely being produced by Tib. Ant.. In contrast, the improvement caused by imposing kinematics is substantial when starting from a somewhat random stimulation pattern that results in 50% of maximal power (see Table). These results are reflected in a small effect of constraint addition on

the tangential pedal force for the optimal solution, and a substantial effect for the 50% power solution (see Figure).

	OPTIMAL		50% POWER	
	N	C	N	C
Tib Ant	12.2	20.0	-2.9	5.6
Soleus	53.6	54.0	-3.3	4.2
Gastroc	18.6	19.1	-3.7	11.2
Vasti	140.1	141.3	54.6	123.5
Rectus Fem	49.0	49.2	-28.8	46.4
Glut max	110.5	110.9	130.8	138.2
Hamstrings	56.8	56.9	66.7	79.3
Iliopsoas	97.0	98.6	55.4	70.0
TOTAL	537.9	550.2	268.8	478.5

It has been argued (Raasch et al., 1997) that in cycling, the activity of some muscles (mostly mono-articulars) is geared towards power production, whereas the activity of others (mostly biarticulars) is geared towards ensuring smooth transitions near top and bottom dead center. The negligible improvement in power output that results from constraining the kinematics for the optimal solution suggests that the optimal stimulation pattern results in kinematics in which all muscles perform near-optimally in terms of power production. In other words, even though biarticulars are not the most important power sources (see Table), their coordination is still geared towards production of power.

It remains to be investigated if the optimal kinematics for the normal, unconstrained system is also optimal for the constrained system and, if not, what the optimal constrained kinematics and the corresponding power output are.

THE MUSCULAR COMPONENT OF PEDALING FORCE IS NOT WELL DEFINED

Jim Papadopoulos¹ and Andy Ruina²

² Theoretical and Applied Mechanics, Cornell University

Ruina@cornell.edu, <http://www.tam.cornell.edu/~ruina/hplab>

INTRODUCTION

Multi-axis load-sensing pedals make it possible to determine the foot forces applied to the pedals as riders aim for certain goals in controlled circumstances such as maximum power at a given rpm and heart rate, the Wingate test, etc. As an example of what is now generally recognized now as a misuse of such data, some early investigators proposed that any radial force component (perpendicular to the pedal path) was harmful to performance. Given that pedal force data is collected and is subject to such misinterpretation, one would like a rational way to evaluate pedal force profiles. What identifies desirable or undesirable pedal forces?

Towards the end of better understanding pedal forces there have been a few attempts to decompose them into parts due to gravity, inertial reactions, and muscle forces. Ross and Miller (1980) proposed a scheme to determine the purely mechanical (gravity and inertia) component of a measured foot force. Kautz and Hull (1993) also proposed a force-decomposition method, which has been used by many researchers. Both of these methods are based on a 2D five-bar linkage model of the pedaling system (bike, crank, foot, calf, thigh). Another decomposition was proposed by Papadopoulos (1987) based on a four-bar linkage approximation (foot and calf combined).

We show that the two five-bar methods are effectively identical, being based (at least implicitly) on an artificial external torque on the foot. From a fundamental standpoint, other equally well defined measures could be defined by instead applying other artificial torques instead, for example to the calf or thigh. In all of these cases the decomposition fails to pass the reasonableness criterion that the net work of claimed muscle-based forces being equal over a revolution of periodic motion to the actual work of the foot on a pedal. On the other hand, the four-bar model is explicitly approximate.

METHODS

In all cases we assume the pedaling system is well modeled as an actuated planar linkage of rigid bodies. Thus all analysis is of the robotics type, being based on momentum and energy balance of a system of interacting rigid bodies.

RESULTS

If an actuated mechanism has one degree of freedom, all joint forces, including for example the force on the pedal, can be rigorously decomposed into a sum three sets: one from gravity, one from inertial terms, and one from actuation

(muscle forces). In this case, the work of the foot on the pedal over a cycle is equal to the work of the muscular (actuated) component over a cycle. The four bar linkage model fits this criterion. However a five bar linkage, having two degrees of freedom, does not allow such a unique decomposition. The fictitious torque approach to making a five bar linkage determinate unfortunately leads to an explicit violation of energy balance; the work of the foot on the pedal is mismatched to the calculated work of the muscular component by the amount of work performed by the fictitious torque.

Another view of the fictitious-torque approach is as a fictitious kinematic constraint. But equally legitimate constraints, on other parts than the foot give rise to different force decompositions (which also violate the energy reasonableness criterion) and give different muscular component of foot forces.

The lack of definition of muscular force comes from the extra kinematic freedom of the five-bar system. Without muscle forces the kinematics would be wild and nothing like actual pedaling. Thus the muscles are needed for postural reasons. The force without muscles is not defined, because the motion could not occur. And with muscles there is no way to fundamentally separate postural from propulsive muscular contractions.

SUMMARY

Because a useful pedal force decomposition ought to be usable for calculating net muscular power, we conclude that all the five-bar methods must be viewed as either wrong or essentially approximate. And the four-bar method, while theoretically better grounded, is explicitly approximate.

We doubt the existence of a well defined muscular component of pedal force and thus question any but approximate reasoning based on the concept.

MECHANICAL ENERGY FLOW DURING MAXIMAL CYCLING

James C. Martin and Bruce M. Wagner

Neuromuscular Function Laboratory, The University of Utah, Salt Lake City, Utah

INTRODUCTION

Internal work has been defined as the work done to accelerate the limb segments (Winter, 1979) and has been assumed to do no external work during gait. Internal work is also thought to be lost during cycling (Wells et al., 1986). However, Ingen Schenau et al. (1990) reported that net joint muscular power during cycling was equal to the sum of power delivered to the crank and the rate of change of mechanical energy in the limb segments (\dot{E}). The sign of the \dot{E} term varied within each crank cycle, indicating that energy was transferred to and from the limb segments and thus may perform external mechanical work. The purpose of this investigation was to determine the quantity of energy lost and transferred as external work to the cranks via the limb segments.

METHODS

Five male cyclists (76 ± 5 kg) performed maximal cycling trials during which pedaling rates ranged from 58 to 190 rpm. The right pedal was equipped with two 3-component piezoelectric force transducers (Kistler 9251) and the pedal and crank were equipped with position sensors (Vishay Spectrol 601-1045). Pedal forces, and pedal and crank position were recorded at a frequency of 200Hz. Two dimensional leg kinematics were determined from the geometric relationships of a five-bar linkage (Hull and Jorge, 1985). Velocity and acceleration terms were determined by finite differentiation. Net joint moments at the ankle, knee, and hip were determined using inverse dynamic techniques (Elftman, 1939). Joint power was calculated as the product of joint moment and joint angular velocity. Pedal forces were decomposed into muscular, gravitational, and inertial components (Kautz and Hull, 1993). Non-muscular crank power was calculated from the gravitational and inertial pedal forces and moments, and crank and foot angular velocity. Kinetic and potential energy in each limb segment were determined from the mass, position and velocity of the center of mass, moment of inertia, and angular velocity of each segment. \dot{E} was determined by finite differentiation. Finally, gravitational and inertial pedal forces and moments were used to determine the net joint moments required to produce those observed non-muscular pedal forces and moments.

RESULTS AND DISCUSSION

Summed joint power was equal to the sum of total crank power and \dot{E} throughout the crank cycle. The non-muscular component of crank power was equal in magnitude but opposite in direction to \dot{E} . Joint power associated with non-muscular pedal forces was equal to the sum of non-muscular power delivered to the pedal and \dot{E} .

Example data for 1 revolution at a pedaling rate of 190 rpm. The rate of change of mechanical energy stored in the limbs (\dot{E} ; ◆) was equal and opposite to the crank power generated by non-muscular pedal forces (◇). The sum of all joint powers which contributed to non-muscular pedal forces (□) was equal to the sum of the crank power and \dot{E} (—).

In this investigation, we used force decomposition to explore the relationships among \dot{E} , net joint power, and non-muscular crank power. We conclude that the energy delivered to the limb segments is conserved rather than lost. That energy is stored for some portion of the crank cycle and subsequently exits the limb segments to perform external work. The ability of the limbs to transfer kinetic and potential energy into external work at the cranks supports the conclusions of Ingen Schenau et al. (1990) who wrote that "...the majority of the power associated with the decrease of segmental energy benefits the power transferred to the pedal..."

These data might be interpreted to suggest that the cost of moving the limbs during cycling should be zero. However, it has been reported that the metabolic cost of producing zero power output increases with increasing pedaling rate (Sidossis et al., 1992). Although some investigators have attributed that increase to mechanical energy losses, the present data do not support that explanation. Rather, they suggest some other phenomena, most likely viscous loss in muscle tissue, are responsible for the that increase in metabolic cost.

THE METABOLIC EQUIVALENT OF INTERNAL WORK IN CYCLING

Alberto E. Minetti

Centre for Biophysical and Clinical Research into Human Movement
Manchester Metropolitan University, UK, a.e.minetti@mmu.ac.uk

INTRODUCTION

While the concept of mechanical internal work (\dot{W}_{INT}) comes from the straightforward need to account for reciprocal acceleration of body segments (not affecting the trajectory of the overall centre of mass, BCOM), its use in walking/running has been debated in relation to the potential interference with external work. This paper is about \dot{W}_{INT} estimation and its metabolic relevance in cycling, where the movement of lower limbs is supposed not to remarkably affect the overall BCOM.

MATERIALS AND METHODS

In a previous paper (Minetti et al. 2001) we measured \dot{W}_{INT} by 3D motion analysis of a stationary cyclist pedalling at different rates. We concurrently developed a rationale for the theoretical estimation of the internal work in cycling, which ended up in the following model equation:

$$\dot{W}_{INT} = k \text{freq}^3$$

where \dot{W}_{INT} is in watt per kilogram, freq in Hz and k reflects the inertial characteristics of the moving segments (lower limbs). The experimental \dot{W}_{INT} data was fitted by the model which proved to be sound (resulting in $k = 0.153$).

In order to get information about the metabolic equivalent of \dot{W}_{INT} we recently undertook the re-elaboration of data from Francescato et al. (1995). The authors measured the oxygen consumption (\dot{V}_{O_2} , W) of subjects pedalling on a cyclo-ergometer at different combinations of external power (\dot{W}_{EXT} , range 20-125 W) and pedalling frequency (range 40-100 RPM). A second set of experiments was done by applying the same protocol to the same subjects after having loaded the lower limb segments with additional mass (+40%).

The model equation for \dot{W}_{INT} was incorporated in a new one,

$$\dot{V}_{O_2} = \frac{(\dot{W}_{EXT} + 75k \text{freq}^3)}{\text{eff}}$$

representing the main determinants of oxygen consumption, where the brackets contain the total mechanical work (assuming the complete separation between the external and internal parts). The value 75 means the mass of a typical subject (since our previous equation was expressed in W/kg, while the data from Francescato et al are in W).

This equation was used as a non-linear multiple regression (Systat, USA) to fit the experimental data from Francescato et al. (1995) and estimate the two unknowns: k (see \dot{W}_{INT} model equation) and eff , namely the efficiency of the conversion of metabolic into mechanical work.

RESULTS AND DISCUSSION

For the unloaded (UL) set of experiments from Francescato et al (1995) the results of the regression were $k_{UL} = 0.150$ (very close to our previous estimation) and $\text{eff} = 0.270$ ($R^2 = 0.980$, $n = 20$). When the same procedure is applied to the loaded experiment (L), the results are $k_L = 0.241$ and $\text{eff} = 0.284$ ($R^2 = 0.942$, $n = 20$).

The results show that: a) the variability of \dot{V}_{O_2} can be almost entirely explained by the different contribution of \dot{W}_{EXT} and \dot{W}_{INT} , both in UL and L conditions, b) k_L is close to what expected on the basis of limb loading ($k_L = 1.4$, $k_{UL} = 0.21$, the difference being probably due to the mass positioning on the limbs), c) R^2 values are high enough to suggest a small effect of assuming, in the regression equation, a constant eff for all the pedalling frequencies and external work. The obtained results allow one to compute the metabolic equivalent of the mechanical internal work of cycling as:

$$\dot{V}_{O_2,INT} = 0.556 \text{freq}^3 \quad \text{or} \quad \dot{V}_{O_2,INT} = 1.66 \text{freq}^3$$

(W/kg) (Hz) (mlO₂/(kg min)) (Hz)

The re-processing of data from Francescato et al (1995), obtained by using a model equation for \dot{W}_{INT} (Minetti et al 2001) indicates that the internal work in cycling can represent a remarkable portion of the metabolic energy expenditure, particularly at high pedalling rates (e.g. about 13.3 mlO₂/(kg min) at 120 RPM).

INTRODUCTION

The total mechanical work done by muscles during a given locomotor task is often assumed to include two independent quantities: "external work" (work done to overcome external resistance, which can be accurately measured) and "internal work" (putative work done to accelerate and decelerate the leg segments, which cannot be directly measured). However, recent pedaling simulation studies have illustrated how muscle forces generate and redistribute energy within the musculoskeletal system to overcome the external workload (e.g. Neptune et al., 2000). Muscle force can cause significant energy transfer from the legs to the environment at given instants during the pedaling cycle such that the external power (rate of doing external work) exceeds the mechanical muscle power. We hypothesize that muscles accelerate and decelerate the legs as an integral part of performing external work, and that there is no **additional independent** mechanical cost associated with moving the legs (i.e., internal work).

METHODS

To investigate this hypothesis, a forward dynamics simulation that emulated observed pedaling kinematics and kinetics of young adult subjects was used (Neptune et al., 2000). The musculoskeletal model and simulation were developed using SIMM/Dynamics Pipeline (MusculoGraphics Inc.) and consisted of a fixed pelvis and right and left legs. Each leg consisted of a thigh, shank, foot and fourteen individual Hill-type musculotendon actuators. The hip, knee and ankle joints were modeled as frictionless revolute.

Figure 1: From approximately 350-95°, muscles generated more power than was delivered to the crank, resulting in an increase in leg power (dME/dt is positive). From 95-170°, even though muscles perform significant positive work and little negative work, the energy of the legs decreased as the muscles transferred more energy from the legs to the crank than was generated by the muscles themselves.

RESULTS AND DISCUSSION

The putative "basis" for calculating internal work is that decreases (increases) in the total mechanical energy during pedaling (Fig. 1) are due to mechanical energy absorption (production) of muscles. However, total mechanical energy decreases are coincident with both external work done at the crank and negative muscle power (Fig. 1). Furthermore, the negative muscle power is not closely matched to the decreasing total energy, with the peak decrease at 110° coinciding with relatively little negative muscle power and substantial negative muscle power occurring with increasing energy at 180°. The most powerful deceleration of the legs is caused by concentric activity in the ankle plantar flexors (e.g., Fig 2.). By acting to decelerate the leg, they transfer energy from the leg to the crank that allows them to deliver much more energy to the crank than they produce.

Figure 2: **A)** Between 90-180°, the gastrocnemius (GAS) transfers significantly more power from the legs to the crank than it produces. **B)** GAS acts to accelerate the foot powerfully into plantar flexion, which creates a pedal reaction force that accelerates the crank and intersegmental forces that decelerate the leg, and therefore reduce its energy.

While muscle forces increase and decrease the leg energy, the energy lost in the deceleration of the legs can and does generate a pedal force tangential to the crank, and thus does positive external work against the environment. As a result, the muscle work done to *increase* the total energy of the legs (considered to be one component of internal work) can be subsequently recovered as external work during the *decrease* in total leg energy (considered to be the other component of the internal work). Therefore, the internal work hypothesis is invalid as a direct measure of the mechanical energy cost associated with moving the legs in pedaling.

THE "EVOLUTION" OF BICYCLE DESIGN AND ITS EFFECTS ON THE EFFICIENCY AND ECONOMY OF CYCLING

P. Zamparo^{1,2} A.E. Minetti¹

¹ Centre for Biophysical and Clinical Research into Human Movement, Manchester Metropolitan University, UK

² Dipartimento di Scienze e Tecnologie Biomediche, Università degli Studi di Udine, I, p.zamparo@mmu.ac.uk

INTRODUCTION

During the whole nineteenth century the combination of the need for individual mobility at an affordable price and the current technological advances produced a rapidly flourishing "evolution" of the bicycle towards higher speeds and better riding economy. In the 1820-1890 time span the speed gain was the result of concurrent technological advancements of wheeled human-powered vehicles and of the "smart" adaptation of the same actuator (the muscle) to different operational conditions (Minetti et al. 2001). The evolution of bicycle design was investigated by measuring the total mechanical work and the energy cost of riding the most relevant historical bicycles.

METHODS

Experiments were performed by 5 subjects (56 ± 11 years, 1.7 ± 0.4 m height and 68 ± 3 kg mass) riding historical bicycles at sub maximal speeds, on a flat concrete road. The investigated bicycles were the Hobby Horse (HH, 1820s), the Bone Shaker (BS, 1860s), the High Wheeler (HW, 1870s), the Rover (RO, 1880s), the Safety (SA, 1890s) and a modern bike (MB, 1970s) as a mean of comparison. For each bicycle: 1) the work to overcome rolling resistance (W_R) was calculated by means of coasting down experiments; 2) the work to overcome air resistance (W_A) was obtained from air density, frontal area and assuming a drag coefficient of 1.1; 3) the mechanical internal work (W_{INT}) was computed from 3D motion analysis (Minetti, 1998); and 4) the economy of progression (C , J m⁻¹) was calculated from the ratio of net metabolic power expenditure (VO_{2NET}) to the speed (v). The net mechanical efficiency (η) of riding each bicycle was computed from the ratio of total mechanical work (W_{TOT} (J m⁻¹) = $W_R + W_A + W_{INT}$) to the net energy cost (C).

RESULTS AND DISCUSSION

At an average net metabolic power of 350 W (e. g. about 1 lO₂ min⁻¹) the improvement in bicycle design allowed one to double the speed of progression: from 2.8 to 5.6 m s⁻¹ in HH

and MB, respectively. The increase in speed was obtained by decreasing the work spent against rolling resistance (W_R : from 24 - 26 J m⁻¹ in HH and BS to 6.6 - 6.7 J m⁻¹ in SA and MB) and the internal work (W_{INT} from 9.8 to 2.5 J m⁻¹ in HH and MB, respectively) whereas the work spent against air resistance (W_A) increased according with the increase in speed (from 2.3 in HH to 9.4 J m⁻¹ in MB). The decrease of W_{TOT} from HH to MB (from 36.3 to 18.5 J m⁻¹) was matched by a proportional decrease of C (from 136 to 70 J m⁻¹) so that the efficiency of cycling remained fairly constant from the nineteenth century to the modern times (0.27 ± 0.01). The relationship between η and progression speed was found to be a downward parabola in each bicycle; its maximum value was attained at increasing speeds (from 2.2 to 5.0 m s⁻¹ in HH and MB, respectively) but at a similar pedalling frequency (of about 1 Hz), a rate which was suggested to be the optimum one for Type I fibers in cycling (Sargeant and Jones, 1995). This finding indicates that bicycle design was not only effective in decreasing the frictional forces residing outside the body, but also allowed the muscles to contract in their optimal operational conditions.

Among the other aspects in bicycle design not considered in this study, two further improvements played an important role in the evolution of cycling: 1) the introduction of the multiple gear system by which muscle contraction speed was made independent from the progression speed; and 2) the adoption of streamlined fairing by which the work spent against air resistance was dramatically reduced (Gross et al., 1984).

PEDAL MOTION DIRECTION AND THE CONTROL OF FOOT FORCE DURING PEDALING

Kreg G. Gruben

Departments of Kinesiology, Biomedical Engineering, and Mechanical Engineering
University of Wisconsin-Madison, Madison, Wisconsin, USA
gruben@education.wisc.edu

INTRODUCTION

Upright human posture is critically dependent on the control of leg muscles to generate force against the ground with appropriate direction and magnitude. The direction of this force must be controlled independent of limb motion. The purpose of this study was to examine the preferred directional control of force for a variety of limb motions at a given limb posture.

Total foot force results from inertia and forces of gravity and muscle while only the muscle component of foot force is directly controlled by the nervous system. Thus, study of nervous system control requires isolating the muscular component of foot force. We accomplish this by constraining limb motion so that the contributions of gravity and inertia are constant. Any changes in total foot force are then due exclusively to muscle action.

Previously we have shown that humans increase foot force with a directionally invariant strategy while pushing against both stationary and moving pedals (Gruben 1999, Gruben & Lopez-Ortiz 2000a, 2000b). The path of the tip of the foot force vector is well-described by a straight line. The orientation of the force path varies around the crank cycle in a pattern that appears to track the changes in pedal velocity direction (Gruben 1999). This changing orientation may be due to changes in limb posture or an attempt by the nervous system to align foot force with the pedal motion to increase mechanical efficiency of power transfer to the crank. However, these effects covary during the task of circular pedaling. Here we determine the effect of pedal motion direction on the orientation of the force path lines.

METHODS

Five healthy adult humans performed pushing efforts against a pedal while it moved in a reciprocating manner along a linear path. A motor controlled pedal motion to be independent of foot force (travel= ± 0.165 m at 40 cycles per second). While lying on their right side on a horizontal platform, participants generated force against a moving pedal with their left foot to match five force target levels. Five directions (40,50,...,80°) of linear pedal motion that passed through a common reference pedal position were tested in sequence. Lines at the extreme

angles passed anterior to the knee or posterior to the hip. The pedal measured the sagittal-plane components of the foot force. For each participant and each pedal motion direction, we constructed a force path as the set of foot forces measured at the instant the pedal passed through the reference pedal position. The orientation of each force path was determined by principal components analysis.

RESULTS

The force paths were well characterized by straight lines. Force path orientation was not affected by the direction of the pedal motion (Fig. 1). The line-of-action of the force paths passed anterior to the hip joint and posterior to the knee joint. The mean force path orientation passes within 0.01m of the whole body center-of-mass (CM) of the typical participant.

SUMMARY

Force path linearity and consistency in direction suggest that the motor control system has a preferred pattern of force output that is independent of limb motion and is directed approximately at the CM. Consistently directing foot force toward the CM is critical for upright posture. Observation of this control in a task that did not require foot force to provide any postural support indicates that this control strategy may be a critical component of a variety of lower limb actions.

Fig. 1 Force Path Orientation Force path orientation (mean \pm sd) was independent of pedal motion direction ($p=0.18$). Each line is the mean of the five participants for one pedal motion direction.

CYCLING BY MEANS OF FES: SIMULATION AND PRACTICAL APPLICATION

Margit Gföhler¹, Thomas Angeli¹ and Peter Lugner²

¹Department of Machine Elements, Vienna University of Technology, Vienna, Austria, email: margit.gfoehler@tuwien.ac.at

²Department of Mechanics, Vienna University of Technology, Vienna, Austria

INTRODUCTION

Functional Electrical Stimulation (FES) has been explored as a means of restoring lost function in the spinal cord injured (SCI). Specific training with FES combines the physiological benefits of the muscle training with the psychological incentive of independent locomotion. In this study, cycling on a tricycle for SCI-subjects using multi-channel FES was investigated in a forward dynamic simulation. The efficiency of the movement is increased by an optimized pedal path, which is realized by a four bar linkage (Angeli et al., 1999). Besides this pedal path, the overall performance is essentially influenced by a number of configuration and stimulation parameters that may be different for each subject.

METHODS

For the dynamic simulation, the rider-cycle system was modeled as a planar rigid body system with frictionless pin joints (Fig. 1). The muscle forces are applied as joint moments. The musculotendon actuators were modeled by a Hill-type mechanical model that was enlarged to provide the proper FES-stimulation behavior.

Figure 1: Scheme of the rider-cycle system with three bar linkage for realization of the optimized pedal path.

Activation patterns for the stimulated muscles / muscle groups gluteus maximus, quadriceps, hamstrings alone and hamstrings and iliopsoas together activated by peroneus reflex were optimized for maximum power output with respect to the angular velocity of the crank. Forward dynamic simulations of steady state cycling and a startup with 50% of maximum muscle activation were used to analyze drive torques and mean power per cycle and the resulting riding performance of the

rider-cycle system. A number of individual parameters are considered in the simulation.

RESULTS AND DISCUSSION

The simulation provides information on the optimal stimulation patterns (Fig. 2), drive torques and power applied to the pedal by the stimulated muscles.

Figure 2: Optimized stimulation patterns for averaged user-specific parameters at crank angular velocity 150 %s.

The results of the simulation and practical tests on a mobile tricycle have shown that SCI-subjects are able to move a tricycle independently with muscle force generated by FES. Still, there are parameters like electrode placement, spasm activity and fatigue which are difficult to predict.

SUMMARY

In this study, FES-cycling on a tricycle was investigated in a forward dynamic simulation. The stimulation patterns were optimized with respect to drive power efficiency for surface stimulation of gluteus maximus, quadriceps, hamstrings, and peroneus reflex assuming averaged individual parameters. The results can be used not only for estimating the riding performance of an individual SCI-subject, but also for the layout of a controller for FES-cycling.

MUSCLE FIBER TYPE EFFECTS ON ENERGETICALLY OPTIMAL PEDALING CADENCE

Brian R. Umberger¹, Karin G.M. Gerritsen², & Philip E. Martin¹

¹Exercise & Sport Research Institute, Arizona State University, Tempe, AZ, USA (brian.umberger@asu.edu)

²Human Performance Laboratory, University of Calgary, Calgary, AB, CANADA

INTRODUCTION

Metabolic energy expenditure exhibits a curvilinear dependence on pedaling rate during steady-state, submaximal cycling. The most economical cadence typically occurs around 50-60 rpm, and has recently been shown to be significantly higher (by 6-7 rpm) in explosively-trained athletes than in endurance athletes (Hintzy et al., 1999). Muscle fiber type differences between subjects were suggested to cause the observed differences in energy optimal pedaling rates, but were not directly assessed. Such experimental investigations are complicated by factors such as individual variations in training history, or difficulties in measuring muscle fiber type distribution. These problems can be circumvented using computer modeling and simulation techniques. Specifically, muscle fiber type distribution can be precisely controlled for each muscle, and studied in isolation from other potentially confounding effects. The purpose of this study was to assess whether differences in muscle fiber type, *per se*, affect most economical cadences as proposed in the literature.

METHODS

Forward dynamic simulations were generated of steady-state pedaling (200 W) at cadences from 40-120 rpm by solving a combined tracking/energy-minimization problem using numerical optimization. The cyclist and bicycle were modeled as 9 rigid segments (trunk, 2 thighs, 2 shanks, 2 feet, crank, frame) actuated by 12 Hill-type muscles per leg. Frictional and inertial loads were applied at the crank to simulate the dynamics of overground riding. Dynamic properties of the muscles (force-velocity relations and active state dynamics) were scaled with fiber type to produce a slow twitch model and a fast twitch model. Static properties (e.g., force-length relations) were identical between models. Metabolic energy expenditure, which also depended on muscle fiber type, was estimated using a model of human muscle energy expenditure (Umberger et al., 2001). Muscle excitation patterns were optimized to minimize the differences between simulated and experimental crank torque and pedal angle data, while simultaneously minimizing energy expenditure. Separate optimizations were conducted for both models at all cadences.

RESULTS AND DISCUSSION

Both the fast twitch and slow twitch models were able to pedal at the target power and cadences (within $\pm 1\%$), while reproducing the major features of experimental pedaling data. Optimized muscle excitation patterns also showed broad agreement with experimental EMG data. The dependence of total body energy rate (including heat liberated by the head, arms, and trunk) on pedaling cadence for the two models is

shown in Figure 1, along with group mean data taken from several experimental studies (e.g., Marsh & Martin, 1993). The energy rates predicted by the two models tended to bound the published experimental values, consistent with muscle fiber type distributions higher than, and less than, average.

Figure 1: Whole body energy rate at different cadences for models with fast twitch (o) and slow twitch (x) muscles, along with experimental data (.) from various studies.

Predicted most economical cadence was higher for the fast twitch model (53 rpm) than for the slow twitch model (48 rpm); a deviation similar to that reported by Hintzy et al. (1999). Differences in the two economy curves can largely be explained by the dependence of muscle mechanical efficiency on pedaling rate in the two models. Mechanical efficiency was higher for the slow twitch model and peaked at a lower cadence than in the fast twitch model. Other factors that influenced the shapes of the global economy curves with increasing cadence were the growing contribution that muscle energy liberation made to total energy, and increasing work done against joint viscosity.

SUMMARY

Differences in energetically optimal pedaling rates have been proposed to be due to variations in muscle fiber type. However, fiber type distribution has usually not been adequately characterized. The results of this computer simulation study suggest that between-subject differences in muscle fiber type do indeed contribute to differences in energetically optimal cadences as suggested in the literature.

MUSCLE FIBRE PROPERTIES AND OPTIMAL CADENCE IN CYCLING

Anthony J. Sargeant

Centre for Biophysical and Clinical Research into Human Movement,
Manchester Metropolitan University, ST7 2HL, United Kingdom. a.j.sargeant@mmu.ac.uk

INTRODUCTION

The identification of optimal cadences for human movement has been the subject of many investigations dating back to, and beyond, Benedict and Cathcart (1913). In this paper the optimal cadence for cycling is considered in relation to three aspects of muscle function; generation of maximum muscle power; muscle fatigue during sustained exercise; and the energy cost of generating muscle power.

Optimal cadence and Maximum Muscle Power:

The optimum velocity of muscle contraction for maximum power output is a frequently used reference point in isolated muscle studies, but its significance in human locomotory exercise has been less widely recognized (despite e.g. A.V.Hill 1922). However, using an isokinetic cycle ergometer system it was possible to identify an optimal pedaling rate of ~120 revs/min for maximum power output during cycling in a large group of male and female subjects (Sargeant, Hoinville and Young, 1981). Subsequently it has been shown that the optimal cadence can be influenced by the effect of, for example, changes in muscle temperature and exercise induced fatigue, a phenomenon which has been termed “acute plasticity” (for review see e.g. Sargeant 1999).

Optimal cadence and the delay of muscle fatigue in sustained exercise:

Human performance is usually dependent upon the ability of skeletal muscle to both generate power, and sustain that power – that is, resist fatigue. At the level of the whole muscle it will be obvious that in sustained exercise a critical factor will be the proportion of the maximum ‘available’ power that is required for the task. Recently it has been reported that in a group of normal healthy males the proportion of the maximum available muscle power required at maximum oxygen uptake when pedaling at 40, 60, 80, 100 and 120 rev/min was respectively 55, 45, 38, 35 and 29% (Zoladz, Rademaker, and Sargeant, 2000): This is simply a consequence of the parabolic nature of the maximum power/velocity relationship but it implies a much greater ‘reserve’ of muscle power at the faster pedaling rates. At first sight this would suggest an advantage to also choosing the optimal pedaling rate for maximum power during submaximal sustained exercise. This however ignores the impact of possible changes in the relative contribution of different muscle fibre types with their different levels of fatigue resistance and mechanical efficiency. Clearly any potential benefit of choosing fast pedaling rates and maintaining a high ‘reserve’ of muscle power generating

capability will be negated if there were a disproportionate increase in energy cost or a reduced resistance to fatigue.

In very short sprints requiring power to be sustained for ~10 s there is typically a reduction of a ~25% in delivered power due to fatigue of a small population of the most powerful but also most fatigue sensitive type II muscle fibres. That fatigue is associated with depletion of high-energy phosphates as shown by analysis of single human fibres isolated from needle biopsy following sprint exercise (Karatzafiri, De Haan, van Mechelen, and Sargeant 2001)

Optimal cadence for generating mechanical power at minimal energy cost:

If exercise is to be sustained for more than a few contractions the efficiency with which chemical energy is transformed into mechanical energy may be of critical importance. Unfortunately little is known about the mechanical efficiency/velocity characteristics of human muscle fiber types. It could be expected that maximal efficiency would occur at a velocity close to, but slightly less than that for maximum power. This suggests an optimal pedaling rate for maximum mechanical efficiency of ~60 rev/min for type I human muscle fibres and ~130 rev/min for the mean of type II. In agreement with this suggestion we have recently been able to show that in high intensity aerobic exercise where type I fibres make the dominant contribution to power output increasing leg muscle temperature results in a decrease in efficiency at 60 rev/min but an increase in efficiency at 120 rev/min. Such opposite changes would be consistent with a rightward temperature shift in the efficiency/velocity relationship (Ferguson, Ball, and Sargeant 2002).

EXAMINATION OF KNEE CONTROL VIA TWO INDUCED ACCELERATION MODELS

Thomas M. Kepple, Karen Lohmann Siegel, and Steven J. Stanhope

National Institutes of Health, Physical Disabilities Branch, Bethesda, MD, USA, tkepple@cc.nih.gov

INTRODUCTION

Although induced acceleration methods can be powerful tools for analyzing the control of the knee joint during walking (Siegel et al., 2001), the results obtained from these models depend on the selection of an appropriate foot-floor constraint. Kepple et al. (1995) previously compared a constraint system that fixed the foot to the floor during foot-flat with one that allowed the foot to rotate about the center of pressure. The fixed-foot model produced a discontinuity in the induced acceleration data when the constraint was released at heel-off. It is not known if this discontinuity is physically realistic. The alternative method of allowing the foot to rotate about the center of pressure produces no discontinuity but does result in increased knee accelerations which may indicate an under estimation of the contribution of the knee extensors to the ground reaction force (Kepple et al., 1995). Neptune et al. (2001) used a visco-elastic foot-floor model in an attempt to more accurately represent the actual foot-floor interface during a simulated walk. The purpose of this paper was to apply a similar visco-elastic model in an induced acceleration analysis and compare it to the previous fixed-foot model.

METHODS

Using a six-camera Vicon system (Oxford Metrics Inc.), data were collected from a single female adult subject walking at a self-selected pace. The subject supplied informed consent under an IRB approved protocol. For each frame of video data, Visual3d software (C-Motion Inc) generated a Solver dataset, which was loaded into ADAMS software (Mechanical Dynamics Inc.). The data set contained a three-dimensional biomechanical model derived from that of Kepple et al. (1997). This model included seven anatomical segments: two feet, two legs, two thighs and a single head-arms-trunk segment. The knees were modeled as revolute joints, the hips were modeled as spherical joints and the ankles were modeled as a universal joints with one medial/lateral axis and one anterior/posterior axis.

Two foot-floor constraints were used and compared. The first constraint (fixed-foot constraint) fixed the foot to the floor during foot flat and allowed the foot to rotate about the center of pressure after heel off. The second constraint was an eight element visco-elastic model based on Gerritsen et al. (1995). The Gerritsen model was modified slightly so that the coefficient used on the vertical displacement in the damping term was reduced to a first order. This change was required in order to allow the visco-elastic deformations to build up in a short enough time period so that there was little change in the position of the segments.

RESULTS AND DISCUSSION

The data indicate that there is generally good agreement between the two models. The mean differences between the models were 27.3 rad/s^2 . The sources of knee acceleration for both models are presented in Figure 1. The fixed-foot model produced the expected discontinuity at heel-off while the visco-elastic model tended to make this transition more smoothly.

Figure 1. Acceleration induced at the knee by the lower extremity joint moments. Data from the fixed-foot model are in black and data from visco-elastic model are in gray.

SUMMARY

Although the visco-elastic model produced a smoother roll-off, the general shapes of the induced acceleration histories were very similar, increasing the confidence that the fixed-foot model correctly estimates the role of the knee extensors during foot-flat. These results are also important because the fixed-foot model produces similar results to the more difficult to implement and computationally expensive visco-elastic model.

GENERATING DYNAMIC SIMULATIONS OF MOVEMENT USING COMPUTED MUSCLE CONTROL

Frank C. Anderson¹, Darryl G. Thelen², and Scott L. Delp³

^{1,2,3} Department of Mechanical Engineering, Stanford University, Stanford, California, USA, ¹ fca@stanford.edu
² Honda Fundamental Research Laboratories, Mountain View, California, USA

INTRODUCTION

Dynamic simulation is a powerful approach for investigating how the elements of the neuromusculoskeletal system interact to produce movement; however, computing neural excitation patterns that produce coordinated movements is difficult. Using dynamic optimization to solve this problem can be computationally costly (Neptune and Hull, 1998) and difficult to implement (Kaplan and Heegaard, 2001). Yamaguchi et al. (1995) devised a pseudo-inverse method for computing muscle forces, but this method does not incorporate the dynamic properties of musculotendon actuators and requires the use of a specific optimization performance criterion. In this paper, we introduce a new approach to computing muscle excitation patterns which we term computed muscle control (CMC). We illustrate the algorithm by computing a set of muscle excitations for pedaling.

METHODS

The CMC algorithm is applied at each time step during a forward dynamic simulation (Figure 1). In a manner similar to computed torque control (Lewis et al., 1993), feedback is used with linear gains (k_v, k_p) to drive the kinematic trajectory of a dynamic model ($\bar{q}, \dot{\bar{q}}$) toward a set of desired experimental kinematics ($\bar{q}_{exp}, \dot{\bar{q}}_{exp}, \ddot{\bar{q}}_{exp}$). Static optimization is used to resolve actuator redundancy by computing a set of desired muscle activations (\bar{a}^*) that would generate a set of desired accelerations (\ddot{q}_d) when steady-state conditions within the muscles are present. Then, an excitation controller is used to transform the desired activations into the excitations (\bar{u}) that drive the forward dynamics model.

Figure 1: Computed Muscle Control Algorithm.

The pedaling model had 3 degrees of freedom and was driven by 30 musculotendon actuators (Neptune and Hull, 1998). Activation dynamics was modeled as a first order process with activation and deactivation times of 15 ms and 50 ms, respectively. Average crank angles and pedal forces from Neptune et al. (1997) were used as experimental input. In the static optimization problem, the sum of squared muscle activations was used as the performance criterion (Anderson and Pandy, 2001), with additional equality constraints included to track the experimental pedal forces (\bar{f}_{exp}).

RESULTS

A set of muscle excitations that produced a coordinated pedaling simulation was found using 15 minutes of computer time on a 1.7 GHz Pentium 4. Simulated kinematics were within one degree of experimental values, simulated pedal forces were within two standard deviations of measured forces (Figure 2(a)), and computed excitations were similar in timing to electromyographic (EMG) patterns (Figure 2(b)).

Figure 2: (a) Computed (black line) and experimental (shaded area) radial pedal forces. (b) Computed muscle excitations for two muscles (solid black lines). A simulated annealing solution (dashed lines) and on-off times from EMG signals (shaded bars) are also shown (Neptune and Hull, 1998).

DISCUSSION

The speed and ease of implementation of the CMC algorithm greatly improves the feasibility of using detailed musculoskeletal models to simulate and analyze movement. The CMC algorithm predicts continuously varying excitations and is approximately two orders of magnitude faster than a simulated annealing approach (Neptune and Hull, 1998). The improvement in speed derives from the fact that only a single forward integration of the state equations is needed, in contrast to the thousands typically required by dynamic optimization.

FORWARD DYNAMIC MODELING OF ACUTE INJURY: EFFECTIVE METHODS FOR OPTIMIZATION, VALIDATION, AND EXPERIMENTATION

A. J. (Ton) van den Bogert, Anne Su, Scott G. McLean, Xuemei Huang

Department of Biomedical Engineering, Cleveland Clinic Foundation, Cleveland OH, USA

bogert@bme.ri.ccf.org, <http://www.lerner.ccf.org/bme/>

INTRODUCTION

When human subjects are used to study mechanisms of acute musculoskeletal injury, we are limited to performing experiments that are within the limits of safety. Computational modeling is the only technique that allows the injury mechanism itself to be studied, and has already found widespread acceptance for simulation of passive movements during vehicle collisions. Only recently have computational models been used to study an acute injury during active movement (ankle sprain, Wright *et al.*, 2000).

The current state of the art has a few limitations that we are trying to overcome. Optimization of a model to fit human movement data typically takes weeks of computer time (Neptune *et al.* 2000) and it is generally not known if a global optimum has been found. Validation experiments must be added to guard against overfitting, which could produce a good fit of the target movement but poor predictions of other movements such as injuries. Finally, experimentation with acute injury mechanisms requires a statistical approach so that conclusions are not based on a single case that was simulated.

COMPUTATIONAL METHODS

A software library was written for forward dynamic musculoskeletal modeling, including Hill muscle models, contact force calculations, and equations of motion generated by SD/FAST (PTC, Needham MA). The easy to use API allows short project-specific driver programs (~500 lines of C code) to be developed quickly. During initialization, the library reads a model description from a text file. The library was optimized for speed, mainly in the muscle modeling computations. Instead of a 3-D muscle path based on geometry, fast regression equations compute only muscle length and its derivatives, the moment arms, as a function of joint angles. The effect of muscles on joint reaction loads is not needed for movement simulation but can still be computed during postprocessing. Occasional extreme stiffness of the differential equations for muscle contraction was overcome by lower bounds on the isometric contractile element force (10 N) and on active state (1%).

RESULTS AND DISCUSSION

Results are shown from a model that was developed to simulate anterior cruciate ligament (ACL) injury during sidestepping. Movement was simulated for 200 ms after heelstrike, and muscle stimulation patterns were optimized using a simulated annealing algorithm to fit a subject's mean movement and ground reaction forces (Neptune *et al.*, 2000). Optimization required 165,000 simulations, 36 hours on a 800 MHz Pentium III. Repeated optimizations confirmed that the optimum was global.

The ability of the optimized model to predict the effect of perturbed initial conditions was quantified by performing simulations starting with the initial conditions of each movement trial. In forward dynamic simulations of unstable systems the prediction error tends to grow exponentially over time. A predicted variable was considered "useful" until the time when the prediction error exceeded the between-trial standard deviation (Fig. 1b). For most variables, predictions were useful for about 100 ms.

Figure 1: (a) Simulated and measured vertical ground reaction force. (b) RMS prediction error and variability. Note that prediction errors rise to 250 N in 200 ms, while the fit error is much smaller.

Once validated, 50,000 more simulations with randomly perturbed initial conditions were performed to study the potential effect of joint angles and angular velocities at heelstrike on ACL injury (Fig. 2). Such Monte Carlo simulations are an effective method to generate a statistically meaningful sample of simulations that can then be further analyzed to quantify probability of injury and study input-output relationships.

Figure 2: Histogram of peak ACL loads obtained by Monte Carlo simulation (N=50,000). Note the logarithmic vertical scale.

We conclude that acute musculoskeletal injury can be effectively studied using validated computational methods. Computation speed is essential, and so is the use of statistical methods for validation and experimentation.

INTRODUCTION

Joint centers and axes of rotation, referred to here as “joint parameters”, are fundamental elements of quantitative gait analysis. Joint parameters derived in the traditional manner are influenced by significant random and systematic errors [Leardini 1999]. In this study we present a new method for determining joint parameters, based on the application of kinematic constraints. The functional method is the most well known alternative method for locating hip centers. Imaging studies and simulations have shown the functional method to be accurate [Leardini 1999, Piazza 2001]. However, recent data indicate that the functional method's variability may be unacceptably large for clinical gait analysis [McDermott 2001]. The functional method is also limited by its restriction to spherical joints, thereby excluding hinge-like joints such as the knee. The results of this study show that the kinematically constrained (KC) method is repeatable and objective for the estimation of both hip and knee parameters.

METHODS

Assume the point \mathbf{q} is a joint center, and is therefore shared by adjacent segments. A motion that maps the segments from time t_k to time t_l satisfies the kinematic constraint,

$$(\mathbf{T}_p - \mathbf{T}_d)\mathbf{q} = \mathbf{T}_p\mathbf{O}_p - \mathbf{T}_d\mathbf{O}_d + (\tilde{\mathbf{O}}_d - \tilde{\mathbf{O}}_p). \quad (1)$$

$\mathbf{T}_{p,d}$ describe the re-orientation of the adjacent segments during the interval, while $\mathbf{O}_{p,d}$ and $\tilde{\mathbf{O}}_{p,d}$ are the segment origins at the interval's end-points. The axis of rotation \mathbf{L}_{kl} , passing through \mathbf{q} at t_k is found using the singular value decomposition theorem. By choosing a second interval with the same starting time, (t_k, t_m) , a second axis of rotation can be found (\mathbf{L}_{km}). The joint center \mathbf{q}_k at time t_k is the mutual intersection of all such axes; determined by first finding the intersections of each pair of axes, and then finding the mode of these pair-wise intersections [Fig. 1]. The average axis of rotation is defined as the mode of the instantaneous axes.

Table 1: Trial-to-Trial Variation: Repeatability

Figure 1. A transverse plane view of the Pelvis (diamonds are the L/R ASIS and PSIS). The KC based hip center (circle) is located at the mode of the pair-wise axis intersections (dots).

Repeatability and objectivity were evaluated using a single healthy adult. The subject donned a standard clinical marker set with additional markers on the thigh and shank that permitted four independent segmental coordinate systems (CS) to be defined. During each session, 10 hip-centering trials (bi-lateral circumduction) and 10 knee-centering trials (flexion-extension) were conducted. Hip centers were calculated using one

pelvic CS and four thigh CS. Knee centers and average knee axes were calculated using four thigh CS and four shank CS.

RESULTS

Hip centers are expressed in the Pelvic CS: Orig. = mid-ASIS, (X,Y,Z) = (ant, lat, sup). Knee parameters are expressed in the Thigh CS: Orig. = mid-condylar, Y = bi-condylar axis (lat), (X,Z) = (ant, sup). Trial-to-trial variations in joint parameters were calculated to assess repeatability [Table 1]. Within trial variations, due to choice of coordinate system (CS-CS), were calculated to measure objectivity [Table 2]. For the CS-CS data, SD and range were calculated for each trial over all CS-CS combinations, and then averaged over the 10 trials.

DISCUSSION

The joint parameters derived with the kinematically consistent method are repeatable and objective. The medial lateral position of the knee center (K_Y) is not well localized by the KC method (1.5 cm SD, 4cm total range). The objectivity data indicate that CS-CS outliers contribute to the high K_Y uncertainty (Range/SD > 4.0). In contrast, the knee axis is well defined. Thus, a hybrid of KC and traditional methods could be used to better locate K_Y . The objectivity and repeatability results suggest that inter-observer consistency should be similar to the inter-trial results. This has been seen in an earlier study [Schwartz 2001]. Further trials are currently being analyzed to re-confirm this hypothesis. The experimental design does not allow for a direct evaluation of accuracy (e.g. RSA, MRI). Indirect measures, including comparisons with regression based hip centers, the mid-condylar point and the bi-condylar axis, are favorable.

INTRODUCTION

Total knee replacement (TKR) has proved to be effective in the elimination of pain associated with degenerative osteoarthritis. Some TKR recipients, however, experience patellofemoral problems, including anterior knee pain, patellar dislocation, and mechanical inefficiency of the extensor mechanism that may limit functional performance postoperatively. Placement of the femoral component in internal-external rotation is both technically challenging and likely to directly influence patellofemoral mechanics. The purpose of this study was to investigate the effects of this surgical error on the actions of muscles using a computer simulation of a seated knee extension task in TKR.

METHODS

The three-dimensional musculoskeletal model upon which the simulation was based included 5 segments (pelvis, femur, patella, tibia, and foot), locked hip and ankle joints, and 6 DOF each at the patellofemoral and tibiofemoral joints. The forces produced by 10 muscles crossing the knee were predicted using a muscle model that incorporated force-velocity as well as active and passive force-length relationships (Delp et al, 1990; Schutte et al., 1993). Medial collateral, lateral collateral, and patellar ligaments were modeled as nonlinear elastic tensile springs (Wismans et al, 1980). Knee extension was driven in open-loop fashion by an excitation signal supplied to rectus femoris (RF) and vastus lateralis (VL), intermedius (VI) and medialis (VM) that was derived from measured EMG (Wilk et al, 1996).

Equations of motion were developed and integrated forward in time using the SIMM/Dynamics Pipeline (MusculoGraphics, Inc.) and SD/FAST (Parametric Tech. Corp.) software packages. A rigid-body contact model was used that permitted multiple frictionless contacts at the patellofemoral and tibiofemoral interfaces. Contacts occurring with an approach velocity normal to the implant surfaces that was above a certain threshold were treated as impacts that were handled by stopping the integration, reassigning velocities using an experimentally determined coefficient of restitution, and restarting the integration. Implant surfaces (IB-II; Zimmer) were located with respect to the bones with the assistance of an orthopaedic surgeon. Misplacement of the femoral component was performed by internally and externally rotating it by 5° about the axis defined by the center of the femoral

head and the midpoint of the transepicondylar axis. The initial position was determined in each case by performing preliminary simulations in which no muscles were active.

RESULTS AND DISCUSSION

Muscle forces and patellofemoral contact forces were smaller when the femoral component was rotated either internally or externally when compared to forces in the unrotated case (Table 1). VM forces were reduced more by internal rotation than they were by external rotation (–10% vs –7%), but the opposite was true for VI (–6% vs –15%) and VL (–9% vs –18%). Internal rotation medially shifted the patella by 4 mm and medially rotated it by 4°. Changes opposite and approximately equal in the patellar motions occurred when the femoral component was rotated externally.

	5° IR	unrotated	5° ER
peak RF force (N)	21.5	23.4	21.0
peak VM force (N)	98.7	110.1	102.2
peak VI force (N)	104.5	111.3	94.9
peak VL force (N)	147.4	161.2	132.4
peak PF force (N)	352.6	397.2	334.1

Table 1: Simulated peak forces in quadriceps muscles and at the patellofemoral (PF) interface with femoral component internally rotated (IR), unrotated, and externally rotated (ER).

These results demonstrate the manner in which component malalignment may affect implant kinematics, but also show how the interaction between the implant and the musculoskeletal system is altered. Similar effects on patellar kinematics were simulated by Heegaard et al. (2001) for internal rotation but not for external rotation. This difference may be due to the use of a more sophisticated contact model or the assumption of constant quadriceps forces.

ON LOW-COST STRATEGIES FOR REDUCING FALL-RELATED INJURIES IN THE ELDERLY

James A. Ashton-Miller, Ph.D.

Department of Mechanical Engineering, Department of Biomedical Engineering, Institute of Gerontology, University of Michigan, Ann Arbor, Michigan, USA [jaam@umich.edu]

INTRODUCTION

Fall-related injuries are projected to reach an annual cost of \$85 billion in the United States by the year 2020 (Englander 1996). Direct medical costs are highest in those over 65 years. Fall-related injuries become more serious with advancing age: for example, twice as many individuals 85 years and older die from falls as do those 65 years and younger. Tinetti found that one-third of community-dwelling elderly fall each year. Some 15 % of these result in serious injury, with women at increased risk. Two-thirds of elderly fallers sustain minor injuries. Even when no injuries result, increased fear of falling can limit activities. Slips and trips cause approximately 50% of these falls, the most common fall direction is forwards, and the upper extremity is the most frequent injury site. However, as Hayes and others have shown, a fall onto the hip will often result in fracture if the impact load exceeds the capacity of the bone to withstand it; these injuries have the greatest morbidity and mortality. So Rule 1 (to avoid a hip fracture) might be: “Avoid hip impact with the ground”.

THE APPROACH

A central tenet of our work is that fall-related injuries are not inevitable: a significant proportion may be prevented using a variety of low-cost strategies. That hypothesis remains to be tested. But given that “an ounce of prevention is worth a pound of cure”, what might that “ounce” of prevention be? How about starting with a set of rules to fall safely by – whether forwards, sideways or backwards. These rules should be based on impact dynamics, and how age affects neuromuscular control and physical and cognitive capacities, learning and memory.

Our low-cost interventions aim to involve a few minutes intervention to yield a lasting change in behavior. The individual must see value in the intervention, learn the skill, and then retain it over months or, preferably, years. A recent doctoral student in my laboratory showed that healthy young males can learn in 10 minutes how to arrest a standardized forward fall with 27% smaller impact forces than normal and 40% less than with straight arms (DeGoede & Ashton-Miller, 2002). These results suggest Rule 2 (for avoiding wrist injury): “Avoid using a straight arm to arrest a fall”. Specifically, for a given fall velocity, it is the combination of elbow flexion angle and wrist-ground relative velocity that determines the impact force. A more recent study showed that some young males retained the ability to arrest a forward fall with reduced impact for several months without practice (McCabe et al. 2001). My own recent experience, tripping at a fast walking speed, showed me that it is possible to fall onto a cement sidewalk without sustaining so much as a scratch. But exactly how this was accomplished is not understood yet

in physical terms. However, we conclude that there is usually plenty of time for the elderly to deploy their arms to protect themselves in a fall (DeGoede et al. 2001).

Traditionally, all falls are viewed as “bad”. But the above studies raise the possibility that healthy individuals may actually need to fall every so often in order to retain the ability to arrest falls safely. A 1-year prospective study in 1100 community-dwelling elderly showed that the mean proportion of falls resulting in serious injury was 7, 4, and 1% for those reporting 1, 2 or ≥ 3 falls per year, respectively (Tinetti et al., 1995), a trend that supports the above contention.

Our studies of forward fall arrests using the lower extremity showed highly significant age and gender differences, and considerable leg strengths being required for rapid stepping responses (Thelen et al, 1997 & 2000, Wojcik et al. 2000 & 2001). Rapid rates of torque development are needed to accelerate the limb, and considerable joint power is required to complete a large step in time, underlining the need for the elderly to retain as much physical capacity as possible.

We have shown that healthy elderly, and even healthy young adults, can unintentionally fall over a stripe of light (when asked to avoid stepping on it, should it suddenly come to their attention, Chen et al, 1994). Healthy elderly could not avoid it reliably if their attention was divided between stepping over it and responding to a secondary (visual-oral reaction time) task (Chen et al. 1996). Neuropsychological measures of executive function were predictive of difficulty with this task (Persad et al. 1995). Thus, Rule 3 (for avoiding fall-related injuries) might be: “Do not allow yourself to be distracted when approaching any hazard/obstacle (that can cause you injury)”.

TAI CHI EXERCISE AND THE PREVENTION OF FALLS IN ELDERLY TRANSITIONING TO FRAILTY

Robert J. Gregor^{1,2}, Steve L. Wolf³

¹School of Applied Physiology, Georgia Institute of Technology, Atlanta, GA

²Center for Human Movement Studies, Georgia Institute of Technology, Atlanta, GA

³Department of Rehabilitation Medicine, Emory University School of Medicine, Atlanta, GA

INTRODUCTION

Ninety percent of hip fractures reported in the United States occur in people over the age of 65. Cost estimates for hip fractures alone are extremely high with most fractures due to falling. In light of these statistics, development of innovative and/or alternative approaches to reduce the severity or incidence of falls appears warranted. Recent emphasis in the exercise and rehabilitation communities has focused on interventions designed to delay or reduce the risk of falling in older adults. In a recent review of exercise programs and their impact on falls risk (Gregg, et al., 2000) physical activities, specifically activities focused on balance and lower extremity strength, were highlighted. For example, the FICSIT trials (Wolf, et al., 1996) were reviewed. The FICSIT trials explored novel interventions including balance, flexibility, endurance, resistance training and physical therapy exercise. Among the balance training therapies was a 16-week Tai Chi intervention that resulted in a 47.5% delay in the onset of first or multiple falls, compared to a 16-week Wellness education or computerized balance training groups. Results from recent studies also suggest an intense Tai Chi training program may improve strength, balance, and flexibility and reduce blood pressure and resting heart rate.

While there is a need for practitioners of geriatric medicine to develop new therapeutic approaches designed to preserve functional ability and to prevent falls in older adults, much of the current information reported is on generally healthy, robust older adults. This investigation was undertaken to study the effects of an intense Tai Chi intervention on older adults transitioning to frailty (Speechley, M. and M.E. Tinetti, 1991).

METHODS

Data reported here represent measurements taken on a group of 50 older adults, volunteers, transitioning to frailty. The group is a self-selected subset of a larger group of 286 older adults recruited at 20 different congregate living facilities to participate in a clinical trial to compare fall rates in an intense Tai Chi exercise intervention group against an education wellness program group as controls (Wolf, et al., in review). Knee extensor strength assessments were made on a Kin Com isokinetic device and gait and balance measures made using two force platforms (Kistler) and a high-speed motion capture system (Peak Performance Technologies). Gait analysis

included trials focused on initiating gait in three discrete directions, gait kinematics and kinetics at a self-selected walking speed and a series of trials (50) involving unexpected turns in three discrete directions as a vehicle to induce unexpected perturbations.

All measures were made during a baseline session before intervention, every four months during the 48-week intervention (Tai Chi twice a week or a Wellness Education class once a week) and then every four months during a one-year follow-up. A total of seven testing sessions over a two-year period were conducted for each of the 50 subjects.

RESULTS AND DISCUSSION

For most of the baseline characteristics the subset of 50 volunteers were similar to the rest of the larger group. There were significant differences however, in two aspects, i.e. the subset of volunteers walked for exercise more regularly and took fewer sedatives than did the larger group. Because of these differences, the subgroup, while remaining in the broadly defined population of “transitioning to frailty” (Speechley, M. and M.E. Tinetti, 1991) was slightly more robust than the larger group. Gait features in the subgroup were also more variable supporting the hypothesis that older adults transitioning to frailty will have greater variability in their gait. The implications these results have on our interpretation of kinematic and kinetic aspects of gait and balance in this subset of 50 subjects will be discussed.

SUMMARY

These data represent results from an extensive analysis on an underrepresented population of older adults, i.e. those transitioning to frailty. Additionally, an intense exercise Tai Chi intervention had very positive effects on rates of falls and selected gait related variables compared to the data from the Wellness Education group. Finally, a more refined set of parameters must be utilized to better define certain subsets in the elderly, i.e. transitioning to frailty.

EFFECT OF HIP PROTECTORS AGAINST HIP FRACTURES

Jes Bruun Lauritzen

Department of Orthopedic Surgery, Traumatology & Hip Clinic, Hvidovre Hospital,
University of Copenhagen, Denmark
Associate Professor DMSc, jblauritzen@dadlnet.dk

INTRODUCTION

Increased research and understanding of the biomechanics of hip fracture has made hip protection a recommended strategy by The European Commission in the "Report on Osteoporosis in the EC – action for Prevention 1998", and a Cochrane review (1999) concludes, that hip protectors seem to reduce the occurrence of hip fractures in selected populations with high risk.

NURSING HOMES RESIDENTS

The positive effect of external hip protectors against hip fractures has been studied in five randomized trials in nursing homes (table 1) and one combined nursing home/ home-dweller study (Cameron).

HOME-DWELLERS

Data are sparse among home-dwellers. Our controlled case cohort study among elderly orthopedic in-patients indicate a comparable effect among those with risk factors for hip fracture (Hindsø & Lauritzen, 2001). Follow-up 1 to 1½ year; n 1590. Primary acceptance was 57%. Users reported 143 falls with impact on the hip protector, and no hip fractures occurred. Two hip fractures occurred while the patients used their hip protectors, but no impact on the hip was reported.

PRIMARY ACCEPTANCE AND ADHERENCE

Compliance has been questioned with the first prototypes, but improved in later studies. Primary acceptance may reach 75 to 100 %. Long-term adherence at two years was 40% in the home-dweller study by Hindsø & Lauritzen (2001).

COST-SAVING

Preliminary, the hip protectors seem cost-saving among elderly women or men.

SUMMARY

Hip protectors are an important supplement in the prevention of hip fractures among nursing home residents, and may also prove to be beneficial among elderly frail home-dwellers.

TO FALL OR NOT TO FALL: THE THRESHOLD OF BALANCE RECOVERY FROM A FALL

Cécile Smeesters, Ph.D.

Mechanical Engineering, University of Sherbrooke, Sherbrooke, Quebec, Canada [cecile.smeesters@gme.usherb.ca]
Research Centre on Aging, Sherbrooke Geriatric University Institute, Sherbrooke, Quebec, Canada

INTRODUCTION

It is only recently that researchers have focused their attention on the biomechanics of responses of both young (YA) and old (OA) adults to postural disturbances that are large enough that balance recovery was not always possible, and on the **mechanisms** responsible for balance recovery during these large postural disturbances. This limited subset of studies on the threshold of balance recovery from a fall is described here.

DISCUSSION

Hsiao and Robinovitch (1998) showed that YA (22-33yrs), who attempted to prevent a fall after the gymnasium mattress they stood upon was abruptly translated, were more likely to fall after *anterior* translations of the feet (63%) when compared to *posterior* (22%) or *lateral* (28%) translations. Most of those who recovered took more than one step.

Wojcik et al. (1999) showed that the maximum *forward* lean angles, YA (19-29yrs) and OA (67-81yrs) could be suddenly released from and still recover balance by taking a single rapid step, were 31.6° and 20.1°, respectively. **Step velocity** and lean angle WERE strongly correlated, but volitional **strengths** in plantarflexion and hip flexion as well as **reaction time** WERE NOT (Wojcik et al., 2001).

Using a concealed obstacle, Pavol et al. (1999; 2001) induced *forward* trips during gait in OA (72±5yrs) who were allowed to use multiple steps. Falls occurred in 16% of trips and WERE associated with faster walking speed and more anterior head-arms-torso centre of mass at the time of the trip, **delayed support limb loading**, excessive lumbar flexion, and/or buckling of the recovery limb. In a similar study with YA males (27±6yrs) and females (29±15yrs), they DID NOT find relationships between voluntary eccentric **strength** of the trunk or hip extensors, voluntary or automatic **reaction time**, **activation amplitudes** and trunk kinematics (Grabiner et al., 1996). Furthermore, in a study similar to that by Wojcik et al. (1999) using the same OA, these authors showed that **postural steadiness** and **stability limits** WERE NOT related to the maximum *forward* lean angle of 15.5° (Owings et al., 2000). Finally, they induced slips during gait in YA (27±4yrs) (Brady et al., 2000). Falls *backwards* occurred in 54% of slips and WERE associated with longer slip durations and displacements, faster velocities of the slipping foot, and smaller angles between the shank and the floor at heel-strike.

Pai (1999) determined a 62% failure rate for balance recovery in YA (22-40yrs) who stood on a platform that suddenly and unexpectedly slipped during the termination of a sit-to-stand task, producing a *forward* translation of the feet. Fourteen (14) of the 15 subjects initiated a backward step and all but one

used multiple steps. The authors showed that a **delay in the step initiation** MIGHT HAVE contributed to substantial descent of the centre of mass, leading to falls by limb collapse.

Cham and Redfern (2001) induced slips in YA (19-30yrs) during gait and showed that the corrective strategies involved in balance recovery included increased knee flexion and hip extension. Falls *backwards* occurred in 25% of slips.

We studied recovery of YA (18-36yrs) from *forward* trips of sustained duration and showed that the threshold trip duration for which balance recovery with a single rapid step is not possible IS associated with volitional hip flexor **strength** and volitional **foot lift-off time** (Smeesters et al., 2001).

CONCLUSIONS

Therefore, the knowledge on the threshold of balance recovery from a fall is still very limited and discrepancies exist between studies on the **mechanisms** responsible. To expand the body of knowledge in this area, we recently complete studies on the effect of age and gender on maximum hip flexion **power** at low and high velocities (Smeesters et al., Submitted) as well as on the abilities of YA and OA to adjust *medio-lateral* step location during a *forward* fall (Thelen et al., Submitted). Results from both of these studies will be presented at this congress.

PHYSICAL PERFORMANCE FACTORS AND FALLS BY OLDER ADULTS: WHAT IS THE WEAKEST LINK?

Tammy M. Owings¹, Michael J. Pavol², Mark Grabiner³,

²Department of Physical Therapy³ and ³School of Kinesiology, University of Illinois at Chicago, Chicago, Illinois and

³Department of Biomedical Engineering, Cleveland Clinic Foundation, Cleveland, Ohio, grabiner@uic.edu

INTRODUCTION

Despite explicit objectives & targets for HP2000, the hospitalization rate for hip fractures was not improved during the 1990's. The Healthy People 2010 program has 28 focus areas, one of which relates to injury prevention, in general and death from falls and hip fractures, in particular. Hip fractures account for about 60% of total hospitalizations for fractures. Since 90% of hip fractures result from falls, the failure to achieve improvement in this public health issue underscores the need for continued research efforts to uncover treatable causes of falls.

Highly visible and widely disseminated position statements regarding exercise and physical activity as means to improve resistance to falls explicitly endorse postural stability and muscle strength as risk factors for falls. For example, "Physical activity...appears to be protective against falling...probably by increasing muscle strength and balance" (US Department of Health and Human Services, 1996). Further, the American College of Sports Medicine maintains that "... benefits from exercise include...improved postural stability, thereby reducing the risk of falling...and fractures".

Age-related changes to postural control and muscle strength likely contributes to the increased incidence of falls by some populations of older adults, perhaps most notably in frail older adults. It is reasonable to expect that age-related changes in postural control influence the likelihood of requiring a stepping response following a postural perturbation. However, it may not be reasonable to expect changes to postural control, in and of themselves, to directly influence the success of the stepping response, which represents a time critical coordination of multiple joint systems.

In contrast, it does seem reasonable that changes in muscle strength and/or power would influence the success of the stepping response. However, a threshold below which strength and/or power must decrease to significantly increase the probability of falls has not been defined. Indeed, in a study of healthy older adults subjected to unexpected trip induced under laboratory conditions, both the strongest and the weakest were unable to avoid falling (Pavol et al., in press).

We previously reported that the contribution of lower extremity coordination to performance of a time critical task was independent of lower extremity strength and accounted for a similar amount of variance (Tomioka et al, 2001). This suggests that even in the presence of adequate strength, the ability to avoid a fall following a large perturbation can be significantly diminished by inadequate lower extremity coordination.

METHODS

A group of 79 older adults were subjected to unexpected accelerations of a motorized treadmill to 0.89 m/s in about 150 ms (Owings et al, 2002). A previously described algorithm based on data from an instrumented safety harness was used to determine if the recovery effort from each trial was successful. Five recovery attempts were collected, with each trial lasting five seconds. The initial attempt was considered an "untrained" response.

RESULTS AND DISCUSSION

Repeated exposure to the treadmill perturbation resulted in a rapid adjustment of recovery biomechanics that resulted in a substantial improvement in the recovery rate. Of the 23 subjects who fell during the perturbation of the first trial, 18 successfully recovered during the second attempt. The modified recovery responses closely approximated the successful initial recoveries. Specifically, the successful, modified recoveries were marked by a faster reaction time, increased recovery step length, smaller trunk flexion angle at toe-off and at recovery foot ground contact, and smaller trunk flexion velocity at toe-off and at recovery foot ground contact, as compared to the failed initial attempt. The rapidity of the response suggests that it occurred independently of changes in muscle strength and or power, and postural control. Collectively, these findings suggest the potential for developing and using the protocol as a clinical tool.

INTRODUCTION

Postural responses are typically described as a pattern of muscle activations or a trajectory of joint motions, each triggered by a disturbance. Although these descriptions are highly useful, one drawback is that they do not describe the biomechanical constraints that limit possible responses. These constraints, such as the maximum allowable ankle torque, imply that postural responses cannot simply scale with perturbation magnitude. Instead, they must change behavior in such a way as to accommodate constraints while still maintaining stability. We devised a continuous feedback control model to test whether postural responses, to backwards perturbations of the support surface, can be described in terms of feedback control gains, and whether these responses are scaled appropriately to accommodate biomechanical constraints.

METHODS

Fig. 1. Feedback control model.

We used a simplified model of human body dynamics in the sagittal plane, incorporating ankle and hip joints. These dynamics were stabilized by a continuous feedback loop, using a set of linear state feedback gains that are selected according to perturbation magnitude. The length of the foot relative to body weight places a constraint on the maximum allowable ankle torque that can be exerted against the support surface, making feedback gains that are used for small perturbations inappropriate for larger perturbations.

We applied fast backward perturbations to 13 healthy young human subjects to provide data for comparison with model. There were five perturbation magnitudes ranged 3 – 15 cm, applied in random order, with each magnitude applied five times in a block. Subjects were asked to maintain balance without stepping or lifting the heels. We measured kinematics and ground reaction forces, and used inverse dynamics to estimate joint torques. For each magnitude, we identified a set of model feedback gains that best matched the kinematics and joint torques, and resulted in a stable closed-loop system. We then examined whether these gains are scaled to accommodate biomechanical constraints on ankle torque.

RESULTS

We found that the simple model was able to reproduce experimental responses reasonably well (Fig. 2), with an average fit $R^2 = 0.91 \pm 0.04$ (s.d.).

Fig. 2. Experimental kinematics and joint torques compared with feedback model fit.

We next tested whether these gains are scaled by the central

nervous system to accommodate the constraint on allowable ankle torque. We found that all feedback gains changed as a function of perturbation magnitude. In particular, ankle torque response to ankle motion (ankle gain T_{ank}/θ_{ank}) decreased as perturbations increased. In the absence of constraints, a single set of gains will stabilize the body for any perturbation magnitude. But with constraints, the allowable ankle torque would be exceeded for larger perturbations. The reduction of ankle gain ($p < 0.01$) indicates that the constraint is accommodated as expected.

Fig. 3. Feedback control gains vs. perturbation magnitude.

CONCLUSIONS

The results show that the trajectories of joint angles and joint torques are gradually scaled with perturbation magnitude. Feedback gains were found to be multivariate in character, meaning that the torque produced at any joint is generally a function of motions not only at the same joint, but other joints as well. The gains also scaled nearly linearly with perturbation magnitude, in accordance with biomechanical limitations on ground reaction torque. The postural adjustments can be described as a feedback scheme with scalable gains.

IMPORTANCE OF PLANTAR-SURFACE MECHANORECEPTION IN POSTURAL CONTROL.

Stephen D. Perry¹, Brian E. Maki², William E. McIlroy^{2,3} and Aftab E. Patla⁴

INTRODUCTION

Sensation from the bottom of the feet has primarily been overlooked as an important contributor to the control of balance. The age-related loss of this sensation has been well documented. In addition to the age-related loss of plantar-surface cutaneous sensation excessive cushioning, found in present day athletic footwear, may further impair this sensation. Our studies and others have demonstrated the contribution of plantar-surface mechanoreception to postural control.

Methods used to understand the role of plantar-surface cutaneous sensation have involved both patients with loss of sensation (e.g. diabetic neuropathy (Inglis et al, 1994), surgical reconstruction of the plantar skin flap (Hamalainen et al, 1992), experimentally induced changes in sensitivity (e.g. hypothermia (Magnusson & al, 1990), standing on foam rubber (Wu and Chiang, 1997), anesthetic (Do et al, 1990)) and facilitation (with ball bearings (Watanabe and Okubo, 1981)). Many studies of postural control have focussed on the measurement of sway during quiet, unperturbed stance. Each study has demonstrated some evidence of a role for mechanoreception in balance control. Recently, vibration applied to the heel and metatarsal region of the sole of the foot induced leaning in the direction opposite to the vibratory stimulus (Kavounoudias et al, 1998), providing a strong indication of the involvement of cutaneous sensation from the bottom of the foot in control of unperturbed stance. To date, very little is known about the contribution of plantar cutaneous mechanoreceptors to dynamic postural control in response to unpredictable perturbations during gait. The potential importance of cutaneous afference in controlling foot-contact is supported by observations that cutaneous sensitivity is up-regulated at the end of the swing phase, just prior to foot contact, during gait (Duysens et al, 1995). Additionally, Zehr and Stein (1999) have suggested that cutaneous reflexes may play important roles during specific phases of the gait cycle. Foot contact and loading information, in combination with information about the distribution of foot pressure relative to the anatomical boundaries of the foot, may also contribute to an internal representation of the location and motion of the centre-of-mass with respect to the base-of-support (Dietz, 1992; Massion, 1992).

Our recent collection of studies has employed either reduction or facilitation of the sensation from the bottom of the feet. These have demonstrated its importance in compensatory stepping (Maki et al, 1999; Perry et al, 2000), terminating gait (Perry et al, 2001) and travelling effectively over uneven terrain (Perry and Patla, 2001). During compensatory stepping

in response to a postural disturbance (young adults), reduced sensation led to an increase in number of steps required to recover balance and a delay in the initiation of the stepping reaction (Perry et al, 2000). Conversely, facilitation (in older adults with moderately insensitive feet) decreased the number of steps required to recover balance and, during continuous perturbations, reduced the extent to which the center of foot pressure approached the edges of the base of support (Maki et al, 1999). During gait termination, reduced sensation led to increased loading and poorer precision/control of foot placement during the last two steps of termination (Perry et al, 2001). Initial results from reduced sensation during uneven terrain have demonstrated an impaired control of side-to-side movement of the body when attempting to walk along a simulated uneven terrain (Perry and Patla, 2001).

INTERVENTIONS

Based upon the initial studies demonstrating the importance of this sensation in balance control (Maki et al, 1999; Perry et al, 2000), we have developed a balance-enhancing insole (Maki et al, 2001). The purpose of this insole is to mechanically facilitate stability-related sensation from the soles of the feet. The targeted population are older adults having age-related loss of this sensation. This population would benefit from this sensory facilitation in order to improve their balance control. The development of this intervention is in its early stages and requires clinical trials to test its efficacy.

UTILIZING BIOMECHANICS TO PREVENT SLIPS AND FALLS

Mark S. Redfern^{1,2} and Rakié Cham¹

¹Department of Bioengineering and ²Department of Otolaryngology
University of Pittsburgh, Pittsburgh, PA, USA

INTRODUCTION

Falls are the leading cause of injury requiring medical attention and are associated with the most severe occupational injuries (Courtney and Webster, 1999). Slipping is the dominant cause of falls. Courtney et al. (2001) reported that slips account for 32 % of falls in young adults and 67 % of falls sustained by the elderly. The causes of slips and falls are complex, involving interactions of environmental and human factors. (Redfern, et al., 2001) The environmental factors include properties of the floor surface (e.g. roughness compliance and topography) and shoe (e.g. material properties and tread), as well as lighting, housekeeping, and changes in elevation. Human factors include the biomechanics of gait, mental set (i.e. attention and alertness), as well as the health of musculoskeletal and sensory systems. When there is a mismatch, the result can be a slip or trip, often resulting in an injurious fall. An ergonomics approach to the prevention of falls is to attempt to design the environment to match the requirements of the person. This involves understanding the physical requirements of the tasks performed (such as standing, walking or carrying) and ensuring that the environment meets the requirements for those tasks. Biomechanical analyses of gait and slipping can be used to understand the physical interactions of the environment and person that leads to falls. The purpose of this presentation is to discuss the role of biomechanics in developing intervention strategies to prevent slips and falls.

ENVIRONMENTAL FACTORS

The dominant methods to prevent slipping have focused on evaluation of the frictional properties of the shoe-floor-contaminant interface using various testing equipment. Many of these devices attempt to measure the coefficient of friction (COF); however, there is no consensus on the best methodology for such testing. Current methods have begun to focus on making the measurements as *biofidelic* as possible, i.e. measure COF under conditions as close to actual gait conditions as possible. In order to accomplish this goal, the biomechanics of gait, specifically of the foot-floor interactions, must be measured through gait analysis.

Studies in our laboratory have defined foot dynamics during various walking conditions. (i.e. Cham and Redfern, 2001). Variables such as heel velocities and accelerations, as well as shear and normal forces, at contact have been established. These studies provide detailed information useful in the design and use of slip resistance measurement devices.

HUMAN FACTORS

Biomechanical studies of the postural reaction to slips and falls are also important to understand the human response. These types of studies are useful in understanding how different populations respond during a slip event.

We have conducted studies to investigate the postural reaction of subjects to slips on different surfaces and how different factors, such as anticipation of slippery conditions, impact those reactions. (Cham and Redfern, 2001). In these studies, subjects were equipped with a safety harness and instructed to walk naturally across a vinyl tile walkway instrumented with two Bertec force plates (FP). Ground reaction forces and whole body motion (Optotrak-3020 motion measurement system) were recorded. After initial dry trials, a soap solution was applied to the floor without the subject's knowledge. The moments generated during the slip are of particular interest in understanding the postural reaction. Flexion moments at the knee and extension moments at the hip have a characteristic response in young, healthy subjects (Cham & Redfern, 2001a) and this response is affected by the expectations of the floor condition by the subject (Cham and Redfern, 2001b). Figure 1 shows an example of the knee moment response during slip. Successful recovery is dependent on the timing and magnitude of this response.

Figure 1: Knee moments during no slip (solid), slip w/ recovery (dashed), and slip w/ fall (dotted). Arrow indicates moment generated in response to slip attempting to recover

ADAPTATION TO SLIPPING AND FALL PREVENTION

(Clive) Yi-Chung Pai and Michael J. Pavol

Department of Physical Therapy, University of Illinois at Chicago,
Chicago, IL 60612-7251, e-mail: cpai@uic.edu

INTRODUCTION

A health threat facing the older adult population is their increasing susceptibility to falling. It is highly likely that the likelihood of suffering a fall depends upon the robustness of one's protective mechanisms and upon the adaptation that can take place to enhance one's protection against falls. We examined this adaptive behavior by investigating whether the central nervous system, when faced with a potential postural perturbation, employs feedforward adjustments to reduce the near-term and overall likelihood of balance loss.

METHODS

Slips were induced, using bilateral low-friction platforms, during a sit-to-stand task in 60 safety-harnessed young adults. Subjects underwent a block of slipping trials, a block of non-slipping trials, then a "random" block of trials. After the first novel and unexpected slip, subjects were aware that a slip "may or may not occur." The state (i.e. horizontal position and velocity) of the body center of mass (COM) at seat-off and the direction of balance loss (forward, no loss, backward) were determined for each trial. Feedforward adjustments were identified as between-trial changes in COM state at seat-off. Effects of these feedforward adjustments on the likelihood of balance loss were quantified using logistic regression.

RESULTS AND DISCUSSION

The likelihood of balance loss in each direction (forward, backward) under each condition (slipping, non-slipping) was significantly related to the COM state at seat-off. After experiencing the first, unexpected slip, subjects adjusted their task execution to increase their COM velocity and shift their COM anteriorly at seat-off (Fig 1), reducing the probability of a backward balance loss. Such adaptive changes in the COM state prior to the slip onset suggest feedforward control.

Fig. 1: Adaptation of the center of mass (COM) position-velocity state at seat-off. Means and standard deviations of COM state are shown for the slipping and non-slipping (N-S) trials within the three blocks of trials performed. Significant changes versus the preceding trial are indicated.

In the subsequent non-slipping and random blocks, subjects readjusted their COM state at seat-off after each unexpected change in the experimental conditions (Fig 1). Adjustments to non-slipping and to slipping conditions respectively acted to reduce the probability of a forward or backward balance loss. Over the longer term, subjects also adapted their COM state at seat-off to decrease their overall likelihood of balance loss in either direction under either condition (Fig. 2).

Fig. 2: Adaptation decreased the probability of balance loss in either a forward or backward direction under either slipping (slip) or nonslipping (NS) conditions. Medians and interquartile ranges of the maximum probability of balance loss, predicted from the COM state at seat-off using logistic relationships, are shown for the three blocks of trials performed.

These findings revealed that the CNS can adapt to the uncertainties in an environment by acquiring "desirable" movement options. Consistent with theoretical predictions [1], such movement options entailed the adjustment of the COM state so that a person had neither the tendency to fall forward during non-slipping conditions nor the tendency to fall backward during a slip. Our findings suggest that, through training similar to the present protocol, it may be possible to induce adaptations in task performance that would increase stability and reduce the likelihood of falling upon a slip.

SUMMARY

Healthy young adults rapidly learned how to improve stability through repeated exposure to a slipping perturbation. This learning was characterized by feedforward adjustments that altered the COM state. Individuals further learned to adapt their task performance to remain stable under both perturbed and unperturbed conditions.

AGE DIFFERENCES IN ABILITY TO ABSORB IMPACT ENERGY IN THE UPPER EXTREMITIES DURING FALLS

Stephen N. Robinovitch, Paula J. Stotz, Sarah C. Normandin
Injury Prevention and Mobility Laboratory, School of Kinesiology
Simon Fraser University, Burnaby, B.C., Canada

INTRODUCTION

While over 90 percent of hip fractures are caused by falls, the vast majority of falls do not result in hip fracture. The strongest determinant of whether fracture occurs is fall severity, as defined by the configuration and velocity of the body at impact (Schwartz et al., 1998; Nevitt and Cummings, 1993). Our previous studies suggest that young subjects tend to reduce fall severity by absorbing energy through contraction of the lower extremity muscles during descent (as one does while sitting or squatting), and by “braking the fall” by impacting the ground with the outstretched hands (Hsiao and Robinovitch, 1998). Exercise programs that seek to enhance these responses have a strong likelihood for reducing hip fractures in the elderly. The efficacy of the upper extremity (UE) response depends on how quickly the hands can be moved into a protective position, and on the faller’s ability to absorb energy in the UE muscles during impact. In the present study, we examined whether declines occur with age in the capacity to absorb energy in the UE muscles during a simulated forward fall.

METHODS

A total of 12 young (Y) women (of mean age 77 ± 6 yrs) and 12 elderly (E) women (of mean age 21 ± 3 yrs) participated in the study. During the experiment, the subject stood leaning at an angle θ from the vertical (initially set to 15°) with her arms fully extended and each hand contacting a force plate (Fig 1). She was instructed to then slowly lower her body weight (similar to the descent phase of a push-up). If she was able to complete the task at a given angle, the experiment was repeated with θ increased by 15° , up to a maximum of 90° . Three trials were acquired for each angle. During each trial, a 7-camera, 60 Hz motion measurement system (Qualisys Inc.) acquired the positions of 27 skin surface markers. Simultaneous reaction forces on each hand were acquired from two force plates (MU2535, Bertec Corp.) at 960 Hz.

Fig. 1. Experimental schematic.

For each trial, we estimated UE energy absorption (for the dominant side) as the integral of the in-line component of hand contact force and the change in length of a vector connecting the hand centre-of-pressure and the acromium. We normalized force by body mass (which averaged 68 ± 11 kg for E and 57 ± 11 kg for Y), deflection by body height (which

averaged 1.59 ± 0.75 m for E and 1.65 ± 0.75 m for Y), and energy by the product (body mass * body height) (which averaged 108 ± 21 kg*m for E and 94 ± 21 kg*m for Y).

RESULTS AND DISCUSSION

Peak magnitudes of energy absorption in the dominant UE, over the entire range of tested angles, were greater for Y than for E (mean = 0.389 ± 0.054 (SD) versus 0.252 ± 0.092 J/(kg*m); mean difference = 0.138 J/(kg*m); $p < 0.001$). This reflected young subjects’ ability to generate greater contact forces (3.31 ± 0.41 versus 2.24 ± 0.74 N/kg; $p = 0.001$), since no difference existed between Y and E in peak arm deflection (0.128 ± 0.02 versus 0.123 ± 0.036 m/m; $p = 0.69$; Fig. 2).

To put these data in context, consider that during recent experiments in our laboratory with young women ($n = 7$) undergoing forward falls onto a gym mat (with the knees impacting before the wrists), whole-body kinetic energy at the instant of wrist impact averaged 0.590 ± 0.338 J/(kg*m). Therefore, if individuals can absorb similar energy in the non-dominant and dominant UE, these combined results suggest that young but not elderly adult females can absorb sufficient energy in their UE muscles to halt downward movement of the body during a fall, and thereby prevent impact to the head or pelvis. Strengthening of upper extremity muscles should enhance the effectiveness of the UE response in elderly individuals.

3D MOTION RECONSTRUCTION FROM UNCALIBRATED 2D VIDEO SEQUENCES - APPLICATION TO FREESTYLE ACL INJURY SITUATIONS

Tron Krosshaug¹, Stig Heir^{1,2} and Roald Bahr¹

¹Oslo Sports Trauma Research Center, PO Box 4014 Ullevaal Stadion, 0806 Oslo, Norway

²Martina Hansens Hospital, Box 23, N-1306 Baerum, Norway

INTRODUCTION

Various injury mechanisms have been proposed for alpine skiing, both for ACL and other ligament injuries (Natri et al. 1999), but the emphasis so far has mainly been on recreational skiing. Much less is known about the mechanisms for serious knee injuries among elite skiers. During recent years, off-piste skiing seems to be growing in popularity. Skiing resorts leave trails ungroomed – giving rise to natural mogul courses that make jumping and “trick-skiing” possible, thereby challenging the more advanced recreational skiers. In our opinion, several biomechanical characteristics of these new trends of skiing compare well with those of freestyle skiing. *We therefore consider freestyle skiing (moguls and aerials) as a suitable model for extreme skiing.*

So far, interviews and visual inspection of videos have been the most common way of extracting information about injury mechanisms. Although other approaches, like mathematical modelling and simulation (e.g. Gerritsen et al. 1995) have been undertaken, a significant problem is that reliable kinematic information from actual injury situations is lacking. Since elite level sports is regularly taped for TV, systematic collection of tapes from injury situations may potentially provide a source of valuable information.

The purpose of this project is to arrive at better 3D descriptions of knee injury mechanisms in elite freestyle skiing through analysis of 2D video sequences, and to describe the events leading up to injury situations.

METHODS

Questionnaires were handed out to all WC teams prior to the season to provide information on former serious knee injuries. A representative at each WC-meeting records the injuries and collects videos retrospectively and prospectively. So far we have received 8 videos (mostly from prior seasons), but we expect to collect at least 15 videos by the end of the season.

An interactive model-based image-matching method will be used for the estimation of 3D motion from 2D video sequences. The commercially available 3D modelling program Poser[®] provides the environment for image matching. The matching procedure consists of the following steps:

- Measuring (if possible) or estimating the anthropometry of the subject and building a customized computer-model (e.g. by changing segment dimensions of an existing model).
- If possible, obtain measures of landmarks in the surroundings (e.g. floor, walls, lines, objects etc.) and build a virtual environment similar to the original.
- “Calibrating” the Poser-cameras at each time step (e.g. adjust the pose and focal length parameters until the virtual surroundings matches the video footage)
- Matching the model to the background person.

Figure 1: A Poser model matching the video sequences, and the comparison with the recorded ProReflex motion.

PRELIMINARY RESULTS

At present, we are comparing results from the method with a 7-camera infra-red 240Hz marker based system (ProReflex, Qualisys, Inc.). Preliminary results indicate that we get a reasonably good match when two camera views are available. However, when only one camera view is available, it is more difficult to make a reliable matching.

DYNAMIC ANALYSIS OF JOINT LOADING DURING SKIING

A. J. (Ton) van den Bogert

Department of Biomedical Engineering, Cleveland Clinic Foundation, Cleveland OH, USA

bogert@bme.ri.ccf.org, <http://www.lerner.ccf.org/bme/>

INTRODUCTION

Large loads can be applied to the joints during skiing. Inverse dynamic analysis (van den Bogert, 1994) can be applied to estimate these joint loads from external forces and kinematics. This can be an effective method to study chronic problems such as overuse injuries. Human subject tests can be done to determine how such injuries can be prevented or treated. For acute injuries, such as fractures or ligament tears, this type of analysis is generally not useful, unless the experimenter is “lucky” enough that an injury happens while the analysis is being performed. Forward dynamic analysis (van den Bogert, 1994) is based on the same laws of dynamics, but it has the potential to generate theoretical movements that are possible, but not observed. Forward analysis requires good constitutive equations that describe how the forces in muscles and skis are generated. For muscles, it is important that the theoretical model response realistically to changes in muscle length and activation. For skis and boots, it is important that force-deformation properties are represented.

In this paper, we will present (1) an inverse dynamic analysis of hip joint loading during cross country and alpine skiing, and (2) a forward dynamic analysis of knee joint loading during the landing from a jump during downhill skiing.

HIP JOINT: INVERSE DYNAMICS

Total hip replacement (THR) is a common and effective treatment for osteoarthritis. With advances in technology, implants last longer and THR is now considered for younger and more active patients. This raises the question which activities can be potentially damaging, and specifically: can skiing lead to loosening of the implant?

Intersegmental forces and moments at the hip joint were determined in nine subjects using accelerometry (van den Bogert et al., 1996), during walking, running, cross-country skiing (two techniques) and alpine skiing (four conditions). Magnitude of the resultant hip joint contact force was estimated by assuming an effective muscle moment arm of 0.06 m (van den Bogert et al., 1999). The results for walking (Fig. 1) agree with recent data from instrumented prostheses.

Distinct differences between the activities were found (Fig. 1), especially between the different conditions of alpine skiing. Under controlled skiing conditions, the contact force was not much larger than for walking. However, the intersegmental force vector indicated that the A-P loading was much larger during downhill skiing. This exerts a torsional load on the stem of the femoral component. Further research is needed to determine whether loosening of the implant should be expected in the long term.

Figure 1: Mean and standard deviation of peak hip joint contact force for the nine subjects. From van den Bogert et al., 1999.

KNEE JOINT: FORWARD DYNAMICS

A two-dimensional musculoskeletal model was used to simulate a landing from a jump during downhill skiing (Gerritsen et al., 1996). The model's inputs were the initial positions and velocities of the body segments just before landing, and the muscle activation levels during the landing. The activation levels were optimized until an optimal match with an observed movement was obtained.

This baseline movement was then perturbed to initiate a backwards fall. When the quadriceps was activated to simulate an attempt at recovery, large quadriceps and external forces occurred that both pushed the tibia anteriorly (Fig. 2). In this particular example, peak anterior force was 2566 N, of which 75% came from the external force. This mechanism is unique to skiing. Similar force magnitudes occur in other sports, but never with the tibia leaning backwards relative to the ground reaction force.

Figure 2: Mechanism for anterior cruciate ligament injury during a balance recovery.

SKI BINDING SETTINGS AND DIFFERENCES BETWEEN SEX

Dr. Marc-Hervé Binet * - (Avoriaz- France)
Dr. Jean Dominique Laporte – (Les Angles - France)
A Bally – (Lausanne – Suisse)

INTRODUCTION

Skiers in France have basically been poorly informed on the standards of adjustment binding and the necessity of their application.

For the last ten years the results of the Médecins de Montagne epidemiological network (this group of 70 physicians established in ski resorts analyse more than 20.000 winter sports injuries each season since 1992) have put forward that the number of knee injuries has increased especially in the female population. The specific risk for a cruciate ligament injury is 3 times greater for adult females than males. This injury occurs with more than 60 % of non release of the ski bindings.

Ski binding adjustment surveys have shown that many skiers were able to ski with lower release levels than those indicated by the international standards, without complaining of inadvertent release. This established fact was confirmed afterwards during many seasons by testing voluntary lower binding setting levels.

These findings have motivated a work group of the AFNOR to suggest an improvement of the ISO standard 11088 for binding adjustments; a documentation leaflet was published (under the number FD S 52-748) proposing a simplification of the ISO table. The adjustments of the ski binding international standards for women and low weights have been lowered . A specific table for women and another for men have been established on the basis of weight, size of the shoe and a correction factor correlated to the type of skier. 7 different types of skiers are described in the AFNOR leaflet..

Profil du skieur Skier type	Corrections à apporter aux tableaux Correction to apply to upper chart
• Débutant adulte (plus de 25 ans) • Skieur de plus de 50 ans • Adult beginner (age : 25 and over) • Skier aged over 50 years old	Monter d'une ligne Move up one line
• Débutant jeune et enfant (moins de 25 ans) • Niveau débrouillé, avec bonne condition physique • Bon skieur, style souple et coulé, privilégiant la sécurité • Young beginner and child (less than 25) • Average level, in poor physical condition • Good skier, with a smooth style, for whom safety is important	Pas de correction No correction
• Bon skieur jeune, style souple et coulé • Niveau débrouillé, bonne condition physique • Good young skier, with a smooth style • Average level, in good physical condition	Descendre d'une ligne Move down one line
• Bon skieur, ski d'attaque sur tous terrains • Good skier, aggressive skiing on all terrains	Descendre de deux lignes Move down two lines
• Très fort skieur, sur terrains engagés • Excellent skier, on difficult terrains	Descendre de trois lignes Move down three lines

Because the actual international standards were badly applied or simply unknown, a large information campaign supported by the national French health insurance was launched aiming skiers and ski equipment renters. For the first year of the mass public campaign a television spot of 30 seconds and 1 000 000 documentation leaflets were distributed by tour-operators, skiing equipment renters and tourist offices. A specific information campaign aimed the ski equipment renters. This campaign has started in autumn 2000 but will continue up to 2003 winter season informing public and renters on the new standards.

RESULTS and DISCUSSION

The evaluation of the impact of the first campaign on the public and on the professionals concerned 2203 interviews on the slopes using a randomised survey method concerning 1597 alpine skiers. 204 interviews aiming ski renters were performed by telephone. It shows that the required binding settings for both female and beginners can be lowered by 15 % without more accidents occurring because an inadvertent release. One the other hand a first effect of the campaign after only one winter season was the first diminution after ten years of augmentation of ACL injuries, but no correlation with the binding settings has been proven. The evaluation of modifications of the settings in the control group shows an important shift of the setting values to lower values for 2001 compared to 1998 and 1999 in the control group that rent skis but there is no significant change in the setting values amongst equipment owners.

CONCLUSION

This suggest that a new definition of ski binding international standards for females with a more attractive presentation could improve the injury situation in alpine skiing.

INTRODUCTION

In Alpine skiing, two primary rotary mechanisms have been identified for anterior cruciate ligament (ACL) injuries to the knee: one with the knee in hyperflexion with rotation (phantom foot), the other in hyperextension with rotation. To date, Alpine ski bindings are not developed to protect the soft tissues in the knee. The long term goal of this research is to determine whether there is a correlation between knee positions and binding forces during likely injury events such that a unique release paradigm for Alpine ski bindings can be prescribed to protect the knee. The objective of this study is (1) to develop and validate a physical model that can be used to investigate situations, which are believed to be crucial for ACL injuries in skiing, (2) systematically apply external and muscular loads to cadaver knees in order to find out the relationship between the resulting knee ligament strain and the binding forces present in that situation.

MATERIAL AND METHODS

An *in vitro* load simulator (Fig. 1) was developed to simultaneously apply 6 degree of freedom loading to a cadaver knee joint and measure knee kinematics, anterior cruciate ligament strain and Alpine ski binding forces and moments.

Figure 1: Device to apply external loads and quadriceps forces to cadaver knee joints with simultaneous measurement of ski binding forces and moments.

with respect to the fixed tibia is permitted, allowing unconstrained motion of the knee joint during application of external rotations to the ski. Anterior cruciate ligament strain is measured directly with a DVRT inserted i.e. into the anteromedial bundle of the ligament. Knee kinematics is measured with an Instrumented Spatial Linkage (ISL) mounted directly to the knee. The cadaver knee is potted and rigidly coupled to a ski boot via a custom-made prosthesis that prevents rotation of the leg within the boot. The boot is mounted onto a multi-axis instrumented ski binding, which is in turn mounted on a test ski attached to the loading frame. The loading frame has a stepper motor which can drive internal/external rotation of the ski about the axis of the tibia.

FIRST RESULTS

Repeatability testing of the device was performed on young male cadavers at flexion angles of 110 and 130 degrees. Internal and external rotation of the ski to ± 30 degrees was performed with incremental quadriceps muscle loading of 700 N to 2400 N. Three trials of at each loading condition were performed. ACL strain, knee kinematics, and binding loads were synchronously recorded. Repeatability was within 5% for repeated trials. The tests performed were below failure levels. Low levels of ACL strain ($\sim 2-3\%$) were recorded, yet measured binding loads were extremely low, and well below release limits. Increasing the level of quadriceps force at these flexion angles and applied rotation angles had little effect on ACL ligament strain, but these results cannot be extrapolated to higher angles of internal/external tibio-femoral rotation or to other knee flexion angles.

STEPS CURRENTLY PERFORMED

Currently numerous tests with additional cadavers are conducted and sensitivity analyses for the different parameters in test are performed. The results from this systematic variation of loading conditions, which also takes into account the different fibre bundles of the ACL will be presented and discussed.

Quadriceps muscle loading is used to set the knee flexion angle and was applied via a tissue clamp attached directly to the quadriceps tendon and controlled by a closed-loop linear actuator. Varus/valgus moments are applied via weights attached to the femur. Superior/inferior motion of the femur

RELEASE SETTING FOR AN ELECTRONIC ALPINE SKI BINDING

Werner Nachbauer¹, Kurt Schindelwig¹, and Herwig Schretter²

¹Department of Sport Science, University of Innsbruck, Innsbruck, Austria

²HTM Sport- und Freizeitgeräte AG, A-2320 Schwechat, Austria

INTRODUCTION

For several years ski binding companies have made attempts to develop electronically controlled ski bindings. This kind of binding generally consists of a transducer to convert physical variables into electrical signals, a micro controller to process the transducer signal, and an electromechanical release device. The incidence of anterior cruciate ligament (ACL) ruptures has increased in the last decade in ski racing as well as in recreational skiing. One major ACL injury mechanism identified is called the phantom foot injury. The purpose of this investigation was to identify the characteristic loading of the binding for the phantom foot injury mechanism and to develop a release criterion for an electronic ski binding.

METHODS

14 subjects imitated the phantom foot injury mechanism in laboratory and field tests. To make sure that no ACL rupture occurred during the tests, the falls were stopped by a trained supervisor and an extra release mechanism allowed the subject to release the boot from the ski by squeezing a lever switch on the ski pole. During the falls the three components of the force acting on the toe and the heel pieces of the binding were measured by using two force plates (Kistler) at a sampling rate of 200 Hz. With the same force plates the forces of 30 subjects were measured during 137 regular runs on different terrain (flat, steep, moguls, ...), on a wide range of snow conditions (coarse, deep snow, icy, ...), and at different speed.

The data analysis consisted of the identification of the characteristic forces on the binding during the phantom foot injury imitation and the comparison of these forces with the forces apparent during regular skiing in order to determine a release criterion for the phantom foot release mechanism.

RESULTS

The falls investigated showed a high tractive and lateral force on the toe piece of the binding. Fig. 1 shows two video frames of the imitation of the injury situation with the normal and lateral forces on the toe piece of the binding. The arrow marks the forces when the binding was released by the subject.

In the following the 137 regular runs were systematically examined with respect to the observed tractive and lateral force on the toe piece of the binding. When only considered the magnitude of these forces then the release criterion was

Figure 1: Normal and lateral forces during the imitation of a phantom foot injury situation.

violated during regular skiing which would cause inadvertent releases. By introducing the time interval of the tractive force the following release criterion for the toe piece of the binding was determined: (a) tractive force greater than 400 N, (b) lateral force greater than 150 N, and (c) the running interval of the tractive force over 0.5 s greater than 50 Ns.

DISCUSSION

A release criterion for the phantom foot injury mechanism was developed. A major problem in determining the release criterion is that the imitation of the injury situation has to be done in a way that no injury can happen. So the forces measured during the imitation give an assumption of what happens during the real injury situation. The high variability in the measured forces during the imitation might be due to differences in the imitation of the falls. Consequently, the release criterion was chosen so that during the 137 regular runs the criterion was not fulfilled. The tentative criterion was implemented into the micro processor of a prototype of an electronic binding. During the winter season 2001/02 first tests with the prototype were conducted. Besides these tests efforts are made to adapt the criterion to different skiing levels or physiques of the skiers.

MODELING OF SLOPE AND TRAJECTORY IN ALPINE SKIING

Joachim Mester, Ralf Roth, Florian Seifriz

German Sport University Cologne, Cologne, Germany

INTRODUCTION

Due to modern computer development, various presentation techniques have been made available in the last years. This refers to digital videos taken from real sport environments as well as to modeling, simulation and animation of movements. Although the scientific background for these techniques has been improved remarkably, there is a delay of penetration into media and even into training in top performance sports.

METHODS

During the last winter FIS-Championships and the Ski-World-Championships 2001 and 2002 for the alpine racing events and for ski-jumping the following groups of techniques were used: At the level of models, deterministic biomechanical models and non-conventional approaches by means of genetic algorithms (GA) for determination and simulation of performance, e.g. “optimal trajectory,” were calculated. The necessary data for the individual skiers result from anthropometrical measurements. The slopes were roughly surveyed with satellite scanning data and additionally with high resolution GPS (LEICA) (see figure 1). These data were processed in 3D-Studio MAX and then used for visualization and animation of the runs (see figure 3). Finally digital videos were manipulated in terms of blending and superimposing two runners into one video (see figure 2).

Figure 1: Model of Slope

RESULTS

Deterministic modeling of the trajectory with individual parameters from the athletes and the various conditions of the slopes is faced with the large number, complexity and interdependence of “independent” variables. Genetic algorithms help to optimize the trajectory. Evolution studies of the algorithms, fitting for run time and/or for distance, show

that saturation effects occur rather early, e.g. after approx. 50 steps (see table 1). A comparison between calculated and real trajectories and run times of world-class athletes demonstrates realistic settings.

Figure 2: Digital video superimposing

Figure 3: Model-based virtual trajectory

Evolution	GA fit for distance		GA fit for time	
	Distance	Time	Distance	Time
1 st Step	259.78 m	10.68 s	266.89 m	10.40 s
50 th Step	225.75 m	9.08 s	237.99 m	8.96 s
100 th Step	224.38 m	9.04 s	238.36 m	8.88 s

Table 1: Evolution of GA

DISCUSSION

These scientific findings and developments raised remarkable interest not only in the various groups of athletes but also in mass media and supplying television companies. This adds new perspectives to research in sport science as these techniques can contribute to an improvement of media presentation as well as to an optimization of athletic training and performance. Especially non-conventional approaches such as GA seem to promise new insights into the complex structure of sport performance.

DYNAMIC SKIING: INFLUENCES OF SNOW AND SKI PROPERTIES

Franz Bruck¹, Lukas Magerl¹, Heinz-Bodo Schmiedmayer¹, Peter Lugner¹, and Herwig Schretter²

¹Institute of Mechanics, Vienna University of Technology, Austria

²Tyrolia HTM, Schwechat, Austria

INTRODUCTION

To be able to investigate by means of simulation how the turn radius performed by a skier is affected by ski properties and/or by the type of snow, a model for the contact between ski and snow is needed.

METHODS

Based on snow measurements similarly to Casolo et al. a contact model was developed that describes the forces that are exerted from the snow to the ski due to the penetration depth and the shearing behaviour. For the validation of this snow force model a ski sledge was used consisting of a pair of skis and a rigid frame, which is fixed to the ski bindings and allows to choose a certain value for the edge angle of the skis. This sledge was put on a slope and autonomously performed a circular-like turn. At the same time the snow conditions were measured on the slope. Sledge runs were carried out for two kinds of skis, a giant slalom ski and a slalom ski. For both ski types the snow model was used to calculate the path of the ski sledge (modelled as a multibody system), and a comparison shows that measured and simulated trajectories coincide very well, see also Bruck et al..

RESULTS AND DISCUSSION

Using the verified contact model the influence of snow hardness on the average curve radii of the sledge was analysed. Two certain kinds of snow are investigated more closely, one can be characterized as “hard snow”, the other one as “soft snow” according to the measured range of snow properties. For both the slalom and the giant slalom ski it is studied how ski properties like bending and torsional stiffness or damping characteristics can change the radius of turn

being made by the ski sledge. By the means of simulation it is possible e. g. to look into the difference it makes to use a ski with high bending stiffness and low torsional stiffness, or to have a ski with low bending, but high torsional stiffness. In addition it is investigated whether it could be advantageous to have a stiffness distribution along the ski differing from a normally used distribution. Besides the direct comparison of average turn radii a further criterion for the assessment of a certain variation of the system is the energy dissipated during a run.

SUMMARY

Using the methods of multibody system dynamics this investigation shows the influence of ski and snow properties on the average turn radius of a ski sledge.

EVALUATION OF THE RELEVANT PARAMETERS TO PREDICT THE BEHAVIOUR OF ALPINE SKIS

Federico Casolo* and Vittorio Lorenzi**

*Politecnico di Milano (casolo@mech.plimi.it) **Università degli Studi di Bergamo (vlorenzi@unibg.it)

Ski trajectory in carved turns is related to ski edging and to snow and ski mechanical and geometrical parameters. Thus, any analytical approach requires to identify the crucial factors and to set a protocol for their experimental evaluation. A first approximation formula by Howe[1] may be used to roughly estimate the mean curvature of an edged ski on a rigid flat surface, knowing only the ski length and the max value of the side-cut. However, we adopt a more refined approach and take into account ski and snow mechanic characteristics and the whole ski shape-camber, side-cut and length-. We estimate ski deformation and trajectory by means of the following differential equat. where only torsional flexibility (ski torsion $\leq 1^\circ$) and “generalized skidding” (absent in ideal turns) are neglected.

$$EJ(x) \cdot y^{IV}(x) + EJ'(x) \cdot y'''(x) + 2 \cdot EJ''(x) \cdot y''(x) + q(x) = 0 \quad \blacksquare$$

$$y(x) = y_0(x) + y_N(x)$$

$$y_0(x) = \text{camber}(x) + \tan(\vartheta) \cdot \left(\text{carving}(x) - \frac{(sc_A - sc_D) \cdot (l - x)}{l} \right)$$

$$sc_A = \frac{\text{width}_A - \text{width}_{\min}}{2} \quad sc_D = \frac{\text{width}_D - \text{width}_{\min}}{2}$$

where EJ is the local ski bending stiffness and the other parameters [2] are shown in the following figures:

The “local skidding”, where only portions of the skis skid, is on the contrary, unavoidable and always occurs because the ski contact on the snow is never perfectly circular. This is one of the causes of the power loss during a turn and its effect can be evaluated by:

$$\int_0^l q \cdot V_{tr} \cdot k \cdot dl$$

where V_{tr} is the velocity component of a ski point in the direction of the local center of curvature of the ski-snow contact line.

The bending stiffness used in eq. \blacksquare for a ski with bindings, boot and anti-vibrating platform, varies very much along the ski length and should be evaluated for each ski set-up: for this aim we use a simple testing apparatus to flex and measure the deflection of the ski segments, compensating the influence of the weight of the not-bent ski portions. The critical point is the evaluation of the snow static and viscous characteristics and of its pressure distribution on the transversal ski section(p) For them, up to now, we use approximate literature data. The computer simulation of alpine ski tracks [2] shows that the ski stiffness plays an important role on the skier's trajectory. The same model can be used for other aims, such as, to design the ideal side-cut which, for given ski stiffness and a specific ski edge, produces a circular contact line and thus avoids local skidding (e.g. for carving races). In order to validate our simulation system we designed a device for measuring pressure distribution and contact line path of an edged ski (below fig.).

SNOW FRICTION AND DRAG IN ALPINE DOWNHILL RACING

Peter Kaps, Werner Nachbauer, Martin Mössner
University of Innsbruck, Innsbruck, Austria

INTRODUCTION

For training purposes we want to visualize an Alpine downhill slope from the view of an elite skier. As slope we have chosen the Streif, a famous and difficult Alpine downhill run in Kitzbühel, Austria. The surface of the slope between the starting area and the end of the Steilhang was geodetically surveyed. The length is approximately 700 m, the difference in height 300 m. The first 30 runners of the FIS World Cup downhill event 2002 were recorded by video cameras. With direct linear transformation we obtained the trajectory of the fastest skier as a function of the time. We call the trajectory with the time history a path. It depends not only on the trajectory but also on the velocity of the skier. It is well known that the speed depends on the drag and the snow friction. These parameters depend strongly on the situation and the skill of the skier. Minimal values occur during straight running when the skier takes an egg position. The snow friction is considerably increased during turns when the skier edges, especially, if the turn is not optimally carved. The drag is increased during difficult parts of the track when the skier takes an upright position. Additionally, the optimal path depends on the strength of the skier. The skier has to exert forces onto the snow to keep his trajectory. These forces are limited due to the constitution of the skier and the consistency of snow.

METHODS

For the fastest skier, a video analysis was performed. A typical frame is given in Fig. 1. Here, the trajectory is represented, additionally. In each frame, the positions of the toe pieces of the bindings as well as the visible control points were manually digitized. With help of the direct linear transformation the position of the skier was obtained in real 3D object coordinates. Finally, the path was obtained by smoothing. For dynamic analyses, the skier is modeled as a mass point. The equation of motion is established in descriptor form (1). The constraint g is given by the trajectory of the skier.

$$\begin{bmatrix} I & 0 & 0 & 0 \\ 0 & I & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} x \\ v \\ a \\ \lambda \end{bmatrix}' = \begin{bmatrix} v \\ a \\ Ma - f - r \\ Gv - g^1 \end{bmatrix} \quad (1)$$

$$g(x, t) = 0, \quad G = \frac{\partial g}{\partial x}, \quad g^1 = \begin{pmatrix} 0 \\ 0 \end{pmatrix}$$

The applied forces f are assumed in the form

$$f = \begin{pmatrix} 0 \\ 0 \\ -mg \end{pmatrix} - \mu N t - \frac{1}{2} c_d A \rho v^2 t, \quad \text{with } t = \frac{v}{\|v\|}$$

For the reaction forces r and the normal force N it holds $r = -G^T \lambda$, $N = \|r\|$.

We assume that the drag $c_d A$ and the snow friction μ are piecewise constant. The values are determined by a least squares argument: the error between measured and computed positions is minimal.

RESULTS

We have computed snow friction and drag for the turn in Fig. 1. The turn starts at $t=0$ and ends at $t=1.92$. The results are given in Table 1. The mean error is less than 4 mm.

Figure 1: Video frame with trajectory of the ski racer

	$t < 0.58$	$t > 0.58$
μ	0.40	0.10
$c_d A$	0.90	0.55

Table 1: Snow friction and drag for the turn in Fig. 1

DISCUSSION

Despite of the short time passed since data collection we can present some preliminary results on a small portion of the investigated slope. We plan to visualize the downhill race from the view of a skier. We hope that the results can be used by the Austrian ski team for training purposes.

ACKNOWLEDGEMENT

The research was supported by a Top Sport Austria project of the Austrian Ski Federation.

BIOMECHANICAL RESEARCH METHODOLOGY IN SKIJUMPING: OVERVIEW AND PERSPECTIVES

Hermann Schwameder and Erich Müller
Institute of Sport Science, University of Salzburg, Salzburg, Austria

INTRODUCTION

Biomechanical research in skijumping has a long tradition. This may be caused by the restrictions and constraints in skijumping which makes it relatively easy to biomechanically describe and analyse the movements. Biomechanical studies primarily proceed within five areas: (1) field studies of hill jumps, (2) lab studies of simulation jumps, (3) wind tunnel experiments, (4) computer simulations of the flight phase and (5) material testing. This paper presents an overview of the biomechanical methods used in these areas. Furthermore, the strength and restrictions of the methods are discussed. Finally, some ideas concerning perspectives in skijumping research methodology will be presented.

METHODOLOGY IN SKIJUMPING

Kinematic methods

Both, in hill and simulation jumps kinematic methods (film and video techniques) are the most frequently used ones. In hill jumps primarily the take-off and the flight phase were analysed. Depending on the point of interest 2D and 3D approaches were used. While the kinematic methods are standardized routines and easy to handle in a lab, the analysis of the flight phase in the field is – due to the large space of movement - a challenging task. The problem has been used by operating with cameras in a series or by panning the cameras. The main purposes of filming hill jumps are to serve an accurate description and to find the most important kinematic parameters related to performance. The analysis of simulation jumps is primarily concentrated on basic research and to compare the coordination pattern between hill and simulation jumps. An important advantage of kinematic methods is that the skier is not influenced by any filming device. So these methods can even be used during competitions. The most severe restrictions of kinematics are the sampling rate and the accuracy to determine the marker and/or joint positions.

Dynamic methods

Two methods are used to measure and analyse hill jumps dynamically. Force plates mounted to the take-off table allow to measure take-off forces with a high sampling frequency. As the skier is not influenced by the measuring device this method can even be used during competitions. The disadvantages of the method are the high costs and the high sensitivity to failure and errors at low temperatures. The second type of dynamic methods used in hill jumps are bindings equipped with load cells and insoles instrumented with measuring sensors. Load cell bindings could yield to the most accurate and most distinct data. The device itself, however, influences the mechanics and the weight balance of the ski-binding system substantially. Sensor instrumented insoles, however, are easy to handle and the skier is hardly irritated by it. Cer-

tain restrictions are usually given by the storage device with respect to weight and size. Furthermore, only forces between foot and boot perpendicular to the sole can be measured.

The force plate is the dominant dynamic measurement system used in simulation jumps. By that the forces and their application points can be measured at a high sampling rate in 3D. For comparative aspects in few studies also mobile dynamic systems (see above) were used in simulation jumps. To estimate aerodynamic forces during take-off in recent studies simulation jumps were measured in wind tunnels.

Electromyography (EMG)

EMG has been successfully used both, in hill and simulation jumps. In combination with kinematic and kinetic data the EMG gives important information of the muscle activity and the muscle coordination during skijumping.

Wind tunnel experiments

The purpose of wind tunnel experiments are to measure and optimize the aerodynamic forces during the flight phase. Studies were presented using both, athletes and models.

Computer simulation of the flight phase

Computer simulations are used to optimize the aerodynamic forces, to serve basics for hill constructions and to estimate the influence of body positions and material to the flight path.

Material properties, construction and design

The development and optimization of material (jumping suit, boots, bindings and skis) is an important issue in skijumping. Both, companies and research institutions work in this area. There are, however, hardly any results available in the literature.

FUTURE ASPECTS AND PERSPECTIVES

Two aspects seem to be important for skijumping research in the future. The first one is referred to the dynamic methods used in hill jumps. An important progress could be made by measuring the horizontal ground reaction forces during take-off, as these components influence the forward body rotation and therefore the quality of the jumps substantially. Another improvement would be the reduction of size and weight of mobile storage devices (e.g. insole systems, EMG).

The second aspect is related to the correlation of material properties with flight length. This information is an important basis for meaningful regulations in skijumping. Regulations regarding to (1) the importance of the jumpers' athletics vs. material, (2) the attraction of competitions both, for athletes and spectators and (3) the safety for the athletes.

THE TRANSITION FROM TAKE-OFF TO EARLY FLIGHT PHASE IN SKI-JUMPING

Gert-Peter Brüggemann¹, Gianpiero DeMonte¹, Paavo V. Komi², Juha Isoletho², Wolfgang Potthast¹, M. Virmavirta²

¹Institute for Biomechanics, German Sport University of Cologne, Cologne, Germany, brueggemann@dshs-koeln.de

²Neuromuscular Research Center, University of Jyväskylä, Finland

INTRODUCTION

The early flight phase in ski-jumping is characterized as the transition from take-off into a stable flight. This phase covers the first 15 to 25 meters or 0.7 to 1.0 seconds, respectively, depending on the size of the jumping hill.

The recently published data on the early flight kinematics (Arndt et al. 1995, Schwameder/Müller 1995, Schwameder/Müller 2001) reported that less than 15% of the variance of total performance (distance jumped) can be explained by the CM parameters (position, velocity) of the take-off. The explained variance at 15m after the take-off through the CM ballistic variables was shown to be less than 20%. When adding five parameters describing the body configuration and indicating aerodynamic variables the explained variance of total performance increased up to about 85% (Arndt et al. 1995). These results demonstrate that the early flight or the transition take-off to stable flight should be the most sensitive phase to determine the total performance in ski jumping. The use of drag and lift forces and gravity acting on the jumper-ski-system in this transition from take-off to early flight are not well or completely understood.

The purpose of this paper was to summarize the results of the biomechanical studies performed at the 1994 and the 1998 Olympic Games in Lillehammer and Nagano, respectively, and to increase the knowledge of the identification of performance limiting factors in the transmission from take-off to flight.

METHODS

The jumps of all participants of the 90m and the 120m hills were recorded by three synchronized cameras. A highspeed video camera filmed the sagittal plane of the take-off at 250 fps (1998 in Nagano) and 200 fps (1994 in Lillehammer). Two cameras operating at 50 fps were genlocked and recorded the take-off and the early flight of the jumpers. The cameras were panned and tilted in order to allow a small object field. The panning and the tilting were controlled via well calibrated landmarks in the background. A specific DLT routine (Drenk 1994) was used to transform the digitized data into the metric space coordinate system. Twenty trials of each competition were chosen for further analysis. Joint centers, reference points on the ski and calibration points were digitized manually using the Peak Motus System. The cutoff frequencies of a second-order Butterworth filter was set at 4 Hz for raw data smoothing. Data of segments' relative mass and moment of inertia were taken from Hanavan's model (Hanavan 1964).

RESULTS AND DISCUSSION

The take-off movement is determined by the strength and power abilities of the jumper and the quality of the take-off.

The crucial point for the jumper during the take-off is to adjust to the external forces (aerodynamic forces, friction between ski and track, ground reaction forces) and to control the posture during the take-off to achieve the best initial conditions for the early flight. Different groups of athletes can be identified using different and individual strategies to solve the problem. The correlations between vertical or resultant release velocity and the total distance jumped show different results and are not very consistent. Among other reasons the different results are due to the various conditions in which the data were collected. The direction of the release velocity vector under the various condition seems to play the dominant role. The direction of the take-off and the release velocity vector has a higher effect on the rotational component than on the linear component. The rotational component determines the angular momentum of the body's forward rotation during the take-off substantially. From that one can conclude that the angular momentum of the body rotation during the take-off play the major important role concerning the preparation of the early flight. A high angular momentum at take-off is more important than a high release velocity in order to reach an early compact flight position. From the results we can conclude that there exists an optimum of the angular momentum for the early flight which means that there is an optimal relationship between ballistic and aerodynamic take-off parameters. The optimum angular (somersault) momentum will ensure the early compact flight position and thus the necessary lift and the drag forces for an optimum flight.

SUMMARY

The take-off and the transition to early flight are the dominant prerequisites for total performance in ski-jumping. An optimum angular momentum at take-off brings the athlete in an advantageous position in the early flight for an optimum use of lift and drag forces. It is substantial for the jumping performance to optimize angular momentum during the take-off in accordance with the torque due to the air stream after take-off, which has to stop the forward rotation at the right moment.

AN EXPERT SYSTEM FOR TALENT IDENTIFICATION AND SUCCESSFUL PERFORMANCE IN SKI JUMPING

Bojan Jost, Janez Pustovrh, Maja Ulaga
Faculty of Sport, University of Ljubljana, Slovenia, bojan.jost@sp.uni-lj.si

INTRODUCTION

The object of the current research has been to establish the model structure of competitive and potential performance of top Slovenian ski jumpers. The knowledge base of a reduced potential performance model of ski jumpers (RPPM) was formed so as to include variables of the morphological and motor sub-spaces. The frame of reference for the variables of the reduced potential performance model was set on the basis of the theories dealing with the issues of the morphological-motor behavior of man. The problem and goal of the research has been to establish the structure of the dimensional configuration of the variables of the competitive and reduced potential model of performance of ski jumpers (RPPM) and to establish the connection between the dimensions of the RPPM (=model variables) and competitive performance in ski jumping. The basic hypothesis of the research was that the individuals in the used sample of ski jumpers significantly differed in their attained competitive performance in the 2001 season and that the differences in performance were associated with the measured variables.

METHODS

To solve the problem of the task and to verify the basic hypothesis of the research, the shell of the expert system "Sport Expert - SPEX" was used. The basic structure of the expert system SPEX is described in Jost, Pustovrh, and Ulaga (1998). The sample included 45 best Slovene ski jumpers, 15 years of age and above. The sample of independent variables represented elementary (n=17) and derived (n=14) motor variables, 4 elementary and 3 derived morphological variables and 2 elementary special morphological-motor index variables. By means of the method of expert decision-making (Chankong, & Haimes, 1983) we established the heuristic rules of conclusion-drawing and decision-making. By means of the computer program we calculated the results on the derived variables of the potential performance model (i.e. the aggregated criteria of the decision tree). The criterion variable of performance was determined on the basis of the mark of competitive performance of ski jumpers in the Slovenian National Championship in the 2001 season.

RESULTS AND DISCUSSION

In the space of the variables (table 1) by which the aggregated mark of the sub-criterion (POTENTIAL PERFORMANCE) was calculated, the mark of the basic motor status (MOTORICS) dominated from the aspect of correlation with the criterion of performance of ski jumpers, with the value of the coefficient of correlation ($r=0.46$; $p<0.01$). The mentioned variable - which was obtained by means of the mechanism of conclusion drawing according to the SPEX method as a linear combination of the elementary motor variables - explained

approximately 21% of the variance of performance of the ski jumpers. The variables which formed the linear multiple function in the morphological space of the psychosomatic status of ski jumpers (MORPHO) have also shown a statistically significant contribution to the performance of ski jumpers ($r=0.40$; $r^2=0.16$; $p<0.01$). In the analysis of performance of ski jumpers we should not neglect the importance of morphological indexes, calculated on the basis of the anticipated functional relations to the physical environment in which ski jumps are realized. In this research, the morphological index of the take-off of ski jumpers showed the largest correlation ($r=0.53$; $p<0.01$). The mentioned index points to a relative relationship between the body weight and leg length. It is assumed that the ski jumpers with a higher relative leg length in comparison to body height have a poorer predisposition for successful take-off and transition into flight.

COMPUTER SIMULATED SKI JUMPING: THE TIGHTROPE WALK TO HIGH PERFORMANCE

Wolfram Müller and Bernhard Schmölzer

Institute of Medical Physics and Biophysics, Karl-Franzens University Graz, Austria
Communicating author, wolfram.mueller@uni-graz.at

INTRODUCTION

Straumann (1927) developed a first analytical model of ski jumping. Jump length optimisation (using a simplified approach) has been discussed by Remizov (1984). We have developed a modelling concept that contains the dependency of the aerodynamic lift and drag areas functions $L(t)$ and $D(t)$ to the flight position (Müller et al. 1995; Müller et al. 1996).

METHODS

For the simulation of the effects of parameter and initial value variations on the jump length a reference jump that had been described in detail before (Schmölzer and Müller, 2002) has been used as a starting point. Characteristics of the reference jump: Approach velocity $v_0 = 26\text{m/s}$; take-off velocity perpendicular to the ramp $v_{p0} = 2.5\text{m/s}$; mass of athlete with his equipment $m = 65\text{kg}$. All simulations use the new profile of the jumping hill in Innsbruck ($K = 120$; Müller and Schmölzer, 2002).

RESULTS AND DISCUSSION

The Figures 1 to 3 point out that the jump length is substantially influenced by several factors: v_0 , v_{p0} (due to the athlete's jumping force), $L(t)$ and $D(t)$, by the wind u blowing, and by the mass m . Ski jumpers are very light (Müller, 2002). L and D depend on the individual flight style and the equipment.

SUMMARY

The simulation of the flight phase in ski jumping enables a detailed investigation of the effects of all initial value and parameter variations that influence the flight and gives us a deeper insight into the extremely difficult multidimensional optimisation problem a ski jumper has to solve in real time.

INTRODUCTION

It has been recognized that skeletal muscles are prone to microstructural injury after eccentric contractions. Evidence from humans and other animals points to disruption at the level of sarcomeres as an early step in the damage process (Fridén and Lieber, 1992; Jones et al., 1997) that alters mechanical characteristics of muscle fibers (Morgan, 1990). In the present study, we investigated changes in mechanical properties of human muscle following repeated eccentric contractions by directly looking at muscle fiber behavior *in vivo*.

METHODS

The subjects were six healthy women and men (18 - 21 yr). Each subject performed maximal voluntary eccentric, unilateral dorsiflexion exercises (100 times) by using an isokinetic dynamometer (Con-Trex, Switzerland) at 60 deg/s. The range of motion of the ankle joint was between -15 and 45 deg of plantar flexion. Before and immediately after the exercise, and after 1, 2, 3, and 4 days (n=3 for day 4), the maximal isometric dorsiflexion torque was measured with ankle positioned at -5, 0, 5, 10, 15, 20, 25, and 30 deg. During the measurement, longitudinal ultrasound images were taken from the tibialis anterior muscle (TA) and fascicle length was determined.

RESULTS

Muscle soreness emerged immediately after the exercise, then peaked after 1 day, and gradually subsided thereafter. The decrease in the range of ankle joint motion followed a similar pattern. The maximal isometric torque decreased after the exercise, then began to increase from day 1 through day 3 but did not fully recover to the initial level. The relationship between ankle angles and passive dorsiflexion torque did not change over the testing period (Fig. 1). The relationship between TA fascicle length and dorsiflexion torque showed a clear shift downward (to lower torque) and to longer fascicle length after the exercise, which gradually came back to the initial position (Fig. 2).

DISCUSSION

The decrease in the maximal torque associated with muscle soreness clearly indicates occurrence of muscle damage by the eccentric exercise (Nosaka et al., 1996). The shift in fascicle length – torque relationship is in concert with the model by Morgan (1990), i.e., “popping sarcomeres” due to excessive lengthening that results in transformation of some sarcomeres into passive elastic tissue. The shift in the length-torque curve

downward to longer fascicle length could have been due to an increase in series compliance (damaged sarcomeres) within the fascicle, and a decrease in elongation of external series elastic component (tendons). This change, however, was not evident from observations at the joint level.

Figure 1: The isometric torque–ankle angle relationship before, immediately after, and 1, 2, 3, 4 days following eccentric exercise (average of six subjects)

Figure 2: The isometric torque–fascicle length relationship (an example from one subject)

MECHANICAL COUPLING OF HUMAN MUSCLES AT VERY LOW FORCES

S.C. Gandevia¹ and R. D. Herbert²

¹Prince of Wales Medical Research Institute, University of New South Wales, and ²School of Physiotherapy, University of Sydney, Sydney, Australia (s.gandevia@unsw.edu.au)

INTRODUCTION

The neural output to muscle and sensory feedback from it will be influenced by the mechanical coupling of muscle fibres and tendons. This has been studied extensively at high forces, but much less at the very low forces used in many everyday motor tasks. The present studies were designed to examine the coupling behaviour of muscle fibres and tendons at very low levels of tension.

METHODS

In the main studies we used ultrasonography to measure changes in the length of muscle fascicles in the relaxed muscles operating at the human ankle (tibialis anterior and medial gastrocnemius). Anthropometric data were used to derive changes in total length of the muscle-tendon unit across a range of ankle (and knee) angles (for detail see Herbert et al. 2002). In additional studies the transmission of forces within muscle was examined indirectly using the contraction of single motor units during weak voluntary contractions of the multitendoned flexor digitorum profundus (< 2% maximum). Spike-triggered averages of the forces under each finger were measured. Lateral force transmission should mean that forces from a motor unit associated with voluntary movement of one finger spread to adjacent fingers.

RESULTS AND DISCUSSION

Overall there was a quasi-linear relation between the changes in fascicle length and the total change in muscle-tendon length. However, in relaxed muscles, the muscle fascicles underwent much smaller changes in length than the muscle-tendon unit. The slope of the relationship between fascicle length and total length was 0.55 ± 0.13 for tibialis anterior and 0.27 ± 0.09 for medial gastrocnemius. These slopes remained well below unity for a range of muscle conditioning manoeuvres. These values could not be fully explained by muscle pennation, or by slackness at the shortest

lengths we examined. This suggests that the tendency for passive movement to be taken up by the tendon was greater for gastrocnemius than tibialis anterior ($P < 0.01$).

Simple calculations show why changes in tendon length must occur at low forces. Changes in muscle length that accompany passive rotation across the full physiological range often greatly exceed the rest length of muscle fascicles. If tendons were inextensible at low forces, muscle fibres would experience impossibly large strains. We deduced that tendons may undergo changes in length that are greater than changes in muscle fascicle length, even though tendons experience smaller strains. This is because the rest length of tendons is often much greater than that of their muscle fascicles.

In the second study, the forces triggered by the discharge of single motor units in flexor digitorum profundus were not uniformly distributed to the fingers. For example, units associated with the index finger distributed more than 90% of their force to the index finger. The ring finger behaved similarly. However, units in the little finger appeared to distribute a greater fraction of their force to the ring finger.

The results suggest that for muscles that do not become slack across parts of their working range, some degree of 'in-series' compliance takes up a significant amount of total length changes. Furthermore, the study of multitendoned muscles may help to place an upper limit on the degree to which intramuscular force transmission at low forces affects performance.

JUMPING INTENSITY DETERMINES THE BEHAVIOR OF THE FASCICLE AND TENDON PARTS OF THE VASTUS LATERALIS MUSCLE

Paavo V. Komi, Masaki Ishikawa and Taija Finni

Neuromuscular Research Center, Department of Biology of Physical Activity, University of Jyväskylä, Finland

INTRODUCTION

Power output of the human skeletal muscle is under influence of muscle-tendon elasticity. In normal stretch-shortening cycle (SSC) activities the interaction between contractile (fascicle) and tendon structures are somewhat controversial. The basic definition of the eccentric part of SSC refers to lengthening of the muscle while it is activated. This concept refers naturally to the entire muscle tendon unit (MTU), but its validity has been questioned to apply to the contractile tissue (Griffiths, 1991; Belli & Bosco, 1992). The present study was designed to examine the behavior of both the contractile (fascicle) and tendon parts of the vastus lateralis (VL) muscle during varying intensity SSC jumps performed in a special sledge apparatus.

METHODS

Eight young male subjects performed one-legged drop jumps (DJ) from the predetermined constant dropping height in a sledge apparatus (Kyröläinen & Komi; 1995). Four different rebound heights were designed as low (80% maximum squat jumping height; SJH), middle (90% of SJH), high (110% of SJH) and maximum intensities. The knee angular movement from contact to lowest position was kept the same in all jumping conditions. The subjects were given visual feedback to control the predetermined lowest position with the knee and ankle angles and the target jumping height. Measurement of EMG activities of the vastus lateralis muscle (VL) was made simultaneously with ultrasound recording of the fascicle length changes. In addition, one subject performed all jumps with an optic fiber inserted into his patellar tendon for in vivo force recordings. During trials kinematic, force plate, ultrasonographic, EMG and patella tendon force data were time synchronized.

Figure 1: Length changes of MTU, tendon and fascicle drawn together with ground reaction force and EMG recordings during low and maximal jumps.

RESULTS AND DISCUSSION

The results indicated that in all conditions the fascicle, tendon and MTU were stretched during the braking (eccentric phase) and shortened during the subsequent concentric phase. Fig. 1 presents these results for the low and maximum intensity rebound conditions. When the VL force was plotted against the MTU velocity (fig. 2) the obtained curves represent the expected F-V relationship for SSC activities (Komi; 1990; Finni et al, 2001). A more detailed examination of the fascicle and tendon length changes revealed that their behavior was different when jumping (rebound) intensity was varied. The fascicles followed different response curves compared to either tendon or MTU. As expected the fascicles demonstrated higher stiffness in the braking phase and the tendon shortening increased in the push off phase with increased jumping intensities.

Figure 2: Instantaneous force-velocity curves of the vastus lateralis muscle in the two intensity jumps.

The observed results must be interpreted to apply to the VL muscle only and to the used SSC exercises. Within this limitation the results confirm the hypothesis that in SSC exercise the performance potentiation results partly from increased muscle stiffness operating efficiently to make the tendon recoil during the push off phase.

MUSCLE CELLULAR AND ARCHITECTURAL CHANGES DUE TO CHRONIC SPASTICITY

Richard L. Lieber and Jan Fridén

Department of Orthopaedics and Bioengineering, Department of Hand Surgery
University of California, San Diego, USA and Göteborg University, SWEDEN
e-mail: rlieber@ucsd.edu

INTRODUCTION

Spasticity that occurs after brain injury can cause severe joint deformity and dramatically affect quality of life. While muscle spasticity is neural in origin there is good evidence that spastic muscles are themselves abnormal. However, there are a paucity of objective data available regarding the properties of normal and spastic human muscle and muscle cells. Thus, the purpose of these studies were to measure sarcomere length-joint angle and isolated material properties of normal and spastic hum muscle.

METHODS

Twelve subjects with radial nerve palsy were used to represent flexor carpi ulnaris (FCU) sarcomere length of “normally innervated” muscle, even though the patients themselves required surgical treatment. While the extensor muscles were denervated, the FCUs had normal central and peripheral innervation. Patients with spasticity ranged in age from 13 to 34 and were receiving tendon transfers secondary to cerebral palsy (n=5) or head injury (n=1). Muscle biopsies were also obtained from normal (n=25) or spastic muscles (n=15) secondary to other surgical procedures. Sarcomere length was measured by intraoperative laser diffraction (Lieber et al. 1994) and cellular passive mechanical properties by *in vitro* biomechanics (Magid and Law, 1983)

RESULTS

Spastic FCU muscles had extremely long sarcomere lengths with the wrist fully flexed ($3.48 \pm 0.44 \mu\text{m}$) compared to the FCU muscles of patients with radial nerve injury ($2.41 \pm 0.31 \mu\text{m}$; Fig. 1

Figure 1: Sarcomere length of normal FCU (hatched bar) compared to spastic FCU. Spastic FCU sarcomere length was significantly longer than normal (asterisk).

In three of the patients with spastic wrist flexion contractures, the slope of the FCU sarcomere length-joint angle relationship was measured and found to be, essentially, normal ($0.017 \pm 0.005 \mu\text{m}/^\circ$, n=3) suggesting that serial sarcomere number (and therefore muscle fiber length) was unchanged in spite of the dramatic absolute sarcomere length change.

Figure 2: Histogram of resting sarcomere length of normal muscle cells (A) compared to spastic muscle cells (B). Spastic resting sarcomere length was significantly shorter than normal.

DISCUSSION

The most dramatic effect observed between cell types, was the consistent and relatively large resting sarcomere length difference between groups. While normal fibers had a resting sarcomere length of $2.20 \pm 0.04 \mu\text{m}$, spastic fibers were about 20% shorter with an average resting sarcomere length of only $1.84 \pm 0.05 \mu\text{m}$ (Fig. 2, $p < 0.001$). Tangent modulus of the sarcomere length-stress relationship in spastic fibers ($55.00 \pm 6.61 \text{ kPa}$) was almost double that measured in normal fibers ($28.25 \pm 3.31 \text{ kPa}$, $p < 0.001$). Overall, these results indicate that spasticity results in a major alteration of normal muscle-joint anatomical relationships. Such an alteration appears unprecedented in either the muscle plasticity or neuromuscular disease literature. In addition, the fact that spastic muscle cells have a shorter resting sarcomere length and increased modulus suggests dramatic remodeling of muscle structural components. While there is evidence in the literature for significant remodeling of muscle after spasticity (Rose et al. 1994; Sinkjaer et al 1993) the details of this remodeling remains to be elucidated.

EFFECTS OF RESISTANCE AND STRETCHING TRAINING PROGRAMS ON THE VISCOELASTIC PROPERTIES OF TENDON STRUCTURES IN VIVO

Tetsuo Fukunaga, Keitaro Kubo, and Yasuo Kawakami
Department of Life Science (Sports Sciences), University of Tokyo,
Komaba 3-8-1, Meguro-ku, Tokyo 153-8902, Japan

INTRODUCTION

Resistance training and stretching have been commonly used for increasing the performances during various human movements. However, we have little knowledge on the influences of these exercise programs on human tendon structures. Recent our observations showed that the execution of either muscle contractions or stretching changed transiently the tendon properties (Kubo et al. 2001a,b). Therefore, it is likely that the tendon properties will be changeable through regular resistance and/or stretching exercises. The present study examined whether resistance and stretching training programs altered the viscoelastic properties of human tendon structures in vivo.

METHODS

Eight subjects completed 8 weeks (4 days /week) of resistance training which consisted of unilateral plantar flexion at 70% of one repetition maximum with 10 repetitions per set (5sets/day). They performed the resistance training on one side (TR) and the resistance training and static stretching training (10 min/day, 7 days/week) on the other side (TRST). Other 8 subjects performed the static stretching training (10 min/day, 7 days/week) on one side (ST) and served as control on the other side. Before and after training, the elongation of the tendon structures in the medial gastrocnemius muscle was directly measured using ultrasonography, while the subjects performed ramp isometric plantar flexion up to the voluntary maximum, followed by a ramp relaxation. The relationship between estimated muscle force (F_m) and tendon elongation (L) was fitted to a linear regression, and then the slope of which was defined as stiffness of the tendon structures. The hysteresis was calculated as the ratio of the area within the F_m – L loop to the area beneath the load portion of the curve.

RESULTS AND DISCUSSION

The stiffness increased $25 \pm 13 \%$ for TR and $23 \pm 20 \%$ for TRST, respectively. There was no significant difference in the relative increase of stiffness between TR and TRST. The hysteresis, on the other hand, decreased $17 \pm 20 \%$ for TRST, but unchanged for TR. For ST, the stretching training produced no significant change in stiffness, but decreased hysteresis $37 \pm 26 \%$. In addition, we investigated the effects of resistance and stretching training on the electromechanical delay, rate of torque development, plantar flexion torque with and without prior stretch. These results suggested that the resistance training increased the stiffness of tendon structures as well as muscle strength and size, and the stretching training affected the viscosity of tendon structures but not the elasticity.

ANKLE AND SUBTALAR KINEMATICS OF THE ANKLE JOINT WITH INTACT, INJURED, AND RECONSTRUCTED LATERAL LIGAMENTS

INTRODUCTION

Foot motion occurring in the ankle joint complex takes place in two separate joints, the ankle (or talocrural) and the subtalar (or talocalcaneal) joint. In vivo range of motion measurements of the relative involvement of the two joints is impossible with non-invasive methods. Therefore, it appeared valuable to measure the complex ankle joint motion under well-controlled laboratory conditions and determine the relative involvement of the two joints in the three main movement directions. The present study investigated the 3-D kinematics of the ankle and subtalar joint under intact joint conditions, after sectioning of the lateral ligaments and after reconstruction procedures with anatomical repair and tenodeses.

METHODS

The effect of ligament injuries and subsequent surgical treatment was investigated in fresh lower leg specimens. The specimens were mounted in a foot movement simulator that imposed computer-controlled moments in one direction of rotation allowing unconstrained motion in the other dimensions. Range of motion measurements were performed in the ankle and subtalar joint with two goniometer linkage systems measuring the relative motion between tibia-talus and talus-calcaneus. The measurements were repeated with the same specimens after ligament sectioning and reconstruction procedures in order to allow for intra-individual comparisons. After testing the intact joint the measurements were repeated following simulated ligament injuries by cutting the anterior talofibular and calcaneofibular ligament (condition LC).

In the first part of the project, three types of tenodeses were performed according to Evans (EV), Watson-Jones (WJ) and Chrisman-Snook (CS).

In the second part, the ligaments were fixed with different anatomical reconstruction procedures: direct repair (DR), peroneus tendon transplant (TT), carbon fiber graft (CF).

RESULTS

Ligament lesions led to an increased inversion and internal rotation predominantly in the ankle joint (Fig. 1). The reconstruction procedures with tenodeses reduced the range of motion in the ankle joint complex but achieved this stabilizing effect by reducing the range of motion in the subtalar joint to a non-physiologic level without correcting the ankle joint instability (Fig. 2). The most pronounced influence was seen after Evans tenodesis whereas the least interfering reconstruction was achieved with the Watson-Jones procedure. In general, the anatomical repairs led to a better restoration of joint kinematics than the tenodeses. In the ankle and subtalar joint the direct repair achieved the best result.

Fig. 1: Changes in ankle joint range of motion normalized to the intact joint (for abbreviations see text).

Fig. 2: Changes in subtalar joint range of motion normalized to the intact joint (for abbreviations see text).

DISCUSSION AND CONCLUSION

The presented results reveal that tenodeses restored ankle joint complex stability at the expense of overcorrecting at the subtalar joint. Anatomical procedures resulted in more physiologic joint kinematics. In general, these findings underline the necessity for anatomical treatment of chronic ankle instability that appears superior to the investigated tenodeses.

INTRODUCTION

The posterior tibialis tendon (PTT) has been described in the clinical literature as a stabilizer of the medial longitudinal arch and of the hindfoot, particularly during the heel-off phase of gait (Baumhauer,1997). Specifically, this muscle counteracts forces and moments, which evert and plantarflex the hindfoot and flatten the arch. Consequently, PTT dysfunction often leads to progressive flatfoot deformity (Gould,1980). This deformity is often associated with excessive stretching of several ligaments, namely the Spring Ligament, Deltoid Ligament, Long Plantar Ligament and Plantar Aponeurosis (Kitaoka,1998). It was hypothesized that disruption of the ligaments reduces the PTT's ability to control the stability of the arch resulting in a progressive collapse of the arch. However, little work has been done to investigate how disruption of these ligaments affects the ability of the PTT to maintain the geometry of the arch. The purpose of this study was to test this hypothesis.

METHODS

An experiment was conducted on five fresh frozen cadaveric lower limbs. The experimental system provided a model of the loading conditions on the foot during heel-off. It consisted of a loading frame interfaced to a tensile testing machine. The tensile machine provided the axial load, and the muscle forces were applied through a system of weights, cables and pulleys. Each specimen was configured in the heel-off position and the load on the PTT was removed to simulate total tendon disruption. Each specimen was tested in the intact condition and after each of the ligaments was sectioned. The order of ligament sectioning was changed between specimens. Geometric data was recorded after each unloading stage. Arch architecture describing the geometric relationship between the bones of the medial longitudinal arch was analyzed from a sagittal projection of the bones (Figures 1,2).

RESULTS AND DISCUSSION

In the intact state, the most significant effects of the PTT on arch architecture were in dorsiflexing the talus and increasing the height of the navicular and medial cuneiform. After the Spring Ligament was sectioned, the PTT still controlled the height of the arch, but its effectiveness in controlling the talus and the height of the navicular was compromised (Figure 1). The PTT still acted to control the inclination of the talus after the plantar ligaments were sectioned but its effectiveness in controlling arch height was compromised as it could not restore the medial cuneiform to its original intact height (Figure 2).

The Effect of the PTT after Sectioning the Spring Ligament

Figure 1

The Effect of the PTT after Sectioning the Plantar Ligaments

Figure 2

SUMMARY

Similar to previous studies, it was found that the PTT controls arch architecture primarily by dorsiflexing the talus and increasing the height of the navicular and cuneiform bones (Kitaoka,1998). Sectioning the plantar ligaments compromised the PTT's ability to control the height of the medial cuneiform. Sectioning the spring ligament compromised the PTT's ability to control the height of the navicular and dorsiflex the talus. These results suggest that surgical treatment of advanced stages of PTT dysfunction must address both the dysfunction of the PTT as well as the collapsed arch.

INTRODUCTION

Interest in ankle joint replacement has increased due to the encouraging survival rates reported of lately in the literature and at professional conferences. Less-than-satisfactory results with a variety of implant designs had previously left the orthopedic community apprehensive about including ankle replacement among the recommended treatments for painful ankle. In comparing early implants with those of the more recent successful implants, several design and technique distinctions can be made. Many of these characteristics, particularly low constraint, are now credited with contributing to the increased success being seen. Nevertheless, since most total ankle implants were originally developed without the aid of concerted engineering design efforts, little is known about their biomechanics. Likewise, due to the many early failures experienced, lower number of ankles replaced, and few retrievals available, objective long-term clinical assessment of the ankle arthroplasty lags far behind that of hip and knee replacement. Now with more ankles being replaced annually, a closer engineering examination of current ankle replacement designs and techniques is warranted in the hopes of averting any potential long term failure, improving design, and encouraging acceptance of this potentially beneficial treatment option. This paper reports on the use of FE methods to examine the relationship between intrinsic constraints, polyethylene stress, and wear in two types of total ankle replacements. A two-component low-constraint device (Agility) and a mobile bearing device (STAR) were examined.

METHODS

Finite element models of the total ankle implants were constructed using Patran 2000 based on manufacturer supplied geometry in the form of IGES files. Analysis was performed using Abaqus 6.1. All software ran on a high performance NT based workstation. Tibial and talar metallic components were modeled as rigid bodies. Polyethylene components were modeled using a finite element mesh comprised of reduced-integration, 8-node Hex elements, or modified 10-node Tet elements, and used an elastic-plastic constitutive model. In the case of the two-component device, (Fig. 1) the superior surface of the polyethylene device is constrained by the metallic tibial backing so contact was modeled between the polyethylene and talar component only. Models of the mobile bearing device (Fig. 2) required two contact interfaces, one at the polyethylene superior surface and one at the inferior surface. The polyethylene bearing in the mobile bearing device is, once loaded, constrained solely by friction and the topography of the contact surfaces. In both models a finite-sliding contact

formulation was used at the contact interfaces. The intrinsic constraints provided by each implant were evaluated by observing relative displacement as a function of applied load. To examine relative contact mechanics and wear potential, quasi-static ankle loading and displacement conditions, representative of those found in normal gait, were applied to the models. Contact and internal stress distributions were recorded for each implant.

Fig 1. Two-Component Device **Fig 2.** Mobile Bearing Device

RESULTS AND DISCUSSION

The contact stress distribution of the two-component device is highly sensitive to relative position and orientation of the components. In this device, high polyethylene contact and internal stresses result when congruency is lost. Several loading configurations, most notably those including internal/external rotational torque in the physiologic range, resulted in loss of congruent contact between polyethylene bearing surface and the talar component. This phenomenon resulted in point and line contact yielding very high contact and internal stresses (> 96 MPa at 5X body weight) in the polyethylene that are predictive of local wear and plastic deformation. Once loss of contact is initiated through torsional rotation, inversion/eversion stability is increasingly lost. Polyethylene yield stresses were reached with as little as 1X body weight axial load and 1.3 Nm torque. Based on the stresses predicted, permanent polyethylene deformation and high local wear can be expected to occur during many physiologic loading activities. In the mobile bearing device, wear is predicted to occur primarily on the inferior surface of the polyethylene bearing where both larger motion and larger contact stresses were found. Despite the maintenance of congruency, contact stresses were not evenly distributed across contact areas and were a function of loading configuration. During flexion of this mobile bearing device, max contact stresses (over 30 MPa were predicted at 5X body weight) were elevated (up to 2X) by friction forces during flexion and by applied shear forces or version moments.

MECHANICAL STABILITY OF ANKLE BRACES UNDER PASSIVE AND DYNAMIC LOADING CONDITIONS

Eric Eils¹, Dieter Rosenbaum¹, Christina Demming¹, Guido Kollmeier¹, Lothar Thorwesten², Klaus Völker²

¹Movement Analysis Lab, Orthopaedic Department, ²Sports Medicine
University Clinics Münster, Münster, Germany, eils@uni-muenster.de

INTRODUCTION

Mechanical stability of ankle braces may either be evaluated under passive or dynamic conditions (Podzielnny/Hennig 1997; Siegler et al. (1997). Passive condition refers to a situation where the ankle joint complex is moved passively in different directions in an unloaded situation. Dynamic condition refers to a situation where subjects are subjected to a fast inversion event on a tilting platform simulating an ankle sprain. These two tests provide objective information about the stabilizing effects of various ankle braces either under laboratory or more realistic conditions. However, at this point it remains unclear, if the obtained findings describing the stability of braces under laboratory conditions can be transferred to a more realistic situation when the foot-ankle complex is loaded with bodyweight. Therefore, the aim of the present investigation was to compare the stability of ten different ankle braces under passive and dynamic loading conditions.

METHODS

24 subjects with chronic ankle instability participated in the project (23±3 yrs, 70±12 kg, 177±8 cm). A mechanical fixture was developed to test passively induced stability of ankle braces in three planes with a standardized torque. Rotation axes for plantar/dorsiflexion, inversion/eversion and internal/external rotation were set perpendicular to each other in alignment with the intermalleolar axis, the long axis of the foot on the level of the estimated location of the subtalar joint and the longitudinal axis of the tibia, respectively. To determine individual torques, the leg was fixed without brace and rotated in each direction to the limits of comfort. The maximum torque for each direction was then used for all conditions and the rotational displacement were measured with potentiometers fixed to the axes. For dynamic stability tests a trap door with a tilting angle of 30° in the frontal plane was used to simulate lateral ankle sprains. A customized goniometer was used to measure the hindfoot inversion angle

inside the shoe. Ten commercially available ankle braces were used in all subjects. Models were subdivided into three categories (rigid, semi-rigid and soft). One shoe model was used in these investigations and the order of testing conditions was randomized. For comparison, the restriction of motion in relation to the no-brace condition was calculated for each direction. A repeated measures ANOVA with the alpha-level set to 5% and the Scheffe post-hoc test were used for statistical analysis.

RESULTS

Under passive and dynamic loading conditions, all braces restricted the range of motion significantly compared to the no-brace condition (Tab. 1). The most distinct reduction was obtained for inversion. Differences between most semi-rigid and soft braces were significant. A high correlation between passively induced and dynamic inversion was found ($r=0.78$; $p=0.0031$). The stabilizing effect was less pronounced during dynamic inversion as compared to passive inversion (Tab. 1).

DISCUSSION

All tested braces significantly restrict range of motion compared to the no-brace condition in passive and dynamic situations. The present results provide an objective basis about mechanical stabilizing characteristics of braces. Correlation between passive and dynamic results for inversion showed that dynamic characteristics are reflected by passive testing but the amount of restriction for dynamic inversion is less than for passively induced movements. Therefore, it should be considered that recommending braces only on the basis of passive support characteristics may be not sufficient for dynamic movements.

INTRODUCTION

Finite element (FE) models of the foot and ankle are becoming increasingly sophisticated. Our laboratory has developed an anatomically accurate FE model that incorporates physiological material properties. In this abstract we describe the current development and validation of our FE foot and ankle model for simulations of quiet stance.

METHODS

The addition of cartilage bodies and the increased degrees of freedom in the model (allowing more bones to move relative to each other) represents an improvement of our laboratory's FE foot and ankle model (Ledoux et al 2000a; Camacho et al 2001). The bones were modeled as rigid bodies; geometries were obtained from CT scans of a 67-year-old male. The ligaments were modeled as springs and dashpots that were anatomically located (Sarrafian 1993); properties were extrapolated from ankle ligament data (Siegler et al 1988). The plantar soft tissue was modeled with hyperelastic elements; the geometry was obtained from the CT scans and the properties from the literature (Lemmon et al 1997). The anatomical description of the cartilage bodies was obtained from the space between bones. The material properties were not physiologic, but were estimated as 100x stiffer than the plantar soft tissue. The foot bones proximal to the metatarsals were free to move independently. The bones of the first ray were grouped together, as were the bones of the 2nd through 5th rays. The mesh was generated with Truegrid v2.1 and the simulation was run with LS-DYNA v960 (Figure 1).

Figure 1: The FE foot and ankle model.

The validation data were collected via a custom designed pneumatic foot-loading frame (Niki et al 2001). The apparatus supported the foot in midstance; a compressive load was applied to the tibia while the tensile forces were applied to the extrinsic muscles. Motion of the bones of the foot (calcaneus, talus, navicular, cuboid, first metatarsal and fifth metatarsal) were quantified with a FastTrak™ Motion Analysis System. Data were collected for a compressive load (400 N) on the tibia and a tensile load (200 N) on the Achilles tendon

(Ledoux et al 2000b). For 10 cadaveric feet, the mean and standard deviation (SD) of the motion of the 6 bones in the 3 cardinal planes, representing 18 performance metrics, were quantified and compared to the predicted motion of the model.

RESULTS AND DISCUSSION

The predicted motion of the FE model paralleled the motion measured of the cadaveric study in the sagittal plane (Figure 2). The two bones that were out of range, the 1st and 5th metatarsals, actual dorsiflexed too much because the model lacks any passive structures on the dorsum of the foot to restrict motion. Overall, the motion of the model was within 1 SD for 14 of the 18 motions, and within 2 SD for 17 of 18.

Figure 2: Sagittal plane motion (dorsiflexion = positive, plantar flexion = negative) of the foot bones for the model and cadaveric specimens (mean +/- 1 SD).

SUMMARY

The ability of the FE foot and ankle model to accurately predict bone movement under postural load has been demonstrated in comparison to experimental measures.

THE LOCOMOTOR BIOMECHANICS OF LARGE TERRESTRIAL VERTEBRATES

John R. Hutchinson

Biomechanical Engineering, 209 Durand, Stanford CA 94305-4038
jrhutch@stanford.edu

INTRODUCTION

As body mass (m_b) increases during ontogeny or evolution, it is increasingly precarious to maintain locomotor performance (e.g., maximum forward velocity) at the same level, especially when $m_b \gg 100$ kg (Garland, 1983). Increasing the relative cross-sectional areas of bones, muscles, and tendons, or the relative lengths of muscle moment arms, is an anatomical specialization that forestalls reduction of locomotor performance at larger sizes. Similarly, adopting a more upright (graviportal, or columnar) limb orientation or using a higher duty factor are behavioral specializations (Alexander, 1985; Biewener, 1990) that can maintain performance. Although the earliest dinosaurs were relatively small ($m_b < 10^2$ kg), multiple lineages of dinosaurs such as sauropods, duckbill dinosaurs, and tyrannosaurs evolved gigantism ($m_b > 10^3$ kg; approaching 10^5 kg in the case of sauropods; Sereno, 1997). Likewise, elephants secondarily evolved gigantism. I ask, as gigantism evolved in these lineages, did locomotor performance decrease as a consequence of increasing m_b , or did anatomical or behavioral specializations keep performance relatively constant despite increasing m_b ?

METHODS

A quasi-static model of *Tyrannosaurus* and other tetrapods was used to estimate the joint moments at mid-stance of rapid bipedal running (Hutchinson & Garcia, in press). These moments, combined with data on muscle anatomy, permitted calculation of how much muscle mass (as a proportion of m_b) would be required to maintain static equilibrium in a given limb orientation. The ratio of the muscle mass dedicated to limb extensors to muscle mass required to balance the limb joints during rapid running is crucial. For extant animals, we used dissections to gather necessary anatomical data, and entered joint angles based on published kinematics. For extinct tetrapods such as *Tyrannosaurus* and smaller dinosaurs, we entered our best estimates of anatomical data and used sensitivity analysis to see how much possible variation in joint angles, muscle fiber lengths and moment arms, and other uncertain parameters changed estimates of the required muscle masses. We also studied healthy elephants in captivity (Hutchinson et al., in press) to see how fast they could move and what gait(s) they used. Trainers in America and Thailand guided 48 elephants (4 African; 44 Asian; $m_b \sim 500$ -5000 kg; age ~ 2 -50 yrs) past stationary cameras (25-200 Hz) to collect kinematic data from ~ 5 -20 trials per elephant.

RESULTS AND DISCUSSION

Giant tetrapods face a particular problem in terms of body composition. As m_b increases, the proportion of m_b that must

be dedicated to extensor muscles (and skeletal elements) supporting the body increases. Because total muscle mass is usually $\sim 50\%$ m_b (Hallgrímsson & Maiorana, 2000); less than 40% m_b as extensors; and skeletal mass is $< 20\%$ m_b (Christiansen, 2001), eventually no more mass can be allocated to extensor muscles or limb bones. In *Tyrannosaurus*, we (Hutchinson & Garcia, in press) showed that roughly 80-90% m_b was required as extensors in order to run quickly with bent limbs. This is impossible, so large dinosaurs like *Tyrannosaurus* presumably straightened their limbs and reduced their relative locomotor performance. Elephants demonstrate that rapid locomotion (> 6 m/s, duty factor < 0.40 , and Froude number > 3.0 ; Hutchinson et al., in press) is possible with columnar limbs but no true aerial phase, which would incur greater impact forces. Elephants maintain walking kinematics as they increase speed, keeping one foot on the ground, but available data suggest that the underlying kinetics switch from walking to running. As size increases, terrestrial vertebrates often first evolve anatomical, then behavioral specializations for maintaining locomotor performance. However, at giant sizes relative and eventually absolute locomotor performance inevitably decline because no specializations can maintain locomotor performance at high levels. Therefore, giant animals are generally restricted to less extreme limb morphologies, gaits, and speeds.

MECHANICAL POWER PRODUCTION FOR ACCELERATION: THE CHALLENGES OF BEING A BIPED

Thomas J. Roberts

Zoology Department, Oregon State University, Corvallis, OR
robertst@bcc.orst.edu

INTRODUCTION

Running animals face challenges associated with the transition from steady-speed running, where net mechanical power output is low, to acceleration, where muscle function must be altered to maximize power output. Two features of this transition may present particularly difficult challenges for bipedal runners. First, balance must be maintained during acceleration while the direction of the ground reaction force changes significantly. Accelerating quadrupeds can transfer more weight to the hindlimbs to maintain the alignment of the ground reaction force and the center of mass (Lee et al., 1999), and human runners lean forward to position their center of mass anterior of the point of force development (Harland and Steele, 1997). Birds must use an alternative mechanism for maintaining balance, because their body posture cannot be altered to position the center of mass more anterior to the hip. Another challenge facing accelerating bipeds is the potentially limited availability of muscles specialized for work vs. power production. Quadrupeds use the large, long-fibered muscles of the hindlimbs to power jumping and accelerations, while distal muscles with long tendons appear to be specialized for spring-like function (Alexander, 1974). Birds have a large concentration of muscle mass in the distal ankle extensors, and must either use these spring-like muscles to perform net work during acceleration, or power acceleration with only a fraction of their available muscle motor.

This paper presents results from high-speed video and force plate measurements of accelerating turkeys. These measurements were used to determine how accelerating bipeds produce the power for acceleration while still maintaining balance.

METHODS

High speed video and force plate measurements were made for 5 wild turkeys accelerating over a 10 meter trackway. Joint positions were determined by analysis in NIH Image. Joint power outputs for single footfalls were calculated from the joint velocity and joint moment measured from coordinated joint position and ground reaction force measurements. Measurements were taken for single footfalls across a range of accelerations, from steady-speed running to the maximal elicited acceleration.

RESULTS AND DISCUSSION

Peak accelerative horizontal ground reaction forces during maximal accelerations were as much as 50% of peak vertical force. With increasing rate of acceleration, turkeys increased their angle of limb protraction and decreased the angle of limb retraction. The change in limb angles positioned the center of mass more anterior to the point of force application during accelerations, thereby maintaining alignment of the ground reaction force and the center of mass. Total stance limb excursion did not change significantly with acceleration.

Net power output at the ankle increased as a function of acceleration. Approximately half of the total power output required to accelerate the body was produced at the ankle. The high net power output at the ankle is consistent with the idea that the relatively short-fibered, spring-like ankle extensors contribute significant net power during acceleration. Analysis of possible transfer of power from knee extensors to the ankle via biarticular muscles indicates that the relatively limited range of knee extension during stance makes significant power transfer to the ankle unlikely.

SUMMARY

Running turkeys alter limb kinematics to produce the high propulsive forces required for acceleration. This appears to be a sufficient alternative to quadrupeds' redistribution of force between the hindlimbs and forelimbs during acceleration. Turkeys use the muscles of the ankle as force-producing springs during steady-speed running and as power producing motors during acceleration. This adaptability in muscle function may be particularly critical for maximizing accelerative power in avian runners because ankle extensors make up nearly one third of the turkeys' hindlimb muscle mass. Birds meet the challenges of bipedal acceleration with flexibility in limb kinematics and adaptability of function in individual muscles.

CHANGES IN FLIGHT MORPHOLOGY INFLUENCE THE SHAPE OF THE AVIAN POWER CURVE

Matthew W. Bundle¹ and Kenneth P. Dial

¹mbundle@selway.umt.edu

Flight Laboratory, University of Montana, Missoula, MT, USA

INTRODUCTION

Investigations into the metabolic cost of flight have yielded power curves of two types, those with a strong dependence upon flight speed (U-shaped) and those that are independent of speed (flat) (Ellington '91). A number of aerodynamic models exist to predict the cost of flight, and all predict power curves that are U-shaped. However, the most accepted of these models (Rayner '93, Pennycuick '89) do not account for changes in airfoil geometry that occur as birds fly across a range of speeds. The influence of airfoil size on the power curve of a flying object can be significant, and birds change their size and shape to an astonishing degree as they fly across their speed range.

Here, we test the hypothesis that birds who dramatically change the surface area of their wings and tail will have a flat power curve. Alternatively, birds with a restricted morphology will have a narrow range of speeds over which they fly economically and will conform to predictions based on aerodynamic theories.

METHODS

Four Budgerigars (38.7g), three Cockatiels (80.5g) and two Black Billed Magpies (190.5g) were trained to fly across a range of speeds in a variable speed wind tunnel while wearing light weight masks designed to capture their expired air. Oxygen consumption and carbon dioxide production were measured using the open flow technique. Simultaneous wing-beat kinematics were obtained from lateral and dorsal high-speed video cameras (500fps).

RESULTS AND DISCUSSION

The budgie and cockatiel power curves show a pronounced U-shape (fig 1). The magpie metabolic power curve by contrast is nearly independent of flight speed. Preliminary kinematic data suggest that magpies reduce the surface area of their wings and tail by 35% as they fly from the slowest to fastest speeds in their range, compared to only 12% for cockatiels.

If a commercial aircraft was able to affect these graduated shape changes, a broad region of flight speeds with no increase in fuel consumption would be produced (thick line fig 2). We suggest that the morphing ability of some bird species may allow them to fly across a range of speeds with little increase in cost, and that this phenomena may explain the existing dichotomy between empirical and aerodynamic studies. We further suggest that avian morphology may play an under appreciated role in influencing the cost of flight.

Figure 1: This is the first time where power curves that are qualitatively different have been obtained using the same methodology. These results suggest that a biological rather than experimental event is influencing the shape of the avian power curve.

Figure 2: Power curves for a commercial aircraft and for the same aircraft if wing area is reduced by 35%. The thick line shows the power curve that would be produced if an airplane were able to perform graduated shape changes similar to those of a magpie.

INTRODUCTION

Cervical spine facet capsular ligaments are thought to be an anatomic site of whiplash injury. Biomechanical studies have shown that whiplash loading is complex and includes phases of combined compression-bending and shear. Epidemiology studies have shown that out-of plane loading as a result of pre-impact head rotation also contributes to risk. In-vitro studies, however, have shown that capsular ligaments have little effect on the mechanical properties of motion segments. As a result, low-grade injury to this ligament would have no effect on segmental kinematics despite potentially serving as a source for whiplash symptoms. Accordingly, our goals were to examine the potential for injury by comparing the full-field capsular ligament strain under, one, two and three dimensional in-vitro loads, similar to those that occur in whiplash, to the strains required to produce injury in the ligament.

METHODS

Twenty-five cervical spine C3-C4 and C5-C6 motion segments were mounted in a test frame in the neutral anatomic position. Specimens were mechanically stabilized and then tested in pure flexion-extension bending; and combined posterior shear, extension and compression. Each test was performed with and without an axial torque. Posterior shear loads varied from 0 to 135 N, compression loads varied from 0 to 325 N, flexion/extension moments from 0 to 2.5 Nm, and axial pre-torques were either 0 or 1 Nm. Two photo absorptive target arrays mounted to the facet capsular ligament and the anterior surface of the vertebral body were stereo-imaged to calculate facet capsular ligament Lagrangian large strain field and motion segment kinematics respectively. Strain to failure was measured by isolating the right facet joint of each motion segment and loading it to failure in axial tension or shear at constant velocity (0.0083 mm/s, 10 mm/s, or 100 mm/s). Failure strain was defined by the maximum principal strain measured at a decrease in load with increasing deformation. Failure was defined as sub-catastrophic if the load subsequently increased. Mechanical quantities were then compared using ANOVAs and paired t-tests ($\alpha = 0.05$).

RESULTS

Strain fields were complex and the site of maximum strain varied with donor, motion segment, and loading condition. Maximum strain did not, however, vary between motion segments ($p > 0.09$). The addition of an axial pre-torque significantly increased facet capsular ligament strain ($p < 0.01$).

Strain to catastrophic failure in tension was insensitive to loading rate. Strain to both catastrophic failure ($94 \pm 84\%$) and sub-catastrophic failure ($35 \pm 21\%$) in shear were significantly larger than strains measured during whiplash-like loading ($17.8 \pm 5.8\%$) ($p < 0.006$). Two specimens from different donors, however, showed larger strains during whiplash-like loading than at sub-catastrophic failure (Figure 1).

Figure 1. Individual strain data, and mean, range, and variance for nine specimens. While the mean data show no risk for injury, comparison of individual data points illustrates potential sub-catastrophic injury risk in two (heavy line) cases.

DISCUSSION

Although strategies to prevent whiplash are being advocated, the risk for injury, the mechanism of injury, and the site of injury remains unknown. This series of experiments showed that some subjects experienced strains during whiplash-like loading that can cause sub-catastrophic capsular ligament failure. The results also suggested that axial rotation of the head increased injury risk. With the additional strain imposed by muscles that insert directly onto the capsular ligaments, these data provide a biomechanical explanation for injuries to the facet capsular ligaments of some subjects during whiplash collisions.

INTRODUCTION

Soft tissue neck injuries, commonly called whiplash, are a frequent and costly consequence of vehicle crashes. The U.S. Department of Transportation estimates 805,000 whiplash cases occur annually, and U.S. insurers pay more than \$7 billion yearly to treat these injuries. Efforts to address whiplash include improving vehicle seat and head restraint designs. Special whiplash dummies like BioRID exist, but currently there are no standard test protocols for evaluating the injury protection performance of new designs. A standard test protocol should anticipate the acceleration likely to be encountered in real crashes. This study examines how different bumper designs attached to the same car model affect the car's acceleration in a rear crash and, in turn, whether the differences in vehicle acceleration affect the injury measures recorded on a BioRID in the car's front seat.

METHODS

Four 32 km/h front-to-rear crash tests were conducted with Volkswagen New Beetles, two of which were equipped with standard U.S. bumpers and two with standard European bumpers. The design difference is that hydraulic dampers attach the U.S. bumpers to the car, while crushable steel box elements attach the European bumpers. Each pair of crashes involved cars with the same bumpers. Sensors fixed to the floor of each struck car recorded crash acceleration.

A BioRID was seated in a front seat of each rear-struck car. Sensors on the dummy's head and first thoracic vertebrae (T1) recorded accelerations used to calculate the neck injury criterion (NIC). A multi-axis force sensor recorded forces applied to the head by the neck.

RESULTS AND DISCUSSION

Figure 1 shows the vehicle accelerations. The differences between U.S. and European bumpers resulted because the front of the striking European cars slid up over the rear of the struck car, thus delaying the struck car's acceleration until stiff

parts of both striking and struck cars were engaged. In contrast, the U.S. striking car fronts pushed solidly against the rear of the struck cars without over-riding them.

Table 1 summarizes injury measures recorded from BioRID sensors. On average, the European bumpers produced higher loads on BioRID's neck, but test-to-test variability was nearly as great as differences between tests with different bumpers.

SUMMARY

Differences in vehicle acceleration timing like those resulting in tests with different bumpers described here do not have a strong influence on neck injury risk as measured by BioRID.

MINOR NECK INJURY MECHANISM IN LOW SPEED REAR IMPACT BASED ON HUMAN CERVICAL VERTEBRA MOTIONS

Koshiro Ono¹, Koji Kaneoka²

¹ Japan Automobile Research Institute, Karima, Tsukuba, Japan kono@jari.or.jp

² Dept. of Orthopaedic Surgery, University of Tsukuba, Tennoudai, Tsukuba, Japan

INTRODUCTION

In order to understand minor neck injury mechanisms, it is said that an in-depth analysis of the relationship among the neck muscular response, motions of cervical vertebrae, intervertebral disc and facet joint injuries is necessary. In this regard, it was decided to conduct experiments using volunteers for the sled tests in low speeds and to compare and analyze the motions of cervical vertebrae upon impact with those under normal physiological conditions. Furthermore, for the parameter study of the head/neck/torso and spine responses, the impact speed, seat stiffness, neck muscle tension, and the alignment of the cervical spine were selected. The main objectives of the study are as follows: 1) to better understand minor cervical spine injury mechanism, 2) to quantify the motion of each vertebra during rear-end impact, and 3) to verify the head/neck/torso kinematics and the spine response under the different conditions.

METHODS

An X-ray cineradiographic system was used to analyze motions of cervical vertebrae of volunteers subjected to rear impacts. The mini-sled was developed that it could simulate the impact accelerations when the rear end of vehicle was collided. Accelerations were measured on the sled, the head, chest (above the first thoracic spine: T1) and front chest of each volunteer. With the application of the head four-channel acceleration measurement (Ono & Kanno, 1996), the shear & axial forces and the bending moment on the occipital condyle were analyzed. The electromyographic responses were measured with EMG electrodes at the sternocleidomastoid (SCM) on each side of neck, trapezius (TZM) and the paravertebral (PVM) muscles on the left side. In order to analyze the volunteers' motions during rear impacts, motions of head/neck/torso were photographed with high speed camera (MEMORECAM: NAC Inc.) at the speed of 500 frames per second, and then fed into a system called ImageExpress (NAC Inc.).

RESULTS AND DISCUSSIONS

The five series of experiments on twenty-five volunteers conducted under this study are shown in Table 1. Some volunteers were involved twice in different series of experiment. The aim of the experiments was to determine the effect of the difference in seat performance (standard or rigid) on motions of cervical vertebrae at the impact speeds of 4, 6 and 8 km/h, respectively. It may be said that the foregoing study discusses the mechanism of spine straightening. The influences of the spine motions on the neck injuries are expressed in patterns per phase of timing after impact as shown in Figure 1, together with the human impact responses. In the initial phase of impact,

lumbar and thoracic vertebrae flex and extend, resulting in their straightening and torso ramp-up motion. Due to the motions of spine and torso, the neck is pushed up during the initial phase and middle phase of impact, and the lower cervical vertebrae extend sharply, resulting in the extension of upper cervical vertebrae and S-shape deformation of neck. Since the rotation axis of the lower vertebrae travels upward because of the above, the facet joint injury mechanism and synovial fold impingement are apt to occur.

SUMMARY

A series of experiments simulating low speed rear-end impacts have been conducted on volunteers. Motions of the cervical vertebrae have been analyzed by means of X-ray cineradiography. Results of the analysis have been compared with those in physical state, and the influences of spine motions on the risk of neck injuries have been discussed. The findings have been obtained on the risk of minor neck injuries based on clinical knowledge, according to the characteristics of human motions during rear-end impacts.

EFFECTS OF MUSCLE ACTIVATION AND SEATING POSTURE IN REAR END IMPACT USING A HUMAN MODEL WITH A DETAILED NECK

Jack van Hoof, Riske Meijer, and Marike van der Horst
TNO Automotive, Crash Safety Centre, Delft, The Netherlands

INTRODUCTION

Neck injuries resulting from rear-end impact rank among the top vehicle safety problems and have serious implications for our society. The mechanisms causing these neck injuries are still not clearly understood. The main reason for this is that it is hard to characterize whiplash both clinically and experimentally. Numerical models of the human body can partly solve this problem, since they provide a relatively cheap and efficient means of gaining insight into the parameters that determine the response of the human body during impact.

METHODS

In this study, a human body model including a detailed model of the neck was used to study the mechanics of the neck during rear-end impact. This model has been validated previously for frontal, lateral, and rear-end impact with responses of volunteers and post mortem human subjects (PMHSs) (Van der Horst *et al.* 2001; Kroonenberg *et al.* 1998). Data in literature indicates that neck muscle activity (Siegmund & Brault 2000) and initial seating posture (Aibe *et al.* 1982, Szabo 2000) are two of the main factors affecting the response of the neck under rear impact conditions. The objective of this study was to use the human model with detailed neck to evaluate the effects of neck muscle activation and seating posture on the head-neck kinematics. The effects predicted by the model were verified with two sets of volunteer rearward sled tests. The model is shown in Figure 1

Figure 1: Human model with detailed neck seated in car seat

RESULTS AND DISCUSSION

In general, the response of the numerical model corresponded well with that of the volunteers. The ramping up observed for the volunteers was slightly higher than predicted by the model. The muscle activation level was found to influence the head kinematics significantly. A higher muscle activation level resulted in a smaller maximum head angle, whereas a longer reflex delay resulted in a larger maximum head angle. The position of the head relative to the head restraint was also found to significantly affect the head and neck kinematics. A forward bent seating posture combined with a low head restraint resulted in a larger head and neck rotation, and a higher neck extension than a straight seating posture with high head restraint. The results of this study indicated that the model can be used in seat design studies to mitigate whiplash injuries.

SUMMARY

In this study, a human body model including a detailed model of the neck was used to study the effects of neck muscle activation and seating posture on the mechanics of the neck during rear-end impact. The effects predicted by the model were verified with two sets of volunteer rearward sled tests. In general, the response of the numerical model corresponded well with that of the volunteers. The results of this study indicated that the model can be used in seat design studies to mitigate whiplash injuries.

INTRODUCTION

Low speed rear-end impact of motor vehicle tend to produce a whiplash injury of the occupants. Whiplash injury is known to be one of the minor injuries occurring to the crash victims. However, the enormous societal cost and incompleteness of the basic information of injury mechanisms make this whiplash injury as one of the most urgent issues to be investigated in the occupant safety field. Various hypotheses for the cause of injury have been proposed based on the experimental and analytical studies. Thus, the supporting findings for the hypotheses would make further progresses of the study like development of whiplash injury criteria and implementation of proper countermeasures. For this purpose, a finite human model has been developed in this study to analyze the kinematics and deformations of body parts during the rear impact.

FINITE ELEMENT MODELING

The model was built on 50% male geometry and consists of deformable neck and torso to which the rigid head and limbs were articulated. Since the main body parts for rear impact event are the neck and torso, they are thus anatomically depicted in detail. The hard and soft tissues in the neck and torso such as vertebrae, muscles, ligaments, organs, discs and fatty tissues were modeled by using the various kinds of finite elements and material properties to represent adequate mechanical behaviors of each component. The other body parts were also included but rather in simplified forms. Rigidly modeled head and limbs are articulated to the neck and torso. Fig. 1 shows the FE human model developed in this study.

VALIDATION

Range of motion for each motion segment of spine (cervical, thoracic, and lumbar) was calculated by applying the moment

of flexion/extension and axial rotation, respectively. And it coincided well with the physiological representative values from the open literature. The kinematic motions of head-neck unit due to the frontal, rear and lateral impacts were also validated with the published results of volunteer tests.

Figure 1: FE Human model for rear impact simulation

LOW SPEED REAR IMPACT SIMULATION

As shown in Fig. 2, a simulation of 4g rear impact with rigid seat was performed to evaluate the overall behavior of the model. The correlation of head CG and T1 accelerations between volunteer tests and simulation showed fairly good agreement. The kinematic changes of spine curvature were qualitatively reviewed as well.

THE EFFECT OF HEAD RESTRAINT PROPERTIES ON TISSUE DEFORMATIONS IN THE CERVICAL SPINE IN REAR-END MOTOR VEHICLE IMPACTS

AF Tencer, SK Mirza, P Huber

Dept of Orthopedics and Sports Medicine, University of Washington, Seattle, WA, USA

INTRODUCTION In several volunteer and cadaveric studies of rear-end impacts, alternative explanations of the effects of impact forces on cervical spinal tissues, related to the mechanism of whiplash, have been proposed. However these different tissue deformations have not been directly compared in the same study. Only a few studies have addressed the effect of properties of the head restraint although the motion of the head and therefore the deformation of the cervical spine are related to the interaction of the head with the head restraint.

METHODS Each of 11 cervico-thoracic spine specimens, with an artificial instrumented skull, was mounted on a sled, which was impacted through its bumper by a pendulum. This caused forces similar to those in a vehicle-to-vehicle rear impact, by comparison to a previous study using volunteers. Each specimen was subjected to 5 sequential tests. At a 2g peak impact acceleration, using a standard head restraint, the effects of head to restraint distances of 4cm and 8 cm were compared. At a 4g acceleration, the effects of a standard and a modified head restraint with initial head to restraint contact and energy absorption were determined. Chest and head accelerations, and shear force at the base of the specimen were measured. Tissue strains monitored included transient local pressure around the C5-6, C6-7 and C7-T1 nerve roots using micro pressure transducers, peak articular facet joint pressures using pressure sensitive film, and facet and vertebral intersegmental planar displacements and rotations from high speed video recordings. Two tailed t tests were used to determine significant differences in measured parameters.

RESULTS Tissue deformations with increasing acceleration Similar to other studies, the lower end of the cervical spine was pushed forward under the initially stationary head due to the rear impact. After the head interacted with the head restraint, it was pushed forward of the spine causing flexion and shear loading. The chest accelerations of this experiment matched those measured in volunteers in a previous study well but the head accelerations were higher, demonstrating the effect of completely passive head motion with no muscle control. Pressure pulses occurred around the lower cervical nerve roots, ranging in peak magnitude from 2.7kPa to 10kPa, and occurring generally after chest but before peak head acceleration. Facet pinching varied with spinal level, with C4-5 and C5-6 having the highest probability (64% and 71% respectively) of pinching. Vertebral intersegmental extension rotations (4 to 9.5 deg) and posterior translations (3.7 to 8.9 mm) peaked near maximum head excursion into the head restraint, at the time of peak head acceleration. Intersegmental shear translations were most sensitive to increasing impact acceleration. **The effect of head restraint properties** Decreasing the head-to-head restraint distance from 8cm to 4cm, with a standard head restraint changed spinal kinematics, for example decreasing C4 -C5

extension from a mean of 7.15deg to 5.53deg and C7-T1 posterior shear from a mean of 2.62mm to 1.95mm. Using a modified head restraint significantly decreased head acceleration, from a mean of 5.73g to 3.58g and shear force, from 168N to 120N, at head to restraint contact. Peak C7-T1 foraminal pressure decreased, from 10kPa to 6.6kPa, as did C6-7 extension, from 9.45deg to 6.85 deg, and posterior intersegmental shear displacement at all levels, by about 20%.

CONCLUSIONS (1) Vertebral rotation, intersegmental shearing, facet pinching, and nerve root compression all occurred with rear impact forces. (2) As the peak impact acceleration doubled, intersegmental shear translations showed the greatest increases. (3) Shear deformations peaked near the time of contact of the head with the head restraint. (4) Decreasing head to head restraint gap reduces spinal shear force and changes spinal kinematics, reducing cervical spine extension and posterior shear. (5) Allowing initial head to restraint contact decreased cervical spine extension and posterior shear, while allowing energy absorption at head contact decreased head acceleration, shear force, and local pressures around the cervical nerve roots.

INFLUENCE OF LIGAMENTOUS INJURIES ON THE UPPER CERVICAL SPINAL KINEMATICS

Karin Brodin, karin@flyg.kth.se

Department of Aeronautics, Royal Institute of Technology, Stockholm, Sweden

INTRODUCTION

Cervical spinal injuries may be very severe, since they have the potential to damage the spinal cord. The upper cervical spine is a frequent location for spinal injuries, Brodin and von Holst 2002. It is important to prevent these injuries and to increase the knowledge of injury mechanisms and how injuries influence the spinal behavior. Stability of the upper cervical spine is highly dependent on ligamentous structures. The interaction of these ligamentous structures with the skeletal system allows extensive motion in the occipitoatlantal and atlantoaxial joints.

The goal of this project was to evaluate how ligamentous injuries influence the motion of the upper cervical spinal joints.

METHODS

An anatomically detailed Finite Element (FE) model of the intact ligamentous upper cervical spine was developed and validated against experiments by Panjabi et al (1991). The developed model included the cortical and trabecular bone of the occiput, atlas, axis, and C3 and all soft tissues structures, such as the disc and ligaments. The occipitoatlantal, atlantoaxial, and facet joints were modeled with sliding contacts and the intervertebral disc was modeled as an anisotropic structure with an incompressible nucleus pulposus.

Figure 1: Posterior views of the intact FE model of the upper cervical spine.

The FE model was modified to incorporate rupture of the ligaments. Transection of all the upper cervical ligaments were implemented in separate models. The FE models were subjected to flexion, extension, lateral bending, and axial rotation by applying moments of 1.5 Nm at the occiput. The resulting rotations and translation of the occipitoatlantal and atlantoaxial joints were compared for the intact and injured models.

RESULTS AND DISCUSSION

The FE model of the upper cervical spine correlated well with the experimental data, see Table 1. Rupture of the transverse ligament significantly altered spinal kinematics for all load cases. Axial rotations were significantly influence by rupture of the alar ligaments, the capsular ligaments, the tectorial membrane, and the posterior atlantoaxial ligament. Extension increased with injuries on the anterior and central ligaments, while flexion was more dependent on the posterior structures. This correlates with *in-vitro* experimental studies, where transection of spinal ligaments have been studied by among others Panjabi et al 1991.

Load case	Joint	Panjabi et al	FE model
Axial rotation	C0-C1 degrees	1.0 - 10.5	6.1
	C1-C2 degrees	24.2 - 46.4	23.3
Flexion	C0-C1 degrees	10.8 - 17.2	18.2
	C1-C2 degrees	9.8 - 16.2	11.3
Extension	C0-C1 degrees	10.8 - 17.2	10.5
	C1-C2 degrees	6.0 - 16.0	14.0
Lateral bending	C0-C1 degrees	2.6 - 8.6	3.0
	C1-C2 degrees	3.8 - 19.6	6.0

Table 1: Results from the validation of the intact FE model.

It is concluded that FE models of the upper cervical spine can contribute to the understanding of spinal injuries.

SUMMARY

The objectives of this study were to analyze the effect of spinal injuries on the motion of the upper cervical spinal joints using FE-models. It was concluded that ligamentous injuries can be studied successfully with the FE method and the transverse ligament was confirmed to play a significant role in the stability of the upper cervical spine. Rupture of several ligamentous structures simultaneously are a potential threat to spinal stability.

COMPARISON OF RELATIVE MOTION BETWEEN THE BRAIN AND SKULL OF THE HUMAN CADAVER FOR ROTATION IN THE CORONAL AND SAGITTAL PLANES

Albert I. King¹, Warren N. Hardy, Matthew J. Mason, and Scott Tashman²
Bioengineering Center, Wayne State University, Detroit, Michigan, USA

¹Distinguished Professor and Director, king@rrb.eng.wayne.edu

²Henry Ford Hospital Bone and Joint Specialty Center

INTRODUCTION

Understanding of head injury mechanisms can lead to appropriate preventative measures. This study examines relative brain motion with respect to the skull using high-speed, biplane x-ray and neutral density targets (NDTs), and builds upon the work reported by Hardy et al. (2001).

METHODS

Inverted, perfused, human cadaver heads were subjected to impacts generating either sagittal or coronal rotation. Specimens were stopped against a rigid surface from steady-state motion. NDTs were implanted in multiple columns of 5 or 6 targets, with 10 mm between targets in each column. The columns are designated as either anterior or posterior ("a" or "p"), and right or left ("R" or "L"), as shown in Figure 1.

RESULTS AND DISCUSSION

Figure 2 shows the brain displacements in the right-posterior NDT column for sagittal plane rotation (SAE 180 Hz: -3519 r/s^2 , -21 r/s). The primary direction of motion for each target is the Major Displacement Axis (MDA). Perpendicular bisectors from each MDA intersect at the Average Instant Center (AIC) of rotation. The orientation the MDAs also rotates from inferior to superior. Similar phenomena are evident in Figure 3, which shows NDT motion in three columns for coronal rotation (SAE 180 Hz: -7695 r/s^2 , -26 r/s).

SUMMARY

The local brain motions follow loop or figure eight patterns, with peak displacements on the order of $\pm 5 \text{ mm}$. These displacements seem to be related to an Average Instant Center. Motion for sagittal and coronal plane rotation is remarkably similar, as is the angular speed of each test. The brain motions exhibit interesting anterior-posterior and right-left symmetry.

BIOMECHANICAL CHARACTERISTICS OF FACIAL FRACTURE IN CHILDREN

Kristy B. Arbogast and Flaura K. Winston

TraumaLink, The Children's Hospital of Philadelphia, Philadelphia, PA
arbogast@email.chop.edu

INTRODUCTION

Facial injuries in children rank high in importance to parents due to the potential for these injuries to result in disfigurement and occur often in motor vehicle crashes. These injuries have been shown to be related to the use of restraints, however the detailed injury mechanism has not been delineated. (Murphy, 2001) An understanding of the injury mechanism must incorporate the changing biomechanical structure of the child's face, i.e. the development of the jaw, the growth and pneumatization of the sinuses, and the emergence of the teeth. (McCarthy, 1990). The objective of this paper is to identify common mechanisms of facial trauma to children in motor vehicle crashes. It was hypothesized that pediatric facial development effects the mechanical compliance of the face and influences the fracture patterns seen after impact.

METHODS

A case-series analysis of 15 children sustaining facial fractures was performed. Cases were identified through the Partners for Child Passenger Safety (PCPS) study between 3/98-3/01, an on-going child-focused motor vehicle crash surveillance system that includes children 15 years or younger in crashes involving 1990 and newer vehicles reported to State Farm Insurance Companies in 15 states and Washington, D.C. Injury and vehicle damage descriptions (included in the claims data) were reviewed to select potential cases for a full-scale on-site crash investigation. Medical, crash, and child characteristics of documented pediatric facial bone fractures were analyzed. The site of facial fracture was further classified as upper (supraorbital bone), middle (nasal, zygomatic, maxillary, and infraorbital bones), or lower face (mandible). Fracture patterns were examined above and below 6 years of age due to this age as a transition point in facial development.

RESULTS AND DISCUSSION

Fourteen crashes involving fifteen children with facial fractures were studied by on-site crash investigation. All children were restrained by an adult seat belt. 11/15 either placed the shoulder belt behind their back or sat in a position only equipped with a lap belt. Nasal fractures were the most common (8/15 children), followed by zygomatic/maxillary fractures (4/15 children), orbital fractures (5/15 children), and mandible fractures (3/15 children). These injuries resulted from excessive torso and head excursion with facial impact. The lap only belt configuration provided little restraint for the upper torso and resulted in greater forward motion and acceleration over the lap belt and greater relative energy upon

impact. Children are at particular risk for this jackknife motion as a greater proportion of their body mass lies above the level of the lap belt. The distribution of fracture location (upper, middle, and lower) with respect to age is shown in Figure 1. In the younger children, less than 6 years of age, all areas of the face are represented in the fracture distribution. In the older school age children, 12/13 fractures occurred to the mid-face. These changes in fracture patterns are associated with changes in facial structure.

Figure 1: Region of facial injury by age group.

In order to develop potential countermeasures for these injuries, a surrogate child face is necessary. The combination of the field crash data and pediatric facial development would suggest that a structure representing the mid-face may be appropriate for an anthropometric surrogate representing the pre-teen. A young school age dummy presents more of a challenge due to the transitional nature of this age in facial development.

SUMMARY

This paper demonstrated that the patterns of facial fracture vary by child age due to the changing structure of the pediatric face. These differences must be incorporated into an appropriate engineering tool to evaluate pediatric facial injury risk and potential countermeasures. This may require different facial construction for dummies of different ages.

INFLUENCE OF IMPACT DIRECTION AND DURATION TO THE HUMAN HEAD IN EVALUATION OF HEAD INJURY CRITERIA: A NUMERICAL STUDY

Svein Kleiven¹ and Hans von Holst^{1,2}

¹Department of Aeronautics Royal Institute of Technology

²Department of Clinical Neuroscience Karolinska Institute
Stockholm, Sweden.

INTRODUCTION

For people younger than 45 years, the frequency of death or severe injury from road accidents is about six times higher than that from cancer (ETSC, 1999). In Sweden, head injuries causes about 78% of the deaths in motor vehicle accidents. When evaluating the consequences of an impact to the head, different injury criteria are used. However, present injury criteria do not take into consideration rotational or directional dependency. Recently a new global head injury criteria, called the Head Impact Power (HIP) was presented (Newman *et al.*, 2000). In that study, it was proposed that coefficients for the different directions could be chosen to normalize the HIP with respect to some selected failure levels for a specific direction. The aim of the present investigation was to study the influence of inertial forces to all the degrees of freedom of the human head evaluated with a detailed FE model.

METHODS

A detailed and parameterized Finite Element (FE) model of the adult human head has been developed. It includes the scalp, skull, brain, meninges, cerebrospinal fluid (CSF), and eleven pairs of parasagittal bridging veins. Separate representations of gray and white matter, and inclusion of the ventricles were also implemented. This model has been described in Kleiven and von Holst (2001). The description of the status of the head model is also available on the home page: <http://www.flyg.kth.se/> (Division of Neuronic Engineering). A total of nine acceleration pulses (pure translation and angular, respectively) were applied to all the non-symmetrical directions of the head. In the study of the angular acceleration components, a squared sinusoidal pulse (\sin^2) with an amplitude of 20 krad/s² and a duration of 5 ms, resulting in a peak angular velocity of 50 rad/s, and a HIP_{max} of 17.3 kW. To obtain a comparison with the angular impulses, a squared sinus with an amplitude of 1580 m/s² and a duration of 5 ms was used for the translational impulses resulting in a HIC of 295 and a HIP_{max} of 17.3 kW. In addition, the durations of the sagittal translational and rotational impulses were varied between 2.5 and 20msec while keeping the HIC and HIP_{max} constant. The models were used to investigate the differences in terms of engineering strain in the bridging veins, ϵ , and the effective stresses, σ_e , and shear strains, ϵ_{shear} , in the brain, due to variation in impact direction and duration.

RESULTS, DISCUSSION AND SUMMARY

The largest strains occurred in the brainstem for the axial impulses. Axial accelerations are usually caused by accidents due to fall, and clinical observations shows that this may lead to DAI in the brainstem (Dirnhofer *et al.*, 1979).

Table 1: Summary of the results from the comparison of translational and angular impulses in different directions.

V. Direction	Cortex		Corpus Call.		Brain Stem		Bridg
	ϵ_{shear}	σ_e	ϵ_{shear}	σ_e	ϵ_{shear}	σ_e	
A.P.	0.20	19.1	0.10	7.9	0.16	30.5	0.02
P.A.	0.33	26.2	0.10	8.2	0.12	21.7	0.05
S.I.	0.19	15.3	0.12	8.4	0.30	48.1	0.00
I.S.	0.19	15.4	0.12	8.4	0.28	45.7	0.03
Lat.	0.29	19.6	0.12	6.3	0.07	15.8	0.06
A.P. Rot.	0.25	19.6	0.14	10.8	0.18	28.6	0.09
P.A. Rot.	0.23	17.6	0.15	10.6	0.19	27.8	0.16
Axial Rot.	0.27	20.4	0.17	12.8	0.08	12.3	0.07
Lat. Rot.	0.19	15.3	0.21	15.2	0.22	32.7	0.09

The findings of larger stresses and strains in the corpus callosum for the lateral angular acceleration support conclusions drawn by Gennarelli (1983). The maximal effective stresses and shear strains in the brain occurred at a later time than the maximal strain in the bridging veins, which also is in agreement with Gennarelli (1983). The present results also verifies a study by Fruin *et al.* (1984) who reported that six out of eight cases with known trauma sites were due to occipital impacts. The shorter durations resulted in a slightly lower values of the stresses/strains in the brain compared to the longer durations for the translational impulses. The opposite occurred for the rotational impulses. However, the differences due to variation in impulse duration were small, corroborating the validity of impulse criteria such as HIC and HIP. No significant differences in the strain of the bridging veins were found for the various impulse durations.

BEHIND ARMOR BLUNT TRAUMA

Cameron R. 'Dale' Bass

Research Assistant Professor, bass@virginia.edu
Center for Applied Biomechanics, University of Virginia, Charlottesville, Virginia

INTRODUCTION

Traditionally, helmets and body armor have been used to stop or blunt penetration of ballistic projectiles, bullets or shrapnel, into the human body. However, the introduction of modern high impact strength deformable materials into helmets and body armor for such ballistic impact protection has increased the potential for significant backface deformation under ballistic impact. Further, for most helmet and body armor systems there is limited space available for such backface deformation. So, systems that suffer no penetration may have a substantial risk of producing severe head or thorax injury from blunt backface trauma, even in systems that do not suffer ballistic defeat. Further, the desire to use even lighter weight head or thorax protection with greater ballistic penetration resistance may lead to increased risk of backface impact injuries. There is, however, no widely accepted, widely available, and sufficiently validated objective technique for evaluating the risk of impact head trauma from helmet backface deformation.

This overview discusses the history and current progress in elucidation of mechanisms of injuries from Behind Armor Blunt Trauma (BABT). This includes a detailed examination of proposed injury mechanisms from high rate cranial trauma and high rate thoracic trauma. The applicability of existing automobile injury criteria, blast injury criteria, and high rate ultrasonic injury criteria is critically examined, and theoretical and experimental progress in understanding high rate head and thoracic injury is discussed.

METHODS

To develop objective test methodologies to assess BABT, an approach for all body regions was developed that includes the common elements:

- **Biofidelic surrogate** – a dummy that is robust, gives a repeatable physical response, and responds in a human manner. Generally, a surrogate should be as simple as possible while still representing the relevant human response.
- **Engineering measurement** – a physical parameter such as force or acceleration that may be used to quantify the physical response of the dummy. Dummies may be instrumented to produce accepted or proposed injury criteria.
- **Injury risk evaluation** – a correlation between an engineering measurement and some injury model.

- **Validation by injury model** – a correlation between the injury risk evaluation and a physical model of injury. An injury risk model has limited value without successful validation using 1) physical reconstruction of an actual injury event, 2) an animal injury model, or 3) a cadaveric human injury model.

RESULTS AND DISCUSSION

This study uses backface deformation of a helmet into a human skull to elucidate the special circumstances in assessing injury risk in high rate blunt trauma. This includes results from helmet dummy and cadaver experiments and mine blast (thorax) biomechanics (Figure 1). The efforts include the verification of physical surrogate models and indication of current model deficiencies.

Figure 1: Simulated Antipersonnel Mine Blast with Hybrid III Surrogates

SUMMARY

To adequately assess the risk of injury from BABT, the development of high rate biomechanical injury models is required. In addition, the establishment of a relationship between a robust surrogate for injury and a validated injury model is crucial in the success of this approach. A roadmap is proposed toward development of comprehensive high rate injury criteria suitable for use with BABT. This roadmap emphasizes the most critical deficiencies in the current research.

COMPARATIVE NECK LOAD MEASUREMENTS IN AN INSTRUMENTED MANIKIN EXPOSED TO PARACHUTE DROPS FROM A UH-60 BLACK HAWK HELICOPTER

B. Joseph McEntire, Frederick T. Brozoski, and Nabih Alem

U.S. Army Aeromedical Research Laboratory, Aircrew Protection Division, Fort Rucker, Alabama

Joe.mcentire@se.amedd.army.mil

BACKGROUND

Paratroopers are exposed to unique injury risks. Some of these risks are associated with the dynamics of parachute opening shock and the parachutist's landing fall. A particularly vulnerable body region is the neck, because the head is likely to flail as the inertial loads overcome voluntary muscular control, loading the neck bony and tissue structure. The addition of head or helmet mounted devices could increase the transmitted neck loads during airborne operations, increasing neck injury risk.

Even soft tissue injuries such as neck strains and sprains could affect soldier performance. Typical acute neck strain symptoms include: stiffness, headache, neck pain, dizziness, nausea, double vision, impaired concentration, impaired memory, irritability, weakness, and others. A soldier experiencing these symptoms would not be expected to complete a mission as efficiently or effectively as they would if they did not experience the symptom. Of course, more serious injuries could have greater operational impact as well as disability and occupational implications.

METHOD

An investigative study was conducted to measure the inertia neck loads during parachute opening shocks. An instrumented Hybrid III test dummy was used in all dynamic tests to sense and record the response loading. This manikin was modified with an articulated spine and internal data acquisition system. Data was recorded at a sample rate of 4000 Hz. After each test, data was downloaded onto a laptop PC and archived. The manikin provides the capability to record 32 data channels, of which 30 were instrumented for recording. Video recordings of the manikin's exit and parachute openings were reviewed and the neck load data were screened to identify occurrences of the parachute riser snagging on the head and helmet. Exits where a head/helmet snag occurred were excluded from the data set as the loads transmitted through the riser contaminated the pure inertia loads under evaluation.

An Army UH-60A Black Hawk helicopter was used to obtain the desired release altitude (700 feet above ground level) and airspeed (110 knots indicated airspeed) for these tests. A standard Army circular, static line deployed, parachute system was used during all aircraft exits. Two different head borne device conditions were utilized to apply discrete mass and mass position conditions to the test dummy. These were the standard airborne helmet (3.56 pounds), and a modified helmet with an additional electronic device (4.30 pounds). Each condition was exposed to 17 repetitions for a total of 34 tests.

ANALYSIS

Two data analysis methods were used. First, a comparison of means was conducted to determine if the addition of the head-mounted weights produced a statistically significant difference ($P \leq 0.05$) in the transmitted neck loads. Within each group, a one-way analysis of variance (ANOVA) was used to compare the means and standard deviations. Then, the peak neck loads and forces were compared to the published injury assessment reference values.

RESULTS AND DISCUSSION

The UH-60 Black Hawk proved to be an efficient means to conduct multiple aircraft exits in a short time period. Repeated manikin aircraft exits were conducted in less than 15-minute cycles. However, attempts to control the manikin's response upon entering the wind-stream proved less successful. Nine helicopter-exit data sets subsequently were eliminated from the analysis for signal contamination resulting from riser snag. The mean moments and forces measured at the C1 load cell are provided in Table 1. None of the peak values exceeded the injury assessment reference values recommended by NHTSA. The associated Nij values, combined loading injury criteria, remain to be calculated.

INFLUENCE OF HELMET MASS PROPERTIES ON HEAD/NECK FORCES DURING HIGH-SPEED EJECTION

G Paskoff

In-Flight Escape Systems Branch, Naval Air Warfare Center - Aircraft Division, Patuxent River, MD

INTRODUCTION

High-speed ejection from the cockpit is a highly chaotic event that is affected by a multitude of factors including airspeed, elevation, pitch, sink, and roll rates, temperature, seat stabilization, parachute type, aircrew weight, and many others. Mission enhancement devices worn on the helmet are used for air-to-air and air-to-ground targeting, night vision, forward looking infra-red views, and flight control information. However, as the number of features increases, the total weight of the system increases. Earlier systems that provided a number of features, in addition to the basic functions of a helmet, weighed close to 6 pounds. More modern systems are approaching 4.8 pounds or less. While the total weight is important, the major factor in the injury potential is the location of the CG of the head and helmet system combined. Typically the CG is placed forward of the occipital condyles and results in high pitch moments about the occipital condyles and C7/T1 which are consistent with cervical injuries reported during ejections. As a result of the expanded aircrew population, the potential exists for smaller anthropometric individuals, male and female, to be at a greater risk of injury during high-speed escape and crash scenarios. The objective of the study was to determine safe requirements for helmet mass properties (weight, center of gravity, and moments of inertia) based on predictions of inertial loads during ejection.

METHODS

A parametric simulation study consisting of hundreds of simulations was performed using the Articulated Total Body (ATB) model to determine the effect that varying helmet weight, center of gravity, and moments of inertia had on head and neck forces during ejection (Ref. 1). This model was able to evaluate the 3-D dynamic response of a system of rigid bodies when subjected to a dynamic environment consisting of applied forces and interactive contact forces (Ref. 2). In addition, tests were conducted on the Navy's ejection tower facility using advanced tactical helmets and compared with results from tests using baseline helmets (Ref. 3).

RESULTS

Simulation results indicated that the head/helmet center of gravity was the most dominant variable in affecting head/neck loading during ejection. The total head supported mass and head/helmet moments of inertia were found to have lesser effects. Test results supported the simulation data and demonstrated that the forward center of gravity of the advanced display helmet resulted in significantly greater tensile loading and flexion moment on the head/neck versus the baseline helmet, during the catapult stroke of ejection.

CONCLUSIONS AND FUTURE WORK

Minimizing head/neck loads during ejection is critical to protecting the life of the aviator. The location of the center of gravity was found to have a major impact on the resultant head/neck forces and moments, particularly in ejection systems that exhibited inherent instabilities. However, many other factors affect the overall dynamics of the ejection that directly impact the loads that are transferred to the aviator. Research in ejection seat technology has proven that improving seat stability during ejection can reduce head/neck loads to tolerable limits even with added head mass and at higher ejection airspeeds. Programs that improve the stability of the ejection seat system will ultimately reduce the likelihood of severe neck injury, even as advances in materials and optics technology result in lighter weight and improved performance helmet systems.

THE STUDY OF DYNAMIC BIOMECHANICAL EVENTS USING DIGITAL FLASH RADIOGRAPHY

Jeffrey A. Adams¹, Peter C. Laurence², and T. Ellory Sanderson³

¹Senior Engineering Technician, jadams@atc.army.mil

³Senior Test Engineer, tsanders@atc.army.mil

U.S. Army Aberdeen Test Center, Aberdeen Proving Ground, Maryland

²Senior Imaging Specialist, Peter.Laurence@enfis.com

Titan Systems Corporation, Pulsed Sciences Division, San Leandro, California

INTRODUCTION

The Aberdeen Test Center has a long history of using flash radiography as a premier diagnostic tool aiding in the design and development of armor and anti-armor weapon systems. Current trends in this testing arena are moving towards the evaluation of personal protection systems used by the warfighter. This type of testing requires an objective re-evaluation of the diagnostic tools and techniques used to obtain the required data. Several legitimate digital techniques will be discussed in this paper as they have been applied in real test scenarios involving high-speed dynamic impact and blast effects on biomechanical specimens.

BACKGROUND

Over the better part of the past three decades, the typical flash x-ray workload at ATC consisted of dynamic test and evaluation of “hard” military materiel including targets, projectiles, guns, and shaped charges. Within the past few years we have realized a shift in this tradition with a significant portion of the projected workload focused on “soft” specimens within the arena of biomechanical studies. With this type of testing, the areas of interest are typically smaller, more detail is often required, and so the ability to digitally extract and enhance information not visible on film is proving invaluable. The first viable digital flash radiography system was fielded by ATC for tank ammunition testing circa 1996, and used KodakTM storage phosphor screens as the imaging medium. The use of this system on ballistic impact studies at the University of Virginia’s Automobile Safety Laboratory will be discussed in detail. Another hybrid system successfully fielded by ATC was comprised of a standard flash x-ray system, a custom-built multi-anode x-ray tube, and a high-speed digital video camera. This combination of technologies was melded into an effective data collection system used to study biomechanical response to blast effects for The Institute of Surgical Research from Fort Sam Houston Texas. The unique circumstances and site-specific test set-up shall be discussed as well.

RESULTS AND DISCUSSION

The use of diagnostic digital imaging has become commonplace in medical institutions throughout the world. Various methods are now available to the medical professional including MRI, CAT Scan, CR, and standard x-ray. One

common and very beneficial trait they share is the ability to access the information in the digital domain, and fortunately this characteristic transfers with the techniques used in digital flash radiography. Although many of the principles used for high-speed studies are anchored in medical imaging, the standard hardware and software packages available to the medical community are virtually useless in the world of high-speed imagery. The duration of some of the slower high-speed events is on the order of a few milliseconds (10^{-3} sec) during which time as many as eight x-ray exposures may be taken. A typical “fast” single exposure in a clinical x-ray setting might be on the order of a few tenths of a second (10^{-1} sec). The challenge of capturing and recording images of high-speed dynamic events while attempting to maintain medical image quality becomes significant. In addition, the need to protect the x-ray equipment and imaging sensors from collateral damage is sometimes a serious challenge in and of itself. These challenges have resulted in the development of many innovative techniques, but more work is needed to further refine the quality of the acquired images. As the medical community becomes more intimately involved with ballistic testing, the need to improve the spatial resolution of digital flash radiographs becomes more apparent. Further investigation into the optimization of x-ray sources and digital imaging techniques has become a priority for ATC. Investigative studies are currently underway and will be discussed in detail.

SUMMARY

In less than a decade, ATC has made considerable progress in its migration from film-based flash radiography into the realm of digital x-ray imaging. With the exception of the high-speed digital video camera, the imaging technologies used in these efforts are hand-me-downs from the medical community. We are realizing an increased interest in biomechanical studies from the military medical community as they relate to soldier systems such as body armor, helmets, and footwear. The inevitable collaboration of the medical and test communities can only foster increased sharing of related technologies. The studies discussed in the paper are a solid representation of this collaborative effort as it plays out in the military test community. These efforts are bound to have far reaching effects on the biomechanical research community in the foreseeable future.

NUMERICAL MODELING OF HUMAN OCCUPANTS AND AUTOMOTIVE SAFETY

King H. Yang and Albert I. King

Bioengineering Center, Wayne State University, Detroit, MI, USA

INTRODUCTION

Locomotion is an essential element of human existence. Because moving on foot is rather inefficient, the idea of utilizing power-propelled vehicles arose fairly early in human history. With the invention of automobiles humans were able to fulfill the desire to move both farther and faster. However, the speed and weight of the vehicles became an inherent safety hazard to their occupants and other road users. Special design considerations are needed to improve the safety of human beings who live in today's automobile-saturated environment.

In 1955, Ford Motor Company promoted a slogan of "Lifeguard Design" advocating automotive safety. Unfortunately, safety did not translate into sales, as consumers were more into style than safety. In the late 1960s, Ribicoff's landmark congressional hearing, the Nader testimony, and the subsequent creation of the National Highway Traffic Safety Administration established a set of minimum standards that auto manufacturers need to meet before they can sell any particular vehicle.

Establishment of safety standards and performance criteria requires the understanding of human responses and tolerances to impact loading. Research methods include but are not limited to: accident and clinical investigations, animal, cadaver, and volunteer testing, and theoretical, physical, and mathematical modeling. Results from these studies were used to design anthropomorphic crash dummies, which in turn were also used to develop and evaluate new concepts for active and passive injury prevention systems. Unfortunately, each of the aforementioned methods has its limitations and, as a result, the dummies currently in use were designed for limited purposes such as for frontal and lateral impact, scenarios that are unlikely to occur in real world crashes. Additionally, significant differences exist between the dummy and the human, for instance, the stiffness of body segments and the inability of the dummy to fully simulate bony fractures. Dummies are made of steel and rubber while the human is mainly composed of bone and muscle.

With the rapid advances in computing power, sophisticated vehicular and dummy models are routinely employed in the design and evaluation of new prototypes. Dummies are mechanical devices that could be simulated accurately. However, the lack of biofidelity associated with mechanical dummies is also reflected in dummy models. Even though the application of dummies and their numerical counterparts have greatly improved crash safety for subjects that are similar in sizes to these dummies in full frontal and lateral impacts, protection provided for other collision directions or for occupants of non-standard sizes is not fully effective. Numerical human surrogates simulating both genders and of different sizes can be used to study impacts from all directions and can offer the general population more protection than what is available now.

The development of such a surrogate requires comprehensive knowledge of human anatomy, the constitutive laws governing a large variety of human tissue, and injury thresholds. Additionally, response data at different loading rates, similar to real world crashes, are needed for model validation. This paper summarizes regional models of the human body, from head to foot, developed at Wayne State University (WSU) over the last decade (1-8). In general, strengths of these models are that they employ an accurate and detailed geometry of the body region, thus rendering it suitable for investigation of injury mechanisms. Some of these models are being used to improve vehicular seat and restraint system design.

COMPUTER MODELS

The WSU brain model simulates all the essential substructures of the head and brain and has been validated against available intracranial pressure, ventricular pressure, and relative displacement between the skull and the brain (1, 8). It is being used to evaluate the efficacy of current helmet designs. The neck model, which includes all seven cervical vertebrae, intervertebral discs, and 15 pairs of passive muscles, has been validated against data obtained in vertical head drop and rearend impact test results (7). It has been applied to study the neck responses when interacting with an airbag. The chest model includes descriptions of the rib cage, heart, lung, and major blood vessels. It has been validated against pendulum impact data from frontal and lateral impacts as well as against lateral sled test data when whole body cadavers slid into a rigid or padded wall (4, 6). The model has been used to determine the mechanism of aortic rupture as well as injury to the upper arm interacting with a side airbag. The abdominal model includes detail descriptions of vital solid organs and major blood vessels while other hollow organs were lumped into three "body bags" to transfer loads (5). This model could be used to simulate the interaction between the seat belt and the abdomen. The lower extremity model includes all main anatomical structures from the pelvis to foot (2, 3). It has been validated against 21 different sets of experimental data and has been applied to study dynamic interactions between the knee and a knee bolster.

DISCUSSION

Around the world, human occupant models, either at the component or whole body level, are also being developed. However, models developed elsewhere emphasize its direct integration into vehicular models. As a result, detailed anatomical representation was sacrificed in favor of the inclusion of the vehicular model. On the other hand, the weakness of WSU models is their high computational cost. Nevertheless, biofidelity issues still exist in models developed at either WSU or elsewhere for impact directions and severities not tested in the model validation process. This concern arises primarily because the experimental data

available for model validation vary greatly due to large variations in biological tissue response. Additionally, existing constitutive laws implemented in simulation software packages are not well suited for modeling human tissues.

Through various in-house and international collaborative projects, these deficiencies are being corrected by studying the epidemiology of automotive related injuries and the material properties of human tissue. More importantly, new experiments are being designed and conducted guided by model predicted results to advance our understanding in injury biomechanics. Once detailed bony kinematics and tissue deformation become available to validate these models rigorously, it is expected that human models will become an efficient tool to assess injury risk of passengers in transportation systems, pedestrians, and other road users.

LOWER EXTREMITY FORCES DURING AN AUTOMOBILE COLLISION: THE INFLUENCE OF MUSCLE PROPERTIES

E. C. Hardin, A. Su and A. J. van den Bogert, hardine@bme.ri.ccf.org

Department of Biomedical Engineering, Cleveland Clinic Foundation, Cleveland, Ohio, USA

INTRODUCTION

Cadavers, dummies and computational models have been used to study automobile collision injuries to the legs (Digges *et al.*, 1995; Rudd *et al.*, 1998). In lieu of active muscles, joint friction and joint torque are generally employed. Considering that muscle tensing could affect injuries (Digges *et al.*, 1995; Parenteau *et al.*, 1996; Rudd *et al.*, 1998; Tencer *et al.*, 2002), models without muscle properties might be incomplete. The purpose of this study was to compare peak lower extremity forces in models with joint friction, joint torque and muscle properties during an automobile collision.

METHODS

A 2-D musculoskeletal model was developed which had seven body segments and six functional right-side muscle groups (glutei, hamstrings, rectus femoris, vasti, gastrocnemius, and soleus) each represented by a three-element Hill model. Vehicular contact surfaces were line segments while body segments contacting these surfaces were given contact elements from the literature (Wright *et al.*, 1998; Digges *et al.*, 1995). The model was implemented in C code using the SD/FAST library for forward dynamics. For the frontal crash simulations, vehicle motion data were obtained from the National Highway Transportation and Safety Administration (crash #2075) and were applied to the contact surfaces. Five models were tested: maximal muscle activation (MX, panic braking), minimal muscle activation (MN), no muscles (NM), joint friction (JT) and joint torque (JT). MN activation values were found by optimizing a weighted cost function using a 4-second dynamic simulation of static driving, resulting in a realistic equilibrium posture and pedal force at minimal muscle activation. Muscles were eliminated from NM, JF and JT. Moments calculated for JF and JT were nonlinear functions of angle and angular velocity, respectively, with saturation levels specified for each joint (Digges *et al.*, 1995). The forces of interest during the crash were those from the ankle joint (A), knee joint (K), rearfoot ground reaction force (RF), Achilles tendon (AT), and calcaneus ($C = RF + AT$).

RESULTS

Peak joint forces (A and K) were greatest in the panic braking model (MX), yet this model also had the lowest peak RF force (Table 1, Fig. 1). Peak AT and C force were 4.5 times and 3 times greater, respectively, during panic braking compared to minimal activation (MX and MN, Table 1). Results for MN and NM were similar, as well as were those for JF and JT.

Table 1: Peak forces (N) in the five models.

Model	A	K	RF	AT	C
MX	4125	3147	629	6445	6941
MN	2001	1073	1202	1430	2569
NM	1451	917	1178	-	-
JF	2783	1813	1547	-	-
JT	2809	1815	1596	-	-

Figure 1: Right ankle force (a) and rearfoot force (b) for MX, JT and MN during the crash.

DISCUSSION

Muscle activation affected peak joint force, as others have suggested (Parenteau *et al.*, 1996; Rudd *et al.*, 1998; Tencer *et al.*, 2002), and would likely exacerbate injuries. A relatively simple method to model muscles is to use joint friction (JF) or joint torque (JT) functions, both of which seem to predict similar joint forces to a model with moderately activated muscles (Fig. 1a). Unfortunately, RF force is overestimated with JT or JF (Fig. 1b). We think this is caused by the saturation of joint torque in these models, effectively resulting in zero muscle stiffness during the dorsiflexion at impact. We conclude that computational models for prediction of lower extremity injury in vehicle collisions require a realistic representation of muscle properties and muscle activation.

OPTIMAL PROTECTION OF HUMANS FROM IMPACT

Walter D. Pilkey

Center for Applied Biomechanics, University of Virginia,
122 Engineer's Way, P.O. Box 400746, Charlottesville, VA 22904-4746
wdp@virginia.edu

INTRODUCTION

The severity of certain injuries often can be reduced if vehicles, seats, sports helmets, etc., are equipped with effective impact isolators. A shock isolator is an engineering device placed between the body to be protected and a base subjected to a transient load. The isolator generates a control force that reduces the intensity of the force transmitted to the body. An important step in the optimal design of shock isolators is a limiting performance analysis.

A limiting performance analysis can be employed to determine the absolute optimal performance of the system with shock isolators. As part of the design process, it is advantageous to know the physical response possibilities (limiting response), irrespective of the actual design configuration. In setting up the limiting performance study, a mathematical model is established in which the isolator is replaced by a generic, time-dependant control function. The limiting performance analysis involves the computation of the time history of the control function corresponding to the minimum of an objective function, while satisfying prescribed response constraints, e.g., a rattlespace.

This talk discusses problems of the limiting performance analysis of systems intended to reduce impact-induced injuries.

METHODS

Analytical limiting performance analyses are possible for limited degree of freedom systems. For complex systems, computational optimal methods are necessary. In particular, linear programming or quadratic programming methods often can be employed.

Critical to a limiting performance study for injury mitigation is a biomechanical injury model. This paper is not concerned with the development of new injury models. Established injury models are used to illustrate the limiting performance analysis.

RESULTS AND DISCUSSION

Limiting performance problems for the success of seats in preventing spinal injuries, the use of seatbelts in reducing thoracic injuries, and the effectiveness of sports helmets in mitigating head injuries are considered. In addition, leg injuries from automobile toepan intrusion are used to illustrate the potential improvement in impact isolation if a pre-impact sensor is available so that the optimal isolator can be "cocked" prior to impact.

It is often contended that injury prevention systems, such as seatbelts, should be constant force systems. This issue is addressed for single and multi degree of freedom systems subject to various pulses.

For the limiting performance of seat systems, the dynamic response index (DRI) is used to predict thoracolumbar-spine fracture injuries. The so-called Lobdell injury models are used to study the dynamics of the human thorax in a crash of a vehicle. The Stalnaker head injury models are utilized in the helmet limiting performance analysis studies.

SUMMARY

It is shown that limiting performance analyses can be used to study the potential injury prevention characteristics of safety devices. It is also shown that preview control can improve considerably the injury reduction potential of an impact isolation system. Finally, the investigation into constant force isolators demonstrates that optimal isolators occur for single degree-of-freedom systems subject to impulse loading. For more realistic models, constant force isolators are not optimal.

A NUMERICAL MODEL PREDICTING UPPER EXTREMITY FRACTURES DUE TO AIRBAG DEPLOYMENT

Jack van Hoof¹, Lex van Rooij^{1,2}, and Jeff Crandall²

¹ TNO Automotive, Crash Safety Centre, Delft, The Netherlands

² University of Virginia, Center for Applied Biomechanics, Charlottesville, Virginia

INTRODUCTION

Forearm fractures are commonly observed in cases where the arm of the driver was close to the airbag door at the time of deployment. Even though these injuries are not life threatening, they can result in long-term disabilities for the victims. Numerical modelling can be used as an efficient and flexible tool to further enhance airbag designs, so that the severity of forearm fractures can be reduced in future. The current paper presents a numerical model that provides an efficient and accurate prediction of forearm fractures due to airbag deployment.

METHODS

The current paper presents a hybrid multibody-finite element model, which provides an optimal combination of efficiency and detailed injury predictions. The main part of the model was taken directly from the MADYMO multibody model of a mid-size male, but the arm was replaced with a detailed finite element arm model adopted from the MADYMO full finite element human body model. The multibody part of the hybrid model provided a biofidelic kinematic response, whereas the finite element arm enabled accurate predictions of the injurious deformations. The model is shown in Figure 1, where it is interacting with a side airbag.

Prior to application, the hybrid model was validated for the same range of multi-directional impact conditions as used for the full multibody and finite element models. The detailed arm model was validated with quasi-static and dynamic 3-point bending tests on cadaver upper extremities. Once the model was validated it was used in applications with airbag models to predict arm fractures resulting from airbag deployment. Published data on failure strains of the bones of the arm were used in injury criteria for arm fractures resulting from airbag deployment.

Figure 1: Multibody human model with FE upper extremity interacting with side airbag

RESULTS AND DISCUSSION

The results obtained in this study showed that the model presented in this paper provided an efficient and accurate prediction of arm fractures due to airbag deployment.

SUMMARY

A hybrid multibody-finite element human model has been developed and validated. The model was used in applications with airbags and provided accurate predictions of arm fractures due to airbag deployment.

²Aprica Kassai, Inc.

INTRODUCTION

This paper describes the design, development and testing of a biofidelic infant dummy weighing 2.5 kg. The dummy can be used to evaluate the efficacy of child seats when used to protect infants.

METHODS

Anthropometric data were obtained from literature and children in a pediatric hospital [Table 1]. Dynaman© 3-D lumped mass occupant simulation model was used to obtain joint loads and other design parameters. Joint ranges of motion were obtained from literature also. Impact response data were also obtained from literature and scaled as needed.

Table 1 : Sample anthropometric data

Parameter	Units	Design Goal
Mass	Grams	2600
Height	mm	450
Arm length (arm to tip of hand)	mm	180
Leg length (crotch to heel)	mm	150
Head Circumference	mm	349
Neck Circumference	mm	172
Neck Length	mm	54
Upper Arm Circumference	mm	80
Leg at Hip Circumference	mm	130
Head Weight	grams	800
Upper Arm Weight	Grams	29
Lower Arm Weight	Grams	22
Upper Leg Weight	Grams	82
Lower Leg (w/Foot) Weight	Grams	48

RESULTS AND DISCUSSION

Preliminary static tests indicate that the dummy is biofidelic in its response [Fig. 2]. A number of sled tests have been conducted in a variety of child seats. Sleds tests indicate that the dummy and instrumentation are robust and that the dummy yields repeatable results. Repeat static tests indicate that the dummy provides repeatable response. Tests on two dummies

indicate that the dummy is reproducible as both dummies provide very similar responses under similar loading conditions [Figs. 3 & 4].

Figure 1: Infant dummy **Figure 2: Neck bending response with corridor**

Figure 3: Neck bending **Figure 4: Thorax comp-**
Response for 2 dummies **ression in repeat tests**

SUMMARY

A twelve segment, instrumented, biofidelic infant dummy has been developed. It weighs 2.5 kg and is instrumented with five tri-axial accelerometers. Data from tri-axial accelerometers at the base and top of the neck can be used to calculate the Neck Injury Criterion (NIC). Head Injury Criterion (HIC) can be calculated using data from the tri-axial accelerometers in the head. The dummy can be used to evaluate the safety potential of various types of child seats to transport infants.

HEAD IMPACTS: ANALYTICAL, NUMERICAL AND EXPERIMENTAL MODELS.

Philippe G. Young

Department of Engineering, University of Exeter, Exeter, EX4 4QF, UK
Senior Lecturer in Biomechanics. philippe.g.young@ex.ac.uk

INTRODUCTION

An overview of some of the work carried out at The University of Exeter on the response of the human head to blunt impact will be presented. Simple analytical expressions were derived to predict global impact characteristics (e.g. duration of impact, peak force transmitted, peak acceleration, HIC) for a fluid-filled spherical shell impacting with a projectile. In addition approximate analytical formulae to predict the onset of a dynamic response in the brain (onset of high intra-cranial pressure and shear transients) were also proposed. The analytical models were based on a number of simplifying assumptions and, in order to test their applicability when complicating effects were considered, realistic patient specific finite element and rapid prototyped models were generated based on 3D medical imaging data. The numerical and physical replica models were tested under a range of impact conditions and results obtained compared with the predictions from the analytical models.

METHODS

A high-resolution T1-weighted whole head MRI scan of a normal young male volunteer was obtained *in vivo* (see Figure 1.a). A three-dimensional finite element (FE) model was generated automatically from the 3D data sets using an in-house developed technique adapted from the marching cubes approach (see Figure 1.b). A rapid prototyped (RP) model based on the same dataset was also generated in parallel (see Figure 1.c).

Figure 1: (a) Rendered image of MRI data acquisition.
(b) Photograph of rapid prototyped skull generated
(c) Rendered image of finite element mesh generated.

RESULTS AND DISCUSSION

The RP model was filled with water to simulate the brain and subjected to low velocity impacts with a range of steel balls of different masses. These impacts were also simulated using the FE model and in Figure 2 the impact durations obtained using both these approaches as well as impact durations predicted by the analytical model are plotted for impact masses ranging from 45 g to 250 g. Excellent agreement is seen between the FE and RP results which in turn are in good agreement with the predictions from the simple analytical model.

SUMMARY

Figure 2: Comparison of FE, experimental and analytical impact durations.

A simple analytical model for key impact characteristics was validated using finite element and rapid prototyped models. As the mass of the projectile decreases the impact duration also decreases and, below a threshold value, it can be shown that there is an increasing likelihood of potentially deleterious pressure and shear strain transients occurring.

INTRODUCTION

Liquid can be instilled into the pulmonary airways during medical procedures such as surfactant replacement therapy, partial liquid ventilation and pulmonary drug delivery. For all cases, understanding the dynamics of liquid distribution in the lung will increase the efficacy of treatment. Recently, Cassidy et al (2001) developed an imaging technique for the study of real-time liquid transport dynamics in the pulmonary airways of rats. This study uses those imaging methods to investigate the effect of respiratory rate on the distribution of an instilled liquid, surfactant, in a rat lung.

METHODS

Lungs from 10 anesthetized Sprague-Dawley rats (~300 g) were removed, cannulated, vertically suspended via the cannula, and placed on 4 cmH₂O positive end-expiratory pressure. A bolus (0.05 ml) of exogenous surfactant (Survanta, Ross Laboratories, Columbus, OH) mixed with radiopaque tracer was instilled as a plug into the trachea of each lung. The lungs were ventilated with a 4 ml tidal volume for 20 breaths at one of two respiratory rates: 20 or 60 breaths/min. During the first five breaths, the movement of radiopaque surfactant in the lungs was imaged at 30 images/s using a microfocal X-ray source and an image-intensifier. After 20 breaths, the lungs were placed on 4 cmH₂O positive pressure and rotated at 2°/s while imaging with the microfocal X-ray device. A 3-D image of the lung was reconstructed using the images acquired during rotation and compared to the 2-D images collected at breath 20.

Transport dynamics of surfactant during the first few breaths were quantified statistically using the center of mass, standard deviation, skewness, and kurtosis of the spatial distribution of surfactant. Additionally, the lung was divided into four regions to examine the homogeneity index, and fraction reached.

RESULTS AND DISCUSSION

Respiratory rate influenced the distribution of instilled surfactant within the airways of the rat lung. Surfactant distribution was more homogeneous throughout the first 5 breaths in lungs respiring at 60 breaths/s than at 20 breaths/s. Figure 1 shows the distribution of surfactant (black regions) in a rat lung after breathing 20 breaths at 60 breaths/min.

Notice that surfactant was located throughout the lung whereas in lungs respiring at 20 breaths/min (not shown), the surfactant resided in the center of the lung.

Figure 1: X-ray image of surfactant + radiopaque tracer (black regions) in a rat lung that was ventilated at 60 breaths/min.

After 20 breaths, surfactant reached a greater portion of the lower lobes than upper lobes of lungs respiring at either frequency. Using the 3-D lung reconstruction, the spatial distribution of surfactant was located and quantified for analysis and comparison with the 2-D images.

LIMITATION OF EXPRIATORY FLOW IN LIQUID VENTILATION

INTRODUCTION

Total liquid ventilation involves filling the lungs with a perfluorocarbon (PFC) liquid, and ventilating with a liquid tidal volume. Liquid ventilation has shown promise for treating acute respiratory distress syndrome (Hirschl 1996). Flow limitation can occur during expiration of the PFC, causing difficulty in achieving the desired minute ventilation, and can result in “breath stacking” in which the end-inspiratory lung volume increases with time. Flow limitation occurs when airway pressures become low enough that airways collapse. Flow limitation (also known as “choked” flow) and airway flutter have been studied extensively in the context of gas ventilation (Elad 1987, Elliot & Dawson 1977, Knudson 1983, Larose & Grotberg 1998, Luo & Pedley 1998), but few studies have investigated flow limitation in liquid ventilation. In this work, we investigate flow limitation in liquid ventilation.

METHODS

New Zealand White rabbits (n=56, mean weight = 3.1 kg ± 0.3 kg) were anesthetized, heparinized, and euthanized. A tracheostomy was performed and one of four different PFCs (PFOB, PP4, FC77, or PFDEC) was instilled into the lungs to an end-inspiratory lung volume (EILV) of either 40 ml/kg or 20 ml/kg. The endotracheal tube was connected to a computer-controlled piston pump which provided a constant flow expiration. The PFC volume remaining in the lungs at choke, V_{ch} , was measured three times for each of three different expiratory flow rates (2.5, 5.0, 7.5 ml/s). The PFC properties are listed in Table 1. Additionally, we have developed a theoretical model of choke in liquid-filled lungs. The model is based on a modified Bernoulli equation, and accounts for the effects of gravity.

RESULTS AND DISCUSSION

Figure 1 contains a plot of V_{ch} vs. flow rate for each PFC with (a) EILV = 40 ml/kg, (b) EILV = 20 ml/kg. V_{ch} does not follow an obvious relationship based on fluid properties. For example, the densities and viscosities of PFOB and PP4 are similar, yet a PFOB-filled lung has a much lower V_{ch} for a given flow rate. We are currently measuring the resistance and compliance of PFC-filled lungs. Our preliminary measurements suggest these may depend on PFC type, possibly involving PFC interactions with surfactant or with the aqueous lining of the lungs. Our model indicates these parameters affect V_{ch} .

SUMMARY

Flow limitation in PFC-filled lungs does not correlate directly with PFC fluid properties. Using our theoretical model, we are currently investigating the reasons for this behavior.

ANATOMICALLY BASED MODELS OF BLOOD FLOW IN THE HUMAN PULMONARY MICROCIRCULATION

Kelly Burrowes, Merryn Tawhai, and Peter Hunter

Bioengineering Institute, The University of Auckland, Auckland, New Zealand
k.burrowes@auckland.ac.nz

INTRODUCTION

An anatomically based mathematical model of the human pulmonary micro-vasculature and blood flow within this network is being constructed as part of the Lung Physiome (<http://www.bioeng.auckland.ac.nz/physiome/physiome.php>). The real capillary network is continuous throughout several alveolar units and at least throughout a single acinus; the model capillary network generated covers a small number of alveolated airways. Blood flow equations are solved through this network, and results are compared with *in vivo* measurements of red blood cell and neutrophil transit times from Presson et al. (1995).

METHODS

The alveolar structure is modeled using a Voronoi mesh that fills a given volume, with faces removed to form alveolar ducts, alveoli, and sacs. The capillary network is generated to be continuous over these alveolar surfaces. A 2D Voronoi network is generated over the surface of a $\frac{3}{4}$ sphere. This mesh is then texture-mapped onto the alveoli geometry. The Voronoi capillary junctions usually comprise, but are not restricted to, 3 segments. The Voronoi meshing method ensures mesh continuity between the septa of adjacent alveolar faces.

The method described by Huang et al. (2001) and Dhadwal et al. (1997) is implemented for the solution of blood flow in the capillary mesh. The resistance is calculated in each capillary segment and mass conservation balances are carried out at each junction. Pressure boundary conditions are applied at the inlet and outlet nodes of the network.

An iterative solution procedure is used: a linear solution of the pressure-flow equations is followed by rheological analysis to update hematocrit values. The rheological analysis takes into account the flow rate solution and feed hematocrit (volume fraction of red blood cells entering the network) to estimate an updated hematocrit field. This process also considers the uneven distribution of red blood cell fluxes.

The resulting pressures throughout the capillary network in turn induce cross sectional dimensional changes in the thin distensible vessels. These effects are taken into account iteratively. The influence of junctional resistances and the difference in flow through corner vessels is also accounted for in the solution procedure.

Calculation of red blood cell and neutrophil transit times through their preferred pathways are used to compare model solutions with *in vivo* measurements.

RESULTS AND DISCUSSION

Figure 1: Normalised flow fields in a test capillary mesh. Red corresponds to 100% of inlet flow; dark blue is zero flow.

The Voronoi meshing procedure has been used to create alveolated airway meshes, and capillary networks. The resulting meshes compare well with recorded anatomical data (Weibel 1963, Sobin et al. 1980, Staub and Schultz 1968).

An advantage of using the texture-mapping procedure to generate the capillary mesh is that the method can be extended to mapping imaged capillary beds to the alveolar surface. That is, the texture-mapping method will ultimately be used to create capillary bed models from images of normal or diseased pulmonary capillaries.

Solution of blood flow and pressure equations has been implemented in the developed capillary network. The accuracy of the model is analyzed by comparison with *in vivo* measurements of red blood cell transit times.

This capillary system will be used to develop a lumped parameter model of pulmonary capillary bed pressure drop, to enable coupling of blood flow solutions in models of the pulmonary arterial and venous trees. The lumped parameter model will provide a pressure transfer function between the arterioles and draining venules. Blood flow in the large vessels is described by solution of Navier Stokes equations with pressure boundary conditions at the main pulmonary artery and vein.

INTRODUCTION

Nasal flow limitation has often been reported in the pathophysiological literature in many circumstances including hyperventilation and, in case of nasal valve pathologies, during quiet inspiratory breathing (Bridger *et al.*, 1970; Proctor, 1977). We have developed a discrete multi-segmental model describing the coupling between inspiratory flow and the nasal wall distensibility. This model has been initially developed to describe the flow-structure coupling in pharyngeal airways with at least two-compliant compartments in series (Fodil *et al.*, 1997), but it has never been applied at the nose level. In the present study, the local wall compliance has been estimated in normal subjects, from longitudinal nasal area profiles obtained, by acoustic reflection, at various predetermined negative values of nasal pressure.

MATERIAL AND METHOD

The two-microphone acoustic reflection method was used to assess the inner geometry of the nose in terms of cross-sectional area versus the distance along the longitudinal airway axis (Louis *et al.*, 2001). This method, associated to the generation of a negative nasal pressure (negative pressures values generated at the nose were -2, -4, -6, -8 and -10 hPa below atmospheric pressure), permitted to assess the relationship between the local nose area and the values of the negative pressure in the nose. Then, the local nasal compliance could be deduced from the slope of the relationship between the local area variation and the various values of constant negative pressure inside the nasal cavity.

MODEL

The developed nasal model only considers the coupling in a part of the nose where the area can be inferred by the acoustic method. Indeed, due to artifacts associated to paranasal sinuses, only the nasal portion of 6 cm-long from the nostril, i.e., the so-called anterior part of the nose, could be explored (Hilberg *et al.*, 1996). The discrete segmental model of the anterior part of the nose included 19 compliant elements in series, which correspond to the spatial resolution of the acoustic method. Each element represents an individualized nasal segment coupled to the inspiratory flow. Area at 0 hPa and compliance of each segment were obtained from acoustic data. For a given value of negative pressure drop between the two ends of the nose, flow and local cross-sectional areas in each nasal segment were numerically computed from flow conservation principle and the generalized form of Bernoulli's equation.

RESULTS

Nasal compliance was found to increase as longitudinal distance from nose entry increases. This softening phenomenon was found to be linked to the amount of vaso-erectile tissues in the nose. Indeed, the variation in compliance with the distance disappeared when a vasoconstrictor was dispensed to the subject. The pressure-flow relationship predicted with the model exhibited a systematic flow limitation pattern. The model also shows that this flow limitation was associated with a major collapse localized in the anterior part of the inferior turbinate. The model results reveal that flow limitation occurs through the coupling between area-variation pressure changes, which is essentially associated to kinetic energy variation, and the local nasal compliance.

CONCLUSION

Although the proposed model oversimplifies the anatomical reality, it appears consistent with the reported flow limitation and area constriction phenomena. Noteworthy, maximum flow predicted by the model for pressure value between 1 and 2 hPa, was in agreement with the reported physiological observations. Thus, the proposed multi-segmental model appears to provide a rationale for flow limitation phenomena through the nose while classical models, based upon rigid wall properties, failed to describe such pathological features.

INTRODUCTION

Diseases such as asthma are often treated with drugs inhaled as an aerosol; controlling particle deposition pattern within the lung airways is, therefore, vitally important. Studies of particle movement in the airflow and local deposition patterns within the lung will be also aid understanding of the early stages of lung diseases. The geometry of a bronchial bifurcation can be characterized by a bifurcating tube with smoothly curving surface and varying cross-sectional area. Because the velocity distribution within the boundary layer can affect the particle deposition, the surface variation will be very important - an idealized, planar geometry will be inadequate to improve understanding of the particle deposition characteristics. In this study, we aim to construct a realistic model of a bifurcation, with smoothly curved surface, particularly at the flow divider, and to investigate the particle trajectory and deposition on the wall using this model.

Figure 1: Bifurcating tube axes. In present study, geometric parameters are $R_A=R_B=10$, $\Psi_A=\Psi_B=35^\circ$, $\gamma=3$. The radius ratio between the parent and daughter tube is 0.775.

METHODS

To describe the curved surface of the model, \mathbf{x}_A and \mathbf{x}_B are defined as two tube axes, which provide density space ϕ_A and ϕ_B around each axes defined by following equations.

$$\phi_A = \frac{G(\mathbf{x}_A)}{r_A} \quad \phi_B = \frac{G(\mathbf{x}_B)}{r_B} \quad (1)$$

$G_A(\mathbf{x}_A)$ and $G_B(\mathbf{x}_B)$ are functions associated with the radius of the tube. The model surface, \mathbf{x}_S is defined to be satisfied when the summation of γ^{th} powers of these density spaces is equal to unity.

$$\Phi(\mathbf{x}_S) = \phi_A^\gamma(\mathbf{x}_A) + \phi_B^\gamma(\mathbf{x}_B) = 1 \quad (2)$$

γ is a parameter to control the sharpness of flow divider. This method can be easily adapted to construct non-planar models by defining two planes, one for each daughter tube axis, as illustrated in Fig. 1.

We calculated steady flow in three bifurcation models, planar ($\beta=0^\circ$), and non-planar $\beta=45^\circ$ and 90° . NS-equations were

solved with the SIMPLER algorithm, supposing the fluid is incompressible Newtonian fluid. Particle trajectories and deposition on the wall were also calculated using resultant velocity fields.

RESULTS AND DISCUSSION

In the planar bifurcating tube the secondary flow at the daughter tube forms a pair of symmetrical vortex. This symmetry was broken when the bifurcation is non-planar, as shown in Fig. 2. The particle deposition pattern was slightly changed by β as shown in Fig. 3, while the deposition efficiencies in each model were almost equivalent in the range of the Stokes number between 0.01 and 1.0.

Figure 2: Secondary flows at the daughter tubes at $Re=1000$. From the left, $\beta=0^\circ$, $\beta=45^\circ$ and $\beta=90^\circ$.

Figure 3: Particle deposition pattern at Stokes number=0.5 and $Re=1000$. From the left, $\beta=0^\circ$, $\beta=45^\circ$ and $\beta=90^\circ$.

SUMMARY

It is necessary to define a reproducible geometry of any model employed because the geometry is an important factor determining local flow features, especially within the bifurcation. In this study we present a formula based method to describe a bifurcation model with non-planar geometry. The steady inspiratory flow field in the non-planar bifurcating tube showed asymmetrical secondary flow pattern in the daughter tube. This caused a change of particle deposition pattern but did not affect to the deposition efficiency. The deposition efficiency increased with Stokes number just as in the planar bifurcating tube.

EFFECT OF TISSUE VISCOELASTICITY AND LUNG SURFACTANT ON EUSTACHIAN TUBE MECHANICS

Samir N. Ghadiali^{1,2} (ghadiali@pitt.edu), J. Douglas Swarts², William J Federspiel¹

¹Department of Chemical Engineering, University of Pittsburgh, Pittsburgh, PA, USA

²Department of Pediatric Otolaryngology, Children's Hospital of Pittsburgh (CHP), Pittsburgh, PA, USA

INTRODUCTION

The development of Otitis media (OM), a common childhood disease, has been associated with Eustachian tube (ET) dysfunction. The collapsible ET is similar to respiratory airways in that the lumen contains a fluid layer, the mucosa, and is surrounded by various soft tissue elements. An impaired ability to open the ET results in negative middle ear (ME) pressures, ME fluid accumulation, and subsequent infection and inflammation. Impaired ET opening may be due to abnormal mechanical properties such as ET elasticity, E_{tube} , and hysteresis, η . E_{tube} may depend on the elasticity of the surrounding tissue and on the mucosa-air surface tension, while η may depend on viscoelastic tissue properties and on surface tension hysteresis due to the presence of surfactant. In this study, the relative importance of tissue and surface tension mechanics is determined by experimentally altering specific structural elements and subsequently measuring E_{tube} and η .

METHODS AND MATERIALS

A modified force-response protocol (Ghadiali et al, 2000) was performed to assess ET mechanics in sedated and anesthetized cynomolgus monkeys (*Macaca fascicularis*, 2-4 kg). During this protocol the ME was inflated at a constant flow rate until the ET opened at the opening pressure, P_{open} . The syringe pump was then programmed to produce a sinusoidal flow rate and pressure transients were measured until stable pressure-flow oscillations were observed. Data for analysis consisted of the pressure and flow rate during the final oscillation cycle, which are plotted as a pressure-flow (P-Q) hysteresis loop in Figure 1. These experimental P-Q loops were analyzed with a simple model of flow in a collapsible tube (Ghadiali et al, 2001). In this model, the pressure drop in the ET, Δp , is related to the flow rate, Q , by a Poiseuille relationship,

$$\Delta p = p(t) - p_d = KQ(t)/A(t)^2, K = 8\pi\mu L \quad (1)$$

where $p_d=0$ is the reference downstream pressure, μ is the viscosity of air, $A(t)$ is the collapsed area, and L is the length of the collapsed segment. The solid mechanics is described by,

$$p(t) - p_{ext} = E_{tube}A(t) + \eta dA/dt \quad (2)$$

where p_{ext} is the external tissue pressure. Once $A(t)$ is calculated from eqn. (1) and dA/dt is estimated with finite-differences, eqn. (2) can be correlated with experimental measurements (solid line in Figure 1). As a result, the ET's compliance, $C=1/E_{tube}$, and hysteresis, η , can be determined.

Figure 1: Experimental/theoretical P-Q hysteresis loop

ET mechanical properties (P_{open} , C , η) were measured in two groups of monkeys. The first group ($n=12$) was used to investigate tissue mechanics by performing measurements before and after paralysis of the left tensor veli palatini (TVP) muscle. The right ear of the second group ($n=6$) was used to investigate the influence of the mucosa-air surface tension by performing measurements under normal conditions, after washing out the mucosa with saline, and after the installment of a pulmonary surfactant (Infasurf). All protocols were approved by the CHP Animal Research and Care Committee.

RESULTS AND CONCLUSIONS

Results of these experiments are summarized in Table 1 where statistical differences were documented using analysis of variance. Muscle paralysis resulted in a decrease in P_{open} , an increase in C , and a decrease in η . The removal of the normal mucosal layer did not significantly alter P_{open} , but did result in a decrease in C and η . Treatment of the mucosa with Infasurf reduced P_{open} and was effective in increasing C and η to baseline values. The large change in C during TVP paralysis indicates that ET elasticity is primarily determined by tissue mechanics. ET hysteresis, however, appears to be equally affected by tissue and surface tension mechanics. Knowledge of how specific structural components affect ET mechanics may lead to improved treatment strategies.

THE INFLUENCE OF CELL TOPOGRAPHY ON EPITHELIAL CELL STRESSES DURING AIRWAY REOPENING

Anne-Marie Jacob and D. P. Gaver

Department of Biomedical Engineering, Tulane University, New Orleans, LA, ajacob@tulane.edu

INTRODUCTION

The lung consists of a series of liquid-lined airways that act as conduits for air traveling from the outside environment to the remainder of the respiratory system. Under both normal and pathological conditions, these compliant tubes may collapse, impeding gas exchange. This results in a liquid occlusion whose surface tension, under extreme conditions, becomes quite large, requiring the excessive pressures of mechanical ventilation to peel apart the airway walls as they reopen. This exerts mechanical stresses on the pulmonary epithelial cells that could potentially lead to damage or modification of their biological function. This study is designed to quantify these stresses on the cellular level in order to better understand the dynamic behavior of the pulmonary system during airway reopening.

METHODS

Figure 1: Schematic diagram of a semi-infinite bubble progressing through a cell-lined airway

We present a 2-D computational model for the flow-driven progression of a semi-infinite bubble through a liquid-occluded airway. The system is modeled as a horizontal channel whose walls, separated by a mean distance $2H$, are sinusoidal with an appropriate amplitude, A , and wavelength, λ , to mimic the real geometry of a cell-lined airway (Figure 1). The liquid film is assigned a constant viscosity, μ , and density, ρ , and the air-liquid interface is characterized by a constant surface-tension, γ . We employed the boundary element method (BEM) in conjunction with lubrication approximations to solve the Stokes

flow equations for the steady-state stresses acting on the cells. Relevant dimensionless parameters examined include:

- $\mathfrak{r} = \frac{A}{H}$, which relates the height of the cells to the average distance separating the airway walls. The relevant values vary from 0.01 in the respiratory bronchioles to 0.75 in more collapsed airways.
- $Ca = \frac{Q\gamma}{2H\mu}$, the capillary number (Q is the 2-D flow rate), which represents the ratio of viscous forces to surface-tension forces. We examined the system's behavior at $Ca = 0.5$, where both viscosity and surface-tension are important.

RESULTS AND DISCUSSION

A characteristic curve of the shear stress acting on the cells lining the model's airway walls is given in Figure 2 for the bubble orientation depicted in Figure 1. The magnitude of this

Figure 2: Dimensionless shear stress along cell-lined airway wall corresponding to Figure 1

stress is maximum at the tip of the bubble ($x=0$) and approaches a Poiseuille shear stress downstream. Our results indicate that corrugations of the airway wall may amplify stresses and result in alterations in cell function.

USE OF COMPUTATIONAL FLUID DYNAMICS TO STUDY INHALED GAS AND PARTICLE TRANSPORT IN THE NASAL PASSAGES

Julia S. Kimbell¹, Rebecca A. Segal, and Bahman Asgharian

CIIT Centers for Health Research, Research Triangle Park, NC, USA, www.ciit.org

¹kimbell@ciit.org

INTRODUCTION

The nasal passages represent the main portal of entry for inhaled gases and particles and contain considerable capacity for uptake, filtering, metabolism, and clearance of inhaled material. For certain air pollutants such as highly water-soluble or reactive gases, respiratory tract airflow patterns can play a major role in determining sites of uptake by the airway lining. These uptake patterns influence the distribution and severity of toxic response and account in part for interspecies differences in susceptibility to associated respiratory tract disease. To better characterize respiratory airflow, uptake, and deposition patterns among species, three-dimensional, anatomically accurate computational fluid dynamics (CFD) models of the F344 rat, rhesus monkey, and human nasal passages were constructed (Kimbell et al., 1997a; Kepler et al., 1998; Subramaniam et al., 1998). The models can be used to test hypotheses about dominant transport mechanisms. Uptake and deposition predictions can be used to assess human health risks. Examples of gas and particle transport simulations are presented here.

METHODS

Three-dimensional computational meshes were reconstructed from serial sections of fixed rat and monkey nasal specimens and from human MRI scans. Steady-state inspiratory airflow simulations were conducted using the commercial software FIDAP (Fluent, Inc., Lebanon, NH) to solve the Navier-Stokes equations for laminar flow. Flow rates corresponding to resting breathing minute volumes were simulated using a uniform velocity profile at the nostrils. Simulation results agreed with observations and measurements of dye streaklines and airflow in hollow nasal molds (Kimbell et al., 1993; Kimbell et al., 1997a; Kepler et al., 1998; Subramaniam et al., 1998).

As an example of gas transport, nasal uptake of inhaled formaldehyde was simulated using FIDAP in the rat, monkey, and human with a condition specifying that flux at nasal walls is proportional to concentration near nasal walls. Formaldehyde gas is quite water-soluble, so constants of proportionality for this condition were determined for mucus- and nonmucus-coated nasal regions from experimental data (Kimbell et al., 2001).

As an example of particle transport, nasal deposition simulations were conducted in the rat, monkey, and human for spheri-

cal particles between 0.5 and 10 μm in mass median aerodynamic diameter. A CIIT computer program in which impaction was the dominant transport mechanism (Asgharian and Anjilvel, 1994) was used to predict particle trajectories and deposition sites. Particles were assumed to have no effect on inspiratory airflow patterns.

RESULTS AND DISCUSSION

Formaldehyde simulations predicted that nasal flux patterns were species-specific. Regions where flux was predicted to be high correlated with areas of nasal tissue damage in formaldehyde-exposed rats and monkeys (Kimbell et al., 1997b; Kepler et al., 1998). These results support the hypothesis that species-specific patterns of nasal tissue damage observed in formaldehyde-exposed laboratory animals are determined by species-specific patterns of formaldehyde uptake. Particle simulations at resting breathing rates predicted as expected that near complete filtration of particles by the nose occurred at a smaller particle size in the rat than in the human. In the rat, predicted nasal deposition efficiencies generally agreed with experimental data, but human simulations overpredicted nasal deposition efficiencies at small Stokes numbers. Potential effects of airflow velocity profiles imposed at the nostrils are being explored.

PREDICTING THE MIXING OF ULTRA-FINE PARTICLES IN A MODEL LUNG ACINUS

Angus Leeming¹ and Robert C. Schroter²

Department of Bioengineering, Imperial College of Science, Technology and Medicine, London, SW7 2BX, U.K.

¹ a.leeming@ic.ac.uk, ² r.schroter@ic.ac.uk

INTRODUCTION

Heyder *et al.* [1973] showed that during normal quiet breathing 10% of all particles reaching the acinar regions of the lung deposit, independent of particle size. These rates of deposition cannot be explained by classical transport mechanisms. Flow in the acinus is Stokesian and both the Brownian diffusivity and gravitational settling of such particles are negligibly small.

New insight was provided by Butler and Tsuda [1997] when they demonstrated convective stretch-and-fold mixing patterns in a rat lung filled with silicone. The mixing associated with these patterns can be very rapid, even for particles with only a small Brownian diffusivity. Nevertheless, the mechanism driving this mixing is still not clear.

One plausible source, geometric hysteresis of the alveolar wall motion over the course of a breath, was illustrated by Tsuda *et al.* [1999] using a model alveolar duct. It consisted of a T-shaped junction of three short, straight, square ducts. The model was filled with silicone oil and alveolar wall motion was simulated by pistons in the two horizontal ducts. The pistons were driven to generate a low Reynolds number, cyclic flow. Their motion had a small amount of asynchrony, adjusted to match the degree of geometric hysteresis found in rabbit lungs. Tsuda *et al.* demonstrated that this system would stretch-and-fold a line of tracer dye, leading to progressively more complex patterns as the cycle number increased.

THE PRESENT STUDY

A realistic structural model of the acinar region is a necessary precursor to truly realistic simulations of the flow processes occurring within the lung. Our group has created just such a model over several years [Denny and Schroter, 1995, 2000]. It provides us with an opportunity to calculate particle dispersions in a alveolar duct model with realistic geometry and dynamic behaviour.

The present study, however, reproduces numerically Tsuda *et al.*'s experimental results, thereby providing a strenuous test of our flow-solver and particle tracking codes. Figure 1 is an illustrative snapshot of the particle field after 40 cycles.

Both the original experiment and this simulation followed the evolution with time of a line of non-diffusive tracer. Real particles in alveolar air have a small but finite diffusivity that will smear out and mix these purely convective patterns. By applying the methods of Wonhas and Vassilicos [2001], the original Tsuda *et al.* analysis can be extended to provide a

predictive tool capable of describing the mixing of such diffusive particles as a function of time.

The mixing properties of the field are determined by the fractal dimension D' of a cut through the interface, a variable that can be calculated from snapshots such as Figure 1. Thereafter, the variance of the particle field scales like

$$E(0) - E(\kappa) \propto \sqrt{\kappa}^{1-D'}$$

where κ is the diffusivity of the particles. Moreover, if, as here, the line of tracer grows linearly with time, then the variance varies like

$$\frac{\partial}{\partial t} [E(0) - E(t)] \propto \sqrt{\kappa}^{1-3D'}$$

Both relations are valid for particles whose diffusive length scales lie within the range where the interface has a well-defined fractal dimension.

Figure 1: Particle dispersion after 40 cycles. The original tracer position is shown across the mouths of the three ducts.

PULMONARY EPITHELIAL CELL-MATRIX SIGNALLING VIA ALPHA-6/BETA-4 INTEGRIN

Susan Margulies¹, Michele Hawk¹ and Valerie Weaver²

Departments of Bioengineering¹ and Pathology², University of Pennsylvania, Philadelphia PA, USA, margulies@seas.upenn.edu

INTRODUCTION

Previously we have demonstrated that primary pulmonary alveolar epithelial cells (AEC's) that were seeded on fibronectin and maintained in culture for five days demonstrated a significant resistance to stretch-induced death compared to those maintained for only one day in culture (Tschumperlin et al, 2000). Furthermore, when seeded on laminin-rich extracellular matrix (ECM) obtained from 5-day cells rather than fibronectin, the AEC's had a stretch tolerance similar to 5-day cells (Oswari et al, 2001). We hypothesized that AEC's have alpha-6/beta-4 integrins at the cell membrane, offering them the opportunity to utilize the unique mechanotransduction pathway between laminin and the intermediate filaments (Green and Jones, 1996). Transferring the load to the intermediate filaments, with larger ultimate strains than actin (Janmey et al, 1990), may be associated with the AEC's ability to tolerate large deformations.

METHODS

Lungs were excised from anesthetized male Sprague-Dawley rats (200-350g), and AEC's were dissociated and isolated, as described previously (Tschumperlin et al, 2000). Cells were seeded at 1.0×10^6 cells/cm² on silastic membranes coated with fibronectin (40µg/ml, Boehringer Mannheim). Wells were cultured in minimum essential medium (MEM), supplemented with 24ug/ml gentamicin and 10% fetal bovine serum (all from Life Technologies). Cells were studied at days 1, 2, and 5 days after isolation, with four cell isolations per time point.

Surface proteins were labeled in the following manner: monolayers were washed 6 times with DPBS (with calcium and magnesium ions) and incubated on ice with Sulfo *N*-Hydroxysuccinimide-Biotin (Pierce, Rockford, IL) for 1h. The cells were washed 3 times with ice cold 50mM DPBS glycine solution and solubilized in RIPA lysis buffer (1% IGEPAL CA-630, 0.25% deoxycholate, 0.1% SDS, 150mM NaCl, 50mM Tris-HCL, pH 7.4) containing 4.8mM EDTA and a cocktail of protease inhibitors. Equivalent amounts of rat protein extracts were preadsorbed by an overnight incubation at 4° C with rabbit IgG coupled to agarose beads (Sigma, Saint Louis, Mo) followed by a 1h incubation with protein A coupled to agarose beads (Invitrogen, Grand Island, NY) at room temperature. Beta-4 integrins were immunoprecipitated from the precleared supernatant by incubation for 2h at room temperature with rabbit anti-integrin beta-4 subunit polyclonal serum, (Chemicon International, Temecula, CA) and protein A coupled to agarose beads. Immunocomplexes bound to protein A agarose beads were washed repeatedly with RIPA lysis buffer eluted in SDS-PAGE sample buffer and separated on 7.5% SDS polyacrylamide gels under nonreducing conditions. Resolved protein was transferred to polyvinylidene difluoride (PDVF)

membranes and incubated with streptavidin HRP (Dako, Carpinteria, CA). Labeled bands were detected using enhanced chemiluminescence (ECLTM)(Amersham Pharmacia Biotech UK Limited, Little Chalfont Buckinghamshire, England) and ECLTM HyperfilmTM and quantified using densitometry.

RESULTS

Data indicate that lung AEC's express detectable levels of beta-4 integrins at 1, 2 and 5 days in culture, as confirmed by a band migrating at the same molecular weight in human mammary epithelial cells (positive control; (Weaver et al 1997)) and its absence in murine fibroblasts (negative control). Band density on each film was normalized to cells at day 1. Across all four gels surface beta-4 levels averaged 168% of day 1 levels by 2 days in culture, and 128% of day 1 levels after 5 days. Data across timepoints were statistically indistinguishable ($p > 0.25$, unpaired Student's *t* analysis).

DISCUSSION

Our immunoprecipitate data demonstrating expression of the beta-4 integrin subunit on the surface of lung AEC's support our hypothesis that the IF's, when ligated to a laminin-rich ECM via the alpha-6/beta-4 integrin, could play a major role in distributing the applied load throughout the cytoskeleton structure. In a similar manner, mechanical integrity and cell viability in keratinocytes in vivo is conveyed primarily through the laminin receptor, alpha-6/beta-4 integrin, and is mediated via intermediate filament-beta 4 integrin interactions (Dowling et al 1996; Jones and Green 1991; Spinardi et al 1995). Ongoing studies are targeting new therapeutic interventions to prevent or ameliorate deformation-induced AEC injury via modulators of the alpha-6/beta-4 integrin mechanotransduction pathway.

FINITE ELEMENT GEOMETRIC MODELS OF THE HUMAN LUNG AND DIAPHRAGM

Premakumar Mithraratne, Geoff Carden, Merryn Tawhai, and Peter Hunter

Bioengineering Institute, The University of Auckland, Auckland, New Zealand
p.mithraratne@auckland.ac.nz

INTRODUCTION

Accurate representation of the geometry of organs is an important factor when modeling their physiological behavior. Here we present anatomically accurate finite element meshes of the human lung and diaphragm derived from the visible human (VH) data (Ackerman, 1998). Development of these high order (cubic Hermite) geometric models forms part of a project aiming to study the integrated performance of lung soft-tissue mechanics, airflow, and pulmonary circulation. The geometric fitting method has been applied successfully to fit finite element surface meshes of various organs of the body (Bradley et al., 1997), and is used to fit a surface mesh to the diaphragm model. The lungs are fitted as a volume mesh - this is the first time that the geometry fitting method has been extended to fit a finite element volume mesh.

METHODS

CMISS, a computational and visualization software package developed by the Bioengineering Institute at the University of Auckland, was used to extract geometric coordinates of data points from visible human (VH) slices. The anatomical images at 5 mm intervals were read into a CMISS graphical window and the circumference of both the lungs were digitized. A total number of 46 images from 300 to 525 mm (0 mm is the uppermost image at the head, and 1871 mm is lowest image at the foot) were used to digitize 3103 data points. For the diaphragm, a similar procedure was adopted and 28098 data points were collected from 95 images. All images were linearly transformed in the xy-plane with respect to the three 'markers' present on each image prior to the digitization, to ensure correct alignment of the sections.

An initial linear volume mesh was fitted to the data iteratively until the root mean square (RMS) error converged to an acceptable value. The first step in this fitting process is to calculate the shortest distance from each data point to the surface of an initial (in this case linear) mesh. An error function is then set up as the summation of the squares of all these distances. The nodal parameters (nodal value and derivatives) that minimize the error function are evaluated by differentiating the error function with respect to each nodal parameter, and equating the resulting expression to zero. This process yields the necessary number of linear equations to determine the nodal parameters. The set of linear algebraic equations thus obtained is solved using a Newton-Raphson method.

The scale factors are held constant during the minimization of the error function. Because the scale factors depend on the nodal position and derivatives, if they were allowed to vary during the minimization process then one would end up with a

computationally expensive non-linear problem. The approach that we have adopted is to hold the scale factors constant during a fit, then update the scale factors post-fit with respect to the new nodal parameters. Because the scale factor update alters the fitted element shape, the fitting and scale factor updates must be repeated iteratively until the overall RMS error reaches a pre-specified limit. For further details of the mathematical formulation of the problem and the various element parameters, the reader is referred to the paper by Bradley et al., (1997).

RESULTS AND DISCUSSION

Figure 1 depicts the fitted bi-cubic Hermite finite element mesh of the diaphragm. The final form of the mesh was obtained after four iterations. The mesh consists of 302 nodes and 124 elements.

Figure 1: Fitted finite element surface meshes (bi-cubic Hermite) of the diaphragm.

It is to be noted that the data derived from the VH images represent partially collapsed lungs and diaphragm as the VH images were obtained from a cadaver. However, these models can be considered as generic geometric models and can be readily transformed into patient-specific models using imaging data. This technique is currently being applied to customize the VH geometry to fit the Auckland skeleton, with the help of 'land mark points' from the VH images and skeleton model.

COMPUTATIONAL ANALYSIS OF INSPIRATORY HEAT AND WATER VAPOR FLUXES IN THE HUMAN NOSE

Sara Naftali¹, Moshe Rosenfeld¹, Michael Wolf² and David Elad¹

¹Department of Biomedical Engineering, Faculty of Engineering, Tel-Aviv University, Tel-Aviv, 69978, Israel, sara@eng.tau.ac.il

INTRODUCTION

Nasal inspiration is important for maintaining the internal environment of the lung, since it equilibrates ambient air with alveolar conditions (body temperature and fully saturated water vapor) on reaching the nasopharynx. The nose has a complex three-dimensional geometry and its inner surface is lined with a layer of wet and warm ciliated mucosa. Numerous studies were aimed at evaluation of the functional role of the nose in health and disease in terms of its temperature and relative humidity (RH) characteristics. However, the complex structure and relative inaccessibility of the nasal cavity have prevented detailed *in vivo* studies of nasal transport characteristics. Accordingly, we developed a complex *nose-like* model in order to study the dynamic capacity of the human nose to warm and humidify environmental air during inspiration.

METHOD

The physical domain of the problem is a *nose-like* model that incorporates the anatomical aspects of the nasal cavity that most affect gas transport patterns, and allows for the removal or addition of functional nasal features as required by the analysis (Naftali *et al.*, 1998). The governing equations are the continuity and Navier-Stokes equations for laminar flow of an incompressible air with constant viscosity and thermal conductivity and the energy conservation (thermal) and convection-diffusion equations. These equations were simultaneously solved for different boundary conditions by implementing the finite volume numerical software of FLUENT. The mesh of the *nose-like* model was composed of 290,115 tetrahedral cells and 607,088 triangular wall faces. The inner walls were assumed to be at alveolar conditions (e.g., 37°C and 100% RH). The flow for quiet breathing was chosen to fit a tidal volume of 0.41 L and 15 breathes per min. The inlet conditions for normal ambient air at the nasal nares was assumed to be 20% RH and 25°C.

RESULTS

Normal breathing was chosen to be the reference case, and then, we investigated the influence of physiological, environmental and pathological variations. Simulation of the reference case

showed that during a day long of quiet breathing a total of 216 kcal of heat and 330 ml of water are transferred from the nasal walls into the inspired air. The fluxes that would bring the inspired air to alveolar conditions (37 °C and 100% RH) were computed from psychrometric data to be 248 kcal of heat and 364 ml of water vapor. Thus, the *nose-like* model is capable of conditioning the inspired air into about 90% of alveolar condition, which is similar to the normal *in vivo* data that the inspired air is normally conditioned to 80-90% of alveolar condition before reaching the nasopharynx. Numerical simulations at different extreme environments (e.g., hot-dry, cold-wet) showed that the inspired air was conditioned in the nasal cavity to about 90% of alveolar conditions regardless of the environmental conditions. The results of daily fluxes from noses after surgical interventions of turbinectomy are summaries in Table 1. The heat and water vapor fluxes from the nasal walls after turbinectomy of the middle or inferior turbinates are about 12-16% smaller than in the normal nose. After turbinectomy of both inferior and middle turbinates, the fluxes are reduced by about 23%.

DISCUSSION

The healthy nose can easily condition the inspired air within about 10% of alveolar conditions regardless of environmental surroundings. The turbinates increase the rate of local heat and moisture transport by improving mixing and by maintaining narrow passages. In problematic noses that require surgical intervention such as turbinectomy, it has been demonstrated that removing of either the inferior or middle turbinate reduces nasal efficacy to condition the inspired air by 12-16%. These results are very useful for evaluation of nasal efficacy at different environmental conditions and for both of planning and assessment of pharmaceutical or surgical intervention.

AN ASYMPTOTIC MODEL OF UNSTEADY AIRWAY REOPENING

INTRODUCTION

Airway reopening is a fundamental process in pulmonary mechanics. It involves the propagation of a bubble of air into a liquid-filled collapsed airway at a pressure (P_b) sufficiently large to overcome the adhesive effects of viscosity and surface tension, yet sufficiently low to minimize damage to delicate airway walls. Understanding the mechanics of reopening is important in developing ventilation strategies and in reducing the risk of ventilator-induced lung injury.

Figure 1: A physical model of airway reopening. The bubble propagates to the right, its volume increasing at rate C , peeling apart wet membranes held under longitudinal tension.

Pioneering work in understanding airway reopening was carried out by Gaver and co-workers (1990, 1995) using bench-top models such as that in Fig. 1. During the initiation of reopening in their experiments, when the bubble is driven into the channel by a constant flow-rate piston, P_b can transiently overshoot its final steady value. This transient pressure peak is physiologically and clinically significant since it might lead to dangerously large stresses being imposed on the airway walls. Our aim is to use a theoretical model to understand and characterise this behavior.

ASYMPTOTIC MODEL

A computational model for the steady reopening problem was developed by Gaver *et al.* (1996), who showed that reopening can be regarded as a peeling process. More recently, Jensen *et al.* (2002) described this problem using an asymptotic model based on the assumption that the membrane tension is large, so that the wall slopes are uniformly small. The model incorporated accurate expressions for the film thickness and the pressure drop near the bubble tip. We extend this asymptotic model to describe reopening as an unsteady initial-value problem for the configuration illustrated in Fig. 1, where the membranes lie between a pair of smooth parallel plates separated by a distance D . The model for unsteady reopening reduces to a fourth-order nonlinear PDE for the evolution of the width of the channel $H(x,t)$ ahead of the bubble tip, subject

to four boundary conditions. Starting from a small initial peeling angle, we seek the evolution of the bubble pressure $P_b(t)$, the bubble speed $U(t)$ and the membrane shape $H(x,t)$.

RESULTS

The results show the following two types of behavior. First, there is the transient peak behavior, similar to that seen by Perun & Gaver (1995). At early times θ and P_b rise slowly and the channel inflates without the bubble tip advancing significantly. At a critical time they both increase rapidly and the bubble begins to accelerate. This causes the channel walls some distance ahead of the bubble tip to bend sharply and correspondingly the fluid pressure there falls rapidly. This low pressure provides a strong adhesive force pulling the walls together and P_b must rise to overcome this resistance. P_b overshoots its steady value; U does the same shortly afterwards. Eventually, P_b settles back down to its steady value. The second type of behavior is when P_b does not exhibit a peak, but simply rises and settles immediately on its steady value. The type of behavior and magnitude of the pressure peak were recorded for a wide range of values of C and D . A monotonic response in P_b occurred when C and D were both low or both high.

DISCUSSION

Our asymptotic model captures transient bubble pressure peaks during the initiation of airway reopening and agrees qualitatively with experiments. The results suggest that it is feasible to avoid transient overshoot by suitably tuning the model parameters, although whether this is physiologically realistic is not yet clear. This model provides a first step towards understanding this phenomenon in a variety of reopening configurations.

ALVEOLAR TRANSPORT DURING TOTAL LIQUID VENTILATION

Ryan C. Patterson, Hsien-Hung Wei, Vinod A. Suresh, and James B. Grothberg

Department of Biomedical Engineering,
University of Michigan, Ann Arbor, MI 48109-2125, USA.
E-Mail: grothberg@umich.edu

INTRODUCTION

During normal, air-breathing respiration diffusive effects dominate alveolar gas transport, because the Peclet number, Pe , for transport of O_2 and CO_2 is much smaller than unity. However, during ventilation with perfluorocarbon liquids $Pe \gg 1$, because of small molecular diffusivities, D , in liquid. Understanding the fluid dynamics and mass transport within an alveolus during total liquid ventilation with perfluorocarbon can lead to an understanding of the mechanisms that affect gas exchange as well as delivery of larger molecules such as medications or genetic material.

METHODS

The alveolus is assumed to be an oscillating sphere of radius $R(t) = R_0(1 + \delta \sin \omega t)$ where δ is a measure of the tidal volume to functional residual capacity ratio. We use a dimensionless time, ωt , where t is dimensional time and ω is the breathing frequency. The flow field inside the alveolus is in the radial direction only with a point source at $r = 0$.

The concentration field is governed by the convection-diffusion equation, which we solve asymptotically in the limit of $Pe \gg 1$. The corresponding mass transfer is discussed in detail with respect to the parameters δ and Pe .

The fluid velocity field is given by Equation 1, and the concentration boundary conditions are $C = 0$ on the alveolar wall and $C = 1$ in the alveolar interior.

$$u_r = \frac{R^2 \dot{R}}{r^2} \quad (1)$$

The transport equation governing this model can be transformed into a Lagrangian reference frame with the local coordinate σ , as shown.

$$\frac{\partial C}{\partial \tau} = \frac{1}{Pe} \frac{\partial}{\partial \sigma} \left[(3\sigma + R^3)^{4/3} \frac{\partial C}{\partial \sigma} \right] \quad (2)$$

Assuming $Pe = \omega R_0^2/D \gg 1$, Equation 2 can be solved using the method of matched asymptotic expansions to obtain an inner and outer solution.

RESULTS AND DISCUSSION

An example of the solution for oxygen concentration at full expiration and full inspiration are shown below. Transport is enhanced at end inspiration because the concentration boundary layer is thin, yielding steep gradients for outward diffusion. Therefore, one way to enhance gas transport during total liquid ventilation may be to include an inspiratory pause in the ventilator duty cycle.

A REALISTIC MECHANICAL MODEL OF THE HUMAN CHEST WALL

Anat Ratnovsky, Uri Zaretsky and David Elad

Department of Biomedical Engineering, Faculty of Engineering, Tel-Aviv University, Tel-Aviv 69978, Israel
anatrat@post.tau.ac.il

INTRODUCTION

The respiratory muscles constitute the respiratory pump which determines the efficacy of ventilation. Any functional disorder in their performance may cause insufficient ventilation. The human chest wall is a complex structure and the contribution of its different components to efficient respiration has been the subject of many simplified models. However, the existing models did not evaluate the performance of individual groups of respiratory muscles and did not calculate the forces generated by them. Furthermore, most of the models used mechanical analogs which could not differentiate between the rib cage and the accessory muscles, and thus, precluded any evaluation of their contribution to respiration in lung disease. In this study we developed a two-dimensional (2D) realistic model of the human chest wall in order to explore the relative contribution of major groups of respiratory muscles in healthy subjects.

THE CHEST MODEL

A 2D mechanical model is proposed for simulations of the mechanical performance of the complex chest wall in the sagittal plan. The model is composed of the major stationary and mobile elements of the chest wall. The stationary elements include the bones of the vertebral column, skull, iliac crest and pelvis. The rib cage forms the mobile part of the model and is composed of ten ribs. Each rib is connected by hinge joints to the vertebral column and sternum at its posterior and anterior ends, respectively (Fig. 1). The respiratory muscles act as actuators of the mobile rib cage.

Figure 1: Rib cage anatomy (left) and the 2D model (right). The black lines represent bones, the green line represents the lung, the red lines represent muscles whose forces were derived from Hill model, and the blue lines represent the muscles whose forces will be derived from this model.

The following major groups of the respiratory muscles are incorporated in the model: diaphragm (costal and crural),

external and internal intercostals, scalene, sternomastoid, rectus abdominis, external and internal oblique, and the transverse abdominis muscles. The lungs opening is inserted in the skull and its caudal end is attached to the diaphragm. Parameters of the model geometry such as the ribs angle at different lung volumes, ribs length and muscles length and position were derived from the literature as well as from radiological fluoroscopy and observation of cadavers in the school of medicine.

RESULTS AND DISCUSSION

The model can be utilized to simulate quasi-static breathing of different respiratory efforts. The governing equations of the model include the force balance equations for the rib cage and the central tendon of the diaphragm, and the work done by the muscles ($\int F dx$) compared with the work of the respiratory system ($\int P dV$). The number of unknowns is larger than the number of governing equations, thus, we incorporated in the set of input parameters all the variables that can be measured in vivo from the lungs and respiratory muscles (Ratnovsky *et al.*, 1999; 2001). These inputs include the following variables, which were simultaneously measured from healthy subjects while performing different breathing maneuvers: mouth pressure, airflow rate (lung volume) and the forces generated by the sternomastoid, external intercostal, rectus abdominis and external oblique muscles. Muscle forces were computed by a Hill-type muscle model from measurements of EMG signals and geometry parameters of the respiratory muscles (Ratnovsky *et al.*, 2001). As a result, the present model for the chest wall can be used to derive the forces generated by the scalene, internal intercostal, internal oblique, diaphragm (costal and crural) and the transverse abdominis muscles at different breathing maneuvers. This new realistic model of the human chest wall may be utilized along with in vivo measurements of breathing variables and EMG signals from easily accessed respiratory muscles in practical procedures for analysis of the relative contribution of major groups of respiratory muscles to lung performance during different maneuver. Then, it may be employed for either clinical diagnosis of the respiratory muscles, as well as monitoring of disease progression or follow up after surgical intervention.

EFFECTS OF BOUNDARY CONDITIONS ON PARTICLE DEPOSITION PREDICTIONS IN HUMAN NASAL PASSAGES

Rebecca A. Segal and Julia S. Kimbell

CIIT Centers for Health Research, Research Triangle Park, NC, USA, www.ciit.org, kimbell@ciit.org

INTRODUCTION

Research in the computation of airflow patterns and particle deposition in human nasal passages is being used to provide information about specific nasal deposition sites and nasal filtering capabilities for lung protection. The goals of these research efforts are both toxicologic and therapeutic in nature. Information on nasal deposition and filtering can lead to knowledge regarding potential toxic effects of exposure to inhaled materials. The same information can also lead to the development of better nasal drug delivery methods.

In previous research, a three-dimensional nasal airway model was reconstructed from digitized MRI data for a healthy human. Steady-state nasal airflow patterns were simulated using the commercial finite element code FIDAP (Fluent, Inc., Lebanon, NH) to solve the computational fluid dynamics flow equations. Simulations were conducted at 7.5 L/min assuming a uniform flow profile at the nostrils and were confirmed by comparison with hot film anemometry data (Subramaniam et al., 1998; Hahn et al., 1993). The flow results were then used as input for an in-house particle deposition computer program (Asgharian and Anjivel, 1994). Predictions of deposition efficiency generally agreed with experimental measurements made by Heyder and Rudolf (1977); however, the simulations overestimated deposition for smaller particles ($< 2 \mu\text{m}$ in mass median aerodynamic diameter (MMAD)). One hypothesis for this discrepancy is that the uniform flow profile imposed at the nostrils artificially enhanced deposition due to impaction.

METHODS

To test this hypothesis, additional airflow simulations were conducted at 7.5 L/min in which a fixed pressure was imposed at the outlet of the model to achieve a realistic pressure drop across the nasal passages. Due to the complexity of the problem, only solutions for the first-order Navier-Stokes problem have converged to date. Nasal particle deposition efficiencies were calculated using simulated airflow velocities from the first-order solutions.

RESULTS AND DISCUSSION

Simulated airflow at the nostrils when flow was pressure-driven showed a nonuniform profile in contrast to the uniform flow field previously imposed (Fig. 1). Deposition efficiencies computed using pressure-driven flow were closer to experimental values than deposition efficiencies calculated using flow computed under uniform profile conditions for particles between 0.5 and $2 \mu\text{m}$ (MMAD) (Table 1). These results suggest that particle deposition in the nasal passages is

probably sensitive to initial particle velocity for particles less than $2 \mu\text{m}$ in MMAD. The accuracy of airflow simulations at the nostrils may have a significant impact on the accuracy of nasal deposition efficiency predictions.

Figure 1: Velocity vectors at the nostril surface. (Left) Plug flow at the nostril surface. (Right) Velocity vectors at the nostril for the first-order solution to flow with pressure boundary conditions. Note the nonuniformity of the velocity field in the pressure-driven flow indicated by the color change.

Table 1: Deposition efficiency values for flow simulations. Note that the pressure-driven results are computed from a first-order solution

MMAD(μm)	Plug Flow	Pressure-Driven	Experiment
0.5	0.254419	0.130702	0.020
1.0	0.256924	0.124073	0.023
2.0	0.284501	0.123687	0.093

CONCLUSION

More realistic boundary conditions describing flow in the human nasal passages leads to more accurate modeling of particle deposition and hence to better models of nasal toxicity and drug delivery.

GRAVITY EFFECTS ON LIQUID PLUG TRANSPORT AND DISTRIBUTIONS IN AIRWAY MODELS

Vinod Suresh and James B. Grothberg

Department of Biomedical Engineering,
University of Michigan, Ann Arbor, MI 48109-2125, USA.
E-Mail: grothberg@umich.edu

INTRODUCTION

Surfactant replacement therapy (SRT), which is commonly used to treat pulmonary surfactant deficiency in infants, and liquid ventilation both involve the instillation of a liquid bolus into the trachea. When the bolus forms an air-blown plug, optimal delivery of the surfactant or perfluorocarbon to various regions of the lung can depend on uniform dispersion through bifurcating airways. In this work we determine the effect of gravitational and surface tension forces on plug shape, which in turn affects the mass split ratio of the plug at successive bifurcations.

METHODS

Figure 1: Schematic of a liquid plug in a bifurcating airway.

A simplified theoretical model is used, involving the pressure and gravity driven quasi-steady motion of a liquid plug of density ρ through a liquid-lined, rigid cylindrical tube. A schematic of the plug in a bifurcating airway is shown in Figure 1. The relative orientation of the parent airway to gravity is given by the angle θ . Close to the body of the plug, a static balance between pressure and surface tension forces determines the shapes of the front and rear interfaces. As seen in Figure 1, the interface shapes are not symmetric about the centerline of the airway due to gravitational effects. These effects are quantified by defining a volume ratio, $\lambda = V_U / V_L$, as the ratio of the plug volume above the centerline to that below the centerline.

RESULTS

Figure 2 plots the volume ratio, λ , as a function of the Bond number ($Bo = \rho g a^2 / \sigma$), which is a measure of the ratio of gravitational force to surface tension, σ , force. These results correspond to an angle $\theta = 0^\circ$. Volume ratios are determined for various orientations of the airway with respect to gravity. The range of Bond numbers considered are typical for SRT in infants (Cassidy *et. al.*). The ratio shows a strong dependence on the Bond number and differs significantly from unity, indicating a highly non-uniform fluid distribution in the plug. The volume ratio in turn affects the quantity of surfactant delivered to each airway at a bifurcation.

Figure 2: Ratio of plug volumes above and below the centerline of the airway for various Bo , $\theta = 0^\circ$.

THREE-DIMENSIONAL AIRWAY CLOSURE: SURFACE-TENSION-DRIVEN NON-AXISYMMETRIC INSTABILITIES OF LIQUID-LINED ELASTIC TUBES

Joseph P. White¹ and Matthias Heil²

Department of Mathematics, University of Manchester, UK

¹jwhite@maths.man.ac.uk; <http://www.ma.man.ac.uk/~jwhite>

²M.Heil@maths.man.ac.uk; <http://www.ma.man.ac.uk/~mheil>

INTRODUCTION

The airways of the lung are thin-walled elastic vessels which are lined with a thin liquid film. This liquid film can undergo a surface-tension-driven fluid-elastic instability which may lead to airway closure via the formation of an occluding liquid bridge. Halpern & Grotberg (1992) studied this problem in an axisymmetric geometry and determined the volume of liquid required to occlude the airways. For physiologically realistic parameter values, the pressure drop across the air-liquid interface can be large enough to cause non-axisymmetric buckling of the airway. Heil (1999) showed that in non-axisymmetrically buckled airways, occluding liquid bridges can be formed with a fraction of the fluid volume required to occlude a corresponding axisymmetric airway. However, the existence of such non-axisymmetric occluding liquid bridges of small volume does not guarantee that they can be realised in the course of the system's evolution from the initially uniform axisymmetric state. We aim to determine if liquid-lined elastic airways that do not contain enough fluid to form an axisymmetric occluding liquid bridge can undergo a non-axisymmetric instability that leads to airway closure.

THE COMPUTATIONAL MODEL

Figure 2 illustrates the model problem. A thin-walled elastic tube is initially lined with a viscous liquid of uniform thickness. Following Heil & White (2002) we model the liquid using an exactly volume-conserving lubrication theory. The airway wall is modelled using geometrically nonlinear Kirchhoff-Love shell theory. The governing equations are solved by a fully coupled finite element method.

RESULTS

The uniform liquid layer is unstable to the Rayleigh instability which leads to the formation of axisymmetric lobes as shown in Fig. 1. The curvature of the air-liquid interface is larger where the lobes are thickest and this increases the compression of the airway wall. If the compression exceeds a critical value then the airway buckles non-axisymmetrically. This increases the liquid surface curvature and thus the tube's compression even further. We show that this feedback mechanism can lead to occlusion of the airway and demonstrate that airway closure is possible at relatively small liquid volumes.

Figure 1: Sketch of axisymmetric airway closure. Axisymmetric occlusion depends upon the liquid volume.

Figure 2: Airway wall and air-liquid surface. A section of the tube wall is not shown.

MODULATION OF CYTOCHROME P450 (CYP) 1A1 and 1B1 and CTGF EXPRESSION BY SHEAR STRESS

S. G. Eskin, N. A. Turner, L. V. McIntire,

Department of Bioengineering, Rice University, Houston, TX , USA

INTRODUCTION

Traditionally, we have chosen genes in endothelial cells to study based on our presupposition of their significance in vascular disease processes. Using DNA microarrays provided changes in unanticipated genes, which might be crucial to cell function and help us to unravel the signalling pathways involved in understanding the effects of shear stress on gene regulation in endothelial cells. For example, the most strongly up-regulated genes, cytochrome P450 CYP 1A1 and 1B1, have only been reported differentially expressed in HUVEC using DNA microarrays. [1]The cytochrome P450 gene families have classically been associated with cellular detoxification mechanisms. Cytochrome P450 1A1 (CYP 1A1) has been postulated to participate in endogenous signaling of oxidative processes. [2] Loss of CYP 1A1 in cultured endothelial cells has been correlated with dedifferentiation. [3] A comparison of senescent fibroblast, epithelial, and HUVEC cell lines reveal that CYP1B1 was up-regulated in HUVEC alone among senescent cell lines.

Connective tissue growth factor (CTGF) was initially purified from HUVEC-conditioned medium, and is elevated in fibrotic lesions, thus may play a role in the development of fibrotic diseases. It is highly expressed in vascular cells of atherosclerotic lesions, but not in normal arteries. CTGF has been found to be down-regulated in shear stressed HUVEC by microarrays. [1]

METHODOLOGY

Third passage HUVEC, seeded on glutaraldehyde cross-linked gelatin coated glass slides, were subjected to 25 dynes/cm² for 24 h in a parallel plate flow chamber in complete medium (M199, 20% fetal calf serum, and antibiotics). Matched control cells were maintained in static conditions. For the β -naphthoflavone treatment, P3 HUVEC were seeded as for shear stress experiments, then maintained in stationary culture in complete medium containing 6 μ g/ml β -naphthoflavone and 1 μ l/ml DMSO, or complete medium with 1 μ l/ml DMSO alone for 72 hours.

RESULTS

Gene expression levels of CYP 1A1, CYP 1B1, CTGF, and ET-1 in P3 HUVEC exposed to shear stress (25 dynes/cm², 24 hrs.). Values are normalized to GAPDH values, then ratios of values for shear stressed to matched static cultured cells are calculated, then the 3 ratios are averaged. Note that the fold changes for CTGF and ET-1 are less than 1, thus these genes are down-regulated. Values are mean \pm S.E.M. n = 3.

Gene	Primary HUVEC	P3 HUVEC
CYP 1A1	12.6 \pm 3.9	10.8 \pm 2.1;
CYP 1B1	15.3 \pm 6.0	23.1 \pm 3.7;
CTGF	0.14 \pm 0.04	0.8 \pm 0.08;
ET-1	0.17 \pm 0.0	0.7 \pm 0.05;

Below are gene expression fold differences in P3 HUVEC incubated with 6 μ g/ml β -naphthoflavone in DMSO relative to DMSO alone for 72 hours (β -NF); and in P3 HUVEC incubated under static conditions in conditioned medium from 24 hr. shear stressed cells. Results were compared to untreated cultures and expression levels were normalized to GAPDH. Values are mean \pm se, n= 3.

Gene	β -NF	Shear Stress Conditioned Medium with cells
CYP 1A1	18.3 \pm 4.2;	5.8 \pm 1.4;
CYP 1B1	4.1 \pm 0.3;	5.8 \pm 0.9;
CTGF	0.8 \pm 0.05;	1.3 \pm 0.1;

DISCUSSION and CONCLUSIONS

The genes that shear stress strongly up-regulated and down-regulated in P3 were consistent with the results obtained in primary HUVEC, although CTGF and ET-1 were less dramatically down-regulated in the passaged cells.

Because the CYP genes were increased so much, and the increases were unexpected, we exposed static cells to β -naphthoflavone. CYP 1A1 was increased 18-fold in response to β -naphthoflavone, compared to an 11-fold increase induced by shear stress. CYP 1B1 was more strongly upregulated by shear stress (15-fold) than by β -naphthoflavone (4-fold), consistent with β -naphthoflavone's selectivity for CYP 1A1.

To assess the presence of CYP 1A1 inducers in the circulating medium, we asked whether conditioned medium from shear stressed cells could induce CYP genes in static HUVEC. CYP 1A1 and 1B1 both showed a 5 fold increase in static cells exposed to conditioned medium from shear stressed cells, whereas CTGF was unchanged.

SHEAR STRESS-INDUCED STRAIN FOCUSING IN THE ENDOTHELIAL CYTOSKELETON

Brian P. Helmke (helmke@virginia.edu)¹, Amy B. Rosen², and Peter F. Davies²

¹Department of Biomedical Engineering, Cardiovascular Research Center, University of Virginia, Charlottesville, Virginia, USA

²Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, USA

INTRODUCTION

The endothelium at the blood-tissue interface plays a critical role in the regulation of both physiological and pathological responses to changes in blood flow. A large number of cellular adaptations in gene and protein expression (Chien et al., 1998; Gimbrone et al., 1997), cell shape and orientation (Levesque and Nerem, 1985), and intracellular structure (Dewey et al., 1981) correlate spatially to both the predicted blood flow force profile along the arterial tree and locations of atherosclerotic lesion development (Ross, 1995). Endothelial cells (ECs) sense the local hemodynamic force profile to generate biochemical signals at multiple intracellular locations (Davies, 1995; Helmke and Davies, in press), but mechanisms that modulate spatial integration of force transmission and signal transduction within the cell remain unclear.

METHODS

ECs expressing green fluorescent protein (GFP) fused to either vimentin or actin were grown to confluence and assembled into a parallel plate flow chamber maintained at 37 °C (FCS2, Biopetech). High-resolution fluorescence optical sections were acquired every 90 s for 15 min (DeltaVision, Applied Precision). A step increase in unidirectional laminar flow was imposed so that wall shear stress was 12 dyn/cm², and image acquisition continued at the same rate for an additional 30 min. Out of focus light intensity was repositioned using a 3-D constrained iterative deconvolution algorithm (softWoRx, Applied Precision). Deconvolved fluorescence optical sections were exported to Matlab for analysis.

The magnitude of GFP-vimentin and GFP-actin displacement during the interval from t_i to t_j in spatial subregions of the cell was measured in 3-D using a displacement index (Helmke et al., 2001) defined as

$$DI(t_i, t_j) = 1 - \frac{\text{Cov}[I(x, y, z, t_i), I(x, y, z, t_j)]}{\sqrt{\text{Var}[I(x, y, z, t_i)] \cdot \text{Var}[I(x, y, z, t_j)]}}$$

where the covariance and variance are computed between pairs of 3-D images I .

In order to compute the spatial distribution of cytoskeletal deformation (Helmke, in press), GFP-vimentin optical sections were skeletonized, and vertices connecting adjacent filament segments were tracked in time. The Lagrangian strain tensor E_{ij} was computed from relative displacements among triads of adjacent vertices, and principal values and axes were mapped as a function of time and intracellular location.

RESULTS AND DISCUSSION

Small magnitude random direction displacements of cytoskeletal elements were measured at steady state. Onset of shear stress induced significant displacement of GFP-

vimentin-labeled filaments within 3 min that was often most pronounced in apical and downstream regions of the cytoplasm. Bending and shortening of GFP-actin filaments was observed near cell edges after onset of shear stress. In addition, increased displacement of GFP-actin was observed that was consistent with lamellipod extension near the edge of the cell in the upstream direction. Thus, shear stress acting at the apical cell surface induces displacement of cytoskeletal filaments that may modulate rapid shape changes.

Spatial maps of cytoskeletal strain magnitude as a function of time revealed localized peak concentrations at discrete sites throughout the cytoplasm, including near the coverslip. Strain focusing was only detectable in these high-resolution maps and not in spatial averages over larger cytoplasmic regions. Onset of shear stress caused an increase in angular dispersion of strain direction, often eliminating a whole-cell preferred orientation that existed before flow onset. In local regions near cell edges, however, preferred strain direction was rotated from parallel to perpendicular to the cell edge, implying that shear stress directly alters mechanical interactions among adjacent cells.

SUMMARY

Onset of shear stress induces rapid displacement and deformation of both vimentin and actin cytoskeletal components. Increased edge motility and shape changes indicate altered actin dynamics. Cytoskeletal network strain focusing at discrete intracellular locations associated with molecular signaling complexes may play a crucial role in initiation of cellular mechanotransduction.

CONTROL MECHANISMS OF THE FLUID SHEAR RESPONSE IN CIRCULATING LEUKOCYTES

Shunichi Fukuda, Peter Marschel, Geert W. Schmid-Schönbein

Department of Bioengineering, University of California San Diego, La Jolla, CA 92093-0412
gwss@bioeng.ucsd.edu

INTRODUCTION

The majority of leukocytes in the circulation are in a spherical state. This is a requirement for free passage of these cells through capillaries. After activation, for example in the presence of pseudopods, the cells become trapped in the microcirculation

While numerous biochemical mediators serve to either down- or upregulate leukocytes, we have identified fluid shear stress to play a central role in this process [1]. Our investigation is designed to identify the mechanisms and consequences of the fluid shear response in leukocytes.

METHODS OF APPROACH

We exposed freshly isolated leukocytes (1g sedimentation) to steady fluid shear at low Reynolds number under controlled flow conditions. Isolation of leukocytes by centrifugation was avoided, since exposure of the cells to accelerations of 300 g or above, even for only a few minutes, serves to suppress or reverse the fluid shear response [1]. We observed under high-resolution light microscopy the cell shape and active pseudopod formation while applying a controlled fluid flow from an adjacent micropipette. The order of magnitude of the fluid shear stress over the surface of the cell (about 1 dyn/cm²) was determined by numerical solution of the Stokes approximation for a Newtonian fluid (buffer) around the cell [2]. As an alternative approach, suspensions of leukocytes were exposed to controlled fluid shear stress (5 dyn/cm²) in a cone-and-plate shear device in whole blood without any isolation. The cells were kept in heparin as anticoagulant. The distribution of the membrane adhesion molecule CD18 was investigated by labelling with a fluorescently conjugated monoclonal antibody and observation under confocal microscopy or with flow cytometry.

RESULTS AND DISCUSSION

Application of fluid shear over the surface of activated and migrating leukocytes (mostly neutrophils and monocytes) leads to retraction of pseudopods. The expression of CD18 integrin on the membrane is reduced at locations with elevated fluid shear, by a process that in part may involve proteolytic enzymes. After stimulation of the cells with inflammatory mediators (platelet activating factor or the tripeptide f-met-leu-phe) the number of leukocytes that respond by retraction of pseudopod is reduced in a concentration dependent fashion. This reduction in the response to fluid shear is accompanied by spreading of the cells and can be simulated by depletion of cGMP in the cell cytoplasm [3]. In contrast, elevation of the cGMP level with cGMP analogous or with nitric oxide donors leads to restoration of the fluid shear response. The ability of

cGMP to enhance the fluid shear response is not associated with CD18 expression, because cGMP has no effect on CD 18 expression under shear. The fluid shear response is also sensitive with respect to the particular membrane integrin. Adhesion of leukocytes via β_2 integrins serves to preserve the shear response, while in contrast adhesion via β_1 integrins inhibits the fluid shear response [4]. This evidence suggests that inflammatory mediators have the ability to suppress the fluid shear response while cGMP may serve to maintain the response even in inflammation. The migration of lymphocytes across endothelium is enhanced by fluid shear even in the absence of chemotactic gradients [5].

SUMMARY

Important biomechanical properties of leukocytes in the circulation are controlled by fluid shear. There exists an interaction between fluid shear and traditional inflammatory mediators or cytokines that serve to activate the cells. These observations are of importance in regards to immune functions of leukocytes, microvascular entrapment of leukocytes and organ function in many diseases, atherosclerotic lesion formation, and tissue repair mechanisms.

DIFFERENTIAL MODULATION OF FOCAL ADHESION DYNAMICS BY SHEAR STRESS AND SERUM DURING ENDOTHELIAL CELL MIGRATION

Song Li¹ and Shu Chien²

¹Department of Bioengineering, UC Berkeley, Berkeley, CA 94720-1762, songli@socrates.berkeley.edu

²Department of Bioengineering and The Whitaker Institute of Biomedical Engineering, UC San Diego, La Jolla CA 92093-0427

INTRODUCTION

The migration of vascular endothelial cells (ECs) plays an important role in angiogenesis and wound healing. The focal adhesions (FAs) and cytoskeleton respond to diverse extracellular signals and regulate cell migration. At FAs, focal adhesion kinase (FAK), via its phosphorylation at tyrosine 397 [p-FAK(Y397)], mediates the FA dynamics and signaling in response to growth factors and integrin-ligand binding. ECs are constantly subjected to fluid shear stress due to blood flow, but the effect of shear stress on the molecular dynamics of FAs during EC migration remains to be determined.

METHODS

Bovine aortic ECs (BAECs) were seeded on fibronectin (1 $\mu\text{g}/\text{cm}^2$)-coated slides in DMEM containing 0.5% serum for 3 hr at ~10% confluence; they were subjected to fluid shear stress, stimulated with 10% serum in DMEM, or kept as static control. To apply fluid shear stress, the slide with BAECs was mounted in a rectangular flow channel created by sandwiching a silicone gasket (0.015-cm thick) between the slide and an acrylic plate. Laminar shear stress was generated by the flow resulting from hydrostatic pressure difference between two reservoirs. The shear stress applied was 12 dyn/cm^2 , a level found in arteries and capillaries.

Cell migration was monitored by time-lapse phase contrast microscopy, and the dynamic motion of individual cells was analyzed by using Dynamic Image Analysis System software. DNA plasmids encoding green fluorescence protein (GFP)-FAK were transfected into ECs by using GenePorter reagent. The dynamics of GFP proteins were monitored by time-lapse confocal microscopy. To detect FAK activation at FAs, BAECs were fixed and stained with a monoclonal anti-p-FAK(Y397) antibody.

RESULTS AND DISCUSSION

Under static condition, ECs showed random migration without any preferential direction. Serum did not significantly affect EC migration. The application of shear stress for 1 hr caused >90% of cells to migrate in the flow direction with a 30% increase ($p<0.05$) of speed. We use “mechanotaxis” to describe the directional migration of cells induced by mechanical forces, analogous to chemotaxis and haptotaxis.

Time-lapse confocal microscopy showed that serum induced lamellipodia and new FAs in many directions, and caused a sustained increase in total FA area. In contrast, shear stress induced lamellipodia and new FAs preferentially in the flow direction (Fig. 1). Then the pre-existing FAs merged, moved,

disappeared and/or segregated from the cells. The total number of FAs decreased by 60% ($p<0.05$), suggesting that shear stress induces FA disassembly. Under continuous shearing, ECs migrated persistently in the flow direction with new FAs forming at the leading edge, and these FAs either turned over quickly or remained stationary until the cell body glides over.

Dynamics of FAK stimulated by serum and shear stress

Figure 1: Dynamics of FAK in ECs stimulated by serum or shear stress. Time-lapse confocal microscopy images taken at three time periods at 15-min intervals are pseudocolored sequentially as red, blue and green. The formation of new focal adhesions (green) is random with serum stimulation, but polarized to the right under flow.

Shear stress induced p-FAK(Y397) phosphorylation under the lamellipodia in the flow direction. Serum induced p-FAK(Y397) in many directions, and the total p-FAK(Y397) level was higher ($p<0.05$) than that induced by shear stress. These results suggest that the polarized change of p-FAK(Y397) at the cell periphery, rather than the total level of p-FAK(Y397), is necessary for effective directional migration.

SUMMARY

We showed that fluid shear stress enhanced EC migration in flow direction (mechanotaxis). We demonstrated the differential regulation of FA dynamics by shear stress (polarized) and serum (random). Our findings indicate that the spatial dynamics of signaling at FAs is critical in directional migration, and that mechanotaxis is an important mechanism controlling EC migration in addition to chemotaxis and haptotaxis.

HYDRODYNAMIC SHEAR AND TETHERING ON E-SELECTIN SIGNALS ADHESION OF HUMAN NEUTROPHILS

Scott Simon¹, Daniel McDonough¹, Fiona McIntosh², Harry Goldsmith²:

¹Department of Biomedical Engineering, UC Davis, Davis, CA, ²Montreal General Hospital, Montreal, Quebec, Canada.

INTRODUCTION Neutrophil recruitment to sites of inflammation from the blood stream is a multistep process involving tethering via selectins and firm adhesion through activation of integrins. At least two critical steps are identified; the first an efficiency of neutrophil capture by tethering via selectins, and next, an efficiency of subsequent transition to firm adhesion through activation and binding of β_2 -integrins. Recently we have reported that tethering and rolling of neutrophils in shear flow over a substrate of E-selectin signals activation of β_2 -integrins and firm adhesion (Simon et al., 2000). Here we study heterotypic and homotypic aggregation in suspension between neutrophils and murine pre B-cells expressing E-selectin (300.19-E) or L-selectin (300.19-L) using cone-plate viscometry to apply a defined shear environment and fluorescence flow cytometry to quantitate aggregation over the time course of shear and activation. The objective of these studies was to examine the molecular mechanisms and shear dependence underlying the transition from tethering to firm adhesion during collisional interactions between neutrophils and 300.19 target cells. Adhesion efficiency was determined by applying two-body collision theory to predict the time course of heterotypic aggregation. Two-body collision doublet lifetime and capture efficiency was also directly observed in shear using in-line a transparent cone plate rheometer and videomicroscopy.

METHODS Human neutrophils (PMN) were isolated from fresh blood and stored in Ca^{++} free buffer prior to the experiment. 300.19 cells, an immortalized murine pre-B-cell line transfected to express either E-selectin or L-selectin expressed similar receptor levels. We used cone plate viscometry to apply a defined shear rate to cell suspensions of neutrophils and either 300.19-E or 300.19-L. Selectin mediated tethering and neutrophil firm adhesion to 300.19-selectin targets were quantified using videomicroscopy and flow cytometry respectively.

Neutrophil-300.19 activation and firm adhesion in a sheared cell suspension was quantitated using two-color flow cytometric analysis of fixed samples over the time course of activation and shear. Cell suspensions were stimulated with low doses ($\sim 2.5\text{nM}$) of formyl peptide, and sheared at $G=600\text{ s}^{-1}$. Using a model of aggregation based on two body collision theory the efficiency of aggregation was extracted from the kinetic data. Collision frequency is computed based on the experimental parameters of cell radius, concentration and the applied shear rate. The efficiency is then defined as the aggregation rate normalized by the total number of collisions per unit time.

High speed video of (250-500 fps) PMN-300.19 collisional interactions were obtained using a transparent counter-rotating cone and plate rheoscope mounted on an inverted microscope (Goldsmith et al., 2001). Heterotypic doublets were observed in the sheared suspension and collisional duration was measured. Doublets rotating past the orientation of predicted break-up for inert spheres ($\Phi = 90^\circ$) were considered to be tethered.

RESULTS AND DISCUSSION Flow cytometric analysis of two color aggregation at shear rate $G=600\text{ s}^{-1}$ stimulated with 2.5nM FMLP elicited formation of both heterotypic and homotypic aggregates. 300.19-E proved to be more efficient targets than 300.19-L under identical experimental conditions as shown by the fraction of neutrophils recruited (20% for 300.19-E vs. 5% for 300.19-L) The efficiency of firm adhesion for capture of 300.19E was 4.5% , as compared to 1% for 300.19-L.

Varying the 300.19 cell concentration in suspension revealed a striking difference in the adhesion efficiency for E-selectin versus L-selectin. While the efficiency of PMN-300.19L aggregation remained constant at a value of $\sim 1\%$ over a range of 300.19 concentrations from 0.3:1 up to 5:1 300.19:PMN, the efficiency of PMN-300.19E aggregation decreased three-fold from 4.6% to 1.6%. It was hypothesized that this drop in adhesion efficiency is due to the longer collisional lifetime of PMN-300.19E doublets. This limits the number of available singlets in the cell suspension as compared to the theoretical model, which is based on elastic collisions between inert spheres. The resulting aggregation kinetics were fit with an apparent efficiency of adhesion that decreased four-fold over a ratio of 300.19:PMN was increased from 0.3:1 up to 5:1 300.19:PMN.

Rheometric observations of collisional interactions confirmed a high efficiency of doublet formation for 300.19E $\epsilon_{\text{hetero}} = 28\%$. The mean lifetime of homotypic doublets was equivalent to that predicted for inert spheres ($\tau_{\text{exp}} = \tau_{\text{theor}}$), whereas for heterotypic doublets $\tau_{\text{exp}} = 5 \times \tau_{\text{theor}}$. Shear stress was increased from 1.1 dyn/cm^2 up to 6.4 dyn/cm^2 at a shear rate of 100 s^{-1} by addition of Ficoll to the suspending media. The lifetime of colliding doublets increased four-fold, along with the efficiency of stable adhesion. These data confirmed by direct observation that shear stress promotes stable adhesion initiated through E-selectin.

The longer lifetime of adhesion via E-selectin also correlated with a greater stability of PMN-300.19E aggregates. To test whether this resistance to disaggregation was due to an increased engagement of activated β_2 -integrins, we assessed active β_2 -integrin expression on neutrophils in heterotypic suspensions. Using mAb 327C, which reports on the active conformation of β_2 -integrin, we found expression to be up to three-fold greater on PMN-300.19E than on aggregates with 300.19L or on homotypic aggregates.

SUMMARY Neutrophil capture of E-selectin expressing target cells (300.19E) exhibited a greater efficiency of adhesion that correlated with a longer adhesive lifetime as compared to L-selectin expressing targets (300.19L). A distinct dependence of integrin activation on the magnitude of shear rate suggests a coupling between fluid mechanical effects of shear and signaling of adhesion.

FLOW REGULATION OF GAP JUNCTIONAL COMMUNICATION AND THE FUNCTIONAL COMPARTMENTALIZATION OF VASCULAR ENDOTHELIUM

Natacha DePaola¹, Lucio Florez¹, Eno Essien¹, Denise Polacek², and Sanghee Kim¹

¹Biomedical Engineering Department, Rensselaer Polytechnic Institute, Troy, New York, USA

²Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, PA, USA

INTRODUCTION

The localization of atherosclerotic lesions coincides with regions of disturbed blood flows where endothelial cells of altered phenotype are adjacent to normal endothelium. *Functional Compartmentalization* of the endothelium refers to the occurrence of neighboring regions with distinctively different cell function.

The endothelium is recognized as a mechanical signal-transduction interface between flowing blood and the vessel wall (Davies et al 1997). However, the cellular and molecular mechanisms by which hemodynamics might alter endothelial cell function leading to lesion development remain unclear. The decentralized model of endothelial mechanotransduction (Davies 1995) predicts that endothelial mechanosensors associated with the conversion of shear stress forces to signals are not restricted to the luminal surface but located at multiple sites throughout the cell, including cell junctions (Osawa et al 1997).

Gap junctions, the only communicating intercellular junctions, allow the direct transport of ions and second messenger molecules between adjacent cells. Connexin proteins forming endothelial gap junctions have been demonstrated to be regulated by shear stress *in vivo* (Polacek et al 1997, Gabriels and Paul 1998) and *in vitro* (Cowan et al 1998, DePaola et al 1999). We hypothesize that fluid shear stress associated with disturbed flows, induce regional changes in endothelial gap junctional communication (GJIC) which in turn, affect cell phenotype, contributing to Functional Compartmentalization of the endothelial monolayer *in vivo* and *in vitro*.

METHODS

Human aortic endothelial cells were exposed to controlled fluid forces in experimental flow chambers that recreate each type of shear stress gradients found at atherogenesis-prone sites. The various components of the stress gradients were studied at several magnitudes either in isolation or in combination. Regulation of the gap junctional proteins Cx43 and Cx40 in the various flow-defined regions was assessed by *in situ* immunolocalization. Regional GJIC was evaluated by single cell microinjections. Immunocytochemistry and image analysis were used to assess the occurrence of endothelial Functional Compartmentalization by regional evaluation of cell shape, proliferation and migration. A GFP-Cx43 construct was used to evaluate Cx43 protein redistribution in real time. GJIC inhibition studies were conducted to determine which of the evaluated cell functions are dependent on functional GJIC.

RESULTS AND DISCUSSION

Simultaneous immunostaining (double-labeling) of the gap junctional proteins Cx43 and Cx40 demonstrated different levels of baseline expression and flow regulation after 6 hours exposure to flow. Both Cx43 and Cx40 were disrupted at cell borders and partially relocated to the cytoplasm in areas of high shear stress gradients. The observed disruption of Cx40 protein at cell borders was more pronounced than that of Cx43. When at cell borders, Cx40 remained co-localized with Cx43. The disassembly of gap junctions by CX43 protein redistribution under flow was evaluated in real time with a GFP-Cx43 construct in transfected cells. The regional differences in connexin protein expression and organization were reflected in inhibition of intercellular communication (dye transfer). A significant decrease in the rate of cell motion was observed in regions of simultaneous high shear and high shear gradients when compared with the average motion rates observed in regions of simultaneous low shear and high shear gradients, where cell motion was not only significantly increased with exposure to flow but persisted for up to 36 hours after flow removal. Protein synthesis inhibition by monolayer pretreatment with cycloheximide resulted in inhibition of cell motion in response to flow. Areas of significant increase in cell motility coincided with areas exhibiting aberrantly localized connexin protein expression.

SUMMARY

The data suggest a prominent role for shear gradients in regulating endothelial cell communication and provide evidence that there are cell signaling processes initiated by flow which continue to alter cell function after cessation of the stimulus. Altered communication rate correlated with areas of altered cell function.

FLUID-STRUCTURE INTERACTION AND COLLAGEN REMODELING IN THE AORTIC HEART VALVE

Frank Baaijens, Ralf Boerboom, Carlijn Bouten, Niels Driessen, Debbie Gawlitta,
Jurgen de Hart, Gerrit Peters and Jacques Huyghe

Department of Biomedical Engineering, Eindhoven University of Technology, PO Box 513, 5600 MB Eindhoven, The Netherlands
e-mail: f.p.t.baaijens@tue.nl

INTRODUCTION

In vitro mechanical conditioning has been demonstrated to be of critical importance in the tissue engineering of heart valves¹. Therefore, after static culturing, cell seeded constructs are placed in a bioreactor and subjected to pulsatile flow conditions. The objective is to stimulate cell proliferation and differentiation as well as extra cellular matrix production. In particular for aortic heart valves, the leaflets have to carry substantial hemodynamic loads, both during the systolic and the diastolic phase. Since collagen fibers are known to provide a substantial part of the structural integrity of the heart valves, the production of sufficient amounts of appropriately aligned collagen fibers appears mandatory. The production and alignment of collagen fibers is known to be strain sensitive, which suggests that the strain distribution, i.e. deformation modes, inside the leaflets must be controlled carefully during *in vitro* conditioning. Furthermore, at implantation the heart valves may not necessarily have to be morphologically identical to the native heart valves, they, however, should be sufficiently functional.

METHODS

Numerical analysis, using the finite element method, of the motion of the leaflets induced by the blood flow^{3,4,5}, provides crucial information about the stresses and strains within the developing tissue as well as the shear stresses imposed on the leaflet surfaces. The numerical method is based on the so-called fictitious domain method³. Fluid-structure interaction between the leaflets and the fluid is achieved via the introduction of Lagrange multipliers on non-conforming meshes, while the dispensability of the aortic wall is accounted for via the Arbitrary Lagrange Euler (ALE) formulation.

Particular emphasis is given on the modeling of the collagen fiber reinforcement of the leaflets. For this purpose a structural approach is adopted that distinctively accounts for the contribution of the matrix and collagen fibers. The impact of fiber reinforcement and aortic wall flexibility on the hemodynamics of the valve is examined. Fiber reinforcement not only substantially reduces the stresses in the matrix, it also stabilizes the motion of the leaflets.

RESULTS AND DISCUSSION

Understanding the impact of mechanical loads as imposed on the tissue inside a bioreactor on the collagen fiber organization is one of the key challenges in the regeneration of the leaflet tissue. Motivated by the work of Peskin and McQueen⁶, it is assumed that remodeling of the collagen fiber network is strain modulated. A rate equation for the volume fraction of a particular fiber is formulated composed of a synthesis and degradation expression. An initially random, isotropic, fiber distribution is assumed that is allowed to remodel according to this rate equation. By imposing physiological loads on the leaflet, the collagen fibers remodel and show a structure that closely resembles the fiber structure of the natural leaflet. This is a first step towards understanding how the mechanical loading in a bioreactor should be modulated to obtain optimal mechanical tissue properties

vesely@bme.ri.ccf.org

INTRODUCTION

A tissue-engineered valve will need to incorporate the complex microstructure of the aortic valve if it is expected to offer durability comparable to that of conventional bioprosthetic valves. Native aortic valve cusps contain three layers of morphologically distinct tissue: fibrosa, spongiosa, and ventricularis. The fibrosa contains large, bifurcating collagen fiber bundles; the ventricularis consists of multiple sheets of elastin; and the spongiosa consists of collagen, elastin, and glycosaminoglycans (GAGs). Collagen fiber bundles are surrounded by tubular sheaths of elastin, which are linked together by elastin struts. Given the complexity of native aortic valve cusps, our approach to tissue engineering the aortic valve has been to fabricate cusps from the basic building blocks: (i) branching collagen fiber bundles; (ii) elastin sheets and tubes; and (iii) a highly hydrated GAG matrix.

METHODS

We have developed the following building blocks:

Collagen fiber bundles were fabricated using the principle of directed collagen gel shrinkage. Fibroblasts were mixed with acid-solubilized rat tail collagen and cast into silicon rubber wells with microporous holders to entrap the gel. Since the gel is constrained in the longitudinal direction, it contracts only laterally forming well-aligned collagen fiber bundles.

The viscoelastic matrix that integrates these components together has been fabricated from divinyl sulfone-crosslinked high molecular weight hyaluronan (hylan) [1], texturized by UV irradiation to enhance cell attachment.

Elastin sheets were grown atop the hylan gels and around the collagen fiber constructs by way of long-term cultures of neonatal rat aortic smooth muscle cells.

RESULTS AND DISCUSSION

Collagen gel contraction increased with higher cell seeding density, the optimal value being 1 million cells/ml. The optimal collagen concentration was 2 mg/ml, producing a failure strength as high as 2 MPa. Branched bundles were formed using appropriately shaped wells (Fig 1).

UV-irradiated gels had highly extended cells throughout their thickness. The confocal studies indicate that cells atop and within the gels actively proliferate. The hylan matrices had stiffness values as high as 40 kPa, and strain to failure in excess of 150%.

Figure 1: Examples of collagen gel shrinkage and a branched constructs (right)

Transmission electron microscopy showed the presence of a uniform elastic membrane at the surface of UV-exposed gels. We also found that an elastin sheath developed around the collagen core after 6 weeks of culture (Fig 2).

Figure 2: Examples of elastin sheath surrounding a collagen fiber bundle (left), and a flat sheet of elastin bound to the texturized hylan gel (right)

CONCLUSIONS

We have therefore fabricated the basic building blocks of the structure of the native aortic valve using tissue engineering principles. These are: (i) strong collagen fiber bundles that branch, (ii) sheets of elastin adherent to an underlying matrix, (iii) tubes of elastin that surround collagen fiber bundles, and (iv) a highly biocompatible, elastic matrix that can integrate all of these components. We are enhancing the mechanical properties of these components further through dynamic tissue culture. Entire leaflets can thus be fabricated from these constructs by growing each of individually, and assembling them together to make the composite tissue-engineering aortic valve cusp.

INTRODUCTION

Heart valve replacement surgeries account for over 70,000 surgeries in the U.S. alone each year. The majority of those replacement valves are either mechanical (mhv) or bioprosthetic (bhv) each of which present different complications post-surgery either bleeding (mhv), calcification (bhv), or thromboembolism (bhv and mhv). Furthermore, both mechanical and bioprosthetic valves are incomplete solutions for children who require replacement valves. Therefore, there is a great demand for living tissue-engineered valves that would be able to grow and respond to the *in vivo* environment.

To date, we have fabricated tissue-engineered heart valves using the tissue-equivalent approach of entrapping human fibroblasts within a forming collagenous network (producing a valve-equivalent, or VE). A solution of cells and collagen monomers is injected into an appropriate mold (patent pending) and gelled. Entrapped cells then begin to compact the network by exerting traction. Appropriate constraint of the compaction produces constructs with the collagen fibrils aligned in a prescribed direction (Barocas et.al.) mimicking the commissure-to-commissure alignment of native valve leaflets and circumferential alignment of the adjoining root.

While the current generation of tissue-engineered valves are geometrically correct and possess the correct collagen fiber alignment, they are significantly weaker due to the lack of extracellular matrix components and general organization of native heart valve leaflets (Vesely et.al.). Thus, we have pursued methods to induce cell-mediated remodeling of the original biopolymer scaffold such that the entrapped cells will replace it with a highly organized, mechanically competent, tissue-like matrix. To effect this change, we use biochemical cues (using fibrin as a scaffold protein combined with growth factors) and mechanical cues (i.e. leaflet bending) to produce tissue engineered valves, and we present the resultant biaxial mechanical, bending, and compositional data.

METHODS

A mold predominantly composed of 5% agarose gel (formed around mounting surfaces) to prevent fibrin adhesion is constructed using an appropriate negative mold. A solution of 3.3 mg/ml bovine fibrin (Sigma) and human foreskin fibroblasts at 1×10^6 cells/ml is injected into the mold, gelled, and incubated for up to 4 weeks in M199 (Gibco) supplemented with 1 ng/ml TGF- β (R&D Systems), 2 ug/ml

insulin (Sigma), 0.01 U/ml plasmin (Calbiochem), 10% FBS (HyClone) and 50 ug/ml ascorbic acid (Sigma). After incubation, the VE is carefully removed and characterized using uniaxial (MTS Systems), planar biaxial (Instron), and bending mechanical tests. Furthermore, VE leaflet sections are histologically characterized using a Masson's trichrome stain and elastin antibody staining.

RESULTS AND DISCUSSION

Preliminary testing of adherent fibrin hemispheres incubated with TGF- β , insulin, and plasmin show definite bands of cell-synthesized collagen and elastin aligned similarly to the compacted fibrin matrix (Figure 1). Furthermore mechanical testing of fibrin samples incubated with growth factors show improved mechanical properties relative to collagen samples and approaching those of cardiovascular tissues.

Figure 1: Left: Trichrome stain of fibrin construct showing cell-deposition of collagen (blue-green) along the top of the construct. Right: Confocal micrograph of a fibrin construct staining showing immunofluorescent staining for elastin.

SUMMARY

We have developed and characterized a fibrin-based tissue-engineered heart valve that is mechanically stronger than a collagen-based valve and more closely resembles the matrix composition and microstructure of the native valve.

THE ROLE OF DYNAMIC STRESSES DURING INCUBATION IN INCREASING TEHV TISSUE STRENGTH

Michael S. Sacks¹, Kristine Gulesarian², David Martin³, John E. Mayer, Jr.²

INTRODUCTION: The need for improved heart valve prostheses is especially critical in pediatric applications, where growth and remodeling are essential. Tissue engineered heart valves (TEHV) have functioned in the pulmonary circulation of growing lambs, and thus can potentially overcome limitations of current prosthetic heart valves. Despite these promising results, significant questions remain. In particular, the role of mechanical incubation conditions is largely unexplored. The following study was conducted provide fundamental information for optimizing TEHV biomaterials.

METHODS: Tri-leaflet valve constructs were fabricated from poly-4-hydroxybutyrate coated polyglycolic acid seeded with ovine endothelial and carotid artery medial cells and first cultured under static conditions for 4 days under static conditions. Next, the valves were either cultured for an additional 14 days under static conditions or under dynamic flow conditions, for a total in both cases of 18 days. A total of six groups were evaluated: 4 days static with and without cells, 18 days static with and without cells, and 18 dynamic with and without cells.

After incubation, valves were removed and shipped in chilled culture media to the Tissue Mechanics Lab for flexural mechanical testing. We utilized the flexure testing device as previously described (Gloeckner, Billiar et al. 1999). A 2 mm x 10 mm circumferentially-oriented specimen was prepared from each leaflet and placed in 100% normal saline, and 15 ~200 μ m diameter graphite markers were attached to one edge. Each specimen was bent in both directions, notated as the “against-curvature (AC)” and “with-curvature (WC)”, with respect to the TE leaflet’s shape. Video images of the specimen were acquired during the test from which the loads and marker displacements were determined. We then utilized the moment-curvature relation for beams undergoing large displacements to determine the effective bending stiffness,

$$E_{\text{eff}}: M = E_{\text{eff}} I \Delta \kappa \quad (1)$$

where $\Delta \kappa$ is the change in specimen curvature, I is the 2nd moment of inertia, M is the bending moment, and E_{eff} the effective tissue stiffness. From the marker positions $\Delta \kappa$ was computed using a spline fit. E_{eff} is determined over the entire bending path by plotting M/I vs. $\Delta \kappa$ so that the slope of the curve at each point is equivalent to E_{eff} . Due to the potential for transmural structural heterogeneity, it is understood that the value of E_{eff} represents the specimen's bending stiffness only for the AC and WC bending directions, respectively. Flexural data from a fresh ovine pulmonary valve are also presented.

RESULTS: The 4 day unseeded control specimens were ~25% stiffer than the seeded controls with no directional differences (Fig. 1). By 18 days under static conditions this trend was reversed, with the seeded specimens almost double in stiffness compared to the corresponding controls (Fig. 1). Interestingly, under dynamic conditions there was not only a greater drop in stiffness, but also a substantial directional

dependence, with the AC stiffness only ~1/2 that of the WC stiffness. Further, the dynamically condition tissues were more similar to the very compliant native pulmonary valve tissue (Fig. 1). When the seeded/unseeded specimen modulus ratios were examined, the dynamically conditioned tissue was ~3 times stiffer than the unseeded control, compared to only ~2 fold change for the statically incubated tissue (Fig. 2).

DISCUSSION: This study reported the effects of static and dynamic incubation conditions for a tissue engineered heart valve biomaterials. Under static culture conditions, we demonstrated that the presence of the deposited extracellular matrix and cellular material can increase the effective stiffness of the TE leaflet by ~two fold. Further, dynamic culture conditions can increase the TE leaflet stiffness by a factor of three compared to unseeded controls. Clearly, mechanical conditions during in-vitro incubation have a dramatic effect on tissue engineered construct’s mechanical properties.

Figure 1: Effective stiffness results for all 6 TEHV groups.

Figure 2 – Ratio of the effective stiffness between the seeded and unseeded controls, indicating that dynamic conditions can increase the effective stiffness by a factor of three.

INTRODUCTION

There is no adequate heart valve substitute for long term implantation for the majority of patients (Korossis 2000). For elderly patients bioprosthetic tissue valves with a life expectancy of 10-15 years provide a satisfactory solution. The heart valve substitute of choice for patients with a greater life expectancy is the mechanical heart valve. However, these valves require long-term anticoagulation therapy. For young adults and children there is a need to deliver a heart valve that will develop with the patient. Homograft valves have been used in this patient group, but they do not retain viability following transplantation. Tissue engineered heart valves coupled with recellularisation have the potential to grow with the patient. An approach is to use natural tissue matrices, either of xenograft or allograft nature. The major challenge in this approach is to develop effective decellularisation techniques to remove foreign cellular elements while retaining the biomechanical integrity of the valvular matrix. This study investigated the effect of sodium-dedocyl-sulfate (SDS), as a decellularisation treatment, on the biomechanical integrity and hydrodynamics of porcine aortic heart valves.

METHODS

Left coronary leaflets were dissected from fresh porcine aortic valves within 4 hours of slaughter. The leaflets were divided into 6 groups and treated according to the protocols listed in Table 1. Haematoxylin and eosin histological staining was performed to all the groups to assess the degree of decellularisation. Circumferential and radial specimens were cut from each of the 6 leaflet groups and tested under uniaxial tensile loading to failure. Whole porcine aortic roots were also treated with 0.1% (w/v) SDS in hypotonic buffer and their functionality was assessed by pressurising them to physiological pressures (120 mmHg) and by subjecting them to simulated pulsatile flow.

Table 1: Leaflet treatments used in the biomechanical study.

Fresh (control)
Isotonic buffer (control)
Hypotonic buffer (control)
Isotonic buffer + 0.03%(w/v) SDS (control)
Hypotonic buffer + 0.03%(w/v) SDS
Hypotonic buffer + 0.1%(w/v) SDS

RESULTS AND DISCUSSION

Isotonic buffer or isotonic buffer with SDS did not alter the biomechanical properties. However, they were not effective decellularisation treatments. Treatment with 0.03% and 0.1% (w/v) SDS in hypotonic buffer produced complete accellularity while retaining the network of elastin, collagen and glycosaminoglycans (Booth 2002). These protocols produced modest changes in the biomechanics of the leaflets by reducing their elastin and collagen phase slopes, as well as by increasing their transition and failure strains. However, the

treatments did not affect the strength of the leaflets (Korossis 2002). Whole porcine aortic roots treated with 0.1% (w/v) SDS in hypotonic buffer and pressurized to 120mmHg presented complete leaflet competence, whereas, when they were subjected to pulsatile flow showed reduced transvalvular pressure gradients (Figure 1) and similar regurgitation volumes compared to fresh, untreated roots. Regarding leaflet kinematics, the treated roots exhibited similar levels of leaflet free edge bending strains compared to the fresh control, as well as physiological opening and closing actions (Figure 2).

Figure 1: Pressure difference vs. root mean square forward flow for fresh and SDS-treated aortic roots (mean \pm 95% C.I.).

Figure 2: Leaflet kinematics of SDS-treated aortic valve.

SUMMARY

The decellularisation protocol used in this study, incorporating SDS in hypotonic buffer, produced complete accellularity of porcine aortic leaflets, causing modest changes in their extensibility. The absence of dead cells as foci for calcification, the retention of the elastin, collagen and glycosaminoglycans, as well as the promising leaflet kinematics and the retention of the leaflet matrix compliance and strength, form a promising platform for further studies. Further work will investigate whether the treated leaflets have adequate durability and will consider *in vitro* recellularisation and penetration of the cells in the leaflet matrix.

MODULATION OF ANABOLIC AND CATABOLIC MECHANICAL SIGNALS IN BONE: FROM MECHANICS TO GENETICS

Stefan Judex
Department of Biomedical Engineering
State University of New York, Stony Brook, NY

A link between mechanical forces and skeletal morphology was first recognized by Galileo Galilei in the early 1600's. Almost four centuries later, the interdependence of form and function to explain the intricate architecture of the skeleton and the changes in bone mass with altered mechanical demands are yet to be elucidated. This incomplete understanding of mechanotransduction from the organ- down to the molecular-cellular level has crippled our efforts to design effective mechanical interventions that promote bone formation without significant side-effects.

Although there is little argument that bone can readily respond to mechanical stimuli, it is more than likely that the inconclusive results of whether exercise is efficacious in increasing bone mass or in preventing its decline reflect our limited understanding of which specific component of the mechanical signal is perceived as osteogenic by the resident bone cells populations. Using *in vivo* strain gaging together with finite element modeling, the ability of candidate mechanical parameters to predict the specific sites of bone formation was tested in an animal exercise-model. We found that a very brief daily running regime was capable of activating periosteal surfaces in the tarsometatarsal middiaphysis of adult roosters. Spatial correlations indicated that new bone was deposited primarily at sites experiencing the least rather than greatest strain magnitudes; regions in which circumferential strain gradients were large. While it is counterintuitive from an engineering perspective that bone formation is activated at sites subjected to low strains, physiologically, it is important to point out that strain gradients are proportional to fluid flow in bone, a byproduct of strain which has been implicated to play an important role in mechanotransduction in bone. Further experiments in growing roosters subjected to both running as well as jump exercises substantiated the importance of mechanical parameters that may be associated with interstitial fluid flow.

The prevailing tenet is that mechanical stimuli have to be large in magnitude to elicit an adaptive response. Recent studies indicated, however, that extremely low magnitude (inducing <10 microstrain in the matrix) mechanical signals readily stimulate bone formation and ameliorate mechanical properties. These potentially clinically relevant stimuli, when applied as low-level whole body vibration to the rat skeleton for 10 min/day, were anabolic to trabecular bone of the proximal tibia while mechanical disuse reduced bone formation rates. This suppression of bone formation was only slightly curbed when disuse was interrupted by 10 min/d of weight-bearing. In contrast, disuse interrupted by 10 min/d of low-level mechanical vibration normalized bone formation rates to values seen in age-matched controls. At the molecular

level, the expression of a gene that is a critical factor for osteoclastogenesis (RANKL) was quantified. Mechanical stimulation for 10 min/d decreased RANKL mRNA levels. Disuse increased RANKL transcripts while disuse interrupted by 10 min of daily mechanical stimulation decreased RANKL levels. Bone formation rates were inversely related to RANKL expression levels across groups ($r^2=0.79$). This work indicated that the low-level stimulus may provide an effective biomechanical intervention for the bone loss which plagues long-term space flight, bedrest, or immobilization and that gene expression is modulated by its mechanical environment.

Murine models of bone adaptation are critical for an integrative biomechanical/molecular/genetic approach to elucidate the adaptive skeletal processes as the mouse genome has been extensively deciphered, specific mouse strains with different bone phenotypes are available (e.g., high and low bone mineral density), and gene function can be tested through selective knockouts or inducible gene expression. While the influence of genetic variations on attaining and retaining bone mass is well established in both mice and humans, it is entirely possible that genetic make-up is also a strong determinant of bone's sensitivity to mechanical stimuli. Three genetically distinct strains of mice were subjected to either 10 min/d of whole body vibration or mechanical disuse. The extremely low-level mechanical stimuli superimposed upon normal daily activities were highly anabolic in the proximal tibia of both low bone mineral density (BMD) and mid BMD mice, while no significant effect of this specific stimulus was detected in the high BMD mice. Disuse diminished bone formation rates and bone volume in mid BMD mice, but failed to significantly influence bone's formative response in the other two strains. This genetic basis of bone's mechano-sensitivity at the tissue level was essentially mirrored at the molecular level. For instance, inducible nitric oxide synthase was significantly down-regulated by a similar percentage in mechanically stimulated mice of those strains that had responded to mechanical stimulation at the tissue level. Extrapolating these results to the human skeleton may provide insight into the inconsistent efficacy of treatment regimens as well as into the individual variation in the pathogenesis of osteoporosis.

In summary, the sensitivity of bone to mechanical stimuli is apparent but the design of interventions that will maximize tissue strength in young adults and prevent its loss in the elderly will require approaches combining biomechanics and genetics at the level of the tissue and the cell. The discovery of genes involved in regulating the skeletal response to mechanical stimuli may uncover novel drug targets that are not addressed by current pharmacological interventions and may also enable rapid advances in tissue engineering.

MOLECULAR MECHANICS OF CARDIAC TITIN'S PEVK AND N2B SPRING ELEMENTS

INTRODUCTION

Titin is a giant elastic protein that is responsible for the majority of passive force generated by the myocardium. Titin's force is derived from its extensible I-band region, which, in the cardiac isoform, comprises three main extensible elements: tandem Ig segments, the PEVK domain, and the N2B unique sequence (N2B-U). Using atomic force microscopy (AFM), we characterized the single molecule force-extension curves of the PEVK and N2B-U spring elements, which together are responsible for physiological levels of passive force in moderately to highly stretched myocardium.

RESULTS AND DISCUSSION

Molecules were stretched using a molecular force probe (Asylum Research, Santa Barbara, CA), an AFM specialized for stretching molecules. Force *versus* displacement curves were collected in repeated stretch and release cycles. Stretch-release force-extension curves of both the PEVK domain and N2B-U displayed little hysteresis: the stretch and release data nearly overlapped. The force-extension curves closely followed worm-like chain behavior. Histograms of persistence length (measure of chain's bending rigidity) indicated that the single molecule persistence lengths are ~1.4 and ~0.65 nm for the PEVK domain and N2B-U, respectively. Using these mechanical characteristics and those determined earlier for the tandem Ig segment (assuming folded Ig domains), we modeled the cardiac titin extensible region in the sarcomere and calculated the extension of the various spring elements and the forces generated by titin, both as a function of sarcomere length. In the physiological sarcomere length range, predicted

values and those obtained experimentally were indistinguishable.

SUMMARY

AFM studies revealed that the PEVK domain and N2B-U both behave as entropic springs, but with different persistence lengths. Persistence length histograms allow the single molecule persistence lengths to be determined; and using the obtained PEVK domain and N2B-U values, a model of the extensible region of cardiac titin can be constructed that simulates very closely the complex extension of titin in the sarcomere and the unique passive force-sarcomere length relation of cardiac myocytes.

INTRODUCTION

The giant elastic protein titin is found in vertebrate muscle, where it spans the half-sarcomere and integrates into the Z-disc and M-line through the N- and C-terminus, respectively.

Titin has been proposed to function as a molecular ruler and as a scaffold for several sarcomeric proteins, including alpha-actinin, myosin, C-protein, T-cap, myomesin, and MURF-1 (Granzier and Labeit, 2002).

Its subdomains perform distinct functions (Gregorio et al., 1999). The N-terminus appears to regulate the assembly of the Z-disc. Titin's I-band region is responsible for the elastic response of the sarcomere. A-band titin has been proposed to serve as a molecular scaffold to coordinate the proper assembly of the thick filament. Titin's c-terminus integrates into the M-line lattice and contains a serine/threonine kinase domain, which shares homology with the catalytic serine/threonine kinase domain of smooth muscle myosin light chain kinase (MLCK). This domain is conserved in evolution and present in titin-like proteins in *C. elegans* and *Drosophila* (Champagne et al., 2000) but no physiological catalytic function has yet been shown.

RESULTS AND DISCUSSION

To investigate the importance of this domain for muscle development, sarcomere stability and function, we have used gene targeting and the cre/lox recombination system to create knockout mice, which can be induced to express titin molecules deficient in the kinase domain. Tissue specific expression of the Cre recombinase has enabled the generation of heart- and striated muscle specific knockout animals.

In heart the kinase domain knockout interferes with embryonic development, while the striated muscle knockout animals survive to term but develop progressive myopathy and die at 5 weeks of age. Morphological and expression profiling analysis suggests that the kinase domain is essential to preserve sarcomere structure, but dispensable to elicit the hypertrophic gene response.

SUMMARY

Our results define a critical role for the titin kinase region in maintaining the structural integrity of the sarcomere. We have generated an animal model in which the role of titin and its binding partners in human disease can be explored, as well as titin's proposed role in stretch-dependent signaling.

NEW APPROACHES TO INTEGRATING MUSCLE FUNCTION AND DESIGN FROM MOLECULAR BIOPHYSICS TO WHOLE-ANIMAL

Lawrence C. Rome*

Department of Biology, University of Pennsylvania, Philadelphia PA 19104 &
The Marine Biological Laboratory, Woods Hole MA 02543

*Email: lrome@sas.upenn.edu

Muscle must perform mechanical work over a wide range of speeds to pump blood, power locomotion, or produce sound energy. My laboratory has been trying to understand how muscular systems are modified for their function. Two central concepts dictate that our experimental approaches must be integrative. First, one cannot understand how a muscle is designed without knowing exactly what it does during normal behavior and second, many of the modifications of muscle for different motor activities take place at the molecular level. Hence our long-standing goal has been to understand, from the level of molecular biophysics to whole-animal biomechanics, how muscular systems are designed to power different movements. This goal has only become feasible recently, because of a technological revolution in two areas: biophysics and musculoskeletal modelling.

The development of new biophysical technologies (e.g., Ca^{2+} -sensitive dyes, caged compounds, single fiber energetics and mechanics) has enabled us, for the first time, to measure the kinetics of pertinent molecular processes of muscle contraction and relaxation. For instance, by using these technologies on the muscles of toadfish, whose twitch speed varies over 50-fold, we (Rome et al 1996, 1999) have been able to demonstrate that 3 modifications are necessary to increase the rate of relaxation: First, the Ca^{2+} transient duration must be sped up, and this is achieved by having many SR- Ca^{2+} pumps and a high concentration of the Ca^{2+} -binding protein, parvalbumin. Second, Ca^{2+} must come off troponin, soon after the fall of myoplasmic Ca^{2+} , and this is achieved by a low affinity troponin which is endowed with a fast Ca^{2+} off-rate. Finally, there must be a modification of the myosin to provide a fast cross-bridge detachment rate constant, g . We found that the super-fast swimbladder muscle which is used to produce a mating call at 200 Hz has the fastest Ca^{2+} transient, the lowest affinity force- $[\text{Ca}^{2+}]$ relationship, and by far the fastest g .

However, there is a cost for speed: the superfast g is accompanied with only a normal attachment rate constant, f . Thus in the steady state, only a small fraction of the cross-bridges are attached at any one time and hence the force generated by the swimbladder muscle is only about 1/10 that generated by locomotory muscles. This trade-off of force for speed (Rome et al. 1999) results in mutually exclusive designs (Young & Rome, 2001): The superfast sound producing muscles generate too little force for powering locomotion, while the locomotory muscles relax too slowly for powering sound production. These biophysical approaches are very powerful and will soon lead to a mechanistic model of muscle contraction that is based on principles of chemical kinetics.

An ultimate goal of this integrative approach is to understand enough about the molecular and macroscopic components of muscular systems, so that we can develop the first

comprehensive model that enables us to predict and understand how alterations in one molecular parameter (e.g., g) might affect whole animal motor performance. For this goal, we are using frogs because their muscle length changes and overall body mechanics during jumps are relatively easily quantified. Previously, by examining the length changes and stimulation pattern of the semimembranosus (a hip extensor), we were able to show that this muscle is designed to generate maximum power during jumping (Lutz & Rome, 1994).

Still, a significant obstacle to integrating from muscle function to locomotion is that the musculoskeletal system of any animal is complex. Frog hindlimbs have in excess of 15 muscles that contribute to overall performance, and these muscles may perform different types of contractions. Thus it is difficult to appreciate and predict whole animal movements from the mechanics of a single (or even several) muscles. Musculoskeletal modeling can be an enormous help by keeping track of the forces generated by multiple muscles, so that the net action of all the muscles can be determined.

My laboratory has recently constructed a realistic skeletal model of jumping frogs containing the bones, joints, masses and moments of inertia of body segments (Kargo et al. 2002). The power of this overall approach is that we can alter components of the muscular system and test how this alteration affects the frog's ability to jump. For instance, by varying the joint degrees of freedom in the model and applying realistic torques around the joints, forward dynamic simulations enabled us to test hypotheses about how the skeletal system of frogs is modified for jumping (i.e., frog has extra joints and extra joint degrees of freedom than humans). As modeling progresses, we will add the muscles (their mass, fiber orientation, placement of the origin and insertion and physiological properties). We will then be able to turn the muscles on in their measured sequence (i.e., EMGs) and the virtual forces and torques will make the frog move. The addition of a molecular model of muscle will then provide us with an unprecedented ability to test how changes in single amino acids of myofibrillar proteins might alter jumping performance. The interactive nature of this model will also make it an excellent platform for teaching biomechanics.

Tendinitis affects millions of people both in the workplace and athletic settings in the United States. The etiology of tendinitis is largely unknown, but it is believed to result from excessive repetitive mechanical loading of tendons, which results in tendon inflammation and degeneration. However, because of the lack of a reliable experimental model, the cellular and molecular mechanisms responsible for the development of tendinitis remain unclear.

We hypothesize that tendon fibroblasts are responsible for the development of tendinitis by producing high levels of PGE₂ and LTB₄, which are regulated by increased expression levels of PLA₂, COX and 5-LO. To test this hypothesis, we have developed a novel model system to study inflammatory responses of human tendon fibroblasts, thereby elucidating developmental mechanisms for tendinitis at the molecular level. The model system consists of a stretching apparatus (Fig. 1A) silicone dishes to grow and stretching tendon fibroblasts. A unique feature of this system is that the silicone dishes contain microgrooved surfaces instead of commonly used smooth culture surfaces (Fig. 1B). We have shown that the alignment, shape and mechanical loading conditions of the human patellar tendon fibroblasts (HPTFs) in this model system are similar to those *in vivo* (Fig. 2).

Fig. 1 A model system to study molecular mechanisms for tendinitis.

Fig. 2 Tendon fibroblasts in microgrooves are elongated and aligned under cyclic uniaxial stretching, which is similar to the cells *in vivo* (H&E staining). Note that arrows point the fibroblasts in the microgrooves (A) and tendon (B).

Using the novel model system, we have studied the production of PGE₂ by HPTFs in response to cyclic mechanical stretching. It was found that cyclic stretching of the tendon fibroblasts induces high levels of PGE₂ in a stretching-magnitude dependent manner. We have also found that cyclic stretching of HPTFs increases expression levels of COX and PLA₂, which mediate synthesis of PGE₂. Cyclic stretching was also found to induce high levels of LTB₄ production and expression of 5-LO, the enzyme that mediates cellular production of LTB₄. In addition, inhibiting COX with indomethacin to block PGE₂ production further increases LTB₄ production by stretched tendon fibroblasts, suggesting that cellular production of PGE₂ is related to that of LTB₄.

In future, the effect of cyclic mechanical stretching on the expression of other inflammatory genes (e.g., IL-1, IL-6 and TNF α) will be investigated using our model system. Further, with a multidisciplinary approach based on mechanobiology, molecular biology, and biomechanics, the effect of stretching-induced PGE₂ and LTB₄ on the biological, biochemical and biomechanical properties of the tendon will be evaluated on an animal model.

COMPUTATIONAL SIMULATION OF TREATMENTS USED FOR PATELLOFEMORAL PAIN AND INSTABILITY

John J. Elias¹ and Andrew J. Cosgarea²

¹Biomechanics Laboratory, Medical Education and Research Institute of Colorado, Colorado Springs, CO, elias@meric.info

²Department of Orthopaedic Surgery, Johns Hopkins University, Baltimore, MD

INTRODUCTION

Lateral patellar instability and anterior knee pain are often attributed to a large Q-angle. The lateral component of the resultant force applied to the patella by the quadriceps muscle group and the patella tendon increases as the Q-angle increases. Surgical and non-surgical treatment methods are used to reduce the lateral force acting on the patella. Computational simulation can be used to evaluate how these treatment methods influence the patellofemoral contact pressure distribution. For this study, two treatment methods were evaluated: surgical medialization of tibial tubercle to reduce the Q-angle and vastus medialis strengthening to decrease the lateral force acting on the patella.

METHODS

A surface model of a knee was created using CT data from the Visible Human Male (National Library of Medicine). Origin, insertion and wrapping points were identified for the vastus medialis, vastus intermedius, vastus lateralis, rectus femoris, and patella tendon. The tibia was flexed about the femur to model a dual limb knee squat. The patella was flexed, and aligned with the femur by aligning the posterior patella with a parallel surface within the trochlea. The quadriceps force was divided among the four muscles (Ahmed, 1983). At each flexion angle, the quadriceps muscles created a knee moment representing a dual limb knee squat (Cohen, 2001). The patella tendon force was determined based on the quadriceps force and the flexion angle (Huberti, 1984). For these input forces, the patellofemoral pressure distribution was quantified using the discrete element analysis technique (Elias, 2002). Surgical variation of the Q-angle was modeled by shifting the patella tendon attachment point on the tibia in the medial/lateral direction. Vastus medialis strengthening was modeled by increasing the percentage of the quadriceps force applied by the vastus medialis by 50%.

RESULTS AND DISCUSSION

The lateral component of the force acting on the patella, the total force applied to the lateral cartilage and the area of cartilage subjected to more than 4 MPa of pressure all increased with the flexion angle. The peak lateral contact pressure was larger than the peak medial contact pressure, with relatively little variation in the peak lateral contact pressure from 70° to 90° of flexion (Fig. 1). At 90° of flexion, the lateral force acting on the patella, the total force applied to the lateral cartilage, and the area of cartilage subjected to more than 4 MPa of pressure decreased by 10%, 5%, and 13%, respectively, as the Q-angle decreased from 25° to 10°. The maximum lateral pressure did not decrease with the Q-angle (Fig. 2). Medializing the tibial tubercle increased the moment

Fig. 1: Variation in the patellofemoral contact pressure distribution during flexion.

Fig. 2: Influence of the Q-angle on the patellofemoral contact pressure distribution at 80° of flexion.

acting to rotate the distal pole of the patella medially, offsetting the expected peak pressure decrease due to a lateral force decrease.

Increasing the vastus medialis force decreased the lateral component of force acting on the patella and the total force acting on the lateral cartilage, but increased the peak pressure by approximately 4% for the four Q-angles. The peak pressure increased despite the decrease in the lateral force due to the increased medial rotation moment caused by the increased vastus medialis force.

SUMMARY

Although both vastus medialis strengthening and surgical medialization of the tibial tubercle reduced the force tending to sublux the patella laterally and the total force acting on the lateral cartilage, the peak pressures did not decrease due to the moments acting on the patella. This study shows that computational modeling may help surgeons get a better understanding of how prescribed treatments influence the patellofemoral contact pressure distribution.

SINGLE MOLECULE MECHANICS AND THE MYOSIN FAMILY OF MOLECULAR MOTORS

James A. Spudich, William Shih, Coleen Murphy, Amit Mehta, Ron Rock, Sarah Rice, Tom Purcell and Matthias Rief.

Stanford University School of Medicine, Stanford, CA 94305.

Employing a combination of biophysical, biochemical and biological approaches, we have examined the role of myosin, actin, and associated regulatory proteins in these processes. Our focus has been on how the myosin family of molecular motors work and the roles that they play *in vivo*. This has involved the development of *in vitro* motility assays, whereby individual filaments of actin move along purified myosin molecules in an ATP-dependent manner, as well as single molecule analyses using laser trapping.

It has been hypothesized that the molecular motor myosin acts by binding to actin and swinging its light-chain binding region through a large angle to provide a ~10-nm step in motion coupled to changes in the nucleotide state at the active site. Direct dynamic measurements to date, however, have largely failed to reveal changes of that magnitude. We used a cysteine engineering approach to create a high-resolution FRET-based sensor that reports a very large ~70-degree nucleotide dependent angle change of the light-chain binding region. The combination of steady-state and time-resolved (with Zygmunt Gryczynski and Joseph Lakowicz, Univ Maryland) fluorescence resonance energy transfer measurements unexpectedly revealed two distinct prestroke states. The measurements also show that bound Mg.ADP.Pi, and not bound Mg.ATP, induces the myosin to adopt the prestroke states.

It is thought that Switch II of myosin, kinesin and G-proteins plays a critical role in relating the nucleotide state to the protein conformation. We examined S456L myosin-II from *Dictyostelium*, a mutant of the Switch II region, whose mechanical activity is uncoupled from the chemical energy of ATP hydrolysis so that actin filament gliding velocities are only one-tenth that of wild type. The mutant myosin exhibits an extended strongly-bound state time and a shorter step size, which together account for the decrease in *in vitro* velocity.

Myosin-V and myosin-VI are quite different from myosin-II and also different from one another. We showed that these motors move processively along their actin tracks. With Mark Mooseker (Yale), Richard Cheney (Univ North Carolina), and Lee Sweeney (Univ Pennsylvania) we employed a feedback-enhanced optical trap to examine the stepping kinetics of these movements. By analyzing the distribution of time periods separating discrete ~36 nm mechanical steps for myosin-V, we characterized the number and duration of rate-limiting biochemical transitions preceding each such step. Based on this, we propose a model for myosin-V processivity involving a tightly coupled motor whose cycle time is limited by ADP release.

HEMODYNAMICS AND ATHEROSCLEROSIS: ARTERIES TO CELLS, AND BACK AGAIN

Don P. Giddens

Wallace H. Coulter Department of Biomedical Engineering
Georgia Institute of Technology and Emory University, Atlanta, GA 30332-0536, USA

Hemodynamics has attracted biomechanics investigators for decades. Early studies made simplifying assumptions, since neither experimental methods nor mathematical/computing tools were sufficiently advanced to allow accurate modeling of actual blood vessels. The simplest approximation, Hagen-Poiseuille flow, was followed by oscillatory (Womersley) flow in a long tube. Gradually, more sophisticated modeling was performed, both computationally and in the laboratory, and flow through stenoses and idealized branches and bifurcations – first with steady and then pulsatile flow – led to a deeper understanding of phenomena that might be relevant to blood flow in real arteries. Gradually, the assumptions of vessel rigidity, Newtonian fluids and idealized geometries have been relaxed as fluid dynamicists tackled increasingly more complex, and relevant, issues. These studies have resulted in a much clearer view of the relative importance of simplifying assumptions and, importantly, when these assumptions can and cannot be made.

Currently, it is possible to perform experiments in laboratory models in which fluid velocity and wall shear are measured using optical techniques in fairly realistic geometric models that mimic the shape and motion of individual vessels. A completely realistic representation of blood is still elusive, not so much due to an inability to employ fluids that model viscoelastic behavior as determined in rheological measurements, but because non-Newtonian blood viscosity results largely from the formation of RBC rouleaux – and the characteristic time for cells to form rouleaux under a given shear condition is different than that for breaking these down.

As hemodynamic modeling advanced, knowledge gained was “correlated” with biological observations. In the case of localization of early atherosclerotic plaques, a number of laboratories produced evidence that not only were plaques localized in curves, branches and bifurcations of arteries, but more specifically these were localized at sites where the fluid dynamic wall shear stress was low – often below 5 dynes/cm². Usually, these locations also corresponded to oscillations in wall shear during the pulsatile cycle. This observation was particularly evident in the human carotid bifurcation where early plaques invariably develop along the outer wall of the carotid sinus rather than at the flow divider itself, although there is also clear evidence of this association in other arteries. Thus, two decades of research by biofluid dynamicists posed – and settled – the issue of “low shear” versus “high shear” as participating in atherogenesis. It is worth adding that this knowledge is still not pervasive in the “rank and file” of

physicians, some of whom still attribute atherosclerotic plaque localization to turbulence and high shear stress.

Recognizing that correlations are often not the same as mechanisms, studies of the effects of fluid dynamics on cellular behavior began to abound, spurred both by the realization that mechanical factors could affect cell function and by new knowledge and tools in cellular and molecular biology. Endothelial cells, in particular, were of great interest; and a body of knowledge gradually developed that showed fluid dynamic effects on cell shape, migration, signaling and molecular and genetic expression. Literally thousands of papers have been published and presented dealing with various – and increasingly detailed – observations of mechanical effects on endothelial cells. How much of this information is relevant to human pathophysiology in general, and to atherogenesis in particular, is still being sorted out. Nonetheless, it is abundantly clear that there is a strong interplay between the local hemodynamic environment in the vicinity of a cell and the structure and function of that cell.

Thus, hemodynamics has provided insight into the pathophysiology of the artery, and it is being used commonly as a tool to probe the molecular biology of cells. Perhaps now is the time for hemodynamics to return to the arteries – and specifically to the arteries of individual human subjects.

Fortunately, our investigative tools are now permitting this. With MRI, for example, we can obtain geometry and flow conditions in individual human vessels, albeit with difficulties in accuracy and resolution. Our computational tools allow description of pulsatile, 3D flows in hours rather than weeks, and our ability to transfer image data to a rapid prototyping device for constructing realistic arterial models is becoming extremely useful. Simultaneously, molecular biology tools that use very small tissue samples to measure infinitesimal amounts of cellular material are giving us “biological” spatial resolution comparable to our computational resolution. Ultimately, noninvasive imaging technology may be able to supplant harvesting tissue samples.

Thus, there is now the potential for a convergence of computing technology, experimental methodology, imaging and molecular biology that may enable us to return to the artery in order to unravel the mystery of atherosclerosis. Perhaps a decade from now we will be able to define specific mechanisms through which vessels remodel, arteries develop plaques and bypass grafts fail.

CELL STRUCTURE AND FUNCTION: PLENTY OF ROOM FOR BIOMECHANICS

Jean-Jacques Meister

Cellular Biophysics and Biomechanics Laboratory,
Swiss Federal Institute of Technology, Lausanne, Switzerland
e-mail: Jean-Jacques.Meister@epfl.ch

INTRODUCTION

Most of the functions performed by cells ultimately involve internal forces, deformations and movements as well as mechanical interactions between the cell and its environment. Moreover, cells are constantly exposed to external forces which may modify their structure, shape and functions.

The rapid growth of molecular and cellular biomechanics is mainly driven by novel experimental techniques, which allow manipulation of single molecules and subcellular components, to measure piconewton forces or nanometer displacements and to dynamically image cell elements. Added to theoretical models, these experimental results allow determination of the mechanical properties of cells and cell components, to understand the building and remodelling of cell structures, to describe the role played by mechanics in cell functions like motility, adhesion or division and to analyze cellular mechanisms of external force sensing and transmission.

This information is of utmost importance to understand the relationship between mechanical forces and cellular functions, to advance techniques in molecular and cellular engineering as well as to design engineered tissues and organs.

BIOMECHANICS AT THE WHOLE CELL LEVEL

The information gained by stressing and deforming a whole cell is twofold. First, mechanical properties and constitutive laws of the cell may be obtained by applying a theoretical model of its principal components (nucleus, cytoskeleton) to the experimental results. Second, the mechanisms involved in the sensing of external forces, in force transmission into the cell as well as its consequences in terms of structural and functional changes of the cell may be studied. Recent results showed for instance that the nucleus is deformed under a deformation of the cell substrate, that the cytoskeleton is remodelled under external stretch or stress and that the constitutive law of the cell is strongly influenced by the ability of the cytoskeleton to deform, flow and reorganize.

MECHANICS OF CELL COMPONENTS

The cell is a complicated structure built with elements of very diverse materials. The knowledge of the mechanical properties of its different components is necessary to predict cell behavior and to analyze the interactions between components. This challenging task has already started. At the level of a single molecule for instance, force-deformation curves of a DNA molecule, obtained by using an optical trap or an atomic force microscope, has revealed conformational transitions from 50 to 150 pN and unzipping around 20 pN. At the level of the nucleus, its elastic modulus (about 5 kN/m²) has been measured by the compression of a single nucleus between two microplates. Other nice works were performed on isolated

cytoskeleton filaments, e.g. measurement of the force-velocity relation of growing microtubules. The cytoskeleton is a three-dimensional deformable dynamic scaffold made of different filaments. There is still a challenge to measure the mechanical properties of the different organizations of this scaffold as well as to build a theoretical model (tensegrity, glassy material) describing the mechanisms of force transmission from the cell membrane to the nucleus and cytoskeleton remodelling.

INTRACELLULAR FORCES AND MOVEMENTS

Different functions of the cell involve internal forces, deformations and movements, which have to be analyzed: the transport of different cargos along microtubules, the deformation of contractile cells like hair and muscle cells, the motion of chromosomes during cell division (mitosis), etc. As an example, the recent real time imaging of molecules transported within chemosensory neurons of C-elegans address interesting questions in biomechanics: mechanisms of transport, relationship between frequency of transport events and chemotaxis, forces and energy involved in this transport, link between characteristics of transport and locomotor response, etc.

CELL MOTILITY

Cell locomotion usually requires active protrusion, adhesion and retraction. The protrusion and the retraction are created by a profound structural and geometrical modification of the cytoskeleton, mainly created by actin polymerization and actin-myosin II contraction, respectively. The knowledge of the mechanical properties of the cytoskeleton during cell locomotion is fundamental to understand the resulting production of coordinated protrusive and contractile forces. Focal adhesions serve as points of traction over which the cell moves. Biomechanics may help to determine the cell-substratum force and to understand the mechanisms that regulate the formation of points of adhesion at the cell front and their release at the rear.

STRUCTURE-FUNCTION RELATIONSHIPS

The ultimate goal of molecular and cellular biomechanics is to identify the relationships between cell shape, structure, mechanical properties and functions. This knowledge is essential to better understand cell physiology during cell growth, cell division, cell motility and signal transduction, as well as cellular pathologies like inflammation, changes of phenotype and cell death.

FUNCTIONAL ADAPTATION AND REMODELING OF BIOLOGICAL SOFT TISSUES

Kozaburo Hayashi

Biomechanics Laboratory, Division of Mechanical Science, Graduate School of Engineering Science
Osaka University, Toyonaka, Osaka 560-8531, Japan, hayashi@me.es.osaka-u.ac.jp

INTRODUCTION

There are many evidences indicating that living organs, bio-logical tissues, and cells are skillfully and optimally designed, and remodel functionally adapting themselves to stress and force. The ability of remodeling and functional adaptation is characteristic of living systems. This lecture deals with a part of our studies on the biomechanical and morphological responses of such biological soft tissues as tendon/ligament and vascular wall to stress and force. The knowledge of these phenomena should contribute much not only to better understanding of basic biology and physiology as well as the improvement of practical medicine but also to the development of new areas in mechanical design and engineering.

EFFECTS OF STRESS ON THE BIOMECHANICAL PROPERTIES OF TENDONS AND LIGAMENTS

Effects of stress deprivation, resumption of stress after stress deprivation, and stress enhancement on the mechanical properties and dimensions of the patellar tendon (PT) were experimentally studied in the rabbit.

A newly developed stress shielding technique was directly applied to the PT for completely releasing stress (complete stress shielding) or partially reducing stress (partial stress shielding, 70% reduction from normal). Both stress shielding very rapidly and markedly decreased the material strength of the PT. The structural strength (load at break) was also much decreased by complete stress shielding; however, it was kept at control level in the case of partial stress shielding. Essentially similar phenomena were observed in the canine anterior cruciate ligament, and also in the rabbit frozen PT for a graft model.

To know the roles of substructural components, the mechanical properties of collagen fascicles (300 μm in diameter) and collagen fiber (1 μm) obtained from the stress-shielded rabbit PT were studied. Stress shielding significantly decreased the tangent modulus and tensile strength of collagen fascicles; however, these changes were smaller than those observed in bulk tendons. There were no changes in the mechanical properties of collagen fibers. These results indicate that ground substances and mechanical interaction between collagen fibers have important roles in the remodeling of tendons and ligaments.

Stress resumption induced after complete stress shielding gradually recovered tendon strength, although the strength did not return to control level. Overstressing to 133 % of normal stress (33 % overstressing), that was induced by removing the medial and lateral one-eighth width of the PT, did not change the material strength, but increased the structural strength to that of the whole intact tendon due to the increase in the cross-sectional area. In the case of 100 % overstressing, which was induced by removing the medial

and lateral one-fourth, strength increased in some tendons but decreased in others.

These results indicate that tendons and ligaments have the ability of adapting themselves to stress changes, although the adaptation does not occur if stress exceeds an allowable range.

RESPONSE OF CULTURED COLLAGEN FASCICLES TO STRESS

To obtain information on the mechanisms of the remodeling of tendons and ligaments, stress effects on the mechanical properties of collagen fascicles were studied using in vitro tissue culture methods. Collagen fascicles obtained from the rabbit PT were cultured under static (24 hours per day) or cyclic (4 Hz, 1 hour per day) stress for 1 and 2 weeks. In each case, a parabolic relation was observed between applied stress and tensile strength. The tensile strength and tangent modulus of the fascicles cultured under zero stress were 50 % of each control level. They were maximal at the applied stresses that are equivalent to 50 and 100 % of the in vivo peak stress in the intact PT in the static and cyclic cases, respectively. Smaller and larger applied stresses than these stresses deteriorate the mechanical properties. The maximum strength and modulus were at control levels in both cases. Thus, cultured collagen fascicles also have an ability of mechanical and structural adaptation to stress.

VASCULAR WALL REMODELING DEVELOPED BY BLOOD PRESSURE AND BLOOD FLOW CHANGES

Biomechanical responses of the common carotid artery to hypertension (HT), low and high blood flow (BF), and the combinations of HT with these BF changes were studied in the rat. Wall thickness was larger in HT animals than in normo-tensive ones; due to the wall hypertrophy, wall circumferential stress was kept at control level. Except for the case of the combination of HT with low BF, the inner diameter of wall was decreased by low BF, and increased by high BF, which kept wall shear stress at control level. Therefore, the arterial wall very well adapts itself to HT regardless of BF. Diameter response to a vasoconstrictor was larger in HT animals than in normotensive and control ones, which suggests that smooth muscle tone is enhanced by HT and it takes an important role in the wall remodeling. Wall properties including wall elasticity and diameter response were also adapted to HT regardless of BF changes, and rather normal properties were retained at high pressure range in HT animals. Essentially similar adaptation phenomenon to HT was also observed in the rabbit femoral vein.

THE NOVEL AERODYNAMICS OF INSECT FLIGHT: APPLICATIONS TO MICRO AIR VEHICLES

Charles Ellington

Department of Zoology, University of Cambridge, Cambridge, England
c.ellington@zoo.cam.ac.uk

The design of small flying machines can take inspiration from the insects and small vertebrate fliers (birds and bats). The flapping wings of these animals produce much greater forces than conventional wings, but the aerodynamic mechanisms responsible for these large forces have only been investigated for insects.

Some butterflies rely on pressure drag for vertical take-off and slow forward flight, and the lift contribution is small. It is ironic that a drag-based mechanism of flight is found for such large insects. It has been postulated that tiny insects, flying at very low Reynolds numbers (Re), must 'swim' through the air because viscosity should reduce their lift-to-drag ratios below unity. However, they rely instead on the lift of their wings, augmented by the fling mechanism, for weight support. Hoverflies, dragonflies and small vertebrates (except hummingbirds) hover with their flapping motion inclined to the horizontal by some 30 degrees. They use dynamic stall on the downstroke to support their weight, and the required lift-to-drag ratio is necessarily low: less than 2.

Most insects (and hummingbirds) hover with an approximately horizontal stroke plane, using lift on both the downstroke and upstroke to support their weight. Their flapping wings must typically produce 2-3 times more lift than can be achieved in steady motion. A leading-edge vortex (LEV) created by dynamic stall is responsible for most of the enhanced lift production. A strong spanwise flow is also generated by the pressure gradients on the flapping wings of

medium and large insects, stabilising the LEV and causing it to spiral out to the wingtip. At the laminar Re appropriate to these insects, we have discovered that the spiral LEV can be maintained indefinitely on rotary wings. The vortex is therefore a steady 3-D rotary wing phenomenon, and not an unsteady flapping mechanism as previously thought. Force coefficients for steady propeller rotation are remarkably insensitive to Re and wing characteristics: camber, twist and leading-edge construction. The flow separation causes a loss of leading-edge suction, and the resultant aerodynamic force is approximately normal to the wing surface. The lift-to-drag ratio is therefore low, typically less than 2, at the angles of attack normally used.

For all of the high-force aerodynamic mechanisms employed by insects at laminar Re , an enhanced lift is only obtained at the expense of a large drag force and poor lift-to-drag ratios. These ratios are appallingly low for conventional aerodynamic designs, and would necessarily entail high power consumption and low aerodynamic efficiency for fixed and rotary wing flight systems. However, insects can incline their wing motion to take advantage of the high drag force, using the resultant aerodynamic force instead of just lift to support their weight. The mechanical power expended against wing drag is therefore incorporated in the induced power, greatly improving aerodynamic efficiency. For small flying machines to exploit the high-force aerodynamic mechanisms of insects to improve their lifting capacity with good efficiency, flapping flight with full control over the wing motion will be essential.

SKIING WITH CARVED SKIS: CHALLENGES ON PERFORMANCE AND SAFETY

Erich Müller, Hermann Schwameder, Christian Schiefermüller
Institute of Sport Science, University of Salzburg, Salzburg, Austria

INTRODUCTION

In recent years many dramatic changes have taken place in Alpine skiing. In ski racing as well as in recreational skiing skis have become much shorter, their side cut has increased to a great extent and binding plates (risers) have been fixed between the ski and the binding. In addition the stiffness of the ski has changed, too. This evolution has, of course, also changed the movement patterns of performing ski turns but might also have changed the risk of sustaining injuries. This paper will present the results of various projects dealing with these aspects.

CHALLENGES ON PERFORMANCE

Carving turn vs traditional turn

An excellent carving ski racer and former world cup ski racer performed 8 test runs on a well prepared piste with both carving (side cut radius: 14 m) and traditional giant slalom skis (side cut radius: 32 m). Kinematic analysis of the runs was done using 3 video cameras and the Peak 3D system. Ground reaction forces were measured by implementing bilateral mobile pedar insoles (Novel) into the boots of the subject. EMG data of 7 leg muscles were collected with the mobile biovision system.

Fig. 1: Comparison between traditional parallel turns and carving turns

Turns with carving skis (CT) in comparison to traditional skis (PT) have higher inward leaning angles (50 – 55°), higher ski edging angles (65 – 70°), higher inside ski load during the steering phase with higher activities of the M. peroneus and

M. tibialis anterior. Turns with carving skis demand obviously a better sagittal balance ability as well as an improved edge steering ability in order to be able to stay centrally positioned over the ski.

The influence of riser height on performance

Ski racers are convinced to be able to race faster using so called risers. So in a further project we had to prove this hypothesis and to try to find the mechanism which might increase the racer's performance. In a field test three different riser heights (0 cm, 1 cm, 2 cm) were used. The course was standardized by gates. 12 runs, using the different ski systems alternatively were performed by a world cup racer. The following parameters were measured: running time, ground reaction forces normal to the ski, anterior/posterior moments or lateral moments respectively. There was a significant decrease of the running time in dependence on the riser height. No significant differences for forces and moments could be found between the different riser heights analysing the whole turn. But if the turn is divided into a steering phase and a very short edge changing phase, the values of the steering phase remain nearly constant, whereas the values of the edge changing phase decrease significantly using higher risers. Therefore risers help to reduce running time as the edge changing can be managed in a shorter time period.

CHALLENGES ON SAFETY

Carving turns and risks of sustaining injuries.

The aim of skiing with carving skis is to perform turns with a small turning radius without any skidding. The turning radius depends on the side cut radius of the ski, the edging angle and the stiffness of the ski and the piste. The smaller the turning radius and the higher the speed the bigger becomes the skier's load. Skiing turns with small radii on high speed might exceed the skier's physiological capacity soon. The use of carving skis with binding plates also increases the probability of catching an edge. The higher the risers between the ski and the binding the smaller edging angle is needed to initiate the catching of an edge and due to the smaller side cut radius of the ski the distance of the lateral deviation from the intended skiing direction becomes too big within a short period of time and therefore makes a successful correction movement impossible. The binding plates are also considered to increase the acting moments in the knee due to the lengthening of the lever arms of the lower leg. As a consequence of these findings the F.I.S limited the maximum standing position for ski racing.

THE ENGINEERING OF VASCULAR SUBSTITUTES

Robert M. Nerem

Georgia Tech/Emory Center for the Engineering of Living Tissues
Petit Institute for Bioengineering and Bioscience
Atlanta, GA 30332-0363, U.S.A.

The engineering of a blood vessel substitute has for a quarter of a century been a “holy grail” within the cardiovascular research community. There is no more important example of the role of biomechanics in all of tissue engineering than that of a blood vessel substitute. Although for some tissues there has been frequently too little attention paid to what today is termed “functional tissue engineering” and in particular to the role of mechanics, the engineering of functional tissue substitutes has in a sense always been the goal of those engaged in tissue engineering.

To address the challenges posed by this “holy grail,” a number of concepts are being pursued. These range from acellular approaches to cell-seeded scaffolds and include the use of collagen-based, polymeric, and cell-secreted materials. As important as the various approaches and contributions have been, each of the currently available concepts falls short in achieving at least one of the important, functional characteristics. So what are these desirable characteristics?

To start with, a primary failure mode of small diameter blood vessel substitutes made from synthetic materials is thrombotic closure. Thus, a critical issue is to provide for non-thrombogenicity. This suggests having an endothelium, or at least an “endothelial-like” cell layer. Such an interfacial, cellular monolayer should be adherent, confluent, and biologically non-activated. In all of these, there is a role of biomechanics. In this a key issue is the identification of a source for the endothelial cells to be used. Are these to be autologous, perhaps recruited from surrounding vessels or obtained either from adipose tissue or from circulating endothelial cells? Or is one’s strategy to be the employment of allogeneic endothelial cells in which case the engineering of immune acceptance will be critical? Long term stem cell technology offers considerable potential. Whatever the case, the functional characteristics including how the cells respond to mechanical forces will be important. Although vascular endothelial cells have been studied extensively in this regard, little is yet known about the effects of mechanical stimuli on circulating endothelial cells and stem cells.

If one seeks to engineer a blood vessel substitute which mimics the complete functionality of a native artery, vasoactivity is a desired functional characteristic. The vascular smooth muscle cell (SMC), the natural neighbor of the endothelial cell is responsible for generating the contractile force necessary to change vessel dimensions. For such vasoactivity to be exhibited, the vascular smooth muscle cell must exist in the appropriate contractile phenotype. In addition, these cells must be oriented in a circumferential

direction within the blood vessel wall. Finally, as noted earlier, vascular SMCs are the natural neighbors to the endothelial cells. As such, another important role for SMCs may be to provide through their presence a more natural environment for the endothelial cells. In doing so, if patency is enhanced, then this may be even more important, than providing for vasoactivity.

There are at least two important mechanical properties for a blood vessel substitute. The first and most basic of these is ultimate strength, frequently denoted simply as burst pressure. For native arteries this is in excess of 2000 mm Hg, and several of the tissue engineering approaches have resulted in burst pressures on this order. A second, potentially very important characteristic has been more difficult to achieve. This is to engineer into a construct a viscoelasticity that matches that of native vessels. The various tissue engineering approaches pursued to date have resulted in constructs with a very limited amount of elastin; thus, a critical problem has been the incorporation of elastin into the wall of the construct.

When a tissue-engineered blood vessel substitute is implanted, there is an integration into the host system which takes place, and associated with this there will be a remodeling. Thus, six months after implantation the characteristics of the blood vessel substitute should not be expected to be the same as those exhibited at the time of surgery. There also is a remodeling, however, which can be induced prior to implantation as part of the process used to grow the tissue. Thus, the in vitro environment can be used to advantage in engineering the remodeling of the tissue substitute. In this it will be critical to understand how biomechanical stimulation can be used and how the biology and the biomechanics integrate with one another in the remodeling which takes place.

Taking all the relevant issues together, we are still a decade away from having an FDA approved, tissue-engineered blood vessel substitute. Of course, not all of the issues are ones related to biomechanics; however, the biomechanical ones are of real significance and thus are deserving of the attention of the entire cardiovascular tissue engineering research community.

MECHANICAL ADAPTATION OF BONE MASS AND ARCHITECTURE: TOWARDS A UNIFIED THEORY

Rik Huiskes & Ronald Ruimerman

Dept. Biomedical Engineering, Eindhoven University of Technology, The Netherlands, r.huiskes@tue.nl

After the cartilaginous bone tissue has mineralized in the embryo, the tissue is modeled to bone by invading bone-forming osteoblasts and bone-resorbing osteoclasts. This *modeling* process continues during growth, producing trabecular patterns that seem mechanically optimized in density and directionality, relative to the external forces. In maturity, the trabeculae are continuously *remodeled* through resorption and apposition of bone tissue at free surfaces, repairing micro-cracks, while maintaining structural optimality relative to external loads. Later in life trabecular number and thickness gradually decrease, when musculo-skeletal activities reduce. So still, the relationship between structure and mechanical loading seems to be maintained. The lasting association between quality and its mechanical demands is a great evolutionary asset, but it also has negative side effects in the increase of fracture risk in the elderly through osteoporosis, and bone resorption around orthopaedic implants through abnormal load transfer (stress shielding.)

We developed and validated an empiric theory to predict periprosthetic bone-density changes due to ‘stress shielding’, assuming them to be coupled to post-operative changes in the local strain-energy density (SED) [1-6]. We used a similar theory to explain density distributions in the proximal femur as adapted to natural load transfer [7]. Although realistic, the results were mathematically invalid due to trabeculation of the FEA mesh, where it was formulated as a continuum. The solution was a separation of actor and sensor functions: osteocytes within the bone trabeculae were assumed as SED sensors, signaling Basic Multicellular Units (BMU’s) of osteoclasts and osteoblasts at trabecular surfaces to add or remove net bone mass [8,9]. This alternative theory explained alignment of trabecular structure to the external loads (modeling) and re-alignment for alternative loads (adaptation).

We have now refined and unified the theory to include the separate activities of osteoclasts and osteoblasts in both *modeling* and *remodeling* of trabecular structure [10,11]. We use dynamic loading variables (SED-rate) which activate osteocytes in the bone matrix to transfer osteoblastic bone-formation stimuli to trabecular surfaces, through the canalicular network. The stimulus received at the surface depends on osteocyte density, mechano-sensitivity and signal decay by distance. Bone is formed at the surface where and while the stimulus exceeds a threshold value. Concurrently, osteoclasts are assumed to resorb bone which is (micro)damaged, the sites of which are determined at random per iteration. Coupling between osteoclastic and osteoblastic

activities in remodeling is governed *implicitly* by the mechanics through SED concentrations around resorption cavities, due to a notching effect [10,11].

Applied in an FEA computer simulation of a bone cube, starting from a conceptual morphology representing the post-mineralized fetal stage, the theory produces a mature trabecular structure, aligned to the external loads, as shown in the figure. The bone volume fraction of the cube initially rises sharply, overshoots, and then stabilizes, as also found with density measurements in growing pigs [12]. Other structural and dynamic predictions were realistic as well.

Based on these results we propose that the mechanical regulation of *modeling* and *remodeling*, *growth* and *adaptation* of trabecular structure can be explained with a unified theory, assuming coupling between osteoclasts and osteoblasts to occur only *implicitly* through the mechanics of load transfer. This implies that modeling and remodeling are just different expressions of the same metabolic cascade. Obviously, many complex biochemical cell-signaling events will play a role in the execution of these metabolic processes; the theory is only a regulatory framework. Our present work is directed at validating the theory by attempts to explain morphological expressions of normal and abnormal metabolic processes that are known to occur in reality.

HAS COMPUTER SIMULATION OF LOCOMOTION DELIVERED ALL ITS PROMISE IN THE PAST 20 YEARS ?

Christopher L Vaughan

Hyman Goldberg Professor of Biomedical Engineering, University of Cape Town, South Africa
Director: MRC/UCT Medical Imaging Research Unit, kvaughan@cormack.uct.ac.za

MODELLING vs SIMULATION

Computer modelling and simulation of locomotion have been utilised by biomechanics researchers for over three decades (Vaughan, 1984). Although often used synonymously, the terms do have different meanings:

Computer modelling refers to the setting up of mathematical equations to describe the system of interest, the gathering of appropriate input data, and the incorporation of these equations and data into a computer program.

Computer simulation is restricted to mean the use of a validated computer model to carry out “experiments”, under carefully controlled conditions, on the real-world system that has been modelled.

It is clear that computer simulation cannot take place without first developing a computer model. Some of the advantages of computer simulation in locomotion research include: safety; time; optimal performance can be predicted; expense; and the ubiquitous availability of microcomputers. However, there also some important limitations: validation is difficult (Panjabi, 1979); advanced mathematics are often required; and the results can often be difficult to translate into practicality.

Almost two decades ago, I stated: “Of one thing we can be certain: the power of computers, particularly the readily available and portable microcomputer, will expand beyond all recognition. We can certainly look forward with confidence to the exciting challenges and benefits that computer simulation of human motion will bring” (Vaughan, 1984). The purpose of this paper is to review the progress that has been made in both the technology of computer simulation and its application to our understanding of locomotion.

THE PROGRESS IN TECHNOLOGY

Whilst the earliest studies on computer simulation of locomotion were performed on mainframe computers, and hand-held calculators have been used in some simple cases (Vaughan, 1983), the vast majority of models have been implemented on personal computers. The changing face of the microcomputer is illustrated in the table above which compares the vital statistics of the original IBM PC in 1981 with its direct descendent, an entry-level machine 20 years later. In all categories, except boot-up time, the improvements have been dramatic, by two or more orders of magnitude.

There have also been outstanding software tools that have become available: SIMM by MusculoGraphics, ADAMS by Mechanical Dynamics, SD/FAST and DADS (Pandy, 2001).

Vital Statistic	1981	2001
CPU speed	4.77 MHz	933 MHz
RAM	64 KB	128MB
Storage	160 KB floppy drive	20 GB hard drive, CD-R, 1.44MB floppy drive
Display	11.5” monochrome text monitor	17” graphic monitor with 16.7 million colours
Operating System	DOS 1.0	Windows 2000
OS Requirements	16KB	32 MB
Boot-up Time	16 seconds	51 seconds
Price	\$3,000	\$1,500

THE PROGRESS IN SIMULATING LOCOMOTION

Locomotion researchers have been the first to embrace cutting edge technologies: (1) *artificial neural networks* have provided insight into the linkage between control and effect, and neuromuscular stimulation (Vaughan, 2002); (2) *dynamic optimisation* has predicted novel and emergent behaviour, including muscle excitation patterns based on minimising metabolic cost (Pandy, 2001); (3) *3D visualisation* has allowed a unique view into the complex integration of EMG, kinematic and dynamic variables; and (4) *finite element analysis* has demonstrated the temporal effects of mechanical loading on bones and other tissues.

There is no doubt that the insights we have gained from computer simulation over the past 20 years have provided startling insights that would not otherwise have been possible. These relate to: basic theories of bipedal gait; the relationship between mechanical energy and muscle coordination strategies; the biomechanical consequences of soft tissue surgery; and the effect of design parameter changes on joint replacement implants. In conclusion, the answer to the question posed by this paper is a resounding “yes”. It will certainly be interesting to see what the next 20 years bring.

FEATURE OF ARTERIAL BLOOD FLOW ASSOCIATED WITH THE BIOLOGICAL FUNCTIONS

Kazuo Tanishita

Department of System Design Engineering, Keio University, Yokohama, Japan, tanishita@sd.keio.ac.jp

MACROSCOPIC APPROACH

The feature of arterial blood flow is characterized by the geometry and mechanical properties of vessel and its peculiar pulsatility, and is associated with the physiological and clinical implications. This motivated to study the fluid mechanics of arterial blood flow. Previously many fluid mechanical studies have been preceded by the idealistic geometries such as constant curvature, bifurcation, branching, taper and planer flow. This approach contributed to establish the fundamentals of the physiological fluid mechanics. For instance, the aortic blood flow is characterized by the strong curvature and intermittent flow waveform developing the peculiar secondary flow (1).

On the other hand, prospective studies became necessary, because they are directly correlated in a subject-specific manner. Recently we focused on the blood flow in the cerebral aneurysms based on the CT-images of patients to anticipate the possibility of rupture and intravascular surgery. We built anatomically realistic models of cerebral aneurysm by the photoforming method and measured the velocity profiles in the aneurysms by LDV and PIV methods. Figure 1 is one of the velocity profiles in the basilar tip aneurysm with small aspect ratio (depth/neck width) (2). This prospective study for the individual patient offers the pertinent information of aneurysm fluid mechanics that is required for the diagnosis and treatment of cerebral aneurysms.

Figure 1. Velocity vectors in the basilar tip aneurysm obtained by PIV

MICROSCOPIC APPROACH

The microscopic viewpoint is essential to understand the function of arterial blood flow, because many previous studies revealed the important bio-chemical process occurred in the endothelial cells and other vessel components associated with the shear stress stimulus by the blood flow. Firstly we focused on the macromolecule transfer process in the endothelial cells with the shear stress stimulus, because transport of macromolecule such as LDL causes to precede the atherosclerotic development. We measured the albumin uptake into the endothelial cells by confocal laser scanning microscopy and obtained the interesting feature of albumin uptake. At 10 dyne/cm², the shear stress

increased the albumin uptake by 30 %. The albumin uptake decreased in proportion as shear stress increased, and minimum uptake was quarter of the control value (3). This albumin uptake process is regulated during the mechano-transduction process and associates with the energy-consuming process in the mitochondria. This brings to measure the activating process of mitochondria by measuring the membrane potentials of mitochondria (4). Low shear stress (10 dyne/cm²) increased mitochondrial membrane potential by 30%. On the contrary, high shear stress (60 dyne/cm²) decreased it by 20%. This observation was consistent with the ATP-dependent albumin uptake into endothelial cells; in other words, the ATP synthetic activity is related to the albumin uptake into the endothelial cells.

The specific mechanisms of mechano-biological interactions alternating shapes and functions have not been fully identified in the individual cells, because of the lack of a detailed description of microscopic flow near the cell surfaces. We therefore developed the velocimetry using the expanded cell models and demonstrated the microscopic flow depending on the three-dimensional cell shape, then determined the wall shear stress distribution on cultured endothelial cells experimentally (5).

Responses of endothelial cells to shear stress due to blood flow are basically heterogeneous. Namely the shear stress distribution on a cell has close correlation not only with the surface geometry of the cell but also with that of surrounding cells, and varied from cell to cell (6).

CONCLUDING SUMMARY

Both macroscopic and microscopic viewpoints indicate that the arterial blood flow is closely involved in the biological function of blood vessels and its integrative viewpoint is essentially important.

INTRODUCTION

The oceans contain more than 50%, by mass, of life on earth. Understanding the locomotion of, nutrient uptake by, and interactions between aquatic organisms is important for fisheries predictions and global warming, for example. This talk will summarise a variety of problems in fluid mechanics and mass transfer in which the author has been involved and which in a small way contribute to the required understanding.

LOCOMOTION

Lighthill (1960, 1975) and Wu (1961) pioneered the analysis of undulatory fish swimming at large Reynolds number. Wu's was a two-dimensional, small-amplitude theory which took account of the vortex sheet shed at the trailing edge. The lateral fluid motions generated by the body undulations were necessarily in the plane of the flow; if the body were removed they would look like a series of vortices, though how they would be shed into the wake remains unclear. Lighthill's "elongated-body theory" was intrinsically three-dimensional and easy to extend to large amplitude, but ignored the effect of the vortex wake on the pressure distribution on the fish body. In this case the lateral fluid motions resembled more a series of potential dipoles in planes perpendicular to the fish centreline. Recent full computations using a panel method (Zhu et al, 2002) and recent experimental measurements (Müller et al, 1997) indicate that the Wu picture, although apparently much more idealised, is closer to the truth, at least for some fish species. The mechanism of vortex shedding is still an open question. Other recent work shows how to relate the pressure distribution around the swimming fish to the variable bending moments generated by the swimming muscles; fish body inertia is a crucial ingredient (Pedley & Hill, 1999).

Micro-organism swimming is a low-Reynolds-number problem. For most flagellates the simple resistive-force theory of Gray & Hancock (1955) is accurate enough, and can also be coupled to a description of the internal generation of bending moments, though there have been numerous more refined calculations. Similarly for ciliates, the envelope model (e.g. Blake, 1971) is accurate enough though more detailed theories can be performed.

NUTRIENT UPTAKE

The effect of a micro-organism's swimming on its nutrient uptake has usually been assessed as if the cell were being translated through the fluid at constant speed by an external force (Karp-Boss et al, 1996). The dimensionless mass transfer (Sherwood number, Sh) is estimated as a function of dimensionless speed (Peclet number, Pe). However, one might expect that the active movements of a cell's swimming

apparatus would stir the concentration boundary layer around the cell and enhance the mass transfer. We have investigated this question using the simplest possible (non-realistic) model of a swimming cell: a spherical squirmer (Lighthill, 1952; Blake, 1971). Indeed, at values of Pe that are not small, the nutrient uptake is considerably enhanced (Magar et al, 2002).

ENCOUNTER RATE

Both phytoplankton and the zooplankton that prey on them perform random walks, both by swimming and because the ocean is turbulent (weakly so except very near the surface). An over-simple formula for the encounter rate proposed by Rothschild & Osborn (1988) has been widely used. We revisited the problem, proposed a somewhat more well-founded formula and tested it successfully against a computational simulation of swimmers in a turbulent flow. We have also used it to predict capture rate – not the same as encounter rate because predators have a variable probability of capturing their prey once they have spotted them (Lewis & Pedley, 2000, 2001). Depending on the turbulence level there are two optimal hunting strategies, "cruise" and "ambush", both of which are found in Nature.

THE CONVERGENCE OF CARDIOVASCULAR GENOMICS AND ENDOTHELIAL BIOMECHANICS

The focal origin of atherosclerosis and its localization to predictable locations in the arterial tree is strongly correlated with regions of complex hemodynamics that include flow separation/reattachment and flow instabilities. The spatial and temporal distribution of forces acting at the haemodynamic interface, the endothelium, can be measured over regions of many cells, or for smaller groupings extending down to the single cell. Mechanotransduction in the endothelium therefore needs to be considered over several scale lengths. This presentation outlines spatial cell and molecular studies of haemodynamic force interactions with endothelial cells.

At a regional level, gene expression, protein organization, and functional differences are illustrated for the cell communication molecule *connexin43* in relation to shear stress gradients and flow separation *in vitro*. This is an example of one gene studied in many cells. Through the use of customized cardiovascular microarrays, the transcription of many genes as a function of regional haemodynamics can be measured by differential transcription profiling ("spatial genomics"). Recent developments in nucleic acid amplification techniques permits refinement to the study of smaller groups of cells. We surmise that the dynamic and large spatio-temporal gradients of shear stress may contribute to regional variability of gene expression *in vivo*.

The hemodynamic force-generating system itself operates over a range of length scales determined both by the geometry of the vasculature (bulk flow characteristics; \square m-cm) and the topography of the individual cells (force distribution; sub- \square m scale). The flow combines with cell micro-topography to distribute forces across the cell surface (sub- \square m) to cytoskeletal elements and connecting proteins (nm- μ m) involved in the mechanotransduction signaling and adaptive gene expression. Furthermore, individual cells are part of an interconnected monolayer capable of cell-cell communication extending over mm-cm. Information obtained at finer scales must therefore be integrated and understood in the context of larger scale events.

Structural and biochemical studies of endothelial mechanotransduction using living cells have provided some mechanistic insights relevant to the genomics studies. Atomic force microscopy defined the surface topography of endothelial cells permitting the calculation of shear stress distribution at subcellular distances over the cell surface. The use of fluorescent protein gene constructs (eg GFP) transfected into cells revealed positional displacement of the cytoskeleton in response to shear stress. And interference optical techniques allowed visualization of adhesion site dynamics in real time demonstrating basal responses to apical flow forces. These studies have led to the *decentralization model* of endothelial mechanotransduction:- hemodynamic forces are transmitted throughout the cell via the cytoskeleton to multiple sites where conversion of mechanical forces to electrophysiological, biochemical, and genetic responses occur. The decentralized model for subcellular haemodynamic responses is outlined and discussed.

STRUCTURE FUNCTION PROPERTIES OF BONE: THE INFLUENCE OF MECHANICAL AND BIOLOGIC STIMULI

Steven A. Goldstein, Ph.D.

Orthopaedic Research Laboratories, University of Michigan, Ann Arbor, Michigan

Investigators have been diligently studying the mechanical behavior of bone for more than 100 years and, specifically, searching to identify the mechanisms that guide its abilities to adapt to physical forces. While the potent influences of mechanical stresses on bone tissue behavior has been characterized and even quantified to a limited extent by a number of laboratories, the specific mechanisms associated with the translation of mechanical forces into regulatory signals mediating cell activity remain incompletely known. As a result, advances in the development of therapies for conditions that might be influenced by physical forces such as fracture healing, implant fixation and perhaps osteoporosis have been limited.

The purpose of this presentation will be to present a series of studies designed to characterize the hierarchical properties of bone and the influence that mechanical and potentially biologic stimuli have on these properties. From a mechanical perspective, the most striking feature of bone is its multi-scale organization. The precise morphology and architectural features at each level of hierarchy have been assumed to play a substantial role in bone's ability to minimize damage, repair rapidly, adapt to changes in physical and biochemical signals, and participate in mineral homeostasis. We have utilized a hierarchical paradigm to study the properties of bone in an effort to gain insight into its dynamic behavior. Our desire to characterize the structure function properties of bone is motivated by two specific interests: (1) to support approaches for the treatment of fragility disorders ranging from osteoporosis to osteogenesis imperfecta and, (2) to evaluate hypothesized mechanisms through which bone receives and adapts to mechanical stimuli. The rationale for this latter motivation comes from the fact that bone extracellular matrix serves as the medium through which all mechanical signals are transmitted to the included cells.

The initiation of bone formation involves the commitment, clonal expansion, and differentiation of progenitor cells, followed by the expression and organization of extracellular matrix proteins in a manner which results in the deposition and eventual mineralization of the tissue. In an effort to quantitatively study the influence of local mechanical or biological stimuli on bone formation, remodeling and adaptation, we have utilized several in vivo models in which both the mechanical and biologic environments were experimentally controlled. The models have included a novel hydraulically activated bone chamber, fracture repair studies that utilize specialized external fixators that allow application of controlled perturbations, as well as, in vitro organ culture systems that enable isolated mechanical or biologic effects to be measured. In all of these studies, we have attempted to quantify and control the local stress or biochemical

environment while measuring outcomes across several hierarchical scales of the tissue. These studies have been extended to test whether mechanical factors also play a role during growth and development of the skeleton.

Results of these studies demonstrated that mechanical forces play an important epigenetic role in regulating shape and morphology of bone structure. Newly formed bone is particularly sensitive to applied mechanical forces which appear to trigger integrin mediated signaling cascades incorporating the formation of focal adhesions, and enacting both src tyrosine kinase and MAP kinase activity. We have also found that we can stimulate analogous bone formation cascades through the local delivery of regulatory biofactors using gene-based technologies. Taken together, these studies have provided some insight into the strategies that may be employed by bone related cells to regulate matrix properties and organization.

ACKNOWLEDGEMENTS

This paper will summarize work from a large group of investigators and their trainees. In particular, I acknowledge Dr. Maria Moalli and Dr. Barbara McCreadie from the University of Michigan. The work was funded by NIH (AR20557, AR34399, AR31793, AR46024), Selective Genetics, Inc., and The Whitaker Foundation.

THE SMALL PROTEOGLYCAN IN TENDON

Kathryn G. Vogel

Dept. of Biology, The University of New Mexico
Albuquerque, NM 87131 kgvogel@unm.edu

INTRODUCTION

It has been nearly 20 years since we undertook the isolation of proteoglycans from bovine deep flexor tendon during my sabbatical year in Sweden. We found that the predominant tendon proteoglycan was a small dermatan-sulfate PG and, of greatest interest, that the core protein of this tendon proteoglycan had a remarkable ability to inhibit the *in vitro* fibrillogenesis of both type I and type II collagen (Vogel et al 1984). This small tendon proteoglycan was later given the name decorin (because it appeared to “decorate” collagen fibrils) and it is now only one of a family of proteoglycans in which the core proteins are characterized by the presence of repeating sequence motifs with high leucine content. Biglycan, fibromodulin and lumican are other members of this family of small leucine-rich proteoglycans, and most of these have a similar ability to affect collagen fibrillogenesis. During this talk I will discuss some of the observations which indicate that decorin plays an important role in regulating the orderly assembly of the extracellular matrix, and therefore the biomechanical properties, of many tissues - including tendon and ligament.

DECORIN BINDS TO COLLAGEN

That decorin binds to collagen was easily demonstrated. It has been much more difficult to figure out just what part of the decorin core protein binds to collagen, and to what part of the collagen it is bound. The decorin core protein is modeled as having a three-dimensional shape like an arch. It is believed that this arch or U-shaped molecule wraps itself crosswise around the long, skinny, collagen triple helix. The correct three-dimensional shape of decorin is necessary for efficient binding to collagen, and regions of decorin core protein important in binding have been identified by recombinant techniques. There are probably multiple points of interaction in more than one of the leucine-rich repeats. The site on the type I collagen molecule to which decorin binds is near the C terminus, within the CB6 fragment of the $\alpha 1(I)$ chain (Keene et al, 2000). Because this location is very close to one of the major intermolecular cross-linking sites of collagen heterotrimers it is hypothesized that decorin might be in a position to regulate collagen fibril stability.

DECORIN AFFECTS COLLAGEN FIBRILLOGENESIS

Purified soluble collagen placed in permissive conditions of salt concentration and temperature will self assemble into fibrils that show the same fine structure as the collagen in tissue. This shows that proteoglycans are not necessary for

fibrils to form. However, when decorin is added to soluble collagen the fibrils form more slowly and are thinner in diameter. The core protein has this effect on collagen fibrillogenesis even after the GAG is removed, but the free GAG does not affect fibril formation *in vitro*. The GAG chains of decorin can be visualized by electron microscopy as filaments sticking out from the surface of the collagen fibril. This image suggests that GAG chains coat the surface of the fibril and could inhibit the lateral association of fibrils. On the other hand, these GAG chains might interact with each other and thereby enhance fiber stability. Collagen fibers formed in the presence of decorin showed an increased ultimate tensile strength compared to fibers formed without added decorin, perhaps as a result of decorin facilitating fibrillar slippage during deformation (Pins et al., 1997). So which is it? Do the GAGs of decorin stick fibrils together, or do they keep them apart? For best function should tissues have more decorin, or less?

THE ROLE OF DECORIN IN TISSUE

That decorin plays a role in fibrous tissue organization was demonstrated by the fragile skin of the transgenic mouse lacking decorin expression (Danielson et al, 1997). In addition, the collagen fibrils of tendon in this knock-out mouse showed large, irregular profiles in cross section and non-uniform axial mass distribution. This observation could result from lateral aggregation of fibrils and is consistent with the *in vitro* result showing that added decorin promotes thinner fibrils, perhaps by inhibiting lateral aggregation. Because thicker collagen fibrils are correlated with greater tensile strength, it is argued that removing decorin could promote the maturation of healing tendon or ligament. In contrast, increased decorin content might disrupt collagen fibers (not a good thing for tendon). On the other hand, added decorin might bind and thus sequester growth factors that would otherwise enhance the formation of weak scar tissue or fibrous adhesions (a good thing for tendon healing).

MOLECULAR BASIS OF CELLULAR RESPONSES TO MECHANICAL FORCES

Shu Chien

Departments of Bioengineering and Medicine and

La Jolla, California 92093-0427, U.S.A.

There is increasing evidence that cells can sense and respond to mechanical stimuli such as pressure and flow, as well as chemical stimuli such as hormones and growth factors. The endothelial cells (ECs) in blood vessels play significant roles in regulating vascular functions in health and disease. The fluid shear stress resulting from blood flow can modulate EC functions by activating sequentially the mechano-sensors, intracellular signaling pathways, and specific transcription factors to modulate gene expression and protein, and hence cellular functions. The vascular endothelial growth factor receptor (VEGFR) on the luminal side of ECs and integrins on the abluminal side have been shown to be mechano-sensors. Other potential EC membrane mechano-sensors are G-proteins, ion channels, and intercellular junction proteins. The activation of these mechano-sensors by mechanical stimuli such as shear stress leads to the triggering of phosphorylation cascades of signaling molecules. For example, the Ras-JNK signaling pathway mediates the shear stress-activation of the expression of monocyte chemotactic protein-1 (MCP-1) gene and protein in response to shear stress. A sustained application of laminar shear stress results in only a transient activation of this signaling pathway

and a transient MCP-1 expression followed by its down-regulation. Sustained laminar shear stress also activates the genes that inhibit vessel wall growth. When ECs are subjected to complex flow patterns simulating these seen in the branch points, the down-regulation of MCP-1 in response to sustained flow does not occur, and the sustained activation of genes such as MCP-1 in the areas with complex flow contributes to atherogenesis. Furthermore, EC mitosis and apoptosis are accelerated in the areas with complex flow. Such accelerated cell turnover leads to an enhanced macromolecular permeability. The temporal and spatial variations in shear stress and flow pattern play important roles in endothelial functions such as monocyte chemoattraction, macromolecular permeability, and cell migration, and hence can play important roles in tissue engineering. The results of interdisciplinary studies at the interface of biomedical sciences and engineering mechanics help to enhance our understanding of the fundamental process of mechano-chemical transduction and the pathophysiological mechanisms underlying cardiovascular diseases.

INJURIES IN SPORT: REDUCTION THROUGH A BIOMECHANICAL INTERVENTION

Bruce Elliott

The School of Human Movement and Exercise Science, The University of Western Australia, Australia

Bruce.Elliott@uwa.edu.au

INTRODUCTION

Research which identifies causal mechanisms associated with injury requires input from many specialists. Winston et al. (1996) proposed that the biomechanist should be an integral part of what they termed 'epidemiological research', if injury control mechanisms were to be understood. This would seem to be essential as most injuries have a mechanically related etiology. van Mechelen et al. (1992) reviewed risk factors involved in sport and suggested a four step prevention process, namely:

1. The collection of epidemiological data (nature, extent and severity of injury) to identify the problem
2. Identify the etiology of the problem
3. Educate the relevant population as to the techniques needed for prevention
4. Evaluate the effectiveness of preventative measures.

This paper will discuss the role of biomechanics in the above approach, as it is applied to reducing the incidence of back injuries in the cricket fast bowler.

EPIDEMIOLOGY

Epidemiological data have clearly shown that the lumbar spine of the cricket fast bowler is the area at greatest risk of injury. The incidence of lumbar stress fractures and disc abnormalities was particularly high in this population of sportspeople.

ETIOLOGY

A prospective and several longitudinal studies using videography and magnetic resonance imaging (MRI) have shown that shoulder alignment counter-rotation during the delivery stride was associated with the development of lumbar stress fractures and disc degeneration (Foster et al., 1989; Elliott et al., 1992; Burnett et al., 1996).

EDUCATION

An annual half day clinic and 6 small group coaching sessions spread over the season were held to assist the bowlers reduce the level of shoulder counter-rotation over a 3-year period. All players had the level of shoulder counter rotation assessed from video and disc status determined from a MRI scan of the lumbar spine on an annual basis.

EVALUATION

Data showed that small group coaching significantly reduced the level of shoulder alignment counter-rotation in young fast bowlers from 35.4° to 21.3° over the 3-year period. The incidence and progression of lumbar disc degeneration were also reduced in parallel with this decreased shoulder counter rotation. Figure 1 shows the differences in MRI data from this study with that of Burnett et al. (1996), where young players were tracked for 3-years with no coaching intervention.

APPLICATION OF MODELS TO UNDERSTAND THE INTEGRATION OF CORONARY VASCULAR CONTROL MECHANISMS.

Jos AE Spaan

Department of Medical Physics, CardioVascular Research Institute Amsterdam
Academic Medical Center, University of Amsterdam
Meibergdreef 15, 1105 AZ, Amsterdam, the Netherlands.

INTRODUCTION

Coronary blood flow must meet the demands of the heart for supply of nutrients for a large range of cardiac work. In a healthy myocardium such is not a problem and resistance vessels can dilate to increase coronary flow by a factor 4 over the value at rest. This flow reserve, however, can be compromised by disease in the larger coronary arteries as arteriosclerosis or in the microcirculation.

The control of coronary flow is the result of interactions of several mechanisms some related to control of vascular smooth muscle tone in resistance vessels and others to mechanical factors related to heart contraction. These mechanisms do vary in nature and strength over the different types of vessels in the arterial tree and different locations in the myocardium. In order to arrive at a clear picture of the interaction between these different mechanisms and at different locations within the vascular tree, models are required.

MECHANICAL FORCES

The compressing force of cardiac contraction reduces intramural blood volume periodically causing the coronary arterial and venous flow to be phasic with about a 180° phase shift. On average, intramural blood volume is lower at a higher HR resulting in an increased coronary resistance component. These compressive forces have a stronger effect on the inside of the heart muscle (sub-endocardium) than on the outside (sub-epicardium). Compressive forces are related to a change of the stiffness properties of the myocardium when the heart goes from diastole into systole and to tissue pressure related to Left Ventricular pressure which transmission through the tissue depends on wall stiffness as well.

The distending force of arterial pressure becomes especially clear when dynamic pressure- flow relations are studied in a non-beating myocardial preparation. That coronary resistance depends on arterial pressure is generally accepted but is mostly implemented in models by taking a constant resistance with a value dependent on the mean pressure of the phasic pressure signal. Interpretation of pressure-flow Bode plots demonstrate clearly a dependence of arterial pressure but interpretation with a model of resistance constant during the pressure variation underestimates intramural compliance 10-20 fold. Including the variation of resistance during the pressure wave results in much better estimates of intramural

compliance. This obviously complicates modeling the resistance distribution in the coronary vasculature but is a necessity when one wants to relate measured signals to physical properties of the circulation.

VASCULAR RESPONSES

Normally smooth muscle tone is continuously adjusted as to match flow to myocardial oxygen consumption and adjusting for flow compromising mechanisms like cardiac contraction and disease in the larger coronary arteries. There are many processes involved in this tone regulation and their effect on local tone are dependent on the vessel segment location within the tree. Since overall coronary resistance is adjusted in arteries between 20 and 400 μm the interactions of these mechanisms in vessel segments and between segments along the tree have to be known.

Models are used here to translate findings from isolated resistance artery studies to studies on the intact heart. A typical example is the interaction of metabolic factors active on the smallest arterioles and flow dependent dilation of upstream vessels having myogenic tone. Hence, flow is a signal integrating downstream and upstream regulatory processes.

DISCUSSION

In the development of comprehensive understanding of coronary blood flow regulation and how this regulation is compromised by disease, a distributed model of the intramural vasculature is needed. This vascular tree should consist out of segments having control properties with input-output relations allowing for inter-segmental communication of control signals and mechanical interaction with the contracting muscle.

BIOMECHANICS OF VERY SOFT TISSUES

Lynne Bilston

Prince of Wales Medical Research Institute
Barker St, Randwick, 2031, Sydney, Australia
l.bilston@unsw.edu.au

INTRODUCTION

Understanding and characterising soft biological tissues is an important part of biomechanics. The “very” soft biological tissues, such as the central nervous system and abdominal organs, have been less thoroughly characterised, and modelling efforts have been frustrated by the complexity of their mechanical responses. Here, I describe our efforts to both measure the viscoelastic properties of some of these tissues, and discuss modelling progress and remaining challenges.

METHODS

Fresh tissue samples (brain, spinal cord, kidney and liver) were obtained soon after death, in order to minimise the effects of biological decay on measured tissue properties. All tissues were bathed during transport, preparation and testing with an appropriate fluid to avoid dehydration. Shear tests were conducted in a Bohlin shear rheometer. Tensile tests were conducted in a benchtop textile testing machine. Elongational/compression tests were conducted in a custom-designed lubricated squeeze rheometer. There has been considerable debate about the use of preconditioning, however it has two great advantages - it produces a repeatable, predictable initial stress state in the tissue at the beginning of testing, and reduces the variability in the test data obtained. It was used in all these data discussed here. Coarse sandpaper on the platens in shear tests was used to prevent slip. Tensile specimens were bonded between tabs using cyanoacrylate adhesive. Testing protocols include shear oscillation, stress-relaxation, creep tests, and constant strain rate tests. Together, this battery of tests allows sufficient data to be collected to determine the linear and nonlinear viscoelastic properties of the tissues.

RESULTS AND DISCUSSION

For all the tissues, the linear viscoelastic limit was found to be of the order of 0.1% strain. Clearly, this is such a small strain that these tissues must be considered to be nonlinearly viscoelastic for all practical loading levels. Moreover, they all demonstrate significant strain-rate sensitivity, as shown in Figure 1. Other key characteristics include the observation that their relaxation moduli and the long-term modulus are dependent on both strain and also, in some cases (eg spinal cord), loading rate, as shown in Figure 2. Indeed, even the shape of the relaxation moduli curves depends on strain, rendering the tissues strain-time inseparable. Various approaches to constitutive modelling for these tissues have been investigated, with varying degrees of success. What is clear, however, is that the simple linear and quasilinear models

that have been commonly used for ligaments and tendons are inadequate for these tissues, because they are nonlinear, and not strain-time separable. Nonlinear differential constitutive models have been used with some success, but their applicability is limited because of the complexity required to accurately reproduce the very complex mechanical response of these tissues. So far, no models of these tissues have incorporated the hydraulic stiffening due to perfusion in living tissues.

Figure 1: Shear response of bovine brain tissue.

Figure 2: Relaxation moduli at 5% strain for rat spinal cord tissue, showing long-term moduli dependent on strain rate.

SUMMARY

Very soft biological tissues pose experimental and theoretical challenges. They are very nonlinear, often strain-time inseparable, and it is difficult to capture all of their complex mechanical behaviour in a constitutive model that is not prohibitively complex. Future challenges include obtaining consistent constitutive models for multiple types of loading (shear, elongation, etc) across a broad range of loading rates, determining the structural mechanisms for their complex behaviour, and measuring and modelling the effects of perfusion on tissue properties.

EFFECT OF VISCOUS FLUID STRESSES ON CELLS AND BIO-ARTIFICIAL CAPSULES

Dominique Barthès-Biesel

Biomécanique et Génie Biomédical, UMR CNRS 6600, Université de Compiègne, Compiègne, France

dbb@utc.fr

INTRODUCTION

A capsule consists of an internal medium (pure or complex liquid), enclosed by a deformable membrane. In Biomedical Engineering, bio-artificial capsules are used in drug delivery systems, artificial organs or cell therapy. A liquid filled capsule is also an appropriate model for a simple cell such as a red blood cell. When such particles are suspended in a flowing liquid, they are deformed by viscous fluid stresses and may sometimes burst. The modeling of this process has two main applications. One is the prediction of cell response to physiological flows and the diagnosis of pathological states. The other is bio-artificial capsule design, with appropriate control of the deformation and breakup. The motion and deformation of a capsule in flow depends on the stress-free initial geometry, the membrane mechanical properties and the rheology of the internal medium. It is the aim of this presentation to study the effect of such intrinsic physical properties on the deformation and burst of cells and bio-artificial capsules suspended in different flow fields.

MEMBRANE MECHANICS

A major issue is the determination of the mechanical properties of the membrane, as these control the resistance of the capsule to applied stresses. Those properties have to be inferred from experiments such as squeezing between two plates for large capsules or micropipette aspiration for cells. In many cases the membrane is very thin and treated as a two-dimensional solid with hyperelastic or visco-elastic properties. Popular membrane constitutive laws include the Mooney-Rivlin (MR) law that assumes that the membrane is an infinitely thin sheet of a 3D incompressible material. For biological membranes, which are almost area incompressible Skalak et al.(1973) law (SK) is usually preferred as it accounts for shear deformation and area dilatation of the material. Recent experiments have shown that gelatin membranes reinforced with a polymer network, are also well described by SK law where the area dilatation and shear modulus are of the same order. However, MR and SK laws lead to quite different membrane behaviors for large deformations (Barthes-Biesel et al. 2002).

MOTION OF A CAPSULE IN FLOW

The general problem consists in analyzing the motion of a capsule freely suspended in another liquid subjected to a known flow field in the limit of small Reynolds numbers. Two free surface flow problems (motion of the internal liquid and of the suspending fluid) and a solid mechanics problem (deformations of the membrane) must be solved simultaneously. An efficient method consists in recasting the Stokes equations in integral form and in using the boundary integral technique. The effect of the membrane rheology on the capsule response can then be assessed by comparing two capsules subjected to the same flow but with different membrane constitutive laws.

Unbounded linear shear flow

Results have been obtained for capsules suspended in elongational flow and in simple shear flow. A capsule with a SK membrane can sustain higher shear stresses than a capsule with a MR membrane. The latter always bursts when the shear stress exceeds a critical value. The model also provides values of the elastic tensions in the membrane and can thus help to predict burst for a given failure criterion of the material.

Pore flow

A capsule is forced to flow through a long cylindrical tube (filtration process or microcirculation). The deformed profile of the particle, the steady pressure drop and center of mass velocity can be computed as functions of geometry, flow rate and membrane rheology. The model predictions are in very good agreement with recent experimental observations of the flow of an artificial capsule in a tube. They can also be used to analyze filtration data on red blood cells in a cell transit analyzer, or to provide a model for erythropoiesis (Diaz et Barthès-Biesel 2002).

INFRASTRUCTURE FOR THE IUPS PHYSIOME PROJECT

Peter Hunter

Chair, IUPS Physiome Commission.
Bioengineering Institute, The University of Auckland, Auckland, New Zealand
p.hunter@auckland.ac.nz

INTRODUCTION

In 1998 the International Union of Physiological Sciences (IUPS) established the “Physiome Commission” whose aim is to: *“Promote anatomically and biophysically based computational modeling for analysing integrative physiological function in terms of underlying structure and molecular mechanisms. Closely coupled to this is the need to establish web-accessible physiological databases dealing with genomic data through bioengineering data to clinical data.”* This talk will present an overview of the current status of the IUPS Physiome Project and, in particular, current plans for developing an infrastructure and industry consortium to support the project on a larger scale than has previously been possible.

METHODS

Ontologies and markup languages

An ontology is the vernacular and rules needed to describe a body of knowledge and a ‘markup language’ provides the structure for capturing this and other information relevant to describing a mathematical model in a machine readable form. The ontologies (and associated markup languages) being developed for the Physiome Project are:

- The mathematical modelling framework for describing the boundary value problem associated with some aspect of physiological function (PhysioML).
- The parameterized anatomical description of organs and organ systems (AnatML).
- The description of tissue composition, structure and function (TissueML).
- The description of cell composition, structure and function (CellML).

Model databases

A large variety of models of physiological function have been published by the worldwide community of bioengineers and physiologists. These models are often difficult for anyone other than the originator to use and are usually difficult to use in combination with other models. The development of the markup languages for encapsulating these models at the cell, tissue, organ and whole organism level will help in overcoming these obstacles but clearly there is also a need for databases of such models which can be downloaded freely from the web. Three-dimensional finite element models of all major anatomical structures in the body are currently being developed (see www.bioeng.auckland.ac.nz) and this should be complete in 2-3 years. About 100 models of cell electrophysiology, signal transduction pathways and metabolic pathways have now been created in CellML format and are

available from www.cellml.org. A primary focus for the Physiome Project over the next two years will be completing the TissueML markup language and establishing a database of tissue models.

Web interfaces and simulation tools

The databases of publications, experimental data and models for the Physiome Project will be substantial. The accessibility and usefulness of these databases will depend crucially on the software tools for accessing them via the web and displaying information. A software development effort is now underway to develop open-source tools for this purpose. Equally important will be access to simulation packages for running the models. A number of such packages are available freely for academic use (see www.bioeng.auckland.ac.nz for a list) and the emphasis now is on developing application programming interfaces (APIs) for the markup languages to allow the authors of these simulation packages to add the code needed to read the markup language files. A related issue is access to high performance computing and in particular ‘grid computing’ (or ‘e-Science’ as it is called in the UK). Web interfaces have been developed to access the PhysioML files defining a model, to run the model on a high performance computer, and to display the results via visualization software.

Model validation

The primary criterion for including a model in the database of markup language files is that it has been published in a refereed journal. It is likely, however, that further curation of this database will be necessary to provide expert judgement on the benefits and limitations of all models in a given area of physiology. A proposal for how this is done and by whom will be presented.

EXPLORING STRUCTURE/FUNCTION RELATIONSHIPS IN ARTICULAR CARTILAGE USING NOVEL EXPERIMENTAL APPROACHES

Neil Broom

Biomechanics Laboratory, School of Engineering, University of Auckland, New Zealand, nd.broom@auckland.ac.nz

ABSTRACT

The durability of most high performance engineering components derives from the fact that they are precisely shaped from materials with clearly defined physical properties and in which structural inhomogeneities and anisotropies are largely eliminated (directional composites are an obvious exception). In such components maximum service stresses can be predicted to a high degree of accuracy. They are designed to function almost exclusively over a quite narrow deformation range (typically strains of less than 0.001). Importantly, this involves mostly one type of deformation mechanism - purely elastic stretching of interatomic or intermolecular bonds in mostly regular crystalline arrays. Stress singularities at interfaces are generally minimized by ensuring material property compatibility, thus allowing the engineer to predict accurately and thus control the stresses to which a crucial component is exposed. Also, conventional materials are generally put into service in a condition of minimal internal residual stress, again so as to enhance the engineer's control of the component's total stress environment.

Almost everything about articular cartilage transgresses these engineering rules. Between its major zones the tissue is highly inhomogeneous and anisotropic at the macro, micro and ultramicroscopic structural levels. Even within each major zone there are major structural inhomogeneities and strong directional effects in terms of both intrinsic extensibility and ease of rupture. Major structural/mechanical discontinuities exist between the surface layer and the underlying general matrix and, most severely, between cartilage and its much more rigid substrate – the subchondral bone. Compared to a conventional precision-engineered component the anatomical environment in which cartilage is required to function over a life time is somewhat imprecise.

Cartilage is also subjected to a wide range of loading rates during normal function. Quite different mechanisms of deformation operate when cartilage is loaded either dynamically or statically. At high rates the tissue behaves approximately as a large-strain elastic material. At lower rates high levels of deformation are attainable via a mechanism involving the time-dependent outflow of fluid through a matrix of ultra-low permeability and this can be approximated as a process of consolidation. Large-scale deformation and rearrangement of the matrix components occurs under such conditions. Cartilage in its unloaded state is also pre-stressed. Residual stresses are built into its structure by virtue of the swelling of the proteoglycan component against the constraining 3-dimensional network of collagen fibrils. Its total response to an external load is therefore a combination of both the stiffness generated by this intrinsic swelling potential

and the resistance to fluid outflow. Articular cartilage is thus a highly complex load-bearing material, and it possesses remarkable durability.

This talk will describe a number of novel experimental approaches we have developed in our biomechanics laboratory both to reveal and quantify the complex structural/mechanical properties of normal articular cartilage and to track what appear to be significant changes in these properties resulting from ageing and degeneration. Specifically the deformation and rupture properties of the articular surface, the relationship between fibrillar network configuration, directional rupture behaviour and swelling propensity of the general matrix, and the toughness or resistance to fracture of the osteochondral region will be discussed.

TENDON EXCURSION AND GLIDING MECHANISM

K. N. An, C. F. Zhao, M. E. Zobitz, P. C. Amadio

Biomechanics Laboratory, Division of Orthopedic Research
Mayo Clinic/Mayo Foundation, Rochester, MN 55905

As integral components of the musculoskeletal system, the primary function of tendons is to transmit muscle force to the skeletal system. Tendon excursion and the gliding mechanism of the tendon, which have direct clinical significance, will be addressed.

TENDON EXCURSION

A pulley type system keeps the tendon path close to the bone when the tendon crosses a joint. In normal anatomy, there is an intimate relationship between tendon excursion and joint rotation that maintains the mechanical advantage of the tendon while preserving the passive and active muscle tension during joint motion. Disturbance of the normal pulley-tendon unit could potentially lead to abnormal joint motion and muscle function. Tendon excursion influences the functional length of the muscle-tendon unit. Due to the length-tension interaction of the muscle contraction, the potential tension generated by the muscle will therefore be influenced by the joint position and tendon excursion. For the postoperative treatment of flexor tendon injury, it has been demonstrated that synergistic wrist motion could eliminate tendon slackness in the palm and improve tendon excursion during passive finger joint motion.

GLIDING RESISTANCE

A tendon sliding through the pulley is analogous to a belt wrapped around a fixed mechanical pulley. Assume that the total arc of contact between the belt and pulley is ϕ , and the tensions on the belt on each side of the pulley are F_2 and F_1 . If the impending motion of the cable is from F_1 to F_2 , then F_2 is greater than F_1 , $F_2 = F_1 e^{\mu \phi}$, where μ is a frictional coefficient. The frictional force $f = F_2 - F_1$.

Based on this theoretical consideration, an experimental system was developed that allows direct measurement of friction at the tendon-pulley interface. To allow tendon excursion, the force applied to the tendon needs to overcome the finger resistance, which includes internal sources such as friction, and external sources such as resistance due to joint stiffness or edema. These sources, combined, make up the work of flexion (WOF). A device has been further constructed which can precisely evaluate these components and be a

reliable tool for the evaluation of finger function after flexor tendon repair in experimental model.

LUBRICANT

Hyaluronate or proteoglycan, in the synovial membrane and the matrix of the tendon, may act as a boundary lubricant, facilitating the gliding by reducing the resistance. The gliding resistance increased significantly after the tendon had been treated with a hyaluronidase solution.

The gliding ability of the flexor digitorum profundus tendon and of the palmaris longus tendon through the A2 pulley was compared. The average gliding resistance between the palmaris longus tendon and the A2 pulley was found to be greater than that of the flexor digitorum profundus tendon. Intrasynovial tendons possess a boundary lubricant on their surfaces. The extrasynovial tendon does not have a synovial membrane, instead it has a paratenon of loose connective tissue.

Further investigation was performed to improve the gliding surface using hyaluronic acid (HA). The gliding resistance of extrasynovial tendons treated with chemically modified HA remained significantly lower than that of tendons treated either with saline or unmodified HA.

TENDON REPAIR AND REHABILITATION

Different suture repair techniques result in various amounts of gliding resistance and thus, the amount of excursion during post-operative rehabilitation can be affected. An in vivo study has been performed comparing a synergistic wrist motion therapy to an immobilized tendon. The results showed the adhesion grade and the adhesion breaking strength in the synergistic wrist motion group was significantly less than those of the wrist fixed group.

MECHANICAL STIMULI AND ENDOTHELIAL CELL MECHANICS

Masaaki Sato

Biomechanics Laboratory, Graduate School of Mechanical Engineering, Tohoku University, Sendai, Miyagi, Japan
sato@biomech.mech.tohoku.ac.jp

INTRODUCTION

It is well known that endothelial cells respond to mechanical stimuli and show changes in cytoskeletal structure, mechanical properties of cell body, cell shape, cell functions, and so on (Davies, 1995). One of those responses are prescribed by mechanical properties of the cell such as stiffness, elasticity, and viscosity. Measurements of the response of cell to mechanical stimuli can provide information on the structure of cytoskeleton, focal adhesion and cell membrane. However, less frequently examined are the mechanical properties of the cells, the cytoskeletal components and the organelles. We have been interested in and have studied the mechanical responses of cultured endothelial cells to flow-imposed shear stress (Sato et al., 1987, 1990, 2000; Kataoka et al., 1998).

In this presentation I would like to show you that the changes in dynamic behavior of actin filaments in living endothelial cells and mechanical stiffness measured by AFM by exposing to shear stress.

CYTOSKELETAL RESPONSES IN LIVING CELLS DURING EXPOSING TO SHEAR STRESS

A plasmid encoding GFP fused to the amino terminus of actin (the vector was cordially provided by Dr. G. Marriott, Max-Planck-Institute for Biochemistry, Germany) was transfected into cultured bovine aortic endothelial cells (BAECs) using a liposomal method. All experiments were performed with confluent monolayers of cell. Cells expressing GFP-actin were observed in flow condition. Fluid shear stress of 2 Pa was applied using the parallel plate flow chamber. Distribution and dynamic behavior of actin filaments in a cell were observed under a confocal laser scanning microscope and the images were recorded on a computer through a high resolution digital CCD camera.

It was already confirmed by separate experiments that localization of GFP-actin coincided with the F-actin filaments stained by rhodamine-phalloidin in ordinary method. The cytoskeletal reorganization during endothelial exposure to flow preceded changes in cell shape. In one example, actin bundles located upstream side in a cell were disrupted and started to align to the flow direction within 30 min. Fine network structure of actin filaments at the downstream side was partly destroyed within 60 min and became the thick bundles along the peripheral edges within 90 min. These bundles started to align to flow direction at around 240 min. Since the focal adhesion proteins, integrins, should play important roles in reorganization of actin filaments, we need to simultaneously observe the dynamic movements (Urbich et al., 2000). At present, we also need more examples to conclude

general moving process of actin filaments in shear stress condition.

CHANGES IN STIFFNESS OF SHEAR EXPOSED CELLS MEASURED BY AFM

Morphology and mechanical properties of BAECs were measured, using a novel atomic force microscope (AFM) system, developed in our laboratory, in conjunction with an inverted confocal laser scanning microscope (Sato et al., 2000). We used this system to examine endothelial cell both in static cultures and exposed to a shear stress of 2 Pa. Initially, the three-dimensional topography of a cell was measured by the AFM and a location was selected for the subsequent measurement of the mechanical response of the cell.

The surface of statically cultured cell was smooth. The cell height was significantly decreased by exposure to shear stress. A relationship between external force, F , and the indentation depth, δ , was obtained for several different locations on a cell. This force-indentation response was modeled using a quadratic equation, $F=a\delta^2+b\delta$, indicating that two parameters, a and b , will be constants which are representative of the mechanical response. Endothelial cells cultured at static conditions demonstrated a polygonal shape and less stiff mechanical characteristics around the nucleus compared to those at peripheral regions. The stiffness of the endothelial cells exposed to shear stress increased with the duration time of exposure. At 6-hour exposures, the stiffness was higher at upstream side of the cell than the downstream side. However, after 24-hour exposure, the stiffness was similar on both sides of the cell. These changes in the stiffness of endothelial cells when those are exposed to shear stress were suggested to correspond with the distribution of stress fibers in the cell.

CRITICAL ISSUES IN THE BEHAVIOR OF HUMAN SKELETAL MUSCLE DURING SSC ACTIVITIES

Paavo V. Komi

Neuromuscular Research Center, Department of Biology of Physical Activity, University of Jyväskylä, Finland

It is believed that stretch-shortening cycle (SSC) in human skeletal muscle is the only normal way of muscle function (e.g. Komi, 2000). Isolated forms of isometric, concentric or eccentric actions do not occur often in real life. Running, walking and hopping are typical examples in human locomotion of how external forces (e.g. gravity) lengthens the muscle. In this lengthening phase the muscle is acting eccentrically, then a concentric (shortening) action follows. The true definition of eccentric action indicates that the muscle(s) must be active during stretch. The combination of eccentric and concentric actions forms the muscle function called stretch-shortening cycle of SSC. This type of sequence in muscle function also involves the important features of preactivation and variable activation. SSC function has a well-recognized purpose: enhancement of performance during the final phase (concentric action) when compared to the isolated concentric mode.

The in-vivo force measurement systems, buckle transducer technique (Komi, 1990), and optic fiber technique (Komi et al, 1996; Finni et al, 2001) have revealed that a nonfatiguing SSC exercise demonstrates considerable performance enhancement with increased force at a given shortening velocity. Characteristic to this phenomenon is very low EMG activity in the concentric phase of the cycle, but a very pronounced contribution of the short-latency stretch-reflex component. The stretch reflex contributes significantly to force generation during the transition (stretch-shortening) phase in SSC action such as hopping and running (e.g. Komi & Gollhofer, 1997).

The common assumption has been that in SSC activities both the muscle fiber compartment and the tendon would change their lengths in phase. This assumption has been challenged, because muscle fibers have been estimated to stay at a constant length (Belli & Bosco, 1992) or they can even shorten (Griffiths, 1991) while the whole muscle-tendon complex may be lengthening. It can therefore be questioned whether the definition of SSC applies equally to two parts of the muscle-tendon complex.

Several studies undertaken to examine the fascicle and tendon length changes combining ultrasound (fascicle length) and optic fiber (tendon force) for the vastus lateralis (VL) and gastrocnemius (GA) muscles simultaneously using different types of jumps and effort intensities. The purpose was to examine further the hypothesis that in the eccentric phase of slow SSC actions the VL fascicle demonstrates much greater increase in length as compared to a faster SSC. Fig. 1. gives representative examples of the behavior of VL and GA fascicles during counter-movement and drop jumps. The following important findings were observed: (1) the fascicle lengthening / shortening does not occur in phase in the two muscles; (2) the fascicle behavior, in addition to the expected

effort dependence, is also very much muscle and joint dependent; and (3) these changes in the fascicle (and tendon) are also dependent on the type of muscle action and movement. Consequently, in multijoint action it is possible that the fascicles of some muscles may demonstrate differences from the “general” rule of lengthening (eccentric mode) and shortening (concentric mode). For example, if the VL fascicle is being lengthened in the braking phase of CMJ, GA may demonstrate either no change in length or even shortening of the fascicle.

Isolation of the fascicle and tendon of the muscle-tendon complex can reveal specific roles the tendon and aponeurosis play in performance potentiation in SSC. But their potential and individual contribution may be clearly dependent on the type of SSC movement and muscle in question. Thus it is difficult to generalize muscle mechanical behavior in SSC from single experimental conditions only.

Figure 1: Examples of the fascicle length changes in the VL and GA muscles in counter movement jumps (left) and drop jump (right) on the sledge. The figures show also respective EMG activities as well as the patella tendon force (optic fiber technique) and the sledge force plate force. The second dashed line refers to the end of the braking phase in the countermovement and drop jump conditions (Ishikawa et al, in progress).

WHAT CAN WE LEARN FROM LOOKING AT BIOLOGICAL PROCESSES, ONE MOLECULE AT A TIME

Steven Chu
Stanford University

Virtually all knowledge of chemical and biochemical processes has been deduced from studies of a large number of molecules. The ability to look at individual molecules has given us new insights into biological processes. As an example, our polymer studies using DNA have fundamentally altered our thinking of polymer dynamics by showing that identical molecules placed under identical conditions take several distinct paths to a new equilibrium state.

We have been applying sensitive fluorescence microscopy to study the behavior of individual biomolecules. Using energy transfer between two dye molecules, a change in relative fluorescence from the two dyes can be used to measure the distance between two locations of a bio-macromolecule. This technique has proven to be particularly powerful in linking

molecular structural information with biological activity measured with molecular biology methods.

Examples of how this work is allowing us to test mechanistic models of how biological systems function will be given. This talk may include our work on the observation an RNA enzyme folding into a biologically active structure, and the discovery of “molecular memory” in the fluctuations of another RNA enzyme, and real-time observation of the unwinding of DNA by a Helicase enzyme. A preview of our work with more complex interacting systems such as the manufacture of proteins by the ribosome, and vesicle fusion that occurs in at the synapse between neurons will also be given.

MECHANISMS OF MECHANOTRANSDUCTION IN CELL PROCESSES AND MICROVILLI

Sheldon Weinbaum

INTRODUCTION

In contrast to the actin cytoskeleton in the main body of the cell, where the actin network forms a gel-like structure that is isotropic, many cells have slender microvilli or cell processes in which the actin network is highly organized into cross-linked axial arrays or bundles in which the long axes of the actin filaments are parallel to one another. Four prominent examples of such structures are the stereocilia in the inner ear, the microvilli in the brush border epithelia of the proximal tubule and small intestine and the cell processes of osteocytes. In this presentation we shall examine the relationship between structure and function in each cellular extension with a view toward developing new insight into the fluid flow induced mechanosensory mechanisms that may be operative in brush border microvilli and osteocyte cell processes. In particular, we shall compare the detailed structures of the filament bundles, the stress and strain amplification that results from fluid dynamic loading, the magnitude of the forces and strains required to activate membrane ion channels and elicit intracellular electrical and chemical responses and the coupling of the cell membrane to intracellular and extracellular matrix structures.

METHODS

Much more is known about the structure and function of the the actin filament bundles in stereocilia and the molecular structure of the the microvilli in the small intestine than the brush border microvilli in the kidney or the cell processes of osteocytes. This anatomical information has been used in Guo et al. (2000) and Yu et al. (2001) to construct new models to quantitatively explore whether the cellular extensions on kidney and bone cells can serve as mechanotransducers when subject to hydrodynamic forces *in vivo*.

RESULTS AND DISCUSSION

The model for kidney microvilli develops a new theoretical approach for predicting the forces and torques in a dense network of brush border microvilli. The elastic modulus of

individual actin filaments and their observed cytoskeletal organization are then used in a an elastic beam model to predict the deformation of microvilli and the strain amplification that is experienced in the terminal web of the cytoskeletal structures at the base of the microvilli. The model provides a quantitatively feasible new hypothesis for the afferent sensory mechanism in glomerular-tubular balance and perfusion-absorption balance in proximal tubule. The model predicts that the forces on the microvilli are only of the order of 0.01 pN, that they are relatively stiff structures which deform less than 5 nm at their tips, but that there is a 40 fold stress amplification at the base of the microvilli which should be sufficient elicit intracellular responses.

The model for the osteocyte cell processes attempts to resolve a long standing paradox, as to why whole tissue strains in bone are at least an order of magnitude smaller than the cellular level strains required in tissue culture to elicit intracellular biochemical responses. The model is based on a new hypothesis and experimental observation that the cell processes are tethered at regular intervals to the canalicular wall by transverse filaments in the pericellular matrix. The model is the first, to our knowledge, to relate flow induced strains on extracellular matrix to the deformation of the actin cytoskeleton and predicts that the effective elastic modulus of the cell process is 200 times stiffer than the measured modulus in the cell body. Thus, the processes should not be sensitive to fluid shear stress as now assumed by many investigators. However, the fluid drag on the transverse tethering elements can create hoop strains in the actin filament bundle of the process which are up to 100 times whole tissue strains. These strains should be sufficient to open membrane ion channels and activate intracellular signaling.

These results are summarized in a recent review paper Weinbaum *et al.* (2001).

CARTILAGE MECHANICS, DIAGNOSTICS AND REPAIR

Michael D. Buschmann

Montreal, Quebec, Canada, H3C 3A7
mike@grbb.polymtl.ca

INTRODUCTION

Articular cartilage of the knee and hip is often considered to be the main tissue affected by Osteoarthritis and other debilitating joint diseases. Thus its normal structure, composition and biomechanical function are of great interest in addition to understanding disease-induced alterations. Once articular cartilage is degenerated or completely removed via erosion to bone, therapies to resurface the joint by cartilage implantation or stimulation of cartilage growth at the eroded site are desired. In this presentation, the biomechanical roles of cartilage components will be reviewed and recent data presented. Strategies to resurface degenerated or denuded articular cartilage will also be discussed as well as biomechanical evaluation of cartilage function in a non-destructive manner in intact joints.

CARTILAGE MECHANICS

Most of the observed mechanical behavior of articular cartilage can be explained within the framework of biphasic theory or poroelasticity. One necessary constitutive characteristic is to consider collagenous and non-collagenous (mainly proteoglycan) components of the solid phases independently since this allows for 1) the description of the well known tension-compression nonlinearity ($\sim 10\times$ stiffer in tension) and 2) the very high ratio of dynamic to equilibrium stiffness ($\sim 10:1$) in compression. The high density of proteoglycan is also essential to 1) furnish about half of the equilibrium stiffness via electrostatic repulsion and 2) to create nanometer sized pores that endow cartilage with its extremely low permeability to fluid flow. Another important characteristic to consider is depth-dependent composition and structure where proteoglycan density increases with depth and collagen fibril orientation changes systematically. Some recent experimental and theoretical results arising from depth-dependent composition and structure include zone-dependent strains, pressurization, and a shifting of strain from zone to zone that do not occur in the absence of depth-dependence. Finally, nonlinear stiffening of collagen fibrils when they are stretched has been recently measured. This stiffening of collagen in tension can exert a great influence on cartilage compressive stiffness since the level of isotropic fluid

pressurization under compression depends to a large extent on the stiffness of the solid matrix in the direction of fluid flow.

CARTILAGE REPAIR

Focal erosion of articular cartilage down to the underlying bone in an area larger than 1cm^2 is considered clinically treatable. Current treatments mainly involve penetration of subchondral bone to induce bleeding and subsequent tissue repair, or osteochondral grafting, or cell-based methods. Recently much effort has been focused on growing cartilage tissue in vitro that could then be implanted. Cell sources include autologous chondrocytes, and stem cells derived from autologous tissue. One goal in this approach is often that the in vitro grown tissue achieves the mechanical properties of normal articular cartilage before implantation. Once this outcome is optimized, tissue implantation, integration with the surrounding cartilage, and its ability to remodel to meet local functional requirements become the main obstacles. Although not yet entirely successful, these approaches are showing promise. Particular attention must be made towards cell selection for phenotype control and the use of an appropriate scaffolding to guide tissue growth.

CARTILAGE DIAGNOSTICS

Unfortunately the most accurate methods to determine cartilage composition, structure and function require tissue removal and destructive analysis. Non-destructive methods can be based on imaging, biochemical markers, or involve direct estimation of mechanical function. In the latter category measurements can be purely mechanical or include electromechanical phenomena. Many of the problems encountered to date in these technologies are similar and involve accurate control and/or measurement of force, displacement, orientation and electrical parameters and a subsequent analysis that provides a useful description of tissue function. A recently developed electromechanical device solves some of these problems and provides a simple diagnostic parameter through a robust user-friendly system. This device allows measurement of non-visible degradation of articular cartilage and can map out focal cartilage degeneration that is both visible and non-visible through the arthroscope.

HOW DO BIOLOGICAL MOTORS WORK?

Myosin V moves processively with large (~36nm) steps and it is believed that myosin V strides along the actin helical repeat using its two heads each with an unusually long neck domain. However, we have recently shown that a deletion myosin V mutant, in which five out of the six IQ motifs were removed (Tanaka et al. Nature 415, 2002), and myosin VI, which naturally has only one IQ motif, both move processively with ~36 nm steps (Nishikawa, et al. BBRC, 2002; Rock, et al. PNAS 98, 2001). Thus, the long neck domain is critical to neither the processivity nor the large step. We discovered by electron microscopy that an S1 form of a

mutant *Dictyostelium* myosin II, in which the 680th Gly is replaced by Val so that it forms a long-life actomyosin complex in the presence of ATP like myosins V and VI, periodically binds along one side of an actin filament at ~36 nm intervals in the presence of ATP. Myosin VI was also found to cooperatively bind to an actin filament at ~36 nm intervals in the presence of ATP. These results suggest that the binding of an activated myosin head evokes “hot spots” on the actin filaments that attract free myosin heads. Based on these findings, we propose that myosin V and VI step on these “hot spots” at every helical pitch along actin filaments, thus producing processive movement with 36 nm steps.

CELLS, GELS AND THE ENGINES OF LIFE: A FRESH APPROACH TO BIOLOGICAL MOTION

Gerald H. Pollack. Dept. of Bioengineering, University of Washington, 357962, Seattle WA 98195

The cell is broadly envisioned to be an aqueous solution in which solutes are freely diffusible. Many mechanisms build on this assumption. Yet, it is well known that the cell is a gel, and not an aqueous solution. Gels and aqueous solutions are quite different: Gels are polymer matrices to which water clings—that's why the cracked egg feels gooey, and why gelatin dessert does not shrivel up despite upwards of 95% water content.

The concept of a gel-like cytoplasm is replete with power. Partitioning of ions between the inside and outside of the cell is directly explainable from the cytoplasm's gel-like character; such partitioning requires zero maintenance energy, unlike ion-pumping mechanisms. The cell's electrical potential is also explainable: substantial potentials are measured in gels, as well as in cells stripped of their membrane. Hence, gel properties can go far in explaining the most fundamental of the cell's static properties.

Polymer gels also undergo phase-transition—transformation from one physical state to another. In so doing, they change volume, ion content, solvency, permeability, etc.—changes similar to those experienced by organelles within the functioning cell. The polymer-gel phase transition therefore has the potential to be a central paradigm for mediating many aspects of basic cell function.

These ideas are explored in depth in a recent book (Pollack, "Cells, Gels and the Engines of Life," 2001 www.cellsandgels.com), and will be outlined at the meeting. In short, it appears that many features of cell function are explained in a straightforward way by the phase-transition mechanism.

A question particularly relevant to those at the biomechanics meeting is whether the phase-transition might be the underlying basis of biological motion. When phase-transitions take place in polymer gels, all constituents move: the polymer (i.e., protein) moves, water moves, and ions move. Thus, a "byproduct" of the transition is vectorial movement of all components. It is shown in the above-mentioned book that such movements constitute a promising candidate for all kinds of biological motions ranging from muscle contraction to cell motility, fluid streaming and transport along microtubules. Further, physical properties of tendons and cartilage, which involve water movements, are also readily explained by this kind of mechanism.

Thus, the gel mechanism provides simple explanations for the genesis of biological motion, which are consistent with available data. These mechanisms are substantially different from those in textbooks, all of which are based essentially on aqueous solution behavior, not on gel behavior.

CARTILAGE NANOMECHANICS, MECHANOTRANSDUCTION, AND TISSUE ENGINEERING

Alan Grodzinsky, Christine Ortiz, Joonil Seog, Delphine Dean, Laurel Ng, Moonsoo Jin, John Kisiday, and Eliot Frank

INTRODUCTION and OVERVIEW

Cells in articular cartilage synthesize an extracellular matrix (ECM) of proteoglycan aggregates and collagens in order to create a dense woven tissue that can withstand joint loading *in vivo*. At the same time, mechanical forces acting on the cells during motion of both healthy and osteoarthritic cartilage can differentially modulate the nanostructure of these ECM molecules which are continually synthesized and secreted by the cells. This feedback system is extremely important for maintenance of healthy cartilage, and for the success of cartilage tissue engineered constructs being developed for the repair of cartilage defects.

METHODS and RESULTS

We have therefore used high resolution force spectroscopy to quantify the electrostatic and steric interactions between glycosaminoglycan (GAG) molecules, a critically important component of cartilage ECM. GAGs have now been end-grafted to the substrate and probe tip of a Molecular Force Probe (MFP), and the measured GAG repulsive forces (fig. 1) have been compared to a hierarchy of theoretical models for the electrostatic repulsive interactions between GAGs using the Poisson Boltzmann equation. In addition, novel AFM imaging of aggrecan proteoglycan (PG), hyaluronan (HA), and PG-HA aggregates are now revealing the structures of these native ECM components that may be more relevant to the physiological wet state without using preparative staining, coating or freezing for traditional electron microscopy. Using a self-assembling peptide hydrogel scaffold, chondrocytes have been subjected to a range of dynamic compressive loads to simulate mechanical forces during joint loading. Appropriate loading regimes have been identified which can stimulate sustained, enhanced synthesis and accumulation of GAG-rich proteoglycans capable of providing cartilage-like stiffness to the neo-cartilage tissue growing within the peptide scaffold (Fig. 2).

DISCUSSION

Cartilage is subjected to wide range of mechanical forces associated with joint loading *in vivo*. These mechanical forces can dramatically alter chondrocyte synthesis, assembly, and degradation of extracellular matrix. Recent studies suggest that there are multiple regulatory pathways by which chondrocytes in cartilage can sense and respond to mechanical stimuli. Chondrocyte mechanotransduction is critically important in the cell-mediated feedback between joint loading, the molecular structure of newly synthesized ECM collagens

Fig. 1. Repulsive forces between charged GAG chains quantified using MFP.

and proteoglycans, and the resulting functional biomechanical properties of cartilage. Current approaches to creating tissue engineered cell-scaffold implants for cartilage repair are incorporating mechanical loading of the developing constructs to optimize their biological and mechanical properties.

FLUID SHEAR STRESS AFFECTS VASCULAR SMOOTH MUSCLE CELL FUNCTION

John M. Tarbell^{1,2}, Shigeru Tada³, Jeff Garanich¹, Kristy Ainslie², and Mete Civelek²

Departments of Bioengineering¹(jmt@psu.edu) and Chemical Engineering², The Pennsylvania State University;

Department of Mechanical Engineering and Science³, Tokyo Institute of Technology

INTRODUCTION

Vascular smooth muscle cells (SMC) are not normally exposed to the direct shearing forces of blood flow because they lie beneath the arterial intima and its endothelial lining layer. When the intima is damaged, as in angioplasty or vascular grafting, SMC are exposed directly to blood flow shear stress. In the intact vessel, SMC are also exposed to fluid shear stress associated with transmural interstitial flow driven by the transmural pressure differential. Interstitial shear stresses have been estimated to be comparable in magnitude to blood flow shear stresses on endothelial cells (order 10 dyne/cm²) and the most superficial layer of SMC may experience significantly higher levels due to entrance effects associated with flow distribution through the fenestral pores of the internal elastic lamina (Tada and Tarbell, 2002).

We have hypothesized that fluid flow shear stress on SMC affects two important functions of the cells: (1) cell migration, which is fundamental to intimal hyperplasia and re-stenosis; and (2) cell contraction, which is essential for blood flow control in response to pressure changes (myogenic response). We have developed in vitro systems to assess migration and contraction in response to well defined shear stress fields as described below.

METHODS

Primary rat aortic SMC were expanded in cell culture flasks containing DMEM + 10% FBS. Then, depending on the experiment, SMC were treated in one of two ways in order to maintain them in a specific cell phenotype. For the "proliferative phenotype", SMC were maintained in DMEM + 10% FBS throughout the duration of the experiment. For the "contractile phenotype" SMC were "starved" (maintained in DMEM, no FBS) in culture flasks for two days and then on quartz slides for two more days prior to experiments that were also run serum-free.

To study cell contraction in response to shear stress, serum-starved cells were plated at sub-confluent density on quartz slides and exposed to a defined level of steady shear stress in a parallel plate flow chamber for 30 minutes while being photographed under a microscope with a video camera. Reduction in cell area was interpreted as cell contraction and quantified in terms of percent area reduction. Intra-cellular calcium (Ca²⁺) was imaged under flow in the parallel plate chamber using the calcium sensitive dye fura-2.

To study cell migration, polycarbonate filters with 8µm pores were coated with Matrigel, an extracellular matrix formulation containing type IV collagen, laminan and other components,

and a monolayer of SMC in the proliferative phenotype was plated on top of the Matrigel. PDGF-BB was placed in the well beneath the filter to serve as a chemoattractant. Migration was quantified by counting the number of cells that migrated to the bottom of the filter. Defined shear stress was applied to the SMC monolayer using a rotating disk apparatus (Sill et al., 1995).

RESULTS AND DISCUSSION

Cells in the contractile phenotype that were exposed to 25 dyne/cm² shear stress decreased their area significantly within 3 minutes and by more than 30% after 30 minutes. The threshold for contraction was about 7 dyne/cm². To our surprise, this contraction response was not accompanied by a response of intracellular Ca²⁺. Additional experiments in calcium free media and with intracellular Ca²⁺ chelators also displayed a significant contraction response to shear stress confirming that shear-induced contraction is not mediated by intracellular Ca²⁺. Additional pharmacological experiments suggested that the shear-induced contraction is mediated primarily through a Rho-kinase intracellular signaling pathway. In contrast, cells in the proliferative phenotype did not contract in response to shear stress but did display a marked intracellular Ca²⁺ response to shear.

Migration of SMC through Matrigel was significantly inhibited by shear stress in a time- and dose-dependent manner. Four hours of exposure to 20 dyne/cm² inhibited migration by 90%. Inhibition of migration over this time frame was still significant at 10 dyne/cm² shear stress but not at 1 dyne/cm². The inhibition of migration is believed to be at least partially due to the restricted action of matrix metalloproteinase-2 (MMP-2). Latent levels of MMP-2 released by SMC were not affected by shear stress whereas active MMP-2 was significantly inhibited by increased shear stress.

Taken together these experiments demonstrate the potential for fluid shear stress on SMC to influence the myogenic response and intimal hyperplasia.

ORTHOTICS ALTER LOWER EXTREMITY JOINT COUPLING: A DYNAMICAL SYSTEMS APPROACH

INTRODUCTION

Foot orthoses are often prescribed for lower extremity injuries. The method by which orthotics relieve symptoms is not well understood as most studies have focused solely on rearfoot motion. However, the rearfoot and knee are linked by their common articulation with the tibia resulting in a necessity for coordination between their motions. Disruption of this coordination is thought to be one of the causes of running-related injuries (Nigg et al, 1993, McClay et al., 1997). Restoration of rearfoot-knee coordination may be a way in which orthotics provide relief of symptoms. One method of investigating joint coordination is through a dynamical systems theory (DST) approach (Hamill, 1999). These authors believe that variability in joint coupling is important and suggest that injured subjects exhibit less variability in their movement patterns. Therefore, the purpose of this study was to compare joint coupling during the stance phase of running in a group of runners treated with two types of orthotic devices. It was hypothesized that coordination would improve with orthotic intervention.

METHODS

Eleven injured runners, presenting to a single physical therapist, volunteered for the study. Each was initially fitted with a standard (STD) custom-molded graphite foot orthoses, but symptoms were not resolved. The subjects were then fitted with inverted (INV) orthoses posted between 15° and 25° which resulted in relief of symptoms. Kinematic and kinetic data were collected from 5 trials and for 3 conditions: no orthotics (NO), STD, and INV. Data from 11 healthy runners served as the controls (CON). They were randomly chosen from a normative database of runners previously collected under a similar experimental protocol. Coordination of rearfoot eversion/inversion and tibial internal/external rotation (RF-Tib) were examined using a DST analysis. Continuous relative phase (CRP) plots were calculated for each condition. For each trial, the CRP plot was divided into 4 phases according to discrete ground reaction force (GRF) events. Phase 1: heel strike to F1, phase 2: F1 to GRF max, phase 3: GRF max to ~75% of stance, phase 4: ~75% of stance to toe off. Mean CRP and variation of CRP was analyzed for each phase. Repeated measures ANOVAs were used to determine differences, if any, in mean CRP and CRP variability between the orthotics conditions (NO, STD, INV). Orthogonal contrasts were used to detect differences compared to the CON group.

RESULTS AND DISCUSSION

The injured runners during the NO condition displayed out of phase coupling compared to CON who exhibited relatively tight coupling throughout the stance phase (Fig 1). However, during the NO condition, the injured group also presented with greater CRP variability which is in contrast to the findings of

Hamill et al. (1999) who reported lower variability in their injured population. They suggested that a lack of flexibility in coordinated movement patterns may lead to overuse injuries. In general, both orthotic conditions (STD, INV) resulted in greater in-phase motion of the RF-Tib and lower variability of coupling compared to the NO condition. This brought the coupling parameters closer to that of the CON group (Fig 1). It is interesting to note that the greatest differences occurred during phase 2 which represents an important transition where the rearfoot and knee reverse their motions. It was surprising to find that the STD condition demonstrated greater in phase joint coupling than the INV during phase 2 yet the latter provided the greatest relief of symptoms. In terms of variability, both orthotic conditions reduced the variability of coupling in phase 2, bringing it closer to the CON group. Again, the STD device resulted in a greater reduction of variability than the INV (Fig 1). It is possible that there is an optimal coordination pattern and an optimal variability of coordination that minimizes the risk of overuse injuries in runners.

Figure 1: RF-Tib CRP means (bars) and variability (lines) for the CON and orthotic groups across the 4 phases of stance. (* significantly different than CON, + significantly different than NO: $p < 0.05$)

SUMMARY

These data suggest that 1) rearfoot and knee motion are tightly coupled during the stance phase of running, and 2) a custom fitted orthotic device can alter the lower extremity joint coupling, as well as variability of that coupling, in a group of injured subjects. More studies using DST are needed to understand the nature of joint coordination in injured runners.

THE EFFECT OF AXONAL INJURY ON THE MATERIAL PROPERTIES OF BRAIN TISSUE

Kurosh K. Darvish, James R. Stone¹, and Jeff R. Crandall

Impact Biomechanics Laboratory (auto-safety.mech.virginia.edu), ¹Department of Neurosurgery
University of Virginia

INTRODUCTION

It has been shown previously that the instantaneous linear shear modulus of brain tissue, in simple shear tests *in vitro*, reduces with strain (Darvish and Crandall, 2002). This softening effect, after about 15% Lagrangian shear strain, which is believed to be the threshold of traumatic axonal injury (Thibault et al, 1990), is permanent. In this study, the strain softening phenomenon was investigated using an animal injury model. This phenomenon can explain why secondary head injuries are more harmful and also provides a means to predict axonal injury based on changes in the material properties.

MATERIALS AND METHOD

The impact acceleration weight drop model was used to produce traumatic axonal injury in rat brain stem. Two points were selected on dissected brain stems for determination of material properties. Point 1, the most rostral point was at the basilar pons. Point 2, the most caudal point, was the caudal medullary pyramids, at the region of the pyramidal decussation. The most axonal damage has been observed at Point 2 (Stone et al, 2000).

The material properties were determined using indentation test. A cylindrical indenter (1.56 mm dia.) was pushed 1.0 to 1.5 mm onto the selected points of the samples using a linear servo system. The ramp time was 50 ms and the hold time was 1 second. The force at the tip of the indenter was measured using an inertially compensated load cell. The viscoelastic shear relaxation function was determined by applying the correspondence principle to the solution of the linear indentation problem in half-space (Sneddon, 1951):

$$L(t) = \frac{4a}{1-\nu} \int_0^t \mu(t-\tau) h(\tau) d\tau \quad (1)$$

It was assumed that the Poisson's ratio ν remains constant ($\nu = 0.49$). $L(t)$ is the time history of the applied force, a is the radius of the indenter, $\mu(t)$ is the shear relaxation function, and $h(t)$ is the time history of the indenter displacement. The relaxation function was assumed in the form of Prony series with three terms (Darvish et al, 1999). The material properties were determined by solving equation (1) numerically, using the actual indenter displacement, and minimizing the difference between the model and the experimental force histories.

RESULTS AND DISCUSSION

The results of the instantaneous and long term shear moduli, $\mu_0 = \mu(t=0)$ and $\mu_\infty = \mu(t \rightarrow \infty)$, for three samples are shown in Table 1. Figure 1 shows representative experimental and model results. These preliminary results showed that in relation to axonal injury, there was significant reduction in the shear moduli at both Points 1 and 2. However, reductions in the shear moduli at Point 2, which sees more axonal damage, were 13% to 15% more. The reduction in the instantaneous shear modulus *in vitro*, for 20% Lagrangian shear strain, was reported to be about 70% (Darvish and Crandall, 2002). Therefore, it can be concluded that in the impact acceleration weight drop model the level of shear strain in brain stem went beyond 20%. The significant difference between the material properties at Points 1 and 2 can be attributed to the difference in the microstructural arrangement of the axons.

Table 1. The instantaneous and the long term shear moduli

Sample	Injury	μ_0 (kPa)		μ_∞ (kPa)	
		Point 1	Point 2	Point 1	Point 2
1	Injured	4.13	4.57	1.85	2.23
2	Non-injured	14.41	36.17	7.29	19.21
3	Non-injured	14.99	32.71	8.67	24.82
Average Reduction (%)		72	87	77	90

INTRODUCTION

Biomechanical investigations are yet necessary to better understand the origin of the glenoid loosening which is the main reason for revision surgery. Some experimental tests have been done. Nevertheless, either they represent only postoperative situations when they are done on cadaveric specimen which is not sufficient to completely study loosening phenomenon or they use bone substitute to study fatigue phenomenon. Moreover, using such tests, it is difficult to appreciate the behaviour inside the bone. Some finite element models of scapula can be found in the literature, but few models were validated using experimental data. So, the aim of this study is to develop a finite element model of a scapula whose behaviour will be validated using global and local results issued from experimental data.

MATERIAL AND METHOD

During a previous in vitro experimental study (Maurel et al., 2002), tests were done on intact and implanted scapulae. Each scapula was placed in a specific box with a cross which allowed to define a referential system bound to the scapula. Nine loads of 500N were applied on the implanted scapulae (eight regularly applied around the prosthesis and one applied in the centre). Two kinds of measurements were done: Strains around peripheral cortex of the glenoid using 6 strains gages placed on precise points and displacements of 4 points (posterior, anterior, superior, inferior) of the implant using 2 CCD cameras (figure 1).

Before experiments, each scapula was scanned in order to obtain the geometry of the tested scapulae. Before scanner, little balls were placed on the scapula to materialise the future position of the gages.

The finite element model was then developed using the ANSYS finite element software. Eight node elements were used for spongy bone and prosthesis. Shell elements were used for cortical. The Young modulus are 300MPa for spongy bone, 16000MPa for cortical bone and 1000MPa for implant (figure 2).

Figure 1: In vitro experimental test

Figure 2: Finite element model

Same loads as in the experimental study were applied on the implant.

Principal strains calculations were done where gages were positioned during in vitro tests and the four implant displacements were calculated.

RESULTS:

The preliminary results were qualitatively coherent with experimental results (figure 3 and 4).

Figure 3: Comparison of principal strains for the 6 gages

Figure 4: Comparison of the displacement of the four points of the implant

CONCLUSION :

We have developed a 3D finite element model of an implanted scapula. Both displacements and strains were used to evaluate the model. Improvements are still necessary and are in progress. When validated, such a model should be useful for better understanding implanted scapula behaviour and for giving information inside the bone. And later, it should allow us to introduce remodelling process in order to analyse implanted scapula behaviour at different delays.

EFFECT OF STRAIN RATE ON CERVICAL SPINE TENSILE MECHANICS

David Nuckley, Suzanne Hertsted, and Randal Ching
Applied Biomechanics Laboratory, University of Washington, Seattle, Washington, USA
Contact: dnuckley@u.washington.edu

INTRODUCTION

Injury criteria used in computational and anthropomorphic test dummy simulations is typically based on experimentally collected biomechanical data. Unfortunately, many of these studies are performed at quasi-static loading rates despite the fact that loading rate and strain rate have been implicated in the underestimation of mechanical properties for dynamic events. Increasing strain rate has been shown to increase the stiffness, modulus, and failure loads of ligamentous tissues [Noyes, 1974; Peterson, 1986; Woo, 1997].

Therefore, this study examined the effects of strain rate on cervical functional spinal units to elucidate the functional range and failure mechanics of these tissues. These efforts provide data for the generation of rate sensitive models which will more accurately represent spinal injury mechanics and support improved injury prevention.

METHODS

Ten fresh cadaveric baboon cervical spines were obtained through the Washington Regional Primate Research Center. The specimens were all male, age 10 ± 0.6 -human equivalent years based upon radiographic assessment of their skeletal maturity. Each specimen was dissected free of all musculature, then sectioned into functional spinal units: Occiput-C2, C3-4, C5-6, and C7-T1. These were then wired and embedded in polymethylmethacrylate for tensile loading. Each functional spinal unit was randomized to a loading rate group (N=8) to minimize the effect of inter-specimen variability and distinguish rate effects alone. The loading rates investigated were 0.5-mm/sec, 5-mm/sec, 50-mm/sec, 500-mm/sec, and 5,000-mm/sec.

Tensile inputs were provided by a servohydraulic testing frame (Model 810 Bionix, MTS Corp., Eden Prairie, MN) which supplied a constant velocity to failure. An inferiorly mounted six-axis load cell measured the force/moment response and the displacement was recorded using a LVDT and high-speed video camera (Eastman Kodak Company, Motion Analysis Systems Division, San Diego, CA). These data were recorded up to 40,000-Hz and filtered with a CFC 1000 (Butterworth low pass 1650-Hz cutoff) digital filter.

RESULTS AND DISCUSSION

The tensile failure load significantly increased (ANOVA, $p < 0.0001$) with increasing loading rate (Figure 1). Within two orders of magnitude there is no difference in failure loads; however statistical contrasts revealed significant differences in failure loads two orders of magnitude or more away. Further, differences between the various cervical spinal levels were observed. The stiffness and modulus of elasticity also increased with enhanced loading rates; however, not to the

same magnitude as the tolerance values. Modulus of elasticity demonstrated a two-fold increase between 0.5-mm/sec and 5,000-mm/sec. The tensile failure strains (1.07 ± 0.31 -mm/mm strain) were not significantly correlated with loading rate, suggesting strain-based failure criteria instead of stress.

Figure 1: Tensile Failure Load by Displacement Rate. This plot depicts spinal-level and loading rate differences in the tensile tolerance of the 10-year old spine.

SUMMARY

Both the functional and tolerance biomechanics of the cervical spine were found to be significantly related to the displacement rate of loading. The failure load tolerance of the neck was most affected by increased rates, while the failure strains appeared insensitive to loading rate. This suggests that cervical functional spinal units fail as a result of excessive strains rather than extreme loads. These data have implications for the functional response of the spine (both structural and material properties) by loading rate and spinal level. Thus, the relationships generated herein suggest that strain rate or loading rate consideration is imperative in modeling efforts aimed at mitigating dynamic neck injuries.

ULTRASONIC ASSESSMENT OF WHITE MATTER PROPERTIES AS A FUNCTION OF AXONAL DIRECTION

Elizabeth M. Rang¹ and Michele J. Grimm²

Bioengineering Center, Wayne State University, Detroit, Michigan, United States of America

¹Graduate Research Assistant, rang@rrb.eng.wayne.edu

²Assistant Professor, grimm@rrb.eng.wayne.edu

INTRODUCTION

The material properties of neuronal white matter are believed to vary depending on the orientation of the axon. Ultrasonic techniques provide a non-destructive method for the characterization of the material properties of tissues, which make them ideal for investigating brain. Acoustic microscopy can be used to measure the velocity of an ultrasonic wave, which can then be related to the tissue material properties. The objective of this study was to evaluate the variation in wave velocity and material properties as a function of axonal orientation for white matter. In order to do this, tissue was obtained from two regions of the brain. The corpus collosum consists of nerve fibers with primarily transverse orientation. Conversely, the brain stem is composed of axons that are oriented longitudinally.

METHODS

The specimen used for testing was fresh lamb brain, obtained locally. The sample was retrieved from the slaughter house and immediately returned to the lab. The skull was opened with a roto-zip saw, and the brain was removed intact from the cranium. Within 1 hour of death, the brain was removed, and the corpus collosum and brain stem were separated from surrounding tissue by blunt dissection. The brain stem was sliced to obtain transverse sections. The tissue was weighed and the volume was measured in order to determine the density (ρ) of the sample. The specimen was sandwiched between plexiglas and aluminum plates, secured, and placed in a bath filled with artificial CSF (Sugawara, 1996) (Fig. 1).

Figure 1: Experimental setup

Each sample was scanned using a Sonix acoustic microscope at a frequency of 90 MHz. Three gates were set up to measure the time of flight (t_1 , t_2 , and t_3) of the wave to the plexiglas, to the plexiglas/white matter interface, and then to the white matter/aluminum interface. The wave velocity (c_p) was calculated from the thickness of the specimen and the time difference between the second and third reflected waves. A combination of bulk and shear moduli ($K + 4G/3$) was then calculated using the measured wave speed and tissue density, from the equation: $c_p = [(K + 4G/3)/\rho]^{1/2}$.

RESULTS AND DISCUSSION

The values obtained for wave velocity and combined modulus ($K + 4G/3$) are given in Table 1 for the two axon orientations. There is a significant difference in both the modulus and velocity values between the two tissue structures. When the ultrasonic wave traveled down the length of the axon in the brain stem sections, the combined modulus was significantly higher than the values obtained for waves traveling perpendicular to the axon orientation in the corpus collosum. As the bulk modulus of a tissue is by definition independent of orientation, the variation in combined modulus can be used to estimate the differences in the shear moduli of the tissue depending on the orientation of the axons. It should be noted that the shear modulus estimated for a transversely isotropic material using an applied pressure wave will be characteristic of shearing along the direction of wave propagation – not perpendicular to the wave front as would normally be expected. Thus, the data indicate a higher shear modulus for white matter for displacements along the axis of the axon (longitudinal samples) compared to shear displacements perpendicular to the axon axis (transverse samples).

	Corpus Collosum				Brain Stem					
Sample	1	2	3	4	1	2	3	4	5	6
c_p [m/s]	452	535	649	529	1299	1442	1377	1349	1411	1442
$K + 4G/3$ [MPa]	277	237	417	379	1967	2422	2121	2035	2302	2404

Table 1: Results for corpus collosum (transverse axons) and brain stem (longitudinal axons).

SUMMARY

The resistance to shear is greater along the axis of the axon compared to perpendicular to the fiber. This confirms what would be expected based on the fibrous structure of the white matter. Acoustic microscopy allows for the characterization of material differences in small tissue specimens without the problems associated with traditional mechanical testing.
